

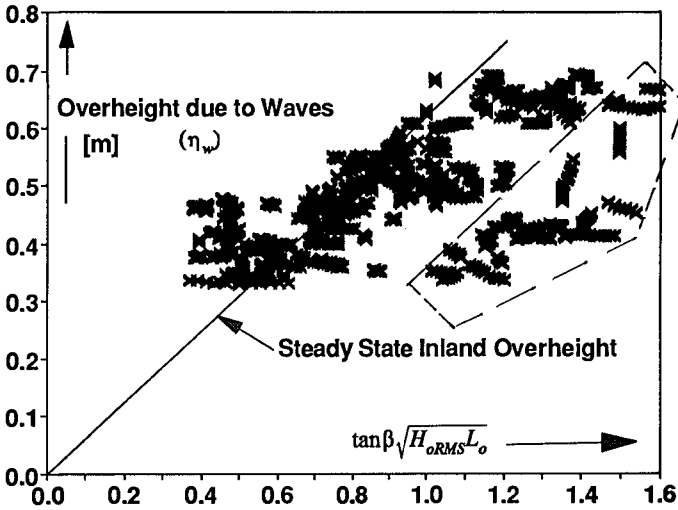

Figure 6. Watertable overheights due to waves : The differences in watertable levels between the exposed Palm Beach and the protected Pittwater Beach.

Figure 7. Watertable overheights due to waves : The differences in watertable levels between the exposed Palm Beach and the protected Pittwater Beach. The same data are used as shown in Figure 6, but refraction is accounted for by using  $H'_{oRMS}$  instead of  $H_{oRMS}$ .

After including the effect of refraction, the same data as shown in Figure 6 are plotted in Figure 7. That is, the equivalent perpendicular deep water RMS wave height  $H'_{oRMS}$  is used

$$H'_{oRMS} = K_r H_{oRMS} = \sqrt{\cos\alpha_o} H_{oRMS} \quad (9)$$

where  $K_r$  is the refraction coefficient and  $\alpha_o$  wave angle between the deep water wave crest and the shoreline. It is seen that the inclusion of refraction improves the correlation.

Figure 7 shows that the watertable overheight due to waves  $\eta_w$  is well correlated with  $\tan\beta\sqrt{H'_{oRMS}L_o}$ . linear regression gives

$$\eta_w = 0.55\sqrt{H'_{oRMS}L_o} \tan\beta \quad (10)$$

and with the vertical scale  $L_R$  of the runup distribution given by

$$L_R = 0.80\tan\beta\sqrt{H_{oRMS}L_o} \quad (11)$$

based on the data from the present study and Nielsen & Hanslow (1991), this gives ( $\alpha_o$  was not known for all data sets)

$$\eta_w = 0.69L_R \quad (12)$$

which corresponds qualitatively to the regular wave result, see Figure 5.

## Conclusions

1. There is a significant lifting of the coastal watertable due to the infiltration from wave runup.
2. The infiltration velocity from the field and laboratory data has a maximum value roughly midway between the shoreline and the runup limit.
3. For regular waves and no tide, steady state inland watertable overheight ( $\eta_w$ -SWL) was found to be  $0.62\tan\beta\sqrt{H_oL_o}$  for both coarse and fine sand sizes and thus independent of the hydraulic conductivity  $K$ .

4. For irregular waves with tides, the inland overheight due to waves  $\eta_w$  is estimated by  $0.55 \tan \beta \sqrt{H'_{\text{ORMS}} L_o}$  and the relation  $\eta_w = 0.69 L_R$  was found.
5. Use of the equivalent perpendicular deep water RMS wave height  $H'_{\text{ORMS}}$  gives better estimation of watertable overheight.

## CHAPTER 154

### A model for cross shore sediment transport

Irene Katopodi and Nikos Kitou<sup>1</sup>

#### Abstract

In this paper a mathematical model for the computation of the cross shore sediment transport for random waves is presented. The model consists of the hydrodynamic, the suspended sediment transport and bed load modules. The suspended sediment concentration is computed with the use of the wave-averaged convection diffusion equation. The vertical structure of both the wave-induced current and suspended sediment concentration are modelled with the use of quasi-3d techniques. Mechanisms for the offshore transport (undertow) and the onshore transport (Lagrangian transport, transport due to wave asymmetry) are included. The model is tested against an experiment with random waves at prototype scale.

#### Introduction

The computation of the sediment transport, being an essential element in the understanding and ultimately the control of the morphological processes is a subject that has received a lot of attention in the last decades. Still, the complexity of the various phenomena has not allowed for predictions accurate enough for the design and maintenance of coastal works. This is one reason for the wide variety of existing mathematical models (for a review, see Roelvink and Brøker, 1993).

In the present model the hydrodynamic and the sediment transport parts are an extension of the work of Katopodi et al (1992) where the wave driven current and the suspended sediment concentration were computed with quasi-3D analytical/numerical methods. Thus the vertical distributions of the velocity and concentration were retained at a computer cost almost similar to that of depth-averaged models. Moreover, with the use of the convection-diffusion equation the horizontal variation of the concentration was resolved, a factor that it is believed to have an important impact to the bed level changes (see Katopodi and Ribberink, 1992). The model is extended for random waves and the Lagrangian drift is incorporated to account for the wave transport.

For the bed load two alternatives based on the formula of van Rijn (1985) were tried, a wave averaged and an interperiod formulation. The latter can take into account the wave asymmetry. The bed slope effect is included in both formulations.

---

1. Democritus Univ. of Thrace, Dept. of Civil Eng., 67100 Xanthi, Greece

Moreover, wave heights, set-up, wave-mean velocities and (total) sediment transport are compared with experimental data from the Delta Flume experiment (S.-Arcilla et al, 1994) conducted in prototype conditions.

### Hydrodynamics

The wave heights are computed from of the wave energy equation.

$$\frac{\partial E_f}{\partial x} = - D_b - D_f \quad (1)$$

where:  $E_f$ ,  $D_f$ , and  $D_b$  are the energy flux, the dissipation due to bottom friction and the dissipation due to breaking.

Battjes and Janssen (1978) proposed a formulation for  $D_b$  proportional to the fraction of breaking waves  $Q_b$ . They also derived the fraction of breaking waves from a simple parameterization of the breaking wave height distribution from a Rayleigh distribution.

The current velocities are computed using the quasi-3D model of de Vriend and Stive, (1987) as modified by Ribberink and de Vriend (1989) to take into account the wave boundary layer effects. This model is based on a profile function technique combined with a 2DH current formulation. The current is divided into a primary component and a number of secondary components due to the vertical nonuniformities of the various driving forces. The effects of wave breaking, bottom dissipation and boundary layer streaming are included. The velocity profile is given as a sum of components due to the various driving forces:

$$U(\zeta) = U_1(\zeta) + U_2(\zeta) + U_3(\zeta) + U_4(\zeta) + U_5(\zeta) \quad (2)$$

where  $U_1(\zeta)$ ,  $U_2(\zeta)$ ,  $U_3(\zeta)$ ,  $U_4(\zeta)$  and  $U_5(\zeta)$  are the primary current, the secondary current due to surface shear stress, the secondary current due to secondary bottom shear stress, the near-bottom drift due to spatial variation of the orbital velocity and the near-bottom drift due to the boundary layer respectively.

The wave and the current model were tested against the Delta Flume'93 experiment (see S.-Arcilla et al., 1994) conducted in the Delta Flume of Delft Hydraulics. The flume dimensions are length 225m, width 5m and depth 7m. The experiment included tests with two geometries, i.e. equilibrium parabolic Dean-type profile with and without a dune, and three "dynamic states", i.e. near-equilibrium, erosive and accretive conditions. The hydrodynamic model is tested against test 1A (profile without a dune, near equilibrium conditions). Narrow banded random waves were used and the wave characteristics were  $T=4.83$  s and  $H_{rms} = 0.62$  m. The  $D_{50}$  of the sand was 0.2 mm. The bed configuration after two hours of wave action is used for the calculations, see Fig. (2). The bed roughness is taken 1cm.

In Fig. (1a) the root-mean-square wave height computed with the model is shown together with measurements conducted with wave height meters. We can see that the overall agreement is rather good.

In Fig. (1b) the computed fraction of breaking waves is presented. Two major peaks can be seen before and after 150m. A third extreme peak appears near the shoreline ( $Q_b=1$ ). As explained by Battjes and Janssen (1978) the wave model is not valid in this region but the solution in the rest of the domain is not contaminated. Nevertheless, the unnatural

Fig.1 a) Wave height, b) Fraction of breaking waves, c) Set-up

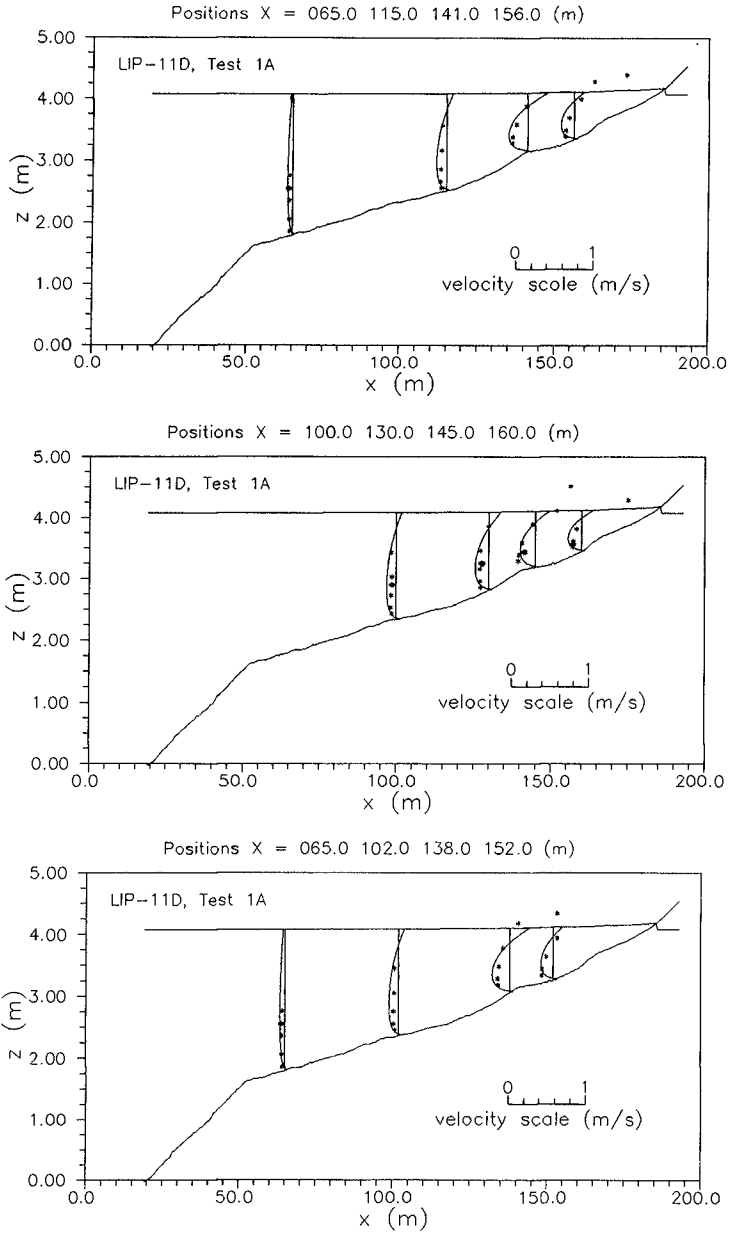

Fig.2 Velocity profiles

behaviour of  $Q_b$  close to the shoreline has a local impact in all the quantities that are computed in the following (e.g. set-up, bed shear stress, undertow, suspended sediment transport, bed load).

In Fig. (1c) the computed set-up is depicted together with measurements from wave height meters (WHM) and pressure sensors (DRO). The latter are considered more accurate (S.-Arcilla et al, 1994). We can see that the set-up is somewhat overpredicted by the model, owing to the formulation of the driving forces in the depth averaged momentum equation (set-down was excluded, see de Vriend and Stive, 1987).

In Fig. (2) the computed horizontal velocity profiles are shown together with the measurements conducted with two component electromagnetic flow meters in several cross sections. The model overpredicts the velocities in all cross-sections. In the main body of the water (under the wave trough) the curvature of the computed profiles is larger than in measurements that tend to have a more uniform profile over the depth. Yet the results are encouraging once certain aspects of the hydrodynamic model can still be improved. Of course the measurements between trough and crest should not be compared with the model due to the partial presence of the water at the sensors during the wave cycle.

### Sediment transport

The total sediment transport is the sum of the suspended sediment and the bed load transport. The suspended sediment transport is computed with the model of Katopodi et al. (1992) where the wave-induced transport caused by the Lagrangian velocity is added. The bed load is modelled with a) the formula of van Rijn (1985) derived for wave averaged transport and b) the same formula applied here for instantaneous transport during the wave cycle. In principle, the instantaneous (or interperiod) formula can take into account the wave asymmetry.

### Suspended sediment transport.

The suspended sediment is computed in terms of the suspended concentration and of the velocity. For the suspended sediment concentration the model of Katopodi and al (1992) is used (see also Katopodi and Ribberink, 1992). This model is based on an asymptotic solution (Galappatti and Vreugdenhil, 1985) of the wave averaged 3D convection diffusion equation. The model uses the mixing coefficient and the near-bed reference concentration of van Rijn (1986).

The depth averaged convection diffusion equation (Katopodi et al, 1992), reads:

$$\bar{c}_e = (1 + V_T + V_X)\bar{c} + T_A \frac{\partial \bar{c}}{\partial t} + L_X \frac{\partial \bar{c}}{\partial x} - T_A \frac{\partial}{\partial x} \left( \epsilon_x \frac{\partial \bar{c}}{\partial x} \right) \quad (3)$$

with

$$T_A = \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s}, \quad L_X = \left( \sum_{i=1}^n \bar{U}_i \frac{\gamma_{22,i}}{\gamma_{11}} \right) \frac{h}{w_s} \quad (4)$$

$$V_T = \left( \beta \frac{\gamma_{23}}{\gamma_{11}} + \frac{\gamma_{24}}{\gamma_{11}} \right) \frac{1}{1+\beta} \frac{\partial z_s}{\partial t} \frac{1}{w_s} \quad (5)$$

$$V_x = \sum_{i=1}^n \left( \frac{\partial}{\partial x} (\bar{U}_i h) \frac{\gamma_{25,i}}{\gamma_{11}} \right) \frac{1}{w_s} \quad (6)$$

where  $\bar{c}$  and  $\bar{c}_e$  are the depth averaged and the equilibrium concentration,  $\bar{U}_i$  the depth averaged horizontal velocities, and  $w_s$  the sediment fall velocity. The coefficients  $\gamma_{ij}$  depend only on the explicit knowledge of the vertical mixing coefficient, the fall velocity and the normalized velocity profiles and are computed before the solution of (3). The coefficient  $\beta$  is the reference level normalized by the depth  $h$ . The index  $i$  denotes the number of similarity profiles that constitute the undertow velocity ( $i=1-5$ ) and the Lagrangian drift ( $i=6$ ).

Equation (3) describes the adjustment of the depth averaged concentration to its equilibrium value. The parameters  $TA$  and  $LX$  are characteristic scales in time and space of this adjustment process (adaptation time, adaptation length). The terms  $VT$  and  $VX$  arise from the vertical coordinate transformation and from the inclusion of the vertical velocities that are computed via the continuity equation, respectively.

The above equation has been derived for "concentration" bed boundary condition (the concentration at the reference level is assumed to adapt immediately to equilibrium conditions). A similar equation holds for "gradient" bed boundary condition (the near-bed vertical gradient of the concentration adapts immediately to equilibrium conditions).

The suspended sediment transport, equation (7), actually is computed in terms of the depth averaged velocity (undertow plus Lagrangian) and concentration and of already computed coefficients (cf Katopodi and Ribberink, 1992).

$$S_x = h \int_0^1 U c \, d\zeta - h \int_0^1 \varepsilon_x \frac{\partial c}{\partial x} \, d\zeta \quad (7)$$

After equation (3) has been solved for  $\bar{c}$ , the vertical concentration profile, if desired, can be constructed in terms of already known profile functions (see Katopodi and Ribberink, 1992).

The effect of the Lagrangian velocity on the sediment particles is incorporated in the model to account for the wave induced transport. In progressive waves there is a net forward motion of the water particles related to the mass carried forward by the wave crests plus the mass deficiency carried backwards by the troughs (Longuet-Higgins, 1969). As a consequence there is also a net forward sediment transport over the wave cycle. In the computation of the concentration the Lagrangian velocity profile is incorporated as a sixth profile:

$$U_L(z) = \omega k \frac{H^2}{8} \frac{\cosh 2k(z+h)}{\sinh^2 kh} \quad (8)$$

where  $\omega$  is the wave angular frequency,  $k$  the wave number,  $H$  the wave height,  $h$  the water depth and  $z$  the vertical coordinate positive upwards the mean water level.

The integral of the above expression (8) over the depth yields the wave mass flux. Although the undertow profile and the Lagrangian profile are in volumetric balance for a steady state cross-shore case, the

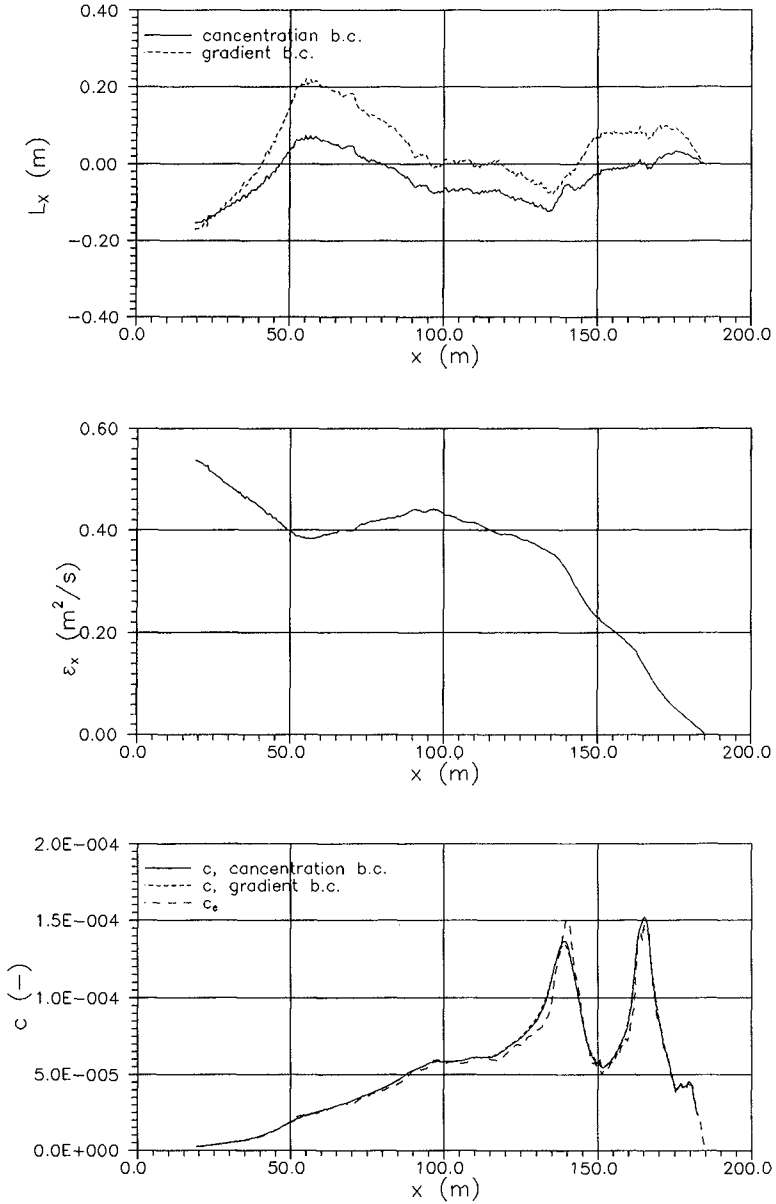

Fig.3 a) Adaptation length, b) horizontal eddy viscosity  
c) Depth-averaged concentration

Fig.4 a) Concentration profiles along the flume.  
 b) Suspended sediment transport (with and without Lagrangian),  
 c) Suspended sediment transport (with and without diffusive part)

resultant sediment transport is not. The sign and the magnitude of the suspended sediment transport depends on the local profile shapes of undertow, Lagrangian drift and concentration.

In Fig. (3a) the adaptation length along the flume is shown for concentration and for gradient bed boundary conditions. The magnitude of the adaptation length is smaller than the space step (0.5m) and as a result the concentration is expected to be close to equilibrium (cf Katopodi and Ribberink, 1992). In Fig. (3b) the horizontal eddy viscosity for the computation of the concentration is shown (Katopodi et al, 1992).

Fig. (3c) presents the depth averaged non-equilibrium concentration for the two bed boundary conditions as well as the equilibrium concentration. Very small differences exist between the equilibrium and the non-equilibrium concentrations, as expected from the magnitude of the adaptation length. Clearly, the concentration adapts immediately to local conditions. The concentration presents two major peaks and a smaller spurious peak near the shore line.

In Fig. (4a) the profiles of the concentration are shown at various cross-sections along the flume. Not much concentration is in suspension and most of it is concentrated near the bottom.

In Fig. (4b) the suspended sediment transports computed with only the wave mean velocity and with the inclusion of the Lagrangian velocity are presented. It is clear that the Lagrangian transport is in the onshore direction and has such a strong influence on the transport that it reverses the sign of the wave mean transport everywhere in the flume.

Fig. (4c) depicts the suspended sediment transport computed with only the first term (convective transport) of equation (7) and with the second term (diffusive transport) also included. The impact of the diffusive transport is strong especially in zones with large horizontal gradients of the concentration (e.g. see the concentration peaks in Fig. 3c).

### Bed Load

For the computation of the bed load two formulations have been tried. One wave averaged and one interperiod. For the wave averaged formulation the formula of van Rijn (1985) was used:

$$\dot{S}_b = (\Delta g D_{50}^3)^{1/2} 0.053 \frac{1}{D_*^{0.3}} T^{2.1} \text{sign}(\dot{\tau}_{cw}) \quad (9)$$

where

$$T = (|\dot{\tau}_{cw}| - \tau_{cr}) / \tau_{cr} \geq 0, \quad \dot{\tau}_{cw} = \mu_c \dot{\tau}_c + \mu_w \dot{\tau}_w$$

with  $\dot{\tau}_{cw}$  the combined bed shear stress for currents and waves as function of  $\dot{\tau}_c$ ,  $\dot{\tau}_w$  the current related and wave related bed shear stress respectively. The critical shear stress for the initiation of motion (Shields) is denoted by  $\tau_{cr}$ .  $D_*$  is the dimensionless particle parameter which is function of the median particle diameter  $D_{50}$ ,  $\Delta$  is the relative apparent density of the bed material and  $g$  the acceleration of gravity.

The formula of van Rijn involves the significant wave height in the calculation of the orbital velocity. In our model  $H_s$  is computed as a function of  $H_{rms}$  and  $Q_b$ .

In the above formulation the waves are used as a stirring mechanism while the current transports the sediment. The formula was chosen because

it contains the same parameters as the reference concentration we used for the suspended sediment part and because it has well proved its validity for unidirectional flows. Of course wave asymmetry can not be implemented.

In asymmetric waves during a short fraction of the wave cycle, strong forward velocities occur transporting big amounts of sediment while during a longer fraction weak backward velocities transport small amounts of sediment. Over the whole wave cycle there is a net forward transport. For short waves (high frequencies) it can be assumed that the asymmetry effect on the sediment transport is concentrated close to the bottom (no time for the concentration to fill the water column) and as such it can be incorporated in the bed load only. For longer waves (low frequencies) the asymmetry transport should be considered for the whole depth. Near the shore the waves are asymmetric.

In order to be able to account for interperiod effects such as the wave asymmetry, following an idea of Ribberink and de Vriend (1989), the same formula (van Rijn) was also used in interperiod mode for the calculation of the instantaneous transport. The only difference now is that the wave related shear stress and consequently the dimensionless shear stress parameter  $T$  as well as the transport are functions of time and vary during the wave cycle. The bed load transport is computed by numerical integration of the instantaneous transport over the wave period.

It is understood that the formula of van Rijn has been calibrated to compute convective wave averaged transport but the use of unidirectional flow formulae for instantaneous transport has been suggested and verified before (see Ribberink and de Vriend, 1989). An additional advantage of the formula of van Rijn is that it is provided with a threshold of motion.

At first the interperiod formula was used for sinusoidal waves to check the tendencies of the bed load transport in relation to the wave averaged formula and the order of magnitude of the transport. Then, a form of asymmetry was added by using non-linear second order Stokes waves.

$$U_{orb}(t) = U_1 \cos(\omega t) + U_2 \cos(2\omega t) \quad (10)$$

In order to avoid a secondary maximum in the trough of the orbital velocity the second harmonic was bounded by the relation  $U_2 \leq U_1/5$ .

Another element taken into account in the bed load formulation is the bed slope effect. This mechanism which is present in nature plays an important role in the morphodynamic computations because it stabilizes the solution by giving the computed bed slope the natural limit of the slope of the bed material internal friction.

In the formulation chosen (see e.g. Fredsøe and Deigaard, 1992) the critical bed shear stress is scaled by a factor  $\alpha_s$  that takes into account the relation of the bed slope to the slope of the internal friction.

$$\alpha_s = \frac{\tan \phi}{\cos \beta (\tan \phi \pm \tan \beta)} \quad (11)$$

where  $\phi$  is the angle of internal friction, property of the bed material and  $\beta$  is the local bed slope. The sign (+) holds for downsloping motion of the water while the sign (-) holds for upsloping motion. In our computations the critical shear stress was taken  $0.18 \text{ N/m}^2$  and  $\phi = 25$  degrees (sand with small amount of organic material).

Fig.5 a) Bed load with and without slope effect (wave-averaged formula),  
 b) Bed load (interperiod formula with sin and Stokes waves),  
 c) Bed load with and without slope effect (Stokes waves)

Although the above formula has a clear meaning in instantaneous mode, it was used also for the wave-averaged formulation once the formula is equipped with the threshold of motion in the parameter  $T$ .

In Fig. (5a) the bed load transport computed with the wave-averaged formula with and without the bed slope effect is shown. Fig. (5b) presents the interperiod bed load transport computed with sinusoidal and with Stokes waves. Fig. (5c) shows the slope effect on the bed load for Stokes waves. The magnitude of the transport in the interperiod formulations is smaller than that of the wave averaged one. The tendencies though are similar as well as the positions of the bed load maxima. It looks encouraging to calibrate the formula for instantaneous use. For Stokes waves the effect of the wave asymmetry is clear compared with sin waves, especially in the offshore region where we have some onshore transport. In general, the presence of the wave asymmetry tends to add onshore transport. The bed load including the slope effect has a noisy shape but it looks that exactly this immediate reaction to the bed slope is needed for the correct computation of the bed level changes.

#### Total load

The total load is the sum of the suspended and the bed load. The total transport is presented for the wave averaged (Fig. 6a) and for the non-linear interperiod bed load formulation (Fig. 6b). We can see that the suspended transport is a small fraction of the total transport, something expected from the computation of the concentration once there is not much sand in suspension. In the interperiod formulation the suspended transport moves the main peak somewhat offshore and results in onshore transport from 50 to 70 m.

In Fig. (7a) the total transport computed with the wave averaged and the interperiod non-linear formulation is shown.

Fig. (7b) shows the measured (total) transport as derived from the measured bed levels at different times of the experiment. The transport estimated from the bed level changes between 02-07, 07-12 and 02-12 hours of the experiment is shown.

As previously mentioned, test 1A was designed to be near equilibrium and it was successful at that. The max difference in bed level between hours 02 and 12 (wave action of 10 hours) was 15 cm locally at the main bar while in most of the flume it was of the order of 1-2 cm. Such small changes would not have an important impact on the hydrodynamic and the sediment transport computations. Thus, although in our model we used the bed configuration after 02 wave hours in the experiment, the computed quantities were compared with all data regardless of the time taken. The transport estimated by such small differences contains large uncertainties. This is why we included in Fig. (7b) all three curves.

The averaged formulation seems to underpredict the transport in the deepest part of the flume (from 0 to 80m) and to overpredict (factor of 2) the transport in the region before breaking (say from 80 to 155m). The peak at 165 m is reproduced at the correct location and agrees rather well in magnitude. The peak at 145 m is shifted about 7 m offshore and its magnitude is clearly overpredicted. The small peak near the shore owes its presence to the unrealistic values of  $Q_b$ .

The interperiod model clearly underpredicts the transport. Again the two peaks in the surf zone are reproduced and the overall shape of the

Fig.6 a) Total and bed load (wave-averaged formula),  
 b) Total and bed load (interperiod formula with Stokes waves)

transport seems to be captured. The shape can be seen more clearly in Fig. (6b). The interperiod model, although with the wave kinematics rather crudely included, seems to be promising if a new calibration of the van Rijn formula is performed.

### Conclusions

A model of cross-shore sediment transport for random waves has been presented. The model consists of the hydrodynamics module, the suspended sediment and the bed load modules. In the suspended sediment module Q-3d velocities and Q-3d concentrations are coupled in a unified formulation while the bed load includes bed slope and wave asymmetry effects.

The behaviour of the hydrodynamic model, in comparison with the Delta Flume data, was rather good. Future improvements would concern correction of the wave model near the shore and the bed shear stress formulation.

Fig.7 a) Total load (wave-averaged and interperiod formula),  
b) Total load (measured)

In the suspended sediment module, the inclusion of the Lagrangian transport was a very important step. The adaptation length for the case examined was very small (and the suspended sediment concentration almost in equilibrium), but this not always the case. The suspended sediment concentrations, although small, should be compared with experimental data.

The wave asymmetry, taken into account in the bed load, was rather conceptually modelled. The wave kinematics should be improved using a suitable wave theory.

The inclusion of the bed slope effect in the bed load is expected to have an important influence on the bed level changes.

The total load was rather good and it is expected to improve as the different modules improve.

Although the model needs certain improvements it has the advantage of integrating most of the components of the cross-shore sediment transport. The swash zone transport, although an important element (see Briand and

Kamphuis, 1993), is not taken into account but before any attempt to include it, the present model has to be improved in the coast line region.

The model should be tested for other dynamic states that would show its capabilities and limitations, starting from tests 1B and 1C of the Delta Flume experiment.

Future research will concern formulation of the model for oblique wave incidence and the coupling of the different modules through the sediment balance equation to yield the bed level evolution.

## NUMERICAL MODELLING OF FLOW OVER RIPPLES USING SOLA METHOD

Hyoseob Kim <sup>1</sup>, Brian A. O'Connor <sup>2</sup> and Youngbo Shim <sup>3</sup>

### ABSTRACT

In order to simulate flow over ripples more accurately than existing approaches, a modified MAC scheme (called SOLA) proposed by Hirt et al.(1975) was adopted in the present study. Primitive equations composed of velocities and pressure were directly solved instead of the usual vorticity and velocity potential function. The governing equations were the Reynolds momentum equations in the x and z directions and the water continuity equation. The driving force was assumed to be the acceleration of the wave orbital movement just above the wave boundary layer. A mixing length hypothesis was adopted to describe the time-and-space varying turbulent eddy viscosity and the shear stress. An explicit difference method was used to solve the equations on a regular grid. The model showed good result when applied to Sato's(1987) laboratory data. The model was applied to a series of ripple tests, using similar hydraulic conditions to Sato, to study the effect of bed ripple steepness and asymmetry. Only a small effect was found on vortex movement and flow characteristics, although a clear offshore vortex movement was found.

### INTRODUCTION

An example of the seabed shows that it is mostly covered by ripples or dunes. Waves or currents affect the generation of ripples directly or indirectly. It is widely known that the flow or sediment transport mechanism in shallow waters is closely related to the ripple parameters. It is an important step to understand the flow over ripples in order to accurately predict the sediment transport and the resulting seabed level change.

Bed material movement over ripples in the wave direction is so complicated that the wave-induced sediment transport rate or direction cannot be simply predicted by empirical formulae. Micro-scale research within the ripple length should help the understanding of sediment transport over ripples. Interesting features related to ripples have been

reported by previous researchers. For example, vortex generation and its contribution to the suspended sediment transport has been well described by previous laboratory or numerical works.

After Bagnold's(1946) pioneering investigation on flow over ripples, laboratory experiments on the flow or sediment movement over ripples have been carried out by Du Toit and Sleath(1981), Sato(1987), Horikawa and Ikeda(1990), Ranasoma and Sleath(1992), and Horikawa and Mizutani(1992). Numerical modelling works have also been undertaken to examine flow or sediment movement over ripples. One ripple length has usually been used as the computational domain of the models. Existing numerical models have adopted the procedure of solving a vorticity equation and a velocity potential function. The existing models can be classified into two groups, an Eulerian grid group, and a Lagrangian discrete vortex method group. Typical models of the former type include Sato S.(1987), Blondeaux and Vittori(1991), Huynh-Thanh and Temperville (1990), and Sato Y. and Hamanaka(1992), while typical models of the latter type include Hansen et al.(1992). The method of solving the vorticity equation is known to have some merits. For example, the continuity equation is automatically satisfied and the pressure need not be solved. However, it has a problem in assigning adequate boundary values at rigid boundaries which is not easy because of the rapidly varying vorticity near them. Once the vorticity field is obtained, the velocity potential function should be solved from the Poisson equation. This procedure involves an iteration step, and produces numerical error, which is a negative aspect of this approach. Model results of the vorticity type proposed by previous investigators have shown rather poor agreement with measured experimental data sets upto the present. Therefore, it is proposed to adopt a method to solve the primitive velocities and pressures instead of the vorticity and velocity potential functions, and compare the two methods.

In the present study, the primitive variables are solved by an existing SOLA method to simulate flow over ripples. A mixing length hypothesis in the zero-equation turbulence closure was adopted to express time-and-space varying turbulent eddy viscosity. The SOLA approach is composed of explicit finite difference schemes. The present model uses a regular grid so that an arbitrary rigid bed boundary geometry can be easily expressed and modified by the rectangular grid points.

The present model is applied to synthetic situations to examine the effect of ripple steepness and non-uniform ripple shape.

## **MODEL DESCRIPTION**

### **Governing Equations**

We have four basic equations for incompressible fluid dynamics, i.e. water continuity and the Reynolds momentum equations in three directions. To simplify the problem, a two-dimensional vertical situation was assumed so that the gradient terms in the y direction disappear in the equations. Then, the governing equations are the water continuity and two Reynolds

momentum equations in the  $x$  and  $z$  directions:

- Continuity Equation

$$\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{w}}{\partial z} = 0 \quad (1)$$

- Momentum Equations

$$\begin{aligned} \frac{\partial \bar{u}}{\partial t} + \bar{u} \frac{\partial \bar{u}}{\partial x} + \bar{w} \frac{\partial \bar{u}}{\partial z} \\ = -\frac{1}{\rho} \frac{\partial \bar{p}}{\partial x} + \left( \frac{\partial(\overline{u'u'})}{\partial x} + \frac{\partial(\overline{u'w'})}{\partial z} \right) + \nu \left( \frac{\partial^2 \bar{u}}{\partial x^2} + \frac{\partial^2 \bar{u}}{\partial z^2} \right) \end{aligned} \quad (2a)$$

$$\begin{aligned} \frac{\partial \bar{w}}{\partial t} + \bar{u} \frac{\partial \bar{w}}{\partial x} + \bar{w} \frac{\partial \bar{w}}{\partial z} \\ = -\frac{1}{\rho} \frac{\partial \bar{p}}{\partial z} + \left( \frac{\partial(\overline{u'w'})}{\partial x} + \frac{\partial(\overline{w'w'})}{\partial z} \right) - g + \nu \left( \frac{\partial^2 \bar{w}}{\partial x^2} + \frac{\partial^2 \bar{w}}{\partial z^2} \right) \end{aligned} \quad (2b)$$

where,  $x, z$  are horizontal and vertical cartesian coordinates, respectively;  $u, w$  are the instantaneous velocity components in the  $x, z$  directions, respectively;  $\bar{u}, \bar{w}$  are the time-mean velocity components in the  $x, z$  directions, respectively;  $u', w'$  are the turbulent fluctuation velocity components in the  $x, z$  directions, respectively;  $\bar{p}$  is the pressure;  $g$  is the acceleration due to gravity; and  $\nu$  is the kinematic viscosity.

The momentum equations are further simplified, firstly, by ignoring the molecular viscosity. Secondly, the turbulent normal stresses are included in the pressure terms. The Reynolds stress term  $\overline{u'w'}$  requires a turbulent closure to complete the system.

### Turbulent closure

Boussinesq's eddy viscosity concept was adopted in the present study. The turbulent stress was assumed to be proportional to the mean-velocity gradients, that is:

$$-\overline{u'w'} = \nu_t \left( \frac{\partial \bar{u}}{\partial z} + \frac{\partial \bar{w}}{\partial x} \right) \quad (3)$$

Prandtl's mixing-length hypothesis was also applied to express the time and space varying turbulent eddy viscosity. Prandtl's mixing length hypothesis relates the eddy viscosity to the local mean velocity gradient and involves a single unknown parameter, the mixing length  $l_m$  as follows:

$$\nu_t = l_m^2 \cdot \left| \frac{\partial \bar{u}}{\partial z} + \frac{\partial \bar{w}}{\partial x} \right| \quad (4)$$

where  $\nu_t$  is the turbulent eddy viscosity,  $l_m$  is the mixing length ( $= \kappa l_{sb}$ ),  $\kappa$  is the von Karman constant, and  $l_{sb}$  is a length scale. In the present model,  $l_{sb}$  is assumed to be the shortest distance from the calculation point to the solid boundaries.

## Boundary conditions

Three kind of boundary conditions were applied in the present model. A zero velocity condition was used at the rigid bottom boundary, and a periodic condition in a ripple length was used at the two side boundaries. At the top boundary a zero shear stress condition was applied where no influences are assumed to be reached at the height of two ripple lengths.

The solution of the Reynolds equations yields velocity and pressure distribution in the flow field. When a submerged structure is exposed to fluid motion, non-uniform pressure distribution occurs adjacent to the structure. In solving the Reynolds equation, this pressure distribution gets into trouble. The MAC(Marker-And-Cell) method was proposed by Welch et al.(1965) at Los Alamos Scientific Laboratory(LASL) of the University of California to treat the problem. After then, the SMAC was proposed by Amsden et al.(1970) and the SOLA by Hirt et al.(1975) at LASL. The SOLA scheme uses a simple method to calculate the pressure by adjusting the tentative velocities iteratively until changes are within a given tolerance in the whole computational domain.

## MODEL VERIFICATION

The present model with the SOLA method was tested against Sato's(1987) laboratory results for non-uniform waves, and asymmetric ripple geometry (Case 7), in order to examine its validity. The ripple had asymmetric geometry with a round crest. The ripple length was 12 cm; the ripple height was 2 cm. The generated waves were close to the Stokes third order wave; first, second, and third harmonics of the near bed orbital velocity amplitude were -29.5, -7.611, and -1.416 cm/s, respectively. Sato's(1987) asymmetric ripple profile was tested, which had a round crest shape.

The spatial increments in the x, z directions were both 0.25 cm. The time increment was 1/800 of the wave period of 2 seconds. The parameter which controls the accuracy of the continuity equation in the SOLA method was chosen to be sufficiently small. The CPU required for the execution of five real wave periods was typically 7200 seconds on a CRAY-2S/YMP machine.

## Flow Field

The vorticity or the shear stress are directly related to the flow information. The model should be able to reproduce the flow fields first. The calculated and measured velocity fields were found to match reasonably well for the whole wave period. Fig. 1 shows the calculated velocities at the wave phase of  $19\pi/10$ (see Fig.10), and Fig. 2 shows the measured velocities at the wave phase of  $3\pi/10$  of Sato's experiment as same phase with this study. The present model results reproduces the correct position and size of the vortex. The above phase is for the flow reversing time, and clearly shows the newly-generated vortex over the ripple trough. It should be mentioned that the present model results show

better agreements with the laboratory experimental data sets than the previous vorticity model results, although the previous models are not systematically assessed in the present work.

### **Vertical Distribution of horizontal velocities**

Fig. 3 shows that the calculated horizontal velocity profile over the ripple trough at the wave phase of  $19\pi/10$  agrees well with the measured values for Sato's experimental conditions. The present model also reproduced the correct position and size of the wave-induced vortex throughout the wave period. The horizontal velocity profile agrees well with the measured one above the level of about half a ripple height from the ripple trough, while the agreement becomes less good near the ripple surface. This would partially be due to the unsatisfactory presentation of the smooth seabed shape with the regular grid.

### **Residual Currents**

Since the residual flow is the secondary flow, it is expected that the agreement between calculated and measured residual flow may not be so good as that of the primary flow. The calculated and measured residual currents (wave period average velocities) are shown in Figs. 4 and 5 respectively. Sato's laboratory wave condition was close to the Stokes third order wave theory, and the order of magnitude of the measured residual current over ripples was about 0.1 cm/s in the offshore direction. The calculated residual current shows similar magnitude and direction, although the separated small circulation cell just next to the ripple crest shows a slightly different pattern from the measured one. The reason for the deviation may eventually be the boundary treatment techniques, which require further investigation.

### **Vorticity Contours**

The vortex (circulation cell) was well reproduced by the present model at the lee of the ripple crest at the wave phase of  $19\pi/10$  in Fig. 6. The calculated vorticity field gives reasonable agreement on the vorticity magnitude with the Sato's laboratory experiment shown in Fig. 7. The secondary vortex proposed by Blondeaux et al.(1991) was also well reproduced by the present model just over the ripple surface.

### **Effect of Sharp Crest Shape**

In order to examine the effect of ripple crest shape (round and sharp), the present model was applied to a sharp crested ripple profile. The ripple crest shape of Sato's Case 7 experiment was modified from a round to a sharp shape for the present numerical test, while all the other parameters for the experiment were retained. The calculated flow field for the sharp crested ripple at the wave phase of  $19\pi/10$  is shown in Fig. 8. The position of the vortex centre is higher, and the area occupied by the vortex is larger than that for the round crested ripple case, as expected. The inter-wave-period (IWP) variation of the maximum absolute vorticities over the round and sharp crested ripples are shown in Fig. 9, which

reveals that the maximum absolute vorticities for the sharp-crested ripple were larger than those for the round crested ripple.

**MODEL APPLICATION**

**Application Conditions**

In order to examine the effect of ripple steepness and ripple asymmetry on the flow over ripples, the present numerical model was applied to various artificial conditions. The model run conditions were the water depth of 40 cm; the wave height of 15 cm; the wave period of 2 seconds. The waves were assumed to be the Stokes third order waves, i.e. the near-bed wave orbital velocity was obtained from the following equation(refer to Fig. 10)

$$u_{\infty} = c ( F_1 \cdot \cos \omega t + F_2 \cdot \cos 2\omega t + F_3 \cdot \cos 3\omega t ) \tag{ 5 }$$

where  $u_{\infty}$  is the near-bed wave orbital velocity outside the wave boundary layer.  $c$  is the wave celerity.  $F_1, F_2,$  and  $F_3$  are the constants in the Stokes third order wave.  $g$  is the acceleration due to gravity.  $k$  is the wave number ( $k = 2\pi/L$ ).  $\omega$  is the angular frequency ( $\omega = 2\pi/T$ ).  $h$  is the water depth.  $a$  is the wave amplitude.  $L$  is the wave length.  $T$  is the wave period. The coefficients of equation (5) can be obtained from following relationships:

$$c^2 = \frac{g}{k} \cdot \tanh(kh) \cdot \left( 1 + a^2 k^2 \frac{8 \cosh^4(kh) - 8 \cosh^2(kh) + 9}{8 \sinh^4(kh)} \right) \tag{ 6 }$$

$$F_1 = \frac{a k}{\sinh(kh)} \tag{ 7a }$$

$$F_2 = \frac{3}{4} \frac{a^2 k^2}{\sinh^4(kh)} \tag{ 7b }$$

$$F_3 = \frac{3}{64} \frac{a^3 k^3 \{13 - 4 \cosh^2(kh)\}}{\sinh^7(kh)} \tag{ 7c }$$

$$a = \left( \frac{H}{2} \right) / \left[ 1 + a^2 k^2 \frac{3 \{8 \cosh^6(kh) + 1\}}{64 \sinh^6(kh)} \right] \tag{ 8 }$$

where  $H$  is the wave height.

The ripple dimensions (length and height) were calculated from Nielsen's(1981) empirical formulae. The ripple profile for the given ripple dimensions was obtained from the following equations proposed by Sleath(1974):

$$x = X_c - (\eta/2) \sin(2\pi X_c / \lambda) \tag{ 9a }$$

$$z = (\eta/2) \cos(2\pi X_c / \lambda) \tag{ 9b }$$

where  $X_c$  is the parameter for a curvilinear coordinate;  $x, z$  are the horizontal and vertical cartesian coordinates, respectively; and  $\eta, \lambda$  are the

ripple height and the ripple length, respectively.

In order to examine the effect of ripple steepness and asymmetry, a fixed ripple length was chosen. The wave height of the ripple ( $\eta$ ) varied between 1.0 and 2.0 cm, and the longer half of ripple length ( $\lambda_1$ ) varied between 4.5 to 6.3 cm. Ripple geometries for the tests are given in the following table:

**Table 1** Ripple geometries for numerical tests

Run Case	Ripple Length (cm)				Height (cm)		Remarks
	$\lambda_1$	$\lambda_2$	$\lambda$	$\lambda_1/\lambda$	$\eta$	$\eta/\lambda$	
RS-1					1.00	0.11	Variation of Ripple Steepness
RS-2					1.25	0.14	
RS-3	4.5	4.5	9.0	0.5	1.50	0.17	
RS-4					1.75	0.19	
RS-5					2.00	0.22	
RA-1	4.50	4.50		0.50	1.50	0.17	Variation of Ripple Asymmetry
RA-2	4.95	4.05		0.55			
RA-3	5.40	3.60	9.0	0.60			
RA-4	5.85	3.15		0.65			
RA-5	6.30	2.70		0.70			

$\eta$  : Ripple height  
 $\lambda$  : Ripple length  
 $\lambda_1$  : Longer half length of ripple  
 $\lambda_2$  : Shorter half length of ripple

## Application Results

Fig. 11 shows the typical flow pattern at a wave phase for case RS-5. Fig. 11 confirms the fact that the near-bed flow turns its direction before the ambient flow (outside the wave boundary layer) turns its direction. Existing one-dimensional vertical wave boundary layer models have also produced the phase shift between the ripple-length-averag boundary layer flow and the outside boundary layer flow. However, the two-dimensional vertical model can track the detailed movement of vortices which directly affect the sediment transport in suspension or as bed load.

### 1) Vertical distribution of horizontal velocities

Fig. 12 (a) shows the vertical distribution of horizontal velocities over the ripple trough at the wave phase of  $18\pi/10$  for various ripple steepnesses, and Fig. 12 (b) for various ripple asymmetry. The centre of the strong vortex generally positions at the ripple crest level. Another weak vortex at the two ripple height is also seen in Fig. 12. The vertical distribution of horizontal velocities for various cases is nearly the same at the upper part above two ripple heights ( $2.0\eta$ ) from the ripple trough.

If the ripple is steep, the level of the vortex centre is generally high at

the wave phase of  $18\pi/10$ . However, if the wave period is not long enough, the vortex cannot grow sufficiently to fill the ripple space between the two crests.

Fig. 12 (b) shows that the position of the vortex centre and the vertical distribution of horizontal velocities are almost the same for various ripple asymmetry. The ripple asymmetry seems not to affect the vortex movement very much.

## 2) Time variation of horizontal velocities

The time variation of horizontal velocities at ripple crest is shown in Figs. 13 (a) and (b). At the ripple crest the horizontal velocities show little difference for various ripple steepness or asymmetry. In contrast to the ripple crest, the velocities at the ripple trough surface for various ripple steepness, see Figs. 13 (c), produces the double peak time variation of horizontal velocity. This pattern is closely related to the vortex motion over the ripple trough.

## 3) Track of vortex

Bagnold(1946) briefly described the track of a vortex over the ripples. Longuet-Higgins(1981) presented the vortex motion by time series using his discrete vortex model. He proposed that the vortex would reach upto the level of  $2.5\lambda$  when the water particle excursion length ( $d_0$ ) is  $1.5\lambda$  from his discrete vortex model results.

In the present study, the track of the separated vortex from the ripple crest was calculated for the case RS-3, see Fig. 14. The calculated movement of the two vortices generated in the onshore and offshore directions is not symmetric due to the asymmetry of the wave orbital velocity in both directions. The vortex generated at the lee side of the ripple crest moves about  $2.5\lambda$  in the onshore direction and disappears, i.e. the vorticity approaches zero after about a wave period time. On the other hand, the vortex generated at the front side of the ripple crest moves about  $3.0\lambda$  in the offshore direction and turns its direction. It disappears after about one and half wave periods.

The movement of the vortex generated at the lee side of the ripple crest for case RS-3 can be divided into 3 phases. The first phase is the generation phase. This starts at the wave phase of about  $3\pi/10$ . The vortex centre moves slightly upwards by the strong offshore ambient wave orbital velocity and slightly sinks down at the wave phase of  $7\pi/10$  due to the weak wave orbital velocity until the wave phase of  $11\pi/10$ . The second phase is the rising phase by the change of the wave orbital velocity direction. During the second phase, the vortex departs from the ripple trough by the onshore return flow. The third phase is the free vortex phase. The rising phase between the wave phase of  $3\pi/10$  and  $11\pi/10$  produces the two peak time variation of horizontal velocity at the ripple trough surface, see Fig. 13 (c).

The behaviour of the vortex generated at the front side of the ripple

crest shows quite different behaviour, i.e. asymmetric movement to the former pair vortex, see Fig. 14. The movement of the vortex generated at the front side of the ripple crest can also be divided into 3 phases. The vortex rises from the wave phase of  $15\pi/10$  to  $19\pi/10$ . The vortex starts to turn its direction at the wave phase of  $19\pi/10$  by the outside return flow. The distance moved is about  $3.0\lambda$ .

#### 4) Vorticity

The vorticity contours for the wave phase of  $19\pi/10$  are shown in Fig. 15. It is interesting to note that the smaller the ripple steepness ( $\eta/\lambda$ ), the larger the vorticity of the separated vortex as shown in Fig. 16 (a) and the maximum vorticity of the separated vortex for all cases was between  $33\text{--}38 \text{ sec}^{-1}$ . If the ripple became steeper, the area occupied by the vortex was expanded. The ripple surface provides higher energy dissipation rate due to the strong bed shear stress which may reduce the vorticity at the vortex centre. On the other hand, ripple asymmetry (cases RA-1 to 5) shows little effect on the vorticity of the separated vortices, see Fig. 16 (b).

The maximum vorticity is shown in Fig. 17 for various ripple steepness and asymmetry at a wave phase of  $15\pi/10$ .

The time variation of maximum vorticity on the ripple surface is presented in Fig. 18 for the cases of ripple steepness and asymmetry variation. In this figure, (+) value indicates the clockwise vorticity.

#### 5) Bottom shear stress

Longuet-Higgins(1981) derived a horizontal velocity distribution for oscillatory laminar boundary layer from the Navier-Stokes equation. Bottom shear stress for oscillatory laminar boundary layer can be derived from that formula, and the phase different between the bottom shear stress and the water particle velocity outside the oscillatory laminar boundary layer is known to be  $45^\circ$ .

In the present study, the bottom shear stress can be calculated from the mixing length assumption, i.e. the multiplication of the mixing length squared and the gradient of vertical velocity as follows:

$$\frac{\tau_b}{\rho} = l_m^2 \left| \frac{\partial \overline{u_p}}{\partial n} \right| \left( \frac{\partial \overline{u_p}}{\partial n} \right) \quad (10)$$

where  $l_m$  is the mixing length ( $l_m = \alpha \cdot l_{sb}$ ),  $l_{sb}$  is the shortest distance from the calculation point to the solid boundaries,  $\alpha$  is the von Karman's constant(0.4),  $u_p$  is the velocity parallel to the solid boundary surface, and  $n$  is the normal direction to the solid boundary.

The time variation of bottom shear stress divided by the density ( $\tau_b/\rho$ ) and water particle velocity(non-scale) at the ripple crest is shown in Fig.

19. Jonsson and Carlsen(1976) proposed that that the phase shifts between the wave orbital velocity and the bed shear stress are  $18^\circ$  and  $31^\circ$  in the onshore and offshore directions, respectively, for a rough turbulent flow over a flat bed with relatively small roughness. The phase differences for the turbulent flows are smaller than that ( $45^\circ$ ) for the laminar flow.

The present model results show that the phase shift between the bottom shear stress and the water particle velocity for the test cases are between  $16^\circ$  and  $40^\circ$ . The value varied depending on the vortex strength. The steeper the ripple, the bigger the phase difference. For the less steep ripple of case RS-1, the phase shift was  $16^\circ$  and  $30^\circ$  in the onshore and offshore directions, respectively. For the steep ripple of case RS-5, the phase shift was  $25^\circ$  and  $40^\circ$  in the onshore and offshore directions, respectively. The ripple asymmetry gives little influence on the phase shift between the bottom shear stress and the water particle velocity.

## CONCLUSIONS

A numerical model is proposed here to obtain the wave-induced turbulent flow information over ripples. The present model directly solves primitive velocities and pressure from the continuity and Reynolds momentum equations. The calculation of pressure term followed the existing technique, SOLA. The turbulence was modelled by a mixing length zero-equation closure. A regular model grid was chosen for the present model.

The numerical model was firstly verified using Sato's laboratory experimental conditions. The model results generally agree well with the measured values in the velocity field, vorticity, and the residual flow field.

The model was then applied to various situations to assess the importance of ripple steepness and asymmetry. In order to examine the effect of ripple steepness and asymmetry, the waves were assumed to be Stokes third order waves. The two vortices generated in the onshore and offshore directions move in a different manner due to the asymmetry of the wave orbital velocity. It moves  $2.5\lambda$  in the onshore direction, and  $3.0\lambda$  in the offshore direction. The vorticity becomes very small after about 1.5 wave periods.

The smaller the ripple steepness, the larger the vorticity for the separated vortex. If the ripple became steeper, the area occupied by the vortex was expanded. The ripple surface provides higher energy dissipation rate due to the strong bed shear stress which may reduce the vorticity at the vortex centre.

The time variation of horizontal velocity at the ripple trough surface shows two peaks, which become clearer for steeper ripples because of the strong vorticity. The two peaks can only be explained by the vortex movement.

The phase differences between the wave orbital velocities outside the

wave boundary layer and the bottom shear stresses at the ripple crest are shown to be about  $30^\circ$  on average. The phase difference slightly varies depending on the vortex strength at the ripple crest.

Judging from the model results, ripple asymmetry gives only a small influence on the vortex movement or the flow characteristics over the ripples.

## ACKNOWLEDGEMENTS

The authors are grateful for financial assistance from the Commission of the European Directorate General for Science, Research and Development under Contract No. MAS2-CT92-0024C. The present work was also undertaken as part of the research project, "The numerical modelling of sediment transport taking account of wave boundary layer characteristics" granted by Cray Research Inc., and System Engineering Research Institute, KIST.

## CHAPTER 156

### Swash Dynamics under Obliquely Incident Waves

Nobuhisa Kobayashi<sup>1</sup>, and Entin A. Karjadi<sup>2</sup>

**ABSTRACT:** A horizontally two-dimensional, numerical model is developed for predicting the time-dependent free surface elevation and fluid velocities in the swash and surf zones under obliquely incident waves. The assumptions of shallow water waves with small incident angles are made to simplify the continuity and momentum equations and reduce computational efforts considerably. The developed numerical model allows gradual alongshore variations of the bathymetry and the incident regular or irregular waves at its seaward boundary. The numerical model is compared with available regular wave data of alongshore uniformity as an initial assessment of the model. The wave height, setup and runup are predicted well. The numerical model with the bottom friction factor calibrated previously for swash oscillations predicts the magnitude of longshore current but can not reproduce the longshore current profile probably because it does not model the transition zone and lateral mixing.

#### INTRODUCTION

A quantitative understanding of swash hydrodynamics and sediment transport on beaches under obliquely incident waves is essential for the design of shoreline erosion mitigation measures such as sand bypassing and beach nourishment. Field and laboratory measurements on the distribution of longshore sediment transport across the surf zone indicated that the distribution was generally bimodal with peaks in the swash and breaker zones (e.g., Bodge and Dean 1987; Kamphuis 1991). Bodge and Dean (1987) observed that the relative significance of the peaks shifted from the breaker zone peak to the swash zone peak as the surf varied from spilling to collapsing conditions. They found that longshore sediment transport in the swash zone might account for at least 5% to over 60% of the total drift. Knowledge of longshore sediment transport in the swash zone is important for the design of a sand bypassing system such as the system based on a jet pump deployed in the swash zone at Indian River Inlet, Delaware (Clausner et al. 1991).

Ryrie (1983) developed a time-dependent numerical model for longshore fluid motion along a straight shoreline with a plane slope generated by obliquely incident monochromatic waves with a small angle of incidence. The numerical model was not compared with any data. The numerical model developed herein is formulated

unlike that of Ryrie (1983) such that it will be applicable to beaches of arbitrary geometry under obliquely incident random waves. Approximate two-dimensional governing equations under the assumptions of shallow water waves with small angles of incidence are derived from the three-dimensional continuity and Reynolds equations (e.g., Rodi 1980) in a manner similar to the derivation of Kobayashi and Wurjanto (1992) of approximate one dimensional equations from the two-dimensional continuity and Reynolds equations. It should be noted that the mechanical energy equation for turbulent flow can be derived from the continuity and Reynolds equations and that the energy equation for turbulent flow is generally associated with the conservation of heat energy (e.g., Rodi 1980).

### TIME-DEPENDENT NUMERICAL MODEL

The cartesian coordinate system  $(x', y', z')$  is defined as  $x'$  = horizontal coordinate normal to the overall orientation of the shoreline;  $y'$  = horizontal coordinate normal to the  $x'$ -axis; and  $z'$  = vertical coordinate with  $z' = 0$  at the still water level (SWL). The prime indicates the physical variables that will be normalized later. Limiting to waves in shallow water, the coordinates  $x'$ ,  $y'$  and  $z'$  are normalized by  $\sigma H'$ ,  $\sigma H'/\theta_c$  and  $H'$ , respectively, where  $H'$  = incident wave height;  $\theta_c$  = reference incident wave angle in radian; and  $\sigma = T'\sqrt{g/H'}$  with  $T'$  = incident wave period and  $g$  = gravitational acceleration. The corresponding fluid velocity components  $u'$ ,  $v'$  and  $w'$  in the  $x'$ ,  $y'$  and  $z'$  directions are normalized by  $\sqrt{gH'}$ ,  $\theta_c\sqrt{gH'}$  and  $H'/T'$ , respectively. The normalized continuity and Reynolds equations are then simplified under the assumptions of  $\sigma^2 \gg 1$  and  $\theta_c^2 \ll 1$  for shallow water waves with small angles of incidence. The simplified equations are integrated from the bottom to the instantaneous free surface using the kinematic bottom and free surface boundary conditions as well as the boundary conditions of zero normal and tangential stresses at the free surface.

The derived continuity and horizontal momentum equations for  $\sigma^2 \gg 1$  and  $\theta_c^2 \ll 1$  are expressed in the following normalized forms (Kobayashi and Karjadi 1995)

$$\frac{\partial h}{\partial t} + \frac{\partial}{\partial x}(hU) = 0 \quad (1)$$

$$\frac{\partial}{\partial t}(hU) + \frac{\partial}{\partial x}(C_1 hU^2) = -h \frac{\partial \eta}{\partial x} - f|U|U \quad (2)$$

$$\frac{\partial}{\partial t}(hV) + \frac{\partial}{\partial x}(C_2 hUV) = -h \frac{\partial \eta}{\partial y} - f|U|V \quad (3)$$

The normalized variables without the prime in these equations are defined as

$$t = \frac{t'}{T'} ; x = \frac{x'}{\sigma H'} ; y = \frac{y'}{\sigma H'/\theta_c} ; h = \frac{h'}{H'} ; \eta = \frac{\eta'}{H'} \quad (4)$$

$$U = \frac{U'}{\sqrt{gH'}} ; V = \frac{V'}{\theta_c \sqrt{gH'}} ; f = \frac{1}{2} \sigma f' ; \sigma = \frac{T'\sqrt{gH'}}{H'} \quad (5)$$

where  $t$  = time;  $h$  = instantaneous water depth;  $\eta$  = instantaneous free surface elevation above SWL;  $U$  = depth-averaged value of the cross-shore velocity  $u$ ;  $V$  = depth-averaged value of the longshore velocity  $v$ ;  $f'$  = bottom friction factor used to express the bottom shear stress in terms of  $U$  and  $V$ ; and  $\sigma$  = ratio between the

cross-shore and vertical length scales. The momentum correction coefficients  $C_1$  and  $C_2$  equal the depth-averaged values of  $(u/U)^2$  and  $(uv/UV)$ , respectively. It is noted that the vertical momentum equation yields essentially hydrostatic pressure in shallow water. Eqs. (1) and (2) with  $C_1 = 1$  are the same as those used previously for predicting the setup and runup of normally incident waves (Kobayashi and Wurjanto 1992). The assumption of  $C_1 = 1$  was suggested to result in an error on the order of 10%. The assumption of  $C_2 = 1$  in (3) may also be made to compute  $V$  using (3) for the temporal and spatial variations of  $U$  and  $h$  computed using (1) and (2). For the case of  $\theta_c^2 \ll 1$ , the dominant cross-shore fluid motion is not affected by the secondary longshore fluid motion varying more slowly in the longshore direction. Furthermore, the variations in the  $y$ -direction appear only in the term  $\partial\eta/\partial y$  in (3) and along the seaward boundary of the computation domain. The alongshore momentum equation (3) is more sensitive to the gradual alongshore variability. In short, the assumption of  $\theta_c^2 \ll 1$  reduces computational efforts considerably and eliminates difficulties associated with lateral boundary conditions for general two-dimensional computations.

The instantaneous quantities  $h, U$  and  $V$  in (1)–(3) include both oscillatory and mean quantities. The time-averaged continuity equation corresponding to (1) yields  $\overline{h\bar{U}} = 0$  to satisfy the condition of no flux into the assumed impermeable beach where the overbar denotes time averaging. The time-averaged momentum equation corresponding to (2) with  $C_1 = 1$  and  $f = 0$  corresponds to the conventional cross-shore momentum equation used to compute wave setup  $\bar{\eta}$  (Kobayashi et al. 1989). The time-averaged alongshore momentum equation corresponding to (3) with  $C_2 = 1$  can be written as

$$\frac{\partial}{\partial x} S_{xy} = -f|U|\bar{V} - \bar{h} \frac{\partial \bar{\eta}}{\partial y} - \frac{1}{2} \frac{\partial}{\partial y} \left[ \overline{(\eta - \bar{\eta})^2} \right] \quad (6)$$

with

$$S_{xy} = \overline{hUV} = \overline{hU(V - \bar{V})} \quad (7)$$

If the setup  $\bar{\eta}$  and the variance  $\overline{(\eta - \bar{\eta})^2}$  related to the root mean square wave height do not vary in the alongshore direction, (6) is similar to the conventional alongshore momentum equation that assumes  $\bar{U} = 0$ . The gradual alongshore variations of the wave setup and variance are as important as the bottom friction and the cross-shore gradient of the alongshore radiation stress  $S_{xy}$  for a small angle of wave incidence. The dispersion or lateral mixing term due to the vertical variations of  $u$  and  $v$  (e.g., Rodi 1980) is neglected in (6) because of the assumption of  $C_2 = 1$  employed here. Svendsen and Putrevu (1994) discussed the vertical variations of the mean velocities  $\bar{u}$  and  $\bar{v}$  and attributed the lateral mixing due to the nonlinear interaction between  $\bar{u}$  and  $\bar{v}$ . The dispersion terms arise from the nonlinear interaction between  $(u - U)$  and  $(v - V)$  integrated over the depth in conventional turbulent flow analyses (e.g., Rodi 1980).

Fig. 1 shows the finite difference grid of constant grid sizes  $\Delta x$  and  $\Delta y$  used in the numerical model. The cross-shore coordinate  $x$  is taken to be positive landward and the alongshore coordinate  $y$  is positive in the downwave direction with  $y = 0$  at the upwave boundary. The seaward boundary of the computation domain is located at  $x = 0$  along the  $y$ -axis. The time step size  $\Delta t$  is allowed to vary in the same way

Figure 1: Finite Difference Grid for Numerical Model

as in the existing one-dimensional numerical model RBREAK2 (Kobayashi and Poff 1994) where  $\Delta t$  is reduced in a semiautomated manner whenever numerical difficulties occur at the moving shoreline. The initial time  $t = 0$  for the computation marching forward in time is taken to be the time when the incident wave train arrives at  $x = 0$  and there is no wave action in the region  $x \geq 0$  and  $y \geq 0$ .

For the known values of  $h$ ,  $\eta$ ,  $m = hU$  and  $q = hV$  at the time level  $t$ , the values of these variables at the next time level  $t^* = (t + \Delta t)$ , which are denoted by the asterisk, are computed in sequence. The value of  $(h - \eta)$  is the normalized depth below SWL which is known for the specified bottom elevation. First, along each of the shore-normal lines at  $y = (i - 1)\Delta y$  with  $i = 1, 2, \dots, I$  where  $I$  is the number of the shore-normal lines,  $h^*$  and  $m^*$  are computed by solving (1) and (2) using the explicit dissipative Lax-Wendroff method (e.g., Richtmyer and Morton 1967) together with the seaward and landward boundary conditions employed in RBREAK2 (Kobayashi et al. 1987, 1989). The obliquely incident wave train at the seaward boundary is specified as input. The computation along each shore-normal line is actually made using RBREAK2. Second, along each of the shore-normal lines at  $y = (i - 1)\Delta y$  with  $i = 2, 3, \dots, (I - 1)$ ,  $q^*$  is computed using (3) together with the computed  $h^*$  and  $m^*$  where  $\partial\eta/\partial y$  in (3) is approximated by a central finite difference based on the values of  $\eta^*$  at the two adjacent lines. Use is made of the MacCormack method (MacCormack 1969) which is a simplified version of the Lax-Wendroff method and has been used successfully for the computation of unsteady open channel flows with hydraulic jumps (e.g., Gharangik and Chaudhry 1991).  $q^*$  is set zero landward of the shoreline node computed by RBREAK2. The seaward boundary condition for  $q^*$  is based on the characteristic equation derived from (3) as explained by Kobayashi and

Karjadi (1995).

When the beach profile and incident wave conditions are uniform in the longshore direction, it is sufficient to compute  $h(t, x)$ ,  $\eta(t, x)$  and  $m(t, x) = h(t, x) U(t, x)$  along the three lines at  $y = 0$ ,  $\Delta y$  and  $2\Delta y$  and  $q(t, x) = h(t, x) V(t, x)$  along the line at  $y = \Delta y$ . The computed  $\eta$  along the three lines are used to ensure the alongshore uniformity of the mean and variance of  $\eta$  used in (6). Even if the beach profile and incident wave conditions vary gradually alongshore, the developed numerical model will be applicable for the computation of the gradual longshore variations of  $h$ ,  $m$  and  $q$  by choosing a larger value of  $I$ , provided that lateral boundary conditions do not affect  $h$ ,  $m$  and  $q$  in the computation domain.

### COMPARISON WITH AVAILABLE REGULAR WAVE DATA

Visser (1991) conducted eight monochromatic wave experiments on 1:10 and 1:20 slopes and presented detailed data on uniform longshore currents, local wave heights, angles of wave incidence, wave setup and runup. The numerical model is compared with four experiments for which the seaward boundary location can be taken to be in relatively shallow water seaward of the breaker line. Table 1 lists the experiment number used by Visser (1991) and the slope and incident wave characteristics specified as input to the numerical model where  $\tan \theta' =$  uniform slope;  $d'_i =$  water depth below SWL at the seaward boundary located at  $x' = 0$ ;  $T' =$  wave period;  $H' =$  incident wave height at  $x' = 0$ ;  $\theta_i =$  angle in degrees of wave incidence at  $x' = 0$ ;  $\sigma =$  ratio between the cross-shore and vertical length scales defined in (5);  $\theta_c =$  reference incident wave angle in radian taken to be  $\theta_i$  in radian; and  $\xi =$  surf similarity parameter given by  $\xi = \sigma \tan \theta' / \sqrt{2\pi}$ . For these experiments, plunging breakers were observed. The assumptions of  $\sigma^2 \gg 1$  and  $\theta_c^2 \ll 1$  may be appropriate except for Experiment 2 with  $\theta_c^2 = 0.206$ . The only empirical parameter involved in the numerical model is the bottom friction factor  $f'$  in (5) where  $f' \simeq 0.05$  has been used for predicting wave runup on smooth slopes in small-scale experiments (e.g., Kobayashi et al. 1989). The value of  $f' = 0.05$  is used here for both cross-shore and alongshore fluid motions.

The obliquely incident regular wave train  $\eta'_i(t', y')$  at  $x' = 0$  for the small angle  $\theta_i$  in radian is assumed to be in the following dimensional form

$$\eta'_i(t', y') = \text{periodic function of } \left( \frac{t'}{T'} - \frac{y'}{L'/\theta_i} \right) = \frac{1}{T'} \left( t' - \frac{y'}{C'/\theta_i} \right) \quad (8)$$

in which  $L'$  and  $C' = L'/T'$  are the wavelength and phase velocity in the water depth

$d'_t$ . Eq. (8) accounts for the phase or time lag along the alongshore coordinate  $y'$ . The periodic function in (8) is specified using Stokes second-order or cnoidal wave theory depending on the value of Ursell parameter (Kobayashi et al. 1987).

The normalized grid sizes  $\Delta x$  and  $\Delta y$  in Fig. 1 need to be chosen to be small enough to resolve breaking waves in the surf and swash zones. For these experiments of alongshore uniformity, it is sufficient to use the three cross-shore lines at  $y = 0$ ,  $\Delta$  and  $2\Delta y$  in Fig. 1. The value of  $\Delta x$  is selected to be on the order of 0.01, corresponding to 200 grid spacings between the seaward boundary and the still water shoreline. The value of  $\Delta y$  is chosen to be the same as  $\Delta x$  to yield the same spatial resolution in the normalized coordinates. A limited sensitivity analysis has indicated that the computed results remain essentially the same as long as  $\Delta y$  is on the order of  $\Delta x$  or less.

First, the detailed computed results for Experiment 2 are presented as an example. The temporal and cross-shore variations of the free surface elevation  $\eta$ , the depth-averaged cross-shore velocity  $U$ , and the depth-averaged alongshore velocity  $V$  are stored along the center line at  $y = \Delta y$ . The temporal variations of  $\eta$ ,  $U$  and  $V$  for the duration  $0 \leq t \leq 300$  at  $x = 0$  (at the seaward boundary),  $x = 0.509$  (immediately seaward of the breaker line),  $x = 0.770$  (in the outer surf zone),  $x = 1.550$  (in the inner surf zone), and  $x = 2.265$  (in the swash zone) are shown in Figs. 2, 3 and 4, respectively. The cross-shore fluid motion represented by  $\eta$  and  $U$  computed using (1) and (2) becomes periodic fairly quickly for  $t \gtrsim 20$  as has been the case with the previous one-dimensional computations for beaches (e.g., Kobayashi et al. 1989). The alongshore fluid motion represented by  $V$  computed using (3) becomes periodic very slowly especially in the vicinity of the breaker line. The very slow response of the alongshore fluid motion is qualitatively consistent with the analytical result of Ryrie (1983) for the periodic solution development as well as the experimental procedure adopted by Visser (1991) who made measurements one hour after the start of the wave maker. In light of Fig. 4, the time averaging denoted by the overbar in the following is performed for the duration  $200 \leq t \leq 300$ .

The computed cross-shore variations of  $\bar{\eta}$ ,  $\eta_{rms}$ ,  $\bar{U}$ ,  $U_{rms}$ ,  $\bar{V}$  and  $V_{rms}$  for Experiment 2 are shown in Fig. 5 where the root-mean-square values representing the magnitude of the oscillatory components are defined as

$$\eta_{rms}^2 = \overline{(\eta - \bar{\eta})^2} ; U_{rms}^2 = \overline{(U - \bar{U})^2} ; V_{rms}^2 = \overline{(V - \bar{V})^2} \quad (9)$$

For example, if  $\eta = 0.5 \cos(2\pi t)$ ,  $\bar{\eta} = 0$  and  $\eta_{rms} = 1/\sqrt{8} = 0.35$ . The normalized uniform slope is indicated by the dashed-dotted straight line in the top figure in Fig. 5. The upper limit of the wave setup  $\bar{\eta}$  is the maximum runup elevation on the slope above SWL because  $\bar{h} \geq 0$  in the region wetted by water. The increase of  $\bar{\eta}$  and the decrease of  $\eta_{rms}$  in the surf and swash zone are approximately linear. On the other hand,  $U_{rms}$  decreases slowly in the surf zone and rapidly in the swash zone.  $\bar{U}$  is negative and represents the cross-shore return current as explained by Kobayashi et al. (1989). The longshore current  $\bar{V}$  is dominant in the surf zone and the oscillatory component  $V_{rms}$  decreases approximately linearly in the surf and swash zone.

Fig. 6 shows the computed cross-shore variations of the normalized quantities in-

Figure 2: Computed Temporal Variations of Free Surface Elevation  $\eta$  at  $x = 0, 0.509, 0.770, 1.550$  and  $2.265$ .

Figure 5: Cross-Shore Variations of  $\bar{\eta}$ ,  $\eta_{rms}$ ,  $\bar{U}$ ,  $U_{rms}$ ,  $\bar{V}$  and  $V_{rms}$

Figure 6: Time-Averaged Cross-Shore Wave Energy and Alongshore Momentum Balances.

volved in the time-averaged cross-shore wave energy equation (Kobayashi and Wurjanto 1992) and the time-averaged alongshore momentum equation (6) where  $\bar{E}$  = specific energy per unit horizontal area;  $\bar{E}_F$  = energy flux per unit width;  $\bar{D}_f$  = energy dissipation rate due to bottom friction per unit horizontal area;  $\bar{D}_B$  = energy dissipation rate due to wave breaking per unit horizontal area;  $S_{xy}$  = alongshore radiation stress given by (7); and  $f|\bar{U}|\bar{V}$  = alongshore bottom shear stress. The top figure in Fig. 6 indicates that the energy dissipation due to wave breaking is dominant and does not occur suddenly in this numerical model which does not account for wave breaking explicitly (Kobayashi and Wurjanto 1992). For these experiments of alongshore uniformity, the computed alongshore gradients of the mean and variance of  $\eta$  are negligible and the time-averaged alongshore momentum equation (6) reduces to  $dS_{xy}/dx = -f|\bar{U}|\bar{V}$ . The bottom figure in Fig. 6 shows that  $S_{xy}$  decreases monotonically in the surf and swash zones. The computed cross-shore variations of  $dS_{xy}/dx$  and  $-f|\bar{U}|\bar{V}$  are essentially the same where  $f|\bar{U}|\bar{V}$  is plotted to distinguish the two curves.

Fig. 7 compares the measured and computed cross-shore variations of the normalized local wave height  $H$  for each of the four experiments listed in Table 1. The agreement is very good in view of no adjustable parameter included in this numerical model to initiate wave breaking. However, it should be stated that this numerical model can not predict wave shoaling without wave breaking over a long distance (Kobayashi et al. 1989).

Fig. 8 compares the measured and computed cross-shore variations of the normalized wave setup  $\bar{\eta}$  together with the normalized uniform slope indicated by the dotted line for each of the four experiments. The agreement is good in the swash zone but the computed mean water level rises too rapidly landward of the breaker line as was the case with the previous comparison by Kobayashi et al. (1989). The numerical model does not predict the transition zone of constant wave setback whose effects on surf zone hydrodynamics were reviewed and elaborated by Nairn et al. (1990).

Table 2 shows the comparisons of the measured and computed maximum setup and runup for the four experiments. The computed maximum setup and runup correspond to the mean and maximum shoreline elevations, respectively, measured by hypothetical wires placed parallel to the above the uniform slope at elevations of 1, 5 and 10 mm,

Table 2: Measured and Computed Maximum Setup and Runup

Expt. No.	Maximum Setup				Runup			
	Computed			Meas.	Computed			Meas.
	1mm	5mm	10mm		1mm	5mm	10mm	
2	0.34	0.29	0.26	0.29	0.38	0.35	0.35	0.43
3	0.34	0.28	0.25	0.31	0.38	0.35	0.35	0.47
4	0.19	0.17	0.17	0.20	0.20	0.20	0.21	0.24
5	0.28	0.23	0.21	0.27	0.31	0.29	0.29	0.34

Figure 7: Measured and Computed Local Wave Height  $H$  for Four Experiments.

Figure 8: Measured and Computed Wave Setup  $\bar{\eta}$  for Four Experiments.

whereas the actual measurements were made visually. The computed results are not very sensitive to the wire elevations and in fair agreement with the measured values except that the numerical model with the bottom friction factor  $f' = 0.05$  slightly underpredicts the visually measured runup. It is also noted that the swash oscillations in the regular wave experiments are very narrow in comparison to swash oscillations on natural beaches that tend to be dominated by low-frequency motions (Guza and Thornton 1982; Holman and Sallenger 1985).

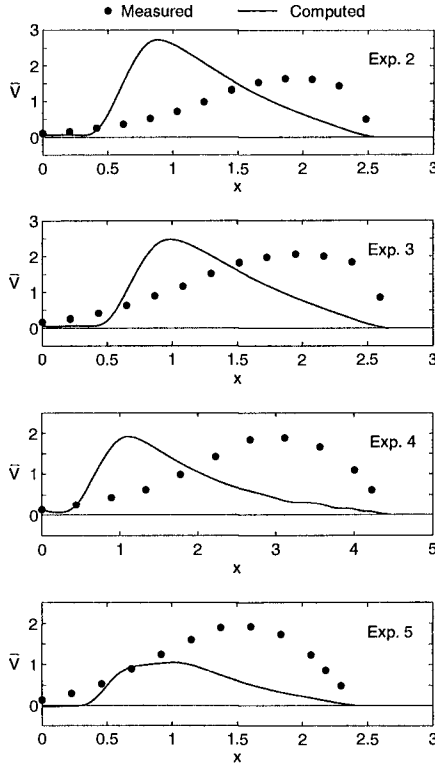

Figure 9: Measured and Computed Longshore Current  $\bar{V}$  for Four Experiments.

Finally, Fig. 9 compares the measured and computed cross-shore variations of the longshore current  $\bar{V}$  for the four experiments. The numerical model with  $f' = 0.05$  predicts the magnitude of  $\bar{V}$  but can not predict the shape of  $\bar{V}$  probably because the numerical model based on (3) with  $C_2 = 1$  does not include lateral mixing (dispersion) and it can not predict the transition zone as shown in Fig. 8. Comparing the similar agreement for Experiments 2 and 3 whose incident wave conditions are listed in Table 1, it may be concluded that  $\theta_c^2 = 0.206$  may still be regarded to be much less than unity. Visser (1984) and Nairn et al. (1990) showed it necessary to delay the initiation of the influence of energy dissipation on the generation of longshore currents until the landward limit of the transition zone. These shortcomings of the numerical model

may be serious for longshore currents generated by regular waves but are much less apparent for irregular waves due to irregular wave breaking and generation of low-frequency motions as presented by Kobayashi and Karjadi (1995) who compare the numerical model with available field data on longshore currents (Thornton and Guza 1986).

## CONCLUSIONS

A horizontally two-dimensional, time-dependent numerical model is developed for predicting swash and surf hydrodynamics under obliquely incident waves. The assumptions of shallow water waves with small incident angles are made to reduce computational efforts significantly and eliminate difficulties associated with lateral boundary conditions. Under these assumptions, the dominant cross-shore fluid motion along each cross-shore line is computed first using the existing one-dimensional numerical model. The secondary alongshore fluid motion, which may vary slowly in the alongshore direction, is then computed using the computed free surface elevation and cross-shore fluid velocity. The developed numerical model is compared with available data for obliquely incident regular waves. The numerical model is shown to predict the wave height, setup and runup well, although it can not model the transition zone. This implies that the existing one-dimensional model for normally incident waves can be used to predict the cross-shore variations of the free surface elevation for obliquely incident waves with small incident angles. The numerical model with the bottom friction factor calibrated previously for swash oscillations predicts the magnitude of longshore current fairly well but can not reproduce the longshore current profile probably because it does not include the transition zone and lateral mixing. The utility of the developed time-dependent model in comparison to conventional time-averaged models with several adjustable parameters (e.g., Nairn et al. 1990) is not apparent for the compared regular wave data for which the swash zone is narrow and the oscillatory alongshore velocity is small relative to the longshore current.

## CHAPTER 157

# WAVE RUN-UP AND SEA-CLIFF EROSION

S.-M. Shih<sup>1</sup>, P. D. Komar<sup>2</sup>, K.J. Tillotson<sup>2</sup>,  
W.G. McDougal<sup>3</sup> and P. Ruggiero<sup>3</sup>

### Abstract

Studies have been undertaken along the Oregon coast to better understand the processes involved in sea cliff erosion in order to develop improved predictions of the susceptibilities of properties to wave attack. A model has been developed that includes evaluations of extreme water elevations measured by tide gauges, calculations of wave run-up levels due to major storms, and a documentation of beach morphology variations that affect the wave run-up and determine the elevation of the junction between the beach and toe of the sea cliff. The occurrence of erosion depends on the combined water levels compared with the beach/cliff junction. All of these factors vary with time and also spatially along the coast. A program has been initiated to measure wave run-up on Oregon beaches ranging from reflective to dissipative in order to test the model predictions.

### Introduction

The erosion of sea cliffs backing beaches generally depends on the run-up of large waves generated by a major storm, superimposed on elevated water levels due to tides and other processes that affect water elevations (storm surge, etc.). Critical is the total level achieved by the water compared with the elevation of the junction between the beach and face of the sea cliff. These factors vary with time, tending

to reach extremes during the winter months so that the susceptibilities of properties to erosion are greatest in that season. The factors can also vary spatially along the length of coast, particularly the morphology of the beach and the degree of protection it offers to the sea cliff from wave attack.

In order to evaluate the susceptibilities of coastal properties on sea cliffs to wave erosion, it is necessary to make quantitative assessments of: (1) potential mean-water elevations due to tides, storm surges, and other processes, (2) the most extreme run-up levels of storm-generated waves, and (3) expected elevations of the beach/cliff junction. The application in this paper is to the Oregon coast, but the techniques can be used on other coastlines, employing wave and water-level data specific to those areas. In this paper we report on analyses of extreme mean-water levels measured by a tide gauge, on calculated wave run-up elevations due to major storms, on a program that has been initiated to measure wave run-up on a variety of Oregon beaches to test the extreme predictions, on efforts to document the beach morphology variations that affect wave run-up and determine beach/cliff junction levels, and on efforts to apply the analyses in coastal-zone management decisions such as the establishment of set-back distances.

## Study Site

Erosion has been common along the Oregon coast due to the high energy of the wave climate and the dynamic behavior of its beaches. Much of this erosion has occurred in sea cliffs backing beaches, of concern in that many communities are sited on uplifted marine terraces that are suffering from sea-cliff recession. The erosion has been episodic, associated with the occurrence of extreme storms, but it also has been spatially variable. This spatial variation is due in part to the tectonic setting of Oregon, which has resulted in different rates of coastal uplift (Komar and Shih, 1993). In general, the southern part of the coast and the northern-most part near the Columbia River are rising faster than the present rate of sea level rise, while the north central stretch has minimal uplift and therefore is experiencing a sea-level transgression due to the global rise in sea level. This coast-wide pattern of relative sea-level change is reflected in the degree of sea

cliff erosion. However, there are also more local controls which include the volume of sand on the fronting beach and the corresponding ability of the beach to act as a buffer between the sea cliffs and storm waves (Shih and Komar, 1994). The north-central portion of the Oregon coast, where erosion has been greatest, is segmented into a series of littoral cells by large headlands, which effectively isolate the stretches of beach within each cell. Sources and losses of sand to the series of littoral cells are highly variable, and this has controlled the amount of sand on the beach and the elevation of the beach/cliff junction. As a result, there tends to be differences in susceptibilities of properties to erosion between the series of littoral cells. It is this high spatial as well as temporal variation in the susceptibilities of properties to erosion that has made it important to develop analysis techniques that can assist in rationally evaluating those susceptibilities.

## Model Development and Process Evaluations

### *The Basic Model*

The model is illustrated in Figure 1. The probability of water reaching the base of a sea cliff backing the beach is dependent on water-elevation factors which include:

1. The tide level within its predicted harmonic cycle;
2. Processes such as storm surge, water temperatures, and the occurrence of an El Niño that produce departures of the mean water level from the predicted tidal elevations;
3. Set-up induced by waves breaking on the beach;
4. The frequency and elevations achieved by the run-up of individual waves above the mean set-up level.

Important to the induced erosion of sea cliffs is the comparison between elevations achieved by the water due to these combined processes ( $H_T + \bar{\eta} + R$  in Figure 1), and the elevation of the junction of the beach face with the sea cliff ( $H_J$ ). Wave-induced property erosion will not occur unless the elevation of the water exceeds the elevation of the beach/cliff junction ( $H_T + \bar{\eta} + R > H_J$ ). Implementation of the model to evaluate the susceptibilities of sea cliffs and associated properties to erosion depends on the ability to quantitatively evaluate the processes that govern water and beach elevations.

Figure 1: The basic model for the quantitative assessment of the susceptibilities of sea cliffs to wave-induced erosion.

### **Extreme Water Levels**

From the above list of water-level factors, it is apparent that tides are generally an important process controlling water elevations on the beach and thus the probability of waves reaching the toe of the cliff. Water-level elevations resulting solely from tide-generating forces are predictable, but there can be significant departures from those predictions due to a number of oceanic and atmospheric processes. The analyses presented here are based on the tide-gauge records from Yaquina Bay on the central Oregon coast. Measurements from that gauge span a sufficient number of years for projections of extreme water-elevations expected within a 100-year time frame.

The yearly extreme high tides recorded at the Yaquina Bay tide gauge have been analyzed to construct the probability curves of extreme water levels shown in Figure 2. The measurements were modeled by the General Extreme Value distribution (Shih, 1992). The results are expressed in terms of recurrence intervals of the water-level elevations, but can also be expressed as the probability of occurrence of a specified level during a given year. Based on the measured water levels, the projected 100-year elevation is about 2.5 meters above mean sea level (MSL). A similar analysis of the predicted yearly extreme tides yields a curve that is displaced well

below that based on measured tides, Figure 2, and yields a projected 100-year predicted tidal elevation of about 2.0 meters, some 50 cm lower than that based on the measured extreme tides.

Figure 2: Analyses of extreme predicted and measured tides based on the yearly maximum elevations recorded on the tide gauge in Yaquina Bay on the central Oregon coast.

The results demonstrate that there are significant differences between predicted and observed extreme tides, with the measured elevations typically being 10's of centimeters higher. This demonstrates the importance of the oceanic and atmospheric processes such as storm surge, water temperatures, etc., that can raise water levels well above predicted tidal elevations. It is important to account for the causes of the differences between the measured versus predicted tides in order to improve our basic understanding of the processes. Detailed analyses of these processes are still underway, but the broad seasonal variations are apparent. Higher water levels occur during the winter off the Oregon coast due to the generally warmer water temperatures (upwelling during the summer makes the water colder and denser, depressing the water-surface level); typically, mean-water elevations are about 20 cm higher during the winter than in the summer (Huyer et al., 1983). A particularly important phenomenon affecting extreme water levels is the occurrence of an El Niño; for example, the 1982-83 El Niño raised water levels by approximately 15 cm above the previously measured high levels for the winter months, on the

order of 35 cm above the average measured levels for those months (Huyer et al., 1983; Pittock et al., 1982).

There can also be daily fluctuations in mean water elevations such as those due to a storm surge as low-pressure fronts cross the coast. This factor has been investigated for only a few specific storms that resulted in property erosion along the Oregon coast (McKinney, 1976). In those few cases the maximum increases in water elevations attributable to storm surge were less than 20 cm. This small magnitude, compared with other coastal areas, results because the storms either crossed the coast too fast to develop a sizable wind set-up of the water, or the extreme waves of the storm were generated by a large fetch but not by extreme winds. More study of storm surge on the Oregon coast is needed, since it still exerts an important control on the total elevation of the water, and thus on the occurrence of sea cliff erosion; furthermore, there may be circumstances when storms do give rise to more significant storm surges on the Oregon coast.

### ***Storm Waves and Run-up Levels***

The second component in the cliff-erosion model is the evaluation of wave run-up associated with major storms. An assessment of this factor requires a good documentation of the deep-water wave climate and a capacity to calculate wave run-up elevations on beaches for those wave conditions.

A variety of wave-data sources is available for the Oregon coast upon which to base projections of extreme-wave parameters, which in turn can be used to calculate extreme run-up elevations. The data sources include the deep-water buoy data of the Coastal Data Information Program (CDIP) of the Scripps Institution of Oceanography, and from the National Data Buoy Program (NDBP) of NOAA. Those buoy-measurement programs began only in the 1980s, and in themselves do not provide a sufficiently long record upon which to base extreme-wave projections. Important in this respect are wave data derived from the microseismometer system operated by Oregon State University at the Marine Science Center in Newport. This system has been in operation since 1971, yielding measurements of significant wave heights and periods four times each day. Direct comparisons between buoy and microseismometer measurements demonstrate that the seis-

momometer yields good data for significant wave heights, while the periods are systematically too large (Tillotson, 1995; Tillotson and Komar, in review). Wave data are also available for the 20-year period from 1956 to 1975, derived from the daily wave hindcasts of the Wave Information Study (WIS) of the U.S. Army Corps of Engineers. Unfortunately, the WIS wave heights are systematically 30% too high in comparison with the direct measurements. An attempt was made to recalibrate the WIS data in order to make it more compatible with the wave climate based on the direct measurements, but the results then yielded too few storm-wave conditions based on a threshold of the significant wave height being greater than 6 meters, the limit used in the extreme-wave analyses. Therefore, the extreme-wave analyses had to rely on the combined measurements of the deep-water buoys (specifically the CDIP buoy offshore from Bandon, Oregon), and the wave data derived from the microseismometer system (Tillotson, 1995; Tillotson and Komar, in review). The data base thereby consists of 23 years of daily wave measurements, during which 24 storms were identified as having deep-water significant wave heights equal to or greater than 6 meters. The largest measured deep-water significant wave height was 7.3 meters, while extreme-wave analyses yielded a wave height of 7.8 meters for the 50-year projection, and a less reliable value of 8.2 meters for the 100-year projection. If a 5-meter wave height is used to define "storms" rather than 6 meters, then the projected 50-year and 100-year wave heights are respectively 8.2 and 8.8 meters.

This established deep-water wave climate has been used to calculate extreme run-up elevations on Oregon beaches backed by sea cliffs. There is a considerable literature derived from studies of wave run-up on structures such as jetties and on natural beaches; Douglass (1990) provides a recent review, and van der Meer and Stam (1992) have undertaken a synthesis of the extensive laboratory results. The analysis approach used here is based mainly on the field measurements of Holman and Sallenger (1985) at the Field Research Facility, Duck, North Carolina, and in particular on the results of Holman (1986) derived from his reanalysis of the data to evaluate extreme run-up elevations. Holman analyzed run-up in terms of the mean run-up level, the significant level (elevation of the

highest one-third), the 2% exceedence elevation, and the absolute maximum run-up elevation achieved during a 20-minute measurement record. In our predictions, we have used the 2% exceedence, denoted by  $R_{2\%}$ . Similar to earlier studies, Holman (1986) found that this run-up elevation can be predicted by the relationship

$$\frac{R_{2\%}}{H_s} = C\xi \quad (1)$$

where  $H_s$  is the deep-water significant wave height,  $C = 0.90$  is an empirical constant established by the measurements, and  $\xi$  is the dimensionless Iribarren number defined as

$$\xi = \frac{S}{(H_s/L_o)^{1/2}} \quad (2)$$

where  $S$  is the slope of the beach face and  $L_o$  is the deep-water wave length given by  $L_o = (g/2\pi)T^2$  where  $g$  is the acceleration of gravity and  $T$  is the wave period. Combining the above equations yields

$$R_{2\%} = CS(H_s L_o)^{1/2} = C \left( \frac{g}{2\pi} \right)^{1/2} S H_s^{1/2} T \quad (3)$$

for the run-up elevation as a function of the deep-water significant wave height and period, and of the beach slope. Equation (3) accounts for the total run-up elevation due to the presence of waves, that is, it combines the wave-induced set-up which raises the elevation of the mean shoreline, and the swash elevation of individual waves beyond that mean shoreline. If analyzed independently, the set-up and swash elevations both have predictive equations like the above relationships, but the coefficients in equation (3) are respectively  $C = 0.35$  and  $0.55$ , which sum to the  $0.90$  coefficient.

Equation (3) has been used to calculate expected run-up elevations associated with the 24 storms during the past 23 years. Here the calculation depends on the wave period during the storms, as well as the wave heights. This emphasizes the importance of storms in that, as is commonly found, there is a broad positive correlation between significant wave heights and periods (Tillotson, 1995; Tillotson and Komar, in review), which combine in equation (3) to yield the most extreme run-up elevations on Oregon beaches during the past 23 years. Those calculated  $R_{2\%}$  values for the 24 storms have been subjected to an extreme-value analysis using the Automated

Coastal Engineering System (ACES) developed by the U.S. Army Corps of Engineers. Assuming a beach-face slope of  $S = 0.03$ , an approximate average for the Oregon coast, the projected 50-year run-up level is  $1.87 \pm 0.15$  meters, while the less reliable 100-year projection is  $1.97 \pm 0.17$  meters (Tillotson, 1995). These magnitudes for the extreme wave run-up are comparable to the total tidal excursion on the Oregon coast, and are much larger than water-level enhancements resulting from storm surge, etc. The calculations, therefore, reconfirm the importance of run-up during storms being a major factor in causing sea-cliff erosion.

### ***Beach Morphology and Elevations***

The elevation of the beach/cliff junction,  $H_j$  (Fig. 1), can vary from one beach to another due to the total quantities of sand within the littoral cells, and with the grain size of the beach sediment. The grain-size dependence has been demonstrated by Shih and Komar (1994) in a study of the Lincoln City littoral cell on the central Oregon coast. This cell is unusual in that there is a pronounced and systematic longshore variation in sediment grain sizes and thus in the beach morphology, ranging from dissipative to reflective systems. The coarser-sand reflective beaches have higher beach/cliff junction elevations, probably resulting from the higher levels that can be achieved by run-up during storms due to the slope dependence  $S$  in the run-up relationships. Furthermore, the coarser-sand beaches undergo larger profile changes through the seasons, and also experience greater profile shifts during individual storms as compared with the finer-sand beaches. Rip currents on the coarser-sand beaches tend to erode larger and deeper embayments into the berm, and this in particular can lower the elevation of the beach/cliff junction, thereby locally and temporally increasing the susceptibility of the property to erosion.

The analyses have established that a critical component to the development of cliff erosion models is the determination of the beach/cliff junction elevation and how it depends on the total quantities of sand on the beach, the coarseness of the sediment, and on factors such as the occurrence of a rip-current embayment that locally lowers the elevation. This

component has been particularly important to the occurrence of cliff erosion episodes along the Oregon coast.

### Measurements of Wave Run-up

In order to test the model that combines water elevations with calculated wave run-up levels, and to better understand the processes involved in sea-cliff erosion, we have begun a program to measure wave run-up on a number of beaches. Swash run-up is measured using the video techniques developed by Holman and Sallenger (1985). This includes beach profile surveys of the swash zone, and the video recording of the run-up signal during high tides, with markers placed on the beach for geometric transformations. The time series of vertical run-up signals were then extracted from the two-dimensional video intensity signal using the beach profile elevations and known geometric positions of the markers. The highest run-up levels achieved during 50-second time intervals were sub-sampled from a 70-minute run-up time series digitized at 1 Hz, giving a total of 82 data points of run-up maxima; a long sampling interval and time series were necessary due to the strong infragravity component in the run-up. The run-up maxima were then analyzed to determine the maximum run-up ( $R_{\max}$ ) achieved during the 70-minute measurement interval, the 2% exceedence statistic ( $R_{2\%}$ ), the 33% "significant" exceedence ( $R_{1/3}$ ), and the mean run-up elevation ( $\bar{R}$ ); all of these measurements include the set-up elevation.

Thus far, three sites along the Oregon coast have been included in the measurement program, representing different degrees of beach sand volumes and buffering capacities, and different beach sand grain sizes and morphologies ranging from strongly dissipative to reflective. The results from the three beaches are given in Figure 3, where all elevations are with respect to mean sea level as established by surveying from nearby bench marks. The tide levels shown are for the times of run-up measurements. At Beverly Beach the maximum run-up exceeded the beach/cliff junction elevation, and the extreme swash was observed to surge up the face of the cliff. Beverly Beach is located within a littoral cell that is deficient in sand volume, and this in part is reflected in the low level of its beach/cliff junction elevation (4.1 meters, MSL) compared

Figure 3: Measurements of wave run-up elevations on three beaches along the Oregon coast, where all elevations are referenced to mean sea level (NGVD).

with the other two beach locations included in Figure 3 (elevations of 6.2 and 5.3 meters, MSL). This difference in part also results from the contrasting grain sizes of the sediments on these three beaches. The lower beach/cliff junction elevation at Beverly Beach, has resulted in a high frequency of wave run-up reaching the toe of the cliff, and in substantially greater erosion compared with most other locations on the Oregon coast.

The other two beach locations included in the run-up measurements, Gleneden Beach and 21st Street Beach, are within the Lincoln City littoral cell (Shih and Komar, 1994). Gleneden Beach is coarser grained and has the steeper slope so it is reflective (summer) to intermediate (winter), while the beach at 21st Street is composed of fine sand and is always dissipative. During the times of run-up measurements, Figure 3, the swash did not reach the beach/cliff junctions at either location, and this is generally the case as cliff erosion is a relatively rare event within the Lincoln City littoral cell due to the large quantities of sand on the beaches. In that cell, rip currents play a particularly important role in locally reducing the beach/cliff junction elevation,  $H_j$ , during the occasions of episodic erosion.

The run-up measurements can be analyzed to test the model predictions, specifically the predicted elevation achieved by the calculated  $R_{2\%}$  run-up level superimposed on the measured tide, compared with the measured results. Although the measurements thus far have not included extreme-storm conditions, the comparisons can still provide a test of the model. The comparisons for the three data sets of Figure 3 are given in Table 1.

Table 1: Model and Measurement Comparisons

Location	Date	Tide (MSL) (meters)	$H_s$ (m)	T (sec)	$R_{2\%}$ + Tide Calc.	Meas.
Gleneden	2/2/91	1.17	1.56	13.1	2.04	2.15
21st Street	2/17/91	1.49	2.76	13.1	2.31	2.88
Beverly Beach	3/17/91	1.29	3.47	14.2	2.47	3.00

In each comparison in Table 1, the predicted water elevation is lower than the measured elevation, the difference ranging from about 10 to 50 cm. This difference results from the calculated  $R_{2\%}$  using equation (3), versus the measured run-up elevation, since the measured tidal elevation is the same in both calculated and measured total water levels in Table 1. This suggests that equations (1) and (3) based mainly on the measurements of Holman and Sallenger (1985) and Holman (1986) at the Field Research Facility, Duck, North Carolina, will need to be revised for the present application to run-up on Oregon beaches. Such a revision at this stage is premature, as we presently have only the three measurement sets shown in Figure 3. A primary objective of our ongoing research is to obtain more run-up data on a greater variety of beaches, at which time refinements in the model calculations can be made.

### Summary and Discussion

The application of the sea-cliff erosion model to the Oregon coast has shown that the predicted tides, elevations of mean water levels due to a variety of processes, and wave run-up during major storms can all be contributing factors to the erosion. Also important is the morphology of the beach, and in particular the elevation of the beach/cliff junction. In some littoral cells on the Oregon coast, this junction elevation is low due to the paucity of sand on the beach, allowing elevated water levels to frequently reach the toe of the sea cliff, resulting in more rapid erosion. In other littoral cells there are sufficient volumes of sand on the beach that it generally can act as a buffer between the water and sea cliff. In those cells rip currents at times cut embayments into the beach and locally lower the beach/cliff junction elevation so that cliff erosion results; the erosion is therefore extremely episodic and spatially variable.

Although the model thus far has been useful in a broad examination of sea-cliff erosion variability along the Oregon coast and in accounting for the susceptibilities of properties to erosion in the various littoral cells, refinements based on additional field data are needed. This is the objective of our on-going research. In particular we are focusing on the video collection of more run-up data on a greater variety of beaches in order to re-calibrate the run-up equations so that they

provide improved predictions. The measurements are also being analyzed to determine the proportions of infragravity versus incident-wave energy so as to provide a better understanding of the dynamics of wave run-up. In that connection, our continuing research is expanding to obtain measurements of water depths and celerities of the bores leading up to the swash, as well as properties of the resulting run-up. The measurements will be used to test and refine models of run-up dynamics and elevation predictions, and to improve the design of shore-protection structures used to reduce sea-cliff erosion.

## CHAPTER 158

### MEASUREMENT OF PARAMETERS, DIRECTION AND RATE OF BEDFORM MIGRATION

R. D. KOS'YAN, I. S. PODYMOV

#### Abstract

Special sensor was developed in the Southern Branch of of the P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences Oceanology Institute, able to register variations of sediment layer thickness in any point of interest on reservoir, sea, channel or river bottom under any hydrodynamic conditions.

Uninterrupted information on geometry, rate and direction of migration of bedforms (ripples, ridges, dunes, bars) in the chosen point of underwater slope can be obtained in the following manner. Three or more sensors are placed by a diver on bottom in a horizontal plane in apieces of equilateral triangle on metal girder. The construction is put deeper into ground to 20-25 cm. Distance between sensors and their spatial orientation are set beforehand. Height and "period" of sand bedforms are found from time variations of sediment layer thickness above any of the sensors. Rate and directions of their migration are calculated by time of bedform crest transit above sensors. Sand wave length is calculated from its "period" and migration rate. A series of laboratory and field experiments has been performed for the purpose of clearing up a sensor working capacity, calibrating and work methods.

#### Introduction

Migration of sand microforms caused by surface waves, wave currents or channel flows plays an important role in cross-shore, longshore and channel sediment transport. This component of overall sediment transport has not been studied, as reliable instruments for continuous measurement of bedform geometry are still lacking.

Geometry parameters of bedforms are usually measured by divers (Manual..., 1975; Kos'yan, 1983; 1987; Miller, Komar, 1980; Dingler, 1974). The diver descends to bottom in calm or slightly wavy weather and while moving along a set route, measures bedform parameters and estimates their shape and spatial orientation in the certain points.

Observation of bedform dynamics by divers has certain disadvantages: information is interrupted, as measurements during storm are not possible; data on rate and direction of

---

The Southern Branch of the P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences. Gelendzhik-7, 353470 RUSSIA

bedform migration can not be obtained; diving works are laborious and expensive.

Method of repeat photography of the same bottom portion from a fixed point (Gizejewski et al., 1982) is used more rarely. Under storm observation of bottom sand layer dynamics seems possible only by measurements taken from rigid trestle bridges, piers and tramways. In other cases the data reflect only post-storm bottom variations.

Uninterrupted information on geometry, rate and direction of migration of bedforms (ripples, ridges, dunes, bars) in the chosen point of underwater slope can be obtained with the use of special sensors.

Such sensor was developed in the Southern Branch of the P.P. Shirshov Institute of Oceanology (Kos'yan, Podymov, 1993; 1994), able to register variations of sediment layer thickness in any point of interest on reservoir, sea, channel or river bottom under any hydrodynamic conditions.

### General description

The sensor (we named it sand level gauge) is destined for the investigation of physical aspects of solid particle movement near the bottom, specifically for measuring velocity of formation and shift of bottom accumulative forms, when studying the dynamics of sea sediments on the shelf and the engineer research for the creation of hydrotechnical constructions, etc.

It is an electron-mechanic device for the determination of instantaneous value of the bottom sediment thickness in a selected point. A method of fixation of sediment pressure on the outer metal diaphragm of the gauge, caused by above sediment thickness variations, is realized in this device. Its technical characteristics are in the table 1.

Table 1. Sea level gauge technical characteristics.

- diameter of a sensible weight accounting membrane	0.1 m
- maximum measured weight	5 kg
- sensibility	0.0002 m
- change of initial value of output signal, when temperature changes in operating range	$< \pm 0.1\%/10^0 \text{C}$
- non-linearity of the output signal according to absolute value	$< 0.7\%$
- time constant	$< 0.1 \text{ sec.}$
- maximum sediment thickness above the sensor during measuring (depends on "arch" effect)	0.25 m
- maximum admissible shift of the membrane during measuring	0.0003 m
- supply voltage	$\pm 15 \text{ V}$
- utilized current (without current load)	$< 0.0005 \text{ A}$
- utilized current (when output signal is the maximum one)	$< 0.0025 \text{ A}$
- output signal	$0 \div 0.02 \text{ A}$
- range of operating temperature	$+1^0 \text{C} \div +80^0 \text{C}$

The structural scheme of the sand level gauge (Fig.1) includes tensoresistive bridge (1), electronic module of signal formation (2) and electronic module of current formation (3).

Tensoresistive bridge represents four tiny semiconducting tensoresistors, which are placed on a single sapphire backing. Tensobridge is constructed in such a way, that a change of environment temperature is equally inherited to every tensoresistor. In addition computer access of resistors according to their parameter identity let to minimize an error connected with the bridge out-of-balance caused by environment temperature change. Electronic module of signal formation fulfills the stabilization of voltage, which feeds the tensometric bridge, and chooses a out-of-balance signal with the help of circuits of differential amplification. Electronic module of current formation passes the out-of-balance signal to the point of data storage and processing.

Fig. 1. The structural scheme of the sand level gauge.

The device is made as a cylindrical casing, inside of it a manometric unit and dynamometer connected kinematically are placed, and a compensating load-bearing element as well, which effects upon the manometer.

The sand level gauge is used in the following manner. One sensor or a group of sensors are deepened into bottom sediments at the depth of 15-20 cm in the selected point of the shelf. The ground surface above the sensor is flattened. The pressure of sediment cover recorded at the moment of installation is assumed as an initial one.

Shift of accumulative bottom forms (ripples, ridges, dunes) through any point of the bottom causes a periodic change of the sediment mass in this point. When a wave crest is passing, the pressure on the external membrane increases, changing the pressure distribution in and provokes the out-of-balance of the bridge system, which is formed by tensoresistors. When a wave trough is passing, the same effects occur, but the sign of out-of-balance becomes a contrary one. Periodic changes of the water static pressure caused by waves or tide cycles are not displayed in the sensor reading as far as they are completely compensated.

Finally, the gauge secures continuous high-grade measuring of the bottom sediment thickness in a wide range of changing static pressure. Thus, a quantitative information about accumulative bottom form movement can be obtained. And then a velocity of its movement under any hydrodynamic conditions can be calculated. An important feature of the gauge is the isolation of dynamometric assembly from external membrane

(Fig.2), that makes easier the compensation of the parameters of the sensor temperature error.

The appearance of the sand level gauge is given in Fig.3.

Fig. 2. The cross-section of the sand level gauge construction.

Fig. 3. The appearance of the sand level gauge.

### Communication and data playback

The sand level gauge is connected with the point of the data storage and processing by 4-core cable. Supply voltage  $\pm 15V$  and a midpoint are transmitted by 3 cable lines. A separate line brings an information signal as a current, which depends on the bottom sediment thickness. An electronic module of current formation is made as a self-tuning current loop with negative feedback, parameters of which do not depend within certain limits on the cable length and resistance. Analog information signal is converted into binary code with the help of dodecadischarge analog-to-digital converter of successive approximation. Output signal of the sand level gauge converted into binary code is being recorded on magnetic carrier of the computer with necessary discreteness.

For the purpose of clearing up a sand level gauge working capacity, calibrating and work methods a series of laboratory and field experiments has been performed.

### The laboratory experiment

The main task of the laboratory experiment is to determine the dependence of sand pressure poured on the sensor under the water on the thickness of sand cover and to assess the influence of different kinds of sand upon the "arch" effect.

Electronic units have not been used in order to eliminate their influence on the transmitting parameters of the sensor. A stable supply voltage fed directly the tensometric bridge. Out-of-balance voltage was recorded by digital voltmeter.

Fig. 4. Grain-size distribution curves for beach and bank kinds of sand, which were used for calibration.

Two kinds of natural sands were used in the experiment. Below they are marked as beach sand and bank sand. According to the data of mineralogical analysis 90% of beach sand are quartz and feldspar with density ( $\rho_s$ ) of  $2.65 \text{ g/cm}^3$ . A mineralogical analysis of the bank sand has not been done but this type of sand contained a considerably large amount of clay. The assessment of the particle form has not been done. Curves of the particle distribution according to their size ( $\Phi = -\log_2 d$ ),  $d$  is a particle diameter) for both kinds of sand are given in Fig.4. Their mean diameter ( $d_{\text{mean}}$ ) is given in the same figure.

The calibrating of the sand level gauge was performed in the tank, which volume was 50 l and the height - 470 mm. The sensor was placed on the bottom of the tank, and then a portion of sand was added. At first the thickness of sand layer covering the membrane of the sensor was 20 mm. The sand layer thickness was recorded continuously. Out-of-balance signal of the tensobridge was fixed by digital voltmeter for every portion of sand. The tank was vibrated after every sand supplement. Then, the vibration was stopped, and 5 minutes later, the thickness of the sand layer above the sensor and a value of analog out-of-balance signal were measured. In the course of calibration simultaneously with sand a small amount of water was added into the tank. The calibration was done firstly for beach sand and then for bank sand. Measuring was stopped, when the tank was brimful with sand.

The check of temperature stability of the sensor work was carried out in this experiment too. Measuring in water without sand has shown that output signal of the sensor remains to be stable one with an error 0.1%, when water temperature changes from  $10^\circ$  to  $30^\circ\text{C}$ .

The check of water static pressure on the value of the out-of-balance signal was performed in another experiment. For this purpose the sensor was being slowly lowered from the trestle-bridge to the depth of 5 m. Out-of-balance signal of the tensobridge did not change.

The results of the sensor calibrating for beach and bank sands are given in Fig.5. As it is seen in diagrams, a good coincidence for different kinds of sand and a high linearity of the characteristics of out-of-balance signal  $U$  on the sand layer thickness  $D$  above the sensor can be observed only when the sand layer thickness is not more than 220 mm. When the sand layer is more thick, the linearity of the dependence is true only for beach sand. Diagram  $U(D)$  for bank sand becomes distorted and its slope. The character of the change of the curve slope points to the reduction of the sand layer thickness influence on the pressure given to sensor. Probably it can be explained by the fact that clay, present in sand, binds sand particles and forms interstitial layers of a high strength. Those layers prevent the pressure to pass from the upper layers to the lower ones. We named as an "arch" effect the phenomenon of distortion of pressure. It is evident, that any loose sediments have an "arch" effect. But the value of layer thickness, from which it begins to display, is a characteristic peculiarity of every definite kind of sediments.

The analysis of the laboratory experiment data shows that, when laboratory calibration data are used for the processing of field measurements, the depth of the sensor immersion into sediments must not exceed 220 mm. But it does not exclude the

possibility of the sensor use in the conditions different from laboratory ones. Only the calibrating *in situ* for every kind of sediment and conditions is necessary.

Fig. 5. Calibration curves for different kinds of sand.

Laboratory test of the sand level gauge was carried out in a wave flume. This flume was 61m length, 0.8m in width and about 0.7m height (Kos'yan, Onishchenko, Philippov, 1988).

Test consisted in the comparison of bed form height  $H$  with  $D$ , measured with the help of the sensor. For this purpose the sand level gauge was buried into sand at the depth of 15 cm in immediate proximity to a glass wall of the flume in such a way that an observer can define exactly the bed form position relative to the sensor. While changing the wave producer period of oscillation during 1-2 s we managed to create sand ripples 6 cm high and to move them along the longitudinal axis of the flume. Fig.6a. shows the measuring data of two ripples which have passed just above the sensor during the laboratory experiment.

#### Full-scale experiment

Field test of the sand level gauge was carried out in the course of international experiments on the Shkorpilovtsy (Bulgaria) testing-ground.

Field test consisted in the recording of the change of bed form height during a storm and in comparison of the sand level gauge reading with the data obtained by divers. The sensor was buried into bottom sediments at the depth of 15 cm in the point

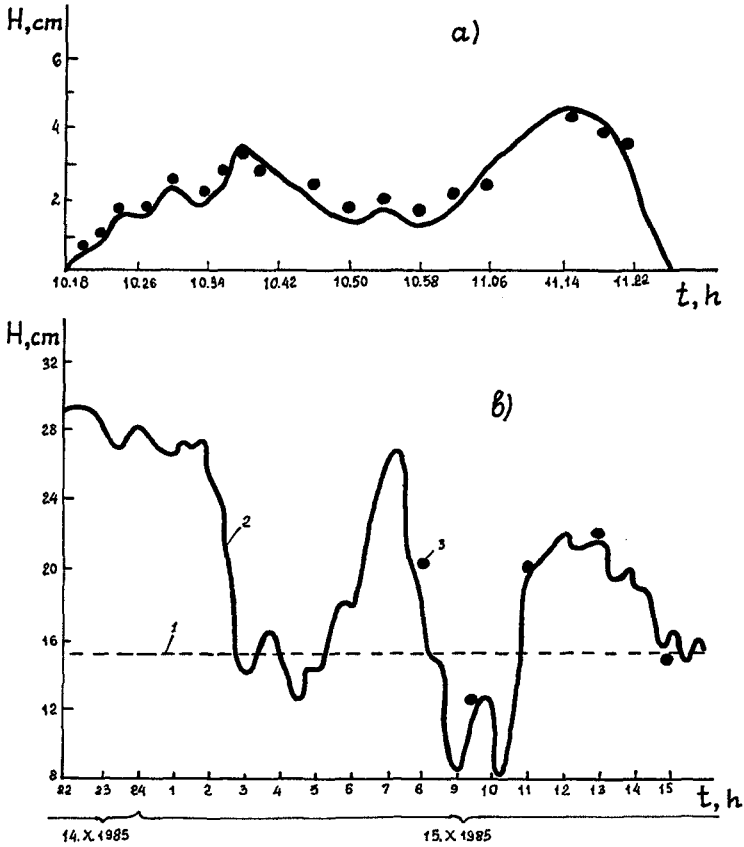

Fig. 6. The results of the change of sediment layer thickness. a - laboratory study, b - field study: 1 - sediment level above the sensor before the storm; 2 - change of bottom relief, measured with the help of the sensor; 3 - change of bottom relief ( $H$ ) observed visually.

where the sea was 4 m deep. Recording equipment was installed on the trestle and it was connected with the sensor by means of shielded cable. There was obtained uninterrupted three day recording of the change of sand layer thickness above the sensor, and at the same time six control measurements of bed

form height were made by divers. The comparison of the sand level gauge reading with the data obtained by divers has shown that the results conform within the accuracy of diver measuring (1-2 cm).

Fig.6b. shows a nature of the change of bottom level at the depth of 4 m during 24 hours in the phase of the storm stabilization. Underwater visual observation confirmed the reliability of instrumental information about little known picture of bed forms near the wave breaking zone. Large sand waves, 14-16 cm high, are covered by ripples, which height ranges from 1 to 4 cm. And the largest ripples are in the troughs of sand waves.

The most intensively sand level gauges were used in joint with the Low Sacsonian Coastal Research Center field investigations in Germany in Autumn, 1994, when complex lithodynamic study in the coastal zone of the Norderney island was done.

Synchronous fluctuations of orbital velocity, suspended sediment concentration and risings of free surface were studied. While measuring it was very important to fix continuously the distance between sensors and eroded bottom. For this purpose under the equipment we buried sensor into sand. It gave us a chance to find sought distance in any moment of measuring. Control measurements of maximum bottom relief deformation during the whole period of observation were done with the help of metal pin with mobile plate. We measured the length of pin from its top to the bottom and then determined changes of bottom level during the time period between measurements. When sand near the pin was washed out, the plate, put on it, dropped.

Fig. 7. The comparison of measuring of an active layer thickness with the help of sand level gauge and metal mobile plate.

When bottom erosion changed into aggradation, the washer was covered with sediments and showed the most low level of the bottom during the period between measurements.

A comparison of the data obtained by measuring of the

bottom form deformation by means of sand level gauge and by classic method, i.e. by measuring with the help of metal pins and plates, was made in the course of lithodynamic investigations. The results of one such a comparison are given in Fig.7 (measuring was done during 12 hours). The technique of obtaining these results, was the following: during the low tide, when a place, where the sensor has been installed, was drained, a metal pin was hammered into sand at the distance of 1 m from the sensor. A heavy flat mobile plate with a hole in its center was put on this pin. The plate dropped along the pin and lied down the sand surface. Necessary measurements were made after a tide cycle, when the place of the pin positioning was drained again. It was supposed that if a deformation of the bottom profile would take place, then the thickness of an active layer in this place could be determined with the help of the mobile plate. If the sediment accumulation was the first stage of the bottom deformation, which was replaced by erosion and then by accumulation again, the quantitative information about the first accumulation was lost. Full line in Fig.7 shows the bottom profile in the measuring point, obtained with the help of the sand level gauge. Here,  $t_1$  is the time of metal plate placing on sand;  $t_2$  is the time of measuring of the depth of the plate sinking.

Introduced notations have the following sense:

$\Delta D_s = D_s(t_1) - D_{min}$  is the thickness of an active layer for the time period  $t_1 - t_2$  according to sensor data. The initial process of accumulation has not taken into account as far as it is not fixed by plate. As it is seen;  $\Delta D_s = 8.5$  cm.

$\Delta D_p$  is the thickness of an active layer, obtained with the help of the plate. According to the results of measuring  $\Delta D_p = 8.0$  cm.

As it is seen from the comparison, the difference is not more than 0.5cm.

While measuring a bench mark pin was used for the absolute tie of the surface sand level to the environment. The sensor position was fixed not by the depth of its burying, but by the distance from the top of the bench mark pin. In such a manner the the recording of sand surface relative to the top of the bench mark pin was done.

As a typical example Fig.8 shows a fragment of 7-day recording of sand surface level relative to the top of the bench mark pin. This fragment was obtained by measuring with sand level gauge (interrupted line). Gaps in the line correspond to low tide, when the place of the sensor positioning was drained, and measurements were not done.

In this figure, level of sand surface measured by a rule from the top of the shelf mark pin in the moments of complete discharge in the point of the sensor installation is marked by small circles. Vertical lines show the thickness of active layer during the period of two measurements, obtained with the help of mobile plates.

### Discussion

The results of the laboratory calibrations and full-scale tests testify to the sand level gauge fitness for the investigation of the physical aspects of solid particle movement in the near bottom water layer, especially for the measuring of

Fig. 8. A typical example of temporal change of the surface sand level and the thickness of an active layer.

the rate of accumulative form formation and shift, when studying the dynamics of sea sediments on the shelf.

Uninterrupted information on geometry, rate and direction of migration of bedforms (ripples, ridges, dunes, bars) in the chosen point of underwater slope can be obtained in the following manner. Three or more described sensors are placed by a diver on bottom in a horizontal plane in apieces of equilateral triangle on metal girder. Distance between sensors and their spatial orientation are set beforehand. Height and "period" of sand bedforms are found from time variations of sediment layer thickness above any of the sensors. Rate and directions of their migration are calculated by time of bedform crest transit above sensors. Sand wave length is calculated from its "period" and migration rate.

The above sensors can be used for routine monitoring of raceway, harbor and river channel silting, and for continuous observation on dynamics of bedforms (ripples, ridges, dunes, bars) under any hydrodynamic conditions in zones practically inaccessible for other observation techniques.

#### Abstract

In the Netherlands the Technical Advisory Committee on Waterdefences (TAW) is developing a new safety philosophy, in which safety levels will be expressed in terms of risk of flooding. At present safety levels are expressed in terms of probability of exceedance of a certain water level. Risk is here defined as the product of probability of failure and expected damage. In order to be able to assess the expected damage, the flooding discharges in case of a dike failure have to be determined. These flooding discharges largely depend on the process of breach growth. The TAW has started a study on the breach growth mechanism, which is carried out by means of a step by step approach. Firstly laboratory experiments have been carried out to investigate the essential features of the total process. Mathematical models have been developed that describe the different phases of the breach growth process as observed in the laboratory. Recently a large field experiment has taken place in order to validate the mathematical models. So far, all research on breach growth has been focussed on sand-dikes and dunes, which implicitly means that the models are upper bound approaches. In next phases of the research programme breach growth in dikes containing less erosive materials such as clay will be investigated.

Introduction

The research described in this paper has been carried out for the Technical Advisory Committee on Water Defences (TAW). This committee is a permanent advisory board for the Dutch Minister of Transport, Public Works and Water Management on all technical aspects of flood defences in the Netherlands. Research is carried out by order of the Road and Hydraulic Engineering Division of the Ministry. The results are supportive to the advises of the TAW. The gained knowledge is published in technical reports and guides with practical design standards.

Fig. 1. The Netherlands.

A large part of the Netherlands is several meters below mean sea level, lake level and flood levels of the rivers Rhine, Meuse and IJssel [fig. 1]. To protect the Netherlands from flooding, a system of 53 so-called dike ring areas has been defined. Each dike ring area is in fact a polder protected by flood defences such as dikes, dunes and special constructions (for instance sluices and storm surge barriers). About 1600 km of dikes, 300 km of dunes and hundreds of special constructions protect the low lying country.

### History of design standards

In Dutch flood protection history the 1953 disaster plays a crucial role and marks a change in approach to flood defence standards. Before 1953 dikes were built based on a level of 0.5 meter above the highest known flood level with a surcharge for wave run-up. This experienced based approach became fatal in 1953. A major part of the south-west of the Netherlands was flooded due to a unexpected high flood level with a return period of 300 years. The damage was enormous: 1853 people were killed; direct economical loss was approximately 14% of the Dutch GNP. Flooding of the economical more important and more densely populated central part of Holland could just be avoided. Directly after this disaster the government installed the so-called Delta-committee which had to recommend about measures to avoid such a disaster in the future. Partly based on an analysis of the economical values of the dike ring area of the central part of Holland, the committee concluded that a design water level with a frequency of exceedance of once in 10,000 years should be appropriate. Under design conditions each dike section should be absolutely safe. Since absolute safety is per definition not achievable, this absolute criterion was translated in a criterion for overtopping: less than 2% of the number of incoming waves were allowed to cause overtopping. For the rest of the Netherlands similar safety levels were derived: depending on the relative economical importance flood defences of other dike ring areas should have a design water level with a frequency of exceedance of 1/4000 or 1/1250 per year.

### Present approach

The present approach is based on the work of the Delta-committee. The safety standards in terms of a certain water level exceedance frequency are still up to date. However throughout the years several adaptations have been made, especially to the design methods. The 2% run-up criterion for instance has been translated into an equivalent overtopping criterion of 0.1, 1.0 or 10 l/m/s depending on the expected strength of the inner slope. For other mechanisms such as geotechnical failure, additional design criteria have been developed. All criteria are related to individual cross section of the dike. No correlations are considered. Only for certain dike ring areas which are situated in the transition regime where a combination of high tides and river discharges cause design water levels, an approach has been followed in which for the overtopping mechanism correlations between individual dike sections are dealt with [TAW/CUR, 1991]. For dunes it was noticed that an

overtopping criterion based on a certain water level was not appropriate. For the determination of the safety of dunes a totally different approach has been chosen for that reason. A probabilistic design standard has been developed in which several stochastic parameters, such as water level, wave height and grain size were taken into account. The safety level has been expressed in terms of probability of failure per dune section. This probability was chosen to be a factor 10 smaller than the water level exceedance frequency of 1/10,000 per year [TAW/CUR 1988].

In general the present approach is not a uniform design method and can be referred to as a 'dike section overloading approach'. In fig. 2 this approach is indicated. On the vertical axis the load  $S_0$  (for example the overtopping discharge) is given. On the horizontal axis the strength (for example expressed in terms of resistance to erosion of the inner slope). In general failure will occur if the load exceeds the strength.

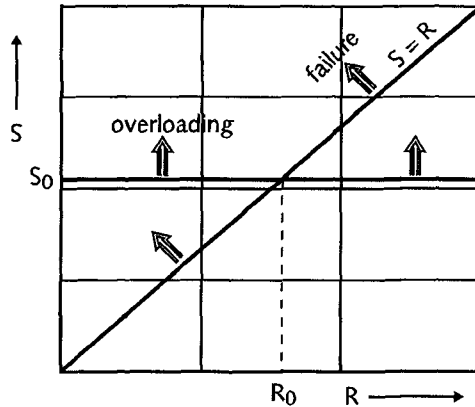

Fig. 2. Overloading approach.

This is the area above the diagonal line. The horizontal line refers to the overloading approach in which the probability that the strength is smaller than an expected value  $R_0$  is not considered.

Thus, features of the present approach are:

- safety levels are partly based on economical analysis (1953 situation);
- probabilistic description of the hydraulic load only (water level

- exceedance frequency);
- deterministic approach of the strength in terms of allowable overtopping rates (0.1, 1.0 or 10 l/m/s);
- a dike section approach: no correlations between dike/dune sections are considered;
- several kinds of merely deterministic approaches for other failure mechanisms like geotechnical failure;
- probability of failure approach for dune sections.

### Future approach

The TAW has decided to aim at a general overall consistent design philosophy. This new approach is referred to as the inundation risk approach. In this approach safety levels will be expressed in terms of risks. Risk is here defined as the value of probability of inundation times the expected damage in case of inundation:

$$R = P_f * D$$

$$R = \text{risk}$$

$$P_f = \text{probability of failure (inundation)}$$

$$D = \text{damage in case of failure}$$

Risk can be expressed in for instance monetary units and/or loss of lives. Load as well as strength will be dealt with in a probabilistic way. Correlations between dike sections will be accounted for. Polders with high values at risk should have a relatively lower probability of inundation than others. In this approach two separate tracks of development have to be distinguished. The first one is the assessment of the risk itself. The other one is the assessment of an acceptable risk level. The former is discussed here.

Several issues have to be investigated. In general the following steps can be distinguished:

- estimation of the probability of failure of the flood defence system;
- estimation of the inundation process in case of failure;
- analysis of the expected damage (material and immaterial) in case of inundation.

For the estimation of the probability of failure all possibly known (physical) causes of failure have to be gathered and arranged

systematically in a so-called fault tree. The top event of the tree is inundation. The branches are all possible failure mechanisms such as overtopping, sliding, erosion of revetments, piping etc. For each mechanism a mathematical model is developed. By means of either Monte Carlo analysis, other level III or level II analysis, the probability of the top event (inundation) is estimated. Of course for the parameters which are involved in the several models statistical information has to be gathered to estimate the distribution function and values for its parameters such as mean value and standard deviation. Much knowledge is already developed on this aspect of the inundation risk approach. Several mathematical models for the description of the failure mechanisms are available now [TAW/CUR, 1990].

For the analysis of the expected damage in case of failure floodings of the past have been analysed. This information is reproduced in mathematical relationships of the inundation parameter (such as inundation depth) and the expected damage as a percentage of the total value of an object. In fig. 3 such a relation is shown for damage to households in relation to inundation depths. In fig. 4 a similar curve is shown for casualties [TAW/CUR, 1990]. It is obvious that for the use of this type of relations a good estimate of the inundation parameters is important. These parameters depend heavily on the flood discharges in case of dike failure. However, knowledge of the flood discharges as a result of dike breaching is poor. Most information is based on eye-witness reports of breach growth events in the past. This information is very difficult to gather and also difficult to relate to the hydraulic and geotechnical conditions of the dike itself. Indeed, this kind of data is extremely unreliable. An example of the result of eye-witness information of the past is shown in fig. 5. From this and other similar figures it can be estimated that the velocity of the widening of a breach, ranges from 0.5 m to 50 m per hour [TAW-C/Delft Hydraulics, 1993b]. From sensitivity analysis it is known that an uncertainty of a factor 10 in the breach widening velocity gives at least a factor  $\sqrt{10}$  in uncertainty of the water level inside the polder and in the time that certain waterlevels are reached [TAW-C/Delft Hydraulics, 1993c]. This leads to an overall uncertainty in the expected damage. This uncertainty in the process might also influence disaster management strategies in which evacuation of inhabitants of a polder is an essential part.

Fig. 3. Damage factor (1.0=100%) for houses and farms as a function of the inundation depth [TAW/CUR, 1990].

Fig. 4. Percentage of persons drowned (proportion of the population) as a function of the inundation depth [TAW/CUR, 1990].

Fig. 5. Development of the breach width as a function of time, based on eye-witness reports.

#### Set up of research programme

To overcome this lack of knowledge the TAW decided in the late eighties to develop a breach growth model which determines flood discharges as a result of initial failure of a flood defence (dunes and dikes). In 1989 an unexpected opportunity occurred to observe a breach growth process in a sand-dike, which was temporarily built in a small tidal inlet (het Zwin) in the Netherlands [Visser et al. 1990]. There was hardly any time for preparation, so the experiment didn't provide many data. However, photographs and video provided sufficient information to start modelling and were helpful in setting up laboratory test series on breach growth. Being aware of the complexity of the process it was decided to start with sand-dikes first. This would provide an upper bound of the process as other materials are expected to be less erosive. It would also provide a good estimation of the processes expected in case of breaching of dunes.

From the Zwin experiment in 1989 it was learned that the process could well be separated in some typical phases. The first phases are described

as the erosion process of the inner slope and the lowering of the crest of the dike, which are two-dimensional processes [Steetzel et al 1992]. This was investigated first in the Schelde-flume at Delft Hydraulics [TAW-C/Delft Hydraulics, 1993a]. After these experiments it was decided to investigate the so-called isolated widening of the breach in the Schelde-basin of Delft Hydraulics. This provided information on the stepwise sliding of the edges of the breach [TAW-C/Delft Hydraulics, 1993b]. During this series an additional experiment was done to investigate the fully three dimensional process. However, this provided only little information because of the limitation of the basin bottom. Mainly for this reason, and also to verify the results obtained in small scale situations, an other prototype experiment was carried out in October 1994 in the Zwin. This time more preparation time was available and extensive measurements were carried out on all relevant aspects of the breach growth process, such as current velocities, waterlevels, scour hole dimensions and of course the development of the breach itself.

### Future research

In 1995 much effort will be put into the finishing of the mathematical modelling for breach growth in sand-dikes and dunes [Visser, 1994]. By means of a sensitivity study, it will be decided which aspects have to be investigated in more detail and which priorities have to be given. Future research will at least be focussed on breaching in dikes composed of less erosive materials.

### Conclusions

As a conclusion it can be pointed out that:

1. Breach growth development is an essential factor in an inundation risk analysis.
2. Breach growth research by means of step by step approach turned out to be an effective way to unravel the complex process.
3. An upper bound model, directly applicable for sand dunes, will be available in the near future (1995)
4. Future research will be focussed on dikes containing less erosive materials.

## CHAPTER 160

### SWASH ZONE WAVE CHARACTERISTICS FROM SUPERTANK

David L. Kriebel<sup>1</sup>

#### ABSTRACT

Measured values of shoreline wave setup and shoreline wave heights are summarized from the SUPERTANK Laboratory Data Collection Project. Water surface elevation time-series in the swash zone were measured by capacitance wave gages that were partially buried in the sand beach. As a result, wave measurements were obtained on the actively eroding/accreting beach-face where little data has traditionally been available. Results presented in this paper include examples of wave transformation across the entire beach profile. Mean water level and wave height conditions at the still water shoreline are then summarized for 19 sets of random wave conditions tested during the first two weeks of the SUPERTANK Project.

#### INTRODUCTION

Despite recent progress in the study of wave transformation across the surf zone, relatively little is known about wave properties near the shoreline or in the swash zone. Most measurements of wave transformation have focussed on the incipient breakpoint and the mid to outer surf zone where there is sufficient water depth to operate various surface-piercing or bottom-mounted wave gages. Wave measurements in the swash zone are generally more difficult to make and, as a result, are not as widely available. One approach used to measure waves in the swash zone has involved remote time-lapse photography of the time-varying runup, e.g. Holman and Sallenger (1985). Another approach, used to record time-series of water surface elevations at specific locations across the swash zone, has involved filming waves as they propagate past reference stakes driven into the beach-face, e.g. Carlson (1984). In contrast, Waddell (1973) and Sonu et al. (1974) present some of the only data available based on use of electronic surface-piercing wave gages to record time-series of water surface elevations in the swash zone.

---

<sup>1</sup>Ocean Engineering Program, U.S. Naval Academy, Annapolis, MD 21402

In this paper, some results of extensive swash zone wave measurements are presented from the SUPERTANK Laboratory Data Collection Project. As part of the SUPERTANK Project, twenty-six wave gages were used to document wave transformation across a sandy beach profile in a large wave tank. Of these, ten capacitance-based wave gages were specifically designed to measure wave transformation in the inner surf zone and swash zone where the beach face was intermittently submerged and exposed. The objective of this paper is to present results of these measurements for wave setup and for wave heights in the swash zone. Examples are first shown for wave transformation across the entire profile; then, values measured at the still water shoreline are discussed as a way of summarizing the extensive swash zone measurements.

## DESCRIPTION OF EXPERIMENTS

The SUPERTANK Laboratory Data Collection Project took place during the summer of 1991 in the in the large wave tank at Oregon State University. The tank is 104 m long and 3.6 m wide. A sand beach with a median grain size of 0.22 mm was placed in the tank with an "equilibrium" form (concave-upward) having a length of about 75 m and a maximum water depth of 3.05 m. A total of 66 different wave conditions, 70 percent using irregular waves, were then tested over almost 129 hours of wave action during the seven-week long project. In general, wave heights ranged from 0.2 to 1.0 meters and wave periods ranged from 3 to 8 seconds. A thorough documentation of the entire SUPERTANK project is given by Kraus and Smith (1994) while a review of the wave transformation measurements is presented by Kriebel and Smith (1994).

Mean water levels and wave transformation measurements were obtained using 26 wave gages between the wavemaker and the runup limit on the sand beach. Of these, 16 resistance wire wave gages were used to record wave properties between the wavemaker and the mid surf zone while 10 capacitance wave gages were used in the inner surf zone and swash zone. The resistance gages were separated at 3.7 meter intervals while the capacitance gages were spaced at 0.9 to 1.8 meter intervals to obtain better resolution in the swash zone. One capacitance gages was normally located close to the still water shoreline, which evolved from run to run as the beach eroded or accreted.

As illustrated in Figure 1, the capacitance wave gages consisted of a single loop of Teflon-insulated 20-gauge copper wire which was lightly twisted so that both ends of the wire were attached to one terminal at the base of a PVC electronics housing. The electronics housing was attached to a stainless steel support frame that was then attached to the side wall of the wave tank. The bottom of the sensing wire loop was attached to the support frame by a non-conductive rubber band in order to maintain a constant tension in the sensing wire. Sensing wires with lengths of 0.91 to 1.83 meters were used.

Figure 1. Illustration of capacitance wave gage used in the SUPERTANK Project.

The capacitance wave gages were partially buried in the sand beach and could record the wave uprush and downrush as well as the saturated sand bed elevation if the bed was exposed in between successive swash events. Water surface elevations and wave heights were measured relative to either: (1) the still water level if the gage was located seaward of the still water shoreline where the sand bed was not exposed at the beginning of the test, or (2) the wet sand surface if the gage was located landward of the still water shoreline where the sand bed was exposed at the start of the test. As a result, the mean wave setup on the exposed beach-face was measured as the increase in the mean (time-averaged) water level above the initial sand bed elevation at the start of the test.

After the mean water level was identified and removed from the wave record, the remaining time-series was subjected to low and high-pass filtering with a filter cut-off at one-half of the peak wave frequency of the target wave spectrum input into the wavemaker. Following this filtering, three time series were available for subsequent analysis: (1) the original or total wave record, (2) the high-frequency wave record containing the wavemaker frequencies and higher harmonic components, and (3) the low-frequency wave record containing wave group and tank seiching frequencies.

Wave heights were determined for each of these three time-series based on both time-domain and frequency-domain analyses. Standard zero-crossing analysis was used to define statistical wave height parameters such as  $HRMS$ ,  $H_{1/3}$ ,  $H_{1/10}$ , and  $H_{MAX}$ . In the swash zone, these wave heights were determined as the vertical height between each wave crest and the exposed sand bed. Standard spectral analysis was then performed to define the zero-moment wave height. Once again, three values were determined as  $HMO$ ,  $HMOL$ , and  $HMOH$  based on the total, low, and high frequency wave records respectively. Based on the filtering, conservation of wave energy requires that the relationship between the various zero-moment wave heights be given as  $HMO = (HMOL^2 + HMOH^2)^{1/2}$ .

## EXAMPLES OF WAVE HEIGHT TRANSFORMATION

Selected results showing typical beach profiles from the SUPERTANK Project are shown in Figure 2, while examples of dimensionless wave transformation across these beach profiles are shown in Figures 3, 4, and 5.

Beach profiles in the SUPERTANK Project varied continuously in response to the incident wave conditions. The initial profile, depicted in Figure 2a, was placed in a concave-upward shape in accordance with equilibrium beach profile concepts. As the experiments proceeded, the initial shoreline receded, the beach face steepened, a bar developed offshore, and the surf zone widened, as illustrated in Figure 2b. This profile is typical of conditions following erosive wave conditions. The profile in Figure 2c is then typical of conditions following accretionary wave conditions in which the bar-trough system was smoothed.

In Figures 3, 4, and 5, dimensionless mean water levels and dimensionless wave heights are plotted against the dimensionless "depth" across the profile. Seaward of the still water shoreline, the initial water depth is considered positive. Landward of the still water shoreline, the "depth" is considered negative when the initial sand bed elevations are above the still water level. The reason for using this format is that the wave transformation can then be shown continuously across the surf zone, to the still water shoreline (depth equal to zero), and across the swash zone to the runup limit. In all cases, the local "depth" is normalized by the significant wave height  $HMO_0$ , measured in 3.05 m of water at the first wave gage nearest the wavemaker.

Results shown in Figures 3 through 5 were obtained from tests using irregular waves having three values of wave steepness,  $HMO_0/L_0$ , equal to 0.005, 0.01, and 0.04, all for TMA spectra having a peak enhancement factor of 3.3. The first case, with the lowest steepness, had a significant wave height,  $HMO_0$ , equal to 0.5 m and a peak period,  $T_p$ , of 8 seconds. The second case then had  $HMO_0 = 0.64$  m and  $T_p = 6$  seconds, while the third case had  $HMO_0 = 0.57$  m and  $T_p = 3$  seconds. The beach profile in each case was similar to that shown in Figure 2b, although conditions at the end of tests with the lowest steepness were more similar to those in Figure 2c.

Figure 2. Typical beach profiles: (a) initial profile, (b) profile after erosive wave conditions, and (c) profile after constructive wave conditions.

Figure 3 shows the normalized wave setup and setdown, defined as ratio of the local mean water level,  $\mathcal{S}$ , to the offshore significant wave height. For the three values of wave steepness, the setdown seaward of the breakpoint is fairly consistent, reaching a maximum of 3 to 5 percent of the incident significant wave height. Setup inside the surf zone and in the swash zone is a much stronger function of wave steepness. The maximum setup near the shoreline ranges between 10 and 20 percent of the incident significant wave height and is larger for the lower steepness waves.

Figure 4a shows the normalized total wave heights, defined as ratio of the local zero-moment wave height relative to the value measured offshore near the wavemaker. For the highest steepness, wave heights decrease slightly between the wavemaker and the dominant breakpoint (at a relative depth of about 1.4) due to the selective breaking of the largest waves in the spectrum. Waves then continue to diminish across the surf and swash zones to the runup limit where the relative depth is  $-0.75$ . For the lower steepness wave conditions, significant wave heights increase by more than 20 percent between the wave maker and the dominant breakpoint due to shoaling effects. Throughout the surf and swash zones, these lower steepness waves produce greater relative wave heights. At the still water shoreline, wave heights are still about 40 to 60 percent of the offshore values and is largest for the smallest wave steepness.

Figure 4b and 4c then show the normalized wave heights for the high and low frequency portions of the wave spectrum respectively. In the offshore region, the low-frequency wave heights are found to be fairly small ( $0.1$  to  $0.2 H_{M00}$ ) and the high frequency waves are dominant. Near the shoreline and in the swash zone, however, the low frequency wave heights are generally the same magnitude, or larger than, the high frequency wave heights. In the three cases shown, high-frequency wave heights at the shoreline are only about 20 to 50 percent of the offshore zero-moment wave height while the low frequency wave heights are 25 to 35 percent of the offshore height. For the two cases with the highest wave steepness, low-frequency wave components have more energy than high-frequency wave components in the vicinity of the shoreline.

Based on visual observations and on spectral analysis, these low-frequency motions are mostly coherent standing waves. Unlike the high-frequency waves in Figure 4b, which are mainly progressive and which show large gradients in the swash zone due to breaking, the low-frequency waves in Figure 4c exhibit these gradients due to the presence of a reflected wave antinode at the sloping shoreline. These low-frequency waves experience strong growth between the breakpoint and the shoreline and may be the result of forced incident wave groups, long-wave generation by the moving breakpoint, and/or long-wave generation by swash zone wave interactions, all augmented by tank seiching and re-reflection of long waves by the wavemaker. The wavemaker was operated with reflection-compensation to absorb reflected waves at the dominant wave frequency but not at these long-wave frequencies.

Figure 3. Dimensionless wave setup for three values of random wave steepness.

Figure 4. Dimensionless wave heights for three values of wave steepness: (a) based on total or unfiltered wave record

Figure 4. (b) based on high-pass filtering at one-half of the peak frequency.

Figure 4. (c) based on low-pass filtering at one-half of the peak frequency.

One interesting result of these measurements is that, despite the effect of the reflective wavemaker boundary, there appears to be a strong correlation between the low-frequency and high-frequency wave heights. Figure 5 shows the ratio between the low- and high-frequency zero-moment wave heights as measured at each wave gage. This ratio is extremely consistent and well-behaved across the entire offshore region from the wavemaker to the mid surf zone. In this region, the ratio of low-to-high frequency wave heights increases from approximately 0.1 near the wavemaker to approximately 0.3 near the bar crest to nearly 0.5 in the inner surf zone. Although there is a slight trend toward increasing ratios for higher values of wave steepness, this ratio is similar for each of the three conditions.

At the shoreline, the ratio of low-to-high frequency wave heights is then a strong function of wave steepness, varying from about 0.5 for the lowest steepness, to about 1.2 for the middle steepness, to about 2.0 for the highest steepness. Thompson and Briggs (1993) considered the same ratio and concluded that the long-wave heights may reach a maximum of about 1.2 times the short-wave heights at the shoreline based on field data from Duck, North Carolina, for conditions where the spectral wave steepness was about 0.01. This seems to be confirmed by the laboratory data, however, the SUPERTANK data suggests that this growth in low-frequency wave components relative to the rapidly decaying high-frequency components depends strongly on the incident wave steepness so that no simple generalization is possible.

Figure 5. Ratio of locally-measured low-frequency significant wave height to high-frequency significant wave height based on filtering at one-half of the peak frequency.

## SUMMARY OF SHORELINE SETUP AND WAVE HEIGHTS

In order to summarize additional data from the SUPERTANK Project, the remainder of this paper will present results of wave setup and wave height parameters measured at the still water shoreline in 19 tests conducted with irregular waves over the first two weeks of the experiment. Figures 6 through 8 show normalized wave setup and zero-crossing wave heights as determined from the total wave record, the high-pass wave record, and the low-pass wave record. Results are based on linear interpolation between wave gages located either side of the still water shoreline. In each figure, values of shoreline setup and wave height are normalized by the offshore zero-moment wave height,  $HM_{0o}$ , and the normalized results are plotted against the incident wave steepness,  $(HM_{0o}/L_o)^{1/2}$ .

Figure 6 shows results for the normalized wave setup at the shoreline. Results from the SUPERTANK Project appear consistent with other lab and field data in which maximum wave setup at the shoreline is generally in the range of 0.15 to 0.2 times the offshore significant wave height. For example, Greenwood and Osborne (1990) suggest a ratio of 0.19 based on field data from Lake Huron. The SUPERTANK data also show a clear trend toward decreasing wave setup for increasing wave steepness, as also found in the literature. In this case, the wave setup ranges between 0.21  $HM_{0o}$  for the lowest wave steepness tested to about 0.11  $HM_{0o}$  for the highest wave steepness tested.

Figure 6. Normalized wave setup at the shoreline from SUPERTANK data.

Figure 7 shows the energy-based zero-moment wave heights at the shoreline,  $HMO_s$ , relative to the offshore zero-moment wave height,  $HMO_o$ , as a function of incident wave steepness. Figure 7a shows the total wave height at the shoreline, while Figures 7b and 7c show the high and low frequency wave height components at the shoreline respectively. As shown in Figure 7a, the wave height at the shoreline can vary between about 40 and 80 percent of the offshore value for the extreme wave steepness tested. While these shoreline wave heights decrease as wave steepness increases, there is little variation for values of steepness above 0.02.

The high and low frequency wave heights at the shoreline, shown in Figures 7b and 7c, show opposing functional dependencies on wave steepness. For the lowest values of steepness, low-frequency wave heights are small, about 0.2  $HMO_o$ , while high frequency wave heights are dominant, up to 0.7  $HMO_o$  or so. As the wave steepness increases, however, low frequency wave heights increase up to about 0.4  $HMO_o$  while high frequency wave heights decrease dramatically to about 0.2  $HMO_o$ . As a result, for the higher values of steepness, the low frequency wave height components (low frequency energy content) is actually twice as large as the high frequency wave components. A reversal in which wave energy band is dominant occurs at a wave steepness of about 0.01.

As shown in Figure 5, the ratio of low-to-high frequency wave height components is fairly stable across the surf zone but shows large differences in the swash zone. Figure 8 then shows this ratio at the shoreline as a function of wave steepness. As discussed previously, high frequency wave heights dominate for the lowest wave steepness tested and the ratio of low-to-high frequency wave heights is about 0.5 or less. Above a steepness of 0.01, however, the low frequency wave heights dominate the swash zone motions such that the ratio of low-to-high frequency wave heights is greater than unity. While there is significant scatter in the data, the ratio is in the range of 1.5 to 2.0 for the highest values of wave steepness which were highly energetic and highly erosive wave conditions.

At the still water shoreline, there is initially zero water depth until the mean water level rises due to wave setup. As a result, the ratio of wave height to still water depth at the shoreline is infinite unless wave setup is considered. With wave setup, the ratio of wave height to water depth (setup) is finite and this ratio is shown in Figure 9 for all 19 data sets. As shown, the ratio of total zero-moment wave height to wave setup at the shoreline is in the range of 3 to 4 and is insensitive to wave steepness. In contrast, the ratio of wave height to water depth in the surf zone is commonly assumed to be approximately one. Based on the SUPERTANK data, the significant wave height at the shoreline is given by  $HMO_s = 3.3 S$  on average. Consideration of the high and low frequency significant wave heights separately does not produce results that are as well-behaved, but on average the high frequency significant height at the shoreline is 2.0 times the wave setup while the low frequency wave height is 2.5 times the setup.

Figure 7. Normalized zero-moment wave heights at the shoreline: (a) total wave height, (b) high-frequency wave height, (c) low-frequency wave height.

Figure 8. Ratio of low-to-high frequency wave heights at the still water shoreline.

Figure 9. Ratio of significant wave height to mean water depth (setup) at shoreline.

As a final consideration, statistical wave height parameters at the shoreline, obtained from a zero-crossing analysis of the total wave record, are shown in Figure 10. This gives  $HRMS$ ,  $H_{1/3}$ , and  $H_{MAX}$  measured at the shoreline, all normalized again by the offshore zero-moment wave height. For the lowest values of wave steepness, it is found that statistical wave heights are a strong function of wave steepness. For these conditions,  $HRMS$  at the shoreline can be 0.4 to 0.5 times  $HMO_o$ ,  $H_{1/3}$  can typically be 0.5 to 0.7  $HMO_o$ , and  $H_{MAX}$  can typically be 0.7 to 1.1  $HMO_o$ . At the other extreme, for the highest values of wave steepness, wave heights are not strong functions of steepness and  $HRMS$ ,  $H_{1/3}$ , and  $H_{MAX}$  are about 0.2, 0.3, and 0.5 to 0.6 times  $HMO_o$ , respectively.

Figure 10. Shoreline wave height parameters based on zero-crossing analysis.

## CONCLUSIONS

This paper has presented selected results of wave setup and wave height measurements from the SUPERTANK Data Collection Project. The main objective of the measurements was to document wave transformation across the beach profile at all locations between the wavemaker and the wave runup limit. This required use of capacitance wave gages, partially buried in the sand beach, to document mean water levels and time-varying wave heights in the swash zone where the initial sand bed elevation was above the still water level of the wavetank.

Several examples have been presented of the random wave transformation across the beach profile for various wave steepness conditions. These measurements show that wave properties in the swash zone are well-behaved despite the fact that waves in this region are intermittently occurring bores that do not propagate on a finite water depth. Results are then shown for wave setup and wave heights at the still water shoreline where the initial water depth is zero.

In the analysis, the wave record is filtered into separate low and high frequency components. In the offshore region, the high frequency (incident band) wave components dominate and low frequency components (wave group and tank seiching frequencies) are small. In the inner surf zone and swash zone, the high frequency components diminish due to breaking while the low frequency components grow and reach a maximum amplitude at the still water shoreline.

For low incident wave steepness, the high frequency portion of the wave spectrum, containing the intended peak frequency of the spectrum and higher harmonics, dominates in the swash zone and is usually larger than the long standing waves at the shoreline. In contrast, for high incident wave steepness, the low frequency portion of the spectrum dominates at the shoreline and in the swash zone. While this paper has documented the characteristic heights of these long wave components, it does not address the possible generation mechanisms for these waves.

## CHAPTER 161

### MORPHOLOGICAL MONITORING OF A SHOREFACE NOURISHMENT NOURTEC Experiment at Terschelling, The Netherlands

Aart Kroon\*, Piet Hoekstra\*, Klaas Houwman\* and Gerben Ruessink\*

Netherlands Center for Coastal Research (NCK)

- \* Institute for Marine and Atmospheric Research Utrecht, Utrecht University, P.O.Box 80.115, 3508 TC Utrecht, The Netherlands.

#### *Abstract*

The morphological behaviour of a shoreface nourishment site is studied. The originally observed patterns in bar development before the nourishment are disturbed by the extra volume of sediment in the cross-shore profile. Attention is focused on the morphological development of the nearshore bars and troughs after the nourishment.

After almost a year, the bar at the landward site of the nourishment showed a reversal in bar behaviour in comparison with the natural conditions as described by Ruessink and Kroon (in press). The bar was slightly moving landward and was growing in height, whereas a similar bar at this position within a non-nourished environment would move seaward and reduce in height. The bar at the seaward side of the nourishment is quickly adjusting itself to the situation before the nourishment.

The bar behaviour after the nourishment is accompanied by a redistribution of the sediments over the profiles. The net amount of sediment losses in the nearshore area is negligible. This also means that the nourished volume of sediments is still available in the central part of the nourishment area. Longshore movements of the nourished volume are in the order of 400 m to the east over a period of about a year, and are not observed in the cross-shore profiles with a longshore spacing of 1000 m.

#### *Introduction*

The coastline of the northern part of the Netherlands consists of a chain of barrier islands alternating with tidal inlets. The beaches and nearshore zones of these barrier islands are composed of sandy sediments. The central parts of the barrier islands do suffer from erosion over the last decades. At Terschelling (figure 1) the shoreline of the central part of this barrier island retreated over the last decades with an average, annual rate of 2.5 to 3 m.year<sup>-1</sup>, which means an average, annual volumetric loss of 110.000 m<sup>3</sup> of sediment within the nearshore zone.

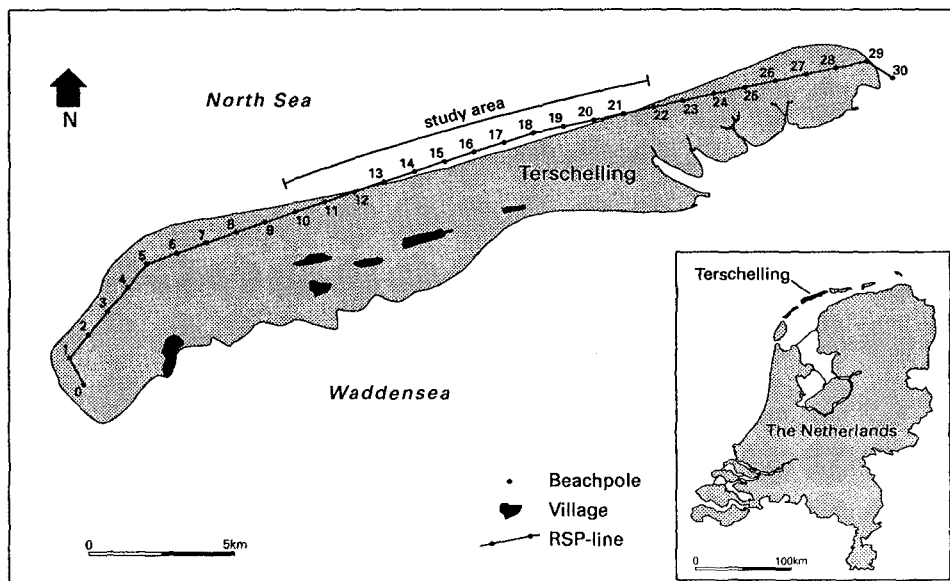

Figure 1 Location of the study area

Since the seventies, the eroding coastal stretches along the Dutch coast are mainly defended by beach nourishments. However, in the early nineties other kinds of soft engineering structures are considered. This resulted in the decision to execute another type of nourishment in 1992, a shoreface nourishment consisting of a submerged volume of sediment filling up a trough between two shore-parallel bars in the outer nearshore zone. Hereby, the design of the shoreface nourishment has to guarantee the same degree of safety as the other measures of shore protection. This means that the artificial volume of sediments must be beneficial for the coastal system for at least period of 10 years.

The scientific EC-MAST2 programme NourTEC has the objective to describe and explain the behaviour of this shoreface nourishment. The behaviour of the nourishment is analyzed in different phases. An evaluation of the behaviour before the nourishment is made by studying the evolution of the barred morphology in the nearshore zone over the last decades (Ruessink and Kroon, in press). The hydrodynamic processes and sediment properties in the barred nearshore zone just prior to the nourishment have been subject of study within a relatively small field campaign ( $T_0$ ; Hoekstra et al., 1994). The behaviour of the barred morphology and the morphodynamics after the nourishment is studied since 1993 by means of detailed process-oriented measurement campaigns.

In this paper, the morphological behaviour of the nourishment site is studied. Attention is paid to the morphological development of the nearshore bars and troughs after the nourishment. These observations are then compared with the natural behaviour of these bars in cross-shore and longshore direction before the nourishment (Ruessink and Kroon, in press). In addition, the sediment budgets within the cross-shore profiles along the nourishment site are computed.

### *Study area and previous results*

The shoreface nourishment is situated at the north coast of the barrier island Terschelling, The Netherlands (figure 1). This north coast of Terschelling is facing the semi-enclosed North Sea and is made of a sandy shoreface, beaches and dunes.

The morphology of the nearshore zone, defined as the upper shoreface, is characterized by two or three nearshore bars. The width of the nearshore zone is about 1400 m and the mean slope is about 1:180. The shoreface nourishment is placed in a trough between two shore-parallel nearshore bars at a depth of -5 to -7 m below mean sea level. The length of the nourishment in a longshore direction is 4.4 km. The median grain size ( $D_{50}$ ) of the sediments in the intertidal zone is about 200 to 250  $\mu\text{m}$ . At the seaward side of the shoreface nourishment site, at a water depth of about 10 m, the median grain size is reduced to about 160 to 180  $\mu\text{m}$ .

The morphological behaviour of the multiple bar system in the nearshore zone of Terschelling, The Netherlands between 1965 and 1993 is analyzed in Ruessink and Kroon (in press). Herein, both the cross-shore and longshore tendencies of the bar behaviour before the nourishment are described. The morphodynamical development of the nearshore bars over the last decades results in the following tendencies:

- The net cross-shore migration of the nearshore bars is in a seaward direction and shows different behaviour with distance offshore. Close to the shore, the volume of the bar is small and the behaviour is quite chaotic, hardly showing any net tendency (stage 1). Further offshore the nearshore bars constantly migrate in a seaward direction until the outer margin of the barred nearshore area (stage 2). At this position the outer nearshore bar declines (stage 3).  
The plane view of the bar is changing from crescentic to straight in an offshore direction. Overall, the bar feature has a 'life-cycle' of about 12 to 15 years;
- The net longshore migration of the nearshore bars is in an eastward direction with an average rate between 800 and 1250  $\text{m}\cdot\text{year}^{-1}$  over the period 1975 - 1993.

The general hydrodynamic conditions are mainly determined by the processes related to the waves and tides. The sea and swell waves are coming from the North Sea from western to northern directions. The mean annual significant offshore wave height is about 1.5 m and has a period of about 6 to 8 s. The highest waves are incident from the west to northwest and have a significant height of about 5 to 6 meter and a period of 10 to 15 s. The wave-related undertow and the longshore and cross-shore wind-driven currents are of major importance in the nearshore zone of Terschelling (Hoekstra et al., 1994). The tides are semi-diurnal and have a neap-tide range of 1.2 m and a spring-tide range of 2.8 m (meso-tidal). The tidal current ellipses in the nearshore are shore-parallel oriented and the eastward flowing flood currents exceed the westward flowing ebb currents.

### *Methods of analysis*

#### **Data set**

The present data set consists of five soundings carried out in lines perpendicular to a longshore reference line which connects the beach poles (the RSP-line, see figure 1). These soundings were executed in April 1993 (just before the nourishment), November 1993 (after the nourishment), January, April, and June 1994. The length of the cross-shore profiles is about 2000 m, and always covers the zone between the beach and the

lower shoreface at -10 m NAP. The longshore spacing between the studied profiles is 1000 m. The cross-shore profiles in the nourishment area are used to describe the morphological development in a morphometric and a volumetric sense.

### Morphometric analysis

The quantitative description of the cross-shore profiles in a morphometric way requires a mean profile equation to which the single measured profiles at different time steps are compared. This mean cross-shore profile equation is determined in two steps. The first step concerns the computation of the mean of all the measured cross-shore profiles at one location over the period 1964 to 1993 (dataset Ruessink and Kroon, in press). This mean cross-shore profile can not be used as a reference profile because it still contains some barred features, due to the limited amount of profile measurements in comparison to the 'life-cycle' of the system. The second step concerns the fit of a mathematical expression to the computed mean profile. An exponential curve fitting procedure was chosen for the nearshore profile between the beach and the lower shoreface. This exponential curve is expressed by:

$$d = d_0 \cdot [1 - e^{-ax}] \quad (1)$$

in which

- d = computed depth of the average profile below NAP [m]
- $d_0$  = depth at the location where the slope of the bed is almost zero [m]
- a = coefficient [ $m^{-1}$ ]
- x = horizontal coordinate, positive in seaward direction [m]

In the Terschelling case, the  $d_0$ -value is 8.7 and the a-value is 0.0018 (see also Ruessink and Kroon, in press).

The residual profile, which is defined as the individual measured profile minus the fitted profile is used for the description of the bar morphology. The dimensions of the bar features are defined in figure 2. The studied dimensions are the depth of the bar crest to NAP ( $d_c$  in m), the position of the bar ( $P_c$  in m), the height of the crest of the bar ( $h_b$  in m) and the width of the bar ( $W_b$  in m) (figure 2).

### Volumetric analysis

The volumetric analysis of the cross-shore profiles is executed in several successive steps. The first step is the determination of the seaward boundary of the dynamic part of the nearshore. This boundary must be located seaward of the closure depth of the cross-shore profiles (see Kroon, 1994). At Terschelling, the location of the -8 m depth contour in the cross-shore profiles matches this requirement.

Thereafter, the sediment volume between the measured cross-shore profile and the -8 m depth is computed across the profile. These computed sediment volumes are determined in a cumulative way from the seaward boundary towards the beach. The trends in the cumulative sediment volumes are finally compared along the nourishment site. Three volumes are hereby selected:

- the nearshore zone, defined as the area between the 0m and -8m depth contour. The width of the nearshore zone was constant for each profile location during the 1993 to 1994 period;
- the seaward half of this nearshore zone;
- the seaward quarter of this nearshore zone.

Figure 2 Definition sketch of morphometric variables

### Results

#### Morphological development after the nourishment

The overall characteristics of the nearshore zone along the nourishment site are summarized in Table 1. The width of the nearshore zone slightly increases from the central nourishment area (profile 16) to the western (profile 13) and eastern (profile 19) side.

Table 1 Bar characteristics profile 17

time	distance offshore [m]	bar crest depth [m]	bar crest height [m]
April 1993	597 - 1077	3.6 - 5.7	2.1 - 1.7
November 1993	607 - 912	3.8 - 4.4	1.9 - 2.7
January 1994	546 - 922	3.5 - 4.6	1.9 - 2.4
April 1994	562 - 978	2.7 - 5.2	2.9 - 2.0
June 1994	530 - 922	2.5 - 5.2	2.8 - 1.9

The cross-shore profile behaviour at several locations along the nourishment site are presented in figure 3.

At about 800 m west of the nourishment (profile 13), the positions of the nearshore bars are almost stable in time. The trough between the two outer bars is slowly filling up from -7 to -5.5 m NAP.

Figure 3 Cross-shore profiles

Figure 3 Cross-shore profiles (continued)

At about 800 m east of the nourishment (profile 19), the position of the most seaward, nearshore bar hardly changes in time. The landward located nearshore bar is moving onshore over a distance of about 50 m between April and November 1993, followed by a seaward shift over the same distance between November 1993 and June 1994.

At the central part of the nourishment area (profile 17), the nourished volume of sediment in the trough between the two outer nearshore bars is easy to trace. The morphological developments in this cross-shore profile can be summarized in three phases:

- filling up of the trough in the nourishment period (April November 1993);
- development of a barred topography at the nourishment site. The outer bar is reduced in height, the trough is increased in depth and the inner bar is increased in volume in a landward direction;
- the bar topography is even more pronounced. The most seaward bar is further reduced in height, while the landward bar at the nourishment site is increasing in height to a value of -2.5 m NAP. The offshore position of this bar crest is stable over the January to June 1994 period.

At the western part of the nourishment (profile 15), the morphological development of the bars is more complex. Before the nourishment, the outer nearshore bar had just disappeared, due to the longshore migration of a bar attachment point that came from the west (Ruessink and Kroon, in press). This means that the morphological development of bars in the cross-shore profile can be better studied at profile 17 where the longshore movements of sediment volumes are only caused by the nourishment in the 1993-1994 period.

For the central part of the nourishment (profile 17), the morphometric variables of the bar topography in time are presented in figure 4. The different lines in this figure represent the successive nearshore bars in the period 1964 to 1994. The two nearshore bars before the nourishment (bar 4 and bar 5 in figure 4) have changed in one large double crested bar (see figure 5). However, for the comparison of the bar behaviour with the autonomous behaviour before the nourishment, both crests are regarded as two bars.

The distance to the shoreline of the inner bar crest (5 in figure 4a) in time is almost constant. The distance to the shoreline of the outer bar crest (4 in figure 4a) is reduced with about 100 m as a result of the nourishment (difference between April and November 1993). Thereafter, the position of the outer bar crest is quite constant in time.

The depth of the inner bar crest to NAP subsequently decreases after the nourishment (5 in figure 4b). The depth of the outer bar crest to NAP is decreasing during the nourishment period (4 in figure 4b) and increasing in the period after the nourishment.

The relation between the bar crest depth and the distance to the shoreline for the autonomous system is presented in figure 6a. According to the three stages of bar behaviour as defined by Ruessink and Kroon (in press), both the inner and the outer crest are in stage 2. This means that the crests should normally have a seaward migrating tendency. However, as a result of the increased volume of sediment due to the nourishment, both the inner and outer crest are firstly moving in the direction of the first stage. The reversal of this tendency to an expected offshore migration has already started at the outer crest position (see April to June 1994).

The relation between the bar height and the distance offshore is presented in figure 6b.

The height of the inner crest of the bar is obviously deviating from the previously observed patterns: the crest is located at greater heights than has ever been recorded in the past (Ruessink and Kroon, in press). The outer crest of the bar is positioned at a location where the observed relation in the autonomous behaviour was weak.

Figure 4 Position of bar crests (a) and depth of bar crests (b) in time

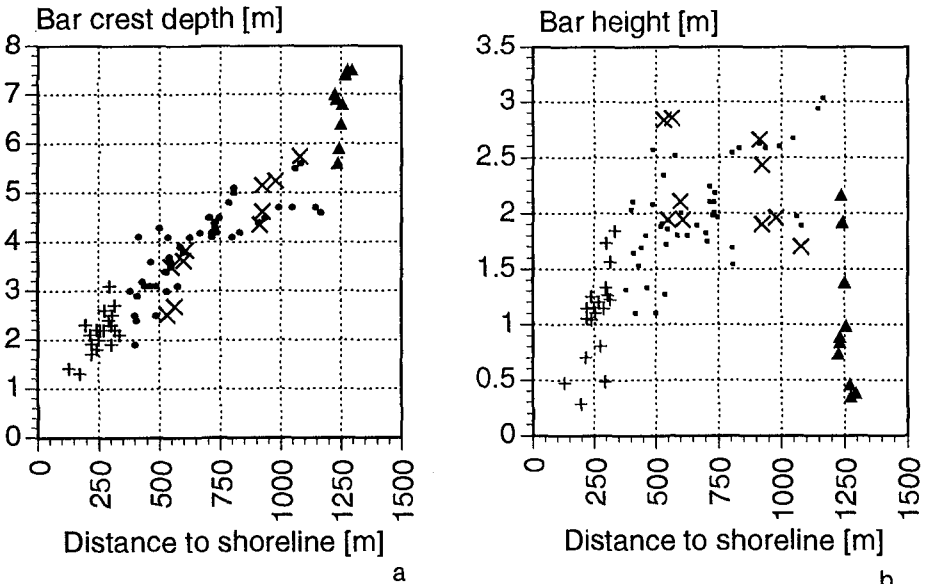

Figure 5 Detailed bar developments using residual profile 17

+ stage 1	• stage 2	▲ stage 3	X double crest
-----------	-----------	-----------	----------------

Figure 6 Position of the bar crests versus bar height (a) and depth of bar crest (b)

Longshore patterns in bar behaviour are observed. The development of the bar patterns in the cross-shore profiles over the nourishment site do suggest a shift in the bar variables towards stage 1. The nourishment will thus increase the duration of stage 2. The relation between the development of the bar pattern at the central part and those at the western and eastern sides of the nourishment area are still not clear. The alongshore shift of the nourishment volume can not be measured with an alongshore profile spacing of 1000m. Detailed soundings in the area have shown a eastward shift of the sediment volume of about 400 m over the period November 1993 to June 1994.

### Volumetric development

The cumulative sediment volumes within the cross-shore profiles are shown in figure 7.

At about 800 m west (profile 13.00) and east (profile 19.00) of the nourishment, the differences in sediment volumes are not influenced by the nourishment. At profile 14.00, there is an overall decrease in the sediment volume over the 1993 to 1994 period. At profile 19.00, the cumulative sediment volumes are almost constant.

At the central part of the nourishment area (profile 17), the sediment volume is increased between April and November 1993, due to the nourishment. Thereafter, there is a slight decrease in the sediment volume.

The spatial distribution of the cumulative sediment volumes in the cross-shore profiles is presented in figure 8. The volumetric changes within the nearshore zone, defined as the area between the 0m and -8m depth contour, are showing an increase of sediment volume after the nourishment in the central part of the nourishment (compare 1 and 2 for profile 15 to 18 in figure 8a), followed by an almost constant volume after this period. At the western end of the nourishment area (profile 14), this tendency is not observed.

Figure 7 Cumulative sediment volumes at certain cross-shore profiles

Figure 7 Cumulative sediment volumes at certain cross-shore profiles (continued)

Figure 8 Spatial distribution of nearshore sediment volumes: a. nearshore area, b. seaward half, c. seaward question.

The influence of the nourishment is even better to see in the volumes of the seaward half of the nearshore zone (figure 8b). It is obvious that the nourishment is effective in the central area (profile 15 to 18). The western area (profile 14) is rather complex. The influence of the nourishment is interfering with the longshore migration of a bar attachment point from the west.

The spatial pattern of the cumulative sediment volumes in the seaward quarter of the nearshore zone is presented in figure 8c. The changes in volumes are negligible small over the period April 1993 to June 1994.

### *Discussion*

The morphological development of the breaker bars in the central nourishment area consists of three phases:

- the pattern of the bars and troughs are disturbed in the nourishment period. The trough between the two outer bars is filled up, and the bar topography has changed in a shore platform with two small undulations at the landward and seaward side. The total volume of sediment in the cross-shore profile between the -8 m to the 0 m depth contours has increased with about  $450 \text{ m}^3 \cdot \text{m}^{-1}$ ;
- just after the nourishment, the profiles are quickly adjusting to the former bar and trough topography. The outer bar crest depth and trough depth are increasing and the inner bar crest depth is decreasing. However, along the nourishment the total volume in the cross-shore profiles between the -8 m to the 0 m depth contours is almost constant, which implies a redistribution of the sediment over the nearshore part of the profile;
- in the period between January and June 1994, the bar and trough topography becomes more pronounced. This is especially the case for the inner bar. The crest of this bar is further growing in height and the depth of the crest is now at about -2.5 m NAP. However, according to the morphometric relations for the natural bars in the period 1964 to 1993, the inner bar must be out of equilibrium and may be flattened off. The behaviour of the outer bar is already typical for stage 2 again. The total volume in the cross-shore profile between the -8 m to the 0 m depth contours is almost constant. The small changes in bar patterns are thus made by the redistribution of sediments over the cross-shore profile.

The observed patterns in time are still not related to the observed hydrodynamics. The observed adaptations of the cross-shore profile to the pre-existing bar morphology is however within the time-span of a month. This means that the modulating mechanisms of the barred topography immediately act upon the disturbed profile.

The increase in the height of the inner bar in the period January to June 1994 may be partly caused by the onshore directed sediment transport by wave-asymmetry processes. However, this remark is still very tentative and will be verified in the next future in two steps by:

- analyzing detailed process-oriented field measurements (see Hoekstra et al., 1994). These measurements are used to verify different wave-, tide- and wind-related processes over the barred cross-shore profile;
- analyzing the type of combined wave- and tidal-sequences over this period (see Kroon, 1994). The analysis of the sequences of the waves (e.g. storm-related events) will be executed in order to understand the representativeness of the observed period within the average, long-term wave climate.

The combined morphometric and volumetric analysis of the cross-shore profiles in the nourishment areas has clearly shown that significant changes in the cross-shore bar and trough patterns may occur with hardly any changes in the nearshore volume over the same period.

The disturbed pattern of the cross-shore morphology due to the nourishment is quickly adjusted. These adjustments, striving to attain a new type of quasi-equilibrium are good indicators of the morphodynamics of the bars on the longer term.

### *Conclusions*

The morphological development of the nearshore bars and troughs after the nourishment is showing the following aspects:

- the disturbed bar morphology caused by the nourishment is quickly adjusting itself to the previously observed pattern. The bar pattern in the central part of the nourishment area is already back within a month after the completion of the works. The former trough at the position of the nourished volume has a similar time of adjustment;
- the bar and trough morphology is still out of dynamic equilibrium. The inner bar crest is growing in height and almost stable at its position, at a location where the previous observed patterns in bar behaviour would suggest a seaward migration and with an almost constant height. The nourishment volume has thus decreased the rate and even reversed the pattern of bar behaviour.

The overall behaviour of the nourishment volume over the year 1993 to 1994 is showing the following aspects:

- after November 1993, no significant net change in sediment volume at the studied cross-shore profiles along the nourishment are observed;
- the only transport of the nourished sediment volume is observed in an eastward longshore direction. This can be expected because the major components of the wind-, wave-, and tide-driven currents are also directed towards the east;
- despite the lack of net changes in the nearshore sediment volumes, there is a redistribution of sediments within the nearshore zone which may be coupled to the behaviour of the bars.

## CHAPTER 162

### Numerical Model for Longshore Current Distribution on a Bar-Trough Beach

Yoshiaki KURIYAMA<sup>1</sup>

#### Abstract

A numerical model for the time-averaged nearshore current in the surf zone is developed to simulate the longshore current distribution on a bar-trough beach that has a peak velocity shoreward of the bar crest. Momentum fluxes due to mass transport under broken waves, which are ignored in other models, are included in the present model. The validity of the model is verified with field data.

#### 1. Introduction

There are two patterns of the time-averaged longshore current distribution on a bar-trough beach. One has a peak velocity seaward of the bar crest, and the other has the peak shoreward of the bar crest. Kuriyama and Ozaki (1993) measured longshore current velocities in the field when a single bar-trough system was formed and waves broke over the bar. They showed that eighty-five percent of the measured longshore current distributions have peak velocities shoreward of the bar crests, whereas fifteen percent have peaks seaward of the bar crests.

The seaward peak can be reproduced by one-dimensional models of the longshore current where the driving force of the longshore current is the cross-shore gradient of radiation stress (Ebersole and Dalrymple, 1980; Larson and Kraus, 1991) because the gradient is largest seaward of a bar crest owing to the large dissipation of wave energy due to wave breaking. On the other hand, the shoreward peak cannot be reproduced by the one-dimensional models. Church and Thornton (1993) and Smith et al. (1993) have recently developed one-dimensional numerical models for the longshore current that include the effect of turbulence due to wave breaking on the driving force through consideration of the surface roller. Although the peak velocities predicted by their models are located shoreward of the peaks predicted by previous

---

1) Senior Research Engineer, Port and Harbour Research Institute  
Nagase 3-1-1, Yokosuka, Kanagawa 239, JAPAN

models, the peaks predicted by their models are still located seaward of the peaks measured in the field. Symonds and Huntley (1980) showed that the longshore gradient of wave setup can cause a shoreward peak. The shoreward peak, however, was sometimes observed when the longshore gradient of the wave setup was small.

The objective of this study is to develop a numerical model that reproduces the shoreward peak in the longshore current even when the longshore gradient of the wave setup is small. It is assumed that the momentum fluxes due to mass transport under broken waves generate the shoreward peak, and the resultant momentum fluxes are introduced into a previous nearshore current model. Longshore current distributions predicted by the present model are compared with those measured in the field.

## 2. Numerical Model

The present model consists of two computationally distinct numerical models: a wave height transformation model and a nearshore current model.

### 2.1 Wave height transformation model

The present model for wave height transformation is based on the Karlsson's model (1969) for directional random waves, which is based on the balance of wave energy. I introduce a wave energy dissipation term as Takayama et al. (1991) did. The energy equation of a wave component with the frequency of  $f$  and the direction of  $\theta$  is expressed as

$$\begin{aligned} \frac{\partial(D_s V_x)}{\partial x} - \frac{\partial(D_s V_y)}{\partial y} + \frac{\partial(D_s V_\theta)}{\partial \theta} &= -D, \\ D_s &= S(f, \theta) \delta f \delta \theta, \\ V_x &= C_g \sin \theta, \quad V_y = C_g \cos \theta, \\ V_\theta &= \frac{C_g}{C} \left( -\cos \theta \frac{\partial C}{\partial x} - \sin \theta \frac{\partial C}{\partial y} \right), \end{aligned} \quad (1)$$

where  $D_s$  is the wave energy,  $S$  is the directional wave spectral density,  $\delta f$  is the frequency band width,  $\delta \theta$  is the directional band width,  $C_g$  is the group velocity,  $C$  is the celerity, and  $D$  is the wave energy dissipation rate. The values of  $D_s$ ,  $C_g$ ,  $C$  and  $D$  are defined for a wave component. The co-ordinate system used in this paper is shown in Figure 1. The positive direction of the  $y$ -axis is seaward. The wave direction is defined relative to the shoreward direction and positive counterclockwise. The vertical axis extends upward.

The principle of the dissipation term proposed by Dally et al. (1985) is used in the present model because the dissipation term can reproduce the wave height stabilization in a uniform depth, which is like the wave transformation over a trough.

Figure 1 Definition sketch of co-ordinate system.

Modification of the dissipation term by Dally et al., which is for one-dimensional monochromatic waves, yields Eq. (2) for a wave component of directional random waves.

$$D = \frac{K}{h} (D_s C_g - D_s \frac{E_s}{E} C_g), \tag{2}$$

$$E_s = \frac{1}{16} \rho g (H_{1/3})_s^2, \quad (H_{1/3})_s = \Gamma h.$$

where  $(H_{1/3})_s$  is the stable significant wave height,  $h$  is the still water depth,  $E$  is the total wave energy, the sum of  $D_s$ ,  $E_s$  is the total energy where the wave height is stable after wave breaking, and  $K$  and  $\Gamma$  are dimensionless empirical coefficients.

I assume that  $K$  and  $\Gamma$  are functions of the beach slope,  $\tan \beta$ , and express them with Eqs.(3) and (4) because the wave energy dissipation in the surf zone is affected by the beach slope. These functions were obtained on the basis of the calculations of the wave height transformation in the surf zone for offshore wave steepness of 0.02 by Goda (1975).

$$K = 1.7 \times 10^\alpha, \quad \alpha = -0.857 \log_{10}(1/\tan \beta) + 0.219. \tag{3}$$

$$\Gamma = -0.14 \log_{10}(1/\tan \beta) + 0.56. \tag{4}$$

The significant wave height,  $H_{1/3}$ , and the principal wave direction,  $\theta_p$ , are calculated by

$$H_{1/3} = 4.0 \sqrt{m_0}, \quad m_0 = \int_0^\infty \int_{-2\pi}^{2\pi} D_s d\theta df. \tag{5}$$

$$\theta_p = \int_0^\infty \int_{-2\pi}^{2\pi} \theta D_s d\theta df / m_0. \tag{6}$$

The significant wave period,  $T_{1/3}$ , is assumed to be equal to that in deep water.

## 2.2 Nearshore current model

### a. Momentum equation

The movements of water particles, which have the maximum orbital velocity of  $v_m$  due to waves, are assumed as shown in Figure 2. Water particles above the wave trough level,  $d_w$ , are transported by the depth and time-averaged nearshore current;  $U$  and  $V$  are the longshore and cross-shore components of the nearshore current velocity. The particles are also transported shoreward by mass transport due to waves at the angle of  $\theta$  and the velocity of  $V_u$ . Water particles below the wave trough level are transported by the nearshore current, and transported seaward at the velocity of  $V_l$  of the return flow, which is perpendicular to the shore. The mass of water transported shoreward by the mass transport is assumed to be equal to that transported seaward by the return flow.

Under the assumptions, the cross-shore flux of the longshore momentum in the surf zone,  $M_w$ , is expressed as

$$\begin{aligned}
 M_w = & \frac{\rho}{T} \int_0^T \int_{d_w}^{\eta} \{ [U + (V_u + v_m \cos \sigma t) \sin \theta_p] \\
 & \{ V + (V_l + v_m \cos \sigma t) \cos \theta_p \} \} dz dt \\
 & + \frac{\rho}{T} \int_0^T \int_{-h}^{d_w} \{ (U + v_m \cos \sigma t \sin \theta_p) \\
 & (V + V_l + v_m \cos \sigma t \cos \theta_p) \} dz dt,
 \end{aligned} \tag{7}$$

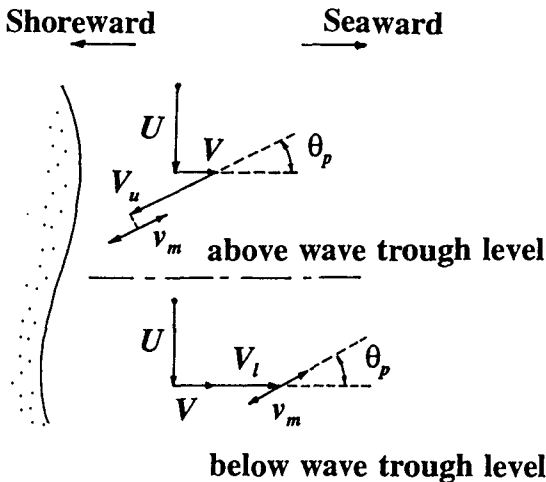

Figure 2 Definition sketch of the assumed movements of water particles above and below the wave trough level.

where  $\rho$  is the density of sea water,  $T$  is the wave period,  $\eta$  is the elevation of water surface,  $z$  is the upward elevation relative to the mean water level,  $\sigma$  is the angular frequency. The value of  $T_{1/3}$  is used as  $T$  in the calculation.

Equation (7) becomes

$$\begin{aligned}
 M_w = & \frac{\rho}{T} \int_0^T \left\{ \int_{-h}^{\eta} U V dz \right. \\
 & + \int_{-h}^{\eta} v_m^2 \cos^2 \sigma t \sin \theta_p \cos \theta_p dz \\
 & + U \left( \int_{d_r}^{\eta} V_u \cos \theta_p dz + \int_{-h}^{d_r} V_l dz \right) \\
 & \left. + \int_{d_r}^{\eta} (V_u^2 + V V_u) \sin \theta_p \cos \theta_p dz \right\} dt.
 \end{aligned}
 \tag{8}$$

The first and second terms on the right-hand side of Eq.(8) represent the momentum flux due to the nearshore current and a radiation stress, respectively. The third term is equal to zero because the mass of water transported shoreward is assumed to be equal to that transported seaward. The fourth term is the cross-shore flux of the longshore momentum due to mass transport by waves.

In most previous models for the nearshore current, the fourth term is neglected because the effect of the mass transport due to unbroken waves on the nearshore current is small. However, the mass flux under broken waves is several times of that calculated with a formula for unbroken waves (Nadaoka and Kondoh, 1982). This means that a momentum flux due to mass transport under broken waves is much greater than that under unbroken waves. Therefore I consider that the momentum fluxes due to mass transport under broken waves are significant for the prediction of the longshore current distribution on a bar-trough beach, and introduce the fluxes into a previous model.

The fourth term,  $M_{bl}$ , becomes Eq.(9) with a surface roller model proposed by Svendsen (1984) as shown in Figure 3; in his model, a water particle in the surface roller is transported shoreward with the celerity,  $C$ ,

$$M_{bl} = \rho P_b e (-C \cos \theta_p + V) C \sin \theta_p,
 \tag{9}$$

where  $e$  is the time-averaged thickness of the surface roller, and  $P_b$  is the fraction of breaking waves, which is introduced for random waves. The value of  $e$  is assumed as

$$e = C_A H_{1/3}^2 / L,
 \tag{10}$$

in which  $C_A$  is a dimensionless coefficient, and  $L$  is the wavelength for the wave period of  $T$ .

Figure 3 Definition sketch of the vertical distribution of time-averaged cross-shore velocity in a surface roller model by Svendsen (1984).

The cross-shore flux of the cross-shore momentum due to broken waves,  $M_{b2}$ , and the longshore flux of the longshore momentum,  $M_{b3}$ , are obtained in a similar way for the value of  $M_{b1}$ ; these are described by

$$M_{b2} = \rho P_b e C^2 \cos^2 \theta_p + (d_r + h) V_i^2. \quad (11)$$

$$M_{b3} = \rho P_b e (C \sin \theta_p + 2U) C \sin \theta_p. \quad (12)$$

The value of  $V_i$  is expressed as Eq.(13), which is derived by Kuriyama(1991) on the basis of Svendsen's model (1984).

$$V_i = \left( C \frac{m_0}{h^2} + P_b C_A \frac{H_{1/3}^2}{hT} \right) \cos \theta_p. \quad (13)$$

Finally, the horizontal momentum equations in the present model for the nearshore current, which contains the momentum fluxes due to surface rollers, are represented by

$$\begin{aligned} \frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} + F_x - L_x + R_x + g \frac{\partial \bar{\eta}}{\partial x} + M_x &= 0, \\ \frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + F_y - L_y + R_y + g \frac{\partial \bar{\eta}}{\partial y} + M_y &= 0, \end{aligned} \quad (14)$$

$$\begin{aligned}
 L_x &= \frac{\partial}{\partial x} \left( \epsilon \frac{\partial U}{\partial x} \right) + \frac{\partial}{\partial y} \left( \epsilon \frac{\partial U}{\partial y} \right), \quad L_y = \frac{\partial}{\partial x} \left( \epsilon \frac{\partial V}{\partial x} \right) + \frac{\partial}{\partial y} \left( \epsilon \frac{\partial V}{\partial y} \right), \\
 R_x &= \frac{1}{\rho(\bar{h} + \bar{\eta})} \left( \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{yx}}{\partial y} \right), \quad R_y = \frac{1}{\rho(\bar{h} + \bar{\eta})} \left( \frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y} \right), \\
 M_x &= \frac{1}{\rho(\bar{h} + \bar{\eta})} \left( \frac{\partial M_{bx}}{\partial x} + \frac{\partial M_{by}}{\partial y} \right), \quad M_y = \frac{1}{\rho(\bar{h} + \bar{\eta})} \left( \frac{\partial M_{by}}{\partial x} + \frac{\partial M_{bx}}{\partial y} \right),
 \end{aligned}
 \tag{15}$$

where  $\bar{\eta}$  is the elevation of the mean water level,  $F_x$  and  $F_y$  are the bottom friction terms,  $L_x$  and  $L_y$  are the lateral mixing terms,  $S_{xx}$ ,  $S_{xy}$ , and  $S_{yy}$  are the radiation stress components, and  $\epsilon$  is a lateral mixing coefficient. The subscripts  $x$  and  $y$  denote the values in the  $x$ -direction and  $y$ -direction.

b. Fraction of breaking waves

Seaward of a bar crest, I assume that the fraction of breaking waves is a function of wave height-water depth ratio as Thornton and Guza (1983) did, and represent it by Eq.(16) with a dimensionless coefficient,  $\gamma$ , which is the wave height-water depth ratio in the surf zone, where all waves are broken.

$$P_b = (H_{1/3} / (\gamma \bar{h}))^4. \tag{16}$$

I introduce the effect of beach slope into the calculation of  $\gamma$  because the wave energy dissipation in the surf zone depends on beach slope. The value of  $\gamma$  is assumed as Eq.(17) on the basis of the calculations of the wave height in the surf zone for offshore wave steepness of 0.02 by Goda (1975).

$$\gamma = 0.68 \exp(4.2 \tan \beta). \tag{17}$$

Shoreward of a bar crest, the fraction of breaking waves is assumed as

$$\begin{aligned}
 P_b &= (P_b)_{bar}, & y_{bar} - 10 < y \leq y_{bar}, \\
 P_b &= (P_b)_{bar} - 0.014(y - y_{bar} + 10)^2, & y \leq y_{bar} - 10,
 \end{aligned}
 \tag{18}$$

where  $(P_b)_{bar}$  is the fraction of breaking waves at the bar crest, and  $y_{bar}$  is the offshore distance at the bar crest. According to visual observations, waves break even shoreward of a bar crest. This means that the fraction of breaking waves does not decrease rapidly from a bar crest although the value predicted by Eq.(16) decreases rapidly from the bar crest. Thus, the fraction of breaking waves shoreward of a bar crest is assumed to be constant near the bar crest and to decrease shoreward proportionally to the square of the distance from the shoreward limit of the constant

$P_b$  zone. The coefficients of Eq.(18) were determined on the basis of visual observation data (Kuriyama and Ozaki, 1993); the units of  $y$  and  $y_{bar}$  are meters.

Near the surf zone shoreward of a trough, Eq.(16) is used again where  $P_b$  estimated by Eq.(16) is larger than that by Eq.(18).

c. Surface roller area parameter,  $C_A$

I assume that  $C_A$  changes according to the development and decay of the surface roller although it is treated as a constant value by Svendsen (1984), because a constant  $C_A$  cannot represent the disappearance of the surface roller in a trough. The development and decay of the surface roller are assumed to be proportional to the fraction of wave breaking; the maximum value of  $C_A$  is determined to be 4.0 on the basis of the field data obtained by Kuriyama (1991). Finally,  $C_A$  is expressed as

$$C_A = 4.0 P_b. \quad (19)$$

d. Radiation stress, bottom shear stress and lateral mixing

The radiation stresses of directional random waves are calculated by Eq.(20) proposed by Yamaguchi(1988).

$$\begin{aligned} S_{xx} &= \int_0^\infty \int_{-\pi/2}^{\pi/2} \rho g \left\{ \frac{C_g}{C} \sin^2 \theta + \left( \frac{C_g}{C} - \frac{1}{2} \right) \right\} D_s d\theta df, \\ S_{xy} = S_{yx} &= \int_0^\infty \int_{-\pi/2}^{\pi/2} \rho g \frac{C_g}{C} \cos \theta \sin \theta D_s d\theta df, \\ S_{yy} &= \int_0^\infty \int_{-\pi/2}^{\pi/2} \rho g \left\{ \frac{C_g}{C} \cos^2 \theta + \left( \frac{C_g}{C} - \frac{1}{2} \right) \right\} D_s d\theta df. \end{aligned} \quad (20)$$

Equation (21) (Nishimura, 1982; Nishimura, 1988) is used for the calculation of the bottom shear stresses,  $F_x$  and  $F_y$ . The value of 0.005 is used as the friction coefficient,  $C_f$ .

$$\begin{aligned} F_x &= \rho C_f \left\{ \left( W + \frac{w_b^2}{W} \sin^2 \theta_p \right) U - \frac{w_b^2}{W} \sin \theta_p \cos \theta_p V \right\}, \\ F_y &= \rho C_f \left\{ \frac{w_b^2}{W} \sin \theta_p \cos \theta_p U - \left( W + \frac{w_b^2}{W} \cos^2 \theta_p \right) V \right\}, \\ W &= \left\{ \sqrt{U^2 + V^2 + w_b^2} + 2(U \sin \theta_p - V \cos \theta_p) w_b \right. \\ &\quad \left. + \sqrt{U^2 + V^2 + w_b^2} + 2(U \sin \theta_p - V \cos \theta_p) w_b \right\} / 2, \\ w_p &= 2(v_m)_b / \pi, \quad (v_m)_b = \frac{\pi H_{1/3}}{T \sin(2\pi h/L)}. \end{aligned} \quad (21)$$

The lateral mixing coefficient proposed by Battjes (1975) is used in the present model. This coefficient is given by

$$\epsilon = Mh \left( \frac{D_{total}}{\rho} \right)^{1/3}, \quad (22)$$

where  $D_{total}$  is the total wave energy dissipation rate and  $M$  is a dimensionless coefficient. Lateral mixing is probably related to turbulence; the turbulence due to breaking waves is much larger than that due to non-breaking waves. Hence, the degree of the lateral mixing in a trough is expected to be smaller than that in the surf zone located shoreward of the trough. Although the lateral mixing coefficient proposed by Longuet-Higgins (1970) is widely used, it seems to be inappropriate for the prediction of the longshore current on a bar-trough beach because the coefficient proposed by Longuet-Higgins, which is proportional to the distance from the shoreline, does not reproduce the difference between the lateral mixing in a trough and that in the shoreward surf zone. On the other hand, the lateral mixing coefficient proposed by Battjes reproduces the difference because it is based on the wave energy dissipation due to wave breaking. Thus, in the present model, I adopt the lateral mixing coefficient proposed by Battjes.

### 3. Model Comparisons with Measurements

The significant wave heights and the longshore current velocities predicted by the present model are compared with the values measured at Hazaki Oceanographical Research Facility (HORF), which is a field observation pier of 427m in length on the Kashima-nada coast of Japan facing to the Pacific Ocean. Water surface elevations were measured with ultrasonic wave gages before and after the measurement of the longshore current. A spherical float having a diameter of 0.2m was used to measure time-averaged longshore current velocities 1m below the water surface. This method with the float was confirmed to be useful for the measurement of the time-averaged longshore current velocity by calibrations with an electromagnetic current meter; there is a strong correlation between the time-averaged longshore current velocity measured by the float and that measured by the current meter (Kuriyama and Ozaki, 1993).

#### 3.1 Calculation conditions

The calculation results for three cases, on March 24, 28 and April 4, 1989, are compared with the measurements. Figure 4 shows the topographic map of the vicinity of the HORF on March 31; this topography is used in the calculations for the three cases because the beach profile changes from March 24 to April 4 were small. The topography was almost uniform alongshore although scour occurred around the tip and the middle of the HORF,  $y=380\text{m}$  and  $y=200\text{m}$ , where piles are concentrated. The calculation areas extend from the shorelines to  $y=650\text{m}$ , and alongshore from  $x=-320\text{m}$  to  $x=320\text{m}$ .

In the calculations of wave height transformation, the grid distances in  $x$ -direction and  $y$ -direction are 10m. The numbers of frequency components and directional components are 10 and 35, respectively. The wave heights,  $(H_{1/3})_{obs}$ , the wave periods,

$(T_{1/3})_{ob}$ , the principal wave directions,  $(\theta_p)_{1/3}$ , and the spreading parameters,  $(s_{max})_{ob}$ , input at the offshore boundaries are listed in Table 1. The Bretschneider-Mitsuyasu frequency spectrum and the Mitsuyasu-type spreading function are given at the offshore boundaries.

In the calculations of wave energy dissipation, a beach slope below 1/100 and that over 1/10 are replaced by values of 1/100 and 1/10, respectively, because Eqs.(3) and (4) are valid for the beach slopes from 1/100 to 1/10.

Figure 4 Topographic map of the vicinity of the HORF.

Table 1 Offshore boundary conditions

Case	Date	$(H_{1/3})_{ob}$	$(T_{1/3})_{ob}$	$(\theta_p)_{ob}$	$(s_{max})_{ob}$
1	March 24	3.20m	11.20s	-20.0°	90
2	March 28	2.47m	8.86s	-25.0°	40
3	April 4	2.03m	8.40s	-10.0°	45

The nearshore currents are calculated with the horizontal momentum equations, Eqs.(14) and (15), and the continuity equation by the ADI (Alternating Direction Implicit) method. The calculations are done for 4000 time step with a step length of 0.4s; the grid distances are 10m.

The nearshore current velocities are assumed to be equal to zero at the offshore boundaries and at the shorelines. The nearshore current velocities and the mean water levels at the side boundaries are assumed to be equal to the values at internal grid points next to the side boundaries.

The longshore flux of the longshore momentum,  $M_{b3}$ , is neglected in the calculations of the nearshore current because the nearshore currents preliminarily calculated by a previous model are almost uniform alongshore.

### 3.2 Wave height

Figure 5 shows the predicted significant wave heights and the values measured at the HORF. The solid lines show the values predicted by the present model, and the closed circles show the values measured before and after the measurements of the longshore current. The predicted values agree well with the measured values except for the data near the shorelines.

Causes of the small disagreement of calculated and measured values near the shorelines are supposed to be infragravity waves and the increase of water depth due to wave setup. When an offshore wave height is large, the amount of wave setup and the infragravity wave height are large near the shoreline. Infragravity waves and the increase of water depth due to wave setup, however, are not taken into account in the present model although the gradient of mean water level is considered in the nearshore current model. Disregard of the two factors results in the disagreement of calculated and measured values near the shorelines.

### 3.3 Nearshore current

Figure 6 shows a comparison of the longshore current velocities measured at the HORF with those predicted by the present model and by a previous model, which does not include momentum fluxes due to mass transport under broken waves; the velocities on March 24 and 28 were predicted with  $M=5$  and those on April 4 were predicted with  $M=10$ . Seaward of the bar crests, the values predicted by the present model and by the previous model increase shoreward; both agree with the measured values. Shoreward of the bar crests, however, the values predicted by the present model and the measured values increase toward shore whereas the values predicted by the previous model decrease. Consequently the longshore current velocities over the troughs predicted by the present model agree well with the measured values whereas the values predicted by the previous model do not.

The Longshore current velocities predicted by a quasi-present model where the fraction of breaking waves shoreward of the bar crest is estimated with Eq.(16) are also shown in Figure 6. The peaks in velocity predicted by the quasi-present model are located at the bar crests, shoreward of the peaks predicted by the previous model and seaward of the peaks measured at the HORF and predicted by the present model.

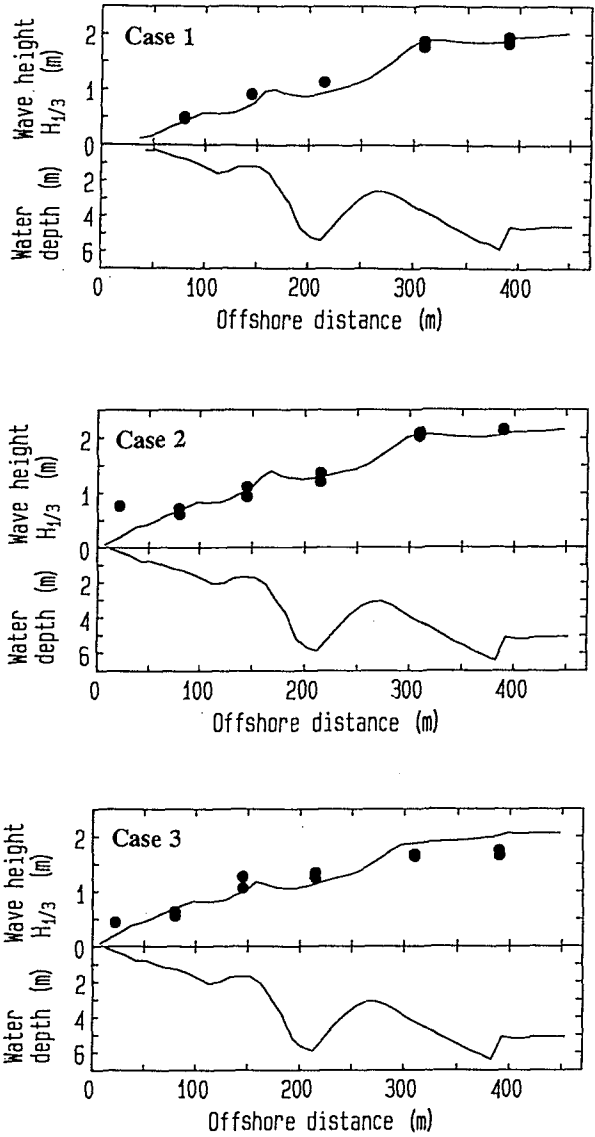

Figure 5 Comparison of the significant wave heights measured at the HORF (circles) with those predicted by the present model.

Figure 6 Comparison of the longshore current velocities measured at the HORF (circles) with those predicted by the previous model (broken lines), by the quasi-present model (thin solid lines), and by the present model (thick solid lines).

#### 4. Discussion and Conclusions

Let us assume that an incident wave angle and the longshore current velocity are positive. Shoreward of a bar crest, the cross-shore flux of the longshore momentum due to the surface roller decreases with travel shoreward owing to the decay of the roller. This decrease means that the cross-shore flux of the longshore momentum transported into a unit volume is larger than that transported out of the volume. Consequently the longshore current velocities calculated by the present model are larger than those calculated by the previous model.

On the other hand, seaward of the bar crest, the cross-shore flux of the longshore momentum due to the surface roller increases with travel shoreward owing to the development of the surface roller. Thus the longshore current velocities calculated by the present model are smaller than those calculated by the previous model. As a result, the longshore current distribution calculated by the present model has a peak velocity shoreward of the bar crest.

The longshore current distributions predicted by the quasi-present model have peaks at the bar crests, seaward of the peaks predicted by the present model because the surface roller calculated by the quasi-present model with Eq.(16) decays rapidly from the bar crest whereas the roller calculated by the present model with Eqs.(16) and (18) propagates without decay near the bar crest, and then gradually decays.

The longshore current distributions on a bar-trough beach predicted by the present model agree with the field measurements, which have peaks in velocity shoreward of the bar crests, better than the distributions predicted by the other two models. The agreement shows that the fraction of breaking waves predicted by Eq.(18) is reasonable shoreward of a bar crest and the momentum fluxes due to mass transport under broken waves are significant for the prediction of the longshore current.

#### Acknowledgement

The author would like to thank Mr. Yasushi Ozaki for analyzing field data. Further acknowledgement is extended to Dr. Nicholas C. Kraus, Director of Conrad Blucher Institute, Texas A&M University -Corpus Christi, for his useful comments that improved this paper.

## CHAPTER 163

### PREDICTION OF BEACH PROFILE CHANGE AT MESOSCALE UNDER RANDOM WAVES

Magnus Larson<sup>1</sup>

**ABSTRACT:** A mesoscale model is presented to calculate the average net cross-shore transport rate and beach profile evolution under random waves. Cross-shore transport formulas for random waves are derived by superimposing the transport from individual waves, which belong to an ensemble that represents the random wave field. The transport relationships for individual waves are based on experiments with monochromatic waves in large wave tanks. The model is validated using beach profile data from the SUPERTANK Laboratory Data Collection Project and three different types of profile evolution events are studied, namely equilibrium erosion with bar formation, berm flooding, and the impact of breaking waves on an offshore mound. Berm flooding includes the erosion of a well-developed summer berm and the erosion of an artificially constructed foredune, and the offshore mound tests encompass narrow- and broad-crested mounds.

#### INTRODUCTION

On a natural beach the random properties of the waves have a major influence on the evolution of the bottom topography. Monochromatic waves typically break in a narrow region across the profile, where incipient breaking of individual waves is a weakly random process that tends to slightly shift the location of the break point back and forth. A random wave field, however, consists of individual waves with different height, period, and direction, implying wave breaking all across the profile. The more evenly distributed forcing of random waves across shore tends to produce a profile with less pronounced morphological features as compared to monochromatic

---

<sup>1</sup> Coastal Engineering Laboratory, Department of Civil Engineering, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, JAPAN (Associate Professor on leave from Department of Water Resources Engineering, University of Lund, SWEDEN).

waves (Larson and Kraus 1989, 1994). Also, in a random wave field individual waves that are potentially constructive or destructive to the beach could exist simultaneously, which makes it more difficult to assess the net effect on the profile evolution (Mimura et al. 1986). Thus, when applying numerical beach profile change models to field conditions the effect of random waves on the profile development should be included through a realistic description of the hydrodynamics and net cross-shore transport rate.

Numerical models of beach profile change may be classified according to the characteristic scale employed in resolving the fluid and sediment motion. Models which attempt to describe scales of motion in time and space compatible with individual waves belong to the class of microscale models, whereas mesoscale models focus on resolving scales of motion that are the result of many waves (Larson and Kraus 1994, 1995). The numerical models by Kriebel and Dean (1985) and Larson and Kraus (1989) are examples of mesoscale models, where the local cross-shore flow pattern is not computed, and the net transport rate is derived directly from the variation in wave properties across shore. These models simulate the effect of random waves by transforming a statistical wave height measure as a monochromatic wave. Such an approach is expected to primarily reproduce the overall beach response and the details of the profile evolution will be less well predicted. For example, if the impact of a storm is simulated the total amount of material moved, including erosion on the foreshore and deposition at an offshore bar, may be in agreement with measurements, whereas the detailed shape of the bar and erosion scarp on the foreshore could differ more. Thus, treating a representative wave measure as a monochromatic wave may characterize the total forcing the profile is exposed to; however, local cross-shore variations in the forcing will be accurately described to a lesser extent.

The main objective of this paper is to present a mesoscale model to predict the net transport rate and resulting beach profile change under random waves. The randomness of the wave field is included from the start in the development of the model equations, and predictive formulas are obtained in terms of simple statistical wave properties. These properties are calculated using the random wave decay model by Larson (1995). The method of superimposing the effect of individual waves is employed for calculating the average net transport rate for a random wave field. The net transport rate distribution for individual waves is estimated from the relationships presented by Larson and Kraus (1989), which involves schematizing the beach profile into different transport regions depending on the wave characteristics. The contribution from individual waves is summed up taking into account if the wave is breaking, non-breaking, or in the swash. Profile measurements from the SUPER-TANK Laboratory Data Collection Project (Kraus et al. 1992) are used to validate the model, including such events as foreshore erosion and bar formation, berm flooding, and the transport at an offshore mound. Because the net transport rate and profile evolution are described at the mesoscale, a robust model is obtained that has potential for describing long-term profile response including seasonal changes. The

model allows the specification of long-term wave statistics as input which is needed to reproduce seasonal changes.

## THEORETICAL CONSIDERATIONS

### Wave Model

A successfully employed technique for modeling the decay of random waves in the surf zone is to calculate wave transformation for individual wave components in the probability density function (pdf) or spectrum, and determine the wave characteristics in the surf zone by superposition of the effect of the individual wave components (Mase and Iwagaki 1982, Dally 1992). Such a simulation technique may be computationally intensive but does not rely on any inferences about the pdf or spectrum in the surf zone (Battjes and Janssen 1978, Thornton and Guza 1983). Larson (1995) presented a model which requires the transformation of a single representative wave only; this model produces results identical or similar to a simulation that involves many wave components.

In the present profile change model, the wave transformation is described by the following equations (Larson 1995),

$$\frac{d}{dx}(F_{rms} \cos\theta) = \frac{\kappa}{d}(F_{rms} - F_{stab}) \quad (1)$$

in which,

$$F_{rms} = \frac{1}{8} \rho g H_{rms}^2 C_g \quad (2)$$

$$F_{stab} = \frac{1}{8} \rho g [(1-\alpha)H_n^2 + \alpha\Gamma^2 d^2] C_g \quad (3)$$

where  $H_{rms}$  is the root-mean-square (rms) wave height for breaking and non-breaking waves,  $H_n$  the rms wave height for non-breaking waves,  $\alpha$  the ratio of breaking waves,  $C_g$  the group velocity,  $\theta$  the incident wave angle,  $\rho$  the density,  $g$  the acceleration of gravity,  $d$  the water depth,  $x$  a cross-shore coordinate pointing offshore, and  $\kappa$  ( $=0.15$ ) and  $\Gamma$  ( $=0.40$ ) empirical coefficients as given by Dally et al. (1985). The wave number conservation equation and the cross-shore momentum equation are solved in parallel with Equations 1-3 to yield the wave properties and the mean water elevation across the profile.

In general,  $H_{rms}$  is obtained by employing numerical methods; this requires the specification of  $H_n$  and  $\alpha$  at each point across shore. For a beach profile with a depth that increases monotonically with distance offshore  $H_n$  and  $\alpha$  may be computed

directly from the local pdf, which is transformed from the offshore boundary neglecting wave breaking and truncated at the depth of incipient breaking for an individual wave. However, for a non-monotonic beach profile, such as a barred profile, an empirical closure relationship must be added to model how  $\alpha$  is affected by wave reforming (Larson 1995). In the latter case, the non-breaking waves may consist of waves that have never been breaking (unbroken waves) and waves that were breaking but have reformed at some seaward point. A Rayleigh pdf is assumed to describe the variation in wave height in the offshore, and the sea is taken to be narrow-banded in frequency and direction.

**Cross-Shore Sediment Transport Model**

Relationships for the net cross-shore transport rate developed by Larson and Kraus (1989) for monochromatic waves were generalized to random waves by treating the random wave field as a collection of individual waves. Under the assumptions of linearity in transport and no interactions, the transport rate distribution generated by random waves was obtained by computing the distribution for each individual wave and then averaging over all waves according to,

$$\bar{q} = \frac{1}{N} \sum_{i=1}^N q_i \tag{4}$$

where  $\bar{q}$  is the average net transport rate at  $x$ ,  $N$  is the number of individual waves, and  $q_i$  the transport rate for wave  $i$  at  $x$ . Different transport relationships are employed depending on if a wave is breaking, non-breaking, or in the swash.

Breaking waves. If the relationship developed by Larson and Kraus (1989) for the net transport rate under breaking waves is substituted into Equation 4, the following expression is obtained for the average transport rate  $\bar{q}_b$ ,

$$\bar{q}_b = \frac{1}{N} \sum_{i=1}^N K \left[ D_i - (D_{eq} - \frac{\epsilon}{K} \frac{dh}{dx}) \right] \tag{5}$$

where  $D$  is the wave energy dissipation per unit water volume due to wave breaking and  $D_{eq}$  its equilibrium value (Dean 1977),  $h$  the profile elevation, and  $K$  and  $\epsilon$  empirical transport coefficients from the monochromatic transport relationship. In developing Equation 5 further, an assumption has to be made regarding the partitioning of the average energy dissipation between erosional and accretionary waves at all points across shore. The random wave model will predict the average energy dissipation; however, no information is obtained on the amount of dissipation that contributes to onshore and offshore transport, respectively. The simplest approach is to assume that each breaking wave at a specific water depth transports similar magnitudes of material, which leads to the following equation (Larson and Kraus 1994),

$$\bar{q}_b = K\xi \left[ \bar{D} - \alpha \left( D_{eq} - \frac{\epsilon}{K} \frac{dh}{dx} \right) \right] \tag{6}$$

where  $\bar{D}$  is the average energy dissipation per unit water volume as given by the random wave model. The function  $\xi$  automatically provides the direction of the transport and weights the influence of the erosional and accretionary waves based on the empirical criterion by Larson and Kraus (1989),

$$\xi = 2 \frac{e^{-\frac{1}{M} \frac{H_{rms0}}{L_o} \left( \frac{wT}{H_{rms0}} \right)^3}}{e^{-\left( \frac{H_{bo}}{H_{rms0}} \right)^2}} - 1 \quad -1 \leq \xi \leq 1 \tag{7}$$

where  $H_{rms0}$  is the deepwater rms wave height,  $H_{bo}$  the wave height at incipient breaking transformed backwards to deep water,  $w$  the sediment fall speed,  $T$  the wave period,  $L_o$  the deepwater wavelength, and  $M$  ( $=0.00070$ ) an empirical coefficient.

Non-breaking waves. The net transport rate seaward of the break point of an individual wave is assumed to decay exponentially with distance offshore (Larson and Kraus 1989). For a random wave field, the contribution to the transport rate from non-breaking waves is estimated to,

$$\bar{q}_u = \frac{1}{N} \sum_{i=1}^n q_{bi} e^{-\lambda_i(x-x_{bi})} \tag{8}$$

where  $n$  is the number of non-breaking waves at  $x$ ,  $x_b$  the breakpoint location,  $q_b$  the transport rate at incipient breaking, and  $\lambda$  an exponential decay coefficient, the latter two variables evaluated at  $x_b$ . Equation 8 sums the contributions to the transport rate from all waves that break landward of  $x$ . The coefficient  $\lambda$  depends on the median grain size and the incipient breaking wave height as for transport by monochromatic waves. Equation 8 is most easily solved by dividing the profile shoreward of  $x$  in a number of grid cells  $n_s$  and adding together the contribution from each cell to the transport rate at  $x$ . Such a method to approximate Equation 8 yields,

$$\bar{q}_u = \sum_{j=1}^{n_s} q_{bj} e^{-\lambda_j(x-x_{bj})} \Delta \alpha_j \tag{9}$$

where  $\Delta \alpha_j$  represents the increase in the ratio of breaking waves in cell  $j$ , which has a length  $\Delta x$  (index  $j$  denotes the grid cell number as opposed to  $i$  that denotes the number of the wave). In Equation 9,  $q_{bj}$  and  $\lambda_j$  must be estimated at all shoreward locations before the transport rate can be calculated.

**Swash waves.** The average net transport rate at a specific location  $x$  in the swash may be obtained by superimposing the transport from all waves that run up passed this location using the equation proposed by Larson and Kraus (1995),

$$\bar{q}_r = \frac{1}{N} \sum_{i=1}^{n_r} q_{si} \left( \frac{h-R_i}{h_s-R_i} \right)^{1.5} \frac{\tan\beta}{\tan\beta_s} \tag{10}$$

where  $q_s$  is the transport rate at the shoreward end of the surf zone located at  $x_s$  where the elevation is  $h_s$  and the beach slope  $\beta_s$ ,  $h$  and  $\beta$  are the elevation and local beach slope at  $x$ , respectively,  $R$  is the runup height, and  $n_r$  is the number of waves that run up passed  $x$ . Equation 10 involves summing transport contributions from all waves that have runup heights exceeding the elevation where the average transport rate is calculated. Based on Equation 10,  $\bar{q}_r$  is approximated in a similar manner to  $\bar{q}_u$ ; the profile shoreward of  $x$  is divided in  $n_{sr}$  grid cells, each cell having a length of  $\Delta x$ , and the contribution to  $\bar{q}_r$  from each cell is summed up to yield,

$$\bar{q}_r = \sum_{j=1}^{n_{sr}} q_{sj} \left( \frac{h-R_j}{h_s-R_j} \right)^{1.5} \frac{\tan\beta}{\tan\beta_s} \Delta\rho_j \tag{11}$$

where  $\Delta\rho_j$  is the change along  $\Delta x$  in the ratio of waves that run up passed  $x$  and  $j$  denotes the grid cell number as before. The pdf for the runup height (needed to calculate  $\Delta\rho_j$ ) may be derived using a transformation for individual wave components in the Rayleigh pdf, where each component is assumed to have a runup height which depends upon the surf similarity parameter (Battjes 1974). The corresponding distribution function  $F(R)$  is obtained by integrating the pdf to yield,

$$F(R) = 1 - e^{-\left(\frac{R}{R_{rms}}\right)^{\frac{2}{1-b/2}}} \tag{12}$$

where  $R_{rms}$  is defined as,

$$R_{rms} = a (\tan\beta_s \sqrt{L_o})^b H_{rmso}^{1-b/2} \tag{13}$$

and  $a$  ( $=1.47$ ) and  $b$  ( $=0.79$ ) are empirical coefficients that determine the functional dependence on the surf similarity parameter (Larson and Kraus 1989).

**VALIDATION OF RANDOM PROFILE CHANGE MODEL**

Profile data from the SUPERTANK Laboratory Data Collection Project (Kraus et al. 1992) were employed to examine the predictions of the model for cross-shore transport and profile change under random waves. First, the random wave model was used to calculate wave transformation in the surf zone, and then the net cross-shore transport rate distribution was determined based on the calculated wave

properties. Finally, the equation for sediment volume conservation was employed to compute depth changes.

Three different types of profile evolution tests were investigated: (1) equilibrium erosion, (2) berm flooding, and (3) waves breaking on an offshore mound. The equilibrium erosion tests involved bar development under random waves, where the profile change decreased with elapsed time as the profile approached an equilibrium configuration under the influence of a steady random wave field. Berm flooding encompassed tests where the foreshore was exposed to marked wave action, including berm and foredune erosion. Two tests were studied involving transport at an offshore mound; one mound was narrow-crested and the other mound was broad-crested. Table 1 summarizes the SUPERTANK Tests used in the model validation in terms of Test number, profile survey time, and wave conditions. The sand used in the tank had a median grain size of 0.22 mm during all SUPERTANK tests and the standard water depth employed in the tank was 3.05 m. The wave conditions in Table 1 represent target values and the generated values were slightly different (the measured wave conditions at the most seaward wave gage were used as input to the model).

Table 1. SUPERTANK Tests used in the present study.				
Profile Event	Test No.	Time of survey	H <sub>rms</sub> (m)	T <sub>p</sub> (s)
Equilibrium erosion	ST_10	910805: 900 910806: 1100	0.57	3.0
Berm flooding	ST_90	910828: 700, 1120	0.49	3.0
	ST_A0	910828: 1500, 1637	0.49	3.0
Offshore mound	ST_J0	910908: 1100, 1610	0.49	3.0
	ST_K0	910912: 700, 1220	0.49	3.0

The preliminary calculations indicated that the initial rate of profile change was satisfactorily reproduced, whereas the development of the equilibrium profile shape was slower than expected and the shape too flat. For example, SUPERTANK Test ST\_10 indicated an evolution towards a barred equilibrium profile under random waves that the model did not reproduce because of small, but significant transport rates even after long time periods. To improve the description in the model of the approach to equilibrium, Equation 6 was modified according to,

$$\bar{q}_b = K\xi \left[ \bar{D} - \alpha^p \left( D_{eq} - \frac{e}{K} \frac{dh}{dx} \right) \right] \quad (14)$$

where  $p$  is an empirical power less than one. The power  $p$  may be considered as a means of taking into account that the transport rate for an individual wave is typically

overestimated in the averaging process. Because  $p < 1$ , the effect on the profile development in parts of the profile where most of the waves are breaking is minor; however, if only few waves are breaking the effect of introducing  $p$  is marked. The quantity  $\alpha^p > \alpha$  effectively produces a profile that is steeper than if the  $p$  is not introduced. In all calculations discussed in this paper a value of  $p = 0.5$  was employed based on trial calculations with several different  $p$ -values, where comparisons were made with SUPERTANK measurements.

The values of the empirical transport coefficients in Equation 14 used in all simulations were  $K = 2.0 \cdot 10^{-6} \text{ m}^4/\text{N}$  and  $\epsilon = 0.0002 \text{ m}^2/\text{s}$ . The value of  $K$  agrees well with the optimum value determined by Larson and Kraus (1989) for profile evolution under monochromatic waves in large wave tanks, who found an overall  $K$ -value of about  $1.6 \cdot 10^{-6} \text{ m}^4/\text{N}$ . However,  $\epsilon$  determined for monochromatic waves is larger than for random waves, mainly because the profile slopes tend to grow steeper for monochromatic waves and a larger value is needed on  $\epsilon$  to reduce this growth in slope. The similar coefficient values found on the  $K$ -value for monochromatic and random waves support the approach to superimpose the contribution from many individual waves to derive the transport rate distribution under random waves.

### Equilibrium Erosion

In Test ST\_10 random waves were employed until a near-equilibrium profile shape developed that had a distinct breakpoint bar in the offshore ( $H_{rms} = 0.57 \text{ m}$ ,  $T_p = 3.0 \text{ s}$ ). Figure 1 displays the calculated and measured profile after 400 min of wave action together with the initial profile. The calculated profile agrees quite well with the measurements, especially on the foreshore and on the seaward side of the bar. The largest discrepancies are found in the trough region, where the measurements show a more marked trough than what the model predicts. This is probably due to the oversimplification of directly relating the transport rate to the energy dissipation. The calculated average energy dissipation is a fairly smooth function across shore, which produces a smooth evolution of the bottom topography. In reality, at incipient breaking there is a pronounced local impact on the bottom, especially for plunging breakers, that could induce a marked peak in the transport rate and enhance trough development. If a large number of the waves break in approximately the same location, a marked trough could appear that the model does not reproduce.

In order to verify that the model predicted the development of an equilibrium profile for random waves, a simulation was performed using the conditions for Test ST\_10 during a period of 7 days. Figure 2 displays the calculated profile at selected times, clearly showing the decrease in profile change with time elapsed. An equilibrium profile has almost developed after 3.5 days with a pronounced bar feature in the offshore.

Figure 1. Comparison between measured and calculated profile from SUPER-TANK Test ST\_10 after 400 min of wave action.

Figure 2. Calculated profiles at selected times for conditions as given by SUPERTANK Test ST\_10.

### Berm Flooding

SUPERTANK Tests ST\_90 and ST\_A0 focused on the foreshore response to random waves. In Test ST\_90 the foreshore consisted of a well-developed berm that was flooded and exposed to erosive wave conditions ( $H_{rms} = 0.49$  m,  $T_p = 3.0$  s). Test ST\_A0 involved a small foredune that was quickly eroded away by the waves (same wave conditions as Test ST\_90). In both these tests the water level in the tank was 3.35 m. Figure 3 displays a comparison between calculated and measured profile for ST\_90 after 50 min of wave action together with the initial profile (only the portion of the profile where any change was recorded is displayed). The model prediction somewhat underestimates the rapid response of the foreshore; in the test material was moved seaward and deposited about 10 m from the shoreward end of the tank. Also, the deposition of material occurred more evenly along the profile than what the model predicts, and the calculations tend to produce a more pronounced depositional feature. However, the overall agreement is satisfactory, which supports the transport relationship employed on the foreshore (Equation 10).

Figure 3. Comparison between measured and calculated profile from SUPERTANK Test ST\_90 after 50 min of wave action.

In Test ST\_A0 the constructed foredune eroded away very rapidly and after 10 min of wave action the foredune was completely flattened. Figure 4 shows a comparison between the model prediction and the measured profile after 10 min together with the initial profile. The calculated profile response is almost as rapid as

the measured response, and the resulting profile shape is well predicted. The transport rate formula employed in the swash zone produces onshore transport if the local slope is negative, which is the case on the shoreward side of the foredune in the beginning of Test ST\_A0. Material is thus moved by the model from the foredune both in the shoreward and seaward direction, speeding up the flattening of the foredune.

Figure 4. Comparison between measured and calculated profile from SUPER-TANK Test ST\_A0 after 10 min of wave action.

### Offshore Mound

Tests ST\_J0 and ST\_K0 were carried out to investigate the response of an offshore mound to random waves if a large portion of the waves broke on the seaward side of the mound. For Test ST\_J0 the mound was narrow-crested, whereas a broad-crested mound was constructed for ST\_K0. The target wave conditions were identical to Tests ST\_90 and ST\_A0. A large portion of the waves broke and dissipated energy on the mound, and the effect on the foreshore of the waves that were severely broken by the mound was minor. Thus, Figure 5 shows only the profile evolution around the mound for Test ST\_J0, and Figure 6 displays the corresponding region for Test ST\_K0.

The narrow-crested mound deflated during wave action with some transport in the shoreward direction, although most of the material moved offshore (Figure 5). The model cannot represent such complex transport conditions and, in the model

Figure 5. Comparison between measured and calculated profile from SUPER-TANK Test ST\_J0 after 150 min of wave action.

Figure 6. Comparison between measured and calculated profile from SUPER-TANK Test ST\_K0 after 220 min of wave action.

predictions, material only moved offshore. Thus, the profile development on the seaward side of the mound is reproduced by the model, whereas the model predicts no change on the shoreward side. The model was able to predict the profile response somewhat better for the broad-crested mound (Test ST\_K0), because little material was pushed onshore by the waves on the shoreward side of the mound (Figure 6). The seaward shape of the mound is well predicted by the model; however, the measurements show a pronounced trough close to the seaward end of the mound that is absent in the calculations. This trough is most likely caused by the complex wave transformation occurring locally at the mound and which the random wave model is unable to represent.

### CONCLUDING REMARKS

The model discussed in this paper represents one of the first attempts to consistently treat random waves in all components of a beach profile change numerical model. Previous approaches to model the profile evolution under random waves have typically involved using statistical wave measures in equations primarily developed for monochromatic waves; these models have not considered the random properties of the waves at the outset of deriving the predictive equations. The new model eliminates the problem related to selecting an equivalent monochromatic wave that reproduces a specific cross-shore phenomenon. The root-mean-square wave height is identified as the characteristic wave to be used in calculating the profile evolution under random waves with the present model.

Comparison with measured profile change under random waves from the SUPERTANK Laboratory Data Collection Project supported the technique of linearly superimposing the transport from individual waves to derive transport rate formulas for random waves. The model validation included such profile evolution events as equilibrium erosion with bar formation, berm flooding, and the impact of breaking waves on an offshore mound. In the mound tests the agreement between the model predictions and the measurements was less good compared to the other tests; this is mainly attributed to the difficulties of accurately predicting the across-shore wave properties over the mound with the random wave model. Also, the effect of the velocity asymmetry in shoaling, non-breaking waves on the mound is not described by the profile model.

After being generalized to random waves, the equation to predict the net sand transport rate in the swash zone derived by Larson and Kraus (1994) modeled profile change on the foreshore satisfactorily during erosional conditions. The model faithfully reproduced the rapid flattening of a foreshore dune indicating that the complex net transport rate distribution, where onshore transport on the shoreward side of the foredune prevailed, was well predicted. However, the model was not evaluated for accretionary conditions, and some modification might be needed regarding the local slope term to obtain a realistic description of berm build-up on the foreshore.

The net transport rate distribution under random waves was derived without specific assumptions about the properties of the random wave field; thus, wave statistics representative for longer time periods could be used as input to the model and long-term predictions of the transport rate and profile evolution may be possible. The characteristic time scale of the profile response discussed in this paper implied that a Rayleigh pdf was a good description of the variation in wave height for the time step employed. For long-term simulations the wave statistics would have to be described by other distributions, but the calculations of the net transport rate and profile evolution could be handled within the framework of the present model. However, because the present model mainly predicts the profile response to breaking waves, additional terms that describe the transport due to non-breaking waves may have to be included to achieve a realistic profile evolution.

### ACKNOWLEDGEMENTS

The SUPERTANK Laboratory Data Collection Project was conducted at the O.H. Hinsdale Wave Research Laboratory, Oregon State University, under the direction of Dr. Nicholas C. Kraus. The SUPERTANK data are courtesy of Dr. Kraus, formerly CERC, now at the Conrad Blucher Institute, Corpus Christi State University. The support from the Japan Society for the Promotion of Science for the research visit of ML to the University of Tokyo is gratefully acknowledged, as well as the assistance from all members of the Coastal Engineering Laboratory during his stay. The research presented in this paper was conducted under the Calculation of Cross-Shore Sediment Transport and Beach Profile Change Processes Work Unit 32530, Shore Protection and Restoration Program, Coastal Engineering Research Center, U.S. Army Engineer Waterways Experiment Station. Contract coordination was provided by the European Research Office of the US Army in London under contract DAJA45-93-C0013.

## CHAPTER 164

# A QUASI-3D SURF ZONE MODEL

Jung Lyul Lee<sup>1</sup> and Hsiang Wang<sup>2</sup>

### ABSTRACT

This paper presents theoretical circulation patterns in both cross-shore and longshore directions on the plane beach slope. In the model an amended form of radiation stress which is consistent with the wave energy flux in the wave-current coexisting field is presented. Comparison of theoretical surf zone properties with laboratory experiments showed good agreements. Finally, a quasi-three dimensional model suitable for the entire nearshore zone is presented by linking the depth-integrated properties with vertical profiles.

### 1. INTRODUCTION

A prominent feature in the nearshore zone is the wave-induced current. It is commonly accepted that the primary driving force is the wave-induced radiation stress first introduced by Longuet-Higgins and Stewart (1961). Modeling this circulation has advanced considerably since the earlier development by Noda et al. (1974) and Ebersole and Dalrymple (1979). Both of these earlier models were driven by a wave refraction model with no current feedback. In recent years, coupled wave-induced circulation models have also been developed (Yoo and O'Connor, 1986; Yan, 1987; and Winer, 1988). All these models depth-uniform circulation patterns and can, therefore, be classified as two-dimensional. They are not suitable for surf zone where current is vertically non-uniform. This feature is particularly prominent in the cross-shore direction because the onshore mass transport produced by the depth-varying momentum flux has to be compensated by the return flow due to the depth-uniform set-up force. This driving mechanism was first suggested by Dyhr-Nielsen and Sorensen (1970) and treated

<sup>2</sup>Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611

analytically by Dally (1980). Effort has since been made to produce cross-shore circulation patterns inside the surf zone such as the undertow model developed by Svendsen (1984), Buhr-Hansen and Svendsen (1984) and more recently, by Okayasu et al. (1988) and Yamashita and Tsuchiya (1990). It is only natural to attempt to develop circulation models that can address both horizontal and vertical variations in the nearshore zone. So far the effort is still few. De Vriend and Stive (1987) recently formulated a nearshore circulation model by employing a quasi-3D approach. At present, this approach is attractive from both theoretical and computational point of view.

One of the handicaps of all the existing depth-varying models whether cross-shore models or three-dimensional models is the pre-requisite on the large number of empirical coefficients that have to be assigned. This severely limits their application as one must be confident on the behavior of these coefficients under various natural conditions. Recently, Lee (1993) presented a formulation on current-wave interaction problems. In there, the radiation stress term in the momentum equation is amended, and two new conservation equations governing intrinsic wave frequency and wave action are introduced. In this paper, this new formulation is utilized to develop a depth-varying circulation model. The difference between the new model and the existing models is quite significant. First of all, since radiation stress is the primary driving force for circulations an amended formula alters this force. Secondly, the new model has stronger theoretical basis and requires fewer empirical coefficients owing to the fact the model must satisfy the additional governing equations. An analytical model for a straight shoreline of uniform slope is introduced first to explore the nature of the model and to facilitate comparisons. A general version suitable for the entire nearshore zone is then developed by linking the depth-integrated properties with depth-varying models. The numerical technique is briefly addressed and examples are given.

## 2. HORIZONTAL CIRCULATION MODEL

The governing equations for the horizontal circulation model are obtained after depth integration and wave-averaging. In order to protect from losing the Eulerian mean quantities at the mean water level, the depth integration is taken prior to wave-averaging them. The strong presence of turbulence is a prominent feature in surf zone. Consequently, the fundamental equations governing the fluid motion should also include the turbulent effects. This is usually accomplished with the introduction of Reynolds stresses by time averaging over the turbulent fluctuations.

### 2.1 Depth-Integrated and Time-Averaged Equation of Mass

Integrating the continuity equation for incompressible fluid over depth and employing the kinematic boundary conditions on the free surface and on the bottom, we get

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} \int_{-h}^{\eta} u dz + \frac{\partial}{\partial y} \int_{-h}^{\eta} v dz = 0 \quad (1)$$

Now let the turbulence-averaged velocity vector,  $\mathbf{U}(u, v, w)$ , and the surface elevation,  $\eta$ , be decomposed into mean current and wave fluctuation, which will be distinguished by the subscript  $c$  and  $w$ , respectively; thus,

$$\mathbf{U} = \mathbf{U}_c + \mathbf{U}_w, \quad \eta = \eta_c + \eta_w \quad (2)$$

where  $\mathbf{U}_w$  and  $\eta_w$  are the residual wave fluctuation which can be removed through the process of wave-averaging, and  $\mathbf{U}_c$  and  $\eta_c$  are the time-averaged value of velocity. The velocity at a particular water level with a mean position of  $(\mathbf{x}_1, z_1)$  is  $\mathbf{U}(\mathbf{x}_1, z_1 + \xi)$ , where  $\xi$  is a location of the vertical trajectory being up and down with the residual wave fluctuation at  $\mathbf{x}_1$ .

Then, we obtain the wave-averaged value of velocity,  $\mathbf{U}_c$ , as

$$\mathbf{U}_c(\mathbf{x}_1, z_1) = \frac{1}{T} \int_0^T \mathbf{U}(\mathbf{x}_1, z_1 + \xi) dt$$

Substituting Eq. (2) and taking the wave-average after expanding in a Taylor series at  $\eta = \eta_c$ , Eq.(1) can be simplified as

$$\frac{\partial \eta_c}{\partial t} + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} u_c dz + \frac{\partial}{\partial x} (\overline{\eta_w u_w})_{\eta_c} + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} v_c dz + \frac{\partial}{\partial y} (\overline{\eta_w v_w})_{\eta_c} = 0 \quad (3)$$

The wave components are given by linear progressive wave theory as follow:

$$\frac{\partial \eta_c}{\partial t} + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} u_c dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} v_c dz + \frac{1}{\rho} \left[ \frac{\partial M_x}{\partial x} + \frac{\partial M_y}{\partial y} \right] = 0 \quad (4)$$

where the  $x$  and  $y$  components of mass flux are defined as

$$M_x = \frac{E' k_x}{\sigma}, \quad M_y = \frac{E' k_y}{\sigma} \quad (5)$$

and  $E'$  is defined as  $\rho g H^2 / 8$ . The mass flux terms are considered the mass transport above the mean water level.

## 2.2 Depth-Integrated and Time-Averaged Equations of Momentum

Assuming that no horizontal viscous stress exist, the horizontal momentum equation in the  $x$  direction is integrated over depth to yield

$$\begin{aligned} & \frac{\partial}{\partial t} \int_{-h}^{\eta} u dz + \frac{\partial}{\partial x} \int_{-h}^{\eta} u u dz + \frac{\partial}{\partial y} \int_{-h}^{\eta} u v dz \\ & = \frac{1}{\rho} \left[ -\frac{\partial}{\partial x} \int_{-h}^{\eta} p dz + p|_{\eta} \frac{\partial \eta}{\partial x} + p|_{-h} \frac{\partial h}{\partial x} + \tau_{Wx} - \tau_{Bx} \right] \end{aligned} \quad (6)$$

where  $\tau_{Wx} = \tau_{zx}|_{\eta}$  is a wind stress in the  $x$  direction and  $\tau_{Bx} = \tau_{zx}|_{-h}$  is the bottom friction. Substituting  $\mathbf{U}$  and  $\eta$  defined in Eq. (2), the time-averaged

quantities is also obtained by expanding  $\eta$  in Taylor series at the mean water level,  $\eta_c$ ,

$$\begin{aligned} & \frac{\partial}{\partial t} \int_{-h}^{\eta_c} u_c dz + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} u_c^2 dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} u_c v_c dz + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} \overline{u_w^2} dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} \overline{u_w v_w} dz \\ & + \frac{\partial}{\partial t} (\overline{\eta_w w_w})|_{\eta_c} + \frac{\partial}{\partial x} (2\overline{\eta_w u_c u_w})|_{\eta_c} + \frac{\partial}{\partial y} (\overline{\eta_w (u_c v_w + v_c u_w)})|_{\eta_c} \\ & = \frac{1}{\rho} \left[ -\frac{\partial}{\partial x} \int_{-h}^{\eta_c} p dz + \bar{p}|_{-h} \frac{\partial h}{\partial x} + \overline{\tau_{Wx}} - \overline{\tau_{Bx}} \right] \end{aligned} \quad (7)$$

where the pressure at the free surface was assumed to be zero and then the total pressure is given as

$$p = \bar{p} + p_w = -\rho \overline{u_w^2(z)} + \rho g(\eta_c - z) + \rho g \eta_w K_p(z) \quad (8)$$

where  $K_p$  is the pressure response factor given by linear wave theory,

$$K_p = \frac{\cosh k(h+z)}{\cosh k(h+\eta_c)} \quad (9)$$

Substituting Eq (8), finally, the depth-integrated and time-averaged momentum equation in the  $x$  direction is obtained;

$$\begin{aligned} & \frac{\partial}{\partial t} \int_{-h}^{\eta_c} u_c dz + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} u_c^2 dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} u_c v_c dz \\ & + \frac{1}{\rho} \frac{\partial S_{xx}}{\partial x} + \frac{1}{\rho} \frac{\partial S_{yx}}{\partial y} + g(h + \eta_c) \frac{\partial \eta_c}{\partial x} - \frac{\overline{\tau_{Wx}}}{\rho} + \frac{\overline{\tau_{Bx}}}{\rho} = 0 \end{aligned} \quad (10)$$

The momentum equation in the  $y$  direction can be similarly obtained,

$$\begin{aligned} & \frac{\partial}{\partial t} \int_{-h}^{\eta_c} v_c dz + \frac{\partial}{\partial x} \int_{-h}^{\eta_c} u_c v_c dz + \frac{\partial}{\partial y} \int_{-h}^{\eta_c} v_c^2 dz \\ & + \frac{1}{\rho} \frac{\partial S_{xy}}{\partial x} + \frac{1}{\rho} \frac{\partial S_{yy}}{\partial y} + g(h + \eta_c) \frac{\partial \eta_c}{\partial y} - \frac{\overline{\tau_{Wy}}}{\rho} + \frac{\overline{\tau_{By}}}{\rho} = 0 \end{aligned} \quad (11)$$

For the case of linear progressive wave and mild slope, the radiation stress terms can be expressed in terms of wave characteristics as

$$S_{xx} = E' \left[ n(\cos^2 \theta + 1) - \frac{1}{2} + 2 \cos \theta \frac{u_s}{C} \right] \quad (12)$$

$$S_{xy} = S_{yx} = E' \left[ \sin \theta (n \cos \theta + \frac{u_s}{C}) + \cos \theta \frac{v_s}{C} \right] \quad (13)$$

$$S_{yy} = E' \left[ n(\sin^2 \theta + 1) - \frac{1}{2} + 2 \sin \theta \frac{v_s}{C} \right] \quad (14)$$

where  $n = Cg/C$  and  $u_s$  and  $v_s$  are the time-averaged current velocity at mean water level. It is noted here that the definition of the radiation stress differs from that given by Longuet-Higgins and Stewart (1961) with the additional advective

terms. The amended form of radiation stress has been proven to be consistent with the wave energy flux in the wave-current coexisting field by Lee (1993).

**3. VERTICAL CIRCULATION MODEL FOR STRAIGHT SHORE-LINE**

For the case of straight shoreline and parallel offshore contours the cross-shore and longshore components are decoupled. This simplifies the mathematical manipulation considerably.

**3.1 Theoretical Undertow Model**

The vertical circulation in the  $x$ - $z$  plane is treated as quasi-steady. Since there is no  $y$ -direction (longshore) variation, the turbulence-averaged momentum equation in the  $x$ -direction (onshore) integrated from any level  $z$  to the mean water level can be written as

$$\frac{\partial}{\partial x} \int_z^\eta uudz - uw|_z = \frac{1}{\rho} \left[ -\frac{\partial}{\partial x} \int_z^\eta pdz + p(\eta) \frac{\partial \eta}{\partial x} + \tau_{zx}|_\eta - \tau_{zx}(z) \right] \tag{15}$$

where the shear stress is assumed to be expressed in the form

$$\tau_{zx} = \rho \nu_t \frac{\partial u}{\partial z} \tag{16}$$

with  $\nu_t$  defined as the total kinematic viscosity, which is composed of both eddy and molecular viscosities in the vertical direction. The shear stress at free surface,  $\tau|_\eta$ , is assumed only due to wind stress  $\tau_W$ . Separating the velocity into the current and wave components and taking time-average, Eq. (15) becomes

$$\nu_t \frac{\partial u_c}{\partial z} |_z = -\frac{\partial}{\partial x} \int_z^{\eta_c} (\overline{u_w^2} - \overline{w_w^2}) dz - \frac{g}{2} \frac{\partial \overline{\eta_w^2}}{\partial x} + \frac{\partial}{\partial x} (2\overline{\eta_w u_c u_w})|_{\eta_c} - g(\eta_c - z) \frac{\partial \eta_c}{\partial x} + \frac{\overline{\tau_{Wx}}}{\rho} \tag{17}$$

The convective term of the mean current was assumed to be small enough compared to the rest. In shallow water, the first term on the right hand side becomes

$$\frac{\partial}{\partial x} \int_z^{\eta_c} (\overline{u_w^2} - \overline{w_w^2}) dz = g \frac{(\eta_c - z)}{(\eta_c + h)} \frac{\partial}{\partial x} \left[ (\cos^2 \theta + 1) \frac{H^2}{8} \right] \tag{18}$$

and the second term reduces to,

$$\frac{g}{2} \frac{\partial \overline{\eta_w^2}}{\partial x} = \frac{g}{16} \frac{\partial H^2}{\partial x} \tag{19}$$

The fourth term can be determined by the depth-integrated equation of momentum, Eq. (10), under the following assumptions; 1) the flow is in steady state, and 2) the effect of squared mean current are negligible. Then, Eq.(10) becomes

$$\frac{\partial \eta_c}{\partial x} = -\frac{1}{\rho g(h + \eta_c)} \left[ \frac{\partial S_{xx}}{\partial x} - \overline{\tau_{Wx}} + \overline{\tau_{Bx}} \right] \tag{20}$$

Substituting Eqs. (18-20) into Eq. (17) and introducing non-dimensional variable,  $z' = (\eta_c - z)/(\eta_c + h)$ , results in,

$$-\frac{\nu_t}{\eta_c + h} \frac{\partial u_c}{\partial z'} \Big|_{z'} = z' \left\{ \frac{g}{16} \frac{\partial H^2}{\partial x} - 2g \frac{\partial}{\partial x} \left( \cos \theta \frac{u_s H^2}{C} \frac{H^2}{8} \right) - \frac{\overline{\tau_{Wx}}}{\rho} + \frac{\overline{\tau_{Bx}}}{\rho} \right\} - \frac{g}{16} \frac{\partial H^2}{\partial x} + 2g \frac{\partial}{\partial x} \left( \cos \theta \frac{u_s H^2}{C} \frac{H^2}{8} \right) + \frac{\overline{\tau_{Wx}}}{\rho} \quad (21)$$

According to the above equation, we can estimate the shear stress at the mean water level,

$$-\frac{\nu_t}{\eta_c + h} \frac{\partial u_c}{\partial z'} \Big|_{\eta_c} = -\frac{g}{16} \frac{\partial H^2}{\partial x} + 2g \frac{\partial}{\partial x} \left( \cos \theta \frac{u_s H^2}{C} \frac{H^2}{8} \right) + \frac{\overline{\tau_{Wx}}}{\rho} \quad (22)$$

and the shear stress at the bottom,

$$-\frac{\nu_t}{\eta_c + h} \frac{\partial u_c}{\partial z'} \Big|_{-h} = \frac{\overline{\tau_{Bx}}}{\rho} \quad (23)$$

Now we assume that the turbulent motions originating from the surface wave breaking is governed by an constant eddy viscosity, and that the boundary layer remains thin. Then, the above equation can be solved explicitly to give the following solution,

$$u_c(z') = u_s + C_{x1} z'^2 + C_{x2} z' \quad (24)$$

where

$$C_{x1} = -\frac{\eta_c + h}{2\varepsilon_z} \left\{ \frac{g}{16} \frac{\partial H^2}{\partial x} - 2g \frac{\partial}{\partial x} \left( \cos \theta \frac{u_s H^2}{C} \frac{H^2}{8} \right) - \frac{\overline{\tau_{Wx}}}{\rho} + \frac{\overline{\tau_{Bx,tb}}}{\rho} \right\} \quad (25)$$

$$C_{x2} = -\frac{\eta_c + h}{\varepsilon_z} \left\{ -\frac{g}{16} \frac{\partial H^2}{\partial x} + 2g \frac{\partial}{\partial x} \left( \cos \theta \frac{u_s H^2}{C} \frac{H^2}{8} \right) + \frac{\overline{\tau_{Wx}}}{\rho} \right\} \quad (26)$$

where  $\varepsilon_z$  implies the constant eddy viscosity which will be estimated in Section 3.3. According to this equation, the mean flow pattern inside the surf zone in the main region is essentially parabolic. The analytical solution for a plane beach is presented to simplify mathematical operation and to facilitate comparisons with data.

The profile given by Eq. (24) contains 3 physical parameters, the surface current, the eddy viscosity and the bottom friction. One of them can be eliminated by constraint that, in the cross-shore direction, the net flow has to be equal to zero for a steady case, or

$$\int_{-h}^{\eta_c} u_c dz + \frac{M_x}{\rho} = 0 \quad (27)$$

where  $M_x$  is wave-induced mass flux. Eliminating  $\tau_b$  from Eqs.(24-26) and (27), the coefficients can be rewritten as

$$C_{x1} = 3(\bar{u} - u_s) - \frac{3}{2} \frac{\eta_c + h}{\varepsilon_z} P, \quad C_{x2} = \frac{\eta_c + h}{\varepsilon_z} P \quad (28)$$

where

$$P = \frac{g}{16} \frac{\partial H^2}{\partial x} - 2g \frac{\partial}{\partial x} \left( \cos \theta \frac{u_s H^2}{C} \right), \quad \bar{u} = -\frac{M_x}{\rho(\eta_c + h)} = -\frac{g \cos \theta H^2}{8 C(\eta_c + h)} \quad (29)$$

### 3.2 Theoretical Longshore Current Model

The longshore current profile can be obtained in a similar manner. For a straight shoreline, the surface gradient as well as the radiation stress gradient in the  $y$ -direction can be neglected. Again, neglecting the convective term of the mean current, the momentum equation in the  $y$  direction yields,

$$\frac{\partial}{\partial x} \int_z^{\eta_c} \bar{v}_w \bar{u}_w dz + \frac{\partial}{\partial x} (\bar{\eta}_w \bar{v}_c \bar{u}_w)|_{\eta_c} + \frac{\partial}{\partial x} (\bar{\eta}_w \bar{u}_c \bar{v}_w)|_{\eta_c} = \frac{1}{\rho} \left[ \bar{\tau}_{W_y} - \rho \nu_t \frac{\partial v_c}{\partial z} \Big|_z \right] \quad (30)$$

Since the second and third terms become zero (Lee, 1983), Eq. (30) is reduced to

$$\frac{\partial}{\partial x} \int_z^{\eta_c} \bar{v}_w \bar{u}_w dz = \frac{\bar{\tau}_{W_y}}{\rho} - \nu_t \frac{\partial v_c}{\partial z} \Big|_z \quad (31)$$

In shallow water, the LHS becomes

$$\frac{\partial}{\partial x} \int_z^{\eta_c} \bar{v}_w \bar{u}_w dz = \frac{(\eta_c - z)}{(\eta_c + h)} \frac{\partial}{\partial x} \left[ g \cos \theta \sin \theta \frac{H^2}{8} \right] \quad (32)$$

by linear wave theory. Substituting Eq. (32) into Eq. (31) gives the following:

$$-\frac{\nu_t}{\eta_c + h} \frac{\partial v_c}{\partial z'} \Big|_{z'} = -z' \frac{\partial}{\partial x} \left[ g \cos \theta \sin \theta \frac{H^2}{8} \right] + \frac{\bar{\tau}_{W_y}}{\rho} \quad (33)$$

Integrating Eq.(33) with respect to  $z'$  with introduction of depth-independent  $\varepsilon_z$  we obtain,

$$\bar{v}(z') = v_s + C_{y1} z'^2 + C_{y2} z' \quad (34)$$

where

$$C_{y1} = \frac{\eta_c + h}{2\varepsilon_z} \frac{\partial}{\partial x} \left[ g \cos \theta \sin \theta \frac{H^2}{8} \right], \quad C_{y2} = -\frac{\eta_c + h}{\varepsilon_z} \frac{\bar{\tau}_{W_y}}{\rho} \quad (35)$$

Or, alternatively,  $C_{y1}$  can be expressed in terms of radiation stress as

$$C_{y1} = \frac{\bar{\eta} + h}{2\varepsilon_z} \frac{1}{\rho} \frac{\partial S_{xx}}{\partial x} \quad (36)$$

For steady longshore current, the depth-integrated radiation stress is balanced by the bottom friction under no wind. The depth-averaged mean longshore current is given by,

$$\bar{v} = v_s + \frac{C_{y1}}{3} + \frac{C_{y2}}{2} \quad (37)$$

### 3.3 Estimation of Surface Velocity and Eddy Viscosity

The solutions for cross-shore and longshore current profiles will be complete if the surface velocity and eddy viscosity are determined. Lee (1993) has shown that the surface current can be determined semi-analytically by virtue of wave action and intrinsic frequency conservation equations; both of them are surface conditions. The solutions briefly summarized here.

The surf zone is assumed to be coherent in that the essential wave-like periodic motion is retained and is quasi-steady when time-averaged over wave period. In this case, the wave action and wave frequency conservation equations are, respectively,

$$\nabla_h \cdot \left( \mathbf{U}_s \frac{H^2}{\sigma_s} \right) = 0, \quad \nabla_h \cdot (\mathbf{U}_s \sigma_s) = 0 \quad (38)$$

Here  $\sigma_s$  denotes  $\sigma$  inside the surf zone. The wave energy equation is modified to reflect dissipation,

$$\nabla_h \cdot \left[ (\mathbf{Cg} + \mathbf{Cg}_D + \mathbf{U}_s) \frac{H^2}{\sigma_s} \right] = 0 \quad (39)$$

with  $\mathbf{Cg}_D$  representing a dissipation velocity. Eliminating a  $\mathbf{U}_s$  term of Eq. (39) based on the first equation of Eqs.(38), the cross shore component of Eq. (39) provides

$$H = \frac{\beta_H}{(Cg_{Dx} - Cg_x)} \quad (40)$$

and also the surface currents are obtained,

$$u_s = \beta_C (Cg_{Dx} - Cg_x), \quad v_s = \beta_L (Cg_{Dy} - Cg_y) \quad (41)$$

with  $\beta$ 's the constants of proportionality. They further assume on two-dimensional beaches of uniform slope that the dissipation inside the surf zone is dominated by the influence of the initial condition at the breaking point and  $\mathbf{Cg}_D$  to be equal to  $-\beta \mathbf{Cg}_b$ . The above equations can then be written as

$$H = \frac{\beta_H}{\cos \theta (\beta Cg_b - Cg)}$$

$$u_s = \beta_C \cos \theta (\beta Cg_b - Cg), \quad v_s = \beta_L \sin \theta (\beta Cg_b - Cg) \quad (42)$$

Thus, the wave height and surface currents are determined explicitly. Figure 1 shows the comparison of wave height variation in the surf zone between the present theory and the laboratory data by Horikawa and Kuo (1966). Figure 2 compares the theory with the laboratory longshore current data measured by Visser (1991).

The vertical eddy viscosity for both cross-shore and longshore components is treated as the same and is estimated from the longshore mean current strength. From Section 3.2 we can obtain,

$$\frac{\overline{\tau_{By,tb}}}{\rho} = \frac{6\varepsilon_z}{\bar{\eta} + h} (\bar{v} - v_s) \tag{43}$$

In a flow field where the turbulent-induced stress dominates the bottom friction, the bottom stress can be approximated by,

$$\frac{\overline{\tau_{By,tb}}}{\rho} \approx \frac{\sin \theta}{C_a} D \tag{44}$$

where  $C_a = \omega/k$  and  $D$  is the local rate of energy dissipation. Based on Eq.(39),  $D$  can be expressed as

$$D = -\nabla \cdot [\beta C g_b \frac{K}{k} \frac{\omega}{\sigma_s} E']$$

Eliminating the bottom stress term from Eqs.(43) and (44), an expression for the eddy viscosity is obtained,

$$\frac{\varepsilon_z}{\bar{\eta} + h} = \frac{\sin \theta D}{6 C_a \rho (\bar{v} - v_s)} \tag{45}$$

which relates the eddy viscosity to the the mean longshore current strength. In the following computation we simply assume that mean longshore current strength is proportional to the surface current strength, that is,

$$\bar{v} = \gamma v_s \tag{46}$$

with  $\gamma$  the ratio of mean current to the surface current. Therefore, the eddy viscosity can be simplified as the following explicit expression,

$$\frac{\varepsilon_z}{\eta_c + h} = -\frac{1}{24(1 - \gamma)\beta_L} \frac{|u_{orb}|}{(1 - Cg/(\beta C g_b))} \frac{\partial}{\partial x} (\cos \theta H) \tag{47}$$

### 3.4 Data Comparisons

In this subsection, each theoretical solution is compared with data measured on the plane beach of uniform slope. Wind stress effect is omitted in the solutions.

#### Undertow Model

The velocity profile is calculated by Eq. (24). Four parameters are to be designated; they are,  $\gamma$ : the ratio of mean current to surface current;  $\beta$ : the dissipation coefficient;  $\beta_C$ : the cross-shore current coefficient; and  $\beta_L$ : the longshore current coefficient.

Figure 3 shows the comparisons of the computed vertical profiles of the cross-shore current with those measured by Buhr-Hansen and Svendsen (1984). The

test conditions were: slope = 1:34.25;  $H_o = 0.12m$  and  $T=1$  sec. The parameters used in the computations are:  $\beta = 1.17$ ;  $\beta_C=0.07$ ;  $\beta_L=5.0$  and  $\gamma=0.982$ . The limiting wave height at breaking point is determined by the Miche's criterion with  $\kappa=0.78$ . Figure 4 plots the profile changes across the untire surf zone using the same paramters as given above. In order to examine the effect of the advection term, the results when the term is neglected are also represented as dotted lines in Figure 5. The effect seems to show the significant deviation from the measurements as it is close to the shoreline under the same input condition. However, the difference also seems to show the overall agreement with the experiments by small reduction of the  $\gamma$  value as shown in Figure 5.

### Longshore Current Model

Figure 6 shows the comparasions between computed profiles and the laboratory data measured by Visser (1991). The test conditions were: slope=1 : 10,  $H_o = 9.6cm$ ,  $T = 1sec$  and  $\theta_o = 16.4^\circ$ . The values of parameters are as follows;  $\beta=1.2$ ,  $\beta_L=5.0$ , and  $\gamma=0.96$ . It is seen that  $\gamma$  plays an important role. A maximum value 1 results in a uniform longshore current profile whereas a value 2/3 results in a no-slip bottom velocity. From the comparisons with experimental data, a value near 0.95 is suggested. Figure 7 plots the longshore current profile variations across the surf zone.

Figure 8 illustrates the three-dimensional current profiles inside the surf zone using the same conditions as Figure 5 with the exception that the input wave is oblique at  $10^\circ$  in deep water clockwise to the shoreline normal. The three-dimensional current forms a clockwise spiral from top to bottom.

### 3.5 Model Adoption for General 3-D Topography

The theoretical models so far developed are for parallel contours. For irregular bathymetries, getting the surface velocity as the surface boundary condition might be ineffective for modelling, so the bottom shear stress in terms of depth-averaged current is considered as the boundary condition instead of the surface velocity. For the prediction of a longshore current this alternative way gives the exactly same result. For that of the undertow, however, this will give the different result. The bottom shear stress suggested by Longuet-Higgins (1970) is now modified for both cross-shore and longshore directions by

$$\overline{\tau_{B,ib}} = \rho F_w |u_{orb}| \gamma \bar{U} \quad (48)$$

where  $F_w$  can be estimated in terms of wave characteristics as

$$F_w = \frac{\beta}{4\gamma\beta_L} \frac{\nabla \cdot (\mathbf{KH}/k)}{(\beta - Cg/Cg_b)} \quad (49)$$

When the bottom shear stress given in Eq. (49) is applied as a boundary condition instead of the surface velocity, three coefficients of the undertow model,  $C_{x1}$ ,  $C_{x2}$

and  $u_s$ , are written by

$$C_{x1} = -\frac{\eta_c + h}{2\varepsilon_z}(P + \overline{\tau_{Bx,tb}}) \tag{50}$$

$$C_{x2} = \frac{\eta_c + h}{\varepsilon_z}P \tag{51}$$

$$u_s = \bar{u} - \frac{C_{x1}}{3} - \frac{C_{x2}}{2} \tag{52}$$

The result is shown in Figures 9-10 for the same experimental conditions as used by Buhr-Hansen and Svendsen (1984) given in Section 3.4. The ‘S.B.C.’ indicates the full theory obtained by the surface boundary condition, and the ‘B.B.C.’ indicates the approximate theory obtained by the bottom shear stress with neglecting the advection term. The full theory was obtained by  $\gamma=0.982$ , the approximate theory by  $\gamma=0.978$ . The comparison with experiments is still in agreement. Therefore, instead of the boundary condition given by surface currents, the bottom shear stress is used in the practical model for the complicated bathymetry, and the advection terms are omitted.

**4. QUASI THREE-DIMENSIONAL MODEL**

The depth-integrated horizontal model is now combined with the vertical theoretical model to a quasi-3D model. This quasi-3D model looks promising since it provides three-dimensional information at almost the same cost of a two-dimensional horizontal model although it produces the relatively simple variation of vertical profile.

Even for the general topography, velocity variation with respect to depth may be approximated as the function of parabola of 2nd order.

$$u_c = C_{x1}z'^2 + C_{x2}z' + C_{x3} \tag{53}$$

$$v_c = C_{y1}z'^2 + C_{y2}z' + C_{y3} \tag{54}$$

where  $C_1$ ,  $C_2$  and  $C_3$  are expressed in terms of wave characteristics and current quantities such as  $H$ ,  $h + \eta_c$ ,  $Q$ (depth integration of velocity vector), and  $\overline{\tau_W}$ :

$$C_{x1} = -\frac{\eta_c + h}{2\varepsilon_z} \left\{ \frac{g}{16} \frac{\partial H^2}{\partial x} - \frac{\overline{\tau_{Wx}}}{\rho} + \frac{\overline{\tau_{Bx,tb}}}{\rho} \right\} \tag{55}$$

$$C_{x2} = -\frac{\eta_c + h}{\varepsilon_z} \left\{ -\frac{g}{16} \frac{\partial H^2}{\partial x} + \frac{\overline{\tau_{Wx}}}{\rho} \right\} \tag{56}$$

$$C_{x3} = \frac{Q_x}{\eta_c + h} - \frac{C_{x1}}{3} - \frac{C_{x2}}{2} \tag{57}$$

$$C_{y1} = -\frac{\eta_c + h}{2\varepsilon_z} \left\{ \frac{g}{16} \frac{\partial H^2}{\partial y} - \frac{\overline{\tau_{Wy}}}{\rho} + \frac{\overline{\tau_{By,tb}}}{\rho} \right\} \tag{58}$$

$$C_{y2} = -\frac{\eta_c + h}{\varepsilon_z} \left\{ -\frac{g}{16} \frac{\partial H^2}{\partial y} + \frac{\overline{\tau_{Wy}}}{\rho} \right\} \tag{59}$$

$$C_{y3} = \frac{Q_y}{\eta_c + h} - \frac{C_{y1}}{3} - \frac{C_{y2}}{2} \quad (60)$$

Substituting Eqs. (53) and (54) into the convective acceleration terms yields

$$\int_{-h}^{\eta_c} u_c^2 dz = \left[ \frac{Q_x^2}{(h + \eta_c)^2} + T_{xx} \right] (h + \eta_c) \quad (61)$$

$$\int_{-h}^{\eta_c} u_c v_c dz = \left[ \frac{Q_x Q_y}{(h + \eta_c)^2} + T_{xy} \right] (h + \eta_c) \quad (62)$$

$$\int_{-h}^{\eta_c} v_c^2 dz = \left[ \frac{Q_y^2}{(h + \eta_c)^2} + T_{yy} \right] (h + \eta_c) \quad (63)$$

where

$$T_{xx} = \left[ \frac{4C_{x1}^2}{45} + \frac{C_{x2}^2}{12} + \frac{C_{x1}C_{x2}}{6} \right] \quad (64)$$

$$T_{xy} = T_{yx} = \left[ \frac{4C_{x1}C_{y1}}{45} + \frac{C_{x2}C_{y2}}{12} + \frac{C_{x1}C_{y2}}{12} + \frac{C_{x2}C_{y1}}{12} \right] \quad (65)$$

$$T_{yy} = \left[ \frac{4C_{y1}^2}{45} + \frac{C_{y2}^2}{12} + \frac{C_{y1}C_{y2}}{6} \right] \quad (66)$$

Substituting into Eq. (10) leads to the following  $x$ -directional modified momentum equation:

$$\begin{aligned} \frac{\partial Q_x}{\partial t} + \frac{\partial}{\partial x} \left[ \frac{Q_x^2}{h + \eta_c} + (h + \eta_c)T_{xx} \right] + \frac{\partial}{\partial y} \left[ \frac{Q_x Q_y}{h + \eta_c} + (h + \eta_c)T_{xy} \right] \\ + \frac{1}{\rho} \frac{\partial S_{xx}}{\partial x} + \frac{1}{\rho} \frac{\partial S_{yx}}{\partial y} + g(h + \eta_c) \frac{\partial \eta_c}{\partial x} - \frac{\overline{\tau_{wx}}}{\rho} + \frac{\overline{\tau_{Bx}}}{\rho} = 0 \end{aligned} \quad (67)$$

The modified momentum equation of  $y$  direction from Eq. (11)

$$\begin{aligned} \frac{\partial Q_y}{\partial t} + \frac{\partial}{\partial x} \left[ \frac{Q_x Q_y}{h + \eta_c} + (h + \eta_c)T_{yx} \right] + \frac{\partial}{\partial y} \left[ \frac{Q_y^2}{h + \eta_c} + (h + \eta_c)T_{yy} \right] \\ + \frac{1}{\rho} \frac{\partial S_{xy}}{\partial x} + \frac{1}{\rho} \frac{\partial S_{yy}}{\partial y} + g(h + \eta_c) \frac{\partial \eta_c}{\partial y} - \frac{\overline{\tau_{wy}}}{\rho} + \frac{\overline{\tau_{By}}}{\rho} = 0 \end{aligned} \quad (68)$$

As noted below, the bottom friction consists of turbulent shear stress and bottom frictions due to viscous and streaming flows, which can be expressed as

$$\overline{\tau_B} = F_w |u_{orb}| \bar{U} + F_c |u_{orb}| (\mathbf{U}_{B,tb} + \mathbf{U}_{strm}) \quad (69)$$

where  $\mathbf{U}_{B,tb}$  represents the bottom velocity induced by turbulent flow and  $\mathbf{U}_{strm}$  is the streaming velocity in the oscillatory boundary.

The continuity equation results in the same equation as before.

$$\frac{\partial \eta_c}{\partial t} + \frac{\partial}{\partial x} (Q_x + M_x) + \frac{\partial}{\partial y} (Q_y + M_y) = 0 \quad (70)$$

5. CONCLUSION

The surface advective terms were added to the conventional radiation stress by taking Taylor series expansion at the mean water level. The resulting radiation stress was proven by Lee (1993) to be consistent with the wave energy flux in the wave-current coexisting field.

The surface properties obtained from the surf zone model enabled us to develop the theory for the vertical circulation model which had suffered obscurity of boundary conditions. In addition, the friction coefficient and eddy viscosity applicable to the turbulent flow in a surf zone have been estimated in terms of energy dissipation. The developed model yielded the theoretical results comparable with laboratory experiments.

Based on the examination of the theoretical model for vertical profiles of currents in steady state, a quasi-three dimensional circulation model suitable for the entire nearshore zone is developed by linking the depth-integrated properties with the vertical profiles.

## CHAPTER 165

### QUANTIFICATION OF LONGSHORE TRANSPORT IN THE SURF ZONE ON MACROTIDAL BEACHES

Field experiments along the western coast of Cotentin (Normandy, France)

Franck Levoy<sup>1</sup>, Olivier Monfort<sup>1</sup>, H el ene Rousset<sup>1</sup> and Claude Larssonneur<sup>1</sup>

**ABSTRACT :** Many *in situ* measurements of hydrodynamic parameters and sediment transport in the surf zone have been carried out on the beaches of the western coast of Normandy. The vertical and cross-shore distributions of the sediment transport induced by breaking waves have been identified in a set of various hydrodynamic conditions. Several longshore sediment transport formulas have been devised. The comparison between measured and computed transport rates enables choice of the best formulation according to the hydrodynamic context. This formulation emphasizes the indirect effect of tidal fluctuations on the wave characteristics and the sediment transport processes.

### INTRODUCTION

For engineering purposes, the prediction of long term evolution of a sandy coastline requires insight into sediment circulation on beaches, specially sand movement along coasts where oblique waves induce longshore currents.

Many formulas exist to calculate the longshore sediment transport in the surf zone, but they have been defined for microtidal environments from experimental research. The goal of this paper is to present field results in a very specific tide dominated environment and to evaluate the performance of some empirical formulas in these hydrodynamic conditions.

**PROJECT SITE**

In order to prevent erosion that was affecting the west coast of Cotentin Peninsula, the local government authorities decided to implement in 1989 a research programme aimed at elaborating a global coastal defence policy (Levoy F., Avoine J., 1991).

Field studies, carried out in the framework of this project constitute the R.O.M.I.S. program, a French acronym for Réseau d'Observations et de Mesures In Situ (field observations and measurements system). The main goals of this program were to understand how sediments responds to various hydrodynamic conditions. It was applied from the Cape Carteret to Mont-Saint-Michel Bay, in a macrotidal area, where the tidal range decreases from 15 m in the South to 12 m in the North during high spring tides (Fig. 1).

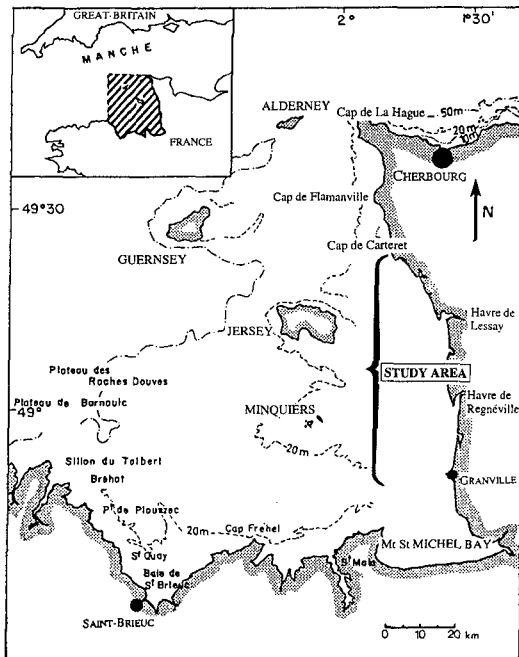

Figure 1. Location map of the study site

Open to the west offshore area, the western coast of Cotentin is exposed to long waves coming from North Atlantic Ocean. The propagation of these waves is affected by a complex bathymetry with numerous shoals and islands. The annual significant wave height in the north of the study area is about 4.2 metres. The attenuation coefficient of waves crossing the Channel island barrier reaches 0.7. The

modal breaker height varies from 0.7 to 0.9 m and Dean's parameter,  $\Omega$  ( $H_b/W_s.T$ ) from 4 to 1.5.

This coast is characterized by a wide tidal flat with a steeper high tidal zone. At high tide, the upper foreshore behaves like a microtidal beach and long waves or, frequently, wind-waves induce opposite residual longshore movements, materialized by opposite spits near small inlets. In the surf zone, plunging breakers are often observed on a steeper beach slope. At mid-tide, spilling breakers take place on a smooth slope.

## MEASUREMENT TECHNIQUES

To quantify the longshore sediment transports, 19 field experiments were carried out under the R.O.M.I.S program. Several parameters were recorded at different locations (table 1):

(1) dynamic parameters:

- tidal variations,
- tidal and wave induced currents with EMC and dye injections,
- on the lower part of the beach, wave characteristics ( $H_s$ ,  $T_p$ ,  $T_s$ , direction of propagation...) with S4DW from Interocean Corporation,
- breaker height with a graduated rod,
- wind conditions.

(2) morphological parameters and sediment characteristics:

- beach slopes with surveys at low tide using an electronic theodolite and infrared-ray distance meter,
- grain-size.

Table 1. Characteristics of the field experimentation conditions

Sediment transport was measured in the breaker zone with streamer traps (Rosati J.D & al., 1990). Cross-shore distribution, with 3 or 4 traps perpendicular to the shoreline, and vertical distribution of sand fluxes, with 4 streamers on a single trap permit to calculate an integrated rate across the breaker zone. The duration of the runs varies from about 5 to 15 minutes on the mid tidal or high tidal zone, with typically one person carrying one trap. The sediment transport rates (Fig. 2) were calculated using the numerical method defined by Kraus and al (1989).

Figure 2. Example of results obtained from runs using sand traps in the surf zone

Various hydrodynamic and morphosedimentary conditions were observed during the experiments. The breaker height varied from 0.5 m to 1.35 m, the peak period, from 3.4 to 16.4 seconds, the  $\gamma$  parameter, from 0.5 to 1.08 and the beach slope from 0.016 to 0.1. The grain size on the beaches increased from the mid-tide beach to the upper foreshore, between 0.210 to 0.510 mm.

**RESULTS**

The first part of the field experiments consisted in measuring the hydrodynamics conditions.

**Breaker and longshore current characteristics:**

The breaker height, measured about 4 metres above the mean sea water level was always greater than the significant wave height on the lower foreshore, about 2 metres under the MSWL. The factor between these parameters varied from 2 to 1.15 when offshore wave conditions increased. During a typical semi-diurnal tidal cycle,

the large variability of wave height induced a large variability of breaker wave characteristics (Fig. 3).

Figure 3. Significant wave height versus breaker height

The measurements confirmed the relationship between the  $\gamma$  parameter (breaker height to water depth ratio) and the beach slope ( $\tan \beta$ ). The modification of the slope along the beach profiles induced a temporal evolution of the  $\gamma$  parameter during a tidal cycle with a constant modification of the breakers characteristics (Fig.4).

Figure 4.  $\gamma$  parameter versus beach slope

Some LST formulas use the longshore current velocity. The comparison between the calculated and the measured longshore velocities with some classical

formulations did not give satisfactory results (Fig. 5). Most of the results were overpredicted. The best agreement between measured and calculated longshore currents was obtained with the Van Rijn formula (1990), derived from the Longuet-Higgins formula (1970). The empirical coefficient of this formulation was found to be equal to 5 in the field experiments (Fig. 6).

Figure 5. Comparison between measured and calculated longshore velocities with various formulations

Figure 6. Measured and calculated velocities of longshore currents with modified Van Rijn formula (empirical coefficient=5)

**Vertical and cross-shore distributions:**

The vertical distributions of sand fluxes were best fitted with an exponential relationship, like the one described by Rosati and al (1991). The correlation coefficient, 0.67, was smaller than those obtained in American programs (0.9 during SUPERDUCK, 0.79 at Ludington), but the hydrodynamics and beach conditions observed along the western coast of the Normandy vary a lot, with specially long and wind-wave conditions (Fig. 7).

Figure 7. Vertical distribution of longshore sediment transport in the surf zone

In fact, there were two types of vertical sediment distributions in the surf zone:

- with long wave periods, suspended sediment transport dominated (Fig.8a),

Figure 8a. Vertical distribution of longshore sediment transport during long wave conditions

- with short wave conditions, the bed-load transport became higher (Fig. 8b).

The bi-modal wave climate in the English Channel explains the dispersion of vertical distribution of sediment transport rates in the surf zone.

Figure 8b. Vertical distribution of longshore sediment transport during wind-wave conditions

For the cross-shore sediment transport distribution in the surf zone, two kinds of peak locations were observed (Fig. 9):

- first, in the swash zone ( $0.15 < X/X_b < 0.35$ ), the normalized sediment transport rate sometimes attained 3 or 4 times the mean longshore sediment transport rate integrated over the width of the breaker zone. These movements were measured during wind-wave conditions, acting on steep beaches with small or medium breaker height.

-the second peak, more classical, was observed near the breakerline ( $0.6 < X/X_b < 0.7$ ). The sediment transport rate was lower than in the swash zone and more homogeneous over the entire surf zone. These circulations were observed during long wave conditions at mid-beach level.

However, as opposed to Kamphuis' experimental investigations (1991), these two kinds of distributions were recorded independently, showing the narrow relationship between the hydrodynamic conditions and the transport processes.

Figure 9. Cross-shore distribution of the longshore sediment transport in the surf zone

### Grain size gradients in the surf zone

The traps used to calculate the sediment transport rate allowed collection of sand grains at several locations in the surf zone. Grain sizes of the bed were used to compare the ground sedimentary stock and the moving materials (Fig. 10).

During long wave conditions and large breaker height, with a well-sorted sediment on the beach, the moving sand grain size was lower than the beach grain size. The vertical and transversal distributions of the grain size were very close. Good mixing of the sediment was observed.

With wind-wave conditions, vertical and transversal grain size gradients appeared. The gradients were more important with a badly sorted sediment on the beach than with a well-sorted material. With bed-load processes prevailing during short wave conditions, only fine sediments were trapped in the upper layer of water. Between the bed and the water surface, the grain size was noted to vary from 1 to 2.

Even with a well-sorted sediment on the beach floor, a transversal gradient was identified. The coarser sediments were located in the swash zone, according to the cross-shore distribution of the sediment transport rate. The finer grain sizes, with a median diameter lower than that of the beach sand, were observed in suspension near the breakerline.

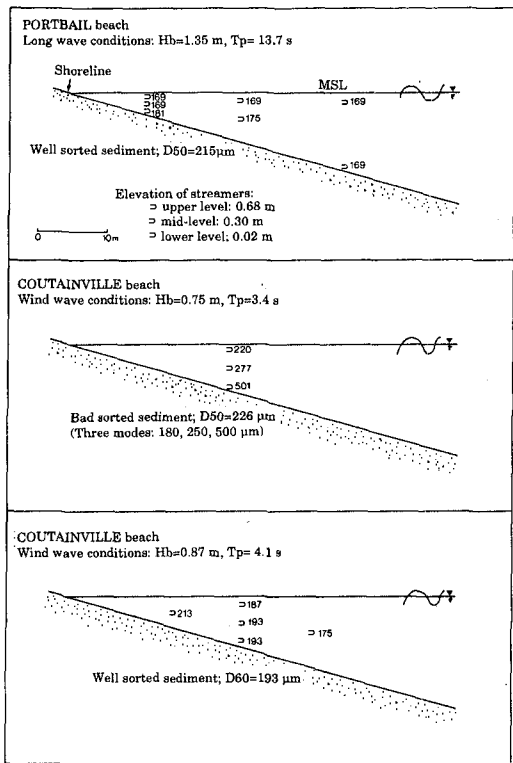

Figure 10. Grain sizes in the surf zone in various hydrosedimentary conditions

**Comparison between measured and calculated rates**

Several L.S.T. formulas were compared with results coming from in situ measurements. Two methods of calculation were used:

- Integral method:

(1) 1986' Kamphuis formula:

$$Q = 1,28 \cdot \frac{H_b^{3,5}}{D_{50}} \cdot \tan\beta \cdot \sin 2\alpha_b$$

with: Q= sediment transport rate (kg/s),

Hb= breaker height (m)

D50= median grain size (m),

tanβ= beach slope

αb = incident wave angle.

(2) 1990' Kamphuis formula:

$$Q = 0,0013 \cdot \left(\frac{H_b}{L_p}\right)^{-1,25} \cdot \tan\beta^{0,75} \cdot \left(\frac{H_b}{D_{50}}\right)^{0,25} \cdot \sin^{0,6} 2\alpha_b \cdot \frac{\rho \cdot H_b^3}{T_p}$$

with:

Q= sediment transport rate (kg/s),

L<sub>p</sub>= peak wave length according to the peak period T<sub>p</sub> (m),

(3) 1982' Kraus formula

$$Q = \frac{A}{\gamma_b \cdot \tan\beta} \cdot H_b^2 \cdot V_l$$

with:

Q= sediment transport rate (m<sup>3</sup>/s),

γ<sub>b</sub>= H<sub>b</sub>/H<sub>t</sub>, H<sub>t</sub> is the mean water depth,

V<sub>l</sub>= longshore current velocity (m/s),

A= empirical coefficient equal to 0.00038

- Local method:

(4) 1989' Van Rijn Formula

In most cases, all these formulas overpredicted the sediment transport rates, especially when the transport was weak. The ratios between computed and measured rates were very high with the Kamphuis formulas, even though the second formulation improved the result (Fig. 11).

Figure 11: Comparison between measured longshore sediment transport rate and calculated rate with the Kamphuis and Kraus formulas.

Best agreement (factor of 1 to 3) was obtained in high energy condition, when the measured rate was greater than about 35 kg/m/mn. But under 5 kg/m/mn, the 1990' Kamphuis formula overpredicted with a factor of 10 and sometimes more for small sediment movements.

Kraus and Van Rijn formulas gave the best prediction of L.S.T. (Fig.12). But it was necessary to adapt the formulation to the hydrodynamical context (Fig. 13):

- on the upper part of beaches, when  $\gamma$  parameter was higher than 0.78 and incidence angle between the wave crests and the shoreline direction was greater than 25 degrees, a factor of about 2 was found between calculated and measured rates. In these cases, LST rates were greater than 10 kg/m/mn.

Figure 12. Comparison between longshore sediment transport rate and calculated rate with Van Rijn and Kraus formulas.

- when wave crest incidence angle was lower than 25 degrees and  $\gamma$  parameter lower than 0.78, the LST rate, in our experiments, was smaller than 5 kg/m/mn. In these cases, formulas overpredicted sediment movements (factor of 5).

A new formulation is proposed to calculate LST rates, taking into account the important variability of the wave approach incidence to the coast and the modification of  $\gamma$  parameter during the tidal cycle.

Figure 13. Comparison between measured longshore sediment transport rate and calculated rate with Kraus formula (the longshore velocities were deduced from field measurements)

Table 2 summarizes the results obtained along the western coast of Normandy. It is necessary to underline the relationship between the tidal level, the beach slope and the breaker type. For each beach state, a new empirical coefficient derived from the Kraus formula can be calculated. But the factor between these two coefficients is about 10. As a result of this, in calculating a global longshore sediment transport, there is an important discrepancy between the upper and the midforeshore rate. This discrepancy is not realistic.

Tidal level	Beach state	Breaker type	Empirical coefficient
high tide	reflective	plunging	$8.36 \cdot 10^{-4}$
mid-tide	dissipative	spilling	$0.73 \cdot 10^{-4}$

Table 2

**CONCLUSIONS**

(1) Several longshore sediment transport formulas have been tested and compared to our field experiment results. The Kraus formula gives the best agreement between the rates computed and the calculated values, during a large set of hydrodynamic conditions. But, it will be necessary to test other formulations in this kind of environment (S.P.M...).

(2) A local adaptation of the empirical coefficient is necessary to adapt the Kraus formulation to the regional hydrodynamic conditions. On macrotidal beaches, the tidal fluctuations, firstly, and the wave climate, secondly, induce a great temporal variability of several parameters in the surf zone. The breaker type, at different levels of the tidal cycle, connected to the beach slope and the water depth, is a parameter

which controls the sediment transport rate. The bi-modality of the wave frequency also induces two kinds of vertical and cross-shore sediment transport distributions, modifying the global sediment movement.

(3) Lots of field data will be necessary to reduce the factor between the new empirical coefficients. Their values should be defined taking into account, quantitatively, parameters that include the breaker type and the tidal fluctuation. The use of a combination between the RTR parameter defined by Masselink and Short (1994) and the  $\Omega$  parameter should be a new way improving modelling of LST on a concave and wide beach profile such as that of macrotidal beaches.

## ACKNOWLEDGEMENTS

This work aimed at defining a global policy of protection of the coastline of Normandy against storm effects was undertaken as a part of the ROMIS program. It was funded by the Conseil Général de la Manche, the Conseil Régional de Basse-Normandie and the Secrétariat d'Etat à la Mer. Our thanks to Edward Anthony for improving the English of the paper.

# CHAPTER 166

## A THREE DIMENSIONAL MODEL FOR WAVE INDUCED CURRENTS

BIN LI and ROGER J MADDRELL

SIR WILLIAM HALCROW & PARTNERS LTD, BURDEROP PARK,  
SWINDON, WILTSHIRE, SN4 0QD, UK

### 1 Introduction

In this paper, a three-dimensional model which is based on the Navier-Stokes equations is developed. The finite volume method and a time-splitting technique are used to solve the equations. Longshore and crossshore currents induced by waves are reproduced by the model and the results are compared with existing experimental data.

### 2 Governing Equations

If, apart from the wave-induced orbital motion, the current involves no strong vertical accelerations, the time-mean pressure can be approximated by:

$$p = p_h - \rho \langle w_w^2 \rangle \quad (1)$$

in which  $p$  is pressure;  $p_h$  is hydrostatic pressure

$$p_h = \rho g(\eta - z) \quad (2)$$

$\rho$  is mass density of the fluid;  $w_w$  vertical component of the wave orbital velocity;  $\langle \dots \rangle$  averaged over one wave cycle.

If, in addition, the Boussinesq-hypothesis is adopted to model the Reynolds stress terms, the wave-and turbulence-averaged horizontal momentum equations can be written as:

Momentum equations:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{\partial}{\partial x} (v_h \frac{\partial u}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial u}{\partial y}) + \frac{\partial}{\partial z} (v \frac{\partial u}{\partial z}) + W_x \quad (3)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial y} + \frac{\partial}{\partial x} (v_h \frac{\partial v}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial v}{\partial y}) + \frac{\partial}{\partial z} (v \frac{\partial v}{\partial z}) + W_y \quad (4)$$

Continuity equation:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (5)$$

where  $u$ ,  $v$  and  $w$  are the velocities in the  $x$ ,  $y$  and  $z$  directions, respectively;  $P$  is pressure;  $W_x$  and  $W_y$  are the radiation stress terms in the  $x$  and  $y$  directions, respectively. These radiation stress components will be discussed in the next section.

### 3 Radiation Stresses

The radiation stress formulae are:

$$W_x = -\frac{\partial}{\partial x} (\langle u_w^2 \rangle - \langle w_w^2 \rangle) - \frac{\partial}{\partial y} (\langle u_w v_w \rangle) \quad (6)$$

$$W_y = -\frac{\partial}{\partial x} (\langle u_w v_w \rangle) - \frac{\partial}{\partial y} (\langle v_w^2 \rangle - \langle w_w^2 \rangle) \quad (7)$$

and it should be noted that

$$\frac{\partial}{\partial z} (\langle u_w w_w \rangle) = 0 \quad \text{and} \quad \frac{\partial}{\partial z} (\langle v_w w_w \rangle) = 0 \quad (8)$$

due to the phase shift between  $(u_w, w_w)$  and  $(v_w, w_w)$ , where  $\langle \dots \rangle$  means time average.

Formulae for the depth averaged radiation stresses are also given here because they will be used later on when the time splitting technique is applied.

$$S_{xx} = \int_{z_b}^{\langle z_s \rangle} \rho (\langle u_w^2 \rangle - \langle w_w^2 \rangle) dz + \frac{1}{2} \rho g \langle (z_s - \langle z_s \rangle)^2 \rangle = [N(\cos^2 \theta + 1) - 1] E \quad (9)$$

$$S_{yy} = \int_{z_b}^{\langle z_s \rangle} \rho (\langle v_w^2 \rangle - \langle w_w^2 \rangle) dz + \frac{1}{2} \rho g \langle (z_s - \langle z_s \rangle)^2 \rangle = [N(\sin^2 \theta + 1) - 1] E \quad (10)$$

$$S_{xy} = S_{yx} = \int_{z_b}^{\langle z_s \rangle} \langle \rho u_w v_w \rangle dz = [N \sin \theta \cos \theta] E \quad (11)$$

where  $N$  is the ratio of the wave group velocity to the wave phase speed.

The water surface roller induced by wave breaking has not been taken into account in the above expressions. If the surface roller due to wave breaking is taken into account, the corresponding stresses can be explicitly expressed as (Svendsen, 1984):

$$\tau = -\frac{1}{h} \frac{\partial}{\partial x} (7 \frac{h}{L} E) \quad (12)$$

where  $L$  is the wave length at wave breaking and it is assumed that the roller induced stress is in the cross-shore direction.

#### 4 Numerical Modelling

The three dimensional model for wave induced currents is governed by the equations given in section 2. Due to the complicated nature of the model, efficient numerical schemes are definitely required to reduce run times as much as possible. In this section, we will use the time splitting technique and the finite volume method to solve the equations.

##### 4.1 Application Of The Time Splitting Method

From the governing equation for wave induced currents it is understood that the surface variation is a function of  $x$  and  $y$ , but not  $z$ . The radiation stresses below wave trough level are hardly varying with  $z$ . First, we introduce depth averaged velocities,

$$\bar{u} = \frac{1}{h} \int_{z_b}^{z_s} u dz \quad \text{and} \quad \bar{v} = \frac{1}{h} \int_{z_b}^{z_s} v dz \tag{13}$$

Then the original governing equations can be split into two main parts. The first part corresponds to water surface set-up and set-down and the mean movement of the wave-induced current:

$$\frac{\partial \eta}{\partial t} = - \int \left( \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) dz \tag{14}$$

$$\frac{\partial u}{\partial t} = -g \frac{\partial \eta}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{xx}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{xy}}{\partial y} - \tau \tag{15}$$

$$\frac{\partial v}{\partial t} = -g \frac{\partial \eta}{\partial y} - \frac{1}{\rho h} \frac{\partial S_{xy}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{yy}}{\partial y} \tag{16}$$

Defining

$$(u', v') = (u, v) - (\bar{u}, \bar{v}) \tag{17}$$

yields

$$\frac{\partial \eta}{\partial t} + \frac{\partial \bar{u} h}{\partial x} + \frac{\partial \bar{v} h}{\partial y} = 0 \tag{18}$$

$$\frac{\partial \bar{u}}{\partial t} = -g \frac{\partial \eta}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{xx}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{xy}}{\partial y} - \tau \tag{19}$$

$$\frac{\partial \bar{v}}{\partial t} = -g \frac{\partial \eta}{\partial y} - \frac{1}{\rho h} \frac{\partial S_{xy}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{yy}}{\partial y} \tag{20}$$

The second part involves solving for the velocity field

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} = \frac{\partial}{\partial x} (v_h \frac{\partial u}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial u}{\partial y}) + \frac{\partial}{\partial z} (v \frac{\partial u}{\partial z}) + W_x + RS_x \tag{21}$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} = \frac{\partial}{\partial x} (v_h \frac{\partial v}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial v}{\partial y}) + \frac{\partial}{\partial z} (v \frac{\partial v}{\partial z}) + W_y + RS_y \tag{22}$$

$$w = - \int_{-h}^z \left( \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right) dz \tag{23}$$

where  $RS_x$  and  $RS_y$  are depth averaged radiation stresses

$$RS_x = -\frac{1}{\rho h} \frac{\partial S_{xx}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{xy}}{\partial y} \quad (24)$$

$$RS_y = -\frac{1}{\rho h} \frac{\partial S_{xy}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{yy}}{\partial y} \quad (25)$$

The first set of the equations is used to obtain the mean velocity field and the water surface elevation, while the second one to obtain the depth-varying velocities  $u$ ,  $v$  and  $w$ . Both sets of equations can be expressed based on time splitting as follows (from  $ndt$  to  $(n+1)dt$ ):

At the first step

$$\bar{u}^n = \frac{1}{h} \int_{-h}^{\eta^n} u^n dz \quad (26)$$

$$\bar{v}^n = \frac{1}{h} \int_{-h}^{\eta^n} v^n dz \quad (27)$$

and

$$u' = u^n - \bar{u}^n \quad (28)$$

$$v' = v^n - \bar{v}^n \quad (29)$$

then

$$\frac{\eta^{n+1} - \eta^n}{\Delta t} + \frac{\partial \bar{u}^{n+\frac{1}{2}}}{\partial x} + \frac{\partial \bar{v}^{n+\frac{1}{2}}}{\partial y} = 0 \quad (30)$$

$$\frac{\bar{u}^{n+\frac{1}{2}} - \bar{u}^n}{\Delta t} = -g \frac{\partial \eta^{n+1}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{xx}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{xy}}{\partial y} - \tau \quad (31)$$

$$\frac{\bar{v}^{n+\frac{1}{2}} - \bar{v}^n}{\Delta t} = -g \frac{\partial \eta^{n+1}}{\partial y} - \frac{1}{\rho h} \frac{\partial S_{yx}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{yy}}{\partial y} \quad (32)$$

$$u^{n+\frac{1}{2}} = \bar{u}^{n+\frac{1}{2}} + u' \quad (33)$$

$$v^{n+\frac{1}{2}} = \bar{v}^{n+\frac{1}{2}} + v' \tag{34}$$

At the second step, we have

$$\frac{u^{n+1} - u^{n+\frac{1}{2}}}{\Delta t} + U_i^{n+\frac{1}{2}} \frac{\partial u^{n+1}}{\partial X_i} = \frac{\partial}{\partial x} (v_h \frac{\partial u^{n+1}}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial u^{n+1}}{\partial y}) + \frac{\partial}{\partial z} (v \frac{\partial u^{n+1}}{\partial z}) + W_x + RS_x \tag{35}$$

$$\frac{v^{n+1} - v^{n+\frac{1}{2}}}{\Delta t} + U_i^{n+\frac{1}{2}} \frac{\partial v^{n+1}}{\partial X_i} = \frac{\partial}{\partial x} (v_h \frac{\partial v^{n+1}}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial v^{n+1}}{\partial y}) + \frac{\partial}{\partial z} (v \frac{\partial v^{n+1}}{\partial z}) + W_y + RS_y \tag{36}$$

$$w^{n+1} = - \int_{-h}^z (\frac{\partial u^{n+1}}{\partial x} + \frac{\partial v^{n+1}}{\partial y}) dz \tag{37}$$

The two sets of equations given above will be solved by different methods. The depth averaged equations will be treated by the alternating direction implicit method (ADI) and governing equations for the depth-varying velocities will be solved by the finite volume technique.

#### 4.2 ADI Solver

It is well known that the Alternative Direction Implicit method, or ADI, has been widely used in two dimensional flow problems. It is used here to solve the depth averaged equation set. Hence, we have:

First step:

$$\frac{\eta^{n+\frac{1}{2}} - \eta^n + \frac{\partial \bar{u}^{n+\frac{1}{2}}}{\partial x} h}{\Delta t} = - \frac{\partial \bar{v}^n}{\partial y} h \tag{38}$$

$$\frac{\bar{u}^{n+\frac{1}{2}} - \bar{u}^n + g \frac{\partial \eta^{n+\frac{1}{2}}}{\partial x}}{\Delta t} = - \frac{1}{\rho h} \frac{\partial S_{xx}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{xy}}{\partial y} - \tau \tag{39}$$

Second step:

$$\frac{\eta^{n+1} - \eta^{n+\frac{1}{2}} + \frac{\partial \bar{v}^{n+\frac{1}{2}}}{\partial y} h}{\Delta t} = - \frac{\partial \bar{u}^{n+\frac{1}{2}}}{\partial x} h \tag{40}$$

$$\frac{\bar{v}^{n+\frac{1}{2}} - \bar{v}^n + g \frac{\partial \eta^{n+1}}{\partial y}}{\Delta t} = - \frac{1}{\rho h} \frac{\partial S_{yx}}{\partial x} - \frac{1}{\rho h} \frac{\partial S_{yy}}{\partial y} \tag{41}$$

It is clear that the solution process presented here is exactly the same as that for a two dimensional flow model like, for example, tidal model. The equations above satisfy the continuity equation from which the water surface variable is obtained.

#### 4.3 Coordinate Transformation

The purpose of the transformation is to restructure the vertical coordinate viz:

$$\sigma = \frac{z - z_b}{\eta - z_b} \quad (42)$$

Using this relationship, the water column at any location between water surface and the sea bottom is transformed into a layer of thickness 1. This transformation introduces additional terms into the equations of motion. However, most of the additional terms introduced by the stretching are contained in the horizontal diffusion terms. Since horizontal diffusion is generally small compared to the vertical diffusion and horizontal advection, only the leading terms need to be retained in general. The derivatives can be obtained as follows:

$$\frac{\partial \sigma}{\partial z} = \frac{1}{h} \quad (43)$$

$$\frac{\partial}{\partial z} = \frac{1}{h} \frac{\partial}{\partial \sigma} \quad (44)$$

$$\frac{\partial^2}{\partial z^2} = \frac{1}{h^2} \frac{\partial^2}{\partial \sigma^2} \quad (45)$$

$$\frac{\partial}{\partial t} = \frac{\partial}{\partial t} + \frac{\partial \sigma}{\partial t} \frac{\partial}{\partial \sigma} \quad (46)$$

$$\frac{\partial}{\partial x} = \frac{\partial}{\partial x} + \frac{\partial \sigma}{\partial x} \frac{\partial}{\partial \sigma} \quad (47)$$

$$\frac{\partial}{\partial y} = \frac{\partial}{\partial y} + \frac{\partial \sigma}{\partial y} \frac{\partial}{\partial \sigma} \quad (48)$$

$$\frac{\partial^2}{\partial x^2} = \frac{\partial^2}{\partial x^2} + \text{higher order terms} = \frac{\partial^2}{\partial x^2} \quad (49)$$

$$(50)$$

$$\frac{\partial^2}{\partial y^2} = \frac{\partial^2}{\partial y^2} + \text{higher order terms} \sim \frac{\partial^2}{\partial y^2}$$

$$\frac{\partial \sigma}{\partial x} = -\frac{1}{h} (\sigma \frac{\partial \eta}{\partial x} + (1-\sigma) \frac{\partial z_b}{\partial x}) \tag{51}$$

$$\frac{\partial \sigma}{\partial y} = -\frac{1}{h} (\sigma \frac{\partial \eta}{\partial y} + (1-\sigma) \frac{\partial z_b}{\partial y}) \tag{52}$$

In general from the transformation formulae given above one can derive the governing equations in the new coordinate system. However, it is convenient to define a vertical velocity as

$$w^* = \frac{\partial \sigma}{\partial t} + u \frac{\partial \sigma}{\partial x} + v \frac{\partial \sigma}{\partial y} + w \frac{\partial \sigma}{\partial z} \tag{53}$$

We can finally obtain the momentum equations in x and y directions:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w^* \frac{\partial u}{\partial \sigma} = \frac{\partial}{\partial x} (v_h \frac{\partial u}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial u}{\partial y}) + \frac{1}{h^2} \frac{\partial}{\partial \sigma} (v \frac{\partial u}{\partial \sigma}) + W_x^* + RS_x^* \tag{54}$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w^* \frac{\partial v}{\partial \sigma} = \frac{\partial}{\partial x} (v_h \frac{\partial v}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial v}{\partial y}) + \frac{1}{h^2} \frac{\partial}{\partial \sigma} (v \frac{\partial v}{\partial \sigma}) + W_y^* + RS_y^* \tag{55}$$

where the radiation stress terms with a star mark use values of the new coordinate. In the time-splitting scheme, the equations are

$$\frac{u^{n+1} - u^{n+\frac{1}{2}}}{\Delta t} + U_i^* \frac{\partial u^{n+1}}{\partial X_i} = \frac{\partial}{\partial x} (v_h \frac{\partial u^{n+1}}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial u^{n+1}}{\partial y}) + \frac{1}{h^2} \frac{\partial}{\partial \sigma} (v \frac{\partial u^{n+1}}{\partial \sigma}) + W_x^* + RS_x^* \tag{56}$$

$$\frac{v^{n+1} - v^{n+\frac{1}{2}}}{\Delta t} + U_i^* \frac{\partial v^{n+1}}{\partial X_i} = \frac{\partial}{\partial x} (v_h \frac{\partial v^{n+1}}{\partial x}) + \frac{\partial}{\partial y} (v_h \frac{\partial v^{n+1}}{\partial y}) + \frac{1}{h^2} \frac{\partial}{\partial \sigma} (v \frac{\partial v^{n+1}}{\partial \sigma}) + W_y^* + RS_y^* \tag{57}$$

where  $U^*$  is the vector velocity in the new coordinate system and

$$U_i^* \frac{\partial}{\partial X_i} = u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} + w^* \frac{\partial}{\partial \sigma}$$

It should be noted that the vertical velocity in the old coordinate system is calculated by

$$w^{n+1} = - \int_{-h}^* (\frac{\partial u^{n+1}}{\partial x} + \frac{\partial v^{n+1}}{\partial y}) dz \tag{58}$$

where no transformation is required.

#### 4.4 Application Of The Finite Volume Method

After transforming the momentum equations into a new coordinate system where the calculation domain is in regular form, the finite volume method is a suitable numerical solver due to its excellent conservation characteristics. The details of this method have been very well described by Patankar in his book (Patankar 1977). The discretization equation for velocity  $u$  is:

$$a_p u_p = a_E u_E + a_W u_W + a_N u_N + a_S u_S + a_T u_T + a_B u_B + b \quad (59)$$

where indexes E,W,N,S,T and B mean the east,west,north,south,top and bottom neighbours respectively, P means central point, and

$$a_E = D_e A (|P_e|) + [F_e, 0] \quad (60)$$

$$a_W = D_w A (|P_w|) + [F_w, 0] \quad (61)$$

$$a_N = D_n A (|P_n|) + [F_n, 0] \quad (62)$$

$$a_S = D_s A (|P_s|) + [F_s, 0] \quad (63)$$

$$a_T = D_t A (|P_t|) + [F_t, 0] \quad (64)$$

$$a_B = D_b A (|P_b|) + [F_b, 0] \quad (65)$$

$$a_p^o = \frac{\Delta x \Delta y \Delta \sigma}{\Delta t} \quad (66)$$

$$b = S_c \Delta x \Delta y \Delta \sigma + a_p^o u_p^o \quad (67)$$

$$a_p = a_E + a_W + a_N + a_S + a_T + a_B + a_p^o \quad (68)$$

where  $S_c$  is the source term including contributions from radiation stresses. The flow rates and conductances are defined as

$$F_e = u_e \Delta y \Delta \sigma \quad D_e = \frac{v_{he} \Delta y \Delta \sigma}{\Delta x} \quad (69)$$

$$F_w = u_w \Delta y \Delta \sigma \quad D_w = \frac{v_{hw} \Delta y \Delta \sigma}{\Delta x} \quad (70)$$

$$(71)$$

$$(72)$$

$$F_n = v_n \Delta \sigma \Delta x \quad D_n = \frac{v_{hn} \Delta \sigma \Delta x}{\Delta y}$$

$$F_s = v_s \Delta \sigma \Delta x \quad D_s = \frac{v_{hs} \Delta \sigma \Delta x}{\Delta y}$$

$$F_t = w_t^* \Delta x \Delta y \quad D_t = \frac{v_t \Delta x \Delta y}{h^2 \Delta \sigma} \quad (73)$$

$$F_b = w_b^* \Delta x \Delta y \quad D_b = \frac{v_b \Delta x \Delta y}{h^2 \Delta \sigma} \quad (74)$$

The Peclet number  $P$  is to be taken as the ratio of  $F$  and  $D$ ; thus,  $P_e = F_e/D_e$ , and so on. The power-law formulation is used here, that is

$$A(|P|) = \{0, (1-0.1|P|)^2\} \quad (75)$$

which means taking the largest of the values in the brackets. More details can be found in Patankar's book.

### 5 Boundary Conditions

Wave breaking on the water surface produces extra momentum. Svendsen (1984) introduced the concept of the surface roller which actually takes into account the effect of wave breaking. The formulae derived by him have been used by many researchers. The essential point of Svendsen's idea is that the surface roller contains a certain amount of shoreward directed momentum, which causes a return flow below the wave trough in the offshore direction. According to his work, the flux induced by the water surface roller can be related to the wave energy. If linear wave theory is used, the wave induced mass flux including the water surface roller contribution can be written as

$$M = \left(1 + \frac{7h}{L}\right) \frac{E}{\rho c} \quad (76)$$

where  $h$  is the water depth,  $L$  is the wave length,  $c$  is the wave celerity,  $E$  is the wave energy density. Actually this formula has already been given in section 3 when discussing radiation stresses. However, in the calculation domain, we need to define a boundary at the water surface, and assumptions are required to tackle this requirement. Here it is assumed that:

1. The thickness of the surface layer is approximately equal to the wave height.
2. The time-averaged velocity in the layer is uniform and it is

$$u_s = \left(1 + \frac{7h}{L}\right) \frac{E}{\rho c} / (\langle \eta_s \rangle - z_{tr}) = \left(1 + \frac{7h}{L}\right) \frac{E}{\rho c} / H \quad (77)$$

3. The mean water surface is located halfway between the wave crest and the wave trough.

The momentum equations solved by the finite volume method are actually only applied to the area below the wave trough. The velocity at the wave trough is

then known from assumption (2) made above, which can be used as the boundary condition at the water surface.

The boundary condition at the sea bottom should include the effects of the wave oscillatory velocities. Liu and Dalrymple (1977) derived a formula for the bottom shear stress under the condition of a weak current and large incident wave angle. Their formula is used here.

## 6 Model Tests And Discussions

Aspects of model stability are considered first before verification tests are carried out. The model is a combination of two sub-models: the first is the ADI model and the second is the finite volume based model for the advection terms. It is well known that the ADI model is stable and accurate if the Courant number is not very large (usually less than 4). On the other hand, the finite volume method used in this paper is also a stable numerical solver. The power-law formula proposed by Patankar (1972) can ensure unconditional stability. It can therefore be concluded that the wave-induced current model is stable.

The model proposed in this paper is tested against available experimental data. The model includes the time variable, and a steady state solution can be obtained if the model is run for a sufficiently long period. Of course for a problem like the simulations of tidal flow, the model can quickly reach a three-dimensional velocity field. Before the model performance was compared against experimental data, a series of numerical tests were undertaken for some simple cases in order to ascertain the capabilities of the model. The cases include horizontal channel flow and a plane beach with a constant slope. As a rough criterion for accessing the model performance, continuity of the flow must be satisfied. After these numerical experiments had been done successfully, the experimental data presented by Stive and Wind (1982,1986) were used to test whether the model could predict cross-shore circulation and water surface set-up.

The experiments were conducted in a wave flume 55m long, 1m wide and 1m deep. A plane, concrete beach with a 1:40 slope was installed. Two experiments have been reported by Stive and Wind in 1982 and in 1986. In the first experiment, two test conditions were used. The first of these was also used for the experiment carried out in 1986. The experimental results from the first test of the first experiment and of the second experiment are used for testing the model. For more details for these experiments the interested reader can consult the original papers.

Comparisons of the results of the model presented in this paper against Stive and Wind's experimental data for water level set-up and cross-shore circulation are shown in figures 1 to 4. In the case of the water surface set-up, it is clear that the agreement between the experimental data and the computational results is reasonable. The velocity distribution over the water depth obtained from the model is plotted against the experimental data. The trend of both experimental and computational results is the same, however, there are obvious differences. If the results from other models are considered, for example, Stive and Wind's model (1986) and Svendsen's model (1986), the results from the present model are acceptable. Some reasons for such differences between the experimental data and the model results are as follows.

1). Wave breaking is a nonlinear process. Although Svendsen (1984) presented

a formula dealing with the surface roller and the results from this formula is reasonable, a much more detailed description is really required.

2). The eddy viscosity formula used in the present model can be improved if the turbulence in the surf zone is better described. It is well known that the turbulent processes in the surf zone are far from understood. Bottom friction is another subject which many researchers are still studying. The bottom friction formula used in the present model is only one of the many available formulae.

3). Wave-current interaction is ignored in the present model and it is ignored in all existing wave-induced current models. How to incorporate wave-breaking into wave-current interaction is a problem which has yet to be tackled.

4). The calculated velocities at water surface are smaller than the values of the experimental data which is probably caused by the inaccurate simulation of the air-water mixture at the surface. Improvement is under way.

From the above statements it can therefore be concluded that the wave-induced current problem is so complicated that numerical results are only rough estimates of the true solutions.

## CHAPTER 167

### INFLUENCE OF OFFSHORE BANKS ON THE ADJACENT COAST

N.J. MacDonald and B.A. O'Connor<sup>1</sup>

#### Abstract

A numerical model has been used to study the influence of offshore sand banks on the wave climate along a stretch of the Belgian coast. Results of the model have been interpreted to provide predictions of wave height under several scenarios, assuming that the banks do not respond quickly to changes in the local hydrodynamic environment. Results show that the sand banks afford substantial protection to the coast and that this effect may be reduced as a result of rising mean sea level and dredging.

#### Introduction

As part of the EC MAST II Programme, the Circulation and Sediment Transport Around Banks (CSTAB) project has brought together coastal engineers, oceanographers and geologists from five European countries to study of the role of sand banks in the processes and development of the nearshore hydrodynamic and littoral environment. The CSTAB project, scheduled to run between 1992 and 1995, is centred around an ambitious field programme measuring hydrodynamics and sediment dynamics in a typical linear sand bank system off the Belgian coast.

The field study site, which includes the inter-tidal and surf zones of the adjacent beach as well as the offshore sand banks, covers an area of approximately 400 km<sup>2</sup>. Since this entire region cannot be covered completely in a field study, computer models are being used to provide the necessary additional information to link together the various field campaigns and to provide a valuable predictive capability. This paper describes the application of a wave climate computer model to quantify the influence of offshore sand

---

banks on the adjacent coast.

### **Sand banks and the coast**

Large linear sand banks are a feature of many continental shelves throughout the world (Off, 1963). These sand banks occur in both tide and wave-dominated coastal seas, and in most instances, do not appear as lone features but as part of a regional group. The sand banks being investigated in the present paper are part of the Flemish Banks, which are situated on the Belgian coastal shelf in the southern North Sea. This bank system can be described, broadly, as a group of linear sand banks of the order of 10 to 20 km in length, 1 km in width and 10 to 20 m in height. A comprehensive review of the Flemish Banks has been presented by de Moor (1989).

One of the effects of offshore sand bank systems is to shelter the adjacent coast. This is believed to result primarily from the increased frictional drag on storm surges and increased friction on, and breaking of, the larger short-period storm waves. This latter feature has also been investigated by Tucker et al. (1983) who studied wave attenuation over a sand bank on the East Anglian coast of the UK. Using measurements taken by two wave rider buoys, they found negligible attenuation for small waves and a saturation level for larger waves determined by the breaking conditions over the bank.

If existing sand banks were reduced in size, or removed altogether from a system, the coast would experience a significant increase in the amount of wave energy reaching it. This would result in intensified erosion of the shoreline and the possible necessity to reinforce existing coastal defences. Sand banks also significantly modify the regional distribution of wave energy impacting on the coast. The local wave height field is determined by interaction with the local currents and the shoaling, refraction and diffraction which results from the reaction of the propagating waves to changes in bottom bathymetry. Changes in the offshore depths, either actual morphological changes or as a result of water level variation, could have serious implications for individual locations along the coast far beyond that expected for the coast in general.

The size and orientation of the sand banks may also change with long-term changes in mean sea level providing sufficient material is available. However, the time scale at which the banks can react may be very long. A number of linear sand bank systems, such as the Celtic Banks, were at one time active but are now moribund, having been unable to respond to rapid changes in sea level. De Vriend (1990) and van de Meene (1994) have both noted that, while the smaller-scale features on the sand banks (such as sand waves or smaller) can react quite rapidly, the morphological time scale of sand bank development is on the order of decades to centuries. In the present work

the bathymetric features are assumed to be unaffected by any change in mean sea level which may result due to climate change.

### **Climate Change**

Recently, studies have indicated that the growth in the level of greenhouse gases in the atmosphere can lead to a gradual increase in mean global temperature. One consequence of a gradual increase in mean global temperature is a rise in mean sea level (MSL). Pirazzoli (1989) found the rate of increase of MSL for the North Sea to be 1.0 to 1.5 mm/year. This was confirmed for the southern North Sea by Jensen et al. (1990) who calculated an average MSL rise of 1.2 mm/year across 12 tidal recording stations over a 100 year period. Jensen et al. (1990) also found some evidence to suggest that MSL increases may be accelerating.

Warrick and Oerlemans (1990) have presented sea level predictions based on a compilation of existing results and new computations. Their High, Best and Low predictions, for the Business-as-Usual scenario are given in Fig. 1. There is considerable spread in the three estimates given - a 20 cm rise in MSL could be realized anytime from 2020 to 2070 - but, all do show a gradually accelerating rise in MSL. For the purpose of the present paper, this Best Estimate will be used to relate simulation water levels to future dates.

Increased MSL will have serious consequences for coastal regions. A higher MSL will result in a general retreat of the shoreline and will allow larger waves to penetrate further inshore. An increase in MSL will also lead to larger tidal ranges because of the decreased frictional losses. This increase in tidal range will result in higher high water levels which will permit even larger waves to penetrate inshore than would be expected from increases in MSL alone.

Another possible consequence of climate change is increased storminess for some locations. Mitchell et al. (1990) have indicated that, while tropical disturbances may increase in frequency, the mid-latitudes may experience reduced storminess as a result of a decrease in the polar to equatorial mean temperature gradient.

### **The Bathymetric Grid**

Surveys from the Belgian Service of Coastal Harbours, were collected to model the region from the banks to the shore in very fine detail. Over 100 000 bathymetric values, with an average separation distance of 5 m, were used to generate the finite difference grid of the area. A contour plot of depths for this grid at the present-day MSL is shown in Fig. 2. The grid is 201 x 181 with a grid spacing of 100 m in both dimensions. The grid has its origin at

(51°07'30"N, 2°40'00"E) and its positive y-axis is aligned at 327° so that the alongshore side, or x-axis, is roughly parallel to the coast.

### The Numerical Model

Due to the size of the area being modelled it was decided to employ a wave-period averaged computer model since this type of model is not restricted to a limiting number of solution points per wavelength. The model selected was a simplified version of the WC2D model which is based on the work Yoo and O'Connor (1986) but which has been substantially improved since its initial development. The model has been validated against numerous laboratory and field results (Yoo and O'Connor, 1986; Yoo and O'Connor, 1988) as well as against wave rider measurements at Flemish Banks taken during the CSTAB field programme (O'Connor, 1993) where computed wave heights were within 5% of measured.

Wave kinematics are obtained through solution of a combined refraction-diffraction kinematic conservation equation for linear surface waves:

$$\frac{\partial K_i}{\partial t} + C_g \frac{K_j}{k} \frac{\partial K_i}{\partial x_j} + \frac{\sigma G}{2h} \frac{\partial h}{\partial x_i} + \frac{C_g}{2kA} \left[ \frac{1}{A} \frac{\partial A}{\partial x_i} \left( \frac{\partial^2 A}{\partial x_j^2} \right) - \frac{\partial}{\partial x_i} \left( \frac{\partial^2 A}{\partial x_j^2} \right) \right] = 0 \quad (1)$$

where  $K_i$  is the wave number vector,  $i=\{x,y\}$ ,  $k$  is the wave separation factor,  $h$  is the depth,  $A$  is the wave amplitude,  $\sigma$  is the wave frequency,  $C_g$  is the group velocity and  $G = 2kh/\sinh 2kh$ . The second term of Eq. (1) describes the advection of wave number, the third describes the effects bottom slope and the final term permits diffraction of the wave field. Since the forcing, and consequently the solution, of the model is steady, the first term in Eq. (1) is retained only as a iteration parameter. An approximate non-linear solution is achieved through use of the non-linear dispersion relation of Hedges (1976).

The wave dynamics are obtained from the combined refraction-diffraction wave energy conservation equation for linear surface waves:

$$\frac{\partial A}{\partial t} + \frac{1}{2A} \frac{\partial}{\partial x_i} \left( A^2 C_g \frac{K_i}{k} \right) + F_b A^2 = 0 \quad (2)$$

The final term in Eq. (2) has been introduced to include the effects of frictional dissipation. The calculation of  $F_b$  using an improved Bijker approach is described in O'Connor and Yoo (1988).

The numerical scheme is a simple explicit formulation with upwinding methods employed for the advection terms. The solution is obtained on a

staggered grid in an iterative approach until a steady-state solution is achieved. Boundary conditions of wave amplitude and wave direction must be supplied at the offshore boundary. At the side boundaries a radiation boundary condition is applied and at the shoreline all energy must be dissipated through breaking.

### **Application to the study site**

Three MSLs were selected: the present-day; +0.25 m; +0.50 m. According to Warrick and Oerlemans (1990), the latter two MSLs relate to the years 2040 and 2075. These levels were used in tests with four wave climates and five wave directions (see Tables 1 and 2). Analyses of a wave hindcast performed for this location by the UK Meteorological Office (pers. comm.) show that wave climates A through D have rates of occurrence of 1.36%, 0.72%, 0.24% and <.01% for the sectors between directions 1 to 5, respectively. No account was made of any tidal effects in the present work.

A  $k_s$  value of 10 cm was used for the roughness height for the area. This value was used to take into account the sub-grid scale bed features, such as the sand waves, mega-ripples, and ripples, that are known to occur on the sand banks in this area.

### **Results**

A simple illustration of the effectiveness of the sand banks in protecting the coast can be seen from the cross-shore transformation characteristics of the model for the present-day bathymetry and for the case where the sand banks do not exist. This is most easily done in a one-dimensional test, so as to eliminate any influence of longshore variability in the bathymetry. For the present-day situation, the wave height field produced by the model for normal wave approach on the two-dimensional bathymetry was averaged between 5 km and 15 km in the alongshore direction from a line 2 km from the coast to the offshore boundary. These were compared with the results of the model for an equivalent plane slope (see Fig. 3). Figure 4 shows the ratios of present-day wave height with banks to plane slope wave height for wave climates A through D. The sheltering effect of the sand bank system is clearly visible in each of the four wave climates. The results also indicate that the sand banks have a greater influence on the larger wave climates, with reductions in wave height approaching 30% a distance 2 km offshore. Clearly, the longer waves are influenced by the bottom bathymetry over a much larger fetch.

When examining the effects of sea level rise on the entire system it is more informative to examine the full two-dimensional results. A typical result of the simulation is shown in Fig. 5. Here a contour plot of wave height is presented for the present-day MSL and an increase of 0.5 m for condition D3 ( $H=5.0$  m,  $T=9.0$  s,  $\theta=327^\circ$ ). Although both patterns of contour lines are

complex, it is evident from their rhythmic pattern that the sand banks have a significant effect on the wave climate in the region. While there are substantial losses in energy over the domain, especially in the shallower regions, there are areas of increased wave height due to the focusing. The sheltering effects of the sand banks are discernible by the decrease of wave height over each successive bank. The increase in MSL has the effect of permitting larger waves to progress further shoreward, as is most evident in the nearshore zone.

Substantial alongshore variation in the change in wave height due to increased MSL was found in most tests. Figure 6 shows the percentage change in wave height for condition 4B along a line 1 km offshore for the two increased MSLs. Under an assumption of a 0.5 m rise in MSL, the resulting increase in wave height varies from 8% to 25%. This alongshore non-uniformity in wave height is reduced to 8% to 10% when the results for all tests are averaged together, as is shown in Fig. 7. The results for the entire domain, see Fig. 8, shows a general pattern of increasing wave height towards the shoreline. Individual wave climates also exhibited some variation, as shown in Fig. 9, where the results for the line 1 km offshore are plotted against projected dates.

In order to illustrate some possible consequences of the effects of offshore dredging on the adjacent coast, a hypothetical dredged region was constructed within the bathymetric grid. This area is delineated by the dashed line in Fig. 10. The depth was reduced to a constant 10.25 m below present MSL over this region, corresponding to approximately  $1.5 \times 10^6$  m<sup>3</sup> of material removed.

A typical contour plot of the change in wave height is shown in Fig. 11 for condition C5. The influence of the increase of depth is apparent almost immediately and extends over a large area, although the differences away from the direct shadow zone are minute. The effect towards the shore is again dependent upon the wave climate. Figures 12a and 12b show the alongshore distribution of the change in wave height for each of the wave climates from directions 1 and 5, respectively. In both cases the wave height immediately behind the dredging site has decreased, while it has increased to either side. In both cases the larger wave climates are affected for a greater distance along the coast.

## Conclusions

Nearshore sand bank systems protect the coast by dissipating wave energy offshore. Rising sea levels, however, will lessen their effectiveness and permit larger waves to reach the coast. For the sea level rise scenario used in the present work, wave heights at a line 1 km off the Belgian coast was

predicted to increase by the order of 10% by 2075. The effects closer to the surf zone may be greater, as increases in wave energy were generally found to get larger towards the shore.

Substantial variation in the change in wave climate along the coast was noted in all tests, although this effect was modulated when tests from several directions were combined. The situation with regards to the sediment dynamics in these locations will more extreme, however, due to the highly non-linear relationship of sediment transport with wave height.

The illustration of possible consequences from the extraction of sediment from the top of an offshore bank showed that in each case the wave height immediately behind the dredging site was decreased while it increased to either side.

## CHAPTER 168

### WAVE RUNUP ON COMPOSITE-SLOPE AND CONCAVE BEACHES

R. H. Mayer<sup>1</sup> and D. L. Kriebel<sup>1</sup>

#### ABSTRACT

Laboratory experiments were carried out for regular and irregular wave runup over non-uniform beach profiles, including both bi-linear and concave "equilibrium" beach profiles. Measured runup is shown to be substantially less than that predicted by the Hunt Formula if the exposed beach-face slope is used to define the typical beach slope. More accurate runup estimates are obtained using Saville's hypothetical slope concept; and, Saville's method is integrated with the Hunt Formula to provide simple analytical estimates of wave runup over complex beach topography.

#### INTRODUCTION

One problem encountered when predicting wave runup on open-coast beaches is the dilemma of how to define the beach slope for use in runup predictive formulas. Most runup design methods have been developed from laboratory tests conducted on uniform beach slopes. For field application, however, where beaches are generally concave in shape, and where offshore sand bars or complex beach berms may exist, the appropriate slope for use in runup calculations is never clear. On natural beaches, different definitions of beach slope can typically differ by a factor of two or three such that runup estimates can vary by a similar amount.

The purpose of this paper is to present a computationally-simple method for calculating wave runup on beaches with composite-slopes or concave shapes. This study consists of two main parts: (1) development of an analytical method for predicting runup on composite-slope or concave beaches and (2) an experimental evaluation of this methodology based on small-scale laboratory tests of wave runup for both regular and random waves.

---

<sup>1</sup> Ocean Engineering Program, U.S. Naval Academy, Annapolis, MD 21402

The analytical approach used in this paper integrates two widely-used methods of predicting wave runup: (1) the Hunt Formula, developed by Hunt (1959) for predicting runup of regular waves on coastal structures with a uniform slope and, (2) the "effective" slope method of Saville (1958), which defines an appropriate average slope for use in predicting runup on composite-slope structures. By combining these analytically, a simple quadratic equation is obtained for wave runup that can be solved in closed form for simplified geometries. This solution is then verified by comparison to wave runup measured in over 340 small scale laboratory tests conducted at the U.S. Naval Academy in both regular and irregular waves.

## BACKGROUND

Most methods of predicting wave runup on open-coast beaches are variations of the Hunt Formula, proposed by Hunt (1959), and rewritten by Battjes (1974) as

$$\frac{R}{H_o} = \frac{\tan\beta}{\sqrt{H_o/L_o}} = \xi \quad (1)$$

where  $H_o$  is the deep water wave height,  $L_o$  is the deep water wave length,  $\tan\beta$  is the tangent of the beach slope, and where  $\xi$  is the surf-similarity parameter which is defined by  $\tan\beta/(H_o/L_o)^{1/2}$ . Battjes (1974) showed that the dimensionless runup is generally equal to  $\xi$  over the range from  $0.1 < \xi < 2.3$  for regular waves acting on uniform, smooth, and impermeable laboratory beaches with slopes typical of many natural beach slopes.

For irregular waves, Battjes (1971) also obtained reasonable predictions of the median runup by using the Hunt Formula expressed in terms of the median wave height. Mase (1989) defined the surf similarity parameter in terms of the deep water significant wave height and, based on analysis of laboratory tests on uniform impermeable slopes, developed empirical correlations between  $\xi$  and the mean runup, the significant runup, as well as other runup parameters. Holman (1986) developed graphical correlations between runup and the surf similarity parameter, again defined by the significant wave height, based on field measurements over complex barred beach profiles.

A discrepancy can be found, however, between the field results of Holman and the laboratory results of Mase. Mase (1989) found that the significant runup measured in his small-scale laboratory tests on smooth plane slopes was approximately twice as large as values measured in the field by Holman (1986). Mase speculates that his expression provides an upper bound to the scattered field data and further attributes the overprediction to the use of smooth impermeable slopes in the laboratory tests. It is our belief, however, that there is a more fundamental cause of this discrepancy related to the effect of beach profile geometry.

This contradiction between laboratory and field values for runup may be partly explained by considering the bi-linear profile in Figure 1a. As pointed out by Hunt (1959), the Hunt Formula will not accurately predict the runup of regular waves on this profile if either the beach-face slope  $m$  or the submerged surf zone slope  $s$  is used. Predictions based on the beach-face slope dramatically over-estimate runup while predictions based on the surf zone slope under-estimate the runup. Hunt (1959) suggested an empirical weighted average of the two slopes  $m$  and  $s$  for bi-linear geometries, but a more general method is required for more complex beach geometries, such as the concave beach profile in Figure 1b.

The most widely-used method for predicting runup over complex geometries was proposed by Saville (1957). Saville suggested that runup predictions over arbitrary geometries should use a hypothetical average or "effective" slope of the entire active surf zone, extending between the wave break point and the runup limit. This approach, however, is cumbersome to apply. It requires a time-consuming iterative solution in which: (1) a runup limit is assumed, (2) an average slope is calculated from the breakpoint to the assumed runup limit, (3) the runup is estimated using this average slope in empirical design curves, (4) the calculated runup is compared to the assumed value. If necessary, the new runup limit is then used to define a new effective slope and the process is repeated until the runup converges on a stable value.

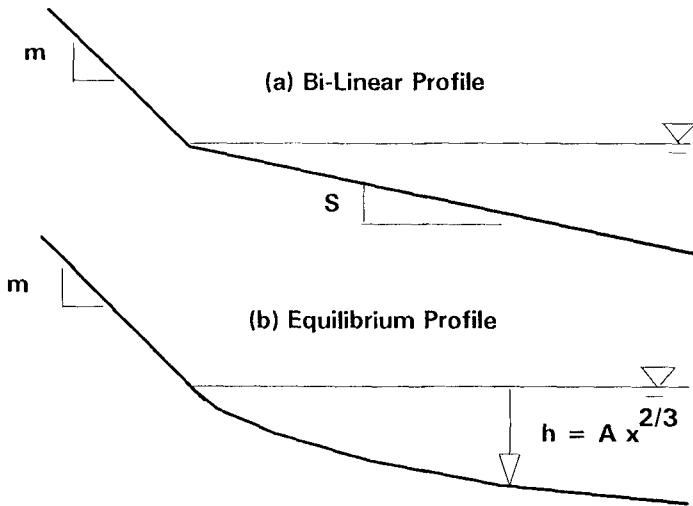

Figure 1. Illustration of idealized beach profiles: (a) bi-linear composite-slope profile and (b) concave equilibrium beach profile.

## INTEGRATED RUNUP METHOD

In this study, the Hunt Formula and the Saville effective slope concept are integrated into one general runup equation for application to open-coast beaches. Because the Hunt Formula is known to describe runup for linear beach slopes, the numerous design curves which are traditionally used with Saville's effective slope method are not required. As a result, the iterative solution procedure recommended by Saville can be avoided, and a single expression for runup on composite-slope and concave beaches is found that can be solved analytically or numerically.

Beach geometries considered in both the analytical and experimental phases of this study are depicted in Figure 1. These include: (1) a bi-linear profile and (2) a concave profile given by the "equilibrium" profile form of Dean (1977). In each case, the exposed beach-face slope is assumed to be linear and the tangent of this slope is denoted by  $m$ . The surf zone is then either represented by a linear slope,  $s$ , or by a concave equilibrium profile form following the theory of Dean (1977) where the depth  $h$  is related to the distance offshore by the relationship  $h=Ax^{2/3}$  in which  $A$  is a parameter relating the general slope of the beach to sediment characteristics.

It is assumed that the physical mechanisms of wave runup are represented by the Hunt Formula in equation (1) which, in dimensional form is given by

$$R = \tan\beta \sqrt{H_o L_o} \quad (2)$$

Following Saville's hypothetical slope concept,  $\tan\beta$  is then defined as the average slope between the incipient breakpoint and the runup limit. As illustrated in Figure 2, this may be quantified numerically as

$$\tan\beta = \frac{R + h_b}{X_R + X_b} \quad (3)$$

where  $h_b$  is the incipient breaking depth,  $X_b$  is the horizontal distance from the shoreline to the breakpoint, and  $X_R$  is the horizontal distance to the runup limit. By combining the expression for average slope in equation (3) into the Hunt Formula in equation (2), a single equation for the wave runup is found in the form

$$R = \frac{R + h_b}{X_R + X_b} \sqrt{H_o L_o} \quad (4)$$

Note that the runup appears on both sides of equation (4) and, in fact, it appears in both the numerator and denominator on the right-hand-side since the horizontal runup limit  $X_R$  is related to the vertical runup limit  $R$  by the slope of the beach face as  $X_R=R/m$ . As a result, equation (4) can be solved for the runup  $R$  in two ways.

For general application over arbitrary beach geometries, equation (4) can be solved iteratively in the form

$$R_{i+1} = \frac{R_i + h_b}{X_{R_i} + X_b} \sqrt{H_o L_o} \tag{5}$$

where the subscripts  $i$  and  $i+1$  denote old and new values in the iteration process. In this approach, the distances  $X_R$  and  $X_b$  are determined directly from the known (measured) beach geometry at each step in the iterative solution. Although perhaps not apparent, equation (5) is much simpler to apply than the traditional effective slope method of Saville (1958) because there is no need to look up runup values from design curves. As a result, this method has the advantage that it could be added to any existing numerical model for surf zone hydrodynamics or sediment transport.

Figure 2. Definition of effective slope for idealized beach profiles.

For idealized open-coast conditions, one way to simplify equation (4) is to assume a uniform beach-face slope,  $m$ , as depicted in Figure 1. The horizontal runup excursion is then related to the vertical runup by  $X_R=R/m$  and equation (4) gives

$$R = \frac{R + h_b}{R + mX_b} m \sqrt{H_o L_o} \tag{6}$$

This suggests that the runup over a concave beach profile will always be less than runup over a uniform planar beach. For concave beach profiles, the breaking depth  $h_b$  is always smaller than the depth of a uniform slope projected out to the breakpoint,  $mX_b$ . The ratio  $(R+h_b)/(R+mX_b)$  is then always less than unity and the runup is less than that predicted by the Hunt Formula using the beach-face slope,  $m$ .

Further interpretation indicates that if the breakpoint is near the still water shoreline (shore-break conditions), then as expected

$$R = m \sqrt{H_o L_o} \quad (7)$$

In contrast, if the breakpoint is far offshore so that the surf zone is very wide, then equation (6) simplifies to the Hunt Formula based on the surf zone slope as

$$R = \frac{h_b}{X_b} \sqrt{H_o L_o} \quad (8)$$

For most other conditions however, the solution will lie in between these limits and is may be determined by first rewriting equation (6) as a quadratic equation

$$R^2 + R m ( X_b - \sqrt{H_o L_o} ) - h_b m \sqrt{H_o L_o} = 0 \quad (9)$$

An analytical solution for wave runup over non-uniform beach profiles is then found to be given by the solution of the quadratic equation

$$R = \frac{m}{2} ( X_b - \sqrt{H_o L_o} ) \left[ -1 + \sqrt{1 + \frac{4 h_b \sqrt{H_o L_o}}{m ( X_b - \sqrt{H_o L_o} )^2}} \right] \quad (10)$$

Interpretation of equation (10) is somewhat difficult but approximate solutions can be found by applying series expansions or by solving equation (9) subject to assumptions regarding the magnitude of each term. Space limitations prevent a full presentation of these results but, in general, results show that the runup is between the limits suggested in equation (7) and (8). For storm conditions, it can be shown that runup is actually given more closely by equation (8) than equation (7), suggesting that the average surf zone slope, not the average beach-face slope, is most appropriate for runup predictions when the wave conditions are energetic.

## EXPERIMENTAL EVALUATION OF INTEGRATED RUNUP METHOD

Over 340 wave tank tests have been conducted in order to verify the integrated approach of combining the Hunt Formula with the Saville effective slope concept in equation (10). Laboratory tests were conducted in the wave basin at the U.S. Naval Academy which is 13 meters long and 5.4 meters wide. Model beach profiles, having shapes depicted in Figure 1, were constructed of smooth impermeable PVC plastic sheets placed on top of an aluminum frame mounted inside a 7.5 meter long and 0.6 meter wide test channel installed in the wave basin. Water depths in the basin were generally kept at 24 centimeters.

Regular and irregular wave tests were conducted on uniform plane slopes and on bi-linear profiles as depicted in Figure 1a. Seven combinations of slopes  $m$  and  $s$  were tested for regular waves while two combinations were tested for irregular waves. Tests were next conducted on equilibrium profiles, depicted in Figure 1b, for regular waves only. In these tests, water levels were varied since, according to the hypothetical slope concept, runup for given wave conditions should be greater when the water level is elevated due to the steeper average slope of the surf zone.

Waves were generated by a piston-type wavemaker and, because of the lack of reflection compensation in the short wave basin, test durations were kept relatively short. In regular wave tests, typically 10 to 20 waves were generated for each combination of wave height and period. For each beach configuration, 20 combinations of  $H$  and  $T$  were tested producing 20 values of wave steepness. For irregular waves, tests were conducted in short "bursts" of about 30 waves. Ten such 30-wave sets were used for each combination of significant wave height and peak period tested so that about 300 waves were obtained for each wave spectrum tested. For each structure geometry, ten values of  $H_s$  and  $T_p$  were used producing 10 values of spectral wave steepness. All random wave tests used JONSWAP wave spectra with a peak enhancement factor of 3.3

Because the goal of this study was to evaluate the integrated runup solution in equation (10), measurements in each laboratory experiment included: (1) incident wave height and period, (2) breaking depth  $h_b$ , (3) surf zone width  $X_b$ , and (4) wave runup. Input to equation (10) consisted of the first three, with incident waves converted to equivalent deep water values. For irregular waves, measurement of input parameters was rather complicated since the breakpoint changes from one random wave to the next. Both the wave runup and the location of each breaking wave were recorded on video tape. Breaker depth was then determined from the observed surf zone width based on the known geometry.

### *Regular Waves on Bi-Linear Profile*

Results of tests conducted with regular waves on bi-linear beach profiles are shown in Figure 3. Each figure shows the normalized runup plotted as a function of the deep water wave steepness on a log-log scale so that the theoretical solutions plot as a straight line. In each figure, three theoretical predictions are shown: (1) the Hunt Formula based on the beach face slope  $m$  from equation (7), (2) the Hunt Formula based on the surf zone slope  $s$  from equation (8), and (3) the integrated runup method using the effective slope concept from equation (10). Though not shown, tests conducted on a uniform beach profile confirmed that both equation (10) and the Hunt Formula gave identical results in good agreement with the measured runup values for plane slopes.

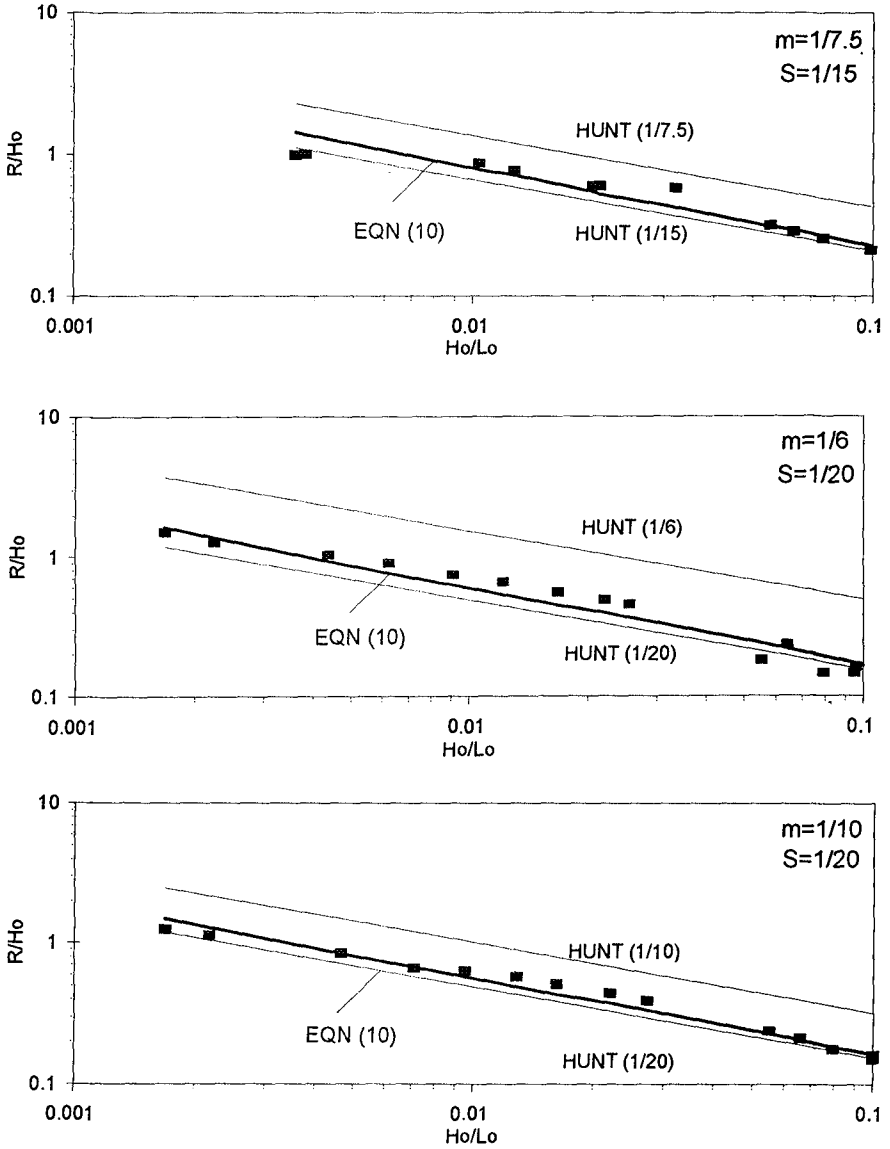

Figure 3. Comparison of measured and predicted runup for bi-linear beach profiles.

Figure 3a shows results for a bi-linear profile with a surf zone slope of 1-on-15 and a beach-face slope of 1-on-7.5. Figures 3b and 3c then show similar results where the surf zone slope was equal to 1-on-20, and where the beach-face slope was 1-on-6 and 1-on-10 respectively. In almost all cases, the measured runup (shown by solid squares) falls between the two limiting predictions based on the Hunt Formula using slopes  $m$  and  $s$ . It can be seen that the integrated method based on the effective slope concept provides a much better prediction in good agreement with the data.

These results suggest that the proposed method - integrating the Hunt Formula with Saville's effective slope concept - is capable of providing a simple unified description of regular wave runup on bi-linear beach profiles. For all 140 tests conducted on bi-linear profiles in this study, the Hunt Formula, based on the traditional use of the exposed beach-face slope  $m$ , over-estimates the runup by an average of 92%. Use of the surf zone slope,  $s$ , gives improved predictions but consistently underestimates the runup with an average error of 20%. The integrated method was found to predict runup to within an average error of 13.5%, although it also was somewhat biased toward under-estimating the runup.

### *Regular Waves on Equilibrium Profiles*

Results of tests conducted with regular waves on equilibrium profiles are shown in Figure 4. In these tests, a single equilibrium profile slope parameter was used with  $A = 0.088 \text{ m}^{1/3}$ . As depicted in Figure 2b, a linear beach-face slope was then joined to this concave equilibrium profile at a depth where the slopes matched. Two linear beach-face slopes were tested, but results in this paper are only shown for one slope,  $m=1/8$ . In Figure 4, three tests results are then shown, corresponding to three different water levels. Figure 4a shows results for a "mean" water level based on a 24.1 cm water depth in the wave basin. Figure 4b then shows a "high" water level condition based on a water depth of 30.4 cm, while Figure 4c shows a "low" water level condition based on a depth of 18.7 cm.

Each figure again shows the normalized runup plotted as a function of the deep water wave steepness on a log-log scale so that the Hunt Formula plots as a straight line. For equilibrium profiles, it is found however that neither the measured runup (solid squares) nor the predicted runup (open squares) based on the integrated method plots as a straight line with the same slope as the Hunt Formula. The reason for this is that, for any given value of wave steepness, the runup depends on the exact values of breaking depth and surf zone width. Because these vary nonlinearly on the concave beach profile based on the equilibrium profile shape  $h=Ax^{2/3}$ , the solution is then a unique function of  $h_b$  and  $X_b$ .

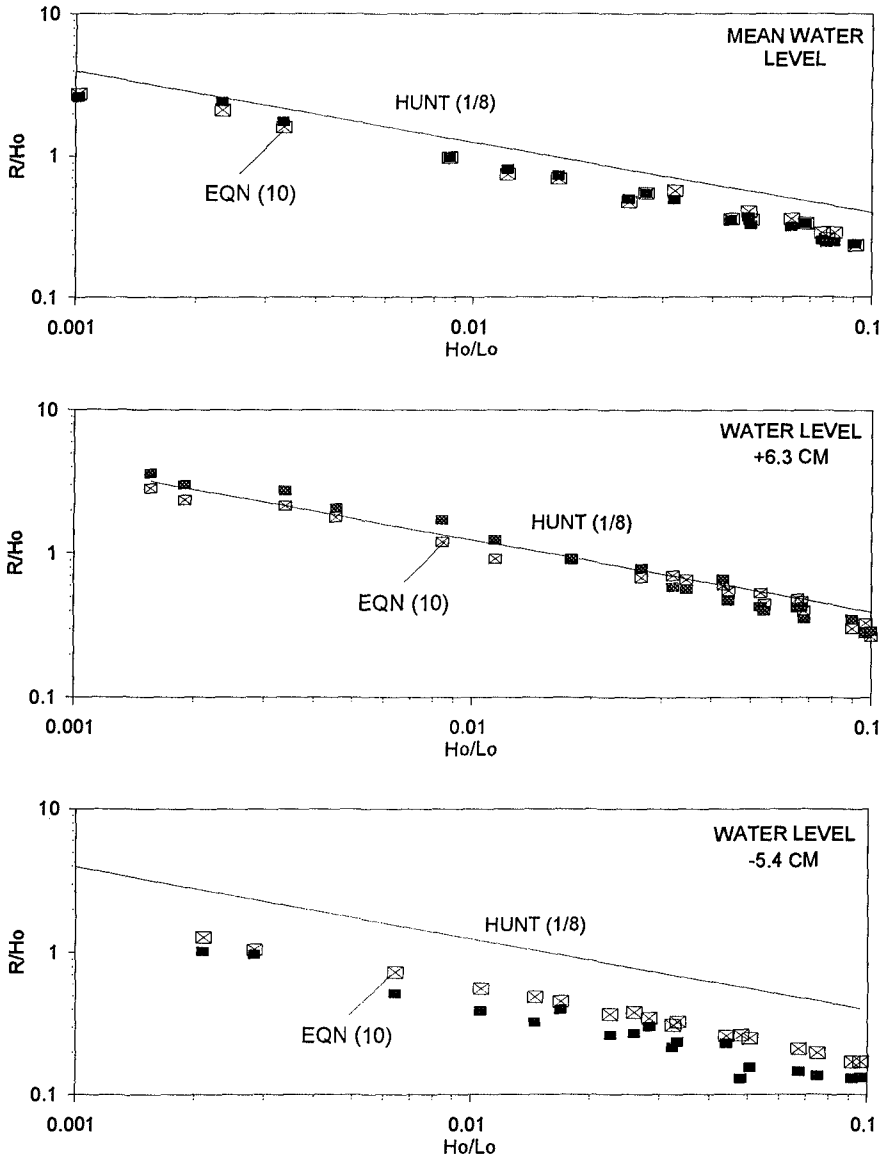

Figure 4. Measured and predicted runup over concave equilibrium profiles with  $m=1$ -on-8: (a) normal water level, (b) high water level, and (c) low water level.

For the mean water level condition, in Figure 4a, predictions based on equation (10) are in excellent agreement with measured values. Both are significantly below predictions from the Hunt Formula using the exposed beach-face slope. The difference is most pronounced for high steepness conditions where, in these experiments, the waves are relatively large and break far offshore yet produce relatively small runup so that the effective slope across the surf zone is fairly small.

In Figure 4b, for "high" water level conditions, measured and predicted runup agree much more closely with values predicted by the Hunt Formula using the beach-face slope. With the elevated water level, most waves now break on, or close to, the uniform beach-face slope so that the entire surf and swash zones are confined to the linear beach-face slope. Only in a few cases, with large waves having higher steepness, did waves break offshore on the concave portion of the profile so that runup was less much than expected from the Hunt Formula.

In contrast, Figure 4c for "low" water levels shows a large reduction in runup for essentially the same wave conditions used in the previous two tests. This is the result of the incipient break point being located far offshore over the concave portion of the profile. Measured runup is far below that predicted by the Hunt Formula using the beach-face slope of 1-on-8. Predictions based on the integrated method are in much better agreement but are somewhat higher than measured values. Figures 4b and 4c illustrate a strong dependence of runup on the profile geometry and water level that is rarely discussed in the literature. This should not be overlooked, however, as the measured values in this study show that runup may differ by about a factor of two over the range of water levels tested.

#### *Irregular Waves on Bi-Linear Profiles*

The integrated runup method in equation (10) was evaluated for irregular wave runup using statistical wave and runup parameters. Since most previous expressions for random wave runup have correlated statistical runup parameters to the incident significant wave height, a similar approach was used in this study. Incident wave conditions were described by both the mean and significant values for wave height and period. The mean and significant values for breaking depth and surf zone width were also determined from the video tape data of breaking waves. With these values as input, equation (10) was then used to predict the mean and significant runup values for comparison to the measured runup statistics.

Results of this analysis confirmed the results of Battjes (1971) that the mean runup could be predicted quite well using the mean wave conditions. Equation (10) gave quite good results when mean wave height, mean breaking depth, and mean surf zone width were used without use of any empirical coefficients. Use of the significant wave height in equation (10) produced runup estimates that were substantially below the measured significant runup. These results seem to indicate that the mean wave

conditions describe the best average slope across the surf zone for use in runup predictions according to the Saville hypothetical slope method. Use of significant wave conditions produced a flatter average slope since the significant breakpoint is located much farther offshore. In the integrated runup method, this smaller effective slope produces smaller runup estimates that do not agree with the measured values.

Examples of runup predictions using the integrated method in equation (10) based on mean wave statistics are shown in Figure 5. Dimensionless mean runup, defined as mean runup normalized by mean deep water wave height, is plotted against the mean wave steepness, defined as the mean wave height divided by deep water wavelength calculated by linear wave theory using the mean wave period of the random sea. In Figure 5a, results are shown for a baseline test on a planar beach profile having a 1-on-15 slope. These results confirm the ability of the Hunt Formula, and the integrated method which is identical to the Hunt Formula for a planar slope, to predict the mean random wave runup on uniform plane slopes. The results are in contrast to the findings of Mase (1989), however, who found that the Hunt Formula did not describe runup on plane slopes.

Figures 5b and 5c then show results for irregular wave runup on bi-linear profiles. It is evident that use of the Hunt Formula based on the exposed beach-face slope gives large over-estimates in the mean wave runup. Use of the integrated method, with the average slope defined by the mean breakpoint and the mean runup limit, then gives much better results. When the results in Figure 5 are analyzed, it is found that the Hunt Formula based on the linear beach-face slope gives an average error of 93% while the use of the Hunt Formula coupled with the Saville effective slope concept gives an average error of just 12%. As with regular waves, the integrated method tends to be slightly biased toward under-estimating the runup.

Additional subjects of concern for design are the distribution of runup about the mean value and the extreme runup statistics. In this study, it has been found that, while incident waves and breaking depths are described quite well by the Rayleigh distribution, the runup distribution is wider than the Rayleigh distribution with both more small runup events and more very large runup events. As a result, the assumption of a Rayleigh distribution for runup is not valid over composite-slope beaches.

Results of this study indicate that the ratio between the significant runup and the mean runup is between 1.5 and 2.0, with an average of about 1.8. In contrast, the Rayleigh distribution would suggest a ratio of 1.6. Similarly, the ratio between the average of the largest ten-percent of the measured runup events to the mean runup varied between about 1.8 and 2.7 with an average of about 2.25. The Rayleigh distribution would suggest a ratio of 2.0. In general, no specific functional dependence was found between these ratios and either wave steepness or the surf similarity parameter, although there was a general trend toward greater ratios for the higher-steepness, more energetic waves.

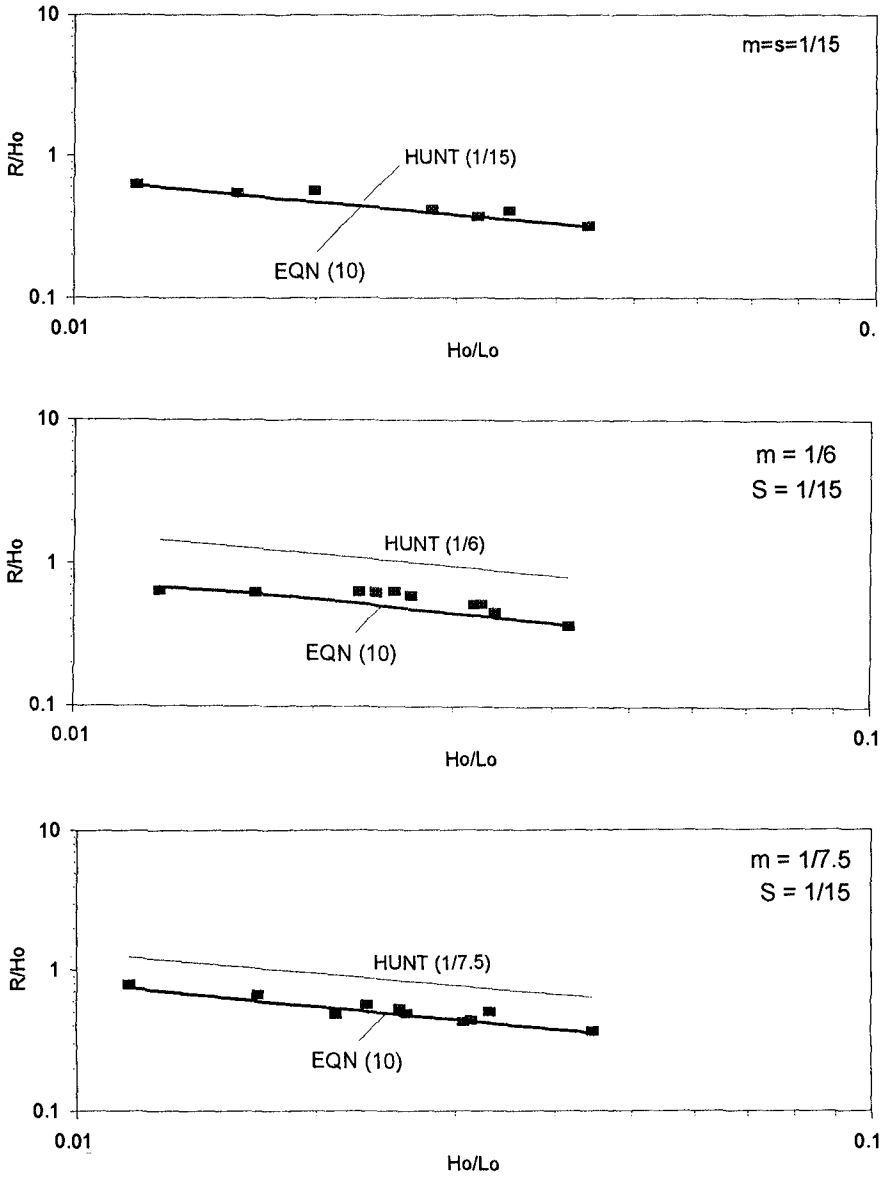

Figure 5. Comparison of measured and predicted runup of irregular waves on (a) linear profile and (b) bi-linear profiles. All wave heights are mean values.

### Alternative Integrated Runup Method

The integrated runup method presented above works well but is complicated by the requirements that: (1) the breakpoint of incident waves must be determined *a priori* and (2) the runup limit is initially unknown and enters the description of the effective beach slope. An alternate effective slope concept of de Waal and van der Meer (1992) overcomes these difficulties by defining the effective slope between points on the profile that are a distance of  $H_o$  above and below the still-water level. For a bi-linear beach profile, the effective slope according to de Waal and van der Meer is given by  $\tan\beta = 2ms/(m+s)$  and the runup based on the Hunt Formula is then

$$R = \frac{2mS}{m+S} \sqrt{H_o L_o} \quad (11)$$

Results of equation (11) for the mean runup are shown in Figure 6. Also shown are the predictions from the integrated method in equation (10) and from the empirical equations of Mase (1989). As shown, the method of de Waal and van der Meer produces results that have approximately the same average error as obtained using the Saville effective slope concept. The method of Mase over-estimates the runup severely primarily since it is based on planar uniform slopes.

Figure 6. Comparison of measured and predicted mean runup in random waves from various prediction methods.

### CONCLUSIONS

This paper has included two main parts: (1) the development of a simple integrated method for predicting runup on composite-slope beaches and (2) the experimental verification of this integrated approach in both regular and irregular waves. It has been shown that by combining the Hunt runup formula with the Saville

effective slope concept, an analytical solution is obtained for runup over idealized bi-linear and equilibrium beach profiles. The solution can also be obtained by iterative methods for use in existing numerical models for surf zone hydrodynamics or beach profile change to estimate the runup over more complicated beach geometries.

The integrated method demonstrates that runup over concave and bi-linear beach profiles is less than would be expected from the Hunt Formula based on use of the exposed beach-face slope. Laboratory tests conducted on impermeable smooth slopes tend to verify the analytical solution for both bi-linear beaches and concave equilibrium beaches in both regular and random waves. While additional work on extreme runup statistics in random waves is needed, preliminary results indicate that the integrated method can be applied directly using the mean incident wave height to estimate the mean runup.

## CHAPTER 169

### Simulation of nearshore wave current interaction by coupling a Boussinesq wave model with a 3d hydrodynamic model

ROBERTO MAYERLE, ANDREAS SCHRÖTER and WERNER ZIELKE <sup>1</sup>

#### ABSTRACT

This paper describes a deterministic modelling system under development at the Institute of Fluid Mechanics in Hannover to simulate three dimensional wave induced currents and the morphological evolution in the nearshore region. It is basically a coupling of a 2d Boussinesq wave model which predicts the wave motion along the horizontal direction with a 3d hydrodynamic, sediment transport and morphodynamic models that simulate the time averaged wave induced currents and the associated changes in the bathymetry due to sediment transport. It is intended to improve the understanding of morphological processes, investigate the impact of sea level rises due to climate change, study extreme events and assess in the selection of cost effective measures for coastal protection. Results of a demonstration of the simulation of the wave induced currents along a nearshore region in the Baltic Sea are shown.

#### 1. INTRODUCTION

Along the coast it is possible to distinguish between the erosion processes due to mean hydraulic conditions, that has an impact on large time scales (seasons, years), and due to extreme hydraulic conditions, that are restricted to small time scales (hours to days). Beach and dune erosion at large time scales are usually due to net positive, longshore sediment transport gradients. Short term erosion takes place occasionally during less frequent extreme events such as storms and hurricanes and the significant profile changes are restricted to the upper part of the coastal profile.

On the other hand, the morphological evolution in the nearshore region is the result of highly complicated three dimensional processes that combine tur-

---

bulent, oscillatory (wave) and current motion. In particular within the breaker zone the turbulence generated by wave-breaking is intensive. A number of hypotheses have been formulated to describe the process of bar formation within the surf zone. Although it may involve several mechanisms, the most reasonable explanation relates to the wave driven circulation currents in the vertical plane known as undertow. If a movable bed with constant slope is exposed to waves, a bar will develop close to the point of wave breaking. This is due to the sediment transport within the breaker zone being directed away from the coast due to the undertow. Besides, intensive wave breaking generates high turbulence levels causing large amounts of sediment to suspend, thus being the transport of this suspended sediment the predominant transport mechanism under such conditions.

Until recently most of the numerical model simulations in the nearshore region have been carried out using 2d models. Although in some cases it is possible to capture the main patterns with depth or laterally averaged models, only part of the sediment transport is taken into account, i. e. either the longshore or the cross-shore sediment transport is captured. In other words the models describe either the transport along with time and depth averaged currents, or the transport due to waves and vertical circulations in a more or less cross-shore profile. In more complex situations, it makes little sense and neither transport should be neglected.

Nowadays, there are a number of numerical models under development for short term coastal profile evolution for direct incoming waves. An intercomparison among six models developed with different degrees of refinement and empiricism was carried out by Hedegaard et al., 1992. The models were tested against experimental results obtained at the large wave flume in Hannover in a pure 2d depth vertical case. The results showed that it is relevant to go to full or quasi 3d modelling of currents and suspended sediment to be able to judge where the major research efforts should be spent in the years to come (Roelvik and Brøker, 1993).

The 3d modelling system under development is intended to handle short term events in the nearshore region and to reproduce wave induced currents and the associated changes in the bathymetry adequately. It is also to improve the understanding of morphological processes, investigate the impact of sea level rises due to climate changes, study extreme events and assess in the selection of cost effective measures for coastal protection. With the improvements in computer efficiency and algorithm performance, process-based or deterministic wave modelling in the time domain are within reach. However, unless the wave phenomena in the horizontal direction is properly simulated there is little gain in going to three dimensional modelling. As linear wave models do not apply well in the nearshore region, the proposed modelling system is a coupling of a 2d nonlinear time discrete Boussinesq wave model with a 3d hydrodynamic and sediment transport models. The wave model computes the wave field along the horizontal direction whereas the 3d model is responsible for the time averaged wave induced currents and the associated changes in the bathymetry due to sediment transport. The suggestions proposed by Svendsen and Lorenz (1989) in solving a modified set of the Navier-Stokes equations for three dimensional wave induced currents were followed. The radiation stresses, wave set-up and wave trough level needed for the solution of these equations result from the

application of the wave model. A description of the approach adopted and a demonstration of the simulation of the wave induced currents along a small stretch on the German coast in the Baltic Sea are presented.

## 2. APPROACH

The three dimensional wave induced currents are described by a set of modified Navier-Stokes and the continuity equations that are solved respectively for the velocities along the horizontal plane and vertical. The velocities along each direction ( $x$ ,  $y$  and  $z$ ) are replaced by three contributions respectively: the mean (current) component ( $U$ ,  $V$  and  $W$ ); a purely periodic component correspondent to the wave motion ( $u_w$ ,  $v_w$  and  $w_w$ ) and a turbulent velocity fluctuation ( $u'$ ,  $v'$  and  $w'$ ) as follows:

$$\left. \begin{aligned} u &= U + u_w + u' \\ v &= V + v_w + v' \\ w &= W + w_w + w' \end{aligned} \right\} \quad (1)$$

The resulting set of modified Navier Stokes equations (Svendson and Lorenz, 1989) are:

$$\frac{\partial U}{\partial t} + \frac{\partial U^2}{\partial x} + \frac{\partial UV}{\partial y} + \frac{\partial UW}{\partial z} + \frac{\partial(\overline{u_w^2} - \overline{w_w^2})}{\partial x} + \frac{\partial \overline{u_w v_w}}{\partial y} + \frac{\partial \overline{u_w w_w}}{\partial z} = -g \frac{\partial b}{\partial x} - \frac{\partial(\overline{\tilde{u}'^2} - \overline{\tilde{w}'^2})}{\partial x} - \frac{\partial \overline{\tilde{u}' v'}}{\partial y} - \frac{\partial \overline{\tilde{u}' w'}}{\partial z} \quad (2)$$

$$\frac{\partial V}{\partial t} + \frac{\partial V^2}{\partial y} + \frac{\partial UV}{\partial x} + \frac{\partial VW}{\partial z} + \frac{\partial(\overline{v_w^2} - \overline{w_w^2})}{\partial y} + \frac{\partial \overline{u_w v_w}}{\partial x} + \frac{\partial \overline{v_w w_w}}{\partial z} = -g \frac{\partial b}{\partial y} - \frac{\partial(\overline{\tilde{v}'^2} - \overline{\tilde{w}'^2})}{\partial y} - \frac{\partial \overline{\tilde{u}' v'}}{\partial x} - \frac{\partial \overline{\tilde{v}' w'}}{\partial z} \quad (3)$$

In the equations  $t$  is the time,  $g$  is the acceleration due to gravity and  $b$  is the wave set-up. The superscripts  $\tilde{\phantom{x}}$  and  $\bar{\phantom{x}}$  have been used to denote respectively ensemble-averaging and averaging over a wave period. The terms  $\partial U^2/\partial x$  and  $\partial V^2/\partial y$  represent the momentum flux from the cross-shore and long-shore currents whereas the  $UV$ -term represents the coupling between the two current components. The  $\overline{u_w^2} - \overline{w_w^2}$  and  $\overline{v_w^2} - \overline{w_w^2}$  are the wave radiation stress components. The  $\partial/\partial x$ -component is one of the key elements in the driving mechanism for the undertow although it is generally small in comparison to other components such as the pressure term  $\partial b/\partial x$ . The  $\overline{u_w v_w}$  is the tangential radiation stress term responsible for creating the longshore flow  $\partial \overline{u_w v_w}/\partial x$  and the crossshore flow  $\partial \overline{u_w v_w}/\partial y$ . The terms  $\partial \overline{u_w w_w}/\partial z$  and  $\partial \overline{v_w w_w}/\partial z$  represent the horizontal stresses created by the oscillatory wave components. The remaining terms are the Reynolds' stresses.

The vertical velocity is obtained by solving the continuity equation similarly to the approach used by Pechon, 1992:

$$\frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} + \frac{\partial W}{\partial z} = 0 \quad (4)$$

The equations are applied only within the central layer, from the bottom boundary layer to the wave trough level. Above the wave trough level, where there is water only part of the time, a current velocity component cannot be defined. Their solution assumes knowledge of the oscillatory wave motion to determine the radiation stresses and to define the wave set-up elevation and the wave trough level. An eddy viscosity model based on the mixing length is used for computing the Reynolds stresses. At the bottom, a partial slip boundary condition related to the logarithmic law is used. At the wave trough level, the wave induced currents are computed similarly to the other nodes located within the central layer, since it is also within the water body. The pressure distribution is assumed uniform along the vertical and the radiation stresses come from the application of the wave model.

### 3. MODELLING SYSTEM

The modelling system includes a wave module that computes the wave related quantities (wave trough level, wave set-up and radiation stress) and 3d hydrodynamic, sediment transport and morphodynamic modules responsible respectively for the three dimensional wave induced currents, sediment transport (bed plus suspended loads) and bed evolution.

The wave module is based on an extended form of the Boussinesq wave equations with improved dispersion and shoaling properties in deeper water (Schröter et al., 1994). Refraction, diffraction, reflection and interaction of the different directions of incoming waves and components are included (Prüser and Zielke, 1990). Short and long water waves of arbitrary shape with high resolution up to depth to wave length ratio of about 1.5 can be handled adequately. It should be stressed that although the equations are solved for the depth averaged wave induced currents along the horizontal directions, a vertical velocity distribution is implicit in the derivation of the Boussinesq equations. A parabolic and linear distribution along the vertical apply respectively for the horizontal and vertical velocities. Besides, since the resulting velocities are already wave induced components, the current component contribution needs to be subtracted in order to determine the oscillatory wave motion and thus the radiation stress distribution along the vertical.

The hydrodynamic module uses a numerical model originally developed at the Center for Computational Hydrosience and Engineering in Oxford, USA. The first author participated in the development, improvement and verification of the model. It was originally developed to solve two Navier-Stokes for the velocities along horizontal directions, the kinematic condition on free surface for the surface elevation and the flow continuity equation for the vertical velocity component (Wang et al., 1992). The model was changed to solve the modified set of Navier-Stokes and continuity equations from the bottom to the wave trough level. It uses quadrilateral structured grids with constant number of nodes along the vertical. Along the horizontal the grid system is kept throughout the simulation whereas along the vertical it adjusts itself to the changes in the wave trough level and bathymetry.

In the sediment transport module, the total load is obtained by adding bed to suspended loads. The bed load is based on empirical equations and the suspended load results from the solution of the convection-diffusion equation.

The influence of the waves on the sediment transport is included. The morphodynamic module or the bed evolution module is assumed to be governed by the sediment continuity equation.

The wave induced currents and the associated changes in the bathymetry are obtained in successive steps using alternatively the wave, hydrodynamic and morphodynamic modules (Figure 1). Along the horizontal directions the grid system is kept the same. A constant number of nodes throughout the domain is defined along the vertical direction for the three dimensional simulations. The simulations for a given bathymetry begin with the wave module and are carried out until the changes in the time integrated wave related quantities are no longer significant. Then the time averaged radiation stresses (at every node within the three dimensional domain), wave set-up elevation and wave trough level are determined. Next, a nearly steady state three dimensional wave induced current is computed below the wave trough, for the same bathymetry, by the hydrodynamic module. In the sediment transport module the total sediment transport is evaluated. Finally, the resulting wave induced currents are used to compute the bed elevation changes by the morphodynamic module. Once the bed evolution anywhere in the domain is significant, the wave module is recalled and updated wave related quantities are determined for the new conditions. This sequence is carried out repeatedly advancing the solution in time.

Figure 1. Modelling system.

#### 4. DEMONSTRATION

Results of a demonstration of the modelling system to the simulation of three dimensional wave induced currents without sediment transport along a nearshore stretch were carried out to show its applicability. The domain simulated (300m longshore by 120m cross-shore) is a small stretch on the German coast in the Baltic Sea (Figure 2) with two lines of groynes (150m apart) normal to the coastal line. The bathymetry was defined from five cross-shore profiles. Wave conditions measured in June 1992 at three gauges located in the center, just upstream of the simulated domain were considered in the simulations. The estimated wave spectrum used in the simulations is shown in Figure 3. Wave

lengths from 15m to 70m and mean water depths from 0.2m to 2.9m were observed. The simulations were carried out for the conditions described above. Only wave induced currents without sediment transport were considered.

Figure 2. Bathymetry of the simulated domain.

*ENERGY DENSITY* [ $\text{m}^2/\text{Hz}$ ]

Figure 3. Measured spectrum of the incoming waves.

The simulations with the wave module (Boussinesq model) were carried out for 500s. Results at this time level are shown in Figure 4. Experience shows that at least 10 nodes are required per wave length in order to capture the main wave phenomena properly. Therefore, a highly refined finite difference grid with 152 by 292 nodes ( $\Delta x = \Delta y = 1\text{m}$ ) in conjunction with time steps equal to 0.1s were used. The information needed to define the three dimensional domain and to solve Eqns. 2 to 4 were obtained by averaging the results obtained in the application of the wave module from the time levels 250s to 500s.

Figure 4. Simulated waves with the Boussinesq wave model.

The three dimensional simulations used a slightly coarser grid along the horizontal directions. The domain was defined by 73 x 38 nodes respectively along the longshore and cross-shore directions. A 4m grid spacing was considered along the horizontal directions. Along the vertical, 10 nodes were placed from the bottom to the elevation of the wave trough level. On the sides of the domain, total slip boundary conditions were used. Results of a quasi-steady state wave induced current field are shown in Figures 5 to 7. In Figures 5 and 6 the resulting three dimensional wave induced currents respectively at the bottom and at the elevation of the wave trough level are shown. Although the circulations are mainly along the horizontal directions, vertical circulations are also present. Notice that in the vicinity of the sand bank the velocities are directed seawards especially near to the bottom.

The tracks of several particles released from two different velocity profiles (see Figures 5 and 6) are shown in Figure 7 to illustrate the highly three dimensional conditions in the vicinity of the sand bank. Although it is difficult to judge without direct comparisons with measurements whether the resulting wave induced currents were adequately captured, it can be seen that they are highly three dimensional.

Figure 5. Three dimensional wave induced currents at the bottom.

Figure 6. Three dimensional wave induced currents at the wave trough level.

Figure 7. Particle tracks.

## 5. CONCLUSIONS

This paper shows the results of a simulation of a stretch on the German coast using a 3d deterministic wave modelling system under development. The results show the models ability in describing highly complicated conditions within the surf zone. The coupling of a Boussinesq wave model with a 3d model implemented with a set of modified Navier-Stokes equations enables the most important wave phenomena of interest to the coastal engineer to be captured. Further improvements and verifications of individual models, treatment of boundary conditions and of the layer between wave trough and wave crest, incorporation of hydrodynamic pressure, improvements to the sediment transport module as well verifications of the modelling system with three dimensional measurements are envisaged.

## 6. ACKNOWLEDGEMENTS

This work is part of the project SFB205 TP B4 sponsored by the German Research Association (*Deutsche Forschungsgemeinschaft*). The authors would like to thank Mr. F. Behrendt for his assistance in the preparation of the figures with an Application Control Environment based on AVS/UNIRAS Visual Systems(Germany) and Dr. Schönfeldt of the Zingst Maritime Observatory - Leipzig University for providing the measurements.

## CHAPTER 170

### EXPERIMENTAL RESULTS OF WAVE TRANSFORMATION ACROSS A SLOPING BEACH

Constantine D. Memos<sup>1</sup>, Member ASCE

#### Abstract

Experiments have been conducted to investigate the transformations of the wave characteristics induced by a uniformly decreasing sea bed. These transformations were recorded on both the frequency and the time domain representations of random wave trains. The coastal zone upwind of severe breaking was studied. Among the findings it is noted the tendency of the spectrum width parameter to decrease at a slowing rate as the waves propagate on shoaling waters. Also, the correlation coefficient between wave heights and periods seems to inversely follow the variations of a measure of the wave heights. A mathematical model has been developed based on existing results for shoaling, wave breaking and decay. This model applicable to a wide area of the surf zone predicts adequately the evolution of the joint probability between wave heights and periods provided by the experimental results.

#### Introduction

Wind wave modeling in the surf zone and the transitional waters is of central importance to coastal engineering. Albeit, shallow water waves in coastal areas are much more complex to model compared to waves in deep water. The transformations of random waves propagating into shallow water are governed by various processes, that are usually described by the source terms in an energy-balance equation. Apart from the wind action on the sea surface, the dissipation due to "white capping" and the nonlinear wave-wave interactions, factors that influence wave propagation in deep water, shallow water waves are additionally affected by processes such as shoaling, refraction, diffraction, reflection, bottom friction and wave breaking due to depth limitation.

---

<sup>1</sup> Civil Engineering Department, National Technical University of Athens, Greece.

Depth-controlled shoaling and wave breaking play a dominant role in modifying the waves as they travel across the beach. The depth-induced wave breaking affects the whole frequency band in a way similar to the shoaling process. In fact, breaking can be regarded as the final stage in a combined shoaling/breaking transformation. This transformation can be tracked either on the frequency spectrum of the incoming waves or on the relevant statistics of wave heights and periods based on the representation of the wave train in the time domain.

The latter representation contains more information on the statistical structure of the sea state and seems to suit better the probabilistic approach to the design of coastal defences.

### Existing Results

Various approaches have been used in the past to investigate and model the transformations to the probability density function (pdf) of the wave heights induced by wave shoaling/breaking due to depth limitation. The earlier models (Collins, 1970; Battjes, 1972; Kuo, 1974; Goda 1975) describe shoaling as only dependant on the local water depth. The common idea of all local-depth models is to cut off the portion of the wave height pdf beyond a breaker height controlled by water depth.

Collins and Battjes used a sharp cut-off of the Rayleigh pdf with all broken waves having heights equal to the breaker height  $H_b$ . Kuo and Kuo assumed the broken waves to have some height smaller than  $H_b$  after breaking and produced a sharply truncated Rayleigh pdf renormalized to unity. Goda's approach constitutes a refined version of the previous methods in that wave breaking occurs with linearly varying probability over a range of wave heights  $H_{b1}$  to  $H_{b2}$ , resulting in a distribution with a gradual cut-off around  $H_b$ . Figure 1 illustrates the above assumptions as regards the modification of the wave height pdf due to wave breaking.

Fig.1 Modification of wave height pdf due to wave breaking

A second type of models (Battjes & Janssen, 1978; Thornton & Guza, 1983; Battjes and Beji, 1992) are based on integrating the energy-flux balance equation with wave height as it is transformed by the shoaling process along a path starting in deep water. Models applying the energy-flux balance calculate wave heights by employing the energy dissipation due to a bore, to model the shallow-water wave breaking. This involves a bore dissipation function adjusted through a variable parameter to each individual breaker type.

To simplify the analysis both types of models assume that the waves are narrow-banded in frequency, so that all wave heights of the distribution are associated with the same average frequency. Therefore, starting in deep water, the wave heights are described by the single parameter Rayleigh pdf, which is modified accordingly as the waves propagate over the shoaling beach.

A further method to tackle the problem of random wave shoaling is the wave-by-wave analysis, that permits more realistic inclusion of the physics of the process. This approach selects randomly offshore waves from a known joint distribution between heights and periods, transforms individual waves and then reassembles the wave heights into probability distributions across the surf zone. In fact recent studies indicate that much of the behavior of random waves in the surf zone can be represented by the behavior of a set of individual regular waves (Dally and Dean, 1986; Ebersole 1987; Dally 1990; etc). Dally (1992) presented such a method by using as input the joint pdf of wave heights and periods proposed by Longuet-Higgins (1983). However, this density function is limited mainly to narrow banded spectra. It is noted that a simpler technique employing only the characteristic wave height and the wave period at peak has been suggested by Kamphuis (1994), avoiding the computations for many regular waves as originally proposed. However, this approach is suited rather for the spectral representation than for the joint pdf of the waves.

### Scope of Present Research

Motivation for the present investigation was provided by recent results regarding the joint pdf of wave heights and periods applicable to the more realistic broad banded power spectrum (Memos & Tzanis, 1994). The scope of this research is to study experimentally the transformations on the time and frequency domain incurred during the initial phases of shoaling in the transitional water depths prior to intense breaking. Also, a synthetic model on the joint pdf of shoaling/breaking waves in a wider zone of a uniformly sloping bed is presented along with some initial results.

The experiments have been conducted in the 50 m-long random wave flume of Imperial College, London and the data analysis was performed at the Technical University of Athens.

### Experimental Set-up

The experiments aimed at studying the behavior of random unidirectional waves propagating over a beach of decreasing depth and they were carried out in a 50m-long random wave flume. The set-up allowed data collection at probes placed over a flat beach sloping at 5.5%, while the water depth was kept around 1m over the horizontal bed of the flume (Fig. 2).

Fig.2 Experimental set- up

The random wave machine spanned the 2.78 m wide flume and was fed with signals of prescribed spectral characteristics. The data were collected from twin wire probes through an analog-to-digital converter. In all 27 runs were carried out, each one having a different input signal.

The transitional waters and outer surf zone was mainly investigated, where wave breaking and set-up occurred at low percentages, thus excluding the significant effect of wave reforming, which could otherwise "contaminate" the results of the present study of the shoaling process. Also, in this region the bed friction effect was rather reduced and could easily be ignored.

The investigation of the transformations referred to both the frequency and the time domain representations of the wave train.

### Main Findings and Discussion

The main results related to the transformation of the power spectrum across the outer surf zone are based on results of 4 representative experimental runs. These findings are the following:

- (a) In general the peak frequency of the input spectrum did not change significantly after the waves have travelled for 31m from the wave machine to the first probe. Also, the peak energy density and the frequency at peak tend to be stable as the waves propagate over the beach. This happened in all 27 runs. The shape of the spectrum around the peak was found to be

stable, too. It is noted that since we are studying the outer surf zone, with little wave breaking the spectrum tends to increase slightly in energy prior to major dissipation due to intense wave breaking.

The above stability of the shape of the spectrum and of the frequency at peak have been reported also by other researchers (Cai et al., 1992; Resio, 1987; etc).

- (b) A systematic modification of the rear face of the spectrum was taking place as the waves propagated into shallower waters. This is due to conservative non-linear effects in accordance with Kitaigorodskii's modification of the tail of the spectrum in shallow water behaving there like  $f^{-3}$  rather than  $f^{-5}$ , where  $f$  the frequency (Bouwes and Komen, 1983).
- (c) A transfer of energy to the forward face of the spectrum was also noticed. This, has again been verified by other investigators (Mase & Kirby, 1992; Resio, 1987).
- (d) A second peak is usually being developed at twice the peak frequency of the spectrum, presumably due to bound waves (Bendykowska and Werner, 1989; Memos, 1990; etc.).

All points mentioned previously can be observed in Fig. 3.

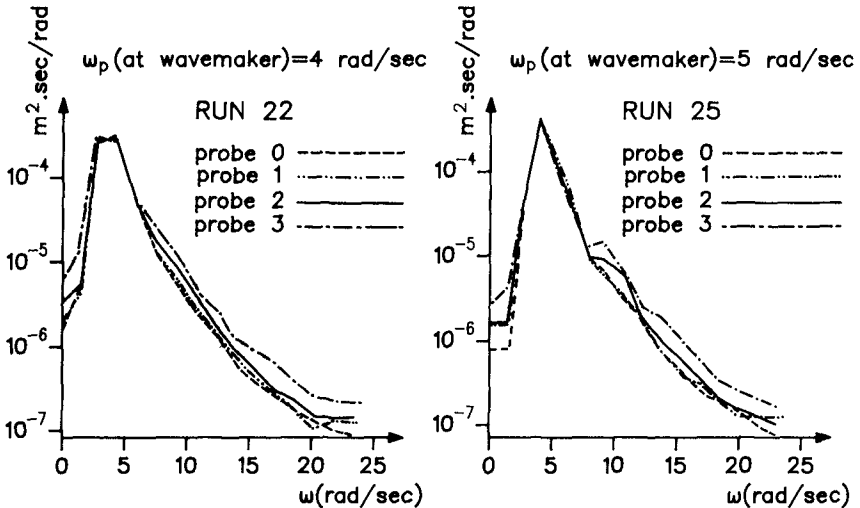

Fig. 3 Modification of wave energy spectrum

- (e) A systematic narrowing of the spectrum established by the decrease of spectral width  $\epsilon$  as the waves propagate from deep water toward the surf zone was detected (Fig. 4). It appears that a lower limit of  $\epsilon$  around 0.4 is reached at the most innershore probe, regardless of the initial width of the input spectrum (with  $\epsilon > 0.4$ ). This seems to be a new result.

Fig. 4 Variation of bandwidth parameter  $\epsilon$  across the beach

Referring to the variation of wave heights and periods across the slope, the following points can be made for the time domain representation of the waves:

- (f) No major deviation of the wave heights pdf from the Rayleigh distribution occurs within the considered zone. Only a small redistribution of energy seems to take place around the peak of the pdf of wave heights (Fig. 5). This has been reported, also, by Thornton & Guza (1983).
- (g) A mild increase of the mean wave period with wave propagation was also detected (Fig.6).
- (h) The joint pdf of wave heights  $H$  and periods  $T$  showed an overall stability in line with the stability displayed by the energy spectrum. This can be seen in Fig. 7, where the corresponding joint pdfs for the 4 locations have been plotted for one run. However, a trend of more  $H$ - $T$  pairs accumulating close to the modal values was uncovered by estimating the double integral  $\int \int p dHdT$  for, say,  $p > 1.0$ . The results for 2 runs shown in Fig. 8 exhibit this tendency. This accumulation can also be verified in the marginal distribution of wave heights along the mean period, as shown in Fig. 9.

Fig. 5 Evolution of wave height distribution

Fig.6 Variation of wave height and period across the beach

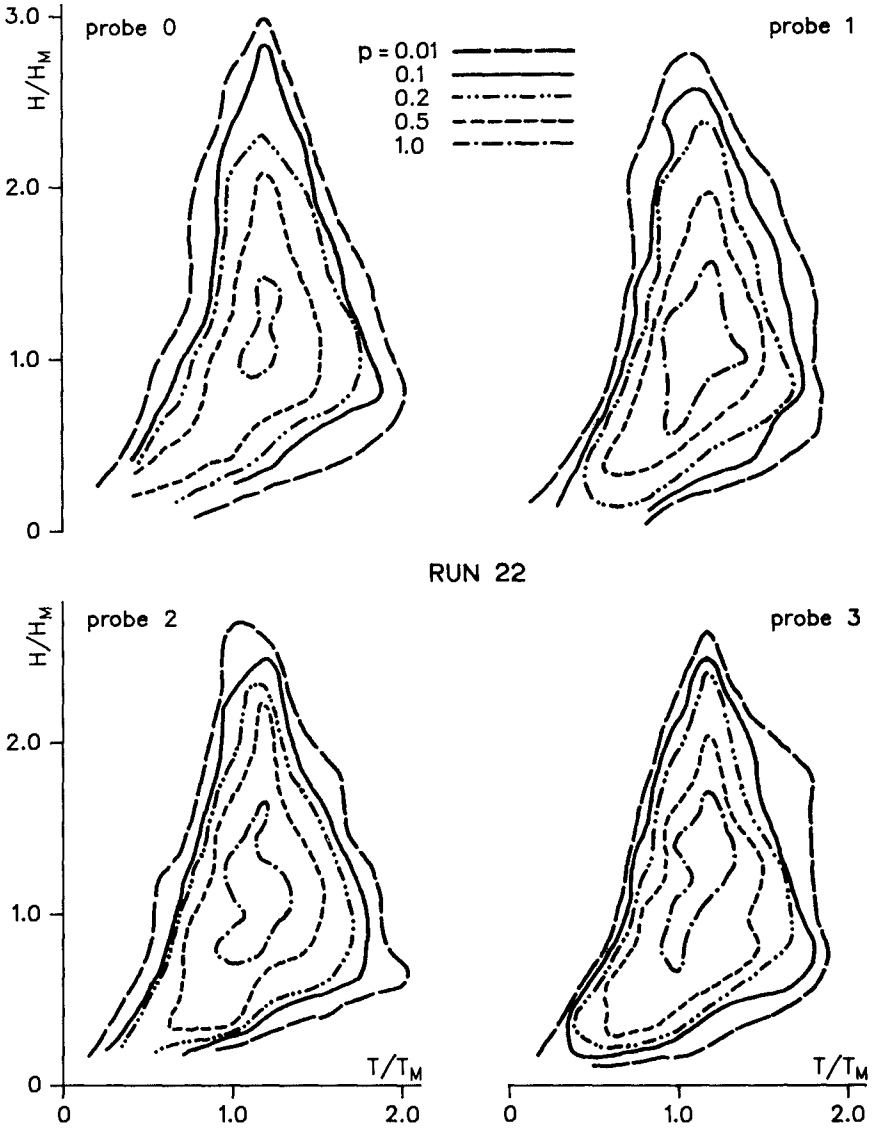

Fig. 7 Joint pdf of H-T at 4 gauges

Fig. 8 Higher probabilities for higher waves

Fig. 9 Marginal distribution of H along the mean period

- (i) The variation of the correlation coefficient  $r$  between wave heights and periods can be seen in Fig. 10. A similar trend with that of the

spectrum bandwidth parameter  $\varepsilon$  can be observed, the difference lying in that  $r$  reaches a minimum value within the outer surf zone under examination. This seems to correspond to the variation of the wave heights over the slope. For decreasing  $H$  we obtain increasing  $r$  and vice versa (cf Figs 6 and 10).

Fig. 10 Variation of  $r(H,T)$  across the beach

This relation can be said that is generally valid in wind waves: for large enough wave heights the inherent correlation between heights and periods becomes looser and the extreme wind waves are in general associated with a narrow band of periods. The same phenomenon is also demonstrated in the scatter diagrams of short term wave heights and periods, which are nearly symmetrical for large wave heights with respect to a vertical axis, implying little correlation between  $H$  and  $T$ .

Based on the experimental data the relationship between the variation of  $r$  and wave height is depicted in Fig. 11, which clearly shows that indeed there exists a kind of law between the two variables.

The horizontal axis denotes the relative increase of the wave height in terms of  $\Delta\bar{H}/\bar{H}$ ,  $\bar{H}$  mean value, and the vertical gives the variation  $\Delta r$ . A main feature of the graph is that for an increase in  $\bar{H}$  we have a corresponding decrease in  $r$ , and vice versa, as already noted previously.

#### A Simple Wave Shoaling/Breaking Model

A mathematical model based on existing results for depth-induced shoaling, wave breaking and decay has been developed to check the experimental data. The wave-by-wave approach, referred to previously, has

been applied. It is noted that this technique is better suited for the surf zone rather than the transitional waters where our experiments were confined. However, its performance in such depths was quite acceptable, as it will be shown later.

Fig.11 Relation between  $\Delta\bar{H}$  and  $\Delta r$ .

Cnoidal wave theory has been assumed to apply for the shoaling process and as a good first approximation the record at probe (0) was assumed to represent deep water conditions. Following Shuto (1974) as modified by Goda (1975), the shoaling transformations given below were taken into account.

$$H = H_0 K(h), \quad h \geq h_1 \tag{1}$$

$$H = H_0 K(h_1)(h_1/h)^{2/7}, \quad h_2 \leq h \leq h_1 \tag{2}$$

where  $H_0, L_0$  deep-water wave height and wavelength

$H, L$  wave height and wavelength at depth  $h$

$$K(x) = 1/\{ [1+(4\pi x)/L \sinh(4\pi x/L)] \tanh(2\pi x/L) \}^{1/2} \tag{3}$$

$$h_1^2 = 0.209 H_0 L_0 K(h_1) \tag{4}$$

$$h_2 = 0.8 h_1 \tag{5}$$

When  $h < h_2$ , then solution of the following equation provides the shoaling coefficient  $K_1 = H/H_0$

$$K_1(\sqrt{K_1 - B}) - C = 0 \tag{6}$$

where  $B = 1.382h/h_0 (H_0/L_0)^{1/2}$  (7)

$C = C_2 (L_0/h)^{3/2} / (2\pi H_0/L_0)^{1/2}$  (8)

$C_2 = 3.693 K(h_1) (h_2/L_0)^{3/2} [(0.558 H_0/L_0)^{1/2} - h_2/L_0]$  (9)

The breaking criterion proposed by Weggel (1972) has been assumed. This reads as follows

$$\frac{H_b}{L} = (1/7) \tanh \left[ \frac{7h_b}{L} \frac{b}{1+\alpha(h_b/gT^2)} \right] \tag{10}$$

where  $H_b$  wave height at breaking

$T$  wave period

$\alpha = 43.75 [1-\exp(-19m)]$  (11)

$b = 1.56 / [1+\exp(-19.5 m)]$  (12)

$m$  bed slope

$h_b$  still water depth at incipient breaking.

Finally, wave decay after breaking has been included in the model after Dally et al. (1985) as follows.

$$\frac{H}{H_b} = \left[ (1+c)(h/h_b)^{(G/m)-0.5} - c(h/h_b)^2 \right]^{1/2} \tag{13}$$

where  $H$  the height of the decaying wave

$$c = \frac{\Gamma^2}{m[(2.5)-(G/m)]} (h/H)_b^2 \tag{14}$$

$G$  decay coefficient ( ~0.2 or lower)

$\Gamma \sim 0.35 \div 0.40$

Applying the above synthetic model to the experimental conditions mentioned earlier and taking as deep water conditions those recorded at probe (0), joint pdfs at locations (1), (2) and (3) can be produced for direct comparison with the experimental data. Figure 12 contains the model results for run 22 which are comparable with the experimental results shown in Fig. 7.

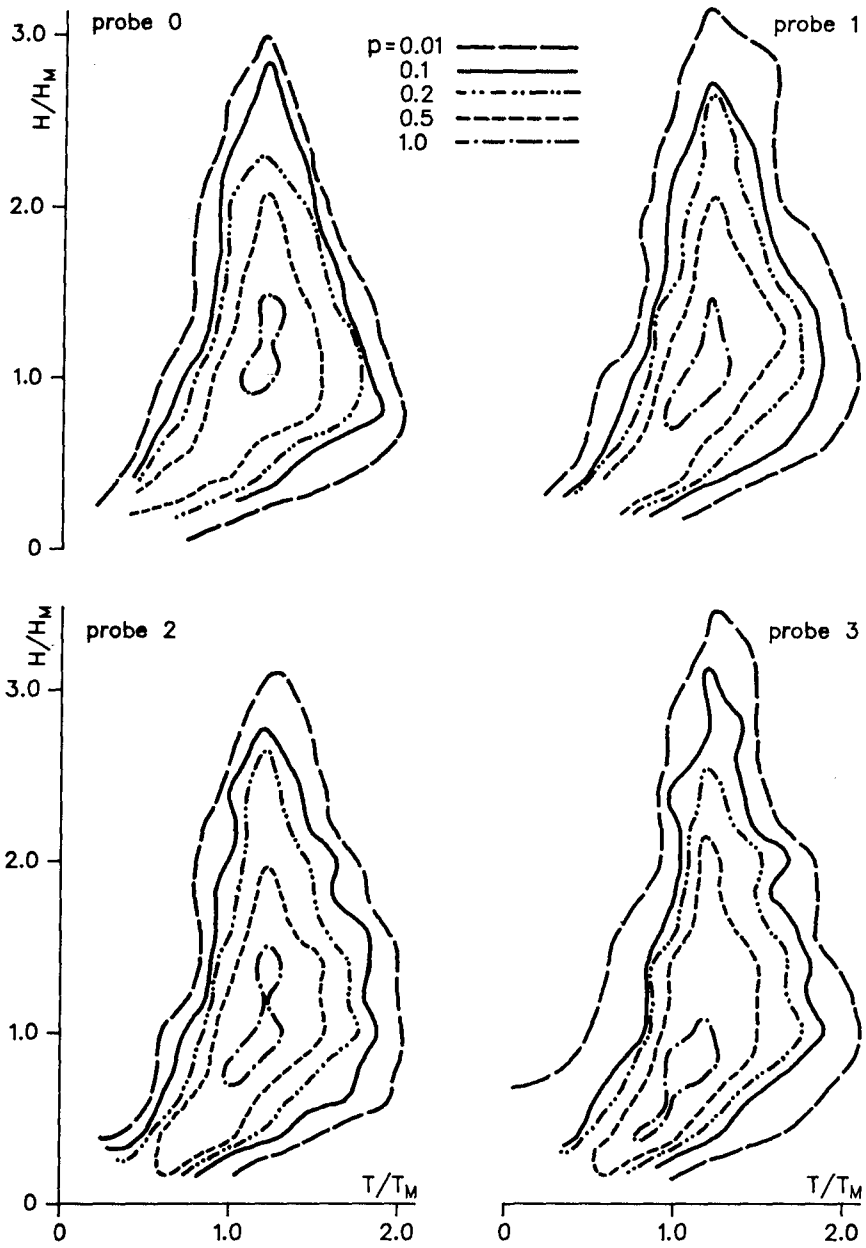

Fig. 12 Model results for run 22

The model results verifies the observed only slight variability of the joint probability structure, as the waves propagate over the sloping bed.

Agreement between the two sets of results is quite acceptable, despite the fact that the wave-by-wave technique is better suited for the surf zone inshore of probe (3), as noted above. Results for other runs indicate the same trend and agree similarly well with experimental data.

### Conclusions

Focusing on the new findings of the present research, we can conclude that the variations of both the bandwidth parameter  $\epsilon$  and the correlation coefficient  $r$  between wave heights and periods across the outer surf zone, follow a trend resulting from a general law governing the correlation between wave heights and periods for large heights. The correlation coefficient  $r(H,T)$  is closely related to the variations of a measure of the wave height across the beach, while the decrease of  $\epsilon$  seems to flatten out within the surf zone.

Also, that a synthetic model developed on existing results can adequately predict the variation of the joint probability density function between waveheights and periods in the outer surf zone of a sloping beach. Improvement of the model is currently underway by abolishing the assumption that the deep water conditions occur at probe (0) and, also, by assuming Stokian waves of the 3rd order rather than cnoidal waves for the shoaling part of the process. This description of the waves may suit better a transitional zone of deeper waters as those present in the experiments.

### Acknowledgments

My thanks are due to Dr K. Anastasiou of Imperial College for helping with the experiments and for providing the original of figure 3. Also, to K. Tzanis of National Technical University of Athens for performing the computations.

## CHAPTER 171

### A RELATIVE INTERCOMPARISON BETWEEN VARIABLE WAVE SHOALING, BREAKING AND TRANSITION ZONE FORMULATIONS

G P Mocke, F Smit<sup>1</sup>

#### **Abstract**

The description of nearshore structural and sedimentary dynamics is highly dependant on a quantification of the nearshore wave regime, which is subject to bathymetry induced transformation effects. Assuming straight and parallel bottom contours, computed wave heights and water levels using variable wave shoaling, incipient breaking, wave decay and transition zone formulations are compared with measurements.

#### **1 Introduction**

Waves approaching the shoreline undergo transformations due to shoaling and refraction effects. The most significant such transformation, however, occurs coincident with the breaking process, where a dramatic change in wave form occurs. Associated with wave height decay is an internal transition from predominately oscillatory, irrotational motion to a highly rotational state where breaker generated turbulent kinetic energy (TKE) is strongly dissipated.

As reviewed by Ham *et al* (1993), complex numerical methods have been relatively successfully applied to the highly non-linear shoaling region. However, in order to have more efficient tools for engineering application a number of analytical formulations have been proposed. In the present study a comparison is made between linear theory and two of the simplest such formulations, namely first order cnoidal and parametrized solutions proposed by Isobe (1985) and Swart (1978) respectively. For defining the onset of wave breaking, the earlier criteria of Weggel (1972) is compared with formulations of Moore (1982) and Larson and Kraus (1989).

Energy dissipation in a breaking wave is often formulated (Battjes and Janssen, 1978) as being equivalent to that across an hydraulic jump. An alternative approach proposed by Dally *et al* (1984) relates the rate of energy dissipation to the excess of energy between the actual and a stable wave energy flux. Despite generally favourable wave height comparisons with measured values, a consistent lag between the maximum gradient of wave energy and that of setup and return flows has been

---

<sup>1</sup> Research Engineers, CSIR, P O Box 320, Stellenbosch 7599, South Africa

observed (Roelvink and Stive, 1989).

Such findings relate primarily to the manifestation of a transition zone immediately after breaking across which waves undergo transformation into turbulent bores. Svendsen (1984) defined the extent of this zone to be equivalent to the area of near constant mean water level. It was proposed by Basco and Yamashita (1986) that the width of this zone would vary in relation to the surf similarity parameter.

Svendsen (1984) incorporated the effect of the transition zone in the energy conservation formulation by including a storage term representing an initial conversion of organized wave motion into forward momentum flux in the roller. A similar term proposed by Roelvink and Stive (1989) considers a local imbalance of production and dissipation of TKE. Drawing on the concept (Svendsen, 1984) of a surface roller "riding" on a wave front, Nairn *et al* (1990) incorporate a relation proposed by Deigaard and Fredsoe (1989) whereby dissipation is modelled as the work performed by a shear stress at the interface between the roller and the organized wave motion. In a fundamentally different approach Okayasu *et al* (1990) incorporate a term representing the initial transfer of kinetic energy to organized large vortices before subsequent conversion to dissipative TKE for an evaluation of the various transition zone relations.

Lacking explicit measurements of energy dissipation rates in the surfzone, the present study deduces the cross-shore distribution of this parameter through an inverse modelling approach that draws on measurement of surfzone TKE.

## 2 Experimental Data

The experimental cases discussed are primarily confined to measurements of regular waves over planar bottom slopes. Test conditions for these cases are summarized in Table 1. The set of measurements constitutes a total of 14 test cases with breaking conditions ranging from weakly spilling to strongly plunging.

For each of the data parameters considered, a root mean square error  $e$  denoting the deviation of predictions from measurements is computed. This statistical parameter, along with a computed bias  $b$  are defined as follows:

$$e = \frac{1}{N} \left[ \sum_{i=1}^N (X_{pred,i} - X_{meas,i})^2 \right]^{\frac{1}{2}} \quad (1)$$

$$b = \frac{1}{N} \sum_{i=1}^N (X_{pred,i} / X_{meas,i}) \quad (2)$$

### 3 Wave Shoaling

Transformed wave heights and water levels ( $\eta$ ) are defined by the 1-D depth-averaged energy and momentum conservation equations:

$$\frac{\partial}{\partial x} (EC_g) = -D_b \tag{3}$$

$$\frac{\partial S_{xx}}{\partial x} = -\rho g d \frac{\partial \bar{\eta}}{\partial x} \tag{4}$$

where E is the wave energy, C<sub>g</sub> the group velocity, D the energy dissipation and S<sub>xx</sub> the radiation stress. In addition to linear wave theory, an adaptation (Isobe, 1985) of the first order cnoidal theory is considered:

$$EC_g = \rho g H^2 (gd)^{\frac{1}{2}} f_2$$

$$\text{with } f_2 = \text{func}(U_s) \sim \frac{32}{15(3U_s)^{\frac{1}{2}}} \left( 1 - \frac{15}{(3U_s)^{\frac{1}{2}}} + \frac{20}{U_s} \right) \text{ for } U_s \gg 1 \tag{5}$$

$$\text{and } U_s = \frac{gHT^2}{d^2}$$

as well as the vocoidal theory of Swart (1978):

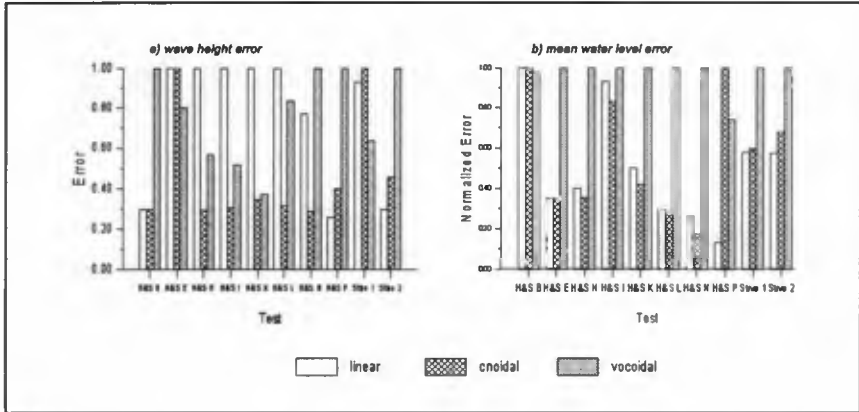

$$EC_g = (e_p + e_k) \rho g H^2 n C, \quad \text{with } e_p \text{ and } e_k = \text{func} \left( \frac{H}{d}, \frac{L}{d} \right) \quad (6)$$

Computed wave height and mean water level variations were compared for several laboratory experiments. An example of such a comparison against the measurements of Stive (1980) is shown in Figure 1. Figure 2 presents a comparative summary of statistical errors for both wave height and water levels in the shoaling region. Results of the error and bias calculations for wave heights and mean water levels for the experimental data simulated are summarized in Figure 3.

No pre-breaking measurements for either the Hattari and Aono(1985) or Nadaoka and Kondoh (1982) cases were available and comparisons could thus not be made. For the rest of the test cases the cnoidal technique provided the best overall estimates of both wave height and mean water levels in most cases. The vocoidal theory, on the other hand, seemed to fare the worst of the three theories tested. However even though the deviation is highest across the shoaling region, the vocoidal theory provided the closest estimation of both wave height and mean water level at the breaking point for most of the test cases. The bias calculations indicated that the linear theory both estimates wave height and overpredicts setdown. The cnoidal theory performs slightly better in estimating both wave height and mean water levels, whilst the vocoidal theory tends to overestimate both these parameters slightly.

#### 4 Wave Breaking

##### *Incipient Breaking*

Three relatively well-established breaking criteria were assessed, namely the criterion of Weggel (1972),

$$\frac{H_b}{d_b} = b_m - a_m \cdot \frac{H_b}{gT^2} \tag{7}$$

where  $H_b$  = wave height at breaking,  $d_b$  = water depth at breaking

$$a_m = 43.8 (1.0 - e^{-19m}), \quad b_m = \frac{1.56}{1.0 + e^{-19.5m}}$$

$m$  = bottom slope

Moore (1982),

$$\frac{H_b}{d_b} = b_m - a_m \cdot 0.083 \left( \frac{H_0}{L_0} \right)^{0.8} \quad (8)$$

and Larson and Kraus (1989):

$$\frac{H_b}{d_b} = 1.14 \zeta^{0.21} \quad (10)$$

with  $\zeta$  = surf similarity parameter =  $m \left( \frac{H_0}{L_0} \right)^{-\frac{1}{2}}$

An example of a comparison for a case of Hansen and Svendsen (1979) is presented in Figure 4. The results for all the test cases indicate that there is very little difference between the 3 breaking criteria. The Larson-Kraus (1989) criterion tends to predict the breaking point in slightly deeper water than either the Moore (1982) or Weggel (1972) criteria. For all intents and purposes the oldest and probably most established of the criteria, namely that of Weggel, seems perfectly adequate to use. The Weggel criterion has the advantage of using only local information in determining the breaking position as the deep water wave steepness does not have to be known. This implies that a wave transformation model using the Weggel criterion can be run using input conditions at any point seaward of the breaker zone.

**Figure 4** Comparison between breaking criteria for Hansen and Svendsen Case N

**Wave Decay**

With the steady state conservation of wave energy flux described by equation (3) it is necessary to quantify the rate of energy dissipation  $D_b$  due to breaking, which is the dominant energy dissipation mechanism in the surfzone. Considering an equivalence to a hydraulic jump the average breaking wave dissipation per unit area has been expressed for random waves by Battjes and Janssen (1978).

In the event of regular waves the above formulation reduces to the bore dissipation expression of Stive (1984):

$$D_b = A_b \frac{\rho g c}{4} \frac{H^3}{d} \quad (10)$$

where  $A_b$  should ideally be greater than unity so as to compensate for the tendency of the hydraulic jump formulation to underestimate wave breaker dissipation.

Dally *et al* (1984) propose a simple algorithm that models waves as undergoing energy dissipation at a rate equivalent to the excess of energy above some stable limit. This approach, which has been referred to as the excess-energy (EE) concept, has been formulated as follows:

$$D_b = \frac{\kappa}{d} [ ECg - F_s ] \quad (11)$$

where  $\kappa$  = decay coefficient  $\sim 0.15 - 0.2$   
 $F_s$  = stable wave energy flux =  $\frac{1}{8} \rho g H_s^2 Cg$   
 $H_s$  =  $\Gamma d$ , (with  $\Gamma \sim 0.35 - 0.40$ )

Both approaches were applied over the whole surfzone using standard coefficients ( $A_b = 1$ ,  $\kappa = 0.15$ ,  $\Gamma = 0.4$ ). The possible reformation of waves was incorporated in the model using a stable wave definition, as proposed by Horikawa and Kuo (1966). An example of results obtained from the two formulations is presented in Figure 5. Relative wave height and water level error and bias statistics are charted in Figures 6 and 7 respectively.

The results indicate that using standard parameters the bore model generally describes the wave height change through the surfzone slightly better than the EE model, with the bias calculations showing the latter tends to underestimate breaker dissipation. An exception to this is in the case of plunging breakers (H&S Case P, H&A Case 3, Stive Case 2) where the bore expression tends to underestimate dissipation rates. However, either of the models can be made to fit the plane slope measurements well using slight parameter adjustments. In the event of a highly irregular bathymetry, particularly under random waves, a limited sensitivity analysis shows neither method to be entirely adequate. As has been previously observed the problem in this regard relates primarily to the effect of wave reformation over trough features. This is

**Figure 5** Comparison between wave heights and mean water levels with the EE and bore breaker models (H&S, Case K)

reflected in an incorrect estimate of the percentage of broken waves, as found by Mocke *et al* (1994) in an inverse modelling exercise using undertow and suspended sediment measurements.

The comparison of calculated mean water levels with measurements indicated quite clearly that the use of the momentum equation as defined in equation (4) is not able to describe the setup in the surfzone adequately at all. This serves to underline the importance of including the transition zone and the "lag" effect on the setup in the formulation.

**5 The Transition Zone**

**Transition zone length**

Defining the transition zone length ( $l_t$ ) as the distance from the breakpoint to a point of

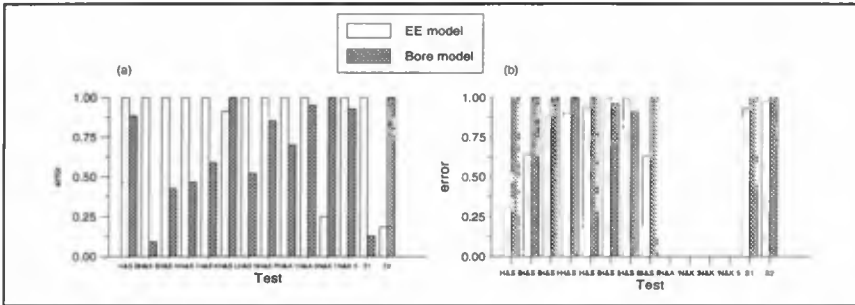

abrupt change in mean water level slope Nairn *et al* (1990) (hereafter NRS) use a data set of laboratory experiments to define the following empirical relation:

$$\begin{aligned}
 l_t &= 0.556 m_b L_b \zeta_b^{-1.465} && \text{for } \zeta_b \geq 0.05 \\
 &= 0 && \text{for } \zeta_b < 0.05
 \end{aligned}
 \tag{12}$$

Zhang and Sunamura (1990) (hereafter ZS) use visual laboratory observations for assessing the process described by Nadaoka *et al* (1989) of a progressive transition from strongly two-dimensional vortices at breaking to oblique vortices. Adapting a temporal relation proposed by the authors, an equivalent expression in terms of distance results:

$$l_t = \left[ 0.02 \frac{H_b}{g T^2 m} \left( \frac{H_b L_b}{\nu T} \right)^{\frac{1}{3}} + 0.12 \right] T c
 \tag{13}$$

Also using visual laboratory observations Okayasu *et al* (1990) (hereafter OWI) define the transition point as the position of roller establishment:

**Figure 6** Normalized root mean square errors for (a) wave height and (b) mean water levels using the EE and bore breaker decay models

**Figure 7** Bias in a) wave heights and b) water levels for breaker decay models

$$l_t = \left( \frac{1}{m} + 4 \right) d_b \tag{14}$$

Quantifying the transition zone length as the area of depressed setdown the above relations are compared to our experimental data set in Figure 8. Being the only formulation based on a similar definition of the transition zone the NRS (1990) expression not surprisingly provides the closest correspondence to measurements. The ZS definition, however, also provides a relatively close comparison. The more qualitatively determined OWI scale, however, tends to consistently predict a transition zone distance that extends beyond the point of change in setup slope. Lacking a more explicit definition of the transition zone, it is impossible at this juncture to make a relative judgement on the proposed relations. So as to assure a certain level of consistency between the comparisons that follow, the empirical NRS relation is considered to define the transition zone length within each formulation.

**Figure 8** Comparison between measured transition zone lengths and predicted lengths using different empirical transition zone length formulations

**Analytical formulations**

In recent years attention has been focussed on obtaining an analytical formulation to describe the contribution of the transition zone after the onset of breaking. These formulations all include the inclusion of a lag/storage term in the energy conservation equation. Our previous equations (3) and (4) are therefore adapted to the form below:

$$\frac{\partial}{\partial x} (E_w C_g) + \Gamma_x = D_b \tag{15}$$

$$\frac{\partial}{\partial x} S_{xx} + M_r + \rho g d \frac{\partial \bar{\eta}}{\partial x} = 0, \tag{16}$$

where  $\Gamma_x$  = lag/storage term  
 $M_r$  = additional momentum flux term

Where the additional energy and momentum equation terms have been formulated as follows by the various investigators:

**Svendsen (1984):**

$$\Gamma_x = \frac{\partial}{\partial x} E_r c \text{ and } M_r = \frac{\partial}{\partial x} (2E_r) \tag{17}$$

where  $E_r$  = roller energy =  $\rho \frac{Ac}{2T}$ , and  $A$  = roller area  $\sim 0.9H^2$

**Roelvink and Stive (1989):**

$$\Gamma_x = \frac{\partial}{\partial x} \beta_r k d c, \quad D_b = -\rho \beta_d k^{\frac{3}{2}}, \quad \text{and } M_r = \frac{\partial}{\partial x} \beta_s \rho k d \quad (18)$$

with  $\beta_r = \beta_d = 1$  and  $\beta_s = 0.22$  and  $k = \text{turbulent kinetic energy}$

**NRS:**

$$\Gamma_x = \frac{\partial}{\partial x} E_r c, \quad D_b = -2\beta g \frac{E_r}{c} \quad \text{and } M_r = \frac{\partial}{\partial x} (0.22 E_r) \quad \text{with } \beta = 0.1 \quad (19)$$

**OWI:**

$$\Gamma_x = \frac{\partial}{\partial x} E_v c_g, \quad D_b = \frac{\partial}{\partial x} E_t c_g, \quad \text{and } M_r = \frac{\partial}{\partial x} \left( \frac{5}{3} E_v \right) \quad (20)$$

where  $E_v = \text{energy of organized vortices}$ ,  $E_t = \text{total wave energy} = E_v + E_w$

OWI proposed that the energy transferred to the vortices is dissipated over a "dissipation distance" proportional to the water depth. Comparisons between the analytical formulations of Svendsen, NRS and OWI were carried out on Stive (1980) case 1. Figure 9 depicts the calculated energy dissipation ( $D_b$ ) and gradient in energy flux ( $\partial EC_g / \partial x$ ) across the surfzone using the three formulations. It may be remarked that both terms are non-zero prior to the breakpoint for the OWI case. This is because energy transfer in the OWI model starts at a position slightly seaward of the breaking point primarily as a means of avoiding an abrupt energy step, and associated numerical instabilities, across this point.

**Figure 9** Calculated gradient in energy flux and energy dissipation for Stive Case 1 using the Svendsen, Nairn *et al* and Okayasu *et al* analytical transition zone formulations

In Figure 10 is shown the computed setup distributions for the same test case. As may be seen from a comparison with the setup computed without transition zone effects, the Svendsen relation shows negligible improvements. Although the other relations are found to be somewhat more satisfactory, comparisons with measurements are found to be generally inadequate. It is difficult to pursue the

**Figure 10** Comparison between setup calculated for Stive Case 1 using different analytical transition zone formulations

analysis in terms of setup measurements as inadequacies may exist in both the adapted energy and momentum relations. Lacking explicit energy dissipation measurements reference is made to available TKE measurements.

#### ***Depth-dependant TKE***

In employing a two equation ( $k, \epsilon$ ) turbulence model as described in Mocke (1991),  $D_b$  rates as determined by the various methods are imposed as a near surface production source of TKE. Considering a dominant diffusion/dissipation balance, computed turbulent intensities for the formulations of OWI and NRS are compared with computations lacking a transition effect. Comparisons with measurements from Stive 1 are shown in Figure 11.

With the breakpoint at approximately  $X = 9$  m, limited transition effects appear to be necessary for the three inner measurement stations. At  $X = 7.5$  m, however, turbulence intensities tend to be overpredicted with the OWI relation showing the most favourable lag effects. Although no measurements were made at  $X = 8.5$  m, the significant discrepancy between predictions at this point immediately following breaking is apparent, with the OWI relation once again showing the most lag effects. Similar findings were observed comparisons against for case 2 of Stive (1980) as well as for the eddy viscosity estimates of OWI.

#### ***Depth averaged TKE***

Further comparative analyses have been made using depth average/equation ( $k-l$ ) and two equation ( $k, \epsilon$ ) turbulence closure modelling. The details pertaining to this approach are comprehensively described in Mocke *et al* (1993). Referring once again to Stive case 1 measurements, depicted in Figure 12 are comparisons between

**Figure 11** Comparison between TKE profiles through the surfzone using the NRS and OWI transition zone formulations

simulations and estimates of depth averaged TKE.

Note the discernible lag after breaking in the increase in TKE, an effect not reflected in simulations made without consideration of transition zone effects. Although the OWI relation provides for more lag influence than the NRS expression, neither approach satisfactorily represents the measurements.

Examining the NRS expression we note that a fundamental assumption is that the effective roller slope used for determining the dissipation rate remains constant throughout the full extent of the surfzone. This assumption inherently assumes no roller development area nor any changes in the form of this feature throughout the surf zone. In an effort to more closely reflect the physical reality, transformation effects are incorporated by artificially varying the roller slope factor  $\beta$  in the cross-shore direction. A limited sensitivity analysis shows a variation of  $\beta$  from 0.01 to 0.07 within the NRS relation provides an improved estimate of the measurements under consideration.

## Conclusions

The comparison between the different shoaling techniques indicates that the first order cnoidal technique provides the closest approximation of wave heights and mean water levels in most of the test cases. However the vocoidal theory provides the

**Figure 12** Calculated depth averaged TKE using the Naim *et al* and Okayasu transition zone formulations compared to measurements

closest estimate of wave height and setdown at the breaking point itself. The comparison between the different incipient breaking criteria indicated that there is little to choose between them, and the Weggel criterion, which has the advantage of requiring only local information, is adequate for most applications.

The EE and bore models were found to provide reliable wave decay predictions for regular waves over simple geometries. Simulations not discussed here however reflect previous findings of inadequate predictions for more complex cases. Many of the integral surfzone processes associated with breaking are furthermore not satisfactorily predicted without incorporation of transition zone effects following initiation of breaking. The formulation of Okayasu *et al* (1990), which attempts to quantify an initial transfer of energy to organized large vortices, appears to be physically and empirically the most appropriate approach. An adaptation of the Naim *et al* (1990) formulation to reflect a changing bore configuration, however provides the best correspondence with measured turbulence intensities.

## CHAPTER 172

### Analysis of Coastal Processes at Toronto Islands

R.B. Nairn, R.D. Scott, C.D. Anglin and P.J. Zuzek<sup>1</sup>

#### Abstract

The paper summarizes the analysis of the coastal processes which have been responsible for the evolution of the Toronto Islands sand spit feature. Both natural and artificial influences have created a situation of a rapidly evolving landform. The purpose of the study was to evaluate the feasibility of rebuilding a school near the shoreline of this rapidly evolving feature. Several different techniques were employed to evaluate the changes including: shoreline recession rate estimates, lake bed surface change comparisons, sediment budget calculations and alongshore and cross-shore sediment transport calculations. These techniques were combined to develop a descriptive model of the changes in order to forecast future changes to the landform over the next 100 years.

#### Introduction

This paper summarizes the findings of an investigation of erosion processes at Gibraltar Point on the Toronto Islands situated along the northwest shore of Lake Ontario in Canada. The Toronto Islands Nature School is located at Gibraltar Point and the future safety of this location with respect to erosion and flooding hazards is dependent on the future evolution of the Gibraltar Point landform. The Toronto Board of Education has plans to construct a new school on and just west of the location of the existing school. The purpose of the study was to investigate the potential future erosion hazards at Gibraltar Point and the implications for constructing a new school at the existing location.

The following sections of the paper provide: an overview of the geomorphology of the Toronto Islands feature including the background of the problem; a description of the analyses used to prepare a representative nearshore wave climate; a review of the historic changes in the shoreline position; an interpretation of changes to the lake bed; an explanation of the descriptive model of the changing landform including future projections; and study findings.

### Study Background and Regional Coastal Geomorphology

The City of Toronto is located on the north shore of Lake Ontario and was founded at this location in 1793 because of the presence of a 9 km long sand spit that provided excellent natural protection for a large harbour (see Figure 1).

A geomorphologic review found that the Toronto Islands feature is a complex (compound) recurved sand spit that has formed and developed over the last 3500 to 5000 years as a result of the following factors: stabilization of the existing lake level ( $\pm 2$  m) over the last 3500 years; a dominant northeast to southwest directed sediment transport; a continuous supply of sediment from the erosion of the Scarborough Bluffs to the east (estimated to be 30,000 m<sup>3</sup>/yr on average); the presence of an underlying shallow and gently sloping bedrock shoreface platform; and the presence of a significant re-entrant angle in the shoreline orientation (i.e. an embayment). This type of feature is characterized by a progressive extension in the direction of the dominant sediment transport (i.e. to the southwest at this site). The ability of the spit to continue its southwestward growth depended on a continued supply of sediment, both to build the subaerial part of the feature, and essentially, to extend the offshore shelf southwestwards.

The continued extension of the spit to the southwest combined with a severe storm event in 1852 resulted in a breach near the location of the present day Eastern Channel. The breach in the spit expanded between 1852 and 1882 to an extent that threatened the future potential for harbour development at Toronto and the associated economic development. In response to this situation, the Toronto Harbour Commissioners embarked on an ambitious plan to stabilize the naturally formed Eastern Gap to create a navigation channel of controlled width and depth. These plans resulted in the construction of the Eastern Channel jetties which were completed in 1892. In order to protect the shore of the islands from future erosion and potential breaching, a seawall and breakwater were constructed over a length of 2.5 km extending westward from the west jetty.

Sand which continued to move along the shore from east to west was deposited in the Eastern Channel. Records show that on average 25,000 cubic metres of sand was dredged from the channel and dumped offshore on an annual basis

between 1896 and 1965. This suggests that most of the annual supply volume of 30,000 cubic metres was prevented from reaching the shore and lake bed of the Islands feature to the west of the Eastern Channel. This situation has resulted in erosion with 1 to 2 m of lake bed lowering offshore of the seawall immediately to the west of the channel. Therefore, the supply of sediment to Gibraltar Point, although mostly cut off at the Eastern Channel, was probably compensated in part by the erosion of the lake bed offshore of the seawall.

The Eastern Headland (also known as the Leslie Street Spit) is a 5 km long artificial spit feature located immediately east of Toronto Islands that has been created through lakefilling (see Figure 1). The spit was originally created to form a protected outer harbour; however, it has also been used as a dump site for construction refuse (mostly concrete rubble from downtown construction projects), and as a confined disposal facility for contaminated dredge spoil from the harbour area. The construction of the headland was initiated in the early 1960's, and although still ongoing today, its greatest offshore extent was reached by 1978.

The headland has two important impacts on the regional coastal processes. First, the historic rate of sediment supply from the east, which had been severely reduced by the construction of the Eastern Channel jetties and subsequent dredging, was eliminated completely with the construction of the headland. The Eastern Channel has only been dredged once since 1965. The second and most important impact of the Eastern Headland has been the modification of the nearshore wave climate through sheltering the eastern half of the Islands from the easterly storm waves. Detailed wave transformation analyses (discussed below) revealed that the zone of influence of appreciable sheltering probably extends no further west than the Centre Island pier at the east end of the Centre Island seawall (refer to Figure 1). The headland does not have a significant impact on the waves which reach Gibraltar Point.

The Toronto Islands Water Filtration Plant is located just east and inland of the Nature School in the Gibraltar Point area. While the intake lines for this facility date back to the late 1800's, the two existing intake lines were completed in the early 1950's. Each line extends almost 1 km offshore and consists of a pipe confined by two steel sheet pile walls, which in places extend up to 2 m above the adjacent lake bed. The eastern intake line has an associated steel sheet pile groyne structure at the shoreline which appears to have been constructed in the late 1940's. These structures act to impede the alongshore transport of sediment.

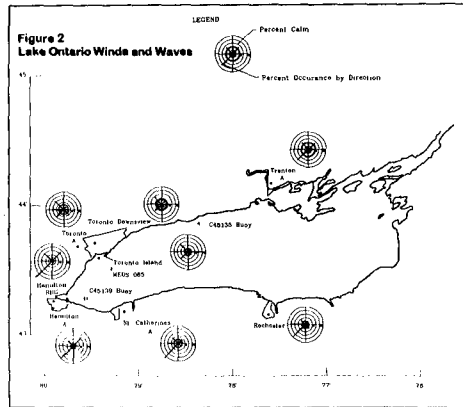

#### Development of a Nearshore Wave Climate

A wind-wave hindcast was performed to develop an estimate of the long term offshore wave climate at the Toronto Islands. A 1D parametric hindcast model based on the approach of Donelan (1980) was used. Research by Skafel and Bishop (1993) has shown that the available 2D dynamic hindcast models do not give superior results to the 1D models when estimating wave conditions on the Great Lakes. A considerable effort was devoted to assessing wind data input for the hindcast model. Overwater wind speeds for a 35 year hindcast period were determined from comparison of several land based wind data records to available overwater wind data records (Figure 2 shows available wind and wave data for Lake Ontario).

The use of a combined wave refraction / diffraction model was vital to the assessment of the nearshore wave climate at Toronto Islands due to the nature of the underwater topography and the influence of the artificial Eastern Headland. The

REF/DIF 1 model developed by Kirby and Dalrymple (1983), which is based on a parabolic approximation of the mild slope equations, was utilized. Model runs were performed for a range of representative wave directions, heights and periods.

Due to its position at the west end of Lake Ontario, the most severe storms are generated by easterly winds over a 250 km fetch. The maximum significant wave height during the 35 year hindcast period was estimated to be 5.6 m with a peak period of 12 s and a direction just north of east. The prevailing winds are from the southwest and the maximum significant wave height from this direction during the hindcast period was 4 m with a period of 10 s. The considerable year to year variability in the ratio of east to southwest storm events, as well as variations in overall annual wave energy, have an important influence on the pattern of morphologic response.

The level of Lake Ontario has an average seasonal fluctuation of about 0.6 m. There is also considerable long term variability with a 2 m difference between the maximum spring high level and the minimum winter low level.

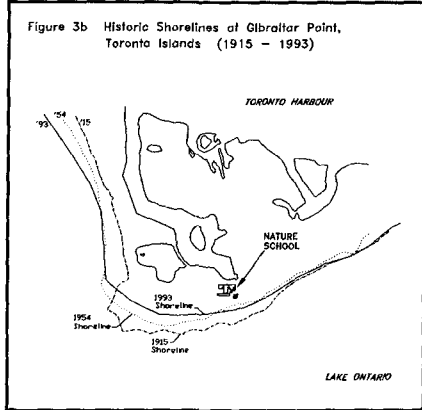

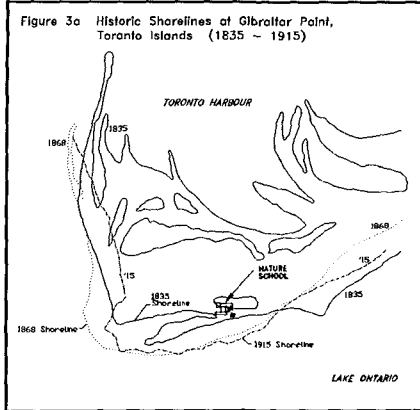

### Change in Shoreline Position

There is a wealth of information on the position of the Toronto Islands shoreline dating back to the initial European settlement in 1793. The accuracy of this information varies considerably; however at the very least, each map or aerial photo provides a snap shot giving some indication of the evolving nature of the Toronto Islands feature at a point in time.

For those sources of data which have an acceptable degree of accuracy, intercomparisons may be made between the different snap shots allowing for the calculation of shoreline recession rates for the various periods. Under the Shoreline Policy of the Province of Ontario, potential hazard areas must be determined in part from an estimate of the shoreline position in 100 years time based on historic shoreline recession rates.

A summary of some of the historic shoreline positions in the Gibraltar Point area that have been corrected for lake level variations are shown in Figures 3a and b. From the shoreline changes between 1835 and 1915 given in Figure 3a, it is evident that between 1835 and 1868 the south facing section of the shoreline moved lakeward

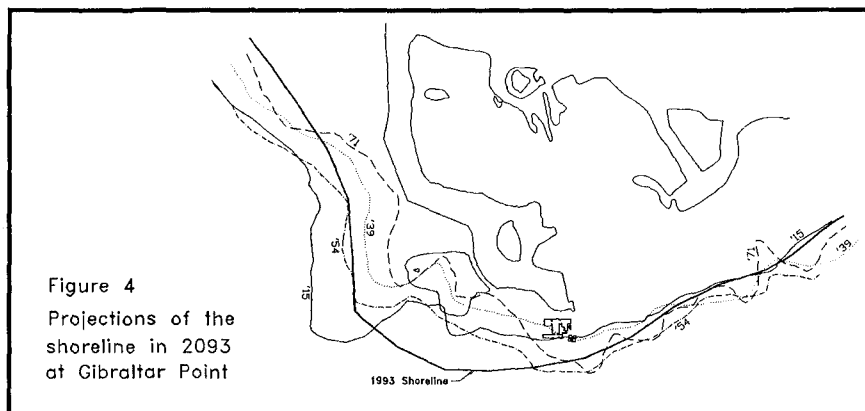

(i.e. the Islands deposit was growing). Between 1868 and 1915 the depositional trend was reversed, possibly due to the influence of the updrift breach. Figure 3b shows that after 1915, erosion was experienced along the south facing shore with deposition along the west facing shore. In the vicinity of the School, and to the east, the shoreline apparently was stable during the period from 1954 to 1993. However, this finding should be considered with caution owing to the highly eroded state of the 1954 shoreline as caused by the abnormally high lake levels in 1951 and 1952.

In summary, the trend of shoreline change cannot be described as a linear process over the period from 1835 to the present. Prior to 1868, the south facing part of the shore was accreting and since at least 1939 the shore has been eroding. Furthermore, short term and temporary changes to the shoreline position caused by the rapid response of the nearshore profile to storm conditions can obscure long term trends that are based on these snap shots.

Under the Provincial Shoreline Policy, one part of the definition of hazard lands (where development is restricted) relates to those areas which will be threatened by erosion within 100 years time. As noted above, the Policy requires that the position of the 100 year shoreline be established through linear extrapolation of historic shoreline recession rates (with a minimum time span of 35 years between snap shots of shoreline position). For the purposes of these investigations, the 100 year shoreline has been established through extrapolating recession rates for all available periods in order to provide a range of results. Two recent surveys were used as a basis of comparison against historic shoreline positions: a 1988 aerial survey and a 1993 ground survey (only the latter set of comparisons are presented in this paper).

The 100 year shoreline position projections, based on a comparison of historic and 1993 shoreline position's, are presented in Figure 4. Generally, these results feature three different zones of shoreline change consisting of deposition along the north part of the west facing shore, dramatic erosion around the strongly curved point and relatively minor changes for the remainder of the south facing shore. As expected, for the shortest comparison period (1971 to 1993) the 100 year position features the greatest variability while the 100 year projection from the earliest shoreline in the comparison (1915) is distinguished by the least alongshore variability. If the process of erosion was linear, it would be reasonable to assume that the 100 year projection based on the latter comparison was the most reliable.

However, a close review of the shoreline positions offshore of the School reveals a distinct difference between projections based on pre- and post- 1940's data. The 1915 and 1939 projections of the 100 year shoreline pass directly through the School site, whereas the more recent projections produce a 100 year shoreline offshore of the existing School. Here it may be postulated that the groyne and intake lines which were constructed for the Filtration Plant in the late 1940's have had an important effect on the shoreline in this area. Therefore, since the effect of this change is not reflected over the full comparison period with the historic shorelines prior to the 1940's, these results do not provide realistic projections of future conditions. In addition, the 100 year projection based on the comparison of the 1954 and 1993 shoreline positions may also be misleading. This result suggests that the shoreline offshore of the School will remain stable or even accrete over the next 100 years. However, it should be recalled that the 1954 shoreline may have been in a temporary highly eroded state. Therefore, any recession rates calculated through comparison to the 1954 shoreline may underestimate future erosion.

In summary, there are several problems with 100 year shoreline projections which assume linear extrapolation. These include the following issues at this site: the erosion process is not linear in time; considerable changes to the regional processes have occurred over the last 100 years; the erosion process will not be linear in the future, as shoreline and lake bed changes will alter the pattern of future change which is related to the transport and redistribution of sediment; existing shoreline protection at Gibraltar Point will not last for the 100 year projection period and obscures the future predictions; the 100 year projections also assume that other structures such as the groyne and the intake lines will be maintained in the future; snap shots of shoreline position may reflect temporary and reversible changes to shoreline position which are not indicative of long term trends, the questionable 1954 shoreline projection is an example of this problem.

Nevertheless, the 100 year projection results do provide some general findings which are pertinent to this investigation. The strongly curved part of Gibraltar Point has been and probably will continue to be the focus of greatest erosion. The pattern of erosion changed sometime in the 1940's, possibly related to the construction of the groyne and intake lines for the Filtration Plant, such that the shoreline east of the School became more stable.

### Changes in Lake Bed Levels and Sediment Budget

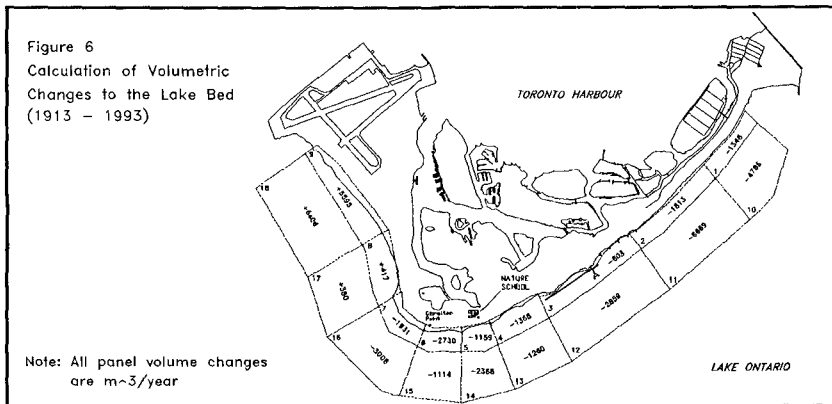

There is extensive information on the water depths offshore of the Toronto Islands dating back to 1793. Comparisons of changes in the lake bed levels between the various bathymetric snap shots provide a more comprehensive perspective of the changing nature of the Toronto Islands feature than does the shoreline change data. The interpretation of long term trends in lake bed change are not obscured by temporary lake level related changes in shoreline position or the effects of structures.

The complexity of an investigation of the temporal change in an irregular three dimensional surface (i.e. the lake bed) is such that the full value of this information in developing an understanding of the problem is seldom realized. Therefore, the bathymetric change data was considered in four different ways, providing the greatest opportunity of maximizing the value of this information.

Contours of lake bed elevation change were prepared by subtracting one lake bed surface from another. This procedure was completed for five separate time periods between 1913 and 1993. Figure 5 provides the results for the full 1913 to 1993 period, and gives an overview of the findings. The outer boundary of the comparison area varies in depth between 6 and 8 m. There is a pronounced erosional zone all around Gibraltar Point with the highest erosion rates found immediately offshore of the western extremity of the Point (i.e. where the shoreline curvature is at a maximum). Up to 5 m of lake bed lowering has occurred in places. Aside from the heavy deposition offshore of the north part of the west facing shoreline and the transition between this zone and Gibraltar Point, the only other relatively stable section of lake bed is a zone located between the groyne (and the east intake line) and the west end of the breakwater. Offshore of the seawall, erosion is prevalent. There is also evidence of deposition off the southwest corner of the shelf which suggests some of the eroded sediment has been lost offshore of the shelf.

The second approach of considering the evolution of the lake bed surface is based on calculations of volumetric change for various "panels". The panels have been selected on the basis of available lake bed information and to describe sections of lake bed which have similar trends of erosion or deposition. This exercise was completed for five different snapshots, one example is provided in Figure 6 for the full period from 1913 to 1993. There are two tiers of panels corresponding to an inshore set and an offshore set separated by the 3 to 4 m depth contour. The volume change estimates for the inner Panels 1 to 9, while showing much variation between periods, reveal some consistent trends. There is sediment sink in Panel 9 offshore of the north section of the west facing shore. Also, Panels 5 and 4 (offshore of the School and the adjacent panel to the east) often feature either lower erosion rates than neighbouring panels, or even deposition.

A comprehensive sediment budget analysis can be applied to the '13-'93 period based on volume change calculations for all of the panels around the shore. As explained earlier, this area now represents a confined littoral cell. For the 80 year period, there was a net loss of  $1,620,000 m^3$  of sediment from the area covered by the panels, or a little over  $20,000 m^3/yr$  on average. While a significant amount of this sediment may have been transported beyond the ends of the panel area (i.e. northwest of Panels 9 and 18, and northeast of Panels 1 and 10), it is likely that a significant proportion of the sediment has been lost offshore beyond the outer boundary of the panels and perhaps over the shelf at the edge of the wide platform which surrounds the Islands feature. Referring to Figure 5, a zone of deposition along the outer edge of Panels 15 and 16 may represent the growth of the shelf caused by the deposition of the sediment that has been transported offshore.

Another manner of interpreting the changes to the lake bed surface through time is to plot the changing position of selected depth contours. The 2, 4 and 6 m contours were selected for this exercise. In addition, by comparing the historic position of the contours to 1993 as a base year, "recession rates" for the contours may be calculated and projected to determine the 100 year position of the contour lines. It is again cautioned that these are linear extrapolations of a non-linear process.

Figure 7a shows the changing position of the 2 m contour around Gibraltar Point. Between 1951 and 1993, the 2 m contour position has remained relatively

stable everywhere east of the west intake line, whereas west of this point this contour has moved rapidly inshore. The recession rates of the 2 m contour line offshore of the Point for the 1951 to 1993 period reach almost 5 m/yr. This is much higher than the long term rate of shoreline recession of about 1.5 m/yr in this area. Figure 7b gives the 100 year projections for the position of the 2 m contour; these also indicate that the severity of erosion may be far greater than is indicated by the projections of the shoreline position. The erosion of the nearshore zone is outpacing the recession of the shoreline, probably as a result of shoreline structures and vegetation (including the root systems of large trees) which delay the shoreline erosion. The fact that the profile shape is changing from convex to concave also helps to explain the differential recession rates between the shoreline and the 2 m contour.

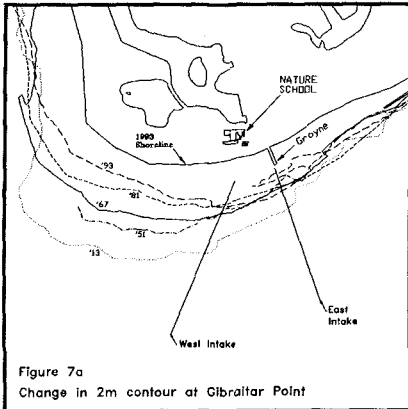

Figure 7a  
Change in 2m contour at Gibraltar Point

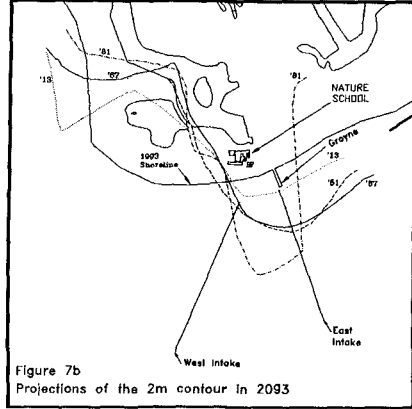

Figure 7b  
Projections of the 2m contour in 2093

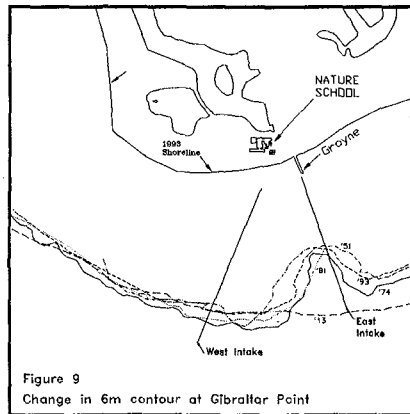

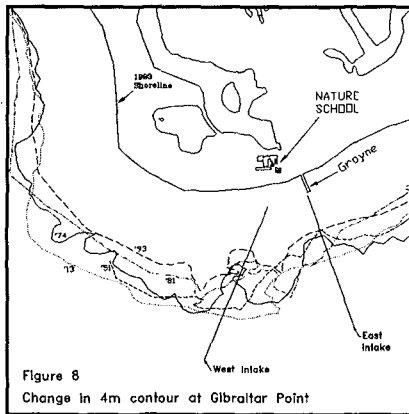

Interestingly, the 100 year projections of the 2 m contour in the vicinity of the School are in much closer agreement (i.e. for the various snap shot comparisons) than were the shoreline projections. The projections highlight the role of the intake lines in stabilizing the position of the 2 m contour.

The 4 m contour has receded inshore considerably at Gibraltar Point, mostly since 1951, although at a slower rate than the 2 m contour, with average rates of about 1.5 m/yr (see Figure 8). Offshore of the Point, there was minimal erosion between 1913 and 1951. Considering the recession of the 4 m contour was initiated about the same time that the intake lines were constructed, it is possible that the lines, by intercepting westward moving sediment, may have accelerated the erosion of the lake bed offshore of the Point.

There are several interesting features of the changing position of the 6 m contour line (see Figure 9). Starting from a point between the intake lines and moving to the west, the 6 m contour has been completely stable in position over the last century owing to the fact that this contour marks the transition from onshore erosion to offshore deposition. The 6 m contour delineates a pronounced depression or canyon around the east intake line that developed over the period between 1913 and 1951. The canyon represents a zone where the intake line acts as a total littoral barrier.

Representative profiles were also plotted for the midpoint of each of the lake bed panel sections. Around Gibraltar Point, these plots revealed the changing nature

of the feature from a depositional zone with a pronounced convex profile to an erosional zone with the related concave profile shape.

### Sediment Transport Predictions

The observed patterns of erosion and deposition that have been discussed in the previous sections have resulted from the transport and redistribution of sediment (e.g. sand). Sediment is transported by the effects of waves and the associated steady currents both in an alongshore direction and in a cross-shore direction. This section presents a brief summary of the results of numerical simulations of these sediment transport processes which were aimed at developing an improved understanding of why the observed changes have occurred and what may happen in the future.

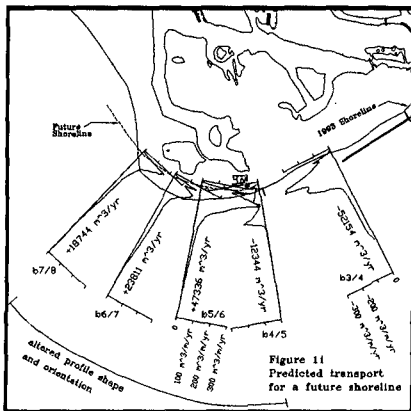

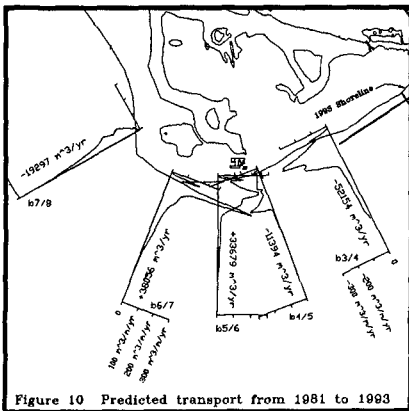

The COSMOS-2D numerical model of coastal processes has been applied to simulate the alongshore and cross-shore sediment transport. This numerical model is based on a deterministic quasi-2D representation of the actual physical processes which result in the transport of sand on a profile or cross-section of the lake bed. The calculation scheme is based on a time-averaged finite difference approach for random wave conditions. A comprehensive description of the model is given in two companion papers: Nairn and Southgate (1993) and Southgate and Nairn (1993).

Estimates of average annual alongshore transport have been made for several profiles around the exposed shore for three separate intervals within the hindcast period (i.e. '58 to '67, '67 to '81, '81 to '93). The alongshore transport estimates were made at the boundaries between the panels to determine the sediment transport entering and exiting each panel. An extensive set of sediment samples indicated that a D50 of 0.2 mm would be representative of the average lake bed conditions. An example of the results for the period from 1981 to 1993 is shown in Figure 10. The profile name indicates the panel boundary (i.e. b6/7 is the boundary between Panels 6 and 7) and the annual average sediment transport rate is given for each of the profiles. The distribution of alongshore transport across the profile is also depicted in the figure, providing an indication of the sediment transport pathways along the shore.

For each of the three periods, the alongshore transport estimates indicate that Panel 7, located offshore of Gibraltar Point, is a divergent zone for net sediment transport. In other words, sand is moving out of this panel at each boundary. This

type of situation results in high erosion rates with a potential annual loss of sediment from the panel equal to the sum of the outgoing amounts at each boundary. The neighbouring Panel 6 to the east, which together with Panel 7 represents the zone of highest observed erosion, has incoming sediment on the west boundary (b6/7) and outgoing sediment on the east boundary (b5/6) for each period. The difference between these two values is usually small, however, it must be recognized that the full potential value at b6/7 may not be realized with the net result being that Panel 6 is probably subject to ongoing erosion due to the alongshore redistribution of sediment from west to east (in other words, the divergent zone may extend into Panel 6).

Panel 5, located offshore of the School, is predicted to be a convergent zone (i.e. with incoming sediment at each boundary) and deposition would be expected to occur. It was noted earlier that Panel 5 features relatively low observed erosion rates compared to adjacent panels. Part of the basis for predicting that Panel 5 is a depositional zone relates to the prediction of potential transport from the east (i.e. at b3/4 and b4/5). Concerning the b3/4 prediction, it is likely that this is considerably overestimated since the offshore breakwater will partially restrict the movement of sand supplied from the east. Also at b4/5, the alongshore transport is influenced by the presence of the groyne and the intake line for the Filtration Plant a factor which also restricts the transport along the shore. In addition, the supply of sediment from the east is now derived from the erosion of the lake bed offshore of the seawall and breakwater, and with time, this source of sediment will be exhausted as deep concave profiles develop next to these structures (this outcome has already been observed along a large section of the eastern part of the seawall).

As the alongshore transport redistributes the sediment through the erosion of Gibraltar Point and deposition along the southwest shore and offshore of the School, the shape of the shoreline changes and this in turn effects the rate at which sediment can be transported by waves. In other words, there is a feedback system whereby the waves alter the shoreline and lake bed, and these changes in turn alter the waves and therefore the sediment transport. In order to assess how future changes to the shoreline shape may influence the future patterns of alongshore transport, estimates were made for a future shoreline position as determined from the shoreline projections discussed earlier. Revised profile shapes were also considered based on the amount of shoreline recession dictated by the assumed future shore position. The future shoreline position and the revised estimates of alongshore transport at each of the panel

boundary profiles are presented in Figure 11. The 1981 to 1993 waves were used, so these results are best compared to those given in Figure 10.

Only Profiles b4/5 through to b7/8 have been modified. Reviewing the results, there is only a minor change in the estimates for Profiles b4/5 and b5/6, but the net transport at b6/7 is halved and the transport at b7/8 has changed direction from west (or clockwise) to east. These findings suggest that in the future the zone of highest "erosional stress" due to alongshore transport will be shifted or extended from Panel 7 (current position) to the east into Panel 6 and to the west into Panel 8. However, the zone immediately offshore of the School (i.e. Panel 5) will remain a zone of deposition as long as the supplies from the west and east are maintained.

A rough estimate may be made of the remaining supply of sediment which may be available from ongoing erosion of the lake bed as a source for westward directed transport reaching Panel 5 offshore of the School. It was determined that the potential transport rate of 23,500 cubic metres per year could be sustained for another 28 years. This calculation suggests that the future supply of sediment to the panel offshore of the School from erosion of the lake bed to the east may be exhausted in 25 to 50 years.

Sediment transport calculations were performed to investigate the influence of the Filtration Plant intake lines and associated groyne structure. It was determined that neither the intake lines nor the groyne represent a significant impediment to alongshore transport under the June 1994 snap shot conditions. However, additional model tests indicated that the groyne helps to maintain a small fillet beach during storm conditions and thus the stability of the shore to the east, and similarly, the intake lines appear to act as submerged groynes helping to hold the 2 m contour offshore at this location, particularly during storm conditions (while along the adjacent shore to the west, the 2 m contour has continued to recede inshore). It is anticipated that with the ongoing erosion of the lake bed offshore of the 2 m contour in the vicinity of the intake lines, the stability of the lines could be threatened in about 50 years from now.

Next, the role of cross-shore transport in the reshaping of the Gibraltar Point feature was considered. Of primary concern is the potential for permanent loss of sediment from the nearshore to offshore locations. The COSMOS numerical model provides a description of the cross-shore sediment transport rates for a nearshore profile. In preliminary tests it was found that only the largest waves result in appreciable offshore loss of sediment (i.e. sediment which is transported beyond the edge of the shelf). Therefore, an input wave file with a relatively small number of representative wave conditions (about 20) could be prepared for the calculation of cross-shore sediment transport at each profile. The offshore loss rates for the entire hindcast period and the sub-periods were then estimated based on the product of the total duration for each representative wave condition and the offshore loss rate determined through the COSMOS simulations. Calculations were made for both the 1993 profile shape and the estimated future profile shape that may exist in 50 to 100 years time. The offshore loss rate over the wave hindcast period (1954 to 1993) was determined to be  $5.06 \text{ m}^3/\text{m}/\text{yr}$  with the 1993 profile shape. For a future profile shape with a flatter slope based on continued shoreline recession, the predicted offshore loss rate was  $3.65 \text{ m}^3/\text{m}/\text{yr}$  representing a 30% reduction from the current rate. As a check on the validity of these estimates, the 1951 to 1993 average loss rate for Panel 15 (i.e. the offshore segment of Profile 6) was found to be  $2860 \text{ m}^3/\text{yr}$ , or about  $5.5 \text{ m}^3/\text{m}/\text{yr}$ , which corresponds well to the calculated rate of  $5.06 \text{ m}^3/\text{m}/\text{yr}$ .

In summary, in the vicinity of Gibraltar Point, alongshore transport processes are causing a redistribution of sand from the Point to the north part of the west facing shore and also towards the area of the intake lines. Thus, the Point is a zone of divergent sediment transport while the area of the intake lines is a zone of convergent sediment transport. Also, there is an ongoing offshore loss of sediment due to cross-shore transport processes. This situation is related to the change in the profile shape from a convex form (which developed when the Point was a depositional feature) to a concave form which is consistent with the present eroding condition.

### Descriptive Model of the Morphodynamics

A descriptive model was developed to relate quantitatively the observed changes in the Gibraltar Point feature to coastal processes, particularly the alongshore and cross-shore transport of sediment which are the driving forces of change at this location. Another aspect of the model is the temporal and spatial schematization which are required to simplify a continually evolving and complex three dimensional problem. From a temporal perspective, the last 35 years were subdivided into three periods ('58-'67, '67-'81 and '81-'93) in part related to the availability of data and also to identify three quite different periods of response. The spatial schematization is based on the "panel" descriptions presented earlier, which consist of an inner and an outer ring of panels, again in part related to data availability and also to identify unique zones of lake bed change. This approach was inspired by the work of Stive and deVriend (1994). As a check on the validity of the descriptive model, the historic observations of change may be compared to the predictions from the model. In essence, the descriptive model is no more than the application of a sediment budget to past changes (with the aid of sediment transport estimates to explain these changes) and the projection of the future sediment budget for periods of 50 and 100 years from the present based on future estimates of sediment transport and sediment supply.

Figure 12 provides a summary of the descriptive model of the evolving morphology at Gibraltar Point over the last 35 years which illustrates the relative magnitude of the incoming and outgoing sediment transport components along with the transfer between the two sections (i.e. the arrows are drawn to represent the relative magnitude of the transport components). This model explains why the west section (Panels 6/7 and 15/16) is eroding at a much greater rate than the east section (Panels 4/5 and 13/14). These transport patterns and associated lake bed changes also translate to shoreline erosion, with the shore along Panels 6 and 7 experiencing high recession rates and the shoreline along Panels 4 and 5 being relatively stable.

Figure 13 provides a summary of the expected pattern of sediment redistribution in the next 50 years (i.e. 1993 to 2043). The offshore loss rates have been reduced to about 70% of the current rate based on the calculations described earlier. The outgoing alongshore transport along the northwest boundary was found to be almost the same as the '81-'93 value, and therefore, is left unchanged. The incoming transport at the east boundary of the east section has been significantly reduced to reflect the remaining supply of sediment available from erosion of the lake bed in Panels 3/12 and 4/13. With the future evolution of the shoreline, the transfer of sediment between the east and west sections is predicted to be reduced to about 25% of the current rate, resulting in a projected transfer of 2,500 cubic metres per year. The expected changes in the second half of the next century (i.e. 2043 to 2093) were also completed but are not presented here. The only difference in the various incoming and outgoing components from the 1993 to 2043 period is that it the supply of transport

from the east will be exhausted by the second half of the next century, thus eliminating incoming sediment on the east boundary of the east section.

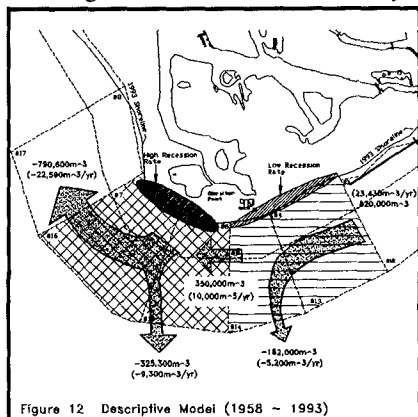

Figure 12 Descriptive Model (1958 - 1993)

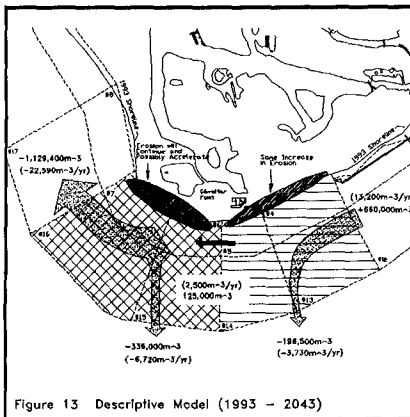

Figure 13 Descriptive Model (1993 - 2043)

For the west section of Gibraltar Point (i.e. Panels 6/7 and 15/16), the findings suggest there will only be a slight decrease in overall sediment loss over the next 100 years. As noted earlier, the shoreline recession has been outpaced by the erosion of the lake bed. The lag in the response of the shoreline is due presence of ad hoc protection structures and natural vegetation, but is also partly explained by the change from a convex to concave profile shape. With the failure or removal of the shore protection structures, it is anticipated that accelerated shoreline recession will occur. Therefore, the linear projections of future shoreline position, if anything, may underestimate the potential shoreline erosion along the inner boundary of Panels 6 and 7.

The results also point to increasing erosional stress on the lake bed of the east section of Gibraltar Point (i.e. Panels 4/5 and 13/14 offshore of the School) through the next 100 years. The analysis presented earlier showed that a linear extrapolation of the historic rate of recession of the 4 m contour over the next 100 years would destabilize the currently stable deposit offshore of the School (i.e. bracketed by the two intake lines, the shoreline and the 2 m contour line). Considering that the descriptive model projects that the erosional stress will be increased in the future, the linear projections may underestimate the future erosion of the lake bed and the future shoreline recession.

The intake lines, which help to stabilize the shoreline and nearshore lake bed offshore of the School, will be increasingly threatened with the projected lake bed lowering. It was noted above that based on the projected rate of recession for the 4 m contour, the stability of the steel sheet piles on either side of the intake pipes would be threatened in 50 to 100 years time. The predictions from the descriptive model suggest that the linear projections underestimate the future lake bed erosion and therefore, the stability of the intake lines could be jeopardized in 50 years time, or possibly less.

### Findings and Concluding Remarks

The findings of shoreline comparisons, which give the projected position of the shoreline in 100 years time based on a linear extrapolation of historic rates, were ambiguous with respect to the security from erosion hazards of the existing Nature

School position. Some projections indicated that the School position may be satisfactory after accounting for 100 years of erosion, while others found the existing School location would be completely eroded in 100 years time. This investigation revealed serious shortcomings in the method of linearly extrapolating historic shoreline recession rates to determine future shoreline positions.

In a review of historic and recent lake bed changes, there were both positive and negative implications with respect to the safety of the School position. On the positive side, the lake bed offshore of the School out to the 2 m depth contour and bracketed by the intake lines has been relatively stable over the last 50 years. Also, the section of lake bed to the east of the intake lines has experienced much less erosion than the lake bed offshore of Gibraltar Point or offshore of the seawall further to the east. However, the continued lowering of the lake bed offshore of the 2 m contour in the vicinity of School over the last 50 years has a very negative implication to the future stability of the shoreline in this area. The various ways of depicting the changes to the three dimensional lake bed surface each provided valuable insight to the nature of the evolving morphology.

The descriptive model of the evolution of Gibraltar Point has shown that erosion of the lake bed offshore of the School will be accelerated in the future. Therefore, the currently stable deposit offshore of the School and inshore of the 2 m depth contour will be destabilized, possibly in less than 50 years time. This outcome will allow the erosion of the shoreline in the vicinity of the School to accelerate. Therefore, the linear estimates of the 100 year shoreline position will underestimate the future shoreline recession. In other words, the existing School position will be susceptible to erosion hazards in less than 100 years time.

The application of a fully deterministic model of changing morphology over a 100 year period was considered to be unrealistic given the current state of our understanding of the processes. As an alternative, the descriptive model extends the traditional sediment budget approach by accounting for possible changes in future sediment transport rates to provide a highly schematized projection of future changes to the morphology of the Gibraltar Point feature.

## CHAPTER 173

### STABILITY AND MANAGEMENT OF AN ARTIFICIAL BEACH

Naofumi Shiraishi<sup>1</sup>, Hoiku Ohhama<sup>2</sup>, Taiji Endo<sup>3</sup> and Patricia G. Peña-Santana<sup>4</sup>

#### ABSTRACT

An example of an artificial beach constructed for recreational purposes is presented. The beach stability and its impact on the marine environment is discussed. Also, the beach maintenance and management during almost 20 years is reported.

#### 1. INTRODUCTION

The venue of the 1975 Ocean Expo-75 was in Okinawa, and for this event an artificial beach was constructed to show the "Expo Beach" marine exposition. This was one of the first artificial beaches to be built for recreational purposes in Japan. Since then, the Ocean Expo Commemorative Park Management Foundation has been in charge of management and maintenance for the public beach. In this paper, first the beach characteristics are described, then the impact of the artificial beach on the marine environment, and the stability of the beach are discussed based on measurement campaigns performed at the site, before and after the beach construction. And finally, the beach maintenance and management programs necessary to preserve it as an attractive recreational facility are reported.

#### 2. EXPO BEACH DESCRIPTION

The artificial beach "Expo Beach" is located in the northern part of Okinawa, Japan. It is laid out in a north-south direction above a natural coral reef, with a maximum width of about 1 km at the north of the beach. At the place where the structures were built, the reef width is about 0.5 km, and this gradually decreases to 0.1 km at the southernmost end. The reef elevation around the

<sup>4</sup>Research Engineer, Nippon Tetrapod Co. Ltd., Tsuchiura, Japan

beach structures is D.L.  $\pm 0 \sim +0.3$  m, and at the reef edge the elevation is D.L.  $+0.5 \sim +1.0$  m. Outside the reef, the slope varies from  $1/3$  to  $1/5$  from north to south, the average water depth is 30 m and this goes down to 60 m in some areas. To the north of the beach there are some notorious reef discontinuities; among these, the most pronounced is located about 200 m from the beach north-headland; here the minimum width is at the reef edge, and this gradually expands inside the reef. A sketch of the reef and the beach layout are shown in *Figure 1*.

*Fig. 1.* Beach and reef layout

*Fig. 2.* Plan view of the artificial beach

For the beach design, a length of about 400 m was available, and to make the best use of this, a "Y" shape was selected for the beach layout, as shown in *Figure 2*. Consequently, the total beach length became about 900 m, and this

was then divided accordingly into three beaches named Ikoi-no-hama, Nagame-no-hama and Asobi-no-hama. These are located on the left, top and right sides of the "Y", respectively. The widths of the beaches are approximately 28 m in the Ikoi-no-hama and Nagame-no-hama, and 44 m in Asobi-no-hama.

In *Figure 3* a typical design cross section of the beaches is shown.

*Fig. 3.* Typical design cross section of the beach

Each beach was designed to fulfill a different main purpose. That is, Ikoi-no-hama was designed to be safely used by young children who just wanted to play in the water, rather than swim. Nagame-no-hama was designed for those who would like to contemplate the seascape scenery. And, finally, Asobi-no-hama was designed for swimmers.

Relatively shallow water depths were therefore accepted for the Ikoi-no-hama and Nagame-no-hama beaches design; but for the Asobi-no-hama beach, deeper water depths were desired to satisfy the swimmers. For this purpose, the sea bottom material was removed to increase depth by 1.0 m. A sand layer of about 20 cm was then spread over this dredged zone. Hence, 80 cm were added to the water depth here; and for the M.W.L. depths of about 1.9 m were ensured for the swimmers in an area of 10 672 m<sup>2</sup>, that is about 9 to 10 times the size of a standard swimming pool. The total volume of extracted rock for this purpose was 14 010 m<sup>3</sup>.

*Table 1* summarized some of the design characteristics of the artificial

*Table 1.* Characteristics of the artificial beach

Characteristic	Amount
total beach area	64 000 m <sup>2</sup>
stones for protection	36 000 m <sup>3</sup>
pedestrian area	7 100 m <sup>2</sup>
green area	4 000 m <sup>2</sup>
changing rooms and showers	400 m <sup>2</sup>
sand nourishment area	42 000 m <sup>2</sup>
sand nourishment volume	56 000 m <sup>3</sup>
sand mean diameter	0.5 ~ 0.7 mm
sand specific weight	2.8

beach, which have remained unchanged throughout the years. The sand nourishment volume shown in *Table 1* was used to fill the beach during its construction, and no surcharge has been necessary since then.

### 3. IMPACT ON THE MARINE ENVIRONMENT

Before the artificial beach was constructed, there was no beach development at the site. A comparison of field studies performed at that time, and those done during the almost 20 years thereafter have allowed an assessment of the beaches marine environmental impact. These field studies are mainly related to the velocity field, wave and tide climate, water quality and marine ecology, and are described in this section.

#### 3. 1. Velocity field

Results obtained from field measurements carried out before and after the artificial beach was constructed are shown in *Table 2*. The measurements of 1973 were performed before the beach construction by taking aerial photographs, at fixed intervals, of buoys deployed in front of the zone destined for the beach. The rest of the results shown in *Table 2* are from measurements taken after the beach construction. The latter results were obtained from measurements at two stations located inside the reef, one at the south of the beach, and the other at its north. The south station was located almost at the same place for all measurement campaigns. The north station, however, was set closer to the beach, outside any notorious reef discontinuity, for the campaigns of 1974 and 1975, and for the campaigns of 1985 and 1986, it was located inside a reef discontinuity. The measurements performed after the beach construction were taken about 50 cm below the water level.

*Table 2.* Current velocity

Year	Velocity during ebb tide (m/s)	Velocity during flood tide (m/s)	Wind velocity (m/s)
1973	0.30 - 0.40	—	—
1974	0.07 - 0.18	0.06 - 0.17	7.0
1975	0.05 - 0.20	0.02 - 0.12	3.5 - 6.0
1985	0.05 - 0.35	0.03 - 0.55	5.0
1986	0.03 - 0.10	0.02 - 0.50	2.0 - 3.0

*Table 2* shows that the respective velocity values are of the same order of magnitude, and that the higher velocities are related to higher wind velocities. It should be noticed, however, that the maximum velocity values were found inside the greatest reef discontinuity, schematized in *Figure 1*. Because during the 1974 and 1975 campaigns the north station was set outside this zone, smaller current velocity values were reported here even though the corresponding wind velocities

were higher, when compared with those values reported from the campaigns of 1985 and 1986.

From measurements taken at other stations, it was found that the maximum velocities reported were obtained at the narrow part of the greatest reef discontinuity. In 1973, velocities ranging from 0.6 to 1.0 m/s during the ebb tide, and in 1986, 0.85 m/s during the flood tide were measured. Relatively high velocities were also found close to the north-headland, where there is another discontinuity; in 1975, velocities of 0.6 m/s were found during both ebb and flood tides, at a station located between the north-headland and the promontory located nearby; and in 1986, velocities of 0.55 m/s during the flood tide were reported to be just in front of this headland.

### 3. 2. Wave and tide climate

The deep water wave conditions used for the beach design are wave height  $H_0 = 7.2$  m, wave period  $T = 12.0$  s, with a SW wave direction. The computed significant wave height in front of the beach, at the depth 2.5 m for H.W.L., is  $H_{1/3} = 1.5$  m.

The results of wave conditions measured before and after the beach was constructed are summarized in *Table 3*.

*Table 3.* Wave conditions

Year	Significant wave		Maximum wave		Wave direction
	$H_{1/3}$ (m)	$T_{1/3}$ (s)	$H_{\max}$ (m)	$T_{\max}$ (s)	
1974	0.21	7.0	0.31	6.8	SW
1985	0.60	6.0	0.65	6.0	NW, SW
1986	0.61	5.1	1.28	2.9	SW

In 1974, the measurements were performed from January to March, and in 1985, during November. In the latter period, two stations were considered, one about 150 m at the SE of the south-headland, and the other about 1 000 m at the NE of the north-headland. The measurements in 1986 were performed in September, during a typhoon. Two stations were selected, one inside the reef, about 200 m at the SE of the north-headland, and the other outside, about 400 m at the E of the same headland. Outside the reef, the significant wave height during the typhoon was 1.88 m, and its related wave period 9.2 s, and the maximum wave height and related period were 3.08 m and 2.5 s, respectively.

Field observations performed outside and inside the reef show that the wave height inside the reef was significantly decreased from the wave height outside; for instance during the typhoon reported in 1986, the wave height inside the reef was about 30% of the wave height outside.

The wave conditions are influenced by the tide as follows: for H.W.L. waves

of longer period and greater height appear, and of shorter period and smaller height for L.W.L. The tide levels of H.H.W.L., H.W.L., M.W.L. and L.W.L. are +2.40 m, +1.90 m, +1.10 m and  $\pm 0.00$  respectively.

### 3. 3. Water quality

Water quality monitoring has shown that the composition of the water inside and outside the reef is similar, so it is presumed that there is enough water circulation inside the reef.

Water quality monitoring is performed twice a year since 1979, once during the Spring time and the other during the Summer. It has been found that the respective average temperatures are about 22 and 28°C. In *Table 4* some results are shown from samples taken before the beach was constructed, in December 1973, and afterwards. In this table, NCB means number of coliform bacteria groups, MPN means most probable number, and the transparency is determined by the secchi disk depth.

*Table 4.* Water components of the artificial beach

Year	Season	NCB MPN/100 ml	Hexane extracts	COD mg/l	Secchi disk depth
1973	Winter	—	—	0.0 ~ 1.3	≈0.3 m
1980	Spring	17.0	not present	0.7	≈0.3 m
	Summer	25.0	"	0.9	≈0.3 m
1985	Spring	0.2	"	0.7	all depth
	Summer	6.0	"	0.8	all depth
1989	Spring	1.1	"	0.5	≈1.5 m
	Summer	0.3	"	0.9	≈1.5 m
1991	Spring	0.3	"	0.4	≈1.0 m
	Summer	0.8	"	0.3	≈1.0 m
1992	Spring	1.5	"	1.0	≈1.0 m
	Summer	0.0	"	0.8	≈1.0 m
1993	Spring	0.0	"	0.6	all depth
	Summer	2.0	"	0.8	all depth

The Japanese standards for water quality at bathing beaches are shown in *Table 5*.

Comparing the measured values with these standards, it is observed that before 1985 the water quality was good, and thereafter it has improved, and it is now considered to be of very good quality.

Furthermore, in addition to the water quality characteristics shown in *Table 4*, the concentrations of elements such as cadmium, arsenic, chromium, mercury, lead, and phosphorus were analysed, and it was found that the amounts

Table 5. Japanese standards for water quality of bathing beaches

Quality	NCB MPN/100 ml	Hexane extracts	COD mg/l	Secchi disk depth
very good	2	not present	≤2.0	≥1.0 m
good	100	not present	≤2.0	≥1.0 m
moderate	1 000	rarely detected	2.0	<1.0 m
bad	>1 000	always present	—	—

detected in the samples were under the acceptable limits so as to be harmless to humans.

### 3. 4. Marine ecology

The marine fauna inside the reef consists mainly of deer's horn coral (*Acropora sp.*). During and just after the beach construction was completed, three campaigns to determine the life expectancy of the corals were carried out. The campaigns took place in November 1974, and April and September of 1975. The mortality rates of the corals at seven stations were determined. Results from the April 1975 campaign show values of the coral's mortality rates that lie between those rates measured during the November 1974 and September 1975 campaigns. Results from these two last campaigns are shown in *Figure 4*.

Fig. 4. Coral's mortality rates

In *Figure 4* is observed that particularly for the stations in front of the beach, the mortality rate increased notoriously. One reason for this was indeed the pollutants derived from the beach's construction. The main reason, however, was the sudden proliferation of a marine creature called crown-of-thorns (*Acanthaster*

*planci*) which feeds on coral. This creature came from a nearby island directly in front of the beach. A campaign to remove part of this species was conducted to preserve the coral reef communities. In 1986, field studies showed that in front of the beach, the coral's mortality rate was less than 30%, and that the prevalent environmental conditions then were also found to be favorable for their steady reproduction.

#### 4. BEACH TOPOGRAPHY CHANGE AND BEACH STABILITY

Nineteen years have passed since the artificial beach was constructed and no re-nourishment has been necessary.

The initial beach slope was 1/15, and it has presently changed as follows: in Nagame-no-hama it is 1/14, in Asobi-no-hama 1/30 and in Ikoi-no-hama 1/32. The wave and current effects on Nagame-no-hama have been the most significant ones; as expected during the design phase. That is to say, the actual state of the beach is now just as predicted. The wave and current effects on Asobi-no-hama and Ikoi-no-hama are weak and therefore their slopes are mild. These slopes had been established in a couple of years after the beach construction. It is surmised therefore that all the beaches are stable.

Once a year, in February, bed profiles have been measured during the last 10 years and the necessary amount of sand to be moved for the beaches' restoration has been determined. Then, in March, the beaches' configuration is restored. The amount of sand moved for the beaches restoration during five years is shown in *Table 6*. And, in *Table 7* the amount of sand moved for each beach during four years is shown.

*Table 6.* Amount of sand moved during the beaches restoration

Year	1990	1991	1992	1993	1994
<b>Amount of sand moved (m<sup>3</sup>)</b>	3 403	5 611	4 321	3 182	2 242

*Table 7.* Amount of sand moved for each beach restoration, in m<sup>3</sup>

Year	1990	1992	1993	1994
<b>Ikoi-no-hama</b>	1 204	1 198	1 668	436
<b>Nagame-no-hama</b>	362	423	541	528
<b>Asobi-no-hama</b>	1 837	2 700	973	1 278

From *Table 6* it is seen that during the five years shown here, the amount of sand moved for the restoration of the beach configuration represents about 5 to 10% of the sand volume used for the beach nourishment.

From *Table 7* it is seen that only for the Nagame-no-hama beach's restoration the sand volume moved is roughly similar each year, whereas for the Ikoi-no-hama and Asobi-no-hama beaches, the amount of sand moved is more irregular.

Table 8. Amount of sand moved during the beach restoration in 1994

Beach	Removed sand (m <sup>3</sup> )	Filled sand (m <sup>3</sup> )
Ikoi-no-hama	249	187
Nagame-no-hama	198	330
Asobi-no-hama	674	604

It seems that the amounts of sand moved for these two last beaches are somehow influenced by the volume moved in the previous year.

In Table 8 the amount of sand removed or used to fill each beach for its restoration in March 1994 is shown; this is schematized in Figure 5. In this figure the negative values of thickness refer to the sand removed, and the positive values correspond to the sand filling.

Figure 5 shows that in Ikoi-no-hama there was sand transport from the middle part of the beach to both its ends, but mainly to its closest land end. In the Nagame-no-hama, the sand transport is offshore, so sand should be returned onshore for its restoration. In the Asobi-no-hama, the sand transport is from the beach ends towards the middle part. During its restoration, sand should be therefore removed from the middle and returned to its ends.

The yearly restoration of the beach similar to that shown in Figure 5 contributes to maintain the beach stability in a functional way.

Fig. 5. Sand moved for the beach restoration in 1994

## 5. BEACH MAINTENANCE AND MANAGEMENT

To protect the environment, the beach is cleaned 250 times each year, and in the water itself, the cleaning is performed 60 times per year. The main problem concerning the environment is the proliferation of seaweeds. The seaweeds that reproduce in the reef are transported to the beach by waves and currents, and since they present an unattractive view to bathers, they are removed periodically.

For the beach restoration, which is performed in March, a bulldozer is used.

The artificial beach is open to the public every year from the first of April to the last day of October. In *Table 9* three year data is shown of the yearly number of visitors to the beach, and from these, the number who used the beach to swim.

*Table 9.* Visitors and bathers using the beach

Year	1990	1991	1992
Visitors	138 484	154 061	350 921
Bathers	86 620	79 536	132 068

*Table 9* reveals that for three consecutive years there has been a continuous increase in the number of visitors and bathers. This may be accredited to the beach maintenance described herein which makes it an attractive recreational facility.

Finally, it may be added that the annual maintenance cost, which includes the beach cleaning and restoration programs, is about fifteen million yen.

## 6. CONCLUSIONS

It is concluded that after the nearly two decades that the artificial beach "Expo Beach" has existed, the facility has to all extents and purposes retained its natural environment unchanged. Yearly restoration of the beach configuration by using only the sand transported by waves and currents effects, *i.e.* without any sand renourishment, has proved enough to maintain the beach stability in a functional way. This task together with the periodical beach cleaning have preserved this artificial beach as a pleasant recreational facility.

Furthermore, the stated artificial beach was constructed on a coral reef which gave a firm foundation for coastal structures.

The study of the stability, maintenance and management of the artificial beach "Expo Beach" is a good example to consider when similar beach construction projects are planned.

## ACKNOWLEDGEMENTS

The authors wish to express their thanks to Mr. H. Maesato of the Ocean Expo Commemorative Park Management Foundation and Mr. T. Yabushita of Nippon Tetrapod Co. for providing us field data, and to Dr. K. Horikawa, President of Saitama University, for his comments on the manuscript.

## CHAPTER 174

# SUSPENDED SEDIMENT PARTICLE MOTION IN COASTAL FLOWS

Peter Nielsen<sup>1</sup>

### Abstract

The motion of suspended sediment particles is discussed with the aim of determining which aspects are important and which ones can be neglected when the goal is to model coastal sediment transport. It is shown that the key lies in the structure of the flow, i e, vortices versus wave orbital motion, rather than in details of the drag law. With a proper description of the flow structure the most important phenomena can be modelled under simple assumption that the sediment velocity is everywhere the sum of the local, instantaneous fluid velocity and the still water settling velocity of the sediment:  $u_s = u + w_o$ . Guide lines are also given for dealing with sediment in numerical models. This paper considers only non-cohesive particles in thin suspensions where the interaction of sediment particles can be safely neglected.

### Introduction

To model the transport of (suspended) sediment one must first understand the way in which suspended particles move with the flow. For many years, this was however considered to be too difficult. - The turbulence was filed away as "complicated" and little progress was made with respect to the motion of suspended particles in organised flows because it was assumed that the general non-linearity of the of drag forces would have to be accounted for in the first approximation.

Recent research has however shown that simple kinematic considerations suffice to describe the most important aspects of suspended particle motion. For example, the important difference between vortices and wave motion, which is illustrated in Figure 1, can be understood through the simple kinematic model

$$u_s = u + w_o. \quad (1)$$

which expresses the assumption that the sediment particle velocity vector  $u_s$  can at all

---

Reader, Department of Civil Engineering, University of Queensland, Brisbane, AUSTRALIA 4072, fax: +61 7 365 4599, e-mail: nielsen@civil.uq.oz.au

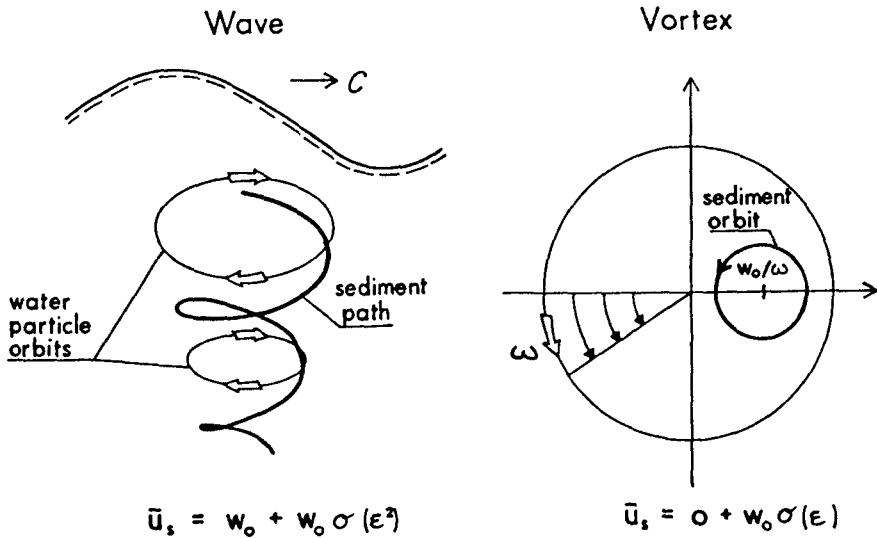

Figure 1: Although vortices and wave motion both have closed elliptical fluid orbits, their influence on suspended sediment are quite different. Vortices will practically eliminate the settling velocity while the effect of wave motion is small of order  $\epsilon^2$  (Equation 2).

times be obtained by adding the still water settling velocity  $w_o$  to the local fluid velocity vector  $u$ .

Under the assumption (1) it can be shown that sediment particles can be trapped along closed paths in most types of vortices as illustrated in figure 3. On the other hand, a wave motion with elliptical fluid orbits has no effect:  $\bar{u}_s = w_o$ , see e.g Nielsen (1992). No consideration of the linear/non-linear nature of the fluid forces is needed to explain these differences. What is important however, is the nature of the organised flow structures like vortices. The essential difference between the vortices and the wave motion in this respect is that the vortices are inhomogeneous while the wave motion is (approximately) homogeneous.

In the following we shall consider, and as far as possibly quantify, the various mechanisms which affect the motion of sediment particles.

### Non-linear Drag

It has long been realised that if the fluid drag force on the particle is non-linear then

this will affect the mean vertical velocity of a particle that settles through a vertically oscillating flow. The effect will be a delay compared to settling through still water.

Several numerical studies, e.g. Ho (1964) and Murray (1970) have been conducted on this effect and an analytical solution was given by Nielsen (1979, 1992). The effect has also been shown experimentally by Ho (1964) who monitored the settling of single particles inside a water filled container which was shaken as a whole in the vertical direction but not stirred. Other types of experiments, which include stirring of the fluid, are not suitable for showing the effect of non-linear drag because the other effects such as vortex trapping and/or fast tracking are likely to dominate in such flows.

The perturbation solution of Nielsen (1979, 1992) shows that the reduction in settling velocity due to quadratic drag on a particle in vertically oscillating fluid with amplitude  $R$  and angular velocity  $\Omega$  is approximately given by

$$\bar{w} = w_o \left[ 1 - \frac{1}{16} \left( \frac{R\Omega^2}{g} \right)^2 \right] \tag{2}$$

showing that the effect the effect is small of order  $\epsilon^2$  where

$$\epsilon = \frac{1}{g} \left| \frac{du}{dt} \right| \tag{3}$$

The solution (2) is compared to Ho's (1964) data in Figure 3. Note that in near-bed coastal flows  $\epsilon \lesssim 1/6$  (Bagnold 1946) and that Equation (2) with  $\epsilon = 1/6$  gives a delay of only  $0.002w_o$ , which is clearly negligible.

Figure 3: The settling delay due to non-linear drag is well described by equation (2) and it is seen that the effect is insignificant when the fluid accelerations are small compared to  $g$ . This is always the case near the bottom in a wave motion.

### Vortex trapping

An effect which can cause much greater delay to sediment settling is the trapping in vortices. If a particle is trapped in a vortex for ever, its settling velocity is obviously eliminated. The potential for vortex like flows to trap particles and bubbles was probably first noted by Stommel (1949) who considered the motion of particles inside a box shaped convection cell. However, this motion is much more complicated mathematically than that of a circular solid body vortex. Tooby et al (1977) and Nielsen (1979) considered the latter and showed that if a sediment particle moves in accordance with the assumption (1) in such a vortex it can be trapped for ever on any circular orbit around the point where the fluid velocity balances its still water settling velocity, and the orbit angular velocity is that of the vortex, cf Figure 3.

*Figure 3:* A sediment particle with settling velocity  $w_o$  can, under the assumption (1) be at rest at the point  $(w_o/\omega, 0)$  or move along any circle around this point with the angular velocity of the vortex motion. See also the photograph by Tooby et al (1977).

In a simple forced vortex the sediment paths are circles around the point  $P_o$  where the fluid velocity is equal and opposite to  $w_o$ . In Rankine vortices and irrotational vortices, the closed sediment orbits still exist in the vicinity of  $P_o$  but they are not circular. See e g Nielsen (1992).

The fact that also irrotational vortices can trap sediment shows that the essence

of the effect is not that the flow is rotational. Rather, it lies in the inhomogeneity of the flow. In fact, the trapping effect is a special case of the loitering effect which is discussed below.

### **Centrifugal effects**

The assumption (1) and hence the solution shown in Figure 3 is valid if the fluid accelerations are small in the sense that

$$\varepsilon = \frac{1}{g} \left| \frac{d\mathbf{u}}{dt} \right| \ll 1 \quad (4)$$

At order  $\varepsilon^1$  another interesting feature of particle motion in flow with eddies becomes apparent. Due to centrifugal effects a heavy particle in a vortex will spiral outwards from the closed path shown in Figure 3 and as a result, sand particles will tend to become concentrated in the border areas between eddies. This concentration effect was noticed by Maxey & Corrsin (1986) through a computer simulation, but the essence of it, i.e., the centrifugal drift of heavy particles towards the edge of the vortices was quantified already by Nielsen (1979) who showed that the time scale  $T_{sp}$  of the spiralling process is given by

$$T_{sp} = \left[ \frac{1}{r} \frac{dr}{dt} \right]^{-1} = \frac{g}{w_o \Omega^2} \quad (5)$$

where  $r$  is the distance from the vortex centre and  $\Omega$  is the angular velocity of the vortex, see also Nielsen (1992) p 186. The centrifugal effect also affects bubbles, but since they are lighter than water, they spiral inwards. This makes the trapping mechanism particularly efficient for bubbles.

### **Fast tracking between vortices**

The fact that dense particles will spiral out towards the vortex boundaries can lead to fast tracking of small, dense particles in strong turbulence. The reason, as shown in Figure 4, is that the particle speed along the preferred tracks is the maximum vortex velocity which may be much larger than the particles still water settling velocity.

The result of this fast tracking is an increase in effective settling velocity  $\bar{w}$  which is theoretically unlimited: the relative, effective settling velocity is proportional to the relative turbulence intensity for strong turbulence. For grid turbulence the factor of proportionality is approximately 0.3

$$\frac{\bar{w}}{w_o} \approx 0.3 \frac{\sigma}{w_o} \quad (6)$$

where  $\sigma$  is a typical turbulent velocity, see Figure 5. A perfectly regular and steady array of vortices would lead to a factor of about 0.4,

*Figure 4:* Due to centrifugal effects, sediment particles will get concentrated along the boundaries between vortices and experience a settling velocity increase if the vortices are persistent enough and strong enough.

A sceptic is of course justified in asking whether the behaviour of particles in a highly artificial flow field as the one in Figure 4 has any relevance to sediment motion in natural turbulence. The answer from experimental evidence is that it has. The available data from grid turbulence experiments is shown in Figure 5 but also experiments in steady open channel flow by Jobson & Sayre (1970) show the fast tracking effect. The Jobson & Sayre experiments show up to a factor 2 increase in

settling velocity for fine sand [ $w_o = 1.1\text{cm/s}$ ] and a more moderate increase of only a few percent for coarse sand [ $w_o = 6.3\text{cm/s}$ ] - a picture which is in qualitative agreement with that of the grid turbulence data.

Figure 5: Measured change in settling velocity due to grid turbulence. For weak turbulence the effect is generally a settling velocity decrease due to the loitering effect and trapping, while strong turbulence results in a (theoretically unlimited) increase. + Murray (1970), o Nielsen (1993).

### Trapping or fast tracking?

In the two previous sections we have seen that vortices can have two opposite, strong effects on the settling of particles. The particles can be trapped inside a vortex or they can be fast tracked along the boundaries of vortices. The question then naturally arises: *Which effect is going to be dominant?*

The answer is that if the sand is fed into the vortex while it is being formed such as it happens with the lee vortices on a rippled sand bed, see e.g. Bijker et al (1976). Then it is going to be trapped for a while and will travel with the vortex for some considerable distance without settling out.

On the other hand, there is no chance of a heavy particle coming from the outside of a vortex and getting onto one of the "trapping" closed trajectories inside. Sediment particles which settle towards a vortex will get swept past the potential

trapping area of the vortex as illustrated in Figure 4. See also Nielsen (1992) Figure 4.6.3.

### **The general loitering effect**

Considering the particle which settles along the vertical symmetry line between the vortices in Figure 4 it can be seen that that even though the spatial average of its velocity ( $\mathbf{u} + \mathbf{w}_o$ ) is  $\mathbf{w}_o$ , the time averaged velocity will be less than  $\mathbf{w}_o$ . Hence particles will settle more slowly through an inhomogeneous flow field than through still (or uniformly flowing) water. This is because the particle spends more time (loiters) with the fluid which moves opposite to its settling velocity.

The loitering effect was quantified by Nielsen (1992, 1993) for a special example and it was shown how this effect might slow the settling of particles in random walk simulated, "structureless" turbulence. That is, while the loitering effect is due to the non-uniformity of the flow field, it is not necessary to deal explicitly with the flow structure.

The loitering represents the essential reason why vortices delay settling while a (almost) uniform wave motion, does not. - Figure 1.

### **Sediment in wave motions**

With coastal engineering applications in mind, it is natural to ask whether a pure wave motion will delay the settling of sediment or the rise of bubbles significantly. It is very difficult to give a complete answer to this. However, for the simple velocity field of a linear shallow water wave

$$\mathbf{u} = \begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} \frac{Hc}{2h} \cos(\omega t - kx) \\ \frac{H\omega z}{2h} \sin(\omega t - kx) \end{pmatrix} \quad (7)$$

the possible effect must be as small as effect of non-linear drag i.e. without significance. In Equation (7)  $H$  is the wave height,  $h$  the water depth,  $c$  the wave celerity,  $\omega$  the angular velocity and  $k$  the wave number.

The equation of vertical motion of a small (with linear drag) particle can be conveniently written as

$$\frac{dw_r}{dt} + \frac{\alpha g}{w_o} w_r + \frac{\partial w}{\partial t} = -\alpha g - \alpha \frac{dw}{dt} \quad (8)$$

where  $w_r$  is the vertical velocity relative to the fluid and  $\alpha = \frac{s-1}{s+C_m}$ ,  $s$  being the relative density of the sediment and  $C_m$  being the added mass coefficient (approximately 0.5 for nearly spherical particles).

If the expression above is inserted for  $w$ , this gives

$$\frac{dw_r}{dt} + \frac{\alpha g}{w_o} \left[ 1 + \frac{H\omega w_o}{2hg} \sin \omega t \right] w_r \approx -\alpha g - \alpha \frac{\omega^2 H z}{2h} \cos \omega t \quad (9)$$

Here it seems safe to neglect the second term in the bracket since its typical magnitude for sand in waves is  $10^{-3}$ . This small term represents the effect of the vertical non-uniformity of the wave motion.

Then, by writing the relative velocity  $w_r$  in terms of the still water settling velocity  $w_o$ :  $w_r = w_o + w_I$  and using

$$z = h - w_o t [1 + O(\epsilon)] \quad (10)$$

we get the following equation for  $w_I$

$$\frac{dw_I}{dt} + \frac{\alpha g}{w_o} w_I \approx -\alpha \frac{\omega^2 H z}{2h} [h - w_o t] \cos \omega t \quad (11)$$

The solutions to this equations are of the form  $A \cos(\omega t + \phi) + B t \cos(\omega t + \psi)$  showing that at the first level of approximation there is no net change of the settling rate due to the wave motion.

Any net change of the settling velocity is thus either due to the non-uniformity mentioned above or due to non-linear drag. In both cases its magnitude will be of the order  $10^{-3} w_o$  for sand in wave motions.

### Sediment in numerical models

For the purpose of dealing with sediment particles in numerical models it is useful to note that the sediment velocity can be written as

$$\mathbf{u}_s = \mathbf{w}_o + \mathbf{u}(t - \delta_t) + w_o \mathbf{O}(\epsilon^2) \quad (12)$$

where  $\mathbf{O}(\epsilon^2)$  denotes a vector function of magnitude  $\epsilon^2$ . The time lag is given by  $\delta_t = w_o/g$  for small particles that settle under the laminar drag law and  $\delta_t = w_o/2g$  for larger particles that settle with quadratic drag, see Nielsen (1979, 1992).

The use of the approximation

$$\mathbf{u}_s \approx \mathbf{w}_o + \mathbf{u}(t - \delta_t) \quad (13)$$

is thus usually justified in natural sediment transport processes and it is very convenient because it does not require explicit consideration of the particle dynamics at all. All

that is needed is a stored value  $u(t-\delta_t)$  of the local fluid velocity at a previous time.

### Frequency response

The expression (13) corresponds to a linear frequency response function  $F(\omega)$  defined by

$$u_s - w_o = F(\omega) U e^{i\omega t} \quad (14)$$

for the dynamic part of the velocity of a particle that moves in a homogeneous, simple harmonic flow  $u(t) = U e^{i\omega t}$ . In terms of the time lag quantified above this frequency response function is given by:

$$F(\omega) = \frac{1}{1 + i\omega\delta_t} \quad (15)$$

and a corresponding gain function is

$$G(\omega) = \frac{1}{\sqrt{1 + (\omega\delta_t)^2}} \quad (16)$$

### Conclusions

The considerations above cover the behaviour of suspended sediment particles in small concentrations where particle-particle interactions can be neglected and the analytical approximations are obtained using perturbation expansions in the parameter  $\epsilon = \frac{1}{g} \left| \frac{du}{dt} \right|$ .

It has been shown that the most important aspects of the motion of such sediment can be understood on the basis of the simple assumption  $u_s = u + w_o$  which is valid for  $\epsilon \rightarrow 0$ .

It has also been shown that the settling delay due to drag non-linearity is negligible (about  $10^{-3} w_o$ ) for sand in wave motions and that the effect of non-uniformity of the wave motion is likely to be equally small.

Vortices can have two strong but opposite effects on the settling of sediment: *Trapping inside the vortices* and *fast tracking between vortices*. The former occurs only when the sand is fed into the vortex during the vortex formation as it happens with lee vortices behind sharp-crested bedforms. Fast tracking occurs when the sediment is settling through a field of vortices. Both of these effects are limited to situations where the typical vortex velocities  $u_v$  are large compared to  $w_o$ . Trapping is possible as long as  $u_v > w_o$ . Fast tracking is not dominant unless  $u_v/w_o \geq 4$ . For

smaller vortex strengths, the particles tend to cut through the vortices (see the illustrations of Maxey & Corrsin (1986)) and doing so they are delayed through the loitering effect and/or trapping.

Numerical modelling of particles in flows where  $\epsilon^2 \ll 1$  can be done very easily using equation (13) which does not require explicit consideration of the particle dynamics.

# Coastal Engineering 1994

Proceedings of the  
twenty-fourth international conference

October 23-28; 1994  
Kobe, Japan

Conference held under the auspices of the  
Coastal Engineering Research Council of the  
American Society of Civil Engineers

Organized by the Japan Society of Civil Engineers

Edited by Billy L. Edge

Published by the  
American Society of Civil Engineers  
345 East 47th Street  
New York, New York 10017-2398

## ABSTRACT

This proceedings contains over 200 papers presented at the 24th International Conference on Coastal Engineering which was held in Kobe, Japan, October 23-28, 1994. The book is divided into six parts: 1) Characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) coastal processes and sediment transport; 5) coastal, estuarine and environmental problems; and 6) case studies. The individual papers include such topics as the effects of wind, waves, storms and currents as well as the study of sedimentation and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and related fields with a broad range of information on coastal engineering.

Coastal engineering 1994: proceedings of the twenty-fourth international conference, October 23-28, 1994, Kobe, Japan  
edited by Billy L. Edge.

# CONTENTS

## PART I

Plenary Session THE PRESENT AND FUTURE OF COASTAL ENGINEERING IN JAPAN.....	1
<i>Yuichi Iwagaki</i>	
Chapter 1 ON THE CHARACTERISTICS OF ONE-DIMENSIONAL SPECTRA AND NON-DIMENSIONAL PARAMETERS OF WIND WAVES.....	12
<i>Toshio Aono, Chiaki Goto</i>	
Chapter 2 SWASH MOTION DUE TO OBLIQUELY INCIDENT WAVES.....	27
<i>Toshiyuki Asano</i>	
Chapter 3 LABORATORY COMPARISON OF DIRECTIONAL WAVE MEASUREMENT SYSTEMS AND ANALYSIS TECHNIQUES .....	42
<i>Michel Benoit, Charles Teisson</i>	
Chapter 4 ACCURACY OF WIND AND WAVE EVALUATION IN COASTAL REGIONS.....	57
<i>Luciana Bertotti, Luigi Cavaleri</i>	
Chapter 5 A SPECTRAL MODEL FOR WAVES IN THE NEAR SHORE ZONE.....	68
<i>R.C. Ris, L.H. Holthuijsen, N. Booij</i>	
Chapter 6 WIND VARIABILITY AND EXTREMES STATISTICS.....	79
<i>Luigi Cavaleri, Luciana Bertotti</i>	
Chapter 7 MEAN FLUX IN THE FREE SURFACE ZONE OF WATER WAVES IN A CLOSED WAVE FLUME.....	86
<i>Witold Cieslikiewicz, Ove T. Gudmestad</i>	
Chapter 8 VERTICAL VARIATIONS OF FLUID VELOCITIES AND SHEAR STRESS IN SURF ZONES .....	98
<i>Daniel T. Cox, Nobuhisa Kobayashi, Akio Okayasu</i>	

Chapter 9	
VORTICITY EFFECTS IN COMBINED WAVES AND CURRENTS.....	113
<i>I. Cummins, C. Swan</i>	
Chapter 10	
WAVES IN AN ANNULAR ENTRANCE CHANNEL .....	128
<i>Robert A. Dalrymple, J.T. Kirby</i>	
Chapter 11	
WAVE DAMPING BY KELP VEGETATION.....	142
<i>Alfonse Dubi, Alf Tørum</i>	
Chapter 12	
NONLINEAR COUPLING IN WAVES PROPAGATING OVER A BAR.....	157
<i>Y. Eldeberky, J.A. Battjes</i>	
Chapter 13	
AN ABSORBING WAVE-MAKER BASED ON DIGITAL FILTERS .....	168
<i>Peter Frigaard, Morten Christensen</i>	
Chapter 14	
WAVE CLIMATE STUDY IN WADDEN SEA AREAS .....	181
<i>Ralf Kaiser, Günther Brandt, Joachim Gärtner, Detlef Glaser, Frerk Jensen, H.D. Niemeyer, Joachim Grüne</i>	
Chapter 15	
FALSE WAVES IN WAVE RECORDS AND NUMERICAL SIMULATIONS.....	192
<i>Marcos H. Giménez, C.R. Sánchez-Carratalá, J.R. Medina</i>	
Chapter 16	
MEASURING WAVES WITH MANOMETER TUBES .....	207
<i>David J. Hanslow, P. Nielsen, K. Hibbert</i>	
Chapter 17	
QUANTITY OF SPRAY TRANSPORTED BY THE STRONG WIND OVER BREAKING WAVES .....	219
<i>Nobuhiro Matsunaga, Misao Hashida, Hiroyuki Mizui, Yuji Sugihara</i>	
Chapter 18	
EXTENSION OF THE MAXIMUM ENTROPY PRINCIPLE METHOD FOR DIRECTIONAL WAVE SPECTRUM ESTIMATION .....	232
<i>Noriaki Hashimoto, Toshihiko Nagai, Tadashi Asai</i>	

Chapter 19	
A REGRESSION MODEL FOR ESTIMATING SEA STATE PERSISTENCE .....	247
<i>Yoshio Hatada, Masataka Yamaguchi</i>	
Chapter 20	
THE MAXIMUM SIGNIFICANT WAVE HEIGHT IN THE SOUTHERN NORTH SEA .....	261
<i>L.H. Holthuijsen, J.G. de Ronde, Y. Eldeberky, H.L. Tolman, N. Booij, E. Bouws, P.G.P. Ferier, J. Andorka Gal</i>	
Chapter 21	
IMPROVED BOUNDARY CONDITIONS TO A TIME-DEPENDENT MILD-SLOPE EQUATION FOR RANDOM WAVES .....	272
<i>Toshimasa Ishii, Masahiko Isobe, Akira Watanabe</i>	
Chapter 22	
TIME-DEPENDENT MILD SLOPE EQUATIONS FOR RANDOM WAVES .....	285
<i>Masahiko Isobe</i>	
Chapter 23	
MODELLING MOVEABLE BED ROUGHNESS AND FRICTION FOR SPECTRAL WAVES .....	300
<i>L.M. Kaczmarek, J.M. Harris, B.A. O'Connor</i>	
Chapter 24	
DIFFERENCE BETWEEN WAVES ACTING ON STEEP AND GENTLE BEACHES .....	315
<i>Kazumasa Katoh</i>	
Chapter 25	
WAVE BREAKING UNDER STORM CONDITION .....	330
<i>Yoshiaki Kawata</i>	
Chapter 26	
APPLICATION OF MAXIMUM ENTROPY METHOD TO THE REAL SEA DATA .....	340
<i>Taerim Kim, Li-Hwa Lin, Hsiang Wang</i>	
Chapter 27	
PROBABILITY OF THE FREAK WAVE APPEARANCE IN A 3-DIMENSIONAL SEA CONDITION .....	356
<i>Akira Kimura, Takao Ohta</i>	

Chapter 28	
ON THE JOINT DISTRIBUTION OF WAVE HEIGHT, PERIOD & DIRECTION OF INDIVIDUAL WAVES IN A 3-DIMENSIONAL RANDOM SEAS.....	370
<i>J.G. Kwon, Ichiro Deguchi</i>	
Chapter 29	
SPECTRAL WAVE-CURRENT BOTTOM BOUNDARY LAYER FLOWS.....	384
<i>Ole Secher Madsen</i>	
Chapter 30	
TIME DOMAIN MODELLING OF WAVE BREAKING, RUNUP AND SURF BEATS .....	399
<i>Per A. Madsen, O.R. Sørensen, H.A. Schäffer</i>	
Chapter 31	
ORTHONORMAL WAVELET ANALYSIS FOR DEEP-WATER BREAKING WAVES .....	412
<i>Nobuhito Mori, Takashi Yasuda</i>	
Chapter 32	
A FULLY DISPERSIVE-NONLINEAR WAVE MODEL AND ITS NUMERICAL SOLUTIONS .....	427
<i>Kazuo Nadaoka, Serdar Beji, Yasuyuki Nakagawa</i>	
Chapter 33	
A GENERALIZED GREEN-FUNCTION METHOD FOR WAVE FIELD ANALYSIS .....	442
<i>Hitoshi Nishimura, Michio Matsuoka, Akira Matsumoto</i>	
Chapter 34	
COUPLED VIBRATION EQUATIONS FOR IRREGULAR WATER WAVES.....	455
<i>Masao Nochino</i>	
Chapter 35	
NONLINEAR EVOLUTION OF DIRECTIONAL WAVE SPECTRA IN SHALLOW WATER .....	467
<i>Okey Nwogu</i>	
Chapter 36	
NON-GAUSSIAN PROBABILITY DISTRIBUTION OF COASTAL WAVES .....	482
<i>M.K. Ochi, K. Ahn</i>	

Chapter 37	
PROBABILITY CHARACTERISTICS OF ZERO-CROSSING WAVE HEIGHT .....	497
<i>Takao Ohta, Akira Kimura</i>	
Chapter 38	
NUMERICAL SIMULATION AND VALIDATION OF PLUNGING BREAKERS USING A 2D NAVIER-STOKES MODEL.....	511
<i>H.A.H. Petit, P.Tönjes, M.R.A. Van Gent, P. Van Den Bosch</i>	
Chapter 39	
WAVE VELOCITY FIELD MEASUREMENTS OVER A SUBMERGED BREAKWATER .....	525
<i>Marco Petti, Paul A. Quinn, Gianfranco Liberatore, William J. Easson</i>	
Chapter 40	
VELOCITY FIELD MEASUREMENTS AND THEORETICAL COMPARISONS FOR NON-LINEAR WAVES ON MILD SLOPES .....	540
<i>Paul A. Quinn, Marco Petti, Michele Drago, Clive A. Greated</i>	
Chapter 41	
THE CONCEPT OF RESIDENCE TIME FOR THE DESCRIPTION OF WAVE RUN-UP, WAVE SET-UP AND WAVE RUN-DOWN .....	553
<i>Holger Schüttrumpf, Hendrik Bergmann, Hans-Henning Dette</i>	
Chapter 42	
BOTTOM SHEAR STRESSES UNDER RANDOM WAVES WITH A CURRENT SUPERIMPOSED.....	565
<i>Richard R. Simons, Tony J. Grass, Wameidh M. Saleh, Mehrdad M. Tehrani</i>	
Chapter 43	
EFFECTS FROM DIRECTIONALITY & SPECTRAL BANDWIDTH ON NON-LINEAR SPATIAL MODULATIONS OF DEEP-WATER SURFACE GRAVITY WAVE TRAINS .....	579
<i>Carl Trygve Stansberg</i>	
Chapter 44	
SHEAR STRESSES AND MEAN FLOW IN SHOALING AND BREAKING WAVES .....	594
<i>Marcel J.F. Stive, Huib J. De Vriend</i>	

Chapter 45		
PREDICTION OF THE MAXIMUM WAVE ON THE CORAL FLAT .....	609	
		<i>Dede M. Sulaiman, Shigeaki Tsutsui, Hiroshi Toshioka, T. Yamashita, S. Oshiro, Y. Tsuchiya</i>
Chapter 46		
DEVELOPMENT OF A SUBMERGED DOPPLER-TYPE DIRECTIONAL WAVE METER .....	624	
		<i>Tomotsuka Takayama, Noriaki Hashimoto, Toshihiko Nagai, Tomoharu Takahashi, Hiroshi Sasaki, Yoshiki Ito</i>
Chapter 47		
BRAGG SCATTERING OF WAVES OVER POROUS RIPPLED BED .....	635	
		<i>Hijime Mase, Ken Takeba</i>
Chapter 48		
NON-REFLECTIVE MULTI-DIRECTIONAL WAVE GENERATION BY SOURCE METHOD .....	650	
		<i>Masahiro Tanaka, Takumi Ohyama, Tetsushi Kiyokawa, Kazuo Nadaoka</i>
Chapter 49		
THE GROWTH OF WIND WAVES IN SHALLOW WATER .....	665	
		<i>L.A. Verhagen, I.R. Young</i>
Chapter 50		
ESTIMATION OF TYPHOON-GENERATED MAXIMUM WAVE HEIGHT ALONG THE PACIFIC COAST OF JAPAN BASED ON WAVE HINDCASTING .....	674	
		<i>Masataka Yamaguchi, Yoshio Hatada</i>
Chapter 51		
RUN-UP OF IRREGULAR WAVES ON A GENTLY SLOPING BEACH .....	689	
		<i>Yoshimichi Yamamoto, Katsutoshi Tanimoto, Karunarathna Harshinie</i>
Chapter 52		
SOLITON-MODE WAVEMAKER THEORY AND SYSTEM FOR COASTAL WAVES .....	704	
		<i>Takashi Yasuda, Takeshi Hattori, Seirou Shinoda</i>
Chapter 53		
ON A METHOD FOR ESTIMATING REFLECTION COEFFICIENT IN SHORT-CRESTED RANDOM SEAS .....	719	
		<i>Hirumune Yokoki, Masahiko Isobe, Akira Watanabe</i>

Chapter 54	
THE DIRECTIONAL WAVE SPECTRUM IN THE BOHAI SEA.....	731
<i>Yuxiu Yu, Shuxue Liu</i>	

Chapter 55	
IRREGULAR WAVES OVER AN ELLIPTIC SHOAL.....	746
<i>Xiping Yu, Hiroyoshi Togashi</i>	

Chapter 56	
PERFORMANCE OF A SPECTRAL WIND-WAVE MODEL IN SHALLOW WATER.....	761
<i>Gerbrant Ph. van Vledder, John G. de Ronde, Marcel J.F. Stive</i>	

## PART II

Chapter 57	
THE GENERATION OF LOW-FREQUENCY WAVES BY A SINGLE WAVE GROUP INCIDENT ON A BEACH.....	776
<i>Gary Watson, Timothy C.D. Barnes, D. Howell Peregrine</i>	

Chapter 58	
INFLUENCE OF LONG WAVES ON SHIP MOTIONS IN A LAGOON HARBOUR.....	791
<i>Volker Barthel, Etienne Mansard</i>	

Chapter 59	
RESONANT FORCING OF HARBORS BY INFRAGRAVITY WAVES.....	806
<i>Gordon S. Harkins, Michael J. Briggs</i>	

Chapter 60	
NUMERICAL SIMULATION OF THE 1992 FLORES TSUNAMI IN INDONESIA: DISCUSSION ON LARGE RUNUP HEIGHTS IN THE NORTHEASTERN FLORES ISLAND.....	821
<i>Fumihiko Imamura, Tomoyuki Takahashi, Nobuo Shuto</i>	

Chapter 61	
A COMPARATIVE EVALUATION OF WAVE GROUPING MEASURES.....	832
<i>E.P.D. Mansard, S.E. Sand</i>	

Chapter 62	
RELATIONSHIP OF A MOORED VESSEL IN A HARBOUR AND LONG WAVE CAUSED BY WAVE GROUPS.....	847
<i>Toshihiko Nagai, N. Hashimoto, T. Asai, I. Tobiki, K. Ito, T. Toue, A. Kobayashi, T. Shibata</i>	

Chapter 63  
 COHERENT STRUCTURE OF TIDAL TURBULENCE IN A ROTATING  
 SYSTEM OF OSAKA-BAY ..... 861  
*Tsukasa Nishimura, Tomonao Kobayashi, Goichi Furuta*

Chapter 64  
 DEVELOPMENT OF A PARTIALLY THREE-DIMENSIONAL MODEL  
 FOR SHIP MOTION IN A HARBOR WITH ARBITRARY BATHYMETRY ..... 871  
*Takumi Ohyama, M. Tsuchida*

Chapter 65  
 THE MEASURED AND COMPUTED HOKKAIDO NANSEI-OKI  
 EARTHQUAKE TSUNAMI OF 1993 ..... 886  
*Tomoyuki Takahashi, Nobuo Shuto, Fumihiko Imamura,  
 Hideo Matsutomi*

Chapter 66  
 QUASI-THREE-DIMENSIONAL MODEL FOR STORM SURGES AND  
 ITS VERIFICATION ..... 901  
*Takao Yamashita, Yoshito Tsuchiya, Hiroshi Yoshioka*

### PART III

Chapter 67  
 ANALYSIS OF PRACTICAL RUBBLE MOUNDS ..... 918  
*N.W.H. Allsop, R.J. Jones, P. Besley, C. Franco*

Chapter 68  
 FRICTION AND CLAMPING FORCES IN WAVE LOADED PLACED  
 BLOCK REVETMENTS ..... 932  
*Adam Bezuijen*

Chapter 69  
 A FIELD EXPERIMENT ON THE INTERACTION  
 WAVES-REFLECTING WALL ..... 945  
*Paolo Boccotti*

Chapter 70  
 THE APPLICATION OF LOAD-CELL TECHNIQUE IN THE STUDY  
 OF ARMOUR UNIT RESPONSES TO IMPACT LOADS ..... 958  
*Hans F. Burcharth, Zhou Liu*

Chapter 71	
STEEP WAVE DIFFRACTION BY A SUBMERGED CYLINDER.....	973
<i>J.T. Aquije Chacaltana, A.F.T. da Silva</i>	
Chapter 72	
WAVE STRESSES ON RUBBLE-MOUND ARMOUR .....	986
<i>Andrew M. Cornett, Etienne Mansard</i>	
Chapter 73	
DAMAGE ANALYSIS FOR RUBBLE-MOUND BREAKWATERS .....	1001
<i>Michael H. Davies, Etienne P.D. Mansard, Andrew M. Cornett</i>	
Chapter 74	
NUMERICALLY MODELING PERSONNEL DANGER ON A PROMENADE BREAKWATER DUE TO OVERTOPPING WAVES .....	1016
<i>Kimihiko Endoh, Shigeo Takahashi</i>	
Chapter 75	
WAVE OVERTOPPING ON VERTICAL AND COMPOSITE BREAKWATERS.....	1030
<i>L. Franco, M. de Gerloni, J.W. van der Meer</i>	
Chapter 76	
AN INVESTIGATION OF THE WAVE FORCES ACTING ON BREAKWATER HANDRAILS .....	1046
<i>Atsushi Hujii, Shigeo Takahashi, Kimihiko Endoh</i>	
Chapter 77	
RUBBLE MOUND BREAKWATER STABILITY UNDER OBLIQUE WAVES: AN EXPERIMENTAL STUDY .....	1061
<i>J.-C. Galland</i>	
Chapter 78	
WAVE LOADS ON SEADYKES WITH COMPOSITE SLOPES & BERMS .....	1075
<i>Joachim Grune, Hendrik Bergmann</i>	
Chapter 79	
COMPUTERISED METHODOLOGY TO MEASURE RUBBLE MOUND BREAKWATER DAMAGE.....	1090
<i>Bruno Chilo, Franco Guiducci</i>	

Chapter 80	
WAVE BREAKING OVER PERMEABLE SUBMERGED BREAKWATERS .....	1101
	<i>Masataro Hattori, Hiroyoki Sakai</i>
Chapter 81	
WAVE FORCES ACTING ON A VORTEX EXCITED VIBRATING	
VERTICAL CYLINDER IN WAVES .....	1115
	<i>Kenjiro Hayashi, Futoshi Higaki, Koji Fujima,</i> <i>Toshiyuki Sigemura, John R. Chaplin</i>
Chapter 82	
OVERTOPPING OF SEA WALLS UNDER RANDOM WAVES .....	1130
	<i>D.M. Herbert, N.W.H. Allsop, M.W. Owen</i>
Chapter 83	
STABILITY OF HIGH-SPECIFIC GRAVITY ARMOR BLOCKS .....	1143
	<i>Masahiro Ito, Y. Iwagaki, H. Murakami, K. Nemoto, M. Yamamoto,</i> <i>M. Hanzawa</i>
Chapter 84	
ROCK ARMoured BEACH CONTROL STRUCTURES ON	
STEEP BEACHES .....	1157
	<i>R.J. Jones, N.W.H. Allsop</i>
Chapter 85	
EFFECT ON ROUGHNESS TO IRREGULAR WAVE RUN-UP.....	1169
	<i>Jea-Tzyy Juang</i>
Chapter 86	
WAVE OVERTOPPING OF BREAKWATERS UNDER OBLIQUE WAVES.....	1182
	<i>Jørgen Juhl, Peter Sloth</i>
Chapter 87	
CONSTRUCTION OF OFFSHORE FISHING PORT FOR PREVENTION	
OF COASTAL EROSION .....	1197
	<i>Takeshi Kawaguchi, O. Hashimoto, T. Mizumoto, A. Kamata</i>
Chapter 88	
TOPOGRAPHICAL CHANGE AROUND MULTIPLE LARGE	
CYLINDRICAL STRUCTURES UNDER WAVE ACTIONS.....	1212
	<i>Chang-Je Kim, Koichiro Iwata, Yoshihito Miyaike, Hong-Sun Yu</i>

Chapter 89	
STABILITY OF RUBBLE MOUND FOUNDATIONS OF COMPOSITE BREAKWATERS UNDER OBLIQUE WAVE ATTACK .....	1227
<i>Katsutoshi Kimura, Shigeo Takahashi, Katsutoshi Tanimoto</i>	
Chapter 90	
ANALYSIS OF NONLINEAR COEFFICIENTS OF REFLECTION AND TRANSMISSION OF WAVES PROPAGATING OVER A RECTANGULAR STEP .....	1241
<i>Wudhipong Kittitanasuan, Yoshimi Goda</i>	
Chapter 91	
OSCILLATORY MOTIONS AND PERMANENT DISPLACEMENTS OF CAISSON BREAKWATERS SUBJECT TO IMPULSIVE BREAKING WAVE LOADS.....	1255
<i>P. Klammer, H. Oumeraci, H.-W. Partenscky</i>	
Chapter 92	
HYDRAULIC CHARACTERISTICS AND FIELD EXPERIENCE OF NEW WAVE DISSIPATING CONCRETE BLOCKS (ACCROPODE) .....	1269
<i>Masanori Kobayashi, Sumio Kaihatsu</i>	
Chapter 93	
EXPERIMENTAL STUDY ON DEVELOPING PROCESS OF LOCAL SCOUR AROUND A VERTICAL CYLINDER.....	1284
<i>Tomonao Kobayashi, Kenji Oda</i>	
Chapter 94	
WAVE-INDUCED UPLIFT LOADING OF CAISSON BREAKWATERS .....	1298
<i>Andreas Kortenhaus, Hocine Oumeraci, Søren Kohlhase, Peter Klammer</i>	
Chapter 95	
LINEAR AND NONLINEAR WAVE FORCES EXERTED ON A SUBMERGED HORIZONTAL PLATE.....	1312
<i>Haruyuki Kojima, A. Yoshida, T. Nakamura</i>	
Chapter 96	
MODERN FUNCTIONAL DESIGN OF GROIN SYSTEMS.....	1327
<i>Nicholas C. Kraus, Hans Hanson, Sten H. Blomgren</i>	
Chapter 97	
RESHAPING BREAKWATERS IN DEEP AND SHALLOW WATER CONDITIONS.....	1343
<i>A. Lamberti, G.R. Tomasicchio, F. Guiducci</i>	

Chapter 98	
DESIGN OF BREAKWATERS AND BEACH NOURISHMENT .....	1359
<i>Christian Laustrup, Holger Toxvig Madsen</i>	
Chapter 99	
CIRCULAR CHANNEL BREAKWATER TO REDUCE WAVE OVERTOPPING AND ALLOW WATER EXCHANGE .....	1373
<i>Dal Soo Lee, Woo Sun Park, Nobuhisa Kobayashi</i>	
Chapter 100	
INCREASED DOLOS STRENGTH BY SHAPE MODIFICATION .....	1388
<i>S.A. Luger, D.T. Phelp, A. Van Tonder, A.H. Holtzhausen</i>	
Chapter 101	
INFLUENCE OF WAVE DIRECTIONALITY ON STABILITY OF BREAKWATER HEADS .....	1397
<i>Y. Matsumi, E.P.D. Mansard, J. Rutledge</i>	
Chapter 102	
COST-EFFECTIVENESS OF D-ARMOR BREAKWATER .....	1412
<i>Josep R. Medina</i>	
Chapter 103	
THE CORE-LOC: OPTIMIZED CONCRETE ARMOR .....	1426
<i>Jeffrey A. Melby, George F. Turk</i>	
Chapter 104	
STABILITY OF ARMOR STONES OF A SUBMERGED WIDE-CROWN BREAKWATER .....	1439
<i>Norimi Mizutani, Teofilo Monge Rufin, Jr., Koichiro Iwata</i>	
Chapter 105	
WAVE INDUCED FLOW AROUND SUBMERGED SLOPING PLATES .....	1454
<i>Hitoshi Murakami, Sadahiko Itoh, Yoshihiko Hosoi, Yoshiyuki Sawamura</i>	
Chapter 106	
SECOND-ORDER WAVE INTERACTION WITH ARRAYS OF VERTICAL CYLINDERS OF ARBITRARY CROSS SECTION .....	1469
<i>Keisuke Murakami, Akinori Yoshida</i>	
Chapter 107	
HYDRODYNAMIC FORCES ON BOTTOM-SEATED HEMISPHERE IN WAVES AND CURRENTS .....	1484
<i>Hidenori Nishida, A. Tada, F. Nishihira</i>	

Chapter 108	
THE PRESSURE FIELD DUE TO STEEP WATER WAVES INCIDENT ON A VERTICAL WALL .....	1496
<i>D.H. Peregrine, M.E. Topliss</i>	
Chapter 109	
RESULTS OF EXTENSIVE FIELD MONITORING OF DOLOS BREAKWATERS.....	1511
<i>D. Phelps, S. Luger, A. Van Tonder, A. Holtzhausen</i>	
Chapter 110	
FAILURE OF RUBBLE MOUND STRUCTURES DUE TO THE STORM DURATION AND THE IRREGULARITY OF OCEAN WAVES .....	1526
<i>Cheong-Ro Ryu, Hyeon-Ju Kim</i>	
Chapter 111	
BLOCK SUBSIDENCE UNDER PRESSURE AND FLOW .....	1541
<i>T. Sakai, H. Gotoh, T. Yamamoto</i>	
Chapter 112	
STABILITY OF ROCK ON BEACHES.....	1553
<i>Gerrit J. Schiereck, Henri L. Fontijn, Wout V. Grote, Paul G.J. Sijm</i>	
Chapter 113	
SHORT TERM WAVE OVERTOPPING RATE OF BLOCK ARMORED SEAWALL .....	1568
<i>Tsunehiro Sekimoto, Hiroshi Kunisu, Tsuyoshi Yamazaki</i>	
Chapter 114	
ESTIMATING THE SLIDING DISTANCE OF COMPOSITE BREAKWATERS DUE TO WAVE FORCES INCLUSIVE OF IMPULSIVE FORCES .....	1580
<i>Kenichiro Shimosako, S. Takahashi, K. Tanimoto</i>	
Chapter 115	
BED SHEAR STRESS AND SCOUR AROUND COASTAL STRUCTURES .....	1595
<i>B.M. Sumer, J. Fredsøe, N. Christiansen, S.B. Hansen</i>	
Chapter 116	
LABORATORY MEASUREMENT OF OBLIQUE IRREGULAR WAVE REFLECTION ON RUBBLE-MOUND BREAKWATERS.....	1610
<i>Charles Teisson, Michel Benoit</i>	

Chapter 117	
STONE MOVEMENT ON A RESHAPED PROFILE .....	1625
<i>G. Roberto Tomasicchio, A. Lamberti, F. Guiducci</i>	
Chapter 118	
THE LARGE SCALE DOLOS FLUME STUDY.....	1641
<i>George F. Turk, Jeffrey A. Melby</i>	
Chapter 119	
H <sub>0</sub> PARAMETER FOR PRELIMINARY DESIGN OF CONVENTIONAL BREAKWATER STRUCTURAL HEAD: DATA ANALYSIS OF SPANISH NORTH COAST HARBOURS .....	1657
<i>Vincente Negro Valdecantos, Ovidio Varela Carnero</i>	
Chapter 120	
NUMERICAL MODELLING OF BREAKING WAVE IMPACTS ON A VERTICAL WALL .....	1672
<i>N.T. Wu, H. Oumeraci, H.-W. Partensky</i>	
Chapter 121	
WIND EFFECTS ON RUNUP AND OVERTOPPING .....	1687
<i>Donald L. Ward, Christopher G. Wibner, Jun Zhang, Billy L. Edge</i>	
Chapter 122	
MODELLING OF WAVE OVERTOPPING OVER BREAKWATER.....	1700
<i>F. Zhuang, C. Chang, J.J. Lee</i>	
Chapter 123	
STRESSES IN TETRAPOD ARMOR UNITS INDUCED BY WAVE ACTION....	1713
<i>Kees d'Angremond, J.W. van der Meer, C.P. van Nes</i>	
Chapter 124	
PORE PRESSURES IN RUBBLE MOUND BREAKWATERS.....	1727
<i>M.B. de Groot, H. Yamazaki, M.R.A. van Gent, Z. Kheyruri</i>	
Chapter 125	
WAVE ACTION ON AND IN PERMEABLE STRUCTURES.....	1739
<i>M.R.A. van Gent, P. Tönjes, H.A.H. Petit, P. Van Den Bosch</i>	
Chapter 126	
PROBABILISTIC CALCULATIONS OF WAVE FORCES ON VERTICAL STRUCTURES.....	1754
<i>J.W. van der Meer, K. d'Angremond, J. Juhl</i>	

## PART IV

Chapter 127	
VELOCITY AND PRESSURE BOUNDARY CONDITIONS FOR FLOW OVER THE PERMEABLE BOUNDARY OF A POROUS MEDIUM.....	1770
<i>Ismail Aydin</i>	
Chapter 128	
PHYSICAL EXPERIMENTS ON THE EFFECTS OF GROINS ON SHORE MORPHOLOGY.....	1782
<i>Peyman Badiei, J. William Kamphuis, David G. Hamilton</i>	
Chapter 129	
LINE-MODELING OF SHOREFACE NOURISHMENT.....	1797
<i>Willem T. Bakker, Nico F. Kersting, Hanz D. Niemeyer</i>	
Chapter 130	
STATISTICAL VARIATIONS IN BEACH PARAMETER CHANGE RATES FOR WALLED & NON-WALLED PROFILES AT SANDBRIDGE, VA.....	1812
<i>John M. Hazelton, David R. Basco, D. Bellomo, G. Williams</i>	
Chapter 131	
A BOTTOM BOUNDARY LAYER SEDIMENT RESPONSE TO WAVE GROUPS .....	1827
<i>J. Lee, S. O'Neil, K. Bedford, R. Van Evra</i>	
Chapter 132	
GEOMORPHOLOGICAL ANALYSIS OF A BEACH AND SANDBAR SYSTEM.....	1837
<i>Chen-Shan Kung, Marcer Stive, Geffery Toms</i>	
Chapter 133	
SUSPENDED SEDIMENT TRANSPORT IN INNER SHELF WATERS DURING EXTREME STORMS.....	1849
<i>O.S. Madsen, T.A. Chisholm, L.D. Wright</i>	
Chapter 134	
SEA BED STABILITY ON A LONG STRAIGHT COAST.....	1865
<i>E. Christensen, R. Deigaard, J. Fredsoe</i>	
Chapter 135	
THE RESPONSE OF GRAVEL BEACHES IN THE PRESENCE OF CONTROL STRUCTURES .....	1880
<i>T.T. Coates, N. Dodd</i>	

Chapter 136	
THE ROLE OF ROLLERS IN SURF ZONE CURRENTS .....	1895
<i>William R. Dally, Daniel A. Osiecki</i>	
Chapter 137	
THREE DIMENSIONAL MORPHOLOGY IN A NARROW WAVE TANK: MEASUREMENTS AND THEORY .....	1906
<i>Robert G. Dean, Tae-Myoung Oh</i>	
Chapter 138	
NUMERICAL SIMULATION OF FINITE AMPLITUDE SHEAR WAVES & SEDIMENT TRANSPORT .....	1919
<i>Rolf Deigaard, Erik Damgaard Christensen, Jesper Svarrer Damgaard, Jørgen Fredsøe</i>	
Chapter 139	
BEACH NOURISHMENT AND DUNE PROTECTION .....	1934
<i>Hans H. Dette, Arved J. Raudkivi</i>	
Chapter 140	
PROFILE CHANGE OF A SHEET FLOW DOMINATED BEACH .....	1946
<i>Mohammad Dibajnia, Takuzo Shimizu, Akira Watanabe</i>	
Chapter 141	
A NONLINEAR SURF BEAT MODEL .....	1961
<i>Zhili Zou, Nicholas Dodd</i>	
Chapter 142	
PIV MEASUREMENTS OF OSCILLATORY FLOW OVER A RIPPLED BED....	1975
<i>H.C. Earnshaw, T. Bruce, C.A. Greated, W.J. Easson</i>	
Chapter 143	
SHEAR INSTABILITY OF LONGSHORE CURRENTS: EFFECTS OF DISSIPATION AND NON-LINEARITY .....	1983
<i>Albert Falqués, Vincente Iranzo, Miquel Caballería</i>	
Chapter 144	
INTERPRETATION OF SHORELINE POSITION FROM AERIAL PHOTOGRAPHS .....	1998
<i>John S. Fisher, Margery F. Overton</i>	

Chapter 145	
SETTLING COLUMNS PARAMETRIC TESTS APPLIED TO COASTAL SEDIMENT CONSOLIDATION.....	2004
<i>Stephane Gallois, Alain Alexis, Pierre Thomas</i>	
Chapter 146	
SEDIMENT-CLOUD BASED MODEL OF SUSPENSION OVER RIPPLE BED DUE TO WAVE ACTION .....	2013
<i>Hitoshi Gotoh, Tetsuro Tsujimoto, Hiroji Nakagawa</i>	
Chapter 147	
WAVE OVERTOPPING AND SEDIMENT TRANSPORT OVER DUNES.....	2028
<i>Mark W. Hancock, Nobuhisa Kobayashi</i>	
Chapter 148	
SEDIMENT TRANSPORT OVER RIPPLES IN WAVES AND CURRENT .....	2043
<i>Gilles Perrier, Erik Asp Hansen, C. Villaret, Rolf Deigaard, Jorgen Fredsøe</i>	
Chapter 149	
IN-SITU DETERMINATION OF THE CRITICAL BED-SHEAR STRESS FOR EROSION OF COHESIVE SEDIMENTS.....	2058
<i>Erik-Jan Houwing, Leo C. van Rijn</i>	
Chapter 150	
CONTROL OF CROSS-SHORE SEDIMENT TRANSPORT BY A DISTORTED RIPPLE MAT.....	2070
<i>Isao Irie, N. Ono, S. Hashimoto, S. Nakamura, K. Murakami</i>	
Chapter 151	
HOW MUCH VELOCITY INFORMATION IS NECESSARY TO PREDICT SEDIMENT SUSPENSION IN THE SURF ZONE? .....	2085
<i>Bruce E. Jaffe, David M. Rubin, Asbury Sallenger, Jr.</i>	
Chapter 152	
BEACH PROFILE SPACING: PRACTICAL GUIDANCE FOR MONITORING NOURISHMENT PROJECTS.....	2100
<i>Timothy W. Kana, Christopher J. Andrassy</i>	
Chapter 153	
WATERTABLE OVERHEIGHT DUE TO WAVE RUNUP ON A SANDY BEACH.....	2115
<i>Hong-Yoon Kang, P. Nielsen, D.J. Hanslow</i>	

Chapter 154	
A MODEL FOR CROSS SHORE SEDIMENT TRANSPORT .....	2125
<i>Irene Katopodi, Nikos Kitou</i>	
Chapter 155	
NUMERICAL MODELLING OF FLOW OVER RIPPLES USING SOLA METHOD.....	2140
<i>Hyoseob Kim, Brian A. O'Connor, Youngbo Shim</i>	
Chapter 156	
SWASH DYNAMICS UNDER OBLIQUELY INCIDENT WAVES .....	2155
<i>Nobuhisa Kobayashi, Entin A. Karjadi</i>	
Chapter 157	
WAVE RUN-UP AND SEA CLIFF EROSION .....	2170
<i>S.-M. Shih, P. Komar, K.J. Tillotson, W.G. McDougal, P. Ruggiero</i>	
Chapter 158	
MEASUREMENT OF PARAMETERS, DIRECTION AND RATE OF BEDFORM MIGRATION .....	2185
<i>Ruben D. Kos'yan, I.S. Podymov</i>	
Chapter 159	
BREACH-GROWTH RESEARCH PROGRAMME AND ITS PLACE IN DAMAGE ASSESSMENT FOR A POLDER.....	2197
<i>Arie W. Kraak, W.T. Bakker, J. van de Graaff, H.J. Steetzel, P.J. Visser</i>	
Chapter 160	
SWASH ZONE WAVE CHARACTERISTICS FROM SUPERTANK .....	2207
<i>David L. Kriebel</i>	
Chapter 161	
MORPHOLOGICAL MONITORING OF A SHOREFACE NOURISHMENT NOURTEC EXPERIMENT AT TERSCHELLING, THE NETHERLANDS.....	2222
<i>Aart Kroon, Piet Hoekstra, Klass Houwman, Gerben Ruessink</i>	
Chapter 162	
NUMERICAL MODEL FOR LONGSHORE CURRENT DISTRIBUTION ON A BAR-TROUGH BEACH .....	2237
<i>Yoshiaki Kuriyama</i>	

Chapter 163	
PREDICTION OF BEACH PROFILE CHANGE AT MESOSCALE UNDER RANDOM WAVES .....	2252
<i>Magnus Larson</i>	
Chapter 164	
A QUASI-3D SURF ZONE MODEL .....	2267
<i>Jung Lyul Lee, Hsiang Wang</i>	
Chapter 165	
QUANTIFICATION OF LONGSHORE TRANSPORT IN THE SURF ZONE ON MACROTIDAL BEACHES .....	2282
<i>Franck Levoy, Olivier Monfort, Helene Rousset, Claude Larssonneur</i>	
Chapter 166	
A THREE DIMENSIONAL MODEL FOR WAVE INDUCED CURRENTS .....	2297
<i>Bin Li, Roger J. Maddrell</i>	
Chapter 167	
INFLUENCE OF OFFSHORE BANKS ON THE ADJACENT COAST .....	2311
<i>N.J. MacDonald, B.A. O'Connor</i>	
Chapter 168	
WAVE RUNUP ON COMPOSITE-SLOPE AND CONCAVE BEACHES .....	2325
<i>Robert H. Mayer, D.L. Kriebel</i>	
Chapter 169	
SIMULATION OF NEARSHORE WAVE CURRENT INTERACTION BY COUPLING A BOUSSINESQ WAVE MODEL WITH A 3D HYDRODYNAMIC MODEL .....	2340
<i>Roberto Mayerle, Andreas Schröter, Werner Zielke</i>	
Chapter 170	
EXPERIMENTAL RESULTS OF WAVE TRANSFORMATION ACROSS A SLOPING BEACH.....	2350
<i>Constantine D. Memos</i>	
Chapter 171	
A RELATIVE INTERCOMPARISON BETWEEN VARIABLE WAVE SHOALING, BREAKING AND TRANSITION ZONE FORMULATIONS .....	2365
<i>G.P. Mocke, F. Smit</i>	

Chapter 172	
ANALYSIS OF COASTAL PROCESSES AT TORONTO ISLANDS.....	2380
<i>R.B. Nairn, R.D. Scott, C.D. Anglin, P.J. Zuzek</i>	
Chapter 173	
STABILITY AND MANAGEMENT OF AN ARTIFICIAL BEACH.....	2395
<i>Naofumi Shiraiishi, Hoiku Ohhama, Taiji Endo,</i> <i>Patricia G. Pena-Santana</i>	
Chapter 174	
SUSPENDED SEDIMENT PARTICLE MOTION IN COASTAL FLOWS.....	2406
<i>Peter Nielsen</i>	
Chapter 175	
LONG-TERM MORPHODYNAMICAL DEVELOPMENT OF THE EAST FRISIAN ISLANDS AND COAST .....	2417
<i>Hanz D. Niemeyer</i>	
Chapter 176	
FIELD OBSERVATION AND NUMERICAL SIMULATION OF BEACH AND DUNE SCARPS.....	2434
<i>Ryuichiro Nishi, Michio Sato, Hsiang Wang</i>	
Chapter 177	
EFFECTS OF CONTROLLED WATER TABLE ON BEACH PROFILE DYNAMICS .....	2449
<i>Tae-Myoung Oh, R.G. Dean</i>	
Chapter 178	
LABORATORY EXPERIMENTS ON 3-D NEARSHORE CURRENTS AND A MODEL WITH MOMENTUM FLUX BY BREAKING WAVES.....	2461
<i>Akio Okayasu, Koji Hara, Tomoya Shibayama</i>	
Chapter 179	
SUSPENDED SEDIMENT CAUSED BY WAVES AND CURRENTS .....	2476
<i>Masanobu Ono, Kyu Han Kim, Toru Sawaragi, Ichiro Deguchi</i>	
Chapter 180	
DEVELOPMENT OF A DUNE EROSION MODEL USING SUPERTANK DATA.....	2488
<i>Margery F. Overton, John S. Fisher, Kyu-Nam Hwang</i>	

Chapter 181	
NUMERICAL MODELLING OF THREE-DIMENSIONAL WAVE-DRIVEN CURRENTS IN THE SURF-ZONE.....	2503
<i>Philippe Péchon, Charles Teisson</i>	
Chapter 182	
SEDIMENT TRANSPORT IN VARIOUS TIME SCALES .....	2513
<i>Zbigniew Pruszek, Ryszard B. Zeidler</i>	
Chapter 183	
SEDIMENT TRANSPORT UNDER (NON)-LINEAR WAVES AND CURRENTS .....	2527
<i>Jan S. Ribberink, Irene Katopodi, Khaled A.H. Ramadan, Ria Koelewijn, Sandro Longo</i>	
Chapter 184	
WAVES AND CURRENTS AT THE EBRO DELTA SURF ZONE: MEASUREMENTS AND MODELLING .....	2542
<i>A. Rodriguez, A. Sánchez-Arcilla, F.R. Collado, V. Gracia, M.G. Coussirat, J. Prieto</i>	
Chapter 185	
A NUMERICAL SIMULATION OF BEACH EVOLUTION BASED ON A NONLINEAR DISPERSIVE WAVE-CURRENT MODEL .....	2557
<i>Shinji Sato, Michael B. Kabiling</i>	
Chapter 186	
AN EXPERIMENTAL STUDY ON BEACH TRANSFORMATION DUE TO WAVES UNDER THE OPERATION OF COASTAL DRAIN SYSTEM.....	2571
<i>Michio Sato, Sadakatsu Hata, Masahiro Fukushima</i>	
Chapter 187	
WAVE BREAKING AND INDUCED NEARSHORE CIRCULATIONS .....	2583
<i>Ole R. Sørensen, Hemming A. Schäffer, Per A Madsen, Rolf Deigaard</i>	
Chapter 188	
ACCURACY AND APPLICABILITY OF THE SPM LONGSHORE TRANSPORT FORMULA.....	2595
<i>J.S. Schoones, A.K. Theron</i>	

Chapter 189	
FIELD VERIFICATION OF A NUMERICAL MODEL OF BEACH TOPOGRAPHY CHANGE DUE TO NEARSHORE CURRENTS, UNDERTOW AND WAVES .....	2610
<i>Takuzo Shimizu, Masahito Tsuru, Akira Watanabe</i>	
Chapter 190	
AN ATTEMPT TO MODEL LONGSHORE SEDIMENT TRANSPORT ON THE CATALONIAN COAST .....	2625
<i>J.P. Sierra, A.I. Presti, A. Sánchez-Arcilla</i>	
Chapter 191	
EROSION AND OVERTOPPING OF A GRASS DIKE LARGE SCALE MODEL TESTS .....	2639
<i>G.M. Smith, J.W.W. Seiffert, J.W. van der Meer</i>	
Chapter 192	
CALCULATION OF TOMBOLO IN SHORELINE NUMERICAL MODEL .....	2653
<i>Kyung Duck Suh, C. Scott Hardaway, Jr.</i>	
Chapter 193	
BEACH IMPROVEMENT SCHEMES IN FALSE BAY .....	2668
<i>D.H. Swart, J.S. Schoonees</i>	
Chapter 194	
BEACH EROSION IN KUTA BEACH, BALI & ITS STABILIZATION .....	2683
<i>Abdul R. Syamsudin, Yoshito Tsuchiya, Takao Yamashita</i>	
Chapter 195	
FUNDAMENTAL CHARACTERISTICS OF A NEW WAVE ABSORBING SYSTEM UTILIZING SAND LIQUEFACTION .....	2698
<i>Shigeo Takahashi, S. Yamamoto, H. Miura</i>	
Chapter 196	
LABORATORY STUDY OF SURF-ZONE TURBULENCE ON A BARRED BEACH .....	2712
<i>Francis C.K. Ting</i>	
Chapter 197	
BEACH EROSION AROUND A SAND SPIT—AN EXAMPLE OF MIHONO-MATSUBARA SAND SPIT .....	2726
<i>Takaaki Uda, Koji Yamamoto</i>	

Chapter 198	
SHORECIRC: A QUASI 3-D NEARSHORE MODEL .....	2741
<i>A.R. Van Dongeren, F.E. Sancho, I.A. Svendsen, U. Putrevu</i>	
Chapter 199	
A MODEL FOR BREACH GROWTH IN SAND-DIKES .....	2755
<i>Paul J. Visser</i>	
Chapter 200	
SCALING EFFECTS ON BEACH RESPONSE PHYSICAL MODEL .....	2770
<i>Xu Wang, Li-Hwa Lin, Hsiang Wang</i>	
Chapter 201	
A NUMERICAL MODEL OF BEACH CHANGE DUE TO SHEET-FLOW .....	2785
<i>Akira Watanabe, Kazuhiko Shiba, Masahiko Isobe</i>	
Chapter 202	
FIELD TESTS OF RADIATION-STRESS ESTIMATORS OF LONGSHORE SEDIMENT-TRANSPORT .....	2799
<i>Thomas E. White</i>	
Chapter 203	
SUSPENDED SEDIMENT CONCENTRATION PROFILES UNDER NON-BREAKING AND BREAKING WAVES .....	2813
<i>Rattanapitikon Winyu, Tomoya Shibayama</i>	
Chapter 204	
MASS TRANSPORT AND ORBITAL VELOCITIES WITH LAGRANGEIAN FRAME OF REFERENCE .....	2828
<i>Stefan Woltering, Karl-Friedrich Daemrich</i>	
Chapter 205	
CROSS-SHORE PROFILE MODELLING UNDER RANDOM WAVES .....	2843
<i>Yongjun Wu, H-H Dette, H. Wang</i>	
Chapter 206	
MULTIPLE BAR FORMATION BY BREAKER-INDUCED VORTICES: A LABORATORY APPROACH .....	2856
<i>Da Ping Zhang, Tsuguo Sunamura</i>	
Chapter 207	
IDENTIFICATION OF SOME RELEVANT PROCESSES IN COASTAL MORPHOLOGICAL MODELLING .....	2871
<i>Hakeem Johnson, Ida Brøker, Julio A. Zyserman</i>	

Chapter 208	
EXPERIMENTAL SHOREFACE NOURISHMENT, TERSCHELLING, (NL) .....	2886
<i>J.P.M. Mulder, J. van de Kreeke, P. van Vessem</i>	

## PART V

Chapter 209	
IMPORTANCE OF PERMEABILITY IN THE SEDIMENTATION CONSOLIDATION PROCESS.....	2902
<i>Alain Alexis, P. Thomas</i>	

Chapter 210	
WAVE-CURRENT INTERACTION WITH MUD BED .....	2913
<i>Nguyen Ngoc An, T. Shibayama</i>	

Chapter 211	
ON RESIDUAL TRANSPORT IN SHALLOW TIDAL BASINS .....	2928
<i>Andrea Balzano</i>	

Chapter 212	
THE EXTENT OF INLET IMPACTS UPON ADJACENT SHORELINES .....	2943
<i>Kevin R. Bodge</i>	

Chapter 213	
THE SPREADING OF DREDGING SPOILS DURING CONSTRUCTION OF THE DENMARK-SWEDEN LINK.....	2958
<i>Ida Brøker, John Johnsen, Morten Lintrup, Anders Jensen, Jacob Steen Møller</i>	

Chapter 214	
EXPERIMENTAL STUDIES ON THE EFFECT OF THE DREDGING ON CHANG-HWA RECLAMATION AREA, TAIWAN .....	2972
<i>Tai-Wen Hsu, Hsien-Kuo Chang</i>	

Chapter 215	
OSCILLATIONS INDUCED BY IRREGULAR WAVES IN HARBOURS .....	2987
<i>C.R. Chou, W.Y. Han</i>	

Chapter 216	
MECHANISM AND ESTIMATION OF SEDIMENTATION IN BANGKOK BAR CHANNEL.....	3002
<i>Ichiro Deguchi, Toru Sawaragi, Masanobu Ono, Sucharit Koontanakulvong</i>	

Chapter 217	
TURBIDITY & SUSPENDED SEDIMENT ASSOCIATED WITH BEACH NOURISHMENT DREDGING .....	3016
<i>Daniel M. Hanes</i>	
Chapter 218	
SOIL MECHANICS OF SHIP BEACHING .....	3030
<i>N.-E. Ottesen Hansen, B.C. Simonsen, M.J. Sterndorff</i>	
Chapter 219	
THE DILUTION PROCESSES OF ALTERNATIVE HORIZONTAL BUOYANT JETS IN WAVE MOTION .....	3045
<i>Hwung-Hweng Hwung, Jih-Ming Chyan, Chen-Yue Chang, Yih-Far Chen</i>	
Chapter 220	
STUDY ON THE BEHAVIORS OF THE COHESIVE SEDIMENT IN THE YANGTZE ESTUARY .....	3060
<i>Xiaochuan Zeng, Yixin Yan, Kai Yen</i>	
Chapter 221	
DISPERSION OF POLLUTION IN A WAVE ENVIRONMENT .....	3071
<i>R. Koole, C. Swan</i>	
Chapter 222	
MODEL OF BIVALVE ON/OFFSHORE MOVEMENT BY WAVES .....	3086
<i>Hisami Kuwahara, Junya Higano</i>	
Chapter 223	
INITIAL GAP IN BREAKOUT OF HALF-BURIED SUBMARINE PIPE DUE TO WAVE ACTION .....	3099
<i>Adrian W.K. Law, M.A. Foda</i>	
Chapter 224	
ANALYTICAL SOLUTION FOR THE WAVE-INDUCED EXCESS PORE-PRESSURE IN A FINITE-THICKNESS SEABED LAYER.....	3111
<i>Waldemar Magda</i>	
Chapter 225	
RESPONSE CHARACTERISTICS OF RIVER MOUTH TOPOGRAPHY IN WIDE TIME SCALE RANGE .....	3126
<i>A. Mano, M. Sawamoto, M. Nagao</i>	

Chapter 226	
HALF-LIFE PERIOD OF SEDIMENTATION—MODEL TEST ON A SCALE 1:1 .....	3139
<i>Helmut Manzenrieder</i>	
Chapter 227	
RISK ASSESSMENT FOR COASTAL AND TIDAL DEFENCE SCHEMES.....	3154
<i>I.C. Meadowcroft, P.H. von Lany, N.W.H. Allsop, D.E. Reeve</i>	
Chapter 228	
WATER OXYGENATION IN THE VICINITY OF COASTAL STRUCTURES DUE TO WAVE BREAKING .....	3167
<i>C.I. Moutzouris, E.I. Daniil</i>	
Chapter 229	
ENVIRONMENTAL ASSESSMENT OF HYPOTHETICAL LARGE-SCALE RECLAMATION IN OSAKA BAY, JAPAN.....	3178
<i>Keiji Nakatsuji, Toshiaki Sueyoshi, Kohji Muraoka</i>	
Chapter 230	
FLOOD AND EROSION CONTROL IN THE CONTEXT OF SEA-LEVEL RISE.....	3193
<i>E. Bart Peerbolte, Herman G. Wind</i>	
Chapter 231	
OFFSHORE BREAKWATERS VERSUS BEACH NOURISHMENTS— A COMPARISON.....	3208
<i>M. Pluijm, J.C. van der Lem, A.W. Kraak, J.H.W. de Ruig</i>	
Chapter 232	
MORPHOLOGICAL MODELLING OF KETA LAGOON CASE .....	3223
<i>J.A. Roelvink, D.J.R. Walstra, Z. Chen</i>	
Chapter 233	
COST-BENEFIT ANALYSIS OF SHORE PROTECTION INVESTMENTS.....	3237
<i>L. Felipe Vila Ruiz, Fernando Bernaldo de Quirós</i>	
Chapter 234	
PARAMETRIZATION FOR CONCEPTUAL MORPHODYNAMIC MODELS OF WADDEN SEA AREAS .....	3251
<i>Ernst Schroeder, R. Goldenbogen, H. Kunz</i>	

Chapter 235	
MUD TRANSPORT AND MUDDY BOTTOM DEFORMATION BY WAVES .....	3266
<i>Daoxian Shen, Masahiko Isobe, Akira Watanabe</i>	
Chapter 236	
WAVE-INDUCED SEDIMENT RESUSPENSION AND MIXING IN SHALLOW WATERS.....	3281
<i>Y. Peter Sheng, X. Chen, E.A. Yassuda</i>	
Chapter 237	
A NUMERICAL MODEL FOR BEACH DEFORMATION AROUND RIVER MOUTH DUE TO WAVES AND CURRENTS.....	3295
<i>Tomoya Shibayama, Akiko Yamada</i>	
Chapter 238	
DEVELOPMENT OF A NUMERICAL SIMULATION METHOD FOR PREDICTING THE SETTLING BEHAVIOR & DEPOSITION CONFIGURATION OF SOIL DUMPED INTO WATERS .....	3305
<i>Kazuki Oda, Takaaki Shigematsu</i>

## CHAPTER 175

### LONG-TERM MORPHODYNAMICAL DEVELOPMENT OF THE EAST FRISIAN ISLANDS AND COAST

Hanz D. Niemeier<sup>1</sup>

#### Abstract

The morphology of the East Frisian Islands and Coast has experienced enormous changes in the course of the last centuries. The resedimentation of medieval sturm bays has played a dominant role within these morphodynamical processes which could no longer only be credited to the impacts of littoral drift. Reconstructions of former coastal morphology have been used to quantify the long-term development of significant parameters for the tidal basins of the East Frisian Wadden Sea. Additionally also the tidal volumes for situations since 1650 could be determined. On this basis the long-term stability of common empirical relationships was checked.

#### Introduction

The East Frisian Islands and Coast are part of the Frisian Wadden Sea which ranges from the eastern part of the Dutch across the German to the southern part of the Danish North Sea coast (fig. 1) and consist of a chain of seven barrier islands separated by tidal inlets from each other through which the tidal basins with intertidal areas and supratidal salt marshes are filled and emptied during each tidal cycle. The tidal range is about 2,5 m and the yearly mean offshore significant wave height is about 0,7 to 1,0 m. It is therefore a mixed energy tide-dominated coast according to the classification of HAYES [1975]. The littoral drift is predominantly eastward directed.

The East Frisian Islands and Coast have been performed at the end of the holocene transgression [KRÜGER 1911; LÜDERS 1951; STREIF 1990] and have experienced enormous morphological changes since then. Though no detailed information is available for that time firstly a superposition of human impacts on this natural development is expected to have been effective when the mainland coast was closed consecutively against the sea by constructing sea dykes since the beginning of this millenium [HOMEIER 1969]. Later on and particularly for the last 350 years the morphological behaviour of the East Frisian Islands and Coast is well documented by the horizontal position of the morphologically representantive markers tidal low and high water lines, dune foot and border lines of supratidal salt marshes [HOMEIER 1962]. Additionally there is even information with lesser accuracy on certain areas available concerning situations until more than 600 years ago (fig. 2). The migration of tidal inlets and barrier islands

-----  
<sup>1</sup>Coastal Research Station of the Lower Saxonian Central State Board for Ecology  
Fledderweg 25, 26506 Norddeich/East Frisia, Germany

has been superimposed interactively by further large scale human impacts interfering with the natural processes. In the course of the last centuries the two most important ones have were:

1. Artificial acceleration of re sedimentation of the medieval storm surge bays at the mainland coast in respect of land reclamation and afterwards consecutively executed partial enclosures of these areas by dyking.
2. The fixation of the four migrating ones of the six tidal inlets separating the East Frisian barrier islands since the middle of the 18th century in order to protect there developing holiday and health resorts.

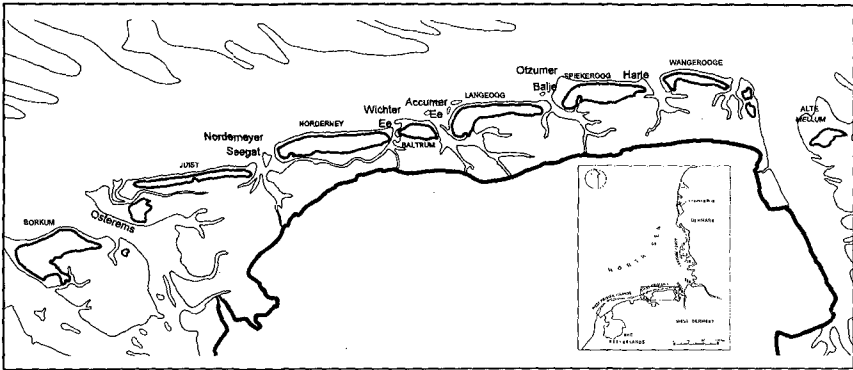

Figure 1. East Frisian Islands and Coast with inserted overview of the North Sea

These large scale morphodynamical processes have mainly taken place in the western and eastern part of the East Frisian Wadden Sea whereas the tidal inlet Accumer Ee and its basin in the central part have remained rather stable in the course of the recent centuries. Beside geological boundary conditions it is also remarkable that in this area no large storm surge bay was ever existent. A detailed knowledge about the background of these developments is of high interest. Not only for improving backward directed process knowledge but also for the development of long-term prognostic tools like empirical morphodynamical models. In order to create a data basis for this purpose the charts containing historical reconstructions of coastal morphology elaborated by HOMEIER [1962] and hydrographic charts have been transferred into a Geographical Information System (GIS) which is used as a database for further evaluation and parametrization.

Figure 2. Reconstruction of the western East Frisian Wadden Sea since 1350 by HOMEIER [1964]

## Extension and enclosure of medieval storm surge bays

### Ley Bay

The Ley Bay ever got its largest extension due to the erosional effects of the catastrophic storm surges of the 14th century and especially due to those of the "First Dyonysis Surge" in 1374 [HOMEIER 1972]. The storm surges in that time were very effective in respect of eroding the flooded areas after dyke failures as their soil consisted predominantly of very erodible peat. Due to that fact the losses of land to the sea were much higher than usual, the extension of the bay did afterwards not fit with the hydrodynamical boundary conditions in order to reestablish a morphodynamical equilibrium. This imbalance caused sedimentation leading to the rise of salt marshes at the borders of the bay supported and accelerated by interfering human reclamation works. These processes changed the system again resulting in further sedimentation [NIEMEYER 1984, 1991b]. The rise of salt marshes allowed a subsequent reclamation and partial enclosures of formerly lost areas (fig. 3). In the course of the centuries the areal extensions of the enclosures decreased until the beginning of this century. But in recent years the advanced tools then available in coastal engineering made even the dyking of intertidal flats possible and not only of those areas which had already reached the stage of supratidal salt marshes. These measures interfered with hydrodynamical-morphological interactions to a much higher extent than the dyking of salt marshes.

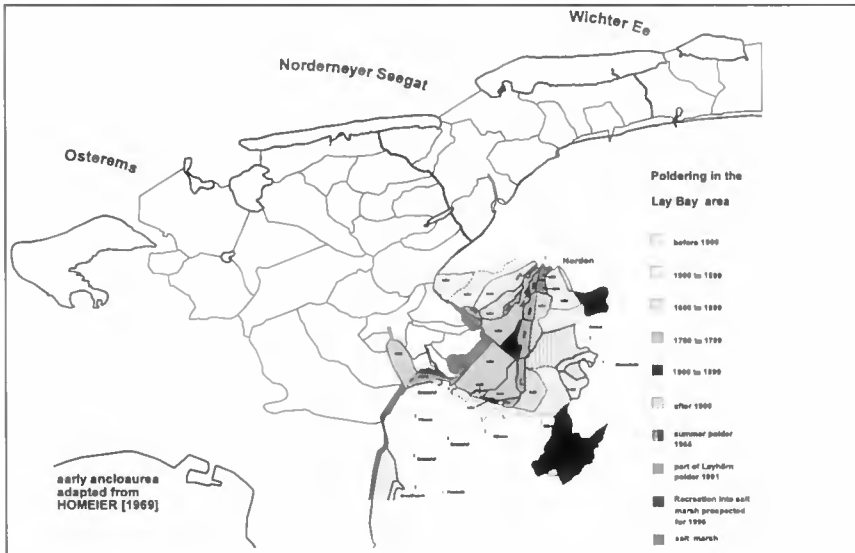

Figure 3. Partial enclosures of the Ley Bay during the last six centuries

### Harle Bay

The Harle Bay already existed at the beginning of dyke construction at the end of the last century. It was silting up and the dyking of growing salt marshes is reported for the 12th and 13th century [HOMEIER 1969, 1979]. In the middle of the 14th century an unknown number of subsequently following storm surges caused the destruction of dyke lines and created erosion in the flooded areas. But the enlarged size of the tidal basin was not in tune with the dynamical equilibrium and in particular the higher intertidal areas silted up due to the absence of waves

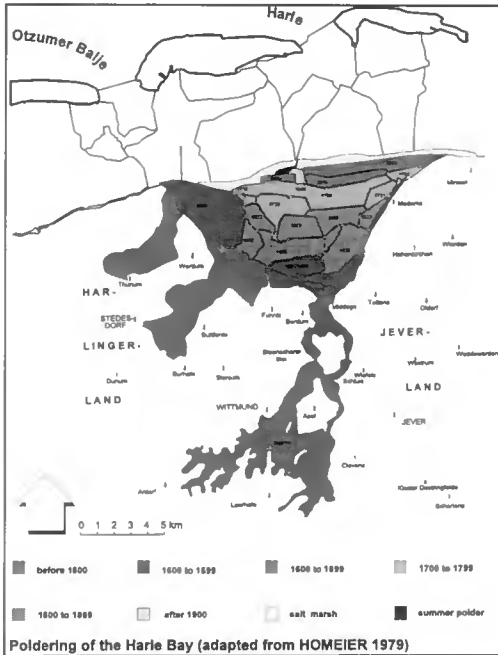

Figure 4. Partial enclosures of the Harle Bay

with sufficient energy to prevent siltation and the subsequent growth of supratidal salt marshes. The nearly continuous silting up occurred since then was followed by partial enclosures of the emerged supratidal salt marshes. More than 50% of the bay area had already been reclaimed at the end of the 16th century and two hundred years later only small remnants of the formerly large Harle Bay existed which mostly were reclaimed until the end of the 19th century. The Harle Bay had disappeared totally and a closed straight coastline was established (fig. 4).

**Morphodynamical impacts of storm surge bay enclosures**  
General remarks

The enclosure of medieval storm surge bays has lead to the following consequences: reduction of basin area, of basin volume, of tidal basin volume and of ebb delta volume in order to provide the basin's requirements for sedimentation. All these changes provoked

additionally changes of local wave climate in the basin leading to a further increase of sedimentation, resulting reduction of tidal volume and again sedimentation until a new equilibrium stage was achieved [NIEMEYER 1991b]. In areas where only small storm surge bays had been created as i. e. g. in the basin of the tidal inlet Accumer Ee in the central part of the East Frisian Wadden Sea (fig. 1) morphodynamical changes during the last centuries have been less dramatic than in those where storm surge bays performed a quantitatively remarkable part of the total basin area.

Western East Frisian Wadden Sea

In comparison to its present total area of about 334 km<sup>2</sup> the basin of the tidal inlet Osterems has experienced a remarkable reduction of about 100 km<sup>2</sup> since the 14th century due to the numerous partial enclosures (fig. 3). Surprisingly the total basin area has nearly remained unchanged since 1650 (tab. 1) whereas more than 40 km<sup>2</sup> have been reclaimed in the Ley Bay during that period (fig. 5). This development and the morphodynamical processes in the remaining parts of the offshore areas must have substantially interacted. A comparison of the situations of 1650 and 1960 using the historical maps evaluated by HOMEIER [1962] makes evident that the basin of the tidal inlet Osterems has compensated nearly all its losses by an eastward extension of its watershed against the basin of the tidal inlet Norderneyer Seegat which can probably be explained by the remarkably larger tidal volume of the Osterems tidal basin. This process cannot be explained due to the direction of the littoral drift, because the migration of the tidal inlet Osterems [HOMEIER & LUCK 1977; STEPHAN 1994] is counterdirectional. This development is in tune with the increase of relative area and respectively tidal volume in the

eastern part of its basin which performs nowadays its largest subsystem. These facts indicate strongly that the morphodynamical processes due to the migration of the tidal inlet Osterems (fig. 5) could be credited to the silting-up and consecutively reclamation by partial enclosures of the Ley Bay.

Figure 5. Morphological development of the tidal inlets Osterems, Norderneyer Seegat, Wichter Ee, of their basins and watersheds between 1650 and 1960 (reconstruction from HOMEIER [1962])

Indirectly also the eastern shift of the watershed between the Osterems and Norderneyer Seegat basins is remarkably influenced by that and not only a consequence of littoral drift. Even the migration of the tidal inlet Norderneyer Seegat must at least partly be regarded as a consequence of the consecutive reduction of the Ley Bay superimposing here littoral drift effects. This statement is contradictory to the qualitative migration models of LUCK [1977] for tidal inlets of the Norderneyer Seegat and Harle type basing on reconstructions of HOMEIER [1962, 1964] and being causally supplemented by NIEMEYER [1990] considering hydrodynamical impacts on ebb deltas and barrier islands. The explanation of migration processes by LUCK [1977] is still very useful in order to provide insight into processes which happened in the past but their cyclic character is doubtful due to regarding littoral drift as steering force of inlet migration. Considering the impact created by the areal reduction of the Ley Bay on primarily the shift of watershed between Osterems and Norderneyer Seegat basin and secondarily on the migration of the tidal inlet Norderneyer Seegat itself a continuation of inlet migration at the same scale could -even in the case of no human interference- not be expected because after the large areal reduction of the Ley Bay an important steering force has nearly disappeared.

The consequences of the migration of the Nordemeyer Seegat for its ebb delta and respectively for the sediment balance on the beaches on the island of Norderney have been described as well as the measures to preserve the coast line and to combat erosion there [LUCK 1977; NIEMEYER 1990, 1991a; KUNZ 1991]. Moreover inlet migration and subsequent morphological changes have also had remarkable impacts on the adjacent mainland coastline [NIEMEYER 1990]: The gradual disappearance of the remnants of the former island of Buise and the reunification of the two inlets to a wider channel with wider spread swash bars in its ebb delta rendered as well possible the impact of higher wave energy up to the opposite mainland coast as the accompanying extension of sublittoral areas between the inlet and the coast (fig. 6). In 1650 there was a broad stretch of supratidal salt marshes in front of the mainland dykes. In 1750 the

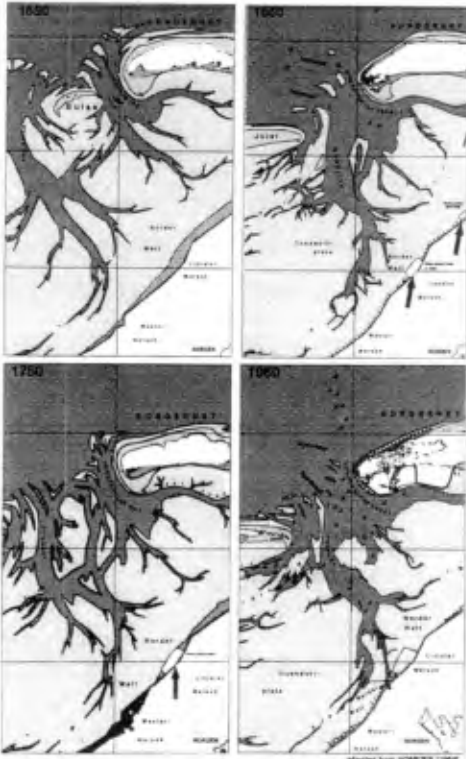

Figure 6. Impact of tidal inlet migration between Juist and Norderney in the period from 1650 to 1860 on the adjacent mainland coast (reconstruction from HOMEIER [1962]) → polders

polder and of a second one which had been erected at the beginning of the 19th century. Both were flooded during the storm surge of 1825 and had afterwards to be abandoned. Starting about 1860 the tidal inlet was successfully fixed by the construction of groynes ranging across the eastern slope of its deep channel.

The areal losses of the Osterems tidal basin have been compensated by an eastward shift of its watershed at the cost of that one of the Nordermeyer Seegat. The same process repeated itself in the interaction of the basins of the Nordermeyer Seegat and of the Wichter Ee (fig. 5): Again the basin with the larger volume shifted the watershed between both remarkably into eastern direction between 1650 and 1860. The western shore of the island of Baltrum experienced in the same period enormous erosion and moved more than 4 km eastward. Since the eastern watershed of the Wichter Ee tidal basin did not shift to the same extent into eastern direction as the western one the basin area was enormously reduced (tab. 1). The differences in the eastward shift of the western and the eastern watershed of the Wichter Ee tidal basin indicate also the impact of the partial enclosures in the Ley Bay on the morphodynamical processes of the tidal inlets and basins in its eastern neighbourhood.

salt marshes in front of the mainland dyke of the Westermarsch had disappeared and a coastline retreat had become necessary after the dyke breaches during the storm surge of 1717. On the one hand the shadow effect of the remnants of the former island of Buisse was no longer effective. On the other had the migration of the inlet channels and of their tributaries led to the superposition of wave systems entering via Buissegat and Norderneyer Gat from the North Sea into that coastal area. Easter of this area the salt marshes in front of the dyke of the Linteler Marsch must have been sufficiently stable in order to encourage people to build a polder. In 1860 the inlets Buissegat and Norderneyer Gat merged to a one-inlet-system called Nordermeyer Seegat. The consequences are primarily a less pronounced ebb delta with smaller shallows being spread wider. The higher concentration of tidal energy effects also a relative increase of sublittoral areas in the basin close to the inlet. Secondly this allows in tune with the wider inlet the input of higher wave energy into the basin upto the mainland coast. Particularly the eastern part of the regarded area has lost shelter due to the morphological changes of the ebb delta and the inlet. The resulting effect is the total disappearance of salt marshes there and as well the destruction of the 1750 already existing

### Eastern East Frisian Wadden Sea

Another example of subsequent consequences of the enclosure of a medieval storm surge bay becomes evident regarding the tremendous relative reduction of the basin area of the tidal inlet Harle since the middle of the 14th century due to the land reclamation in the area of the former Harle Bay leading finally to its total enclosure. The reduction of basin area and corresponding tidal volume initialized consequently as well a decrease of cross-sectional area and width of the tidal inlet as of the seaward extension and volume of the ebb delta (fig. 7). This process was accompanied by an eastward migration of the tidal inlet Harle, an erosion and retreat of the eastern shore of the island of Wangeroog, a remarkable eastward extension of the island of Spiekeroog and a corresponding shift of the watershed between the tidal basins of the Otzumer Balje and Harle, whereas the eastern watershed of the Harle tidal basin did not move remarkably within the same period. A comparable eastward shift of the latter one was probably impossible because the neighbouring Jade estuary with its much higher tidal volume and resulting kinetic energy hampered such a reaction. Since also the watershed between the basins of the Accumer Ee and Otzumer Balje has migrated easterly to a much lesser extent than that one between the Otzumer Balje and the Harle, the basin area of the latter one experiences a large reduction while the Otzumer Balje basin's area increases significantly. Correspondingly the island of Spiekeroog enlengthened by more than 4 km or more than 80 % (fig. 7).

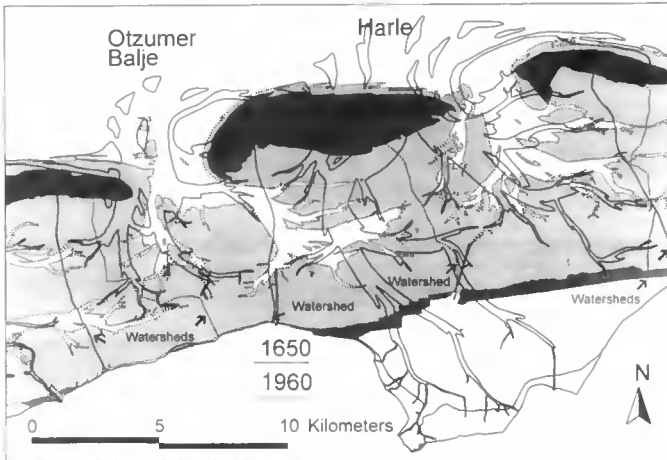

Figure 7. Morphological development of the tidal inlets Otzumer Balje and Harle, of their basins and watersheds between 1650 and 1960 (reconstruction from HOMEIER [1962])

This differences in inlet, ebb delta, island and migration are not explainable by littoral drift though not counterdirectional. But it is evident that the reduction of area and tidal volume of the Harle basin is intensively steered by the silting up of the Harle Bay. Therefore this must be regarded as the major steering impact for the enormous morphodynamical changes in this area.

#### **Quantittative change of characteristic basin parameters**

##### Total basin areas $A_b$

The total area of the tidal basins in the East Frisian Wadden Sea experienced a reduction of more than 13 % between 1650 and 1860 and afterwards fluctuated around a value of 85 % of the 1650 existing area (fig.8, tab. 1). The losses must mainly be credited to the reduction of the

Figure 8. Relative development of total basin areas  $A_b$  (in percentages) in the East Frisian Wadden Sea

storm surge bays, particularly to that of Ley and Harle Bay with an reclaimed area of more than 80 km<sup>2</sup> during that period. Corresponding to the already described morphodynamical development of the western East Frisian Wadden Sea the basin areas of the Osterems and of the Norderneyer Seegat experienced maximal losses of about 10 % being later reduced to about 5 % whereas the basin area of the Wichter Ee was reduced by more than 55 % (fig. 8, tab. 1). The total reduction of the three basin areas is some what larger than the corresponding reduction of the Ley Bay between 1650 and

1960, but this could probably be explained by a phase shift of morphodynamical adaption to former silting up of bay areas.

		1650	1750	1860	1912	1930	1960	1975	1990

		100,00	84,52	52,03	42,60	48,31	41,20	40,89	43,49

Tab. 1 Total basin areas 1650 - 1990

The basin area of the Accumer Ee has remained in the same order of magnitude independently from the enormous morphodynamical developments both in the western and eastern neighbourhood of that area. In the eastern East Frisian Wadden Sea the tidal basin area of the Otzumer Balje increased by about 30 % between 1650 and 1960. This increase was compensated by losses of basin area of the Harle of more than 45 % (fig.8, tab. 1). The total loss of area for both basins is also higher than the correspondingly reclaimed areas in the Harle Bay. But here also the same explanation fits as for the western part of the East Frisian Wadden Sea. The area of partial enclosures was until the end of the 19th century only an indirect measure of long term silting up, because in that time dykes were only built on supratidal salt

marshes which had been silted up earlier. In connection with the phase shift of morphodynamical adaption this quantitative differences must not necessarily be inconsistent with the basic idea. Moreover the phase shift of morphodynamical adaption of the seaward basin area to bay reduction becomes i. e. g. evident by the response of the Harle basin with a remarkable areal decrease until 1912 (fig. 8, tab. 1) whereas the most partial enclosures had already been carried out at the end of the 18th century (fig. 4).

Sublittoral and Intertidal basin areas  $A_{sl}$  and  $A_i$

Figure 9. Relative development of intertidal basin areas  $A_i$  (in percentages) in the East Frisian Wadden Sea

Figure 10. Relative development of sublittoral basin areas  $A_{sl}$  (in percentages) in the East Frisian Wadden Sea

The intertidal areas of the East Frisian Wadden Sea have both absolutely and relatively much more decreased (fig. 9, tab. 2) than the total basin areas (fig. 8, tab. 1). Correspondingly the sublittoral areas have as well absolutely as relatively increased (fig. 10, tab. 3). But this tendency is not uniform for all tidal basins: It is valid for those ones with as a small reduced total area like Osterems and Nordermeyer Seegat, a nearly constant one like Accumer Ee or even enlarged one like Otzumer Balje. Contradictory in those basins which total area experienced reduction like those ones of the Wichter Ee and the Harle the tendency is different. In the Harle basin both intertidal and sublittoral areas have experienced nearly the same amount of relative reduction whereas in the Wichter Ee basin the sublittoral areas have been relatively more reduced than the intertidal ones (fig. 9, tab. 2; fig. 10, tab. 3). In total the tendency of reduction for the intertidal areas being evident until 1960 has been substituted by a fluctuation of less than 3 % since then (fig. 9, tab. 2) which is generally in tune with the development of the total basin areas (fig. 8, tab. 1).

Contradictory the until 1930 rather stable figures for the sublittoral basin areas tend to fluctuate more significantly since then (fig. 10, tab. 3). Partly this effect might also be caused by changes in the seaward boundary of the basins for the different surveys due to the chosen determination of the seaward inlet cross-section for computations.

Tab. 3: Sublittoral basin areas 1650 - 1990

### Supratidal salt marsh areas $A_{sm}$

The interactions of hydro- and morphodynamics in the storm surge bays created favourable boundary conditions for the growth of supratidal salt marshes as described before. But these were more and more dyked by subsequent partial enclosures. The deceleration of silting-up due to the reduction of the bays' oversize effected primarily also a deceleration of salt marsh (fig. 3 + 4). Though only insufficient data are available for the time before 1650 the areal development of salt marshes from then still reflects that process (fig. 11, tab. 4): The total area of supratidal salt marshes in the East Frisian Wadden Sea has been reduced from 1650 to 1750 by about 20 % and then again until 1860 by another 12 %. The decrease between 1860 and 1930 has again decelerated to less than 5 % even followed by an increase of nearly 4 % until 1960. The subsequent reduction of about 5 % until 1975 has growth and secondarily in tune with partial enclosures a reduction of existing salt marsh areas been a consequence of the

enclosures of salt marshes by construction of new dykes due to the guidelines for coastal safety established after the catastrophic storm surge of 1962 seawardly of the old ones.

Regarding the tidal basins separately the developments do not reflect the same uniform tendency (fig. 11, tab. 4): The Osterems tidal basin has lost nearly 60 % of its supratidal salt marsh areas between 1650 and 1860, particularly due to the partial enclosures in the Ley Bay. But it regained about until 1975 about 20 %, particularly to salt marsh growth in the Ley Bay in spite of executed partial enclosures in the same period. The initial losses of salt marsh areas in the tidal basin of the Norderneyer Seegat have already been explained as a consequence of inlet migration and changes of local wave climate with a decrease of about 55 % from 1650 to 1750. But already between 1750 and 1860 the continuous losses (fig. 6) were overcompensated by salt marsh growth in other areas of the basin. Since then salt marshes areas have increased until 1975. The losses of supratidal salt marsh areas in the tidal basin of the Wichter Ee must

particularly be regarded as a consequence of the enormous reduction of its total basin area which is also evident for the changes between 1960 and 1975. The pursued reduction of salt marshes in the tidal basin of the Accumer Ee since 1650 must be primarily credited to the seaward movement of dyke lines whereas the continuous growth of salt marsh areas in the tidal basin of the Oztumer Balje is particularly a consequence of the described extension of its total basin area since 1650.

Tab. 4: Salt marsh areas 1650 - 1975

The reduction after 1960 is an effect of the dyking of salt marshes. Between 1750 and 1912 salt marsh areas in the tidal basin of the Harle have as well decreased as the total basin area due to re-sedimentation and partial enclosures of the Harle Bay. Until 1960 then a certain growth appeared in tune with the stabilization of the tidal basin which only experienced a slight reduction after 1960 due to dyking of salt marshes.

### Evaluation of tidal volumes

The parametrization of Wadden Sea areas in the framework of the project WADE was carried out in order to establish empirical relationships between these parameters describing morphodynamical equilibrium conditions. A parametrization of morphological parameters like areas must be sufficient for that purpose, the evaluation of hydrodynamical parameters is additionally necessary for reaching the aim. The most common hydrodynamical parameter used in empirical morphodynamical relationships is the tidal volume. The evaluation of tidal volumes for defined areas is no problem if detailed surveys or maps are available and the representative tidal high and low water peaks are known. But in the case of the reconstructed historical coastal morphology of 1650, 1750 and 1860 by HOMEIER [1962] there are only the contour lines of mean tidal high and low water and the border lines of the supratidal salt marshes available. Furthermore measurements of tidal water levels providing reliable data have been carried out in the East Frisian Wadden Sea since the end of the 19th century (fig. 14). Therefore the evaluation of tidal volumes for these dates requires extra efforts.

The substitution of complex tidal basin morphology by only mean high and low water contour lines has been exercised by WALTHER [1972] in order to avoid enormous computational efforts without the aid of modern computers:

$$V_T = TR \cdot (A_b + A_{sl}) / 2$$

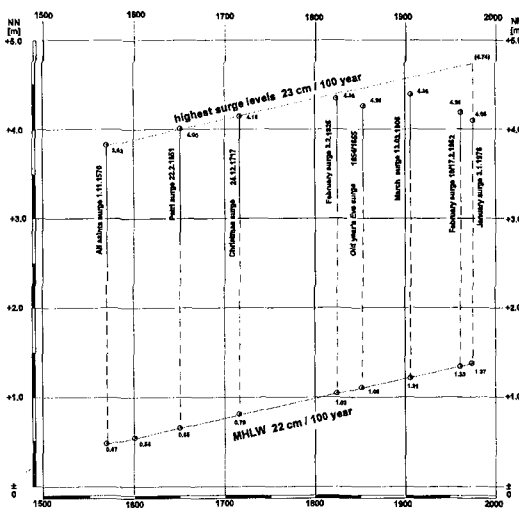

Figure 12. Reconstructed historical mean high tide and storm surge water levels and long-term trends, island of Wangeroog, tidal inlet Harle [LÜDERS 1977]

Since there is nothing reported about the accuracy of this method a calibration test for recent data sets was carried out with the data of all six East Frisian tidal basins from the surveys of 1960, 1975 and 1990. Surprisingly the deviation from data being evaluated with the aid of a GIS was on the average about 6 % (fig. 12) which is in the same or even in a lower order of magnitude as the measuring accuracy of data from hydrographic surveys. Based on these results the method of WALTHER [1972] is a suitable tool for the evaluation of tidal volumes for the situations of 1650, 1750 and 1860 for the reconstructed coastal morphology. In order to keep the data comparable the tidal volumes for the surveys since 1912 were also determined by the same method.

Figure 13. Yearly mean high water levels and tidal ranges since 1896 and corresponding mean trends, island of Norderney, tidal inlet Norderneyer Seegat

Beside the before mentioned data of tidal water levels there are also reconstruction of historical mean higher water and storm surge levels available. A very valuable data set has been elaborated by LÜDERS [1977] for the island of Wangerooge at the shore of the tidal inlet Harle (fig. 1) based on historical levellings being transferred to present datum and metric scale (fig. 13). These long-term data set has nearly the same rising velocity as that one being measured in the course of the last 100 years at the tidal gauge at the island of Norderney in

the tidal inlet Norderneyer Seegat (fig. 1 + 14). The measured data make also a parallel increase of tidal range with rising high water levels evident (fig. 14). Referring to the documented rise of high water levels since 1570 it is reasonable that the tidal range has increased since then by nearly the same order of magnitude as for the last century. Based on this assumption the tidal volumes for the morphological situations of 1650, 1750 and 1860 have been evaluated by taking into account an increase of tidal range between 1650 and 1900 of 10 cm per century (fig. 15, tab 5). This figure is used in order to consider the long-term tendency of tidal boundary conditions of the morphodynamical development in the investigation area. The evaluated tidal volumes are quantitative not very sensitive against a possible inaccuracy of  $\pm 5$  cm/century, the fluctuation of the tidal volumes is therefore less than 2,5 %.

Figure 14. Comparison of tidal volumes computed with a GIS from detailed morphological maps and evaluated by the method of WALTHER [1972]

The tidal volumes of the tidal basins in the East Frisian Wadden Sea have in total remained nearly constant over the regarding the long-term development. The increase of tidal range measured since the end of the 19th century (fig.14) and expected to have also occurred with a similar coincidence to the rise

Figure 15. Relative development of tidal volumes (in percentages) of the tidal basins in the East Frisian Wadden Sea

of mean tidal high water since the 16th century (fig. 13) has compensated the reduction of basin areas. For the midterm development of the last decades with nearly stable total basin areas the tidal volume has not experienced a remarkable increase whereas the tidal range has also increased during this period (fig. 14); for 1975 even a significant reduction occurred (fig. 15, tab. 5) which can partly be explained by the reduction of the total basin areas (fig. 8, tab.1). According to the reduction of total areas the

		1650	1750	1960	1912	1930	1960	1975	1990

Tab. 5: Tidal volumes of the East Frisian Wadden Sea tidal basins 1650 - 1990

tidal volumes of the Wichter Ee and Harle have decreased significantly. Correspondingly the tidal volume of the Oztumer Balje has increased overproportional in respect of other tidal basins. The Accumer Ee has in 1990 a tidal volume which is 20 % higher than 1650, whereas the total basin areas for both dates are nearly constant. The tidal volume of the Osterems has experienced remarkable fluctuation which are generally in tune with the development of its basin areas. That one of the Norderneyer Seegat has generally increased. The fairly reduction of its basin areas must have been compensated partly by the increase of tidal range. Furthermore the shape of the basin and the relation of intertidal and sublittoral areas might have been of importance.

Long term stability of empirical relations

The morphological changes in the East Frisian Wadden Sea [HOMEIER 1962, LUCK 1977] has decelerated enormously in the course since the middle of the last century and particularly

since the beginning of this one. The fixing of four of the six inlets since the beginning of this century and particularly the coincidently nearly finished re-sedimentation and land reclamation in the areas of the medieval storm surge bays has effected that development. Therefore morphodynamical changes in the East Frisian Wadden Sea occur not only self-evidently on much lower time scales but also on smaller length scales leading to a morphodynamical quasi-equilibrium, which in the long run is expected to be only temporarily. But nowadays a mid-term dynamical equilibrium could be assumed which is expressed by a number of well-established semi-empirical relationships being evaluated on a data basis with sufficient density for that purpose. That method for a functional parametrization of morphodynamical processes has proved as a success for coastal research and for coastal engineering planning since decades [O'BRIEN 1931; WALTHER 1972; EYSINK 1979, 1991; NIEMEYER 1991]. One of the important relationships describing a morphodynamical equilibrium is that one between total basin area and tidal volume which has been introduced by EYSINK [1979] and was used in the framework of the Dutch coastal defense study as a tool for the estimation of the impacts of an accelerated relative sea-level rise.

Figure 16. Correlation of total basin areas  $A_b$  and tidal volumes  $V_T$  since 1650

In order to get a deeper insight into those documented long-term morphodynamical processes occurring at the East Frisian coast since 1650 these relationship has also been adapted to the evaluated parameters being available for all situations from 1650 to 1990 beside that one of 1912 for which not a complete data set was available. Though the incorporated assumption of a dynamical equilibrium could not be assumed as valid for the situations between 1650 and 1860 the relation e. g. between tidal volumes and intake areas of the basins are for all situations rather strict (fig. 16). In respect of the experience gained from recent data [EYSINK 1979, 1991] this result is not trivial, because these data sets incorporate also a variation in tidal range due to its regional differences. Looking at the data sets from 1960, 1975 and 1990 including also the sub-systems of the tidal basins for the same parametrization for the East Frisian Wadden Sea this effect is evident only for the larger values of 1990 (fig. 17). A first explanation of this discrepancy is the only use

of data for mid-term developments: As tidal ranges varies to a much lesser extent than for the long-term time scale, statistical scattering is of the same or even bigger order of magnitude than the structural differences due to tidal range variation.

Figure 17. Correlation of basin areas and tidal volumes for the tidal basins and subsystems in the East Frisian Wadden Sea (surveys 1960, 1975, 1990).

Further emphasis will be laid on finding a reliable explanation and detecting the mechanism steering that process. The solution to this problem is of high importance because these relations provide the basis for conceptual or empirical model like the Box-model of VAN DONGEREN & DE VRIEND [1994] being up to now the only promising tool for morphodynamical modelling of future mid- and long-term development. A successful treatment will therefore deliver a valuable basis not only for current problems with structural erosion but also for the foreca-

sting of prospected long-term morphodynamical processes due to changing boundary conditions like an expected acceleration of relative sea-level rise.

An obvious explanation would be a change of hydrodynamical boundary condition. Considering that possibility the changes of tidal range over the time were taken into account though no measured data before 1891 were taken into consideration and the figures for 1860, 1750 and 1650 were evaluated on the basis of an assumption. But this assumption is regarded as rather sound and in every case as a sufficient basis to look for indications for a qualitative change of empirical relationships for morphodynamics: The data reflect a pronounced correlation of the factor a of the relationship

$$A_b = a \cdot V_T$$

Figure 18. Correlation of the coefficient a from  $A_b = a \cdot V_T$  with tidal range TR

and tidal range range TR (fig. 18). Obviously those correlations depend particularly on the anticipated change of tidal range before 1891. In order to estimate the effect of a misjudgement a variation of  $\pm 5$  cm per century is taken additionally into consideration. The result makes evident that the tendency of the correlation is still evident (fig. 18). Therefore it must be concluded that for long term investigations in the same area the variation of the tidal range must be taken into consideration in order to describe the relationship between total basin areas and tidal volumes with sufficient accuracy.

## Conclusions

The resedimentation of storm surge bays at the East Frisian mainland coast has been a major steering impact of morphodynamical processes in five of the six tidal basins of the East Frisian Wadden Sea during the last centuries. As well the shifting of basin watersheds, the migration of inlets as the changes in size and position of the barrier islands can no longer only be credited to littoral drift. Furthermore they could not be regarded as a cyclic process which would have continued without the fixing of tidal inlets since the middle of the last century.

A reliable quantitative approximation of tidal volumes is also possible for the reconstructions of historical coastal morphology of Wadden Sea areas. The accuracy of these figures is sufficient for use in the framework of empirical relationships used for empirical and conceptual morphodynamical modeling. It has become evident that relationships being used for empirical or conceptual modeling which have been established for data sets covering only a period of a few decades or even less could not in every case be regarded as valid for long-term periods like centuries. This was demonstrated for the well known relationship of tidal basin areas and tidal volumes which is in the long run dependent on tidal range variations.

## Acknowledgements

This work was carried out in the framework of the Dutch-German research project WADE (Wadden Sea Morphological Development in respect of an accelerated relative sea-level rise). The German part is sponsored by the GERMAN FEDERAL MINISTRY FOR RESEARCH AND TECHNOLOGY (BMFT) under contract no. MTK 0508. The author is very grateful to the assistance he got from colleagues of the CRS Section of Coastal Hydrodynamics: H. Alberts, R. Goldenbogen, T. Hartkens, R. Kaiser, W. Liebig, M. Puschmann and E. Schröder transferred the reconstructions of historical coastal morphology and recent maps into the GIS, extracted data and elaborated graphics. Finally it is urgently necessary to stress the fact that this kind of investigation was only possible on the basis of the reconstruction of historical coastal morphology being carried out successfully by the author's late colleague Hans HOMEIER between 1949 and 1980.

## Field Observation and Numerical Simulation of Beach and Dune Scarps

Ryuichiro Nishi<sup>1</sup>, Michio Sato<sup>1</sup>, and Hsiang Wang<sup>2</sup>

### ABSTRACT

Beach and dune scarps are prominent erosional features and probably interfere with post-storm beach profile recovery because of wave reflection on the scarp face during high tide and reduced swash height. As examples, beach and dune scarps, created by typhoon waves on the Pacific Coast and on the East China Sea Coast in Kagoshima Prefecture, were investigated. The highest scarp elevation on these coasts were found to be approximately to 7 m on the Pacific Coast and 10 m on the East China Sea Coast. Following the field observation, a numerical study was conducted to study the generation of scarps.

### INTRODUCTION

A sandy beach and dune will be vulnerable to storm waves and storm surge when a severe storm approaches to a coastal zone. These high waves will change cross-shore profile significantly and cause shoreline recession. Following beach and dune erosion by a storm, a beach profile recovery process will take place under the incidence of ordinary waves. This process probably correspond to a ordinary profile suggested by Johnson (1949). Regarding cross-shore profile recovery, it is mentioned by Kriebel (1986) that "Time scales of beach profile recovery are highly variable. It is generally known that recovery processes occur on much slower time scales than erosion. As observed by Meyer (1936); " the time required for the bar to move shoreward under normal conditions is four to six times as long as to form the bar during storm conditions." Recovery typically occurs over time scales of several days to several months. In some extreme cases, recovery may take on the order of several

<sup>2</sup> Dept. of Coastal and Oceanographic Engineering, 336 Weil Hall, University of Florida, Gainesville, Florida 32611, U.S.A.

years due to the infrequent onshore motion of sand in deeper water. On the other hand, observations immediately after the peak of a storm indicate that a large portion of the eroded volume may recover within one to two days, seemingly accelerated by elevated water levels and fairly energetic but constructive wave conditions." The study at Ocean City, Maryland by Randall and Kraus (1993) also suggested that large amount of profile recovery occurred during the last part of storm condition.

The recovery process depends on the wave condition during and after the storm, as well as on the post-storm beach profile such as scarps and longshore bar features, because the cross-shore profile interacts with a wave transformation and effects the resulting cross-shore sediment transport rate. Beach and dune scarps are significant erosional features and probably retard post-storm recovery by ordinary waves, because some of the low steepness waves with constructive force under the normal circumstance have undermined a foot of scarp and reflected by a vertical scarp face during high tide. As an example, the dune scarp was caused by the Typhoon 9119 in Kashiwabara beach, Kagoshima in 1991. The height of dune scarp was nearly 7 m according to the Minami Nippon Daily Newspaper. Once these scarp features are generated by storm waves, potential risk for properties behind the dune/beach will increase, because there is either only a narrow beach or no beach at all to dissipate incident wave energy and to resist destructive forces of successive storms. Since the average annual wave height along Japan Coast has increased in the last decades and the sediment supply from river is decreasing due to the structures placed in river, again it seems that the rate of beach profile recovery might be slower compared to the last decades. Therefore, from an engineering point of view, it is important to collect the data of erosional features and antecedent recovery process for the purpose of improving shore-protection and coastal management. It is also recognized that dunes have several functions, such as (i) serving as soft structures against storm surge and severe wave attack including tsunami waves, (ii) filtering effect of wind blown sand and salt by the coastal forest on and behind the dune, (iii) sediment source to the foreshore and longshore bar in a severe storm condition, (iv) a habitat and nesting area for sea animals and vegetation, (v) a setback area for the sea-level rise as well as storm surge, and (vi) a recreational area for local residents and tourists, etc. Therefore, proper dune management is very important.

Regarding numerical studies of dune erosion, there are several numerical methods, from two dimensional to quasi-three dimensional, to predict the dune erosion quantitatively. (Vellinga (1983, 1986), Kriebel and Dean (1984, 1985), Stieve and Battjes (1984), Sargent and Birkemeier (1985), Larson and Kraus (1989, 1990), Kriebel (1990), Wang and Miao (1992), Steetzel (1993), etc.) However, there is very little knowledge of physical processes on the beach and dune erosion and resulting scarps under a severe storm condition. (For instance, Kana (1977), Vellinga (1986), and Fisher (1986)). It is necessary to obtain enough physical knowledge on dune erosion process, however it is almost impossible to obtain a data set of beach and dune profile evolution just before and during the storm activity in the natural condition. Therefore, field surveys are usually carried out between and after storms.

Strictly speaking, the beach profile after the storm contains an information of beach profile recovery, since the waves may have high constructive force in the last part of storm period according to several beach profile predictors, for instance Kraus et al. (1991).

In the current study, field observations were conducted to study the geomorphological features of dune and beach scarps, and generation of scarp by storm waves. Based on these field observations, a numerical study has been carried out to simulate the scarps.

## FIELD OBSERVATION OF SCARPS

The coast line of Kagoshima Prefecture, which exceeds 2200 kms, suffered extensive damage by two of the biggest typhoons in this century, one in 1991 and the other in 1993. Due to these recent and successive severe typhoons, beach and dune scarps have been generated along the Fukiage coast which extends about 30 km south to north on the East China Sea, and along the Shibushi coast which extends about 8.2 km on the Pacific Coast in Kagoshima. The locations of these two coasts are shown in Fig. 1.

**Fig. 1. Locations of study areas**

### Cross-shore processes

The maximum height of dune scarp at Fukiage Beach was nearly 10 m, and an initial stage of dune scarping is shown in Fig 2. It can be seen that the dune has a steep seaward slope, and has a vertical face at the foot of the dune which was truncated by waves. Other field surveys have been carried out at Kashiwabara Beach on the Pacific Ocean Coast. Since dune scarp, beach nourishment, and beach scarp after the nourishment have alternatively appeared in this study area, the physical processes in this coast are probably particularly attractive from coastal engineering view point. Therefore, scarps in this area are mainly discussed in this paper. General characteristic of this coast are shown by a series of photographs, and then the longshore distribution of scarps will be discussed based on the field data.

Dune scarps at Kashiwabara Beach caused by Typhoon 9119 is shown in Fig 3. The photograph was taken one year after the Typhoon 9119, thus the foot of the dune is partially filled by onshore sediment transport. The height of dune scarp just after the Typhoon was about 7m according to the local newspaper (Minami Nippon Daily News), and the height of scarp shown in Fig. 3 was about 5 m. Because the shoreline and the crest of the dune regressed further landward, there was little foreshore remaining to dissipate wave energy. As a result, part of the coastal forest on and behind the dune was damaged by the collapse of dune and by the wind-blown salt. To protect the coastal forest and properties, a beach nourishment project was carried out in the beginning of 1993. The nourishment project area shown in Fig. 4 extends 2 km to cover the highly eroded beach. A few months after the beach nourishment project, storm waves caused by one of the biggest typhoons in this century, Typhoon 9313, for which the lowest pressure was 914 hp(mb), affected the project area, and produced beach scarps which extended along the whole nourished beach. Beach scarps in the central area of the project is shown in Fig. 5. In contrast to the nourished beach, there was little beach scarp at the neighboring natural beach. This difference probably arose from the fact that the nourished nearshore beach profiles was much steeper than the natural or equilibrium beach profile. The field survey showed that the maximum height of beach scarp was close to 3m where the shoreline retreated significantly landward. In addition, it was noted that the most severe damage was located in the same area as that of the heaviest dune scarp area produced by preceding Typhoon 9119 which caused a maximum of 7 m dune scarp.

To reduce further beach and dune erosion by an antecedent typhoon, it is necessary to accurately estimate the beach and dune profile before and after the typhoon. Then, the behavior of the dune and beach profile under the action of another storm can be predicted. Unfortunately, in the present case, beach profile data before the typhoon was not available to the authors and the field data were collected only after the generation of dune and beach scarps.

Field observations showed that swells with low steepness during high tide easily reach to the foot of scarp and undermine the vertical scarp face, while a low steepness swell has the constructive force in general. Following the undermining, the

(Photograph taken one year after the typhoon)**

**Fig. 4. Beach nourishment at Kashiwabara Beach in 1993.**

**Fig. 6. Moment of collapsing (the sand blocks are falling)**

vertical layer of sand above the scoured foot loses support and collapses around the foot of scarp, and is deposited at the foot with an angle of repose. Fig. 6 shows the moment of collapsing of a scarped face. The block of sand which is in motion can be seen in the middle of the figure. The sand deposited at the foot of the scarp is transported offshore by successive waves and probably supplies sand to enhance the generation of longshore bar. This cross-shore process repeats itself at the end of wave attack during high water level. Thus, beach scarp plays a role as a moving boundary for the wave and moving sediment source for which a sand layer with a certain thickness is cut from the scarp face at distinct moments in time. It is also expected that the cross-shore sediment transport rate has a peak at the position of scarp during the collapse of the scarp face. This kind of process was also noted by Vellinga (1986) that " The first series of waves reaching the dune front causes erosion and a consequent lowering of the beach just in front of the dunes. After a number of waves the foot of the dune is eroded to such an extent that the dune front becomes unstable. Then, a slice of sand of between 0.2 and 2.0 m thick

(depending on the height and form of the dune) slides down, forming a pile of sand at the foot of the dune. This volume of sand is then gradually eroded by the waves. After some 50 to 100 waves, the pile of sand is cleared away and a new dune front instability occurs. In course of time it takes longer and longer before the pile of sand is removed. The rate of dune erosion decreases with time."

**LONGSHORE PROCESSES**

In contrast to the ordinary dune erosion which is two dimensional, scarp on this beach shows a longshore curved distribution. To see a planform, the beach width, defined as a length from the vegetation line to the crest of the scarp, is shown in Fig.7. In addition, the height of beach scarp is shown in Fig. 8. There is a T-

**Fig. 7. Width of the beach at Kashiwabara Beach**

**Fig. 8. Height of the beach scarp**

shaped groin at the south end ( $x=0$  m) for which the longshore sediment transport further south is blocked at this boundary. It is seen that the beach is wider around the groin ( $x=0$ m), gradually decreasing in width to the north, and reaches a minimum width of 35 m at the location of  $x=1300$  m. Because of the narrow width of the beach in this area, waves break just near the dune and occasionally strong winds scatter the blown salt around the coastal forest. As a result, the coastal forest at this location has been damaged and many pine trees have withered. Also, the height of beach scarp was a maximum of 3 m around the area where the beach was the narrowest, and it was smallest at both the north and the south sides of the nourishment project area. It is noted that the position of the highest beach scarp caused by Typhoon 9313 was consistent with the position of the highest dune scarp caused by the Typhoon 9119.

## NUMERICAL TESTS

Based on the knowledge gained with the above field surveys, a numerical study was conducted to examine the cause of erosion and the generation of dune and beach scarps. Regarding numerical modeling of dune erosion, Vellinga (1983,1986), Kriebel and Dean (1984, 1985), Kriebel (1990) and other researchers have proposed two-dimensional cross-shore models. Here the SBEACH model (Larson and Kraus, 1989, 1990) has been applied to simulate dune and beach scarps. Because waves on a natural beach are random and their wave height distribution in offshore region might be expressed by the Rayleigh distribution, a simple model for the beach profile evolution due to random waves is also applied to simulate the dune erosion. Due to space limitation, the SBEACH model is only briefly reviewed.

### *SBEACH model*

The main structure of this model is composed of three sub-programs, (1) wave transformation, (2) cross-shore sediment transport, and (3) profile change calculated from conservation equation for bed material as the same in the other two-dimensional models. This model can be classified as semi-open model which uses an equilibrium beach profile concept. In contrast to the equilibrium concept which was originally developed by Dean (1977), Moore (1982) and Kriebel and Dean (1984), the SBEACH model simulates the generation of bar-trough features, avalanching, and some beach profile recovery. The wave transformation calculation is based on the model proposed by Dally (1984) and Dally et al. (1985 a,b) which is shown by Eq.(1).

$$\frac{\partial}{\partial x} (F \cdot \cos \theta) + \frac{\partial}{\partial y} (F \cdot \cos \theta) = \frac{\kappa}{d} (F - F_s) \quad (1)$$

where,  $F$  is the energy flux of progressive wave,  $\theta$  is the incident wave angle,  $x, y$  are coordinates normal and parallel to the coast respectively,  $\kappa$  is an empirical decay coefficient, and  $d$  is the total water depth which is the sum of still-water depth  $h$  and the mean water level  $\eta$ . In the present study, the wave angle is restricted to normal

incidence, so that the  $y$  component is negligible.  $F_s$  is the energy flux of a stable wave. The mean water level  $\eta$  is computed as follows;

$$\frac{\partial S_{xx}}{\partial x} = -\rho g d \frac{\partial \eta}{\partial x} \quad (2)$$

where,  $S_{xx}$  is the radiation stress,  $\rho$  is the density of the water, and  $g$  is the acceleration due to the gravity.

The cross-shore sediment transport rate in the surf zone is a type of energy dissipation model for which the transport rate is proportional to the difference between the actual wave dissipation per unit water volume,  $D$ , and the energy flux in equilibrium condition,  $D_{eq}$ . The local slope term is also added to the transport rate to account for the slope effect as shown :

$$q = K(D - D_{eq} + \frac{\epsilon}{K} \frac{\partial h}{\partial x}) \quad (3)$$

where,  $q$  is the net cross-shore sediment transport rate,  $K$  is an empirical coefficient for the sediment transport, and  $\epsilon$  is an empirical coefficient,  $h$  is a still water depth. To compute the depth change (profile change) in a time increment  $\Delta t$ , conservation equation for bed material is used as;

$$\frac{\partial h}{\partial t} = \frac{\partial q}{\partial x} \quad (4)$$

## NUMERICAL RESULTS

Because the natural beach with mild foreshore slope showed less damage compared to the nourishment area in Kashiwabara beach, the effect of beach slope on the generation of scarps was studied, first. Regular waves were applied for a plane beach with 1/10, 1/15, 1/20 uniform slope, respectively. Numerical results of the beach profile evolution and resulted scarps are shown in the Fig. 9 for regular waves with height 2.3 m and period 6.0 sec. It is seen that the shoreline was retreated as the wave duration increased, and sediment which was eroded around the shoreline was transported offshore to generate a longshore bar. The resulting scarped face migrated shoreward, while the shoreline retreated. It is clearly seen that the steeper is the initial beach profile, the higher is the resulting beach scarp. It appears that the numerical predictions agrees qualitatively with the field data.

Second, a composite dune-beach profile was used to generate dune scarp under a steady storm surge condition. It meant that the storm surge level did not vary in time. A 1-m and 2-m steady storm surge was added to the still water level.

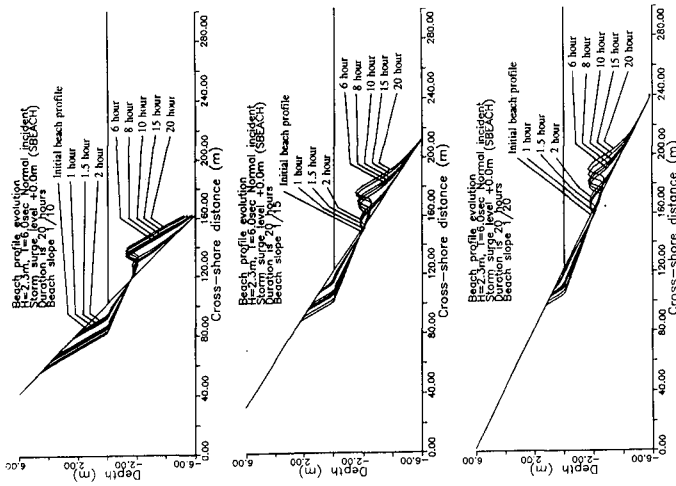

Fig. 9. Calculated beach profile evolution on beaches of different slope

Fig. 10. Dune erosion during storm surge

Numerical results for the case of no increase in water level, and 1-m increase in water level during the storm are shown in Fig. 10. It is seen that longshore bars were generated by waves and migrated offshore with the passage of time. Corresponding to the migration of longshore bars, the sediment around the shoreline was transported offshore and then the dune erosion started. The resulting dune scarp became higher, while the cross-sectional area of dune erosion widened with time. In addition, it is clear that the larger the increase in water level due to storm surge, the higher the dune scarp for these cases. This is interpreted that the slope of the dune face is usually steep compared to the foreshore slope, so the slope where the stormy waves act probably is steeper during a high increase in water level. Therefore, the dune profile is eroded much more and as a result higher dune scarp appears.

Since the dune material is usually finer than the beach material, it is more easily carried away by the storm waves. However, the effect of different grain sizes between beach and dune is not taken into account in the present study. Vegetation also functions to strengthen a dune face, but its role is not taken into account in the present study.

As shown in Fig. 7 and Fig. 8, the beach scarp in this study area exhibits a longshore curved shape in terms of height and width. This curvature was perhaps caused by a negative gradient of longshore sediment transport. However, there was little shoreline progress along the coast even at the T-shaped groin just after the Typhoon 9113, though storm waves caused a significant beach erosion at the central area of nourished beach. It is expected that if the longshore sediment process mainly governs the topography change at this area, the area beside the groin should prograde or a part of the beach should widen, but there is little evidence to show such shoreline changes in this study area. Therefore, it is believed as a first step of the research that the longshore curved beach scarp was probably caused by an incident wave field which has a longshore uneven wave height, caused by an artificial island in front of the study area and dredging hole in the offshore region, and is mainly manifested in the cross-shore sediment transport. It is noted that this assumption need to be verified by a bathymetry data covering the area from the dune to beyond the depth of closure for considering the sand budget and a direction of sediment movement. However, such data were not available for this study.

The uneven longshore wave height distribution was calculated by eq. (5)

$$H(y) = H_1 + H_2 \sin^2 \left( \frac{2\pi}{400} y \right) \quad (5)$$

where,  $H(y)$  is the wave height at shoreline position  $y$ ,  $H_1$  was set to be 1.0 m, and  $H_2$  was set to be 3.0 m. Based on this wave height distribution, beach profile evolution and scarp were computed at 50 m spatial intervals alongshore. Fig. 11 shows a numerical result for this case. In accordance with the field data, the

**Fig. 11. Longshore curved scarping calculated by numerical model**

numerical result shows a longshore curved scarp as well as curved longshore bar. The height of the beach scarp in the central region is the highest corresponding to the height of incident wave height. The crest line of the scarp also shows a curved longshore distribution.

## CONCLUDING DISCUSSION

The general characteristics of the dune and beach scarps at the Fukiage beach and the Kashiwabara Beach, Kagoshima, were investigated in field surveys. Dune scarp caused by the Typhoon 9119 and beach scarp by the Typhoon 9313 show similar longshore curved distribution. It was observed that once a vertical scarp face was generated, the waves directly attacked the scarp face during high water and undermined the foot of the scarp. As a result, blocks of sand collapsed, deposited at the foot of the scarp and was transported offshore by successive waves. This is a straight-forward process and agreed well with a set of physical model data by Dette et al. (1992). In addition, there was little evidence to show that the negative gradient of longshore sediment transport dominated the scarp generation in this study area. It was also shown by a numerical study that the steeper is the beach face the higher is the resulting scarp.

The sediment budget in the study area should be confirmed in the future. It is expected that the direct measurement of scarp generation and the recovery process at the foot of scarp are required for further investigations. The estimation of the sand movement in the offshore region and depth of closure due to extreme typhoons is

also necessary, because it could be a source of onshore sediment transport during the beach profile recovery. Although it is not discussed in this paper, there is a man-made island of 192ha area and also a dredging area near the study site which strongly affect local wave fields and result in the change of planform of the beach. Before the Typhoon 9119, the planform of the beach was significantly changed by a construction of the man-made island and was narrowed especially around the area where dune and beach scarp had been generated by severe storm waves. Thus, a further study of the wave field affected by islands can help the proper coastal management at this area.

### **Acknowledgements**

The authors would like to express their special thanks to Prof. Nicholas C. Kraus at the Conrad Blucher Institute for Surveying and Science, Texas A&M university - Corpus Christi, for his kind comments and recommendation. The authors also appreciate Mr. Iwamoto, Mr. Ikeda, and other members of the Coastal Engineering Lab. at the Department of Ocean Civil Engineering, Kagoshima University. This study was partially supported by the research grants of the Ministry of Education, Japan and by Kagoshima National University.

## CHAPTER 177

# EFFECTS OF CONTROLLED WATER TABLE ON BEACH PROFILE DYNAMICS

Tae-Myoung Oh<sup>1</sup> and Robert G. Dean<sup>1</sup>

### ABSTRACT

The purpose of this study is to improve general understanding of beach profile dynamics as affected by the interaction between the beach profile and the water table level within the beach by presenting the results of laboratory and numerical studies. Two series of laboratory experiments were conducted in “large” and “small” wave tank facilities. Special attention was given to elevated water table levels to investigate whether or not erosion of the beach face is enhanced. The results of the large wave tank experiments demonstrated a surprising influence of beach water table on profile dynamics including changes in the bar region. Although the experiments in the small wave tank used correctly scaled sand, it was found that the effects documented in the large scale tests could not be duplicated. Furthermore those results were supported by numerical simulation of the internal flow inside the beach. One possibility for the difference is that the sand in the large scale tests was more poorly-sorted than that in the small scale experiments.

### INTRODUCTION

For a permeable beach, we would expect an internal flow within the beach, which might be driven by the mean pressure due to the ground water table level inside the beach and/or wave induced set-up. If the mean pressure gradient is large enough to stabilize or destabilize the sand particles, it may affect the sand transport and resulting profile evolution.

Attempting to demonstrate the effect of percolation, Bagnold (1940) prevented free percolation through the sand by placing an impermeable steel plate just below the sloping beach surface. The thin layer of the sand above the plate was at once removed as soon as waves attacked, resulting in erosion of the beach.

Grant (1948) noted, by observations of the fluctuations in the width and slope of beaches in southern California, that the position of the ground water table

---

<sup>1</sup>Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611

within the beach played an important role on deposition and on erosion of the foreshore and backshore. He suggested that a higher water table than mean sea level accelerated beach erosion, and conversely, a lower water table might result in pronounced aggradation of the beach. Emery and Foster (1948) found that the escape of water from the lower part of the beach may exert an appreciable upward force on the sand particles, sufficiently large to destabilize them, resulting in erosion of the beach.

Based on possibilities of beach stabilization, test installations of the beach drain system have been conducted in the laboratory and in the field; this approach consists of burying a pipeline along the beach to maintain the water table level at a lower one than the mean sea level by pumping.

Machemehl, French and Huang (1975) conducted laboratory experiments to determine the effects of a sub-sand filtering system on the stability of a beach profile, which consisted of well pipes buried perpendicular to the shoreline and pumping  $136.3 \text{ cm}^3/\text{s}/(\text{m of beach})$ . The results showed that the drain system caused deposition on the beach face and stabilized the sand at the offshore zone by inducing a flow into the beach, but it had a negligible effect in the breaking zone since turbulence by wave breaking was too strong to be controlled by the drain system.

Kawata and Tsuchiya (1986) performed laboratory experiments to examine the effects of beach drain for the case of solitary and regular waves on the beach face. With a relatively fine sand for the solitary wave tests, the beach face was much steeper with pumping than non-pumping cases. With much coarser sand for the regular wave cases, it was recognized that the pumping system was effective under storm wave conditions by reducing the sand transport, thus stabilizing the beach near the shoreline.

Terchunian (1988) reported on a prototype beach drain system installed along 180 m of the beach at Sailfish Point on Hutchinson Island, Florida. The system had been in operation over two years and beach profiles were taken monthly to determine the efficiency of the system. The system appeared to result in a stabilization of the beach as moderate accretion occurred while the updrift and downdrift beaches showed erosion.

However, the interaction mechanism of beach drain system is not obvious since some laboratory results appeared to result in no significant effects of water table levels on the beach profile changes. Bruun (1989) claimed that the method ought to be more effective in mild conditions than storm conditions as the velocities (and energy levels) are far higher in the surf zone during a storm. Ogden and Weisman (1991) performed two-dimensional laboratory experiments to assess the effectiveness of a beach drain system on stabilization. Tests were carried out with a very fine sand (median diameter of  $0.145 \text{ mm}$ ) under irregular waves. Even with a fairly long duration of waves, they could not find any significant differences in the final profiles. They suggested that the beach drain would not be effective where there is a negligible tide.

This paper presents the results of laboratory studies to investigate the effects of controlled water table on beach profile dynamics. To achieve this goal, two series of experiments were conducted in "large" and "small" wave tanks at three different water table levels while the other factors (e.g., wave height, wave period, water depth, initial beach slope, etc.) were fixed to constant values with regular waves. The water table levels included : (a) normal water table level which is the same as mean sea level, (b) a higher level and (c) a lower level than the mean sea level. Special attention was given to elevated water table levels to investigate whether or not erosion of the beach face is enhanced. The results of numerical studies are also presented to simulate the internal flow inside the beach and to understand the interaction mechanism.

### LARGE WAVE TANK EXPERIMENTS

The first experiment was conducted in the "large" wave tank facility of the Department of Coastal and Oceanographic Engineering at the University of Florida, which is approximately 36 *m* long, 1.8 *m* wide and 1.8 *m* deep. A long partition has been constructed along the tank center line dividing it into two channels each of 0.9 *m* width. A planar beach was formed with initial slope 1:18 and composed of poorly-sorted fine sand with a median diameter of 0.24 *mm* and a sorting coefficient of about 1.0. (At first, the beach was considered as composed of well-sorted fine sand with a median diameter of 0.2 *mm* and a sorting coefficient of 0.5. However, it was found that the fine sand was underlain by well-sorted coarse sand with a mean diameter of 0.4 *mm*, which appeared to affect the overall permeability of the beach.) Regular waves with a period of 2.0 *seconds* and height of 0.16 *m* were generated. The water depth at the toe of the beach slope was 0.47 *m* at mean sea level. Details are provided in Oh and Dean (1992).

The experiment was conducted at three different water table levels, which were regulated sequentially to: (1) normal water table level which was the same as mean sea level (1.5 *hours*), (2) a higher level (+11.0 *cm* during 2.0 *hours*) and (3) a lower level than the mean sea level (-11.0 *cm* during 1.5 *hours*). The duration of each test with the same water table level was determined based on an assessment that the beach profiles were near equilibrium and would not significantly change beyond this test duration. Throughout the test program, the beach profiles were monitored at one-half hour intervals.

The higher water table (at 1.5 *hours*) was established by raising the entire water level in the wave tank and allowing the ground water table to equilibrate with no waves acting. The tank water level was then lowered and the water table level in the beach was maintained by excavating a small depression in the berm below the desired water level, which was then maintained by filling periodically with a hose. For the lower water table, the procedure described above was followed except that water was siphoned out of the excavated hole in the beach berm to maintain the desired level.

### SMALL WAVE TANK EXPERIMENTS

A total of 8 "small" wave tank experiments was carried out (1) to evaluate the repeatability of the large wave tank experiments and (2) to illustrate beach profiles that would have occurred if the water table had not been altered or regulated with different sequences from the first experiment. This tank is 15 m long, 0.9 m high and 0.6 m wide, and is equipped with a piston type wavemaker with a mechanically controlled motion and with one glass wall panel and one steel wall.

Table 1 lists the experiment identification number, total wave run duration, water table level condition, and a brief description of each experiment. The experiments were scaled from the large wave tank experiment according to the fall velocity parameter (Dean, 1985) for a well-sorted fine sand with mean diameter of 0.21 mm and a sorting coefficient of 0.5 with a length scale of 1:1.7, and the waves were modelled according to the Froude relationship. Regular waves with a period of 1.5 sec and a height of 11.0 cm (rather than 9.5 cm as would be required by scaling) were used due to wavemaker limitations, and were measured by a capacitance-type wave gage. Figure 1 presents a schematic diagram of the initial profile and other experimental details.

Table 1: Description of Small Wave Tank Experiments

Exp. No.	Water Table Level		Note
	Duration(min)	Level(cm)*	
SW01	230	0.0	Reference test
SW02	230	+6.5	High water table level
SW03	230	-6.5	Low water table level
SW04	0-69	0.0	Repeat test of Large wave tank experiment
	69-161	+6.5	
	161-230	-6.5	
SW05	0-69	0.0	Effect of sequence of changing water table level
	69-161	-6.5	
	161-230	+6.5	
SW06	0-69	0.0	Elevated water table level
	69-545	+11.0	
SW07	0-1166	+16.5	Elevated water table level
SW08	0-890	-11.0	Lowered water table level
	890-2201	+11.0	Elevated water table level

\* Zero refers to the mean sea level (MSL). Hence, positive value represents the water table level above MSL.

The desired water table level in the berm was maintained by excavating 2-D depressions across the tank. These excavations were connected to a constant

Figure 1: Schematic Diagram of the Initial Profile and Other Experimental Details

head reservoir through plastic tubes so that water was siphoned out of or into the excavated holes to maintain the desired water table level. During the experiments, this method worked very well. However, bubbles appeared sometimes inside the tubes due to prolonged experimental duration; at which time, they were removed by allowing a small amount of flow from the excavated holes to the reservoir, or vice versa.

### INTERACTION MECHANISM

Consider a sand particle, as shown in Figure 2, on the bed which has a slope  $\theta$  and experiences a lift force  $F_L$ , a portion of which is due to an upward or inward flow perpendicular to the sand surface.

Figure 2: Free Body Diagram for a Sediment on a Sloping Bed with an Internal Flow System

The critical Shields parameter for motion downslope can be written as;

$$\frac{W \sin \theta + F_D}{W \cos \theta - F_L} = \tan \phi_s \quad (1)$$

where,  $W$  is the submerged weight of the sediment,  $\theta$  is the bed slope,  $\phi_s$  is the angle of repose of the sediment, and  $F_D$  is the drag force acting on the particle. The lift force component due to the flow out of bed,  $F_L'$ , can be expressed as;

$$F_L' = \frac{u}{K} \rho g V \quad (2)$$

in which,  $u$  is the average flow velocity perpendicular to the sand surface,  $K$  is the hydraulic conductivity (or permeability),  $\rho$  is the mass density of water,  $g$  is the gravitational acceleration, and  $V$  is the volume of the sediment. Finally, the critical Shields parameter,  $\psi_c$ , as affected by both the bed slope and the internal flow system, can be given as;

$$\frac{\psi_c}{\psi_{c0}} = \cos \theta \left[ 1 - \frac{\tan \theta}{\tan \phi_s} - \frac{u/K}{(s-1) \cos \theta} \right] \quad (3)$$

where,  $\psi_{c0}$  represents the critical Shield parameter on the impermeable bed with no slope, and  $s$  is the ratio of mass densities of sediment to water. In order to reduce the effective weight of the sand particles and therefore their stability, hence, the upward flow velocity should be sufficiently large or local slopes of the beach should be quite steep, where the sand particles had marginal stability.

### NUMERICAL MODELING

Considering a beach of uniform porosity with internal flow velocity that obeys Darcy's law, the internal flow system is governed by the Laplace equation;

$$\nabla^2 \phi = 0 \quad (4)$$

where,  $\phi$  is the hydraulic head defined as;

$$\phi = z + \frac{p}{\rho g} \quad (5)$$

in which,  $z$  is the elevation from the tank bottom,  $p$  is the pressure,  $\rho$  is the mass density of water, and  $g$  is the gravitational acceleration. Equation (4) can be solved efficiently by the Boundary Integral Equation Method (BIEM) if the proper boundary conditions are given at the tank bottom, beach profile, seepage face, phreatic surface inside the beach and lateral ends of tank. The transient state can be included in Equation (4) through the time-varying boundary conditions at the beach profile and phreatic surface; however, steady-state was considered in this paper. If  $\phi$  is known, then the internal flow velocity can be computed from Darcy law;

$$\mathbf{u} = -\mathbf{K}\nabla\phi \quad (6)$$

where,  $\mathbf{u}$  is the average velocity across a given area of sand, and  $K$  is the hydraulic conductivity. In this paper, hydraulic conductivity was measured by using a permeameter based on constant/variable method, and was found to be 0.022 cm/sec for the sediment used in the small wave tank experiments.

### RESULTS AND DISCUSSIONS

As illustrated in Figure 3, the results of the large wave tank experiments demonstrated a surprising influence of beach water table on profile dynamics including changes in the bar region. Figure 3 shows the profiles during normal, higher and lower water table levels. During normal water level, sand was transported both onshore and offshore resulting in deposition at the berm and at the bar, and the profiles were approaching an equilibrium. As soon as the higher level was established, however, very large changes occurred at the bar crest with relatively smaller changes at the bar trough; the bar started to move landward rapidly at the initial

stages and stayed stationary at the later times. During the higher level, sand was transported onshore and deposited at the berm and at the depositional area located immediately landward of the bar trough. The increased water table level caused a strong landward transport, which is contradictory to previous studies that higher water table level enhances erosion. However, there was erosion immediately seaward of the berm. Also it can be seen that relatively small changes occurred with the lower water table level. The only noticeable trend was a limited deposition in the scour hole at the base of the beach face.

(a) NORMAL WATER TABLE

(b) HIGHER WATER TABLE

(c) LOWER WATER TABLE

Figure 3: Profiles during Normal, Higher and Lower Water Table Levels in the Large Wave Tank Experiment

Based on the results of the large scale tests, the following can be concluded: (1) the effect responsible for the changes in the profiles appeared to be a destabilization of the bottom particles in areas of pre-existing marginal stability with the eroded particles transported to stable areas, (2) the increased water table appeared to be effective far offshore, which was somewhat surprising, and (3) the lowered water table appeared to result in a much more stable beach by introducing a downward flow into the beach and the resulting effects were much less.

Although the experiment in the small wave tank used correctly scaled sand, it was found that the effects documented in the large scale tests could not be duplicated. In fact, all of the various small scale test results were nearly the same up to a testing time in excess of 3 *hours*. Based on the conclusions drawn above, several possible causes can be considered: (1) effects of coarser sand layer overlain by fine sands in the large wave tank experiments, (2) more poorly-sorted sand in the large scale tests than that in the small scale tests, (3) different wave height from that required by scaling, and (4) microorganisms inside the beach under prolonged submergence, which may influence the sand permeability. Other possibilities could be explained by the numerical studies.

As shown in Figure 4, calculations demonstrated that a small upward flow of water emerged through a porous sand bed, which is driven by wave-induced set-up only within a linear beach. However, the magnitude of the ratio  $\frac{u}{K}$  appears too small to reduce the effective stability of the sand particles. Even with a fairly steep beaches, as shown in Figure 5, the effect of upward flow was not significant although the overall stability of the bottom particles on the steep beaches was reduced due to the effect of the slope. Higher water table levels intensified the magnitude of the internal flow, as shown in Figure 6; however, the effect of upward flow appeared to be small compared with the effects of steep slope. Hence, these results of the small scale tests suggested that the altered water tables had no effects on the beach profile dynamics, which is contradictory to the conclusions from the large scale experiments. More definite conclusions can be reached only by further research including a more comprehensive comparison of numerical modeling results with measurements.

## CONCLUSIONS

Based on the present laboratory and numerical studies, the following conclusions and recommendations are described.

Large scale tests demonstrated that upward flow of water emerged through a porous sand bed due to both the higher water table level and wave-induced set-up and appeared to destabilize the bottom particles in areas of pre-existing marginal stability with the eroded particles transported to stable areas. However, the effects documented in the large wave tank experiments were not verified by the small scale experiments even with the correctly scaled sand. Furthermore, numerical results on the steady-state beach system supported the small scale test results. Several possible reasons were suggested, which need further study.

Figure 4: Internal Flow by Wave-Induced Set-Up within a Beach of Uniform Slope

Figure 5: Internal Flow by Wave-Induced Set-Up for a Typical Beach Profile

Figure 6: Internal Flow by Wave-Induced Set-up and Elevated Water Table Level for a Typical Beach Profile

There is a substantial need for additional carefully controlled laboratory experiments with different range of sediment sizes and sorting (thus permeabilities) from the present experiments. The numerical modeling should be improved to include the transient state boundary conditions and the effects of coarser sand layer overlain by fine sands as in the large scale tests.

## CHAPTER 178

### LABORATORY EXPERIMENTS ON 3-D NEARSHORE CURRENT AND A MODEL WITH MOMENTUM FLUX BY BREAKING WAVES

Akio Okayasu<sup>1</sup>, Koji Hara<sup>2</sup> and Tomoya Shibayama<sup>3</sup>

#### Abstract

Laboratory experiments are performed in a wave basin to investigate the characteristics of three dimensional distribution of the nearshore current. Direction and amplitude of the nearshore current significantly change along the vertical axis and have spiral distribution. A quasi 3-D model which gives the 3-D distribution of nearshore current is proposed. Momentum flux due to the large vortexes formed on the front face of breaking waves is included in the model to evaluate the depth averaged current. The model is examined with the experimental results.

#### 1. Introduction

In order to predict the sediment transport or material diffusion in the coastal field, 3-D structure of nearshore currents should be considered. Recently, some models for the 3-D distribution of nearshore current were presented. De Vriend and Stive (1987) investigated the vertical distribution of nearshore current on a beach uniform in the alongshore direction. Svendsen and Lorenz (1989) presented a model for 3-D nearshore current by composing cross-shore and alongshore velocities. Sanchez-Arcilla *et al.* (1992) proposed a quasi 3-D model by combining a 2-DH nearshore current model and an 1-DV undertow model. However, few comparisons were done with measured velocity. The actual 3-D characteristics of nearshore current is not clarified yet.

Visser (1984) measured alongshore current in a basin which simulated an infinite beach in the alongshore direction. In general, it is difficult to control the side boundaries to obtain a uniform current field in the alongshore direction, which may not be necessary as far as the primary purpose is to examine numerical models with the data. In the present study, velocity measurements were performed in a closed laboratory basin to obtain vertical profiles both for cross-shore and alongshore currents in the surf zone for three different beach topographies. The importance of undertow for nearshore circulation was confirmed. The characteristics of the 3-D structure of nearshore currents has been investigated from the measured profiles.

In the surf zone, the mass flux by the organized large vortices (surface rollers) formed in the front face of the waves must be taken into account to evaluate the cross-shore current in 2-DV plane (see *e.g.* Svendsen, 1984). It is considered that momentum flux by the large vortices is also significant. In the present paper, a 2-DH model is proposed in which the momentum flux due to the large vortices is included to evaluate the two dimensional current field. This 2-DH nearshore current model is expanded to a quasi 3-D model by coupling with an 1-DV undertow model which gives vertical distribution of cross-shore component of nearshore current. The model is examined with the experimental results.

## 2. Experiments on 3-D nearshore current distribution

### 2.1 Experimental arrangement

A 9 m by 9 m wave basin was used for the experiments. This wave basin had a 1/20 slope which was uniform in the alongshore direction, and a regular wave generator which could generate obliquely incident waves. The 1/20 slope had a 1.05 m of 1/3 slope at the toe. Steal wave guides were placed on the slope along the wave propagation direction in order to control current patterns to be relatively simple and stable. Figure 1 shows the plan and side views of the wave basin.

The experiments were performed under 3 different conditions which were, Case 1: obliquely incident waves (wave angle;  $\alpha = 10$  deg) + plain slope, Case 2: normal incident waves + circular shoal, and Case 3: normal incident waves + rectangular shoal. The diameter of the circular shoal in Case 2 was 100 cm and the water depth at the top of the shoal was 8.0 cm. The length and width of a top horizontal bed on the rectangular shoal in Case 3 were 120 cm and the water depth there was 4.0 cm. The distances between the wave guides at the both sides of the test sections were 530 cm for Case 1 and 400 cm for Cases 2 and 3. The experimental conditions are listed in Table 1. In the table,  $h_i$  is the still water depth at the offshore constant depth region,  $T$  the wave period,  $H_i$  the incident wave height.

### 2.2 Data acquisition and processing

Table 1 Experimental conditions

case	beach type	$h_i$ (cm)	$T$ (s)	$H_i$ (cm)	$\alpha$ (deg)
1	plain slope	49.7	1.33	5.5*	10
2	circular shoal	49.0	1.36	4.8	0
3	rectangular shoal	49.0	1.20	7.0	0

\* estimation

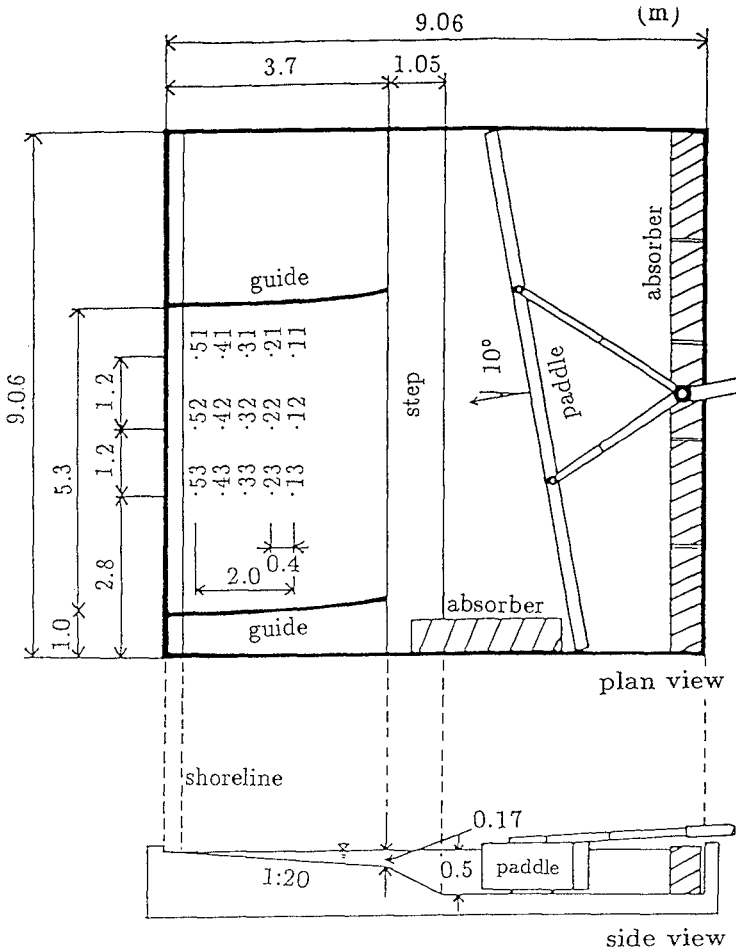

Fig. 1 Plan and side views of the wave basin (Case 1).

Cross-shore and alongshore components of velocity were independently measured by using an optic-fiber laser Doppler velocimeter (FLV). The currents were measured on 15 to 28 vertical measuring lines which located both inside and outside of the surf zone. Water surface elevation was separately measured by a capacitance type wave gage at the same locations. 5 to 16 measuring points were arranged from 2mm above the bottom to the wave crest level along each measuring line to obtain velocity profiles. The arrangement of the measuring lines for Case 1 is shown in Fig. 1.

Since the FLV used in the experiment was for one-component of the velocity vectors, velocity measurements were done twice for cross-shore and alongshore directions at each measuring point by rotating the optics. The velocity was measured over 10 wave periods with data rate of about 50 data per second.

The steady current component,  $\bar{u}$  and  $\bar{v}$ , of the velocity was calculated by integrating the measured instantaneous cross-shore and alongshore velocities,  $u(x, y, z; t)$  and  $v(x, y, z; t)$  over 10 wave periods and dividing by the total measuring time. At the measuring points above the wave trough level,  $u$  (or  $v$ ) was assumed to be 0, if no datum was found for more than 0.1 second.

### 2.3 Experimental results

Comparisons between the depth averaged velocity and the velocity close to the bottom are shown in Figs 2 and 3 for Cases 1 and 2, respectively. The contribution by undertow to the bottom velocity can be obviously seen in both cases. The figures show that even if the depth-averaged velocity can be predicted well, it should not be enough to evaluate the bottom shear stress or the sediment transport rate.

Figure 4 shows vertical profiles of cross-shore and alongshore steady current  $\bar{u}$  and  $\bar{v}$  at measuring lines in the central section for Case 1. The measuring line 12 located just before (offshore side) the breaking point and 52 was around the still water shoreline. As for the cross-shore direction, the profiles look similar to those observed for undertow in two dimensional wave flumes (see *e.g.* Okayasu *et al.*, 1988), and are shifted by the depth averaged velocity.

In the alongshore direction, the measured velocity is almost constant over the depth. However, since velocity near the bottom show the influence by the bottom boundary layer, the distributions look similar to the log profile in general. Above the wave trough level, velocity shows less value than that below, because the instantaneous velocity was not integrated while the measuring point was out of the water. The results shown here are different from those by Visser (1984) in which the profiles showed linear distributions. From the figures, it can be said that it is possible to evaluate the 3-D distribution of nearshore currents by composing the cross-shore and alongshore currents which are separately obtained.

Figure 5 shows examples of 3-D distribution of nearshore current for Case 1. The point No. 13 located around the breaker line, No. 42 was at the middle

Fig. 2 Depth averaged and near-bottom velocity for Case 1.

Fig. 3 Depth averaged and near-bottom velocity for Case 2.

of the inner region of the surf zone. The velocity vectors of nearshore current change the direction significantly along the vertical axis, and have spiral distributions. The figure also indicates the existence of strong onshore current above the trough level which should contribute to the lateral mixing of the sea water as well as the undertow.

### 3. Quasi 3-D nearshore current model with momentum flux by large vortexes

A quasi 3-D nearshore current model proposed in the present study can be divided into three parts which are 1) calculation for wave field, 2) calculation for 2-DH current field, and 3) calculation for vertical distribution of the

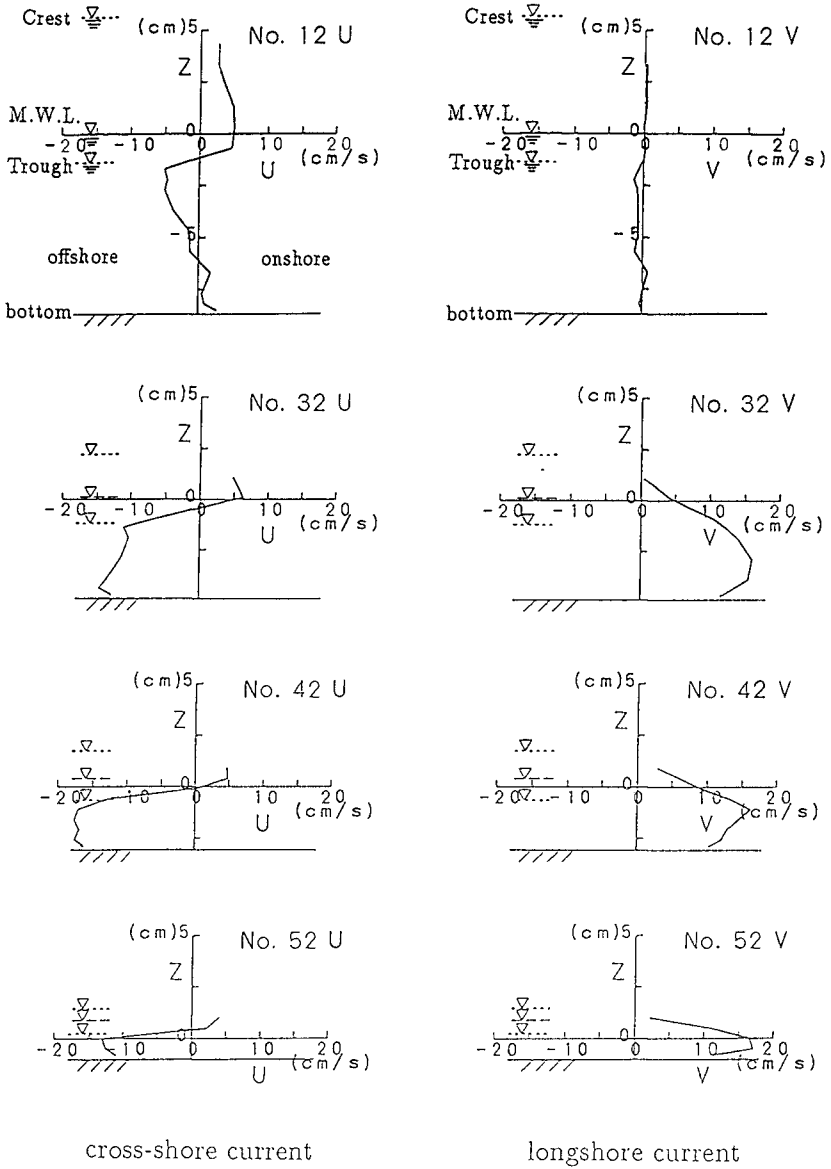

Fig. 4 Vertical distributions of cross-shore and alongshore current (Case 1).

Fig. 5 3-D distribution of nearshore current (Case 1).

current. For the wave and current fields, a 2-DH model which is similar to one proposed by Ohnaka *et al.* (1988) is used. In the current model, both of the momentum flux by wave motion and the momentum flux due to the large vortexes formed on the front face of breaking waves are considered as driving forces to induce the nearshore current. In the wave field calculation, as the wave-current interaction is considered, the shoreline change is predicted with an iteration process between wave and current field calculations.

The depth averaged current in the wave propagation direction is expanded on the vertical axis to obtain the undertow profile by using a method proposed by Okayasu *et al.* (1990). In the direction normal to the wave propagation direction, constant value is given for vertical distribution of the current as found in the experimental results shown in the previous section. Finally, 3-D distribution of the nearshore current is obtained by composing those profiles with an assumption that the interaction between them is negligible as described in Svendsen and Lorenz (1989)

### 3.1 2-DH wave-current model

In order to evaluate the wave field, the following time-dependent mild slope equation in which wave-current interaction is taken into account is used after

Ohnaka *et al.* (1988):

$$m \frac{\partial \zeta}{\partial t} + \nabla \cdot (\mathbf{U}\zeta) + \nabla \cdot (n\mathbf{Q}) = 0 \quad (1)$$

$$\frac{\partial \mathbf{Q}}{\partial t} + \omega c^2 \nabla \frac{\partial \zeta}{\partial \sigma} + f_D \mathbf{Q} = 0 \quad (2)$$

$$m = 1 + \frac{\sigma}{\omega} (n - 1), \quad n = c_g/c \quad (3)$$

in which  $t$  is the time,  $\nabla$  the differential operator in horizontal directions,  $\zeta$  the surface elevation,  $\mathbf{Q}$  the flow rate by waves,  $\mathbf{U}$  the steady current,  $c$  the phase velocity vector,  $c_g$  the group velocity vector and  $f_D$  the attenuation factor by wave breaking.  $\omega$  is the angular frequency without current and  $\sigma$  the relative angular frequency with current. Since the calculation procedures are also similar to those by Ohnaka *et al.*, only the differences will be described hereafter.

The breaking point is determined by using the ratio of water particle velocity to wave celerity. Isobe (1987) approximated the ratio of it at the breaking point by the following formula:

$$\begin{aligned} \left(\frac{\hat{u}}{c}\right)_b &= 0.53 - 0.3 \exp\left(-3\sqrt{\frac{h_b}{L_0}}\right) \\ &+ 5(\tan\beta)^{3/2} \exp\left\{-45\left(\sqrt{\frac{h_b}{L_0}} - 0.1\right)^2\right\} \end{aligned} \quad (4)$$

where  $\hat{u}$  is the horizontal velocity at the still water level,  $c$  the celerity,  $h$  the mean water depth,  $L_0$  the deep-water wavelength,  $\tan\beta$  the bottom slope and subscript  $b$  denotes the quantity at the breaking point.

The attenuation factor  $f_D$  by wave breaking is expressed as

$$f_D = \alpha_D \tan\beta \sqrt{\frac{g}{h} \left(\frac{\hat{Q} - Q_r}{Q_s - Q_r}\right)} \quad (5)$$

which was given by Watanabe and Dibajnia (1988). In Eq. (5),  $\alpha_D$  is a parameter which linearly increases from 0 to 2.5 around the breaking point, then takes a constant value 2.5 in the inner region (see Okayasu *et al.*, 1990). The bottom slope  $\tan\beta$  is the average value of the bottom slope near the breaking point,  $g$  the acceleration of gravity,  $\hat{Q}$  the amplitude of the flow rate.  $Q_s$  and  $Q_r$  are  $\hat{Q}$  on constant slope and for wave recovery zone, respectively.

After calculation of the wave field, the current field and the wave setup are evaluated by using wave momentum flux. The obtained current field is

feedback to the wave field calculation and an iteration process is done until the steady solution can be obtained both for the wave and current fields.

The following basic equations are used to solve the current field:

$$\frac{\partial \bar{\zeta}}{\partial t} + \nabla U(h + \bar{\zeta}) = 0 \quad (6)$$

$$\frac{\partial \mathbf{U}}{\partial t} + (\mathbf{U} \cdot \nabla) \mathbf{U} + \mathbf{F} - \mathbf{M} + \mathbf{R} + g \nabla \bar{\zeta} = 0 \quad (7)$$

in which  $\mathbf{F}$  is the bottom friction term,  $\mathbf{M}$  the horizontal mixing term and  $\mathbf{R}$  the radiation stress term. In the calculation, momentum flux due to the organized large vortexes (surface rollers) formed on the front face of breaking waves is taken into account as described in the next section.

### 3.2 Effect of large vortexes on nearshore circulation

Okayasu *et al.* (1990) proposed a 1-D (cross-shore) wave breaking model in which energy flux due to large vortexes formed near the wave crests is taken into account to evaluate the energy dissipation by wave breaking. In the model, the wave energy is once transferred to the energy of large vortexes before changing to the turbulence energy. The momentum flux by these large vortexes affects the balance of the mean water level, the setup. In the 2-DH field, the influence on the momentum balance should appear on the nearshore current field. In the present model, the effect of the momentum flux due to large vortexes are investigated by coupling with a numerical nearshore current model in the following manner.

It is assumed, as Okayasu *et al.* (1990) did in the breaking process, that the energy of waves,  $E_w$ , dissipates to turbulence through the energy of large vortexes,  $E_v$ . If the energy transfer from waves to large vortexes is irreversible, the energy transfer rate  $T_B$  can be expressed as

$$T_B = -\nabla \cdot (c_g E_w) \quad (8)$$

in which  $c_g E_w$  is the energy flux by wave motion. The organized large vortexes propagate with the wave crests. Since the phase velocity  $c$  is nearly equal to the group velocity  $c_g$  in the surf zone, the energy flux by the large vortexes can be approximated by  $E_v c_g$ , which satisfies the following equation:

$$\nabla \cdot (c_g E_v) = T_B - D_B. \quad (9)$$

where  $D_B$  is the dissipation rate per unit area through turbulence by wave breaking.

In the model of Okayasu *et al.*, energy transferred from wave motion to large vortexes at a certain location equally dissipates over the dissipation length,  $l_d$ , which is determined by the local water depth. As the large vortexes

move with the wave crests, the energy transfer process must be considered along the wave propagating direction. However, the energy of large vortexes in the present model is calculated by using  $x$ -components as follows with assumptions that the angle of the wave propagation is very small to the  $x$ -axis in the calculating grids and the change of the angle within the length  $l_d$  is also negligible:

$$T_{Bx} = -\frac{\partial c_{gx} E_w}{\partial x} \quad (10)$$

$$D_{Bx} = \int_{-\infty}^x t_d(x, x') dx' \quad (11)$$

$$\frac{\partial(c_{gx} E_w)}{\partial x} = T_{Bx} - D_{Bx} \quad (12)$$

where  $c_{gx}$  is the  $x$ -component of  $c_g$ .  $t_d$  is evaluated after Okayasu *et al.* (1990).

By assuming the internal velocity distribution in a vortex, the momentum flux due to organized large vortexes,  $S_v$ , can be evaluated from  $E_v$  as follows:

$$S_v = \frac{5}{3} E_v. \quad (13)$$

The total radiation stress including the additional radiation stress due to  $S_v$  in the horizontal plane can be described as

$$\left. \begin{aligned} S_{xx} &= S'_{xx} + S_v \cos^2 \alpha \\ S_{yy} &= S'_{yy} + S_v \sin^2 \alpha \\ S_{xy} &= S'_{xy} + \frac{1}{2} S_v \sin 2\alpha \end{aligned} \right\} \quad (14)$$

where  $S'_{xx}$ ,  $S'_{yy}$  and  $S'_{xy}$  are radiation stresses due to pure wave motion and  $\alpha$  the angle of wave propagation to the  $x$ -axis. The influence by the organized vortex motion to the wave motion is neglected here.

### 3.3 Vertical distribution of undertow

The vertical distribution of cross-shore current is evaluated by the undertow model proposed by Okayasu *et al.* (1990). It is assumed that the large vortexes are formed along the wave crest lines and move to the wave propagating direction in which the undertow is also considered.

In this model, the undertow profile is essentially determined by the energy dissipation rate at that location. The cross-shore component of nearshore current only shifts that fixed profile to the positive or negative direction. Therefore, even if the magnitude of cross-shore component of nearshore current is comparable to that of undertow, the interaction between them which should exist in nature is not considered. In the present cases, the nearshore current is not so strong. However, if it is large, such influence must be taken into account.

In the direction normal to the wave propagation direction, no depth dependent velocity component is given to the steady current obtained by the 2-DH nearshore current model.

#### 4. Comparisons with measured values

The calculated nearshore current is compared with the measured values for Case 1. Sinusoidal waves which have the wave period,  $T = 1.33$  s and the wave height,  $H = 5.5$  cm are given along  $x$ -axis at the offshore boundary of the computational domain. The shoreline boundary makes an angle of 10 degree to  $y$ -axis. The bottom slope is 1/20, the grid space is 8 cm for both of  $x$  and  $y$ -axes. The side boundaries are treated as perfect reflective straight boundaries.

##### 4.1 Comparisons of 2-DH current field

Figures 6 (a) and (b) show the 2-D nearshore current which are calculated by the conventional model and the present model, respectively. Arrows with broken lines show the measured steady current averaged over the total depth. For both figures, the small clockwise circulation which can be seen at the left upper corner of the measured field is not predicted by the models. This may be because of the straight side boundaries and unevenness of the bottom of the basin which could not be controlled enough at the measurements.

The calculated alongshore current in Fig. 6 (b) is larger than that in Fig. 6 (a). This shows that the increment of the momentum flux by wave breaking has a considerable effect on the nearshore circulation. It can be seen that the model with the momentum flux by large vortexes generally gives the better estimates.

Figures 7 (a) and (b) give comparisons between calculated and measured currents at 5 mm above the bottom. Figure 7 (a) is for the model without the large vortexes by wave breaking and Fig. 7 (b) is for the present model. Figure 7 (b) gives the better agreement. It can be said that the influences both by the large vortexes and the three dimensionality due to undertow should be considered for the estimation of the near bottom velocity.

##### 4.2 3-D distribution of nearshore current

The calculated and measured profiles of cross-shore current are shown in Fig. 8. The location is denoted by the measuring point shown in Fig. 1. The profiles are well estimated here, but the general agreement is strongly dependent on the accuracy of the 2-DH model.

Figure 9 gives the 3-D distribution of calculated and measured nearshore currents in the middle of the surf zone. The calculated values are only obtained below the wave trough level. However, it can be concluded that the present model estimates the 3-D distribution of nearshore current well in this region.

#### 5. Conclusions

(a) Calculation without momentum flux due to large vortexes

(b) Calculation with momentum flux due to large vortexes

Fig. 6 Measured and calculated depth averaged nearshore current (Case 1).

In the present study, laboratory experiments were performed on nearshore current induced by regular waves in a wave basin. Characteristics of three dimensional distribution of the nearshore current was investigated. A model was proposed in which momentum flux due to large vortexes formed on the front face of breaking waves was included to evaluate two dimensional current field in the basin. This 2-DH nearshore current model was expanded to a quasi 3-D model by coupling with an 1-DV undertow model which gave vertical distribution of cross-shore component of the nearshore current. The model was examined with the experimental results. The conclusions of the present study are as follows.

- 1) Direction and amplitude of the nearshore current significantly change along

(a) Calculation without momentum flux due to large vortexes

(b) Calculation with momentum flux due to large vortexes

Fig. 7 Measured and calculated near-bottom velocity (Case 1).

the vertical axis and have spiral distribution. It is necessary to consider the vertical distribution of nearshore current to evaluate near bottom velocity in the surf zone.

- 2) Profiles of cross-shore currents look similar to those observed in 2-DV wave flumes. Alongshore currents take almost constant values over the depth. Therefore, it may be possible to evaluate the 3-D distribution of nearshore currents by composing the cross-shore and alongshore currents which can be separately obtained.
- 3) Momentum flux by the large vortexes of breaking waves causes significant change on the nearshore current field. A 2-DH numerical model in which this additional momentum flux is taken into account improves the

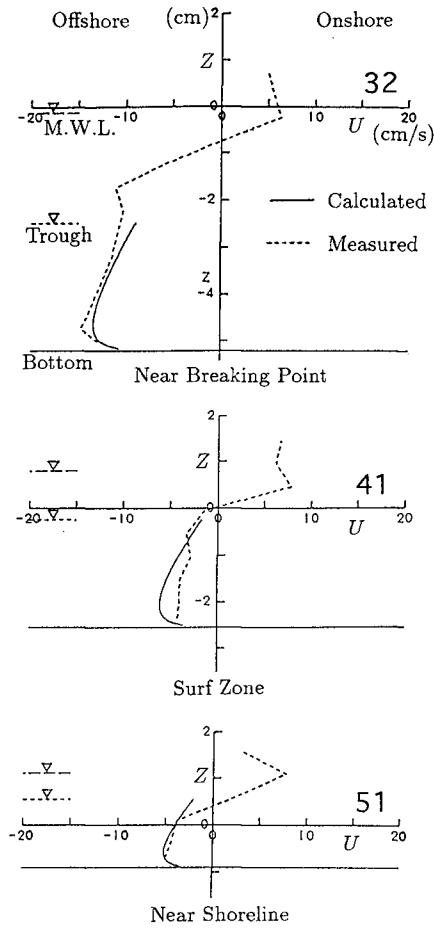

Fig. 8 Measured and calculated profiles of cross-shore current.

estimation of the nearshore current field.

- 4) A quasi 3-D nearshore current model presented in this paper can predict the 3-D distribution of nearshore current below the wave trough level.

## CHAPTER 179

### SUSPENDED SEDIMENT CAUSED BY WAVES AND CURRENTS

Masanobu Ono<sup>1)</sup>, Kyu Han Kim<sup>2)</sup>, Toru Sawaragi<sup>3)</sup> and  
Ichiro Deguchi<sup>4)</sup>

#### **Abstract**

A procedure to estimate vertical diffusion coefficient and reference concentration of time averaged suspended sediment concentration caused by waves and current are discussed based on experimental results obtained in a laboratory.

It is found that the non-dimensional diffusion coefficient normalized by the product of shear velocity  $u^*$  and the equivalent roughness  $k_s$ , is more closely related to the Shields' number when the shear velocity is evaluated by using the equivalent roughness where the effect of ripple geometry is taken into account. The reference concentration is not a unique function of the sediment Shields' number. Incident wave period has also influence on the reference concentration.

#### **Introduction**

Waves and currents around coastal structures and navigation channels have large spatial gradients that cause non-equilibrium sediment transport. In the analysis of topographic changes around these obstacles, we have to take into account the effect of non-equilibrium property of sediment transport. Especially, non-equilibrium property of suspended sediment rather than that of bed load plays very important role. Because it takes bed particles a little time to adopt themselves to the new surroundings and there is an instantaneous adjustment to equilibrium state in the very vicinity of the bottom.

To evaluate suspended sediment transport rate based on an advection-diffusion equation, we have to know both concentration and transporting velocity. The authors have already developed highly accurate numerical procedure for solving the advection-diffusion equation by applying a split-operator approach (Komatsu, et al., 1985). The accuracy of the numerical procedure deeply depends on a boundary

<sup>1)</sup>Research Assoc., <sup>3)</sup>Prof., and <sup>4)</sup>Assoc. Prof., Dept. of Civil Engineering, Osaka University, Yamada-oka, Suita-city, Osaka 565, Japan

<sup>2)</sup>Assis. Prof., Dept. of Civil Engineering, Kwan-Dong University, Korea

condition at the bottom (reference concentration or vertical sediment flux at the bottom) and diffusion coefficient. Until now, many studies have been conducted about suspended sediment due to waves in equilibrium state. Only a few have been carried out about the non-equilibrium suspended sediment concentration and the effect of current superposed on waves.

The aim of this study is to investigate the effect of current on suspended sediment, especially the reference concentration and the vertical diffusion coefficient of suspended sediment, through experiments.

### **Typical example of topographic change caused by non-equilibrium sediment transport**

First of all, we briefly examine the characteristics of non-equilibrium suspended sediment concentration measured in an experiment and an applicability of the numerical procedure for predicting non-equilibrium sediment concentration. Figure 1 shows the typical example of non-equilibrium suspended sediment transport caused by waves and current.

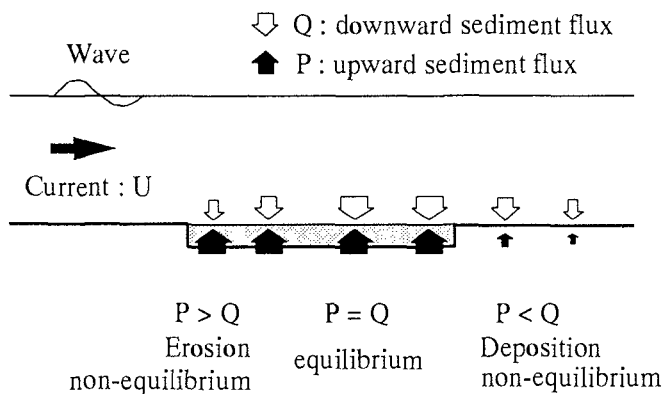

Fig. 1 Typical example of non-equilibrium suspended sediment transport

The waves and current are in the same direction on a horizontal bottom where a part of the bottom was replaced by a movable bed. Around the both sides of the movable bed, non-equilibrium suspended sediment transport takes place due to the unbalance of upward and downward sediment flux. Near the upstream end of the movable bed, only upward transport occurs and there is little settling flux and water depth increases. Near the downstream end of the movable bed, there is no upward sediment flux and only settling flux exists. It is needless to say that the water depth decreases there.

To predict non-equilibrium suspended sediment concentration numerically, the details of which I will mention later, we have to give reference concentration and diffusion coefficient. We should fundamentally use reference concentration and diffusion coefficient for suspended sediment under the non-equilibrium condition.

However, there are various degree of non-equilibrium property and it is difficult to obtain universal expression of reference concentration and diffusion coefficient under the non-equilibrium condition. Then we tentatively use those values obtained from the experiment under the equilibrium condition.

Figure 2 shows the comparisons of measured and calculated distribution of suspended sediment concentration. Fig.(a) is the non-equilibrium state near the upstream end of the movable bed. Fig.(b) is the results near the downstream end of the movable bed. x axis is taken positive in the direction of waves and currents from the edge of upward movable bed.

(a) Distribution of non-equilibrium sediment concentration near the upstream end of the movable bed

(b) Distribution of non-equilibrium sediment concentration near the downstream end of the movable bed.

Fig. 2 The comparisons of the numerical results and measured value of the vertical distribution of non-equilibrium suspended sediment concentration. (h=20cm, D=0.012cm, U=17cm/sec, T=1.25sec, H=6cm)

In spite of the usage of reference concentration and diffusion coefficient of equilibrium condition, the numerical results coincide with the measured results relatively well. So we can judge that we can predict non-equilibrium suspended

sediment concentration by applying the split operator approach provided that we can give the reference concentration and diffusion coefficient even under the equilibrium state.

### **Experiments for diffusion coefficient and reference concentration of equilibrium suspended sediment concentration**

Experiments were carried out in two two-dimensional wave tanks of different size. Length, depth and width of a large tank were 30m\*1.9m\*1.8m and those of a small tank were 30m\*0.9m\*0.7m. Two kinds of bed materials of mean diameter  $D=0.012\text{cm}$  and  $0.035\text{cm}$  were used to make a movable bottom of the length 3m (in a small tank) and 6m (in a large tank). All experiments were conducted on a horizontal bottom of water depth between 10cm to 40cm. The range of wave height was 5cm to 20cm and wave period was 1second to 2.5seconds. In the small tank experiments, we generated current in the direction of wave propagation. The relative magnitude of current and wave  $U/u_b$  varied from 0 to 0.9, where  $U$  is the depth averaged velocity of current and  $u_b$  is the water particle velocity at the bottom due to waves. Some parts of the experiments were conducted by generating irregular waves of Bretschneider-Mitsuyasu type frequency spectrum.

Suspended sediment concentration was measured by using an optical sensor and sampling of sediment laden water. Figure 3 shows an examples of vertical distributions of time averaged suspended sediment concentration measured at the crest and the trough of the ripple.

Fig. 3 Examples of vertical distributions of time averaged suspended sediment concentration measured at the crest and the trough of the ripple. ( $h=20\text{cm}$ ,  $D=0.012\text{cm}$ ,  $T=1.5\text{sec}$ ,  $H=6\text{cm}$ )

As has already been pointed out by many researchers, there is not any significant difference between the vertical distribution of time averaged concentration

measured on the crest and that measured at the trough and the time averaged concentration of suspended sediment became a log-linear vertical distribution. This implies that the diffusion coefficient of suspended sediment  $\kappa_z$  becomes constant through the depth.

In the figure, our methods to determine diffusion coefficient and reference concentration from experimental results are also illustrated. We evaluated diffusion coefficient from the vertical distribution of suspended sediment concentration and the relation shown by Eq.(1) that is derived from the usual one-dimensional diffusion equation in a steady state.

$$\kappa_z = -\frac{w_f z}{\log(c/C_0)} \quad (1)$$

where  $\kappa_z$  is the diffusion coefficient,  $w_f$  is the settling velocity.

The value of reference concentration  $C_0$  was determined from concentration at the crest level of ripples.

In the analyses of the diffusion coefficient and reference concentration, the experimental results obtained by other researchers that have already been published in journals and proceedings are also used together with our experimental results.

### Estimation of bottom shear stress and shear velocity under wave-current coexisting field

The diffusion coefficient and reference concentration are deeply related to a bottom shear stress or friction velocity under wave-current coexisting field. Equation (2) is our expression of the bottom shear stress  $\tau_{cw}(t)$  due to waves and current derived by solving a turbulent boundary layer equation (Deguchi, 1995) where the maximum shear velocity  $u_{cw}^*$  is given by Eq.(3).

$$\begin{aligned} \tau_{cw}(t) &= \tau_c + \tau_w(t) \\ &= \rho u_c^{*2} + \rho \hat{u}_{bp} \sqrt{\kappa \sigma z_0 u_{cw}^*} (R_{wp}^{\prime 2} + I_{wp}^{\prime 2})^{1/2} \cos(\sigma t - \psi') \quad (2) \\ \psi' &= \tan^{-1}(I_{wp}' / R_{wp}') \end{aligned}$$

$$\frac{u_{cw}^*}{u_b} = \frac{u_c^*}{u_b} + \sqrt{\kappa \left( \frac{z_0}{a_b} \right) \left( \frac{u_{cw}^*}{u_b} \right) (R_{wp}^{\prime 2} + I_{wp}^{\prime 2})^{1/2}} \quad (3)$$

$$R_{wp}' = 1 - \frac{\ker' q_0 \ker q_0 + \kei' q_0 \kei q_0}{(\ker q_0)^2 + (\kei q_0)^2}, \quad I_{wp}' = \frac{\ker' q_0 \kei q_0 + \kei' q_0 \ker q_0}{(\ker q_0)^2 + (\kei q_0)^2}$$

where  $q_0 = 2\{z_0 / (\kappa u_{cw}^* / \sigma)\}^{1/2}$ ,  $u_c^*$  is the bottom shear velocity due to current,  $z_0$  is the height of roughness element,  $\sigma$  is the angular frequency,  $\kappa$  is the Karman's constant and  $\ker$  and  $\kei$  are the real and the imaginary parts of the modified Bessel Functions of 2nd. kind,  $\ker'$  and  $\kei'$  are the derivatives of  $\ker$  and  $\kei$ , respectively.

The depth-averaged velocity  $U$  is calculated by integrating the steady velocity between  $z=z_0$  and  $h$ . From this relation, the bottom shear velocity  $u_c^*$  with respect to the mean current is expressed by Eq.(4)

$$\frac{u_c^*}{u_b} = \frac{1}{2} \left\{ -\left(\frac{\alpha_2}{\alpha_1}\right)\left(\frac{u_{cw}^*}{u_b}\right) + \sqrt{\left(\frac{\alpha_2}{\alpha_1}\right)^2\left(\frac{u_{cw}^*}{u_b}\right)^2 + 4\kappa\left(\frac{U}{u_b}\right)\left(\frac{u_{cw}^*}{u_b}\right)\frac{h-z_0}{\alpha_1}} \right\} \quad (4)$$

$$\alpha_1 = h \ln(\delta_w/z_0) - \delta_w + z_0 \quad \alpha_2 = h \ln(h/\delta_w) - h + \delta_w$$

where  $\delta_w$  is the thickness of wave boundary layer.

Figure 4 illustrates the comparison of measured and calculated distribution of mean current. Solid line is the calculated vertical distribution of mean current velocity without waves and the broken line is the calculated velocity profile in the case of wave and current coexisting field. Open and closed circles in the figure are the time averaged measured velocity in the cases of no waves and wave-current coexisting field.

Fig. 4 Vertical distribution of mean current velocity in the case of wave and current coexisting field. ( $h=20\text{cm}$ ,  $D=0.012\text{cm}$ , current,  $U=7.0\text{cm/sec}$ ; wave and current : $T=1.5\text{sec}$ ,  $H=6\text{cm}$ ,  $U=7.5\text{cm/sec}$ )

The velocity was measured by an electromagnetic current meter. It is found that the calculated velocity profile reproduce the measured profile. It is also found that the presence of waves increases the kinematic eddy viscosity that results in the steep velocity profile.

**Results and discussion**

**(1) Diffusion coefficient**

Here we examine the expression of diffusion coefficient based on the continuity equation of suspended sediment concentration that is expressed by Eq.(5).

$$\frac{\partial c}{\partial t} + \frac{\partial}{\partial x}(cu_s) + \frac{\partial}{\partial z}(cw_s) = 0 \quad (5)$$

We decompose the variables in Eq.(5) into steady part, wave and turbulent components and express each component by using an over bar(-), subscript p and (') as follows:

$$c = \bar{c} + c_p + c'$$

$$u_s = \bar{u}_s + u_{sp} + u_s' \quad (6)$$

$$w_s = -\bar{w}_f + w_{sp} + w_s'$$

Substituting these components into Eq.(5) and taking time average, we obtain Eq.(7)

$$\frac{\partial \bar{c}}{\partial t} + \frac{\partial}{\partial x}(\overline{cu_s}) - \frac{\partial}{\partial z}(\overline{cw_s}) = \frac{\partial}{\partial x} \left( \kappa_x \frac{\partial \bar{c}}{\partial x} \right) + \frac{\partial}{\partial z} \left( \kappa_z \frac{\partial \bar{c}}{\partial z} \right) \quad (7)$$

where the diffusion coefficient is expressed by Eqs.(8) and (9).

$$\kappa_x = -(\overline{c_p u_{sp}} + \overline{c' u_s'}) / \frac{\partial \bar{c}}{\partial x} \quad (8)$$

$$\kappa_z = -(\overline{c_p w_{sp}} + \overline{c' w_s'}) / \frac{\partial \bar{c}}{\partial z} \quad (9)$$

The first term of Eq.(7) is neglected in a steady state. We assume here that horizontal gradient of mean current velocity is negligibly small and all variables are uniform in x-direction. Then Eq.(5) becomes a usual one dimensional diffusion equation.

On the other hand, Schmidt number is usually defined as Eq.(10)

$$\text{Schmidt number} = \varepsilon_z / \kappa_z \quad (10)$$

where  $\varepsilon_z$  is the kinematic eddy viscosity. It is often assumed that the order of Schmidt number is unity. If we adopt this assumption, the diffusion coefficient can be expressed in the same way as the kinematic eddy viscosity. We used the following form of the kinematic eddy viscosity as shown in Eq.(11) to solve the boundary layer equation:

$$\varepsilon_z \approx \kappa u_{cw}^* l \quad (11)$$

where  $l$  is the length scale.

According to this expression, we assume that the velocity scale and length scales of the diffusion coefficient be the shear velocity  $u^*$  and equivalent roughness  $k_s$ . The value of  $u^*$  depends on the expression of  $k_s$ . In the following, we will examine the relation between non-dimensional diffusion coefficient and Shields' number calculated by using two different expression of  $k_s$ , Eq.(12) and (13). Eq. (13) is proposed by Nielsen(1992) includes the effect of ripple geometry.

$$l = k_s = 2.5D \quad (12)$$

or

$$k_s = 8\eta^2 / \lambda + 5\phi_D D \quad (13)$$

Fig.5 is the result obtained by using Eq.(12) where we assume that the value of  $k_s$  is a unique function of  $D$ .

The vertical axis is the diffusion coefficient normalized by dividing measured diffusion coefficient by the product of  $u^*$  and  $k_s$ . The horizontal axis is grain roughness Shields' number  $\phi_D$  defined by Eq.(14).

$$\phi_D = u^{*2} / (\sigma' gD) \tag{14}$$

where  $u^{*1}$  is the shear velocity calculated by using Eq.(12),  $\sigma'$  is the immersed grain density,  $g$  is the gravity acceleration. In this case plotted data scatters in a wide range.

Fig. 5 Relation between non-dimensional diffusion coefficient and grain roughness Shields' number

Fig.6 shows the relation between non-dimensional diffusion coefficient and ripple roughness Shields' number  $\phi_\eta$ .

The vertical axis is again the non-dimensional diffusion coefficient and the horizontal axis is the ripple roughness Shields' number  $\phi_\eta$  defined by Eq.(15).

$$\phi_\eta = u^{*2} / (\sigma' gD) \tag{15}$$

where  $u^*$  is the shear velocity calculated by using Eq.(13).

Fig. 6 Relation between non-dimensional diffusion coefficient and ripple roughness Shields' number

In this case, the scattering of data becomes small when compared with the data shown in Fig.(5). This implies that the length scale of the diffusion coefficient depends on vortex formation around ripples.

In the figure, the results obtained in the irregular wave experiments are also shown. The bottom shear velocity is calculated by using wave characteristics with respect to the rms wave height.

It was reported that there were no regular ripples on the bottom and sheet flow transport just begun in the case where ripple roughness Shields' number is greater than three. When  $\phi_\eta$  is larger than 0.7, the non-dimensional diffusion coefficient varies from 0.1 to 0.6. In the region where  $\phi_\eta$  is smaller than 0.7, non-dimensional diffusion coefficient increases a little with the increases in the value of  $U/u_b$ . In this region, waves have not large power to bring sediment into suspension and contribution of current to suspension becomes relatively large. However, it required further investigation about turbulence generated by ripples and diffusibility of suspended sediment to quantitatively estimate the value of diffusion coefficient.

**(2)Reference concentration**

We have already proposed semi-empirical expression for predicting reference concentration based on energetic consideration. The outline of the derivation of the expression for reference concentration are shown below.

We assumed that a part of the turbulent energy of vortex generated in the ripple trough is used to bring sediment into suspension. Tunstall and Inmen (1975) evaluated the kinematic energy of vortex formed in the trough of ripples that is expressed by Eq.(16) (see Fig. 7)

$$Ev = 2.26\rho(\Gamma/2\pi)^2 \tag{16}$$

where  $\Gamma$  is the strength of vortex circulation and is given by Eq.(17).

$$\Gamma / 2\pi = 0.39u_b\eta \tag{17}$$

The work  $W_v$  that is required to keep suspended sediment of the concentration  $C_0$  in the vortex whose diameter  $r_v$  is estimated by Eq.(18)

$$W_v = \rho C_0 \sigma' g w_f (T/2) r_v^2 \tag{18}$$

where  $r_v$  is expressed by the relation of Eq.(19).

$$r_v = 0.6\eta \tag{19}$$

Fig. 7 Vortex generated on the ripple

We further assume that a part of  $E_v$  is used to keep sediment into suspension.

$$W_v \propto E_v \tag{20}$$

This leads to the following expression for  $C_0$ .

$$C_0 = \beta u_b^2 / (\sigma' g w_f T) \tag{21}$$

where  $\beta$  is the empirical coefficient.

When we replace  $u_b$  by using a shear velocity, we can finally obtain the expression of the reference concentration

$$C_0 = 0.49(\alpha \phi_D)^{1.77} \tag{22}$$

$$\alpha = D / (f_w w_f T)$$

where  $f_w$  is Jonsson's friction factor and  $T$  is wave period.

Figure 8 shows the relation between measured reference concentration  $C_0$  and grain roughness Shields' parameter  $\phi_D$ .

Straight lines in Fig.8 are the reference concentrations calculated from Eq.(22) for the various values of  $\alpha$ . In the figure, expression of reference concentration proposed by Fredsøe et al.(1978) is also shown. Measured reference concentration increases with the increase of the value of  $\alpha$  as was predicted by Eq.(22).

Measured reference concentration caused by wave and current decreases with the increase in the value of  $U/u_b$ . A ripple geometry was deformed into asymmetry by the presence of current. Significant suspended sediment cloud was generated only once within one wave period from the steep side of the ripple. Consequently, time

averaged concentration at the bottom (reference concentration) decreases when current exists.

To figure out the reference concentration in the presence of current, further investigation is required about asymmetrical property of generated ripples and flow field on them.

Fig. 8. Relation between measured reference concentration  $C_0$  and grain roughness Shields' parameter  $\phi_D$ .

## **Conclusions**

Characteristics of the vertical diffusion coefficient and the reference concentration of time averaged suspended sediment concentration caused by waves and current are examined based on the experimental results obtained in laboratory.

It is found that the non-dimensional diffusion coefficient normalized by the product of the shear velocity and the roughness element is closely related to the ripple roughness Shields' number when the shear velocity is evaluated using the relative roughness that includes the effect of ripple geometry. When ripple roughness Shields' number is larger than 3, ripples lose their two-dimensional shape and the non-dimensional diffusion coefficient becomes small.

Current superimposed on waves deforms ripple shape into asymmetry and the reference concentration of suspended sediment caused by waves and current decreases with the increase in the relative magnitude of current  $U/wb$ . The reference concentration is not a unique function of the sediment Shields number and incident wave period also influence the reference concentration as was expected from the energetic consideration shown in the paper.

## CHAPTER 180

### Development of a Dune Erosion Model using SUPERTANK Data

Margery F. Overton<sup>1</sup>

John S. Fisher<sup>2</sup>

Kyu-Nam Hwang<sup>3</sup>

#### Abstract

A model predicting dune erosion under storm conditions has been developed using data from SUPERTANK laboratory experiments. In this model, the swash approach is applied with the basic assumption that the volume eroded from the dune is a function of the swash force acting on the dune. The swash force is characterized with swash parameters, specifically the swash height, the swash velocity and the swash period. For given storm conditions, the model predicts wave height variation across-shore, swash height variation on the beach face, swash velocity, swash period, swash forces and finally volume eroded at the dune. Predictions of swash parameters and dune erosion are compared with measurements from SUPERTANK laboratory experiments.

#### Introduction

A lot of effort has been made to develop a prediction model for dune erosion by storm events and the resulting beach profile. An extensive research program for the process of dune erosion due to wave impact was started by Fisher and Overton (1984). Their approach for the process of dune erosion is based on the interaction of the wave swash and the dune. This approach treats the dune erosion phenomenon as a time-dependent process in which a series of successive uprushes attack the dune face. Each individual uprush erodes a finite volume of sand which in turn is deposited on the eroding beach.

Currently, the most important achievement in the development of a dune erosion model due to wave impact is the experimental observation of the linear

relationship between swash force and dune erosion. This linear relationship has been confirmed through field measurements (Fisher et al., 1986) and laboratory experiments (Overton et al., 1988). Therefore, it is possible to predict the dune erosion from this relationship if the swash force is known for the given storm conditions. However, limited knowledge of swash parameters, which are identified as swash height, swash velocity and swash period, has discouraged the development of a quantitatively (or even qualitatively) reliable predictive model.

It is therefore highly instructive to understand qualitatively the hydrodynamics of the swash zone in terms of waves generated by storms outside the surf zone. These waves commonly serve as an input for the prediction of transformed waves in the surf zone. For this purpose, a set of experiments designed to simulate dune erosion under storm conditions at prototype scale was conducted in the large wave tank at the O. H. Hinsdale Wave Research Laboratory, Oregon State University as part of SUPERTANK Laboratory Data Collection Project. Through the analysis of SUPERTANK laboratory data for the swash parameters, an attempt is made in this study to produce useful information regarding hydrodynamics in the swash zone, and to develop a predictive model for dune erosion by wave impact.

Figure 1. Configuration of flume and location of wave gages.

**Laboratory Experiments**

The experiments were designed to simulate dune erosion under storm conditions at prototype scale. Flume configurations with the locations of wave gages are shown in Figure 1. A dune of 5 ft height was constructed with fine sands

of median grain sizes,  $d_{50}$ , of 0.23 mm. A vibrating compactor was used to consolidate the artificial dune. Sixteen resistance wave gages designed at OSU (Dibble and Sollitt, 1989) were used to obtain wave data across-shore and ten capacitance type wave gages were placed on the beach in front of the dune to collect swash data. The OSU data acquisition system sampled the wave gages at a rate of 16 Hz. The pre- and post-test beach and dune profile were surveyed. Additionally, dune position was documented by a 35 mm camera before, during and after each experiment. Each photograph of the dune included the profile of the dune face and a 2 ft by 2 ft standard grid to determine scale.

Thirteen experiments were successfully conducted. The design conditions of each test are given in Table 1. The design wave heights,  $H$ , ranged from 1.640 ft to 2.625 ft while the wave periods,  $T$ , ranged from 3 sec to 6 sec. The duration of the tests,  $T_d$ , ranged from 10 minutes to 30 minutes and the water level (WL) varied from 9.5 ft to 11.0 ft. The water level is defined as the distance from the original bottom of the flume to the still water surface.

Test #	$T_d$ (min)	$T$ (sec)	$H$ (ft)	WL (ft)	Test #	$T_d$ (min)	$T$ (sec)	$H$ (ft)	WL (ft)
1	10	3.0	2.625	9.5	8	20	3.0	2.297	10.5
2	20	3.0	2.625	9.5	9	20	3.0	2.297	10.5
3	30	4.5	2.625	9.5	10	20	4.5	2.297	10.5

7	30	3.0	1.640	9.5					

Table 1. List of Experimental Design Parameters.

Using a standard Fourier Transform, frequency domain analyses were performed on the SUPERTANK hydrodynamic data collected in the prebreaking and breaking zone. The wave parameters calculated from frequency domain analyses are *rms* and significant wave height. Both time domain analyses and frequency domain analyses were performed on the time history of the water surface variation in the swash zone. The swash parameters calculated from time domain analyses are mean value of swash height, swash peak height, swash velocity, swash period. The representative swash heights calculated from the power spectra are *rms* and significant swash height.

Typical features of an individual swash recorded during the experiment are given in Figure 2. Height of swash is defined as the difference between the background height and the height of the plateau before the start of the backwash. The velocity of the leading edge of the swash (or swash velocity,  $V_{sw}$ ) is determined by identifying the time at which the swash hits the first and the second probes on

the beach. The swash period  $T_{sw}$  of an individual swash is defined as the time between the initial swash hits.

Figure 2. Definition of swash parameters.

Survey data was used to determine the dune and beach profiles for each test. A polynomial smoothing method was applied to the survey data to obtain the depth data equally spaced in the horizontal direction. Specific volume eroded at the dune,  $Q_e$ , was determined from the before and after profiles of the dune face as recorded on 35 mm film, and checked with survey profiles of the beach and dune. In order to differentiate between beach erosion and dune erosion, the initial face of the dune was used to define the seaward extent of the dune.

An individual swash force acting on the dune is defined as

$$F_{swi} = \rho V_{swi}^2 H_{swi} \quad (1)$$

where  $\rho$  is the density of the water,  $H_{swi}$  is an individual swash height and  $V_{swi}$  is the swash velocity. While quantifying the force for an individual swash is possible using (1), it is not always possible to measure the amount eroded due to that loading. One possible way is to use the "summing-up" method by Overton et al. (1988), in which the summation of the force in a given interval of time versus the volume of eroded in the same time interval becomes the quantity evaluated. Each individual swash force was determined by (1) and summed up to obtain the total swash force,  $F_{sws}$ , for a given duration of time. Linearity between dune erosion and swash force was examined. Figure 3 shows the estimated data and the best linear

fit line with a  $R$ -squared value of 0.90. An apparent linear relationship exists between dune erosion and swash force.

Figure 3. Linearity of dune erosion as a function of swash force.

### Modeling of Swash Parameters

Swash parameters required for the prediction of dune erosion are the swash height, swash velocity, and swash period. In the current stage of modeling dune erosion due to wave impact, individual swashes (or waves) are not considered. Instead, statistically representative swash parameters (e.g., mean, rms and significant swash) are used to develop the prediction model.

A beach profile in the cross-shore direction is divided into three regions: the prebreaking zone, surf zone, and swash zone. In order to predict the swash height in the swash zone with a given condition in deep water, it is necessary to predict the cross-shore variation of wave height in the prebreaking and surf zone. Linear wave theory has been used to determine wave height across-shore from deep water to the initial break point of waves. Wave height transformation in the surf zone has been calculated by applying the breaking wave dissipation model by Thieke and Sobey (1990).

#### Modeling of Wave Height

Several models have been developed to predict surf zone wave height variation, based upon the conservation of energy equation (Battjes and Janssen; 1978, Dally, et al.; 1985, and Stive; 1984). The steady-state, depth-integrated

equation governing the energy balance for waves propagating directly towards shore is simply

$$\frac{\partial F}{\partial x} = -D \tag{2}$$

where  $F$  is the wave energy flux,  $x$  is the distance along the propagation path, and  $D$  is the rate of energy dissipation per unit plan area due to breaking.

Thieke and Sobey (1990) established a form of a predictive equation for the breaking wave dissipation as

$$D = f_{bw} \omega E \tag{3}$$

where  $f_{bw}$  is a dimensionless breaking wave dissipation coefficient,  $\omega$  is the spectral peak frequency and  $E$  is the wave energy. Adopting a simple direct partition estimator yields an expression for  $f_{bw}$ :

$$f_{bw} = \alpha \left( 1 + \frac{H_m^2}{H_{rms}^2} \right) \exp \left( - \frac{H_m^2}{H_{rms}^2} \right) \tag{4}$$

where the coefficient  $\alpha$  is of order  $1/\pi$  (or perhaps  $H_b/(\pi h)$ ),  $H_m$ , a local limiting wave height, is order of  $0.83h$  and  $H_{rms}$  is the root-mean-square wave height.

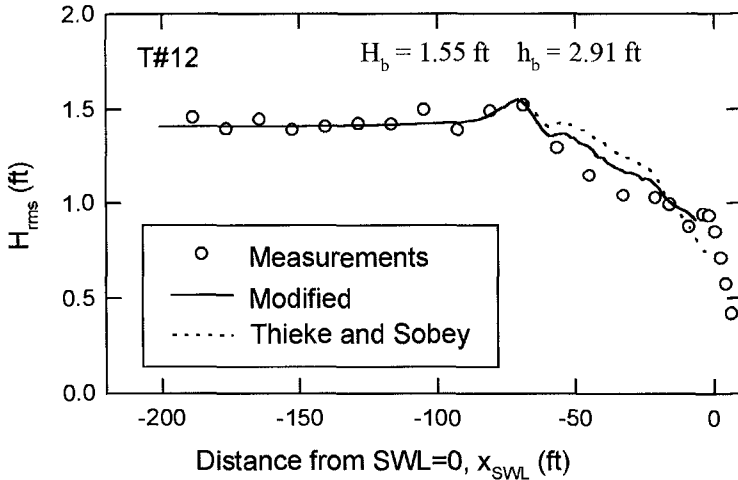

Figure 4. Measured and predicted wave height variation in the prebreaking and breaking zone.

Predictions by Thieke’s model for wave height variation in the surf zone are shown in Figure 4 as a dotted line. The measured  $rms$  wave height has been computed by  $2\sqrt{2}\sigma$  ( $\sigma$  is a spectral estimate of the standard deviation of the water surface). While the trend predicted by Thieke’s model is physically reasonable, the model underpredicts significantly the wave height near the swash zone. In order to obtain more accurate predictions of the wave height near the swash zone, a modification to Thieke’s model has been made to decrease the breaking wave

dissipation near the swash zone. Calibrating the predicted wave heights (by Thieke's model) to the measurements, the quantity of the coefficient  $\alpha$  in (4) was computed for all 13 tests. By scaling arguments it can be shown that Thieke's model is improved when the coefficient  $\alpha$  is related to  $H_b$ ,  $h_b$ , and  $H_o$  by the following expression :

$$\alpha = 0.8 \frac{H_o}{H_b} + \left( 23.06 \frac{H_b}{h_b} - 5.79 \right)^{-1} \frac{H_b}{H_o} \quad (5)$$

where  $H_b$ ,  $h_b$ , and  $H_o$  are the initial breaking wave height, the corresponding depth, and deepwater wave height, respectively. Note that prediction of wave height in the middle of the surf zone (beach profile section between -50 and -30 ft of xSWL) was sacrificed to obtain the best prediction near the swash region. It was necessary since the wave height predicted at the end of the surf zone is used as an initial value for the prediction of swash height in the swash zone. The model predictions with the modified coefficient  $\alpha$  are shown as a solid line in Figure 4. Near the swash zone, agreement between predicted and measured wave height is excellent.

Figure 5. Significant swash height variation on a beach face for Test #5.

#### Modeling of Swash Height

Since the swash phenomena in nature is so complicated, no attempt has been made to express, in a simple manner, the swash height variation on a beach face. Figure 5 shows the measured significant swash height ( $H_{sws}$ ) variation versus beach face elevation ( $y$ ) for Test #5. The elevation of beach face represents the positive elevation above the still water level (SWL) and the negative elevation below it. The most important experimental observation is that the swash height decreases linearly with beach face elevation, which is apparent in all 13 tests. This

linearity of the swash height on the beach face plays a key role in establishing a model for swash height variation.

Applying boundary conditions of i)  $H_{sws} = 0$  at  $y = y_{max}$  and ii)  $H_{sws} = H_{swso}$  at  $y = 0$ , this linearity yields a prediction model for the swash height :

$$1 - \frac{H_{sws}}{H_{swso}} = \frac{y}{y_{max}} \quad (6)$$

where  $H_{swso}$  represents a significant swash height at  $y=0$  and  $y_{max}$  is the beach face elevation where a significant swash height becomes zero.

Note that if  $y_{max}$  is known for a given deep water wave condition, (6) becomes an initial value problem and can be used directly to compute the swash height for a given elevation. In order to quantify  $y_{max}$  for each test, the left side of (6) was computed with the measured swash height and plotted with  $y$ . The best linear fit lines (crossing the origin) to the measured data allow determination of  $y_{max}$  for each test. The significant swash height at  $y=0$ ,  $H_{swso}$ , for each test has been determined by the interpolation of the measured swash height.

Figure 6. Comparison of  $y_{max}$  with the mean runup height by Mase et al. (1984).

Since  $y_{max}$  can be physically interpreted as a representative runup height for irregular waves climbing on the beach, it would be valuable to examine  $y_{max}$  with respect to the existing models for runup heights. Mean run-up heights for each test were computed from the runup height equation proposed by Mase and Iwagaki (1984). The comparisons between  $y_{max}$  and the computed runup heights are shown in Figure 6. It is noticed that  $y_{max}$  appears to matches roughly with mean runup heights  $R_m$  by Mase et. al (1984), as  $y_{max}$  deviate by at most a factor of 2 from  $R_m$ .

The swash height variation in the swash zone was predicted using (6). The comparisons between the measured and the predicted swash height variation in the swash zone for Test # 5 are shown in Figure 7. The solid line represents the predicted swash height variation using  $R_m$  computed from runup equation by Mase et. al (1984).

Figure 7. Comparison between predicted and measured swash heights for Test #5.

#### Swash Velocity Model

In order to develop a prediction model for swash velocity, it is assumed that it is possible to idealize the water particle as a solid particle which retains its identity. Thus, a particle of swash height,  $H_{sw}$ , is considered to move up and down the beachface as a solid particle would. If the normally incident waves are considered, a force balance implies

$$m \frac{dV_{sw}}{dt} = -mg \sin \theta - \frac{f}{8} \frac{m}{H_{sw}} |V_{sw}| V_{sw} \quad (7)$$

where  $m$  is a mass of the water particle,  $V_{sw}$  is a swash velocity,  $g$  is the gravitational acceleration,  $\theta$  is the beach slope and  $f$  is a friction factor. For simplicity, a frictionless planar beach is assumed. Eliminating common terms and applying initial conditions of  $V_{sw} = V_{sw0}$  at  $x=y=0$  (where  $x$  is the distance in the water particle translation direction from the location of  $SWL=0$ ), simple integration of this equation yields

$$V_{sw} = \sqrt{2g(y_{\max} - y)} \quad (8)$$

where  $y$  is the elevation positive from SWL.

The swash velocity for each test has been predicted from (8). The comparisons between the measured and the predicted velocity are given in Figure 8. Note that the predicted velocity matches well with the measured significant velocity.

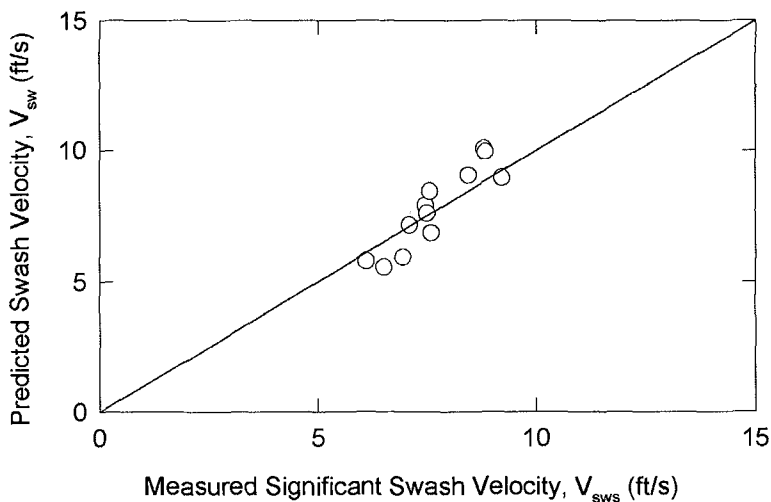

Figure 8. Comparison of the predicted swash velocity to the measured swash velocity.

#### Modeling of Swash Period

In order to develop a prediction model for swash period, a possible simple method is to apply a model which predicts the probability of wave overtopping for offshore structures. Since the probability of runup can be expressed as  $T_{sw0}/T_{sw}$ , the runup prediction model becomes

$$T_{sw} = T_{sw0} \exp \left[ \left( \frac{y}{R_{rms}} \right)^2 \right] \quad (9)$$

assuming that the runup height on natural beaches has a Rayleigh distribution. In (9),  $T_{sw0}$ , and  $T_{sw}$  are the initial swash period at  $y=0$ , and the swash period at any elevation of  $y$ , respectively, and  $R_{rms}$  is the *rms* value of runup height.

Note that in order to apply (9) for the prediction of swash period, it is necessary to express both  $T_{sw0}$  and  $R_{rms}$  in terms of known deepwater wave conditions or swash variables. It is possible to express  $T_{sw0}$  with  $T_o$  using the laboratory data by Mase and Iwagaki (1984). They indicated that the ratio of the number of deep water waves to the number of runup waves,  $N/N_o$  (or  $T_o/T_{sw0}$ ), varies nonlinearly with the deep water wave condition, expressed as the Iribarren number. Fitting a second order polynomial to their experimental data yields

$$\alpha = \frac{T_o}{T_{sw0}} = 0.69 \xi^{(0.42 - 0.08 \ln \xi)} \quad (10)$$

where  $T_o$  is the deepwater wave height and  $\xi$  is the Iribarren number (or surf similarity parameter). From the analysis of the laboratory measurements, Hwang (1995) also gives a linear relationship between  $R_{rms}$  and  $y_{max}$  :

$$y_{max} = 1.65 R_{rms} \quad (11)$$

From (10) and (11), the swash period is given as

$$T_{sw} = \frac{T_o}{\alpha} \exp \left[ \left( \frac{1.65 y}{y_{max}} \right)^2 \right] \quad (12)$$

A comparison between the predictions and the measurements for the swash period is shown in Figure 9. The predictions for the swash period are in good agreement with the measurements.

Figure 9. Comparison of the predicted to the measured swash period.

#### Modeling of Swash Force

Previously, the summing-up method has been used to relate the swash force to the volume eroded at the dune. However, applying this method directly to the prediction model for dune erosion is computationally intensive since each swash has to be computed and summed up for each time step (usually 20 minutes). An alternative approach is to use statistically representative swash parameters, such as mean, *rms* and significant values. As an example, a swash force by mean parameters may be defined as

$$F_{swm} = \rho \frac{T_d}{T_{swm}} V_{swm}^2 H_{swm} \quad (13)$$

where subscript  $m$  represent the mean values of the swash height, the swash velocity, and the swash period. Note that the ratio  $T_d/T_{swm}$  in (13), which represents the number of swash hit at the dune face, is introduced to scale the total swash force for a given duration of test.

Figure 10. Relationship between  $F_{swm}$  and  $F_{sw}$ .

The swash force by mean parameters was computed with the measured mean swash parameters for each test. Comparisons of the swash force using (13) with total swash force ( $F_{sw}$ ) obtained by summing-up method are shown in Figure 10. It is interesting to notice that swash force defined by mean swash parameters is linearly related with the swash force by the summing-up method. The linear relationship obtained by the best fit line is

$$F_{swm} = 0.69F_{sw} \quad (14)$$

### Predictive Model for Dune Erosion

The dune erosion model predicts the volume eroded at the dune due to wave impact. The model consists of an input data routine, prebreaking zone wave height routine, surf zone wave height routine, swash zone hydrodynamics routine, dune erosion routine, and an output routine. As initial input data, the model requires the deepwater wave conditions and initial beach and dune profile data. Linear wave theory is used to determine the wave height from deepwater or a specified water depth offshore to the breaking point. Shoreward of the breaking

point, a modified form of Sobey's prediction model is used to compute the wave height. The swash zone hydrodynamics routine computes each statistically representative swash height, swash velocity, and swash period. Once the swash parameters are determined, the corresponding swash force is computed and used to calculate the volume eroded at the dune.

In order to determine the wave heights across-shore, the model uses an explicit solution scheme in which quantities known at a specific grid point are used to determine corresponding quantities at the next grid point. Propagation of individual waves is not described by the model.

Figure 11. Comparison of predicted dune erosion to the measured dune erosion using predicted  $R_m$  from runup equation.

Dune erosion was simulated for all 13 tests using the data from SUPERTANK laboratory experiments. Data used for each prediction were the significant wave height at Gage #14, peak spectral wave period at Gage #14, mean wave period at Gage #14, beach and dune profile, test duration, and dune toe location. Assuming that  $y_{max}$  can be replaced by runup height, the runup height equation proposed by Mase and Iwagaki (1984) was used for the computation of  $y_{max}$  which was required for the prediction of all swash parameters (swash height, swash velocity and swash period). Comparisons of model predicted dune erosions with measurements for all 13 tests are shown in Figure 11. It is easily noticed that the prediction of dune erosion by model is not successful. The model predictions deviate by as much as a factor of 4 from the measured dune erosion.

Since the runup height equation has been used for the prediction of  $y_{max}$ , a slight modification to the model was made to check the effect of the runup height on the prediction of dune erosion. Instead of calculating the runup height and using it as  $y_{max}$ , the measured  $y_{max}$  was used for the simulation of swash force and dune erosion for each test. Predictions of dune erosion using the measured  $y_{max}$  are shown in Figure 12 and compared with the measured dune erosion. It is obvious that predictions are much improved, as the model predictions deviate by at most a factor of 2 from the measured values.

Figure 12. Comparison of predicted dune erosion to the measured dune erosion using the measured  $y_{max}$ .

Clearly,  $y_{max}$  is a significant factor and plays an important role in the prediction of dune erosion. Consequently, it is concluded that quantitatively good prediction for dune erosion can be obtained by improving the ability of prediction of  $y_{max}$ .

## Conclusions

A simulation model has been developed using SUPERTANK experimental data to predict dune erosion due to wave impact. The analysis of the laboratory data confirmed an apparent linearity between swash force and dune erosion. With a modification of Sobey's model, predictions of wave height variation in the surf zone were improved, especially near the swash zone. Swash height, swash velocity, and swash period predicted by the model agreed well with the laboratory measurements. However, the model predicted dune erosion with limited success. An uncertainty in the value of  $y_{max}$  is the primary cause which led to the failure of

the prediction of dune erosion. The results indicate that improvement in the dune erosion model will depend upon more reliable estimates of runup height.

## CHAPTER 181

### Numerical Modelling of Three-Dimensional Wave-Driven Currents in the Surf-Zone

Philippe Péchon<sup>1</sup> and Charles Teisson<sup>1</sup>

#### Abstract

The numerical modelling of time-averaged three-dimensional currents due to breaking waves is presented. The basic equations and the closures are described. The driving terms in the momentum equations are the radiation stresses derived from "organised" velocity of waves and the roller contribution. The model is validated on measurements collected in a flume. The application to the case of a rectilinear beach with oblique incidence wave displays a helicoidal circulation. In the situation of a detached breakwater with a normal wave, depth-integrated currents show two large symmetrical cells in the lee of the structure whereas streamlines near the bottom converge spirally toward the centres of the eddies.

#### Introduction

Longshore currents induced by breaking waves are often assumed to be responsible for changes in the shoreline plan-shape on extend of some kilometres (Horikawa 1988 , Southgate 1987 , Péchon, 1982). However the action of cross-shore currents have to be taken into account for the prediction of detailed bathymetry variations, for instance when appraising the impact nearby coastal structures (Hansen and Svendsen 1984 , Okayasu 1989).

A compound system is being developed to simulate wave, current and sediment transport patterns for the design of coastal projects. The module for time-averaged wave-driven 3D-currents is presented ; the physical concept and applications are described. In this article we focus on the wave-driven currents due to breaking phenomena exclusively. The wave is assumed to be regular and the wave pattern is supposed to be known here, resulting from the wave module of the system.

## The Three-Dimensional current model

### The equations

For sake of clarity the Navier-Stokes equations are considered in the case of a two-dimensional motion in a flume :

$$\begin{aligned}\frac{\partial u}{\partial t} + \frac{\partial u^2}{\partial x} + \frac{\partial uw}{\partial z} &= -\frac{1}{\rho} \frac{\partial p}{\partial x} \\ \frac{\partial w}{\partial t} + \frac{\partial uw}{\partial x} + \frac{\partial w^2}{\partial z} &= -\frac{1}{\rho} \frac{\partial p}{\partial z} \\ \frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} &= 0\end{aligned}$$

where  $u$ ,  $w$  are the horizontal and vertical components of the instantaneous velocity,  $p$  is the pressure. The viscous molecular terms are neglected in the highly turbulent environment.

As it is proposed in Svendsen and Lorentz (1989), the velocity is separated into three contributions : a mean current ( $U$ ,  $W$ ), a purely periodic current ( $u_w$ ,  $w_w$ ) corresponding to wave motion, and turbulent fluctuations ( $u'$ ,  $w'$ ). The time-averaged equations reads, the overbar indicating averaged quantities :

$$\begin{aligned}\frac{\partial U}{\partial t} + \frac{\partial U^2}{\partial x} + \frac{\partial UW}{\partial z} + \frac{\partial \overline{u_w^2}}{\partial x} + \frac{\partial \overline{u_w w_w}}{\partial z} &= -\frac{1}{\rho} \frac{\partial \bar{p}}{\partial x} - \frac{\partial \overline{u'^2}}{\partial x} - \frac{\partial \overline{u' w'}}{\partial z} \\ \frac{\partial U}{\partial x} + \frac{\partial W}{\partial z} &= 0\end{aligned}$$

and the vertical momentum equation leads to (Stive and Wind, 1982) :

$$\bar{p} = \rho g (\bar{\xi} - z) - \rho \overline{w'^2} - \rho \overline{w_w'^2}$$

where  $\bar{\xi}$  is the free surface level. By substitution in the momentum equation :

$$\frac{\partial U}{\partial t} + \frac{\partial U^2}{\partial x} + \frac{\partial UW}{\partial z} + \frac{\partial (\overline{u_w^2 - w_w^2})}{\partial x} + \frac{\partial \overline{u_w w_w}}{\partial z} = -\frac{1}{\rho} \frac{\partial \bar{\xi}}{\partial x} - \frac{\partial (\overline{u'^2 - w'^2})}{\partial x} - \frac{\partial \overline{u' w'}}{\partial z}$$

The derivative  $\partial (\overline{u_w^2 - w_w^2}) / \partial x$  is the wave radiation stress. The term  $\partial \overline{u_w w_w} / \partial z$  created by waves is also considered whereas the term  $\partial (\overline{u'^2 - w'^2}) / \partial x$  is neglected except in the roller. Dropping the time derivative term, the 2 DV equations reduce to :

$$\begin{aligned}\frac{\partial U^2}{\partial x} + \frac{\partial UW}{\partial z} + \frac{\partial (\overline{u_w^2 - w_w^2})}{\partial x} + \frac{\partial \overline{u_w w_w}}{\partial z} &= -g \frac{\partial \bar{\xi}}{\partial x} - \frac{\partial \overline{u' w'}}{\partial z} + t \\ \frac{\partial U}{\partial x} + \frac{\partial W}{\partial z} &= 0\end{aligned}$$

where  $t$  is the contribution of the roller of the breaking waves,  $t = -\partial \overline{u'^2} / \partial x$ .

**The closures**

The terms which depends on the periodic current of breaking waves are expressed in function of the input wave characteristics and the energy dissipation (Longuet-Higgins 1970, Dingemans et al 1986, Deigaard and Fredsoe 1989) :

$$\frac{\partial (\overline{u_w^2 - w_w^2})}{\partial x} = \frac{1}{\rho h} D$$

with  $D$  : energy dissipation  
 $C$  : wave celerity  
 $h$  : mean water depth

$$\frac{\partial \overline{u_w w_w}}{\partial z} = \frac{1}{2\rho h} D$$

It is noted that the contribution of non-breaking waves in the expression of the radiation stress is not included here. Apart from the roller, Reynolds stresses are given using the eddy viscosity concept :

$$\overline{u'w'} = -v_t \frac{\partial U}{\partial z}$$

A uniform turbulence viscosity distribution is adopted, following Svendsen et al (1987) :

$$v_t = Mh \left(\frac{D}{\rho}\right)^{1/3} \text{ The constant } M \text{ is taken to be } 0.03$$

The contribution of the roller in the term  $-\overline{\partial u'^2} / \partial x$  can be expressed by approximating the horizontal velocity profile as suggested by Svendsen (1984) :

Fig.1 Vertical profile of velocity in the surfzone

He proposed :  $\bar{e} = 0.9 H^2 / L$  with  $H$  : wave height  
 $L$  : wave length

$$\text{So we obtain } \int_{z_1}^{z_2} u'^2 dz = C^2 \bar{e} = 0.9 \frac{C^2}{L} H^2$$

The time-averaged entrainment force  $t$  due to the roller is specified uniform from the wave trough to the mean water level, on a layer thickness of  $H/2$ . It follows :

$$t = - \frac{2}{H} \frac{\partial}{\partial x} \left( 0.9 \frac{C^2 H^2}{L} \right) = - \frac{1.8}{HT} \frac{\partial C H^2}{\partial x}$$

Introducing the flux of energy  $E_f$ , in shallow water :

$$E_f = \frac{1}{8} \rho g H^2 C_g \approx \frac{1}{8} \rho g H^2 C$$

$$t = \frac{14}{\rho g} \frac{D}{HT} \quad \text{where } D = -\frac{\partial E_f}{\partial x} \text{ energy dissipation}$$

$T$  : wave period

### *The exchanges of momentum and mass through the surface*

In quasi-3D models (Wind and Stive 1987, Sanchez-Arcilla et al. 1992) the equations are generally solved from the bottom to the trough level and a shear stress is specified at the boundaries. Moreover the mass flux above trough level is given as an input.

Since the present model is fully three-dimensional, the time-averaged equations have to be solved from the bottom to the mean water level. The total flux of momentum due to breaking waves which is introduced in the computational domain is specified through the radiation stresses distributed over the water column and the force  $t$  on a thickness  $H/2$ . It follows that it is not relevant to impose any additional shear stress at the surface in this model ; so the shear stress is set to zero.

Fig. 2 Vertical distribution of forces

In nature the wave-induced mass-flux above the mean water level is not nil in and out the surf-zone and the horizontal variation of this quantity induce also mass flux through the time-average surface. Walstra et al (1994) take this effect into account in a 2DV model by adding a term in the continuity equation and they allow vertical velocities through the surface boundary. Since this type of circulation occurs for breaking as well as non-breaking waves, we chosen here to solve it separately with a Boussinesq type model which reproduces it automatically. This part is not presented in this paper.

## **Applications**

### *Cross-shore currents in a flume*

The numerical model has been applied with standard parameters to the case of a flume which had been investigated on a physical model (Buhr-Hansen and Svendsen, 1986).

The bottom profile is parabolic (fig. 3). The generated wave is regular with a period of 2.0 s and at the breaking point the wave height is 0.17 m and the still water depth is 0.20 m. The wave field specified in the numerical model is the one measured on the experimental set-up.

The computed undertow added to the mean currents due to wave motion has been compared to measurements collected in the surf-zone. In this case the currents due to wave motion (non-breaking contribution) is estimated with a non-linear wave theory (analytical solution of Serre equations) depending on the wave height. The numerical results were in good agreement with measured velocities.

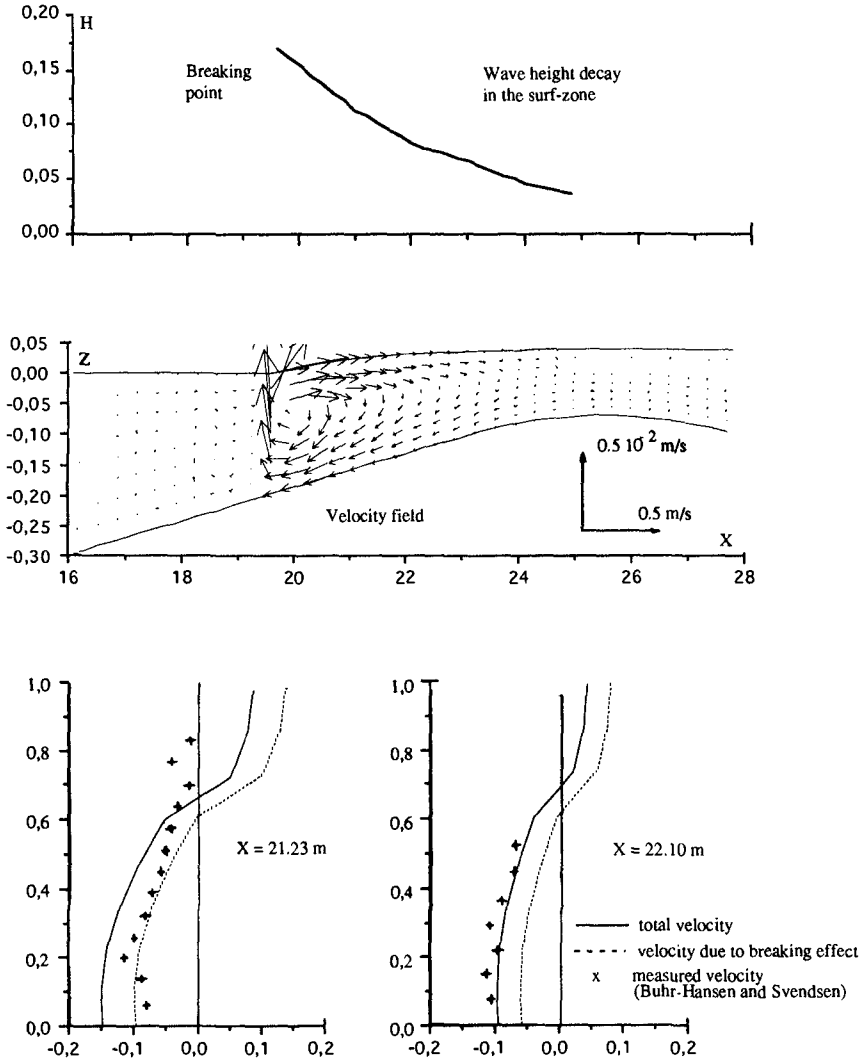

Fig. 3 Wave-driven currents in a flume  
Comparison with measurements

**Three-dimensional circulation along a rectilinear beach.**

The studied domain had a constant bottom slope equal to  $2/100$ , the off-shore water depth was 9.0 meters. The wave height at the deeper limit was 2.0 m, the period 8.0 s and the incidence  $25^\circ$  (fig. 4). All boundaries were closed in this test, with a slipping condition.

Wave propagation was computed with a simple refraction model and the decay in the surf-zone was deduced from the energy equation where the energy dissipation in the bore is assumed to be similar to an hydraulic jump one.

In this situation an helicoidal wave-driven flow occurs in the domain (fig. 5) and the velocity near the bottom is oriented offshore. This qualitative result is confirmed by field observations (Ingle 1966) but measurements are not available for validation. Moreover it is pointed out that the "non-breaking contribution" of wave motion is not included in this result.

Fig. 4 Wave propagation along a rectilinear coast

Fig. 5 Currents induced by breaking waves - Particle tracks

### *Currents near a the detached breakwater*

The bottom slope is constant and equal to 3/100. The still water depth is 5.0 meters at the off-shore frontier and it is 0.5 meter at the shoreline. The off-shore boundary is open while the three others are closed and combined with slipping conditions. The detached breakwater is 100 meters long and it is located at 100 meters from the shoreline. The still water depth at the toe of the structure is 3.5 meters.

The wave at the open boundary is 2.5 meters high, its period is 8.0 seconds and its incidence is normal to the coast. For this preliminary simulation the wave field is schematised, the wave-driven terms are nil in the lee of the structure and the wave height decay elsewhere in the surf-zone is given by a formula. Of course this wave field is very crude but the aim of this test is to display vertical heterogeneity of the velocity pattern. A more accurate computation of the wave field is planned in the future.

The depth-averaged flow pattern shows two large and symmetrical eddies behind the breakwater (fig.6). The maximum velocity reaches 1.5 m/s. In order to see three-dimensional effects, particles tracks computed with the bidimensional velocity fields near the bed, near the surface and with depth-averaged one are also visualised on figure 6. The streamlines near the bottom are oriented toward the centre of the eddy while the others describe large cells. This difference between the depth-averaged and the near-bed flow patterns is crucial for sediment transport modelling.

### **Conclusion**

The computation of time-averaged wave-driven currents in the surf-zone for schematical 3D cases gives satisfying qualitative results. The model have already been compared successfully with measurements collected in experimental flumes but additional validation tests are needed in three-dimensional situations.

The wave pattern in practical studies can be complex and its prediction requires a sophisticated wave model, especially if hydrodynamic results are used to determine sediment transport. It can be provided by bidimensional infragravity wave models (based on Boussinesq or Serre equations) which also simulate wave height decay in the surf-zone (Hamm et al. 1993, Karambas et al. 1992, Schäffer et al. 1992). The total velocity in the surf zone is the combination of the three-dimensional currents induced by breaking waves and the instantaneous wave velocity. However some care have to be taken in the summation of the two velocity fields because the current resulting from the wave model also partly includes the breaking effect. So the component which comes from breaking in the wave model must be subtract before adding the two velocity fields.

## Sediment Transport in Various Time Scales

Zbigniew PRUSZAK & Ryszard B. ZEIDLER<sup>1</sup>

### Abstract

Some basic sediment movement characteristics such as critical velocities of motion, bed load layer thickness, as well as local and overall sediment transport have been measured in field at Lubiatowo, Poland.

The survey was carried out in a multi-bar (4–5 bars) Polish coastal zone with the medium grain diameter  $D_{50}$  from 0.2 to 0.25 mm. Irydium glass grains tracer, close in size to the natural sand, has been used. The investigations embodied 8 hydrodynamical situations in various climates of waves and currents.

For oblique wave incidence it has been found that local intensity of longshore sediment transport can reach 40–100 kg/(m h) under storm conditions, strongly dependent on local bed topography. The overall sediment transport rate across the entire surf zone can exceed  $7 \cdot 10^{-3}$  m<sup>3</sup>/s under storm conditions. For weak wave motion the bed surface layer of sediment transport has a thickness of several grain diameters, while it may be even 4–6 cm thick during storms. Vertical distributions of sediment concentration beneath of bed surface are identified. Transport rates are related to the product of squared breaker height and longshore velocity. Annual time series of sediment transport are presented.

### 1 INTRODUCTION

Coastal zone is characterized by intensive sediment transport and considerable morphodynamic changes. Because of its importance as an interface of the atmosphere, the sea, the land and engineering structures, its dynamics should be well understood.

Some primary quantities describing sediment transport in the coastal zone include critical speeds of incipient movement, thickness of the bedload layer and velocity distribution within this layer, and the resulting bedload transport rate.

For the purposes of this study, we distinguish short-term changes (hours, at most days) mainly associated with a single storm, meso-scale ones (weeks or months) and long-term changes (years or decades). In this paper, emphasis is placed on the first and third scale.

Field studies provide a reliable background for understanding coastal processes and drawing conclusions on various estimates of sediment transport quantities. Numerical models are still inaccurate and require validation based on field measurements.

This paper describes results of recent field studies, thus expanding the earlier investigations by Pruszk & Zeidler (1992). The sediment transport experiments were carried out at the IBW PAN Coastal Research Facility off Lubiato.

## 2 FIELD DATABASE

The Coastal Research Facility (CRF) at Lubiato is situated on the southern Baltic beach and shore of transitional nature, which experiences neither accretion nor erosion in long time scales. The short-term variability of shore processes is evidenced by cyclic occurrence of erosion bays or accretion cusps every 30 years (Pruszk 1993).

The shore at Lubiato is dissipative mild slope one with conspicuous four bars about 110, 190, 370 and 650 m from shoreline (Fig. 1). An ephemeral unstable bar is sometimes visible close to the shoreline (some 30–40 m away). The median grain diameter  $D_{50}$  varies between 0.2 and 0.25 mm. The littoral drift is substantial since the net annual wave momentum flux is oriented obliquely to the shoreline. Wave breaking in the Lubiato surf zone is pronounced at a few locations, identified with underwater bars. During average storms the significant wave reaches the height  $H_s \approx 2\text{--}3.5$  m with the period  $T$  from 5 to 7 s at the seaward boundary on the depth of 7 m. As a result of the subsequent transformation, the mean wave height falls to 1–1.5 m on the depth of 2–3 m (about the second and third bars) while the mean wave period becomes 4–5 s.

Along with parameters of wind, waves, currents and other hydrologic factors, topographic features have been measured at Lubiato since 1983 on a 2.7-km beach and nearshore zone extending some 800 m from shoreline. The beach profiles have been arranged every 100 m, and have been recorded every four weeks. Subaqueous profiles extending to about 100 m from shoreline have been measured systematically every four weeks since 1991.

In our tracer studies of sediment transport we have been using iridium glass grains close in size to the natural sand. The half-life period of the radioisotope is 74.4 days.

The 1993–1994 field campaign included *inter alia* the disposal of six tracer batches at six different locations of the Lubiato coastal zone, as depicted in Figure 1. The disposal points were chosen so as to monitor the three characteristic subareas of the coastal zone shown in Figure 1, as already pursued by Pruszk & Zeidler (1992).

The sediment transport investigations were carried out in two series in autumn 1993 and spring 1994. Simultaneous measurements of waves, currents and wind were conducted during the radioisotopic studies. The measurements were continued regularly every three hours at two locations of the surf zone denoted by D1 and D2 in Figure 1. An exemplary record of wind, waves and currents along and across shore is given in Figure 2.

Ninety four core samples 40 cm in length were taken from the sea bed. The samples originate from various areas coupled with the movement of tracer plumes. The samples were analysed in 2-cm layers by the use of a very sensitive scanner. Both location and intensity of the radiotracer in plumes was measured from a boat with a special monitoring and recording apparatus. Examples of

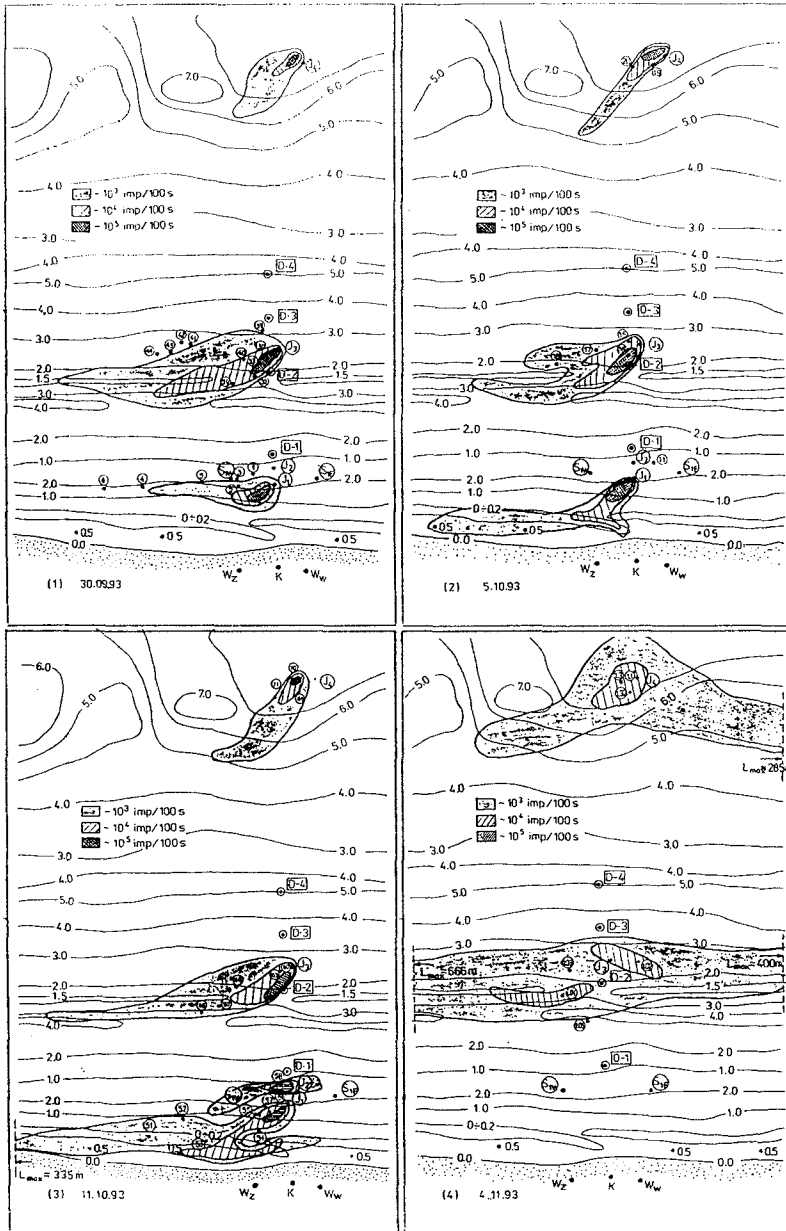

Figure 3. Radiotracer plumes at CRF Lubiato, fall 1993; (52) etc. tracer sampling location, (imp) - pulse; (I) - injection spot; (S) - sand trap

subsequent locations of 3-4 plumes out of total six are shown in Figure 3 for the first measurement series of autumn 1993.

Simultaneously with the observations and measurements of the radio-tracer, measured at two locations of the surf zone were suspended loads up to 2 m above sea bed, at stations denoted by  $S_{1E}$ ,  $S_{1W}$  and  $S_4$ , as in Figure 3. The suspended load was measured separately for longshore and cross-shore directions. Tracer grains were identified in every sample.

### 3 SEDIMENT MOVEMENT FIELD STUDY

#### 3.1 Critical velocities

Two primary thresholds of sediment transport can be identified under waves and currents:

- incipient motion of single grains  $V_{cr}^{(1)}$
- critical velocity of bulk transport identified with the movement of the bed-load layer having the thickness  $a$ , i.e.  $V_{cr}^{(2)}$ .

From recent investigations, including those by Pruszek & Zeidler (1988), it is known that the motion of single grains having the median diameter  $D_{50}=0.10-0.25$  mm and the density  $\rho_s=2650$  kg/m<sup>3</sup> occurs at  $V_{cr}^{(1)} \approx 8-12$  cm/s. In exceptional cases coupled with local bathymetry and random disturbances of wave motion, those velocities can be smaller than 8 cm/s or greater than 12 cm/s, up to 20 cm/s.

The other sediment transport threshold lies at  $V_{cr}^{(2)} \approx 40-50$  cm/s or even 20 cm/s for fine particles having  $D_{50}=0.08-0.10$  mm. The bulk motion of sediment grains can obviously occur in layers of different thickness. It can be assumed that the incipient motion occurs in a thin layer of a few sand grains when the flow velocity reaches about 30-40 cm/s, and it is fully developed at currents reaching 50-70 cm/s, when the moving layer of sediment is considerably thicker.

#### 3.2 Sand grain speed

Once the critical velocity  $V_{cr}^{(1)}$  is surpassed, the sediment is likely to move in a very thin surficial layer. The grain speed at the mud line  $v_{ml}$  will depend on the intensity of water flow. As the latter increases, the grain speed will also change but the sediment at the mud line will move much faster than that beneath. The bulk motion of sediment in the deeper layers is much slower than the mud line velocity  $v_{ml}$  as illustrated in Figure 4. Sediment grains participating in the mud line motion are much more mobile and their speeds exceed that of the deeper layers by a factor of two and more.

The discrimination of the bed surface layer at mud line and bulk transport of sediment grains is schematized on the right hand side of Figure 4. The experimental relationships between the mean grain speed and water velocity for the two distinct sediment layers are shown on the left hand of the same drawing. In our analysis of sediment transport characteristics in the above layers, we have followed the distinction of three characteristic subareas of the coastal zone having different hydrodynamic and morphodynamic conditions, as identified at CRF Lubiatowo by Pruszek & Zeidler (1992), cf. Figure 1.

Figure 4. Mean longshore sediment speed versus velocity of longshore current

The mean longshore mud line velocity of sediment grains within the entire active cross-shore profile is given as follows:

$$\overline{v_{ml}} = 0.0013 \overline{V_i} \tag{3.1}$$

while the bulk transport velocity reads

$$\overline{v_{bt}} = 0.0003 \overline{V_i} \tag{3.2}$$

where  $\overline{V_i}$  = longshore current velocity averaged over respective subarea ( $i = 1, 2$  or  $3$ ).

The sediment transport velocities obtained for the Polish conditions of the South Baltic are smaller by an order of magnitude than those given by Kraus et al. (1982). The discrepancy indicates that such relationships are regional and depend on local parameters. It should be noted that the grain speed given by Kraus et al. (1982) is presented as a function of the longshore current velocity averaged across the entire shore profile, not a specific subarea, as in our analysis.

### 3.3 Bedload layer thickness

Examples of a few vertical distributions of the radiotracer in the three subareas of motion are presented in Figure 5. Zero denotes that the radioactivity of the selected layer was smaller than 600 pulses/100 s, that is below the natural background of sea bed activity. Upon thorough analysis of the obtained distributions one can identify stratification of sediment transport in sea bed. Major concentrations of the radiotracer occur at the mud line and seldom deeper than about

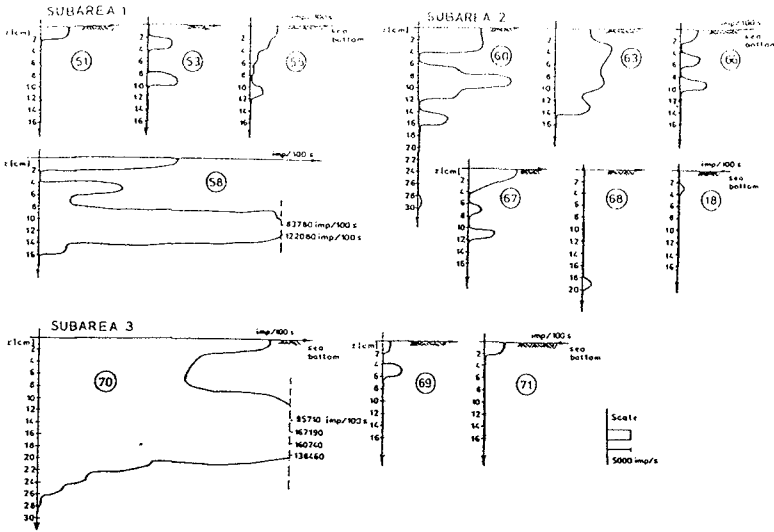

Figure 5. Vertical distributions of bedload as judged from the 1993 tracer studies at CRF Lubiatowo; (imp) pulses.

15 cm below mud line. It was only in one case that tracer concentration of 640 pulses/100 s was detected 30 cm below bed surface (sample No. 70). In that case the sample was taken in the immediate vicinity of the disposal point, and the initial radioactivity was rather high. The results and the analysis suggest that it is only during storms that the bed surface layer of moving sediment exceeds 2 cm in thickness, while the latter can be assessed at a few or several grain diameters for average waves, whereas the maximum thickness of 4-6 cm could be expected at very severe storms. The thickness of the bedload layer also depends on local bed topography. Considerable differentiation of the thickness is noted about an underwater bar crest.

It should be emphasized that the values given above refer to the active bedload layer in which all moving sediment grains are in motion at the same time and move in the same direction.

From our recent and earlier investigations it can be concluded that the bedload layer thickness corresponds to the estimate given by Kraus et al. (1982):

$$a = 0.027 H_b \tag{3.3}$$

in which  $H_b$  = breaker height at a depth of 2-3 m (about the second bar).

### 3.4 Sediment transport

#### 3.4.1 Cross-shore transport

Sediment transport rate can be computed by the following formula:

$$q = q_{ml} + q_{bt} = (\rho_s - \rho)(\bar{v}_{ml}a_{ml} + \bar{v}_{bt}a_{bt}) \tag{3.4}$$

Figure 6. Cross-shore distribution of cross-shore sediment transport rate in five classes of waves.

where  $\bar{v}$  denotes time-averaged sand speed (either along or across shore), the index *ml* denotes mud line and *bt* stands for bulk motion.

The most intensive net cross-shore transport occurs at the second and third bar in the cases of average or high waves, as illustrated in Figure 6. The sediment transport rate at crests of those bars can reach 25 kg/(m h) during storm phases. Local maxima can even amount to 35-40 kg/(m h). The transport rate decreases in the seaward direction and for the average wave conditions it is about 5-10 kg/(m h) in subarea 3. For the predominant oblique wave incidence it can be assumed that a local ratio of cross-shore transport rate to the longshore one oscillates about 1:3-1:4. However, it should be noted that the above mean values can deviate substantially from instantaneous rates because of the high variability of sediment transport.

It has been found that the cross-shore transport in the troughs between bars is negligible, so that practically all grains move about bar crests. The resulting movement of sediment in the cross-shore direction can be coupled with the displacement of bar crests. The latter can be both landward and seaward.

### 3.4.2 Longshore sand transport (local)

The longshore sediment transport depends on the nature and intensity of waves and currents and on local topography. In local terms, the sediment transport is a function of sand grain speed  $v$  and the thickness of transport layer  $a$ , and can be approximated as follows:

The cross-shore variability of the longshore sediment transport rate computed by Equation 3.4 is illustrated in Figure 7 for a few selected wave-current cases. The most intensive longshore sediment transport appears to occur at sec-

Figure 7. Cross-shore distribution of longshore sediment transport rate in five classes of waves.

ond and third bars, and decreases both seawards and shorewards. It is worthwhile to note the existence of a relatively high sediment transport in between bars, particularly in areas of the prevailing wave breaking, in our case again about second and third bars. This finding is not widespread, and contrary arguments on the low importance of the troughs in the overall longshore sediment transport have often been raised. In many instances, particularly at smaller wave incidence angles, the longshore sediment transport rate between bars is of the same order as that on bars. In some situations the troughs did not permit cross-shore spreading of sediment, especially if they were deeper and steeper.

By and large, the longshore sediment transport under weak waves (breaking between second bar and shoreline, with breaker height much lower than 1 m) occurs only in subarea 1, and its rate does not exceed 5-8 kg/(m h). As the wave height increases (wave breaking between third bar and shoreline, mean breaker height slightly below 1 m), the longshore sediment transport occurs in a wider surf zone and extends up to the fifth bar at maximum. Depending on local longshore current and wave parameters, the longshore sediment transport rate may vary between 5-30 kg/(m h) in subareas 1 and 2 and 0-15 kg/(m h) in subarea 3.

The longshore sediment transport rate increases substantially under storm conditions, when waves break far away from shoreline and at many locations across the surf zone, with the mean breaker height above 1 m. Hence in subarea 1 the local magnitude of  $q_s$  reaches 100 kg/(m h) and varies from 40 to 100 kg/(m h) about bars. In subarea 2 the longshore transport is similar, but often even exceeds the earlier magnitude. In subarea 3 the transport rate decreases considerably, and falls to 30 kg/(m h) about the fifth bar. Further seawards one observes transport rates falling to 5-10 kg/(m h) at depths of 6-7 m. Obviously, the transport rate can be higher under extreme storms. In general, the longshore transport rate during storms is a few times greater than at average waves.

Figure 8. Dependence of littoral drift rate on the product  $H_b^2 \bar{V}$ .

3.4.3 Littoral drift rate

From our experiments and the analysis of the obtained data it follows that the littoral drift rate i.e. the overall longshore transport rate across the coastal zone (assumed 950 m wide for the purposes of this study) reaches  $3-7 \cdot 10^{-3} \text{ m}^3/\text{s}$  under conditions of intensive waves approaching the shore at angles from 10 to  $30^\circ$ . Of course, local unit transport rates vary across the shore, as pointed out above. If waves are very high and conspicuously oblique then the transport rate can exceed  $7 \cdot 10^{-3} \text{ m}^3/\text{s}$ , while at lower waves under our conditions the transport rate varied from  $0.35 \cdot 10^{-3}$  to  $2.3 \cdot 10^{-3} \text{ m}^3/\text{s}$ .

The overall longshore transport rate can be presented as a function of  $H_b^2 \cdot \bar{V}$ , where  $\bar{V}$  represents the mean longshore velocity of water. It appears that the relationships between the sediment transport rate and that quantity (Fig. 8) can be approximated by two straight lines. For smaller values of the quantity  $H_b^2 \cdot \bar{V} = 0-0.15$ , thus small and medium waves, the function  $q = f(H_b^2 \cdot \bar{V})$  reads:

$$q_l = K(H_b^2 \cdot \bar{V}) = 0.023(H_b^2 \bar{V}) \tag{3.5}$$

For higher waves and storms, with  $H_b^2 \cdot \bar{V} > 0.15$  the function is as follows:

$$q_l = q_0 + K_1(H_b^2 \cdot \bar{V} - 0.15) = 0.00225 + 0.008(H_b^2 \bar{V}) \tag{3.6}$$

It seems that the above relationships can be used for the forecast of the overall longshore transport rate in short time scales.

Upon comparison of the results obtained under this study and our earlier investigations (Pruszek & Zeidler 1992), versus other sources of data, one can say that the formula must be site specific. From investigations by Drapeau et al.

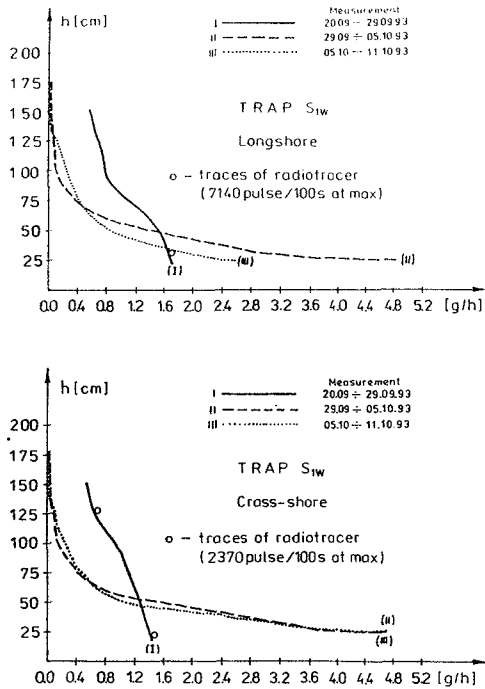

Figure 9. Vertical distributions of sediment concentration in sand traps; trap slots aligned along shore (upper) and across shore (lower).

(1990) carried out in the North Atlantic in the presence of strong tides it follows that the proportionality factor  $K$  in Equation 3.5 is 0.278. On the other hand, Kraus et al. (1982), under mesotidal conditions, obtained  $K=0.024$ . It may be seen that this proportionality factor coincides with ours up to  $H_b^2 \cdot \bar{V}=0.15$ , while a conspicuous deviation is noted for higher values of that parameter, i.e. higher waves.

### 3.4.4 Suspended sediment

The concentration of suspended sediment is higher in subarea 1, with predominant wave breaking and high turbulence, than in subarea 3. Under storm conditions (cf. Fig. 2), the sediment was picked up from the sea bed in subarea 1 to reach the free surface. In cases of less intensive waves (situations II and III) the sediment was kept in suspension up to 1-1.2 m above bed, that is middepth at the investigated location (Fig. 9).

The radioactive tracer was disposed of some forty metres away from sand traps. It was found at different elevations up to 1.3 m above bottom. This indicates that the radiotracer moves not only as bedload but also in suspension, quite high above sea bed. The proportions between bedload and suspended load are difficult to define as they depend on many factors such as intensity of wave mo-

Figure 10. Annual time series of wind (upper) and the resulting littoral drift rate (lower).

tion, circulation and currents, local topography and sediment properties. From different observations and estimates, including those with radiotracers, it can be assessed that about 70-80% of total transport belongs to bedload under weak wave conditions, or even about 100% in exceptional cases. On the other hand, storm conditions bring about intensive suspension, and bedload and suspended load become of the same order, whilst suspended load can clearly predominate under very intensive storm conditions. The latter structure is typical of the surf zone, about wave breaking line and on small depths. On greater depths bedload seems to prevail. It should also be added that suspension is usually preceded by bedload.

### 3.4.5 Mesoscale sediment transport

From many observations and investigations it appears that major effects of the longshore sediment transport are noted in time scales counted in days, months and even years. Our field studies provide a certain insight into the yearly structure of the longshore sediment transport. If one averages over a day the causative sequence of events bringing about the sediment transport (wind, waves, currents, sediment transport), then one obtains a picture permitting conclusions on the yearly structure of sediment transport rates. This is illustrated below and in Figure 10 where both wind input and the resulting sediment transport itself are shown. It should be recollected that only causes, not sediment transport itself are measured in the yearly series. The sediment transport rate was computed from Equations 3.5-3.6.

From our computations and the distributions shown in Figure 10 it appears that although daily transport rates can exceed  $1000 m^3/day$  (across the entire surf zone), the resulting mean net monthly rate is only  $4000 m^3/month$ , corresponding

to the mean annual rate of 50000 m<sup>3</sup>. It is also visible that the yearly course of sediment transport is stepwise: some 25% of the mean monthly amount of sediment transported can be derived from a single storm.

#### 4 CLOSING REMARKS

Upon comparison of our results with other investigations and findings it can be concluded that many sediment transport formulae are site specific, or depend on particular environmental properties embedded in those formulae. Hence from studies by Drapeau et al. (1990) for the North Atlantic and strong tidal effects it appears that the parameter  $K$  is 0.278. Kraus et al. (1982) conclude that  $K$  is 0.024 for a nontidal shore with a single bar. On the other hand, from our measurements for the Polish Baltic conditions the coefficient is identical with Kraus's if the characteristic quantity  $H_b^2 \bar{V} < 0.15$  predominates, while it deviates considerably if that quantity is above 0.15, i.e. for intensive wave conditions. The observations, measurements and conclusions drawn for the two ranges of  $H_b^2 \bar{V}$  above and below 0.15 add an interesting message to the linkage between sediment transport rate and its causes.

No matter how approximate and incomplete, the annual distribution of sediment transport rate shown in Figure 10 for the Polish Baltic conditions contains an important information on the stepwise nature of sediment transport. The estimates shown can be regarded as typical of the southern Baltic.

It is worthwhile to emphasize our finding that the sediment transport between bars can be quite conspicuous particularly at locations of the most frequent wave breaking (our bars II and III) This is contrary to the widespread belief that the sediment transport in troughs is much less important than that on bar crests.

#### Abstract

Two series of experiments were carried out in the Large Oscillating Water Tunnel of Delft Hydraulics, which was recently extended with a recirculation flow system. Combined wave-current boundary layer flows were studied with a mobile sand bed in the sheet flow regime. Detailed intra-wave concentration and velocity measurements were carried out and revealed a three-layer system, i.e. a pick-up layer, a sheet flow layer and a suspension layer. In the suspension layer time-lag effects of the sediment concentration led to sediment fluxes in upstream direction. The suspended sediment was more confined to the near-bed region than according to diffusion theories, most likely due to turbulence damping. The horizontal time-dependent and net sediment fluxes were concentrated in the sheet flow and pick-up layer. Measured net sediment transport rates could be described as a linear relation with the third-order velocity moment  $\langle U^3 \rangle$  near the bed.

### Introduction

The understanding of the physical processes near the sea bed in combined wave-current flows plays an essential role in the description of the sediment transport in the coastal zone. A general lack of basic knowledge on the interaction between waves, currents, sediments and the sea bed in the combined wave-current boundary layer exists. The validity of various mathematical models can hardly be assessed due to the low number of measurements available, especially at prototype scale (Horikawa, 1988). The present study is focused on the boundary layer processes in the case of high bed-shear stress conditions (Shields parameter  $> 0.6$ ). In this regime the sea bed is plane with sheet flow and suspension as the dominating transport modes. A research programme is concentrated around the Large Oscillating Water Tunnel of Delft Hydraulics in which the wave-induced near bed oscillatory flow and sediment transport phenomena can be simulated in the scale of nature (1:1). The present research is a follow-up of earlier work by Ribberink and Al-Salem (1994) and Al-Salem (1993) whom collected a large series of data on the sediment dynamics in mainly asymmetric oscillatory flow conditions. They verified and developed several mathematical models for the description of the observed phenomena. In 1992 the tunnel was extended with a recirculation flow system (see Figure 1) which enabled the superposition of net currents to the oscillatory flow. During a first experimental programme the behaviour of the tunnel flow and the various bedform regimes were investigated in regular wave-current conditions (Ramadan, 1993).

Figure 1 The Large Oscillating Water Tunnel with its recirculation system

In the present paper the main results of two experiment series (series C and E) are presented. Series C was focused on the influence a net current superimposed on asymmetric (second-order Stokes) waves on time-averaged quantities such as the suspended load and the net sediment transport rate.

During series E detailed time-dependent (intra-wave) measurements were carried out in the suspension layer and the sheet flow layer in a number of sinusoidal wave/net current combinations.

The main objectives of the experiments were: i) to increase the understanding of the wave-current boundary layer processes in the case of mobile sandy beds, and ii) to obtain a number of datasets to be used for the development of sediment transport models.

For the complete experimental results, reference is made to the original data reports, i.e. Ramadan (1993), Ribberink (1994) and Katopodi et al (1994).

### Experimental set-up and programme

The Large Oscillating Water Tunnel (LOWT) has the shape of a vertical U-tube with a long rectangular horizontal section and two cylindrical risers on either end. The desired oscillatory water motion inside the test section is imposed by a steel piston in one of the risers. The other riser is open to the atmosphere. The test section is 14 m long, 1.1 m high and 0.3 m wide. A 0.3 m thick sand bed can be brought into the test section, leaving 0.8 m free for the oscillatory flow above the bed. The range of the oscillatory velocity amplitudes is 0.2-1.8 m/s and the range of periods is 4-15 s. The LOWT, extended with a recirculation flow system for the generation of a steady current, is shown in Figure 1. The maximum capacity of the two pumps is 100 l/s and 20 l/s. The maximum superimposed mean current velocity in the test section is 0.5 m/s. The two risers are used as sand traps, moreover the recirculation system is provided with a 12 m long pipe sand trap.

As a follow-up of previous research with asymmetric (second-order Stokes) waves (Ribberink and Al-Salem, 1994), a series of experiments was conducted (series C) with asymmetric waves combined with following and opposing currents (following current = a positive current in the direction of the crest half wave cycle motion). In total 10 conditions were investigated. Series C was mainly aimed at the measurement of time-averaged concentrations and sediment transport rates. Each condition was repeated 3-5 times. Each test started with a flat horizontal sand bed. Table 1 gives the main flow characteristics of series C, i.e. the pump discharge  $Q$ , the mean current velocity in the test section  $\langle U \rangle$ , the root mean square velocity of the oscillatory flow part  $\tilde{U}_{rms}$  and the wave period  $T$ . Sand was used with characteristics  $D_{10} = 0.15$  mm,  $D_{50} = 0.21$  mm and  $D_{90} = 0.32$  mm.

Detailed time-dependent measurements were carried out during series E for four sinusoidal wave/net current conditions (see Table 2). From E1 to E4 the oscillatory velocity amplitude  $\hat{U}$  decreases but the net current velocity increases in such a way that the third-order velocity moment  $\langle U^3 \rangle$  of the horizontal oscillatory flow (above

the wave boundary layer) is approximately constant. This choice was based on the linear relation between the net transport rate and  $\langle U^3 \rangle$  as found by Al-Salem (1993) for only (asymmetric) waves. During 5 series of experiments different measuring techniques were used and 115 tests (tunnel runs) were carried out using the same sand as for series C.

Table 2 Experimental conditions series E (sheet flow)

Suspended sediment concentrations in the range of 0.1 - 50 g/l were measured with a transverse suction technique for time-averaged values (series C, E) and an optical infra-red light extinction technique OPCON for time-dependent values (series E).

The large (time-dependent) concentrations in the sheet flow layer ( 100-1600 g/l) were measured with an electro-resistance technique CCM (series E).

Time-dependent velocities were measured with a 2 component forward-scatter laser-doppler flow meter LDFM for mainly clear water (series C, E), an electro-magnetic flow meter EMF in the suspension layer (series C,E) and a high-speed video technique HSV for grain velocities in the sheet flow layer (series E). Net sediment transport rates were measured with a mass-conservation technique using sand trap volumes and measured bed-level changes. For more detailed information about the techniques, reference is made to Katopodi et al (1994).

Suspended sediment

During the 10 series C and 4 series E conditions totally 81 time-averaged concentration profiles were measured with the transverse suction technique in the layer between 1-1.5 cm and 25 cm above the bed.

In Figure 2 all suspended concentration profiles of series E are plotted on a log-log x-y scale. The straight best-fit lines imply a vertical distribution according to the following power-law:

$$\frac{\langle C(z) \rangle}{C_a} = \left( \frac{z_a}{z} \right)^\alpha$$

where  $C_a$  is a reference concentration at the level  $z_a$  and the power  $\alpha$  is a concentration decay parameter.

Despite the different combinations of waves and currents during series E, the best-fit lines are almost parallel, indicating that the power  $\alpha$  is almost constant ( $1.9 < \alpha < 2.4$ ).

Also for the series C experiments the power-law distribution (1) fitted well with the measurements. The concentration decay parameter  $\alpha$  varied between  $1.6 < \alpha < 2.3$ .

Figure 2 Time-averaged concentration profiles of suspended sediment, series E

Ribberink and Al-Salem (1994) found the same power-law form for a large number of waves-only cases in the sheet flow regime (same sand). The power  $\alpha$  was almost constant ( $\alpha \approx 2.1$ ) in a wide velocity range ( $U_{rms} = 0.3-1.2$  m/s). Figure 3 shows power  $\alpha$  as a function of the maximum Shields number  $\theta'_{max}$  (maximum value during the wave cycle) for the 'waves alone' measurements and the new 'waves + currents' measurements.

$\theta'_{max}$  is computed on the basis of the maximum bed-shear stress during the wave cycle according to:

$$\theta'_{max} = \frac{\tau'_{b,max}}{(\rho_s - \rho) g D_{50}}$$

Herein  $\tau'_{b,max} = 0.5 \rho f_{cw} (\langle U \rangle + \hat{U})^2$  with the combined wave-current friction factor according to the theory of Jonsson (1966) using  $k_s = D_{50}$  as bed roughness height. The measured values of  $\langle U \rangle$  at  $z = 10$  cm above the bed are used as input for the formulation.

Figure 3 shows that all measured values of  $\alpha$  (for waves alone and waves + currents) scatter around  $\alpha = 2$ , showing no relation with the Shields number.

Figure 3 Concentration decay parameter  $\alpha$  vs. maximum Shields number

In the case of a time-invariant sediment mixing or diffusion coefficient increasing linearly with distance above the bed, diffusion models for suspended sediment generate a similar power-law distribution for the time-averaged concentration (see Ribberink and Al-Salem, 1994). However, the models generally lead to decreasing values of  $\alpha$  (= Rouse number) for increasing Shields numbers. This is due to an increasing turbulent or sediment mixing coefficient with increasing bed-shear stress. The full line in Figure 3 represents the theoretical solution of the Rouse number. It is shown that the measured concentration decay is always greater than the theoretical decay and shows no relation with the Shields number.

Apparently, the suspended sediment is more confined to the near-bed region than the theory predicts. Moreover, the result indicates the increasing importance of turbulence damping above the mobile bed (sheet flow layer) for increasing Shields numbers.

The measured time-dependent behaviour of the suspended sediment concentrations during experiment E1 is shown in Figure 4. In the lower part ensemble-averaged concentrations measured with OPCON are shown during one wave cycle at three elevations near the bed. The upper part shows the time-dependent horizontal velocity (at  $z = 20$  cm) as well as the vertical position of the piston driving the oscillatory flow.

It can be observed that the concentration exhibits two peaks that roughly coincide with the maximum downstream and upstream velocities. Due to the asymmetry of the flow (downstream velocity amplitude  $>$  upstream velocity amplitude) the two peaks are not of equal magnitude. Two other generally smaller concentration peaks occur near the moments of flow reversal. Similar peaks were observed by Al-Salem (1993) for waves only. A possible explanation for their existence may be found in turbulence generation due to shear instabilities in the bottom boundary layer (see Foster et al, 1994).

Figure 4 Time-dependent suspended sediment concentrations, E1

With increasing distance above the bed the concentration decays rapidly and the concentration maxima occur at a later moment (time lag effect). At higher elevations

the maximum concentrations occur even after the next flow reversal, indicating history effects from a previous half wave cycle.

From E1 to E4 the flow asymmetry increases due to an increasing net current velocity/oscillatory velocity ratio (see Table 2). Simultaneously, the concentration measurements show an increasing history effect of the 'downstream' half cycle during the 'upstream' half cycle. Moreover, the concentration peaks at flow reversal become less dominant. For more detailed results, see Katapodi et al (1994a).

### Sheet flow

At lower elevations near the bed ( $z < 1$  cm) the sheet flow layer is entered with very large sediment concentrations (100-1600 g/l). Time-dependent concentration measurements were carried out with the CCM. The CCM was brought into the test section from below through the sand bed in order to minimize possible flow disturbance. The lower part of Figure 5 shows ensemble-averaged concentrations (E1) at various elevations around  $z = 0$ . The elevation  $z = 0$  is defined as the mean bed elevation before/after the experiment (without sediment motion). The upper part of Figure 5 shows the time-dependent velocity at  $z = 20$  cm.

Figure 5 Time-dependent concentrations in the sheet flow layer, E1

Two layers with different behaviour can clearly be observed, i.e. a pick-up layer with minimum concentrations in phase with maximum velocities and a sheet flow layer with maximum concentrations in phase with maximum velocities. In the pick-up layer two phases occur during each wave cycle with no sediment motion and maximum sand concentration (settled sand, near  $U = 0$ ), which are both followed by a phase with lower concentrations due to the vertical pick-up of grains. In the sheet flow layer ( $z > 0$ ) the phase behaviour is opposite, reflecting the exchange of sand with the pick-up layer (see also Al-Salem, 1993). Near the moments of flow reversal large concentration peaks with a short duration occur, which are probably related with similar peaks as observed in the suspension layer somewhat later in time (see Figure 4). In general, all series E experiments show very small phase shifts between the concentration peaks at different elevations, indicating that time-lag effects are of minor importance in these near-bed layers.

The concentrations in the sheet flow layer do not show the asymmetry of the two half cycles as observed in the suspension layer of E1. However, for E2...E4 the increasing flow asymmetry effect becomes also visible in the sheet flow layer.

Figure 6 shows the complete time-averaged concentration profile on a log-linear x-y scale for all layers of E1 obtained from the CCM, OPCON and SUCTION measurements. The approximate positions of the suspension layer ( $C < 100$  g/l), the sheet flow layer ( $C > 100$  g/l) and the pick-up layer are indicated.

In the upward direction the concentration profile shows the transition from a convex shape (pick-up layer) to a concave shape (suspension layer), reflecting the presence of different physical mechanisms of the mixing process.

Figure 6 Time-averaged concentration profile of E1, a three-layer system

A high-speed video camera (500 frames/s) was focused through the glass side wall 2 cm inside the test section on a vertical image of 1.55 x 2.15 cm parallel to the oscillatory flow direction. A time counter on the video image was synchronized with

the piston motion. Two different particle tracking techniques were applied to measure the grain velocities at a number of phases of the cycle at several elevations above the bed.

Figure 7 shows measured horizontal grain velocity profiles of E1. Large velocity gradients occur especially in the sheet-flow and pick-up layer.

Figure 7 Horizontal grain velocity profiles of E1 (obtained with high-speed video)

#### Sediment fluxes and net sediment transport rates

By multiplication of the horizontal velocities  $U(z,t)$  (LDFM, EMF) and concentrations  $C(z,t)$  (OPCON), time-dependent horizontal sediment fluxes  $\phi(z,t)$  were calculated in the suspension layer. The same was done in the sheet flow layer using the horizontal grain velocities (HSV) and the concentrations (CCM). The result of this analysis for experiment E1 is shown in Figure 8, using a log-linear x-y scale (with  $\phi = \pm 10^{-3}$  m/s as separation between negative and positive fluxes). The dimensionless volume concentration is used for the flux computation, and thus the sediment flux unit is m/s.

Maximum fluxes occur at the moments of maximum downstream and upstream velocity (above the wave boundary layer) in the sheet flow layer. Deeper into the sheet flow and pick-up layer the fluxes gradually reduce. A very strong reduction of the fluxes occurs in the suspension layer. The net horizontal sediment fluxes over the wave cycle were computed by time-averaging, making distinction between a current related and a wave related contribution, according to:

$$\langle \phi(z,t) \rangle = \langle U(z,t) \cdot C(z,t) \rangle = \phi_c + \phi_w$$

$$\phi_c = \langle U(z,t) \rangle \cdot \langle C(z,t) \rangle$$

$$\phi_w = \langle \tilde{U}(z,t) \cdot \tilde{C}(z,t) \rangle$$

Herein  $\tilde{U}$  and  $\tilde{C}$  represent the periodic parts of  $U$  and  $C$  after subtracting the wave-mean values  $\langle U \rangle$  and  $\langle C \rangle$  respectively. The distinction between  $\phi_c$  and  $\phi_w$  was only possible in the suspension layer where the mean velocity  $\langle U \rangle$  could be computed with a reasonable accuracy.

Figure 8 Time-dependent horizontal sediment flux profiles, E1

Figure 9 shows the computed net sediment flux profiles of the suspension layer of E1.

Figure 9 Net horizontal sediment flux profiles in the suspension layer, E1

It can be observed that due to time lags of  $\tilde{C}$  with respect to  $\tilde{U}$  (phase differences) a negative wave related flux is present at elevations  $z > 2$  cm. However, this negative contribution is almost compensated by the positive contribution of the current-related flux (the latter is positive by definition). Closer to the bed ( $z < 2$  cm) both contributions become positive and a relatively large positive total net flux results, showing a strong increase in the direction of the bed.

The complete total net horizontal flux profile for E1 is shown in Figure 10. In comparison with Figure 9 the scale of the horizontal axis had to be changed considerably (factor 10), due to the large magnitude of the net fluxes in the sheet flow and pick-up layer. The fluxes in the suspension layer can now hardly be recognized, indicating their minor importance for the total net sediment transport rate.

Figure 10 Total net horizontal sediment flux profile, E1

The fluxes in the sheet flow and pick-up layer show a considerable scatter, which is mainly caused by the low number of measured grain velocities per wave cycle in combination with a low accuracy of the grain velocity measurements. Vertical integration of the flux profile was carried out to estimate the total net sediment transport rate during E1. The obtained transport rate ( $120 \cdot 10^{-6} \text{ m}^2/\text{s}$ ) agreed reasonably well with the (relatively accurate) total net transport rate as obtained with the mass conservation technique ( $92.4 \cdot 10^{-6} \text{ m}^2/\text{s}$ ).

Also the experiments E2...E4 confirmed the result of experiment E1, namely that the net transport rate is mainly concentrated in the sheet flow and the pick-up layer. Even for E4 with the greatest net current the contribution of the suspension layer to the total net transport rate is minor. The previously mentioned relatively small

suspended sediment mixing above the mobile bed, most likely caused by turbulence damping effects of the sheet flow layer, is responsible for this phenomenon.

The results are only valid for the investigated conditions. It is expected that for finer sand, an increased current dominance (with respect to the waves) and in cases with rippled beds the importance of suspended sediment will strongly increase.

Al-Salem (1993) showed that in case of asymmetric 2<sup>nd</sup> order Stokes waves the net sediment transport is also concentrated in the sheet flow layer (same sand). Ribberink and Al-Salem (1994) showed that the net sediment transport can be described with a linear function of  $\langle U^3 \rangle$ , i.e. the third-order moment of the horizontal velocity above the wave boundary layer.

The measured net sediment transport rates of the series C and the series E experiments (totally 69 tunnel runs) were used to verify this relation in the case of combined waves and currents. The result is shown in Figure 11.

Figure 11 Measured net sediment transport rates vs. velocity moments  $\langle U^3 \rangle$

As the net current velocity is a function of the elevation above the bed and the velocity moment is computed on the basis of measured velocities, a choice was made for  $z = 10$  cm (series C) and  $z = 20$  cm (series E). Both elevations are above the wave boundary layer. The influence of the difference in the selected elevation (10 or 20 cm) on Figure 11 appeared to be minor.

The 'wave+current' cases in Figure 11 show approximately the same correlation between  $\langle q_s \rangle$  and  $\langle U^3 \rangle$  as the previous 'waves alone' cases.

The reasonable success of this relation (for this sand type and the selected experimental conditions) can be explained by the concentration of the sediment

transport near the bed (sheet flow layer) and the quasi-steady character of the transport process in this layer.

### Conclusions

Two experimental studies were conducted in the Large Oscillating Water Tunnel of Delft Hydraulics which was recently extended with a new recirculation system. Detailed time-dependent measurements were carried out in the combined wave current boundary layer in sheet flow conditions (series E) using a number of measuring techniques, among them a high-speed video technique for the measurement of grain velocities in the sheet flow layer. Series C concerned time-averaged measurements near the bottom. The datasets obtained can be used for the verification and development of boundary layer flow and transport models. In the present study a first analysis of the experimental results was presented.

The main conclusions are:

1. The time-dependent measurements of series E revealed a three layer transport system, viz. a pick-up layer, a sheet flow layer and a suspension layer with:
  - 4 concentration peaks per wave cycle in the sheet flow and suspension layer, (2 main peaks related to the maximum downstream and upstream velocities and 2 peaks near flow reversal),
  - increasing phase lags for increasing elevation in the suspension layer and almost no phase lags in the sheet flow and pick-up layer.
2. The time-averaged suspended sediment concentration profiles showed a similar negative power distribution as found during previous experiments with only waves. The concentration decay parameter  $\alpha$  appeared to be almost constant ( $\approx 2$ ) for all experiments (waves alone and waves + currents). The measured concentration decay near the bed was larger than the predicted decay of a theoretical diffusion model (with a time-invariant diffusion coefficient) and did not show the expected decrease for increasing Shields numbers. This is probably caused by turbulence damping effects above the mobile bed (sheet flow layer).
3. Using the time-dependent velocity and concentration measurements horizontal time-dependent and time-averaged sediment fluxes were computed and analyzed. The horizontal fluxes were concentrated in the sheet flow and pick-up layer near the bed. The contribution of the suspension layer to the total net flux appeared to be minor.
4. Due to the quasi-steady character of the transport process in the sheet flow and pick-up layer the measured net sediment transport rates of series C and series E showed a similar linear relation with  $\langle U^3 \rangle$  as obtained during previous experiments with asymmetric waves and no current.

### Acknowledgements

The series C experiments were carried out in the framework of the Coastal Genesis research programme in the Netherlands and were funded by the Ministry of Transport and Public Works (Directorate General Rijkswaterstaat).

The series E experiments were part of the European programme "Access to Large-scale Facilities and Installations" and were funded by the Commission of the European Communities, Directorate General for Science, Research and Development, contract no. GE1\*-CT91-0032 (HSMU). The research was executed by a European team with members, apart from the authors, also P. Ruol, C. Lodahl, A. Crosato and H. Wallace. The data analysis and reporting was partly done in the framework of the MAST G8, Coastal Morphodynamics research programme of the Commission of the European Communities, contract no. MaS2-CT92-0027. The assistance of M. Janssen with the computation of the sediment fluxes is greatly acknowledged.

## CHAPTER 184

### WAVES AND CURRENTS AT THE EBRO DELTA SURF ZONE: MEASUREMENTS AND MODELLING

Rodriguez,A.; Sánchez-Arcilla,A.; Collado,F.R.;  
Gracia, V. Coussirat M.G. and Prieto J. <sup>1</sup>

#### Abstract

The wave incidence and the wave-induced circulation in the surf zone (SZ) is studied from both experimental and numerical point of view. The *DELTA'93* experiments were carried out in the Trabucador bar of the Ebro Delta, in the Spanish mediterranean coast. The emphasis of *DELTA'93* was on the SZ vertical flow structure, measuring simultaneously undertow and longshore current in a barred profile. The numerical simulation with *NEARCIR* Q3D model assumes longshore uniformity and stationarity. The wave decay, 2DH currents and 1DV undertow and longshore currents are modelled. The agreement is quite reasonable as can be seen in the included figures.

#### Introduction

The Ebro delta, one of largest in the Mediterranean, is located on the Spanish coast, 200 Km Southwest of Barcelona (figure 1). As in many other deltas of the world, the Ebro delta is experiencing a severe erosion due to the nearly total reduction of solid river discharges associated to dam construction (Jimenez and S.-Arcilla, 1993). Because of this there is an important monitoring activity around the deltaic coastline from which hydrodynamic, morphodynamic and meteorological data have been extracted to support the surf-zone campaign, which is the main object of this paper.

The data recorded during the surf-zone campaign, which took place along the Trabucador bar, will be described in this paper, together with some references to the wealth of previously recorded information along the deltaic coastline. The numerical model used to simulate surf-zone processes and to gain insight into the physics at the Ebro delta surf-zone during the time of the campaign, is the *NEARCIR* model presented in (S.-Arcilla et al., 1990/1992). This Q3D model works at the current time-scale and is structured into three modules:

---

<sup>1</sup> Lab. Ing. Marítima , L.I.M., Univ. Politécnic de Cataluña, U.P.C.  
Av. Gran Capitàn s/n, 08034 Barcelona, Spain.

- i. Wave Propagation Module (based on the kinematic conservation principle and the wave action balance equation).
- ii. Depth Uniform Current Module (based on the 2DH rigid-lid mass and momentum equations).
- iii. Depth Varying Current Module, including the Bottom Boundary Layer (this module is briefly described for completeness within this paper).

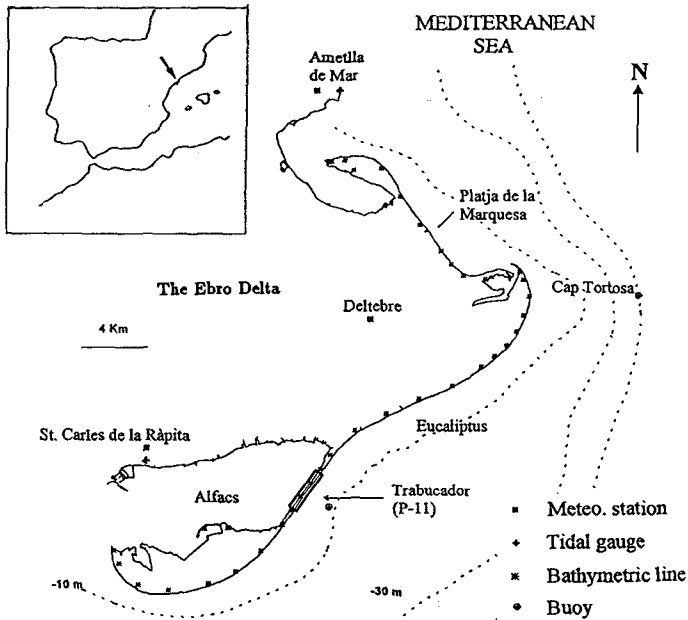

Figure 1. The Ebro Delta

### DELTA '93 Field Experiments

The motivation for this campaign was the lack of detailed 3D data on surf-zone hydrodynamics in a microtidal environment. The campaign was thus focussed on the 3D structure of wave-induced circulation, i.e. on the simultaneous vertical structure of shore-normal (undertow) and shore-parallel (longshore current) flows. Because of this, and trying to avoid excessive complexities and/or unknowns, it was decided to look for an alongshore uniform beach subject to unidirectional waves and a time interval without significant wind.

Based on these considerations and because of the availability of previously recorded field data, the Trabucador bar in the Ebro delta was selected as the most suitable coastal stretch to carry out the surf-zone field exercise. The campaign was centered around the beach profile P11 (see figure 1). The obtained field data include bathymetry, shoreline, wave data outside and inside the SZ, mean water levels across the SZ, and the associated velocity fields (both

horizontal and vertical structure).

The bathymetry in the field site is shown in figure 2. Only relatively modest bottom variations were recorded during the three days of the campaign, which allows assuming a steady bottom geometry for the hydrodynamic analyses. The wave climate was recorded at 50 m and 7.5 m water depth by means of two directional wave rider buoys recording 20 minutes every 3 hours. An Etrometa step wave-gauge was located at the beach sledge, which was used to monitor hydro- and morphodynamic conditions across the surf-zone from the shoreline down to 2.5 m water depth. A BW video camera, placed at 20 m height, was used to record SZ images from which, after digital image processing, information on wave direction, breaking intensity, etc. could be obtained. An X-band radar was also used to measure mean surface roughness (mean wave height) and low-frequency oscillations of the mean water level in the SZ and adjacent nearshore area.

Figure 2. The Trabucador bar bathymetry (P11) for 16/December/93.

Some wave field characteristics plus 2DH circulation and mixing patterns derived from the video images using the developed digital processing technique have been presented in Redondo et al. (1994). This technique allows to quantify the time and space evolution of sea surface tracers (foam, dyes and Lagrangian buoys) and the horizontal mixing properties associated to dye spots.

The vertical structure of horizontal instantaneous velocities was measured with six electromagnetic current meters (Delft Hydraulics-S type) placed in a vertical pole at the sledge, see figura 3. The vertical spacing of the electromagnetic sensors (ems) range from 0.10 to 0.20 m above the bottom up to maximum level of 0.80 m above the bottom, with a sampling rate of 20 Hz allowing therefore to measure some macroturbulence features. Simultaneously with the velocities, the local water level evolution was measured at the same vertical with the step wave-gauge mentioned above (sampling rate 4 Hz). The MWL was computed by averaging the free surface time series, while crest and trough

Figure 3. Movable Sledge with: 6 EMS, 1 WG, 3 OBS, 1 COMPASS, Data-Logger and 1 Optic-Prism).

levels were obtained as the mean of the upper "1/3" series of individual crest and trough values. The crests and troughs were obtained after numerically filtering the original water-surface series to remove the effect of long waves and other alien-phenomena.

### Waves: Measurements and Modelling

#### Wave Features

Table 1 summarizes the 5 cases measured during the *DELTA'93* experiments.

Cases	Date	I. E. L.	Spectra	$T_p$ (s)	Sea State	Test n.
I	26/05/93	High	doubled-peak	$T_{p1}$ 18 $T_{p2}$ 3	unsteady	-
II	15/12/93	Low	wide	7.5	Q-steady	NT1-NT4
III	16/12/93 a.m.	Medium-High	sharp	6.0	Q-steady	NT5-NT7
IV	16/12/93 p.m.	Medium	sharp	5.5-7.0	unsteady	NT8-NT12
V	17/12/93	Low	wide	7.5	steady	-

Table 1: Measured conditions I.E.L.: Incident wave energy level; Spectra: type of wave spectra;  $T_p$ : wave period; Test n.: Test number

In this paper only cases III and IV, measured during 16th December 1993, are considered for an in-depth analysis because they were the most complete cases with strong enough wave-induced currents. There are several potential sources of error, such as the linear interpolation in directional wave data recorded every

3 hours by the buoy (to have time correspondance with the wave gauge data recorded every half-hour), the spreading in wave direction given by the buoy or those inherent to the measurement equipment and processing techniques. In spite of this, there was reasonable agreement between the surf-zone spectra from wave-gauge and video images data, showing a good correspondance of frequencies or dominant periods. The comparison between wave angles from the video (VTR) and the ems is not finished because of the large amount of data-processing necessary to obtain a mean angle of wave incidence. The incident wave conditions during the 16th December 1993 (outside and inside the SZ) are summarized in tables 2 and 3. Hrms (m) is the root mean square wave height, Tp(s) is the wave period,  $\theta_m$  is the mean angle of wave incidence, X is the crossshore coordinate,  $h$  is the mean water depth and  $U$ - $V$  (m/s) are the depth-averaged cross- and alongshore velocity components at different sledge positions (test) inside the surf-zone.

Wave incident conditions (DWR)				
Test	Hrms (m)	Tp(s)	$\theta_m$	GMT
5	.61	6.0	177.0	10:04
6	.60	6.1	175.3	10:55
7	.59	6.3	173.0	12:05
8	.50	5.7	179.5	14:07
9	.44	5.4	183.3	15:07
10	.43	5.4	180.6	15:46
11	.425	5.6	176.1	16:20
12	.42	5.8	171.9	16:51

\* (mean below wave trough level  $z_{tr}$ )

Table 3: Hydrodynamic conditions from *WG* and *ems*

An image processing technique, still under development, has also been used to evaluate the acrossshore distribution of the intensity of wave breaking,  $Q_b$ . From an image threshold intensity associated to breaking, the breaking wave distribution acrossshore can be determined for a time series of beach profile transects derived from the video record. The processing technique is able to reproduce some of the features of the acrossshore evolution of the fraction of breaking waves, as derived from e.g. the Battjes and Janssen (1978) (hereinafter

BJ'78) model (figure 4).

Figure 4. Measured and computed Qb for case III (around 100 waves)

Wave Propagation

The wave conditions for cases III and IV were quasi-stationary, although in this latter case a transient component was also apparent (see test 8 in figure 5). Wave decay due to breaking has been modelled using the BJ'78 approach for random waves (neglecting bottom dissipation). In spite of the lack of perfect stationarity the obtained results are quite reasonable (figure 6). The single value used for the dissipation parameter  $\alpha$ , leads to overestimating the higher wave values near the shore. Moreover, in this shoreline region, the shoaling process dominates over the breaking-induced decay which yields some oscillations in the cells of the computational domain close to the shoreline (not appreciable in figure 6).

Figure 5. Wave height (Hrms) at 7.5 m depth from DWR

Figure 6. Wave decay Case IV. The different lines correspond to the varying conditions at the offshore boundary corresponding to the SZ-test time.

To achieve a reasonable setup prediction, a general sea level rise due to storm-surge has to be assumed in the field data. This general sea level rise has been estimated in 15cm and 8cm for cases III and IV respectively, using an iterative process. The resulting setdown/up predictions are reasonable although the fit is far from perfect. There is not yet a satisfactory explanation for this mean water level behaviour (figure 7). The predictions of the angle of wave incidence are in general acceptable (see figure 8), although numerical results overpredict systematically the experimental data from the ems. The origins for this could be the procedure used to derive an angle of wave incidence from the ems data, the spreading in wave angle given by the directional buoy (which is quite high when compared to the accuracy of the computations) or wave current interaction effects which have not been considered in this preliminary analysis.

Figure 7. Wave setdown/setup for Case III.

Apart from the incident wind waves, there was evidence of stationary long waves with a period of around 40 s in the water surface time series. This long period pulsations are more clear in the spectral and moving average analysis of the velocity time series, both for the longshore and undertow components. These pulsations were uncoupled for longshore and cross-shore currents in most

of the measured tests. The longer period oscillations and the macroturbulence features are still being processed and will not be further discussed in this paper.

Figure 8. Incident wave angles for Test 6, Case III

The current measurements have shown the coexistence of a strong longshore current with a clear undertow crossshore distribution. The general pattern of measured data agree with the expected 3D "helicoidal" current structure shown in figure 9. Additionally it was observed the maxima for cross- and longshore components located at roughly the same across-shore coordinate.

Figure 9. Measured 3D current field structure for Case IV.

### Depth Averaged Currents

The velocity data were obtained after debugging, compass-correction and quality controls applied to the "raw" time series. The mean (referring to time and depth average) current values were calculated after time and vertical averaging over the series length (from 20 to 40 minutes depending on the record) and from the bottom up to the highest sensor (always below trough level).

Eulerian (ems) and Lagrangian (buoys and dye-spots) current velocities have been compared for the same time and space intervals, showing reasonable agreement even though the potential sources of error are different for each type of measurements. The main sources of error include the dye-spot location in the vertical, inaccuracies of the pixel-coordinates transfer function, ditto for the ems-orientation, limitations of the scale range and those inherent to the processing/filtering technique.

The 2DH currents have been modelled assuming an alongshore uniform beach which implies a mass balance restriction per profile. The bottom shear stress is modelled using a standard linear expression and the horizontal eddy viscosity coefficient follows the De Vriend and Stive (1987) (hereinafter DVS'87) proposal. These values agree well with the experimental data obtained from the processing of dye dispersion images (see Rodriguez et al, 1995). The numerical domain extends up to the shoreline, considering dynamically the "dry-flood" problem in that region.

The obtained results are quite reasonable (see figure 10) with two maxima roughly in the region of the two bars present in the profile. The mean cross-shore flux, obtained using the external mass flux closure submodel of DVS'87, is acceptable only in some regions. This point must be clearly improved in the future, from which better longshore current predictions can be expected.

Figure 10. Longshore currents for Case IV. The different lines correspond to the hydrodynamics conditions of fig. 6.

### 1DV Structure of Currents

The vertical flow structure during *DELTA'93* was monitored with six ems

placed at 0.1, 0.2, 0.3, 0.4, 0.6 and 0.8 m above the bottom, at a single vertical pole located at the sledge. Measurements above  $z_{tr}$  were used to estimate the mass flux during the "wet intervals". Measurements below  $z_{tr}$  were used to characterize the vertical profiles of longshore and cross-shore currents, outside the bottom boundary layer (BBL).

The undertow profiles show a maximum near the bottom as expected according to previous experimental information (see e.g. Okayasu, 1989 or Smith et al., 1992). The longshore current profiles below  $z_{tr}$  show a mildly increasing trend upwards rather than a constant value.

The 1DV module, described in S.-Arcilla et al. (1992), splits the total current velocity vector into depth uniform,  $\vec{u}$ , and depth varying,  $\vec{u}'$ , components. The crest-to-trough layer is not solved because it is considered exclusively via its interaction with the middle layer at trough level through the imposition of the appropriate boundary conditions. The BBL model is inspired on the one proposed by Fredsøe (1984), whose solution leads to algebraic expressions of logarithmic form that have been here parameterized to achieve an economic solution. The middle layer equations are solved using a power series approximation,  $\sum_1^N a_i z^i$ , to reproduce the vertical variation of  $\vec{u}$ .

It can be shown theoretically (S.-Arcilla et al, 1992) that the middle layer equation may not converge under certain conditions. Because of that, in general, the profile obtained consists of a first logarithm within the BBL, from  $z_o$  up to  $z_b$ , ( $z_b - z_o = \delta_m$ ), a second one up to a given  $z_l$  level, and from this level to  $z_{tr}$  the power series  $a_i z^i$ .

The "optimal"  $z_l$  level to achieve an efficient convergence and to avoid artificial profile distortions is here considered to be  $z_l \simeq 0.2z_{tr}$ . The trough level  $z_{tr}$  has been estimated as:

$$z_{tr} = \max [0.8h; h - 0.5H_{rms}]$$

The  $\vec{u}$  model needs three main external closure submodels to determine the  $\vec{u}$  profile: a) the shear stress  $\langle \tau_{tr} \rangle$  at trough level, b) the mass flux over this level,  $\langle \bar{Q}_s \rangle$ , and c) the eddy viscosity vertical distribution,  $\nu_t(z)$ .

For the case of longitudinal uniformity, the mean cross-shore velocity  $\bar{u}$  is obtained using a  $Q_s$  expression similar to the one proposed in DVS'87. This expression, which is given by:

$$\langle Q_{sx} \rangle = (1.0 + 7.0 Q_b \frac{h}{L}) \frac{E}{\sigma} K_x$$

does not fit well the experimental  $\bar{u}$  (see figure 11). In the  $\langle Q_{sx} \rangle$  formula  $Q_b$  is a measure of the breaking intensity,  $h$  is the water depth,  $L$  the wave length,  $E$  the wave energy density,  $\sigma$  the wave frequency and  $K_x$  the  $x$  component of the wave number vector.

Figure 11. Crest-to-trough mass flux calculated according to DVS'87 and measured mean flow values (across-shore distribution)

The closure model for  $\langle \vec{\tau}_{ir} \rangle$  uses the general expression proposed by Deigaard (1993), which extends the 1-dimensional expression obtained in Deigaard and Fredsøe (1989). The closure model for the eddy viscosity allows either a constant or a parabolic form for  $\nu_t$ . The resulting expression is made up of two terms, the first one corresponding to the current induced eddy viscosity (similar to the one proposed in e.g. Coffey and Nielsen (1984)) and the second one corresponding to the breaking induced eddy viscosity similar to the value proposed by DVS'87 and Battjes (1983).

The resulting undertow profiles for cases III and IV are obtained with a constant  $\nu_t$  and  $N = 20$  in the middle layer equations, see figures 12 and 13. The continuous line represents the modelled undertow using as mean return flow the experimental value, while the dashed line represents the modelled undertow with an analytically calculated mean mass flux. It is apparent that the model fits much better the measured vertical structure when the experimental mean mass flux is used. The obtained fit is quite satisfactory even though there are no data from the bottom boundary layer.

The values above trough level, also indicated in the figures, have only been used to calculate the mean mass flux. Points I and II, physically "unrealistic", have been disregarded. No explanation for these two points is available. It can be, thus, concluded that most of the profiles show a good agreement between experimental and modeled values in the middle layer. This agreement is also reasonable near the bottom, although there is a small trend to underestimate measured current values in the lower part of the water column.

The corresponding longshore current vertical profiles for cases III and IV are shown in figures 14 and 15. The model results, which are preliminary, have been obtained using a parabolic power series. The solution with the complete power series is now being tested although the fit appears to be reasonable enough with the second order approach.

### Final Remarks

The *DELTA'93* field campaign is a modest field effort with respect to other experimental studies (e.g. DUCK, SUPERDUCK, NSTS, B-BAND, EGMOND, C2S2, NERC, DELILAH, etc.). The emphasis of *DELTA'93* was on the SZ vertical flow structure since the Mediterranean sea is an adequate environment to study this kind of processes, due to its microtidal range and medium wave energy-level characteristics.

The developed methodology works successfully eventhough there were some difficulties to define what was the still water level and what was the mean water level due to setup, setdown and storm surge. The identification of different flow modes (e.g. splitting up between low frequency, high frequency and current type motions) needs to be careful due to the non-negligible dependence on the filtering/processing techniques.

Long period pulsations are clear in the spectral analysis of the velocity time series, both for the longshore and undertow components. These pulsations were uncoupled for longshore and cross-shore currents in most of the tests.

The general pattern of measured data in the SZ agree with the expected 3D "helicoïdal" current structure (figure 9). The maxima for cross- and longshore components happen at roughly the same across-shore coordinate.

The undertow profiles show a maximum near the bottom and the longshore current profiles below  $z_{tr}$  show a mildly increasing trend upwards rather than a constant value.

A good estimation of  $Q_b$  from video images needs time series longer than 100 waves period.

The disipation model have showed difficulties in the fitting of the measured data when it was applied in the considered domain.

With respect to the modelling effort a general conclusion is the inherent limitation of field data to accurately validate numerical models. These numerical models always simulate a much simplified situation with respect to the field one, which precludes any definite and accurate validation conclusions for the time being.

In the wave modelling part there were in general good agreement with a slight overpredicted wave heights and some decay/shoaling oscillations near the shoreline. The main trouble with respect to the depth-averaged current modelling were the current overpredictions near the shoreline because of the decay oscillations just mentioned.

The 1DV model showed a good enough fitting of the vertical profiles, although the mass flux submodel should be improved due to its sistematic underpredictions. It was also noted a slight trend to underestimate the current values near the bottom.

### Acknowledgements

This work was undertaken as part of the Surf Zone Research project of LIM-UPC. It was funded jointly by the Programa de Clima Marítimo PCM-MOPTMA and the Ministerio de E. y C. (DGICYT) of Spain, with some support from the MAST-II G8M Project of the E.U. We want to thank the research staff of LIM-UPC, particularly J Gomez, J Sospedra and all those who endured the field work. Thanks are also due to G Voulgaris and MA Tenorio from Southampton University for their OBS and radar; and to MJF Stive and JM Redondo for their helpful collaboration "before, during and after" the experiments.

# A numerical simulation of beach evolution based on a nonlinear dispersive wave-current model

Shinji Sato<sup>1</sup> and Michael B. Kabiling<sup>2</sup>

## ABSTRACT

A numerical wave model based on the Boussinesq equation was extended to the computation of two-dimensional wave-current field including diffraction, refraction and wave breaking. The energy dissipation due to wave breaking was modeled by a momentum mixing term using eddy viscosity. Beach deformation was estimated based on the wave-current field simulated in the nearshore region. Energetics-based equations were used to estimate the total sediment transport in the cross-shore and longshore directions. The model applicability was confirmed with laboratory experiments.

## 1. INTRODUCTION

In the nearshore region, where water depths are shallow and amplitudes are relatively large, waves are highly nonlinear characterized by asymmetric orbital motion of the water particle. This nonlinearity becomes increasingly dominant with decreasing water depth. Hence, it is expected that numerical models based on the linear wave theory will not provide an accurate simulation of the nearshore wave phenomenon. Moreover, since the nearshore current is caused by the gradient of nonlinear radiation stress, it cannot be estimated simultaneously with the wave variables in linear wave models.

The Boussinesq equation can be considered as one of the valid nonlinear dispersive wave theories for finite amplitude wave transformation. The nearshore currents generated by the wave action can also be determined from nonlinear wave computation using the Boussinesq equations. The performance of the Boussinesq equations in 1-D wave transformation was evaluated by Madsen and Warren (1984)[10], Abbott *et al.* (1984)[1], and McCowan (1987)[13]. It was noted that Boussinesq equations with various forms of the dispersion terms generally performed well in the shallow water region. Madsen *et al.* (1991)[11] also presented a method of extending the validity of the Boussinesq equations to deeper water. The use of the Boussinesq equations was extended to the surf zone by more recent researches by Schäffer *et al.* (1992)[16], Karambas *et al.* (1992)[8] and Sato *et al.*

(1992)[15]. It was shown that with the use of an appropriate additional term expressing the momentum mixing due to wave breaking, the Boussinesq equations give reasonable results even inside the surf zone. However, most of the previous works in this area have been confined to 1-D wave modeling.

In this study, the nonlinear dispersive wave model based on the Boussinesq equation is extended for wave transformation in two horizontal dimensions. A new breaking criterion using the ratio of the water particle velocity at the crest surface to the wave celerity for three-dimensional wave field is presented. A momentum mixing term is introduced to simulate the energy dissipation due to wave breaking and thus extend the use of the Boussinesq equations into the surf zone. These two factors extended the wave-current model application into the surf zone. A beach run-up sub-model similar to that used by Iwasaki and Mano (1979)[5] was added to extend the model application up to the swash zone. It also allowed for the estimation of the beach deformation beyond the initial shoreline. Results from the numerical computations are compared with previous theoretical works and with existing laboratory data.

## 2. WAVE AND CURRENT MODELING

### 2.1. Governing equations

The Boussinesq equations for 2-D incompressible flow applicable for a horizontal or mildly sloping bottom are used as the basis for the governing equations. Additional momentum mixing terms  $M_{Dx}$  and  $M_{Dy}$  were added into the Boussinesq equations to simulate the energy dissipation due to wave breaking inside the surf zone. Another term was also added to include the effect of the bottom friction. The governing equations thus read:

$$\frac{\partial \eta}{\partial t} + \frac{\partial Q_x}{\partial x} + \frac{\partial Q_y}{\partial y} = 0 \tag{1}$$

$$\frac{\partial Q_x}{\partial t} + \frac{\partial}{\partial x} \left( \frac{Q_x^2}{d} \right) + \frac{\partial}{\partial y} \left( \frac{Q_x Q_y}{d} \right) + g d \frac{\partial \eta}{\partial x} \tag{2}$$

$$= \frac{1}{3} h^2 \left( \frac{\partial^3 Q_x}{\partial x^2 \partial t} + \frac{\partial^3 Q_y}{\partial x \partial y \partial t} \right) - \frac{f_w}{2 d^2} Q_x \sqrt{Q_x^2 + Q_y^2} + M_{Dx}$$

$$\frac{\partial Q_y}{\partial t} + \frac{\partial}{\partial x} \left( \frac{Q_x Q_y}{d} \right) + \frac{\partial}{\partial y} \left( \frac{Q_y^2}{d} \right) + g d \frac{\partial \eta}{\partial y} \tag{3}$$

$= \frac{1}{3} h^2 \left( \frac{\partial^3 Q_x}{\partial x \partial y \partial t} + \frac{\partial^3 Q_y}{\partial y^2 \partial t} \right) - \frac{f_w}{2 d^2} Q_y \sqrt{Q_x^2 + Q_y^2} + M_{Dy}$

where as shown in Fig. 1,  $Q_x(x,y,t) = \bar{u}_x d$  and  $Q_y(x,y,t) = \bar{u}_y d$  are the depth-integrated flow rates in the x-axis and y-axis directions respectively,  $\bar{u}_x = \bar{u}_x(x,y,t)$  and  $\bar{u}_y = \bar{u}_y(x,y,t)$  are the depth-averaged water particle velocities in the x-axis and y-axis directions respectively,  $d(=h + \eta)$  is the total water depth,  $h = h(x,y)$  is the still water depth,  $\eta = \eta(x,y,t)$  is the water surface elevation,  $g$  is the acceleration due to gravity,  $f_w$  is the bottom friction coefficient, and  $M_{Dx}$  and  $M_{Dy}$  are the momentum correction terms in the x-axis and y-axis directions respectively.

An Alternating Direction Implicit (ADI) finite difference scheme with a double sweep algorithm on a staggered rectangular grid region was used in the wave-current computations. In all

Figure 1 Definition sketch of a typical wave profile.

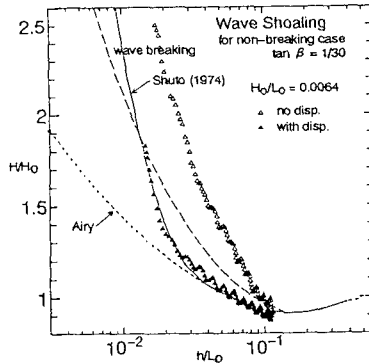

Figure 2 Wave shoaling under 1-D non-breaking wave computations.

computations, monochromatic first-order cnoidal waves were generated at the incident boundary. The incident boundary was set as an absorbing boundary which allowed the reflected waves to pass through freely. An absorbing boundary was defined by solving the radiation problem along this boundary. The computation started from still water and continued until both wave and current fields reached equilibrium state. The time required to reach the equilibrium was about 40 wave periods in the present computations.

### 2.2. Wave shoaling

To verify the numerical scheme, 1-D non-breaking wave computations ( $M_{Dx} = M_{Dy} = 0$ ) were performed on a rectangular region where the onshore boundary was set as an absorbing boundary which allowed the non-breaking waves to pass through freely. The still water depths at the incident and onshore boundaries were set to  $0.12L_0$  and to just below the wave breaking limit respectively. Numerical computations for bottom slope  $\tan\beta = 1/30$  to  $1/20$  were made with incident wave condition  $H_0/L_0 = 0.0064$  where  $H_0$  and  $L_0$  are the deep water wave height and wavelength respectively.

Figure 2 shows the ratio of the wave height to the deep water wave height  $H/H_0$  for computations with and without the dispersion terms. The small undulations were caused by small amounts of wave reflection arising from the bottom slope as well as the onshore boundary. The values of  $H/H_0$  from nonlinear non-dispersive wave computations overestimate wave shoaling. In contrast, those from nonlinear dispersive wave computations adhere closely to the theoretical curve presented by Shuto (1974)[17]. This indicates the importance of including the dispersion terms in nonlinear wave computations. These results confirmed the capability of the Boussinesq wave model for wave shoaling up to the breaking limit.

### 2.3. Two-dimensional wave breaking criterion

In order to establish an appropriate 2-D wave breaking criterion for nonlinear dispersive waves in a multi-directional wave field, the ratio of the water particle horizontal velocity at the surface of wave crest  $u_{max}$  to the wave celerity  $c$  at the breaking point was investigated. The aim of the investigation is to determine the critical ratio at incipient wave breaking.

The wave celerity  $c$  was taken to be equal to the celerity in the direction of the maximum horizontal water particle velocity  $u_{max}$  which occurs at the crest surface. The ratio  $u_{max}/c$  was thus

estimated by:

$$\frac{u_{smax}}{c} = \frac{|\vec{k} \cdot \vec{u}_{smax}|}{\sigma} \quad (4)$$

where  $\vec{k}$  is the wave number vector and  $\sigma$  is the angular frequency. The wave number  $\vec{k}$  was determined from the gradient of the phase lag  $\Phi$ . The phase lag was estimated from the Fourier analysis of the computed water surface elevation  $\eta(t)$ . A quadratic vertical distribution of the horizontal velocity was assumed. Based on the investigation, the critical values of  $u_{smax}/c$  was found to be in the range  $0.4 \leq u_{smax}/c \leq 0.70$  depending on the bottom slope and incident wave condition.

## 2.4. Energy dissipation due to wave breaking

Significant amount of energy is dissipated by the turbulence generated by the breaking of waves. Several momentum correction models have been proposed so far to simulate wave damping in the surf zone (e.g., Karambas and Koutitas, 1992, Schäffer *et al.*, 1992). Watanabe and Dibajnia (1988)[21] presented a numerical wave model based on the linear wave theory. It computes wave transformation by using a set of time-dependent mass and momentum conservation equations that are equivalent to the mild-slope equations. The functional form of  $M_D$  that was used in the wave transformation computations from this linear wave model for which results well agree with laboratory data is:

$$M_D = -f_D \cdot Q = -\alpha_D \tan \beta \sqrt{\left(\frac{g}{\bar{d}}\right) \left(\frac{\hat{Q} - Q_r}{Q_s - Q_r}\right)} \cdot Q \quad (5)$$

where  $f_D$  is an energy dissipation coefficient,  $Q$  is the discharge per unit width,  $\alpha_D$  is a coefficient which is 2.5 inside the surf zone and zero elsewhere,  $\tan \beta$  is the bottom slope,  $\bar{d}$  is the mean total depth,  $\hat{Q}$  is the amplitude of discharge per unit width,  $Q_s$  is the wave induced flow rate inside the surf zone, and  $Q_r$  is the flow rate amplitude of recovered waves. Based on the experimental data of Isohe (1986)[4] and Maruyama and Shimizu (1986)[12] respectively,  $Q_s$  and  $Q_r$  can be estimated as:

$$Q_s = 0.4 (0.57 + 5.3 \tan \beta) \sqrt{g \bar{d}^3} \quad (6a)$$

$$Q_r = 0.135 \sqrt{g \bar{d}^3} \quad (6b)$$

Wave breaking however, involves strong turbulence and momentum mixing particularly at the front face of the wave. The energy dissipation is a direct result of the diffusion of momentum in the surf zone. It is therefore necessary to use a more appropriate form of  $M_D$  that can better describe these phenomena. Sato *et al.* (1992)[15] presented an energy dissipation term that was proportional to the diffusion of the momentum. The following formulation of  $M_{Dx}$  and  $M_{Dy}$  by Sato *et al.* (1992) in terms of an eddy viscosity  $\nu_B$  was used to describe the momentum exchange due to turbulence.

$$M_{Dx} = \nu_e \left( \frac{\partial^2 Q_x}{\partial x^2} + \frac{\partial^2 Q_x}{\partial y^2} \right) \quad (7a)$$

$$M_{Dy} = \nu_e \left( \frac{\partial^2 Q_y}{\partial x^2} + \frac{\partial^2 Q_y}{\partial y^2} \right) \quad \text{with} \quad \nu_e = \nu_n + \nu_l \quad (7b)$$

The functional form of  $\nu_B$  was analogically deduced from Eq. (5). By assuming sinusoidally varying  $Q$ , the form of  $\nu_B$  for long waves becomes:

$$\nu_B = \frac{\alpha_D g \bar{d} \tan \beta}{\sigma^2} \sqrt{\left(\frac{g}{\bar{d}}\right) \left(\frac{\hat{Q} - Q_r}{Q_s - Q_r}\right)} \quad (8)$$

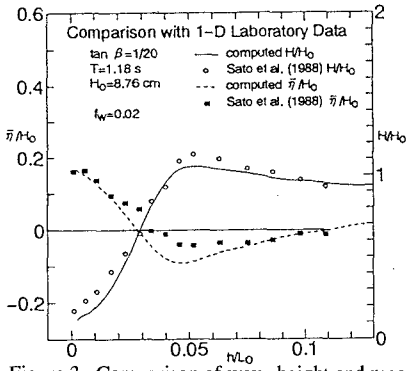

Figure 3 Comparison of wave height and mean water surface.

The form of  $\nu_b$  in Eq. (8) is consistent with Eq. (5). Sato *et al.* (1992) confirmed that the momentum mixing model given by Eq. (8) is capable of simulating the tilting of the wave profile as the wave propagates into shallow water.

Equation (8) is used only in the surf zone and the eddy viscosity  $\nu_b$  is zero outside the surf zone. However, this will result in the appearance of enormously large velocities at sharp corners of structures located outside the surf zone. These large velocities occur in places where there is a sudden difference in wave height and mean water level. They are likely to occur in sharp corners like at the tip of a detached breakwater. To avoid these large

velocities, additional viscosity is introduced. An appropriate form for this additional viscosity  $\nu_l$  is found to be similar to that proposed by Longuet-Higgins (1970)[9] and is given by

$$\nu_l = 0.016 l \tan \beta \sqrt{g d} \tag{9}$$

where  $l$  is the horizontal distance from the shoreline. The magnitude of  $\nu_l$  is set to be much smaller than  $\nu_b$  so as not to cause additional wave damping.

### 2.5. One-dimensional wave transformation

Data from a series of 1-D laboratory experiments conducted in a wave flume by Sato *et al.* (1988)[14] were used to verify the wave transformation capability of the present model in the surf zone. In one wave flume experiment, the instantaneous surface elevation and the near-bottom velocity at several points were measured along a line in the direction of the wave propagation. The bottom slope was  $\tan\beta= 1/20$ , the still water depth at the incident boundary  $h_i = 40$  cm, the monochromatic incident wave period  $T = 1.18$  s and the incident wave height  $H_o = 8.76$  cm.

The computed non-breaking wave heights as well as the mean water level  $\bar{\eta}$  well agree with the measurements as shown in Fig. 3. With the inclusion of the momentum mixing terms into the Boussinesq equations, the computed  $H/H_o$  in the surf zone also agree well with the measured  $H/H_o$ . From the profile of  $\bar{\eta}/H_o$ , it can be seen that the model is capable of simulating the wave set-down before wave breaking and the subsequent wave set-up after wave breaking.

The computed instantaneous water surface elevation  $\eta(t/T)$  and near-bottom velocity  $u_b(t/T)$  were compared with the measurements. Figures 4(a) and 4(b) show  $\eta$  and  $u_b$  respectively at two measuring points located before and after wave breaking. In these figures,  $t$  denotes the time within one wave period and  $x$  is the horizontal distance from the still water shoreline.

The best agreement between computation and measurement seems to occur before wave breaking. This is expected since the Boussinesq theory has been proven to be a valid nonlinear wave theory for non-breaking water waves. Inside the surf zone, there is a good agreement of the computed  $\eta$  with the data. The computed near-bottom velocity  $u_b$  also agrees fairly with the data. The slight deterioration in model accuracy in the surf zone may be due to three reasons. First, the Boussinesq theory may not be valid for such strongly nonlinear dispersive waves where wave nonlinearity and wave dispersion do not have the same order of magnitude. Second, strong turbulent mixing generated by wave breaking cannot be well simulated by the simple eddy viscosity approach that uses a constant

Figure 4 Time history of water surface elevation  $\eta(t/T)$  and near-bottom velocity  $u_b(t/T)$ .

eddy viscosity value for one wave period. Third, the assumption of a nearly horizontal slope may have caused this inaccuracy. In spite of these, the model can be regarded to be applicable in the region outside the surf zone and fairly accurate within the surf zone.

### 3. BEACH DEFORMATION MODELING

#### 3.1. Total sediment transport equations

Two sediment transport equations were used by Kabiling and Sato (1993)[7] in modeling 3-D beach deformation. The first of which was used to simulate the sediment transport due to the current. It can be expected therefore that cross-shore sediment transport will not be simulated. On the other hand, the second model based on the Bailard (1981)[2] equations, was seen to be inaccurate around the breaking point. To improve the accuracy in estimating sediment transport around the breaking point and at the same time to include the sediment transport due to asymmetric oscillatory motion of nonlinear waves during one wave period, another set of energetics-based sediment transport equations is needed.

The bed load and suspended sediment equations were formulated to include a threshold value for the initiation of sediment transport. In the case of bed load transport, this threshold value can include the effect of wave breaking on the bed load transport. The bed load transport  $\bar{q}_b(t)$  at any time  $t$  was formulated as:

$$\frac{\bar{q}_b(t)}{\sqrt{(\rho_s/\rho - 1)gD_s^3}} = \alpha_b |\Psi(t)|^a [\max(\Psi(t) - \Psi_c, 0)]^b \cdot \frac{\bar{u}_b(t)}{|\bar{u}_b(t)|} \tag{10a}$$

where  $\alpha_b$ ,  $a$  and  $b$  are parameters that need calibration,  $\Psi_c$  is the critical Shield's parameter for the initiation of bed load transport,  $\bar{u}_b(t)$  is the near-bottom velocity at time  $t$ ,  $\rho_s$  is the density of the sediment particle, and  $\rho$  is the density of water.

Investigations by Kabiling and Sato (1993) on their second sediment transport model based on Bailard (1981) equations revealed that the overestimation of the total sediment transport at the breaking point was mainly coming from the estimation of the suspended sediment transport which was modeled in terms of the near-bottom velocity raised to the fifth power. This can be corrected by

expressing suspended sediment transport as a function of near-bottom velocity raised to less than the fifth power. Furthermore, it was revealed that the first sediment transport model by Kabiling and Sato (1993) was able to simulate the suspended sediment transport. This leads one to adopt a form for the present suspended sediment transport equation in the form:

$$\frac{\bar{q}_s(t)}{w_s D_s} = \alpha_s [\max(\Psi(t) - \Psi_c, 0)]^p \cdot \frac{\bar{u}_b(t)}{|\bar{u}_b(t)|} \tag{10b}$$

where  $\bar{q}_s(t)$  is the suspended sediment transport rate,  $w_s$  is the sediment particle fall velocity, and  $\alpha_s$  and  $p$  are parameters that also need calibration. Equation (10b) is different from the second sediment transport by Kabiling and Sato (1993) since it is expressed as a function of the instantaneous near-bottom velocity. This will result in the inclusion of the effect of nonlinear waves on the suspended sediment transport. In both Eqs. (10a) and (10b), the Shield's parameter is estimated using the Jonsso (1966)[6] friction coefficient:

$$\Psi(t) = \frac{f_w}{2} \frac{[\bar{u}_b(t)]^2}{(\rho_s / \rho - 1) g D_s} \tag{11}$$

The total sediment transport in the present model is estimated by the summation of Eqs. (10a) and (10b). Sediment transport rate in the swash zone was overestimated due to the large velocity moments from highly nonlinear waves that are usually found in this zone. The direction of the net sediment transport was also seen to have been always in the offshore direction which indicated that the offshore rush was larger than the onshore rush. This may be due to the big difference in the water depth during onshore and offshore rushing of the shoreline. During the offshore rush, total water depth is less than that during the onshore rush so larger velocities will result during the offshore rush. In order to avoid unrealistic erosion, sediment transport rate in the swash zone was linearly interpolated between the sediment transport at the still water shoreline and the zero sediment transport at the maximum beach run-up point.

To calculate the local bottom elevation change due to the sediment transport, the sediment conservation equation proposed by Watanabe *et al.* (1986) is used. The sediment conservation equation is given by

$$\frac{\partial h}{\partial t} = - \frac{\partial z}{\partial t} = \frac{1}{1 - \lambda_v} \{ \nabla \cdot (\bar{q} + \epsilon |\bar{q}| \nabla \cdot h) \} \tag{12}$$

where  $z$  is the bottom elevation,  $\lambda_v (=0.4)$  the sediment porosity, and  $\epsilon$  is a coefficient that reflects the effect of local bottom slope on the sediment transport.

### 3.2. Two-dimensional beach deformation

Watanabe *et al.* (1980)[19] measured the change in beach topography in a wave flume. In one set of the experiments, the initial bed slope was  $\tan \beta = 1/20$  and the sediment mean diameters were  $D_s = 0.2$  and  $0.7$  mm respectively. Monochromatic incident wave periods were 1.0, 1.5, and 2.0 s while wave steepness varied from 0.006 to 0.073. The beach was exposed to wave action for a period of one hour. At the end of this period, the beach profile was measured and the cross-shore sediment transport rate was computed based on the measured beach deformation.

One-dimensional wave computations for six cases were done. Based on the computed velocity field, Eqs. (10a) and (10b) with Eq. (12) were used to estimate the beach deformation for each case. The values of the parameters in Eqs. (10a) and (10b) were  $\alpha_s = 1.0$ ,  $a = 0.5$ ,  $b = 1.0$ ,  $\alpha_x = 3.5$ ,  $p = 1.0$ , and  $\Psi_c = 0$ . Since surf zone beach deformation is of prime interest in the present study, the

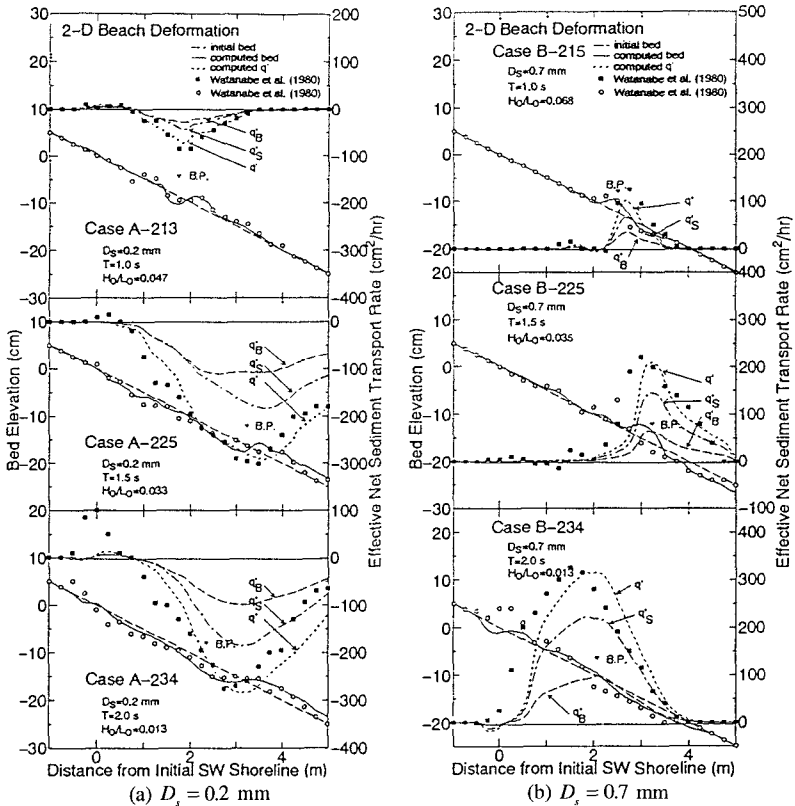

Figure 5 Computed bed elevations and cross-shore effective net sediment transport rates.

values of  $a$  and  $b$  were such as to make the bed load proportional to  $u_b^3$ . The beach deformation time step  $\Delta t'_e$  was estimated following Watanabe *et al.* (1986):

$$\Delta t'_e \leq \min \left\{ \frac{1}{2} \frac{\Delta x^2}{\varepsilon |\bar{q}_x|_{\max}}, \frac{1}{2} \frac{\Delta y^2}{\varepsilon |\bar{q}_y|_{\max}} \right\} \quad (13)$$

where  $\Delta x$  and  $\Delta y$  are the grid spacing in the x-axis and y-axis respectively,  $\bar{q}_x$  and  $\bar{q}_y$  are the net total sediment transport rates in the x-axis and y-axis respectively and  $\varepsilon = 4.0$ .

(1) Fine Sediment

Figure 5(a) shows the computed bed elevation, cross-shore net bed load  $q'_b$ , suspended sediment  $q'_s$ , and total sediment  $q'$  transport rates (which are positive in the onshore direction) for  $D_s = 0.2$  mm and  $\tan\beta = 1/20$  (Cases A-213, A-225 and A-234). The closed triangle indicates the computed location of the breaking point. When compared with the measured beach topography (open circle) and computed net sediment transport rate (closed square) of Watanabe *et al.* (1980), the

magnitude of the computed beach deformation and sediment transport rates have the same order of magnitude. This confirmed the values of the parameters used in Eqs. (10a) and (10b).

The direction of the sediment transport as computed by Watanabe *et al.* (1980) was generally offshore. Sand ripples were observed during the experiment which indicated the predominance of suspended sediments. The direction of sediment transport was simulated correctly by the present model with suspended sediment transport accounting for approximately 60% of the maximum total sediment transport which occurred at the breaking point. Unfortunately, this cannot be confirmed with the data since the contributions of bed and suspended load cannot be separated in the laboratory experiment. The location of the breaking point was correctly estimated by the wave model and generally was between the initial and final measured location of the breaking point.

## (2) Coarse Sediment

Computation results for Cases B-215, B-225 and B-234 where  $D_s = 0.7$  mm are shown in Fig. 5(b). When compared with measurements of Watanabe *et al.* (1980), it can be seen that the computed beach deformation and net sediment transport rates are also consistent. The computed sediment transport was onshore-directed which is consistent with those computed by Watanabe *et al.* (1980). Watanabe *et al.* (1980) noted that the bed load was predominant in cases where  $D_s = 0.7$  mm. At this sediment size, the computations in this study still indicate the predominance of the suspended sediment. This renders inconclusive the investigation on whether the present sediment transport model can simulate properly the proportion of bed load and suspended sediment transports.

## 3.3. 3-D beach deformation

In a 3-D beach deformation laboratory experiment, Watanabe *et al.* (1986)[20] measured the wave heights, currents, and beach deformation around a detached breakwater. Sand with a median grain diameter of 0.2 mm was placed on a 4 m long by 7.2 m wide wave basin with an initial slope of  $\tan\beta = 1/20$ . A 1.5 m long and 0.5 m high model detached breakwater was placed parallel and 1.8 m offshore from the initial shoreline. Monochromatic waves with period and wave height  $T = 0.87$  s and  $H_s = 4.5$  cm respectively were incident normal to the initial shoreline. The bottom topography was measured at  $t = 0:00, 2:37, 5:05$  and  $6:55$  (hr:min). The location of the breaker line was determined from overhead photographs taken near the middle of each time duration while the wave height and current fields were measured from  $t = 0:00$  to  $2:37$ ,  $t = 2:37$  to  $5:05$ , and  $t = 5:05$  to  $6:55$ .

To verify the wave-current model performance under steeper bottom slopes and to verify the 3-D beach deformation model, numerical results were compared with measurements from this experiment. Two-dimensional numerical computations on a half-width of the wave basin were done. The uniform grid spacing was  $\Delta x = \Delta y = 4$  cm, the computation time step was  $\Delta t = 0.035$  s, and the bottom friction coefficient was estimated from the Jonsson (1966) friction factor formula. The incident boundary was set as an open boundary while the adjacent side boundaries were fully reflecting boundaries.

### (1) Breaker Line

The computed breaker line location at  $t = 0:00$  is shown in Fig. 6 taken at quasi-steady state that was achieved after 40 wave periods. In Fig. 6, it can be seen that the general location of the computed breaker line agrees with the measurements of Watanabe *et al.* (1986). Simulation by the present wave-current model was particularly good in the region behind the breakwater. This confirmed the applicability of the 2-D wave breaking criterion in a predominantly 2-D wave field.

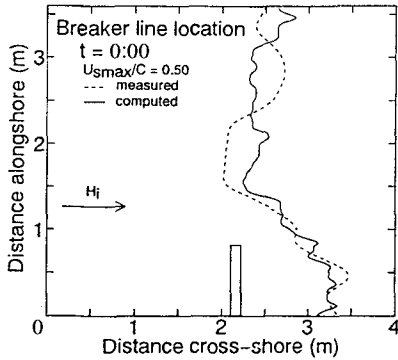

Figure 6 Comparison of breaker line location.

topography at  $t = 2:37$ , the second 2-D wave-current computation followed by the second 3-D beach deformation computation were made and results were compared with measurements during the period  $t = 2:37$  to 5:05.

The wash zone sediment transport was found to have been largely overestimated by the model as was discussed in 2-D beach deformation modeling. Hence, the sediment transport vector in the wash zone was linearly interpolated between those at the still water shoreline and maximum beach run-up point. The computed beach topographies are shown in Figs. 7(a) and 7(b). Compared with the laboratory measurements, it can be seen that the accretion behind the breakwater was simulated well. The alternate pattern of erosion and accretion in front of the breakwater was also simulated as well as the erosion at the tip of the breakwater. Some discrepancies still exist particularly at the region beyond the tip of the breakwater where the measured erosion was simulated at about 1 m onshore. When the computed and measured breaker line locations are compared, it can be observed that in this region, the computed breaker line was located onshore by roughly the same amount. This may explain the discrepancies in this region. This is further reinforced by the fact that both the measured and computed breaker lines are located along the steepest change in their respective bottom topographies. Moreover, the instantaneous near-bottom velocity may not have been estimated accurately in the region.

Comparing with results from the simple sediment transport model by Kabiling and Sato (1993), the present model simulated the beach topography change due to asymmetric nonlinear waves in the region bounded by  $x > 2.0$  m and  $y > 1.5$  m where  $x$  is the cross-shore distance from the incident boundary and  $y$  is the alongshore distance. In this region, erosion was simulated in the offshore side of the breaker line while accretion was simulated on the onshore side of the breaker line. In general, the measurements were qualitatively simulated by the present model and computations are consistent in magnitude particularly in the region located behind the breakwater.

### (3) Wave Height and Nearshore Currents

The wave height and currents computed from the bottom topography at  $t = 2:37$  are shown in Figs. 8 and 9 respectively. These figures show results from computations started from still water conditions. The currents are the time average of the computed velocity field over one wave period. Agreement with measurements was improved over those presented by Kabiling and Sato (1993). The

### (2) Beach Deformation

Equations (10a) and (10b) were used to estimate the 2-D sediment transport based on the computed 2-D velocity field. The parameters used in Eqs. (10a) and (10b) were  $\alpha_B = 1.0$ ,  $a = 0.5$ ,  $b = 1.0$ ,  $\alpha_S = 3.5$ ,  $p = 1.0$ , and  $\Psi_r = 0$ . These values are similar to those used in 2-D beach deformation in the previous section. Equation (12) was then applied to calculate the 3-D beach deformation. The time step in the beach deformation computation was estimated by Eq. (13) with  $\varepsilon = 4.0$ .

The first 2-D wave-current computation followed by the first 3-D beach deformation computation gave results that were compared with measurements during the period  $t = 0:00$  to 2:37 (hr:min). Using the newly computed beach

Figure 7 Computed beach topographies.

computed wave height shown in Fig. 8 exhibits an overall agreement with the measured wave height particularly in the surf zone. This can be observed by comparing Fig. 8 with Fig. 5.10 in Horikawa (1988)[3]. The nearshore circulation pattern behind the breaker was simulated well by the present model as seen upon comparison of Fig. 9 with Fig. 5.10 in Horikawa (1988). The computed current magnitude was found to be consistent with the observed nearshore circulation pattern.

## 4. CONCLUSIONS

A two-dimensional nonlinear dispersive wave-current model was presented on the basis of the Boussinesq equations. The wave breaking criterion that is based on the ratio of water particle velocity at the surface of the wave crest to the wave celerity was found to accurately predict the breaker line location for a three-dimensional wave field. The correction terms that were introduced into the momentum equations were found to sufficiently simulate the wave decay caused by the

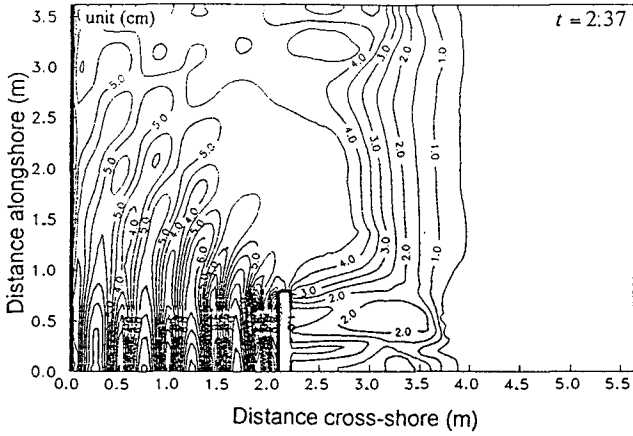

Figure 8 Computed wave height after initial beach topography change.

Figure 9 Computed currents after initial beach topography change.

momentum mixing and strong turbulence at the front face of the breaking wave. The wave set-up and set-down as well as the nearshore current have been simultaneously simulated by the model. The temporal variation of water surface elevation and near-bottom velocity was accurately estimated outside the surf zone. The accuracy of the estimation in the surf zone was slightly impaired. This can be caused by the use of a constant eddy viscosity during one wave period, the limited accuracy of the Boussinesq theory to weakly nonlinear and weakly dispersive waves, and by the assumption of a nearly horizontal bottom.

Beach evolution around a detached breakwater was estimated on the basis of the computed wave-current field. There was a general agreement and consistency with laboratory data of the 3-D beach deformation simulation result. The accretion behind the breakwater was simulated. The present sediment transport model was found to simulate surf zone sediment transport in the cross-shore and longshore directions including that caused by asymmetric wave motion. However, the present model was still seen to be unable to simulate the sediment transport in the swash zone.

# An experimental study on beach transformation due to waves under the operation of coastal drain system

Michio Sato\*, Sadakatsu Hata\*\* and Masahiro Fukushima\*

## ABSTRACT

The performance of a coastal drain system was investigated experimentally. When the drain pipe was buried in the seaward area of a shoreline, the system was most effective. When the discharge is large, the drain system could accumulate a large amount of sediments on a beach face even under erosive wave conditions without drainage. The flow toward shore induced by drainage seemed to play an important role.

## INTRODUCTION

The coastal drain system has been publicized to be a new effective soft approach to coastal erosion control and beach restoration that has no impact on human activity and the environment (Parks,1989; Vesterby,1991). However, there seemed to have been negative view on the performance of it e.g. Bruun(1989). Moreover, this system does not seem to have enough physical basis which enables us to design optimum system.

The purpose of this study is to investigate experimentally the function, performance and optimum location to install of a coastal drain system.

The results showed that this system has a potential ability to accumulate a large amount of sediments on a beach even under storm wave conditions and it protects the landward area of the drain pipe at the worst.

The reason the system work has been explained by relating effects of drain to the net sediments carried due to runup-down wash processes of waves on a beachface. Our experimental results showed, however, that the flow toward the shore generated by drain in surf zone carried suspended sediment and migrated a bar toward the beachface and seemed to play the most important role.

## EXPERIMENTS

A series of experiments was carried out using a wave basin of 26.7m long, 14m wide and 1.2m deep (Figure 1) to take a survey of the performance of coastal drain system by comparing the beach profile of drained part with the one of part where

Figure 1. Experimental Setup

Figure 2. Measuring lines

Figure 3. Cross section of the beach.

the system was not installed. The beach profile of each side was obtained as the mean profile of 16 measuring lines perpendicular to the initial shoreline(Figure 2).

A drain pipe of 7m long was installed under the beachface of the left half of the beach parallel to the shoreline. The diameter of the pipe was 50mm. Filter sheet of 10mm thickness was bound round the pipe. Then, the pipe was buried under the beach face of 1/20 slope. The initial covering was 50mm (Figure 3).

The dependence of the performance on location of the system was investigated to find optimum location to install by changing the relative location of the drain pipe from landward to seaward of the shoreline. Water depth was changed to change the relative location of the system from the shoreline instead of changing the location of the system itself.

The experimental conditions are shown in Table 1. According to the classified laboratory beach profiles by Sunamura and Horikawa, runs 2,3 and 6 are expected to produce erosive beach profiles of Type I and runs 4 and 5 were expected to produce accretive profiles of Type III(Figure 4).

Table 1 Experimental conditions

Run No.	Wave Period	Wave Height	C	Type	Location
1	2.0sec	10cm	7.3	II	1
2	1.0	10	11.6	I	1
3	1.0	10	11.6	I	2
4	2.0	5	3.7	III	2
5	2.0	5	3.7	III	3
6	1.0	10	11.6	I	3

Figure 4. Classified laboratory beach profiles(Sunamura and Horikawa, 1974)

The pump used was 2.2kw and the discharge was 0.33l/sec/m when the covering was 50mm. This discharge was equivalent to about 4 percent of flux that balances with the mass transport of the wave,  $E/\rho C$  ( $E$ : wave energy density;  $\rho$ : density;  $C$ : wave celerity). The velocity of water infiltrated into the bottom was about 2 percent of the settling velocity of the bottom sediments ( $d_{50}=0.29\text{mm}$ ).

As the discharge of the drain system for the experiments mentioned above was relatively small and invariable, we used a small wave flume of 13m long, 0.4m wide and 0.4m deep to investigate the dependence of the performance of a coastal drain system on discharge (Figure 5). Discharge of the drain system installed in the flume was variable by changing the engine speed and larger (maximum discharge was 1.6 l/sec/m).

Figure 5 Experimental set-up

## RESULTS AND DISCUSSION

Figure 6 is one of the experimental results under accretive wave conditions. The ordinate  $\Delta d$ , is the net change of the bottom level from the initial beach profile (Figure 7). Black circles in the figure denote the relative location of drain pipe from the shoreline (left vertical dashed line; another vertical dashed line indicates the wave breaking point). The profiles of upper part of the beach face could not be obtained by the surveys after 18 and 24 hours wave action because the berms of drained side developed too high to measure using our profiler. These results showed that the drain system enhanced accretion.

Figure 8 is one of the results under erosive wave conditions. The profiles of drained side after 18, 24 and 36 hours wave action show accretion on beach face in spite of the erosion in the rest side. This accretion ceased and turned into erosion as the erosion in the inshore region proceeded. However, the drainage reduced the erosion. Figure 9 shows the difference of shoreline change with time between the drained

Figure 6 Result under accretive wave condition

Figure 7 Definition of  $\Delta d$

Figure 8 Result under erosive wave condition

Figure 9 Changes of shoreline

side(full line) and the rest(dashed line). The ordinate is the distance of shoreline from a reference point on the back shore. This figure shows the retrogression speed of the became smaller by drainage.

These experimental results confirmed that a coastal drain system advances accretion of sediments on the beach face under accretive wave conditions and retards beach erosion under erosive wave conditions even if the discharge is not so large.

**Effect of location of the drain pipe**

Next, we consider the dependence of performance of a coastal drain system on the location of the drain pipe.

Figure 10 shows the comparisons of beach changes between drained side and the rest due to twelve hours accretive wave action. The best results were obtained when the drain pipe was installed in the seaward of the shoreline.

Figure 11 is a result of twelve hours erosive wave action. In this figure, there was no discernible difference between the two beach profiles. However, the difference became discernible after twenty-four hours wave action(Figure 12). This result also shows that seaward of a shoreline is the best to install. As we quitted the experiment for the case of landward installation after eighteen hours elapsed, results of two locations were depicted in Figure 12. Examination of the result after eighteen hours wave action did not affect the above conclusion.

When the system was installed at a shoreline or somewhere landward of beach face, we were impressed to see visually the infiltration of runup waves into the beach and sheet-like sediments left and piled up on a berm for accretive wave conditions. For erosive wave conditions, however, the erosion of inshore zone was retarded most for the cases of seaward installation.

Figure 10 Comparison of beach change among three locations of drain pipe after 12 hours accretive wave action

Figure 11 Comparison of beach change among three locations of drain pipe after 12 hours wave action

Figure 12 Comparison of beach change among two locations of drain pipe after 24 hours wave action

### Effect of discharge

As the discharge of the drain system for the experiments mentioned so far could not be changed, we used a small wave flume to investigate the dependence of the performance on discharge. Discharge of the drain system installed in the flume was controllable by changing the engine speed and the maximum discharge was 1.6 l/sec/m. As the discharge increases, the system becomes effective even for storm wave conditions. Figure 13 is an example of such cases. Figure 13 (a) shows the change of beach profile when the drain system was not operated. Just seaside part from the shoreline and offshore part were eroded and sediments from both parts formed a bar. When the discharge was 0.4 l/sec/m, there was no erosion of the part just seaside of the shoreline (b). For the case of 0.7 l/sec/m discharge, accretion of sediments in the inshore area resulted on a large scale after two hours' wave action. Observations of the sediment motion showed that a large amount of suspended sediments of the offshore zone moved toward the shore and a bar which was formed at the same location as the cases (a) and (b) in early stage grew and migrated to the shore with time.

The function of a coastal drain system has been regarded as the reduction of sediments which are carried away by backwash than are brought to the beach face by uprush. It is because drainage lowers the water table and intensifies downward percolation of wave runup which lessens water runs down than runs up.

However, our results revealed the idea that, when a shoreward flow induced by the drain system overcame the wave induced flow component to offshore like undertows, the system became effective even under erosive wave conditions without the coastal drain system. In any case, the shoreward flow seemed to play an important part when a drain pipe is buried in seaside area of a shoreline.

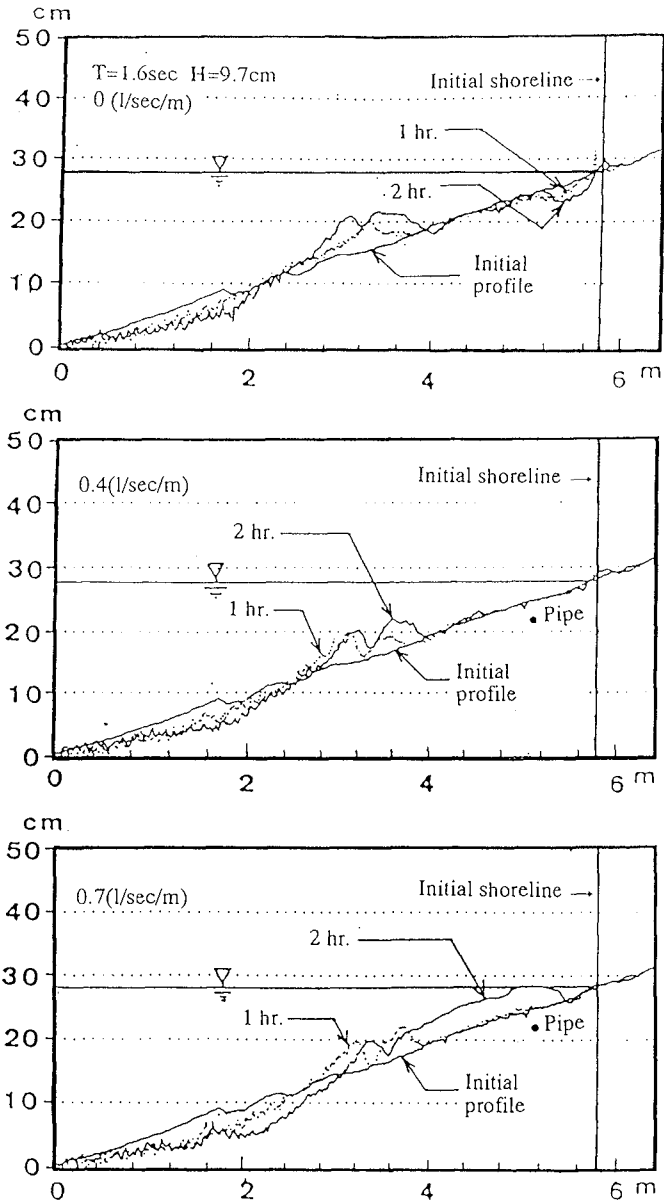

Figure 13 Changes of beach profile with discharge

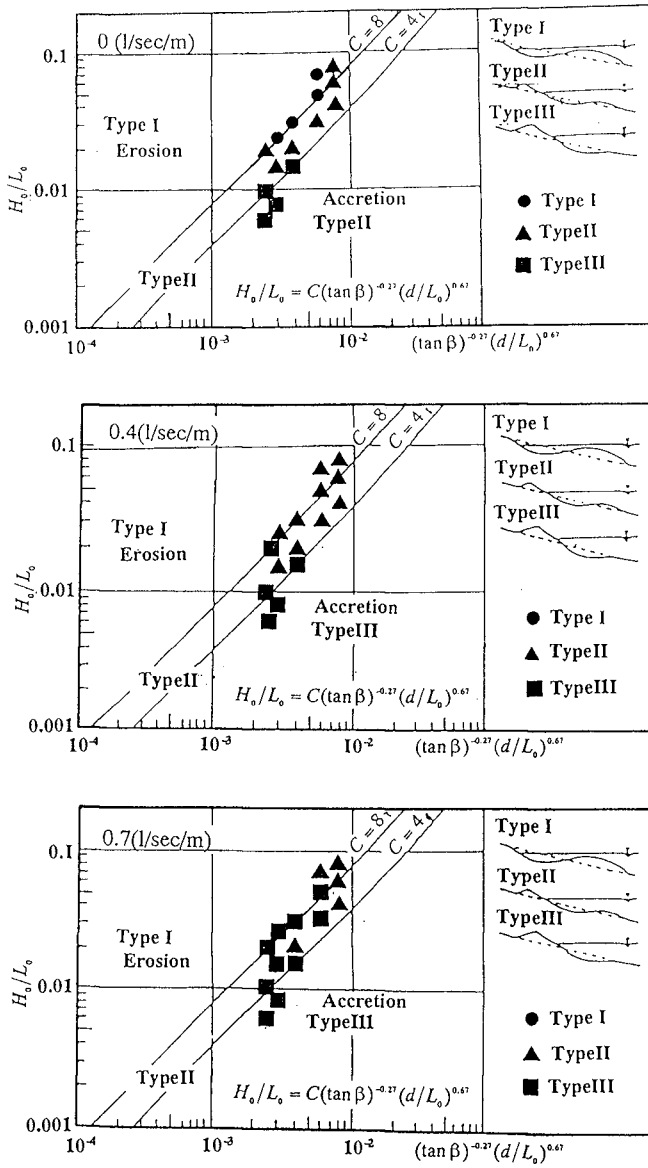

Figure 14 Change of beach type with discharge

Figure 14 shows the change of classified beach profiles with discharge. We can see that some of Type I profiles changed into Type III as the discharge increased. This shows that the coastal drain system has a potential ability to coastal erosion control.

### CONCLUSION

The performance, function and optimum location to install of a coastal drain system was investigated experimentally.

From the experimental results, it was confirmed that a coastal drain system advances accretion of sediments on the beachface for accretive wave conditions and retards beach erosion for erosive wave conditions.

Comparisons of the performance among three installation locations showed that seaward area of a shoreline was most appropriate for the installation.

As the discharge increases, the system becomes effective even for storm wave conditions.

The flow toward shore induced by drainage in the surf zone carried suspended sediments and migrated a bar toward the beach face and seemed to play the most important role.

## CHAPTER 187

### WAVE BREAKING AND INDUCED NEARSHORE CIRCULATIONS

Ole R. Sørensen †, Hemming A. Schäffer†, Per A. Madsen†, and Rolf Deigaard‡

#### ABSTRACT

Wave breaking and wave induced currents are studied in two horizontal dimensions. The wave-current motion is modelled using a set of Boussinesq type equations including the effects of wave breaking and runup. This is done without the traditional splitting of the phenomenon into a wave problem and a current problem. Wave breaking is included using the surface roller concept and runup is simulated by use of a modified slot-technique. In the environment of a plane sloping beach two different situations are studied. One is the case of a rip channel and the other concerns a detached breakwater parallel to the shoreline. In both situations wave driven currents are generated and circulation cells appear. This and many other nearshore physical phenomena are described qualitatively correct in the simulations.

#### 1. INTRODUCTION

State of the art models for wave driven currents are based on a splitting of the phenomenon into a linear wave problem, described e.g. by the mild-slope equation, and a current problem, described by depth-integrated flow equations including radiation stress. Wave-current interaction effects such as current refraction and wave blocking may be included in these systems by successive and iterative model executions.

A more direct approach to the problem would be the use of a time domain Boussinesq model which automatically includes the combined effects of wave-wave and wave-current interaction in shallow water without the need for explicit formulations of the radiation stress. In the present work this direct approach is used in the study of wave-induced current phenomena in two horizontal dimensions.

The drawback of traditional Boussinesq models is that they cannot reproduce the effects of wave breaking. This precludes the modelling of surf conditions and thus the primary cause of wave driven currents. Prüser (1991) and Kabling and Sato (1993) have modelled the effects of wave breaking by

**Figure 1** Cross-section and components of assumed velocity profile of a breaking wave with a surface roller.

including eddy viscosity terms in the equations. In general this approach tends to smear out the effects of breaking over the whole wave cycle. Thus basic physical phenomena like, for example, the pronounced vertical asymmetry in breaking waves may not be reproduced.

Schäffer et al. (1992, 1993) incorporated wave breaking in a Boussinesq model by assuming a redistribution of momentum as a surface roller develops, taking the roller to be a passive bulk of water moving with the wave celerity. Accordingly, the vertical distribution of the horizontal velocity was approximated by the simple profile shown in Fig. 1. This was originally suggested by Svendsen (1984). Based on the idea of Deigaard (1989) the surface rollers were identified by a simple geometrical method. Despite the rather simple approach the results for e.g. wave height decay and set-up were promising. This work continues in two directions. One is confined to cross-shore processes (Madsen et al., 1994) while the other (present paper) deals with obliquely incident waves and wave induced circulations.

A number of coastal wave phenomena, such as the generation of infragravity waves, are sensitive to the conditions at the shoreline. For example, a natural beach tends to reflect most energy at low frequencies, while energy in the high frequency range is almost fully dissipated. Reproducing this as well as many other physical phenomena in a numerical model requires a runup condition allowing for a moving boundary. In the present model the formulation of such a shoreline boundary condition is based on a modified version of the slot-technique described by Tao (1983). This method is described in Madsen et al. (1994).

## 2. WAVE BREAKING AND RUNUP IN A BOUSSINESQ MODEL

### 2.1. Governing equations

Assuming the simplified velocity profile shown in Fig. 1 to be valid in case of wave breaking, the following modified version of the Boussinesq equations appear

$$\frac{\partial p}{\partial t} + \frac{\partial}{\partial x} \left( \frac{p^2}{d} \right) + \frac{\partial}{\partial y} \left( \frac{pq}{d} \right) + \frac{\partial R_{xx}}{\partial x} + \frac{\partial R_{xy}}{\partial y} + gd \frac{\partial \eta}{\partial x} + \psi_1 + \frac{\tau_x}{\rho} = 0 \quad (1a)$$

$$\frac{\partial q}{\partial t} + \frac{\partial}{\partial y} \left( \frac{q^2}{d} \right) + \frac{\partial}{\partial x} \left( \frac{pq}{d} \right) + \frac{\partial R_{yy}}{\partial y} + \frac{\partial R_{xy}}{\partial x} + gd \frac{\partial \eta}{\partial y} + \psi_2 + \frac{\tau_y}{\rho} = 0 \quad (1b)$$

Here  $(p, q)$  is the depth integrated velocity in the Cartesian coordinate system  $(x, y)$ ,  $d = h + \eta$  is the instantaneous depth and  $\eta$  is the surface elevation. The definition of the surface roller terms are

$$R_{xx} \equiv \delta \frac{(c_x - \frac{p}{d})^2}{1 - \frac{\delta}{d}} \quad (2a)$$

$$R_{xy} \equiv \delta \frac{(c_x - \frac{p}{d})(c_y - \frac{q}{d})}{1 - \frac{\delta}{d}} \quad (2b)$$

$$R_{yy} \equiv \delta \frac{(c_y - \frac{q}{d})^2}{1 - \frac{\delta}{d}} \quad (2c)$$

as derived by Schäffer et al. (1992, 1993). Here  $\delta = \delta(x, y, t)$  is the thickness of the surface roller determined in a heuristic geometrical way as given below. Components of the wave celerity are denoted  $c_x$  and  $c_y$ .

The terms denoted  $\psi$  are dispersive Boussinesq type terms which in shallow water may be taken from Peregrine (1967). Here we use the version derived by Madsen et al. (1991) and Madsen and Sørensen (1992):

$$\begin{aligned} \psi_1 \equiv & - \left( B + \frac{1}{3} \right) h^2 \left( \frac{\partial^3 p}{\partial x^2 \partial t} + \frac{\partial^3 q}{\partial x \partial y \partial t} \right) - Bgh^3 \left( \frac{\partial^3 \eta}{\partial x^3} + \frac{\partial^3 \eta}{\partial x \partial y^2} \right) \\ & - h \frac{\partial h}{\partial x} \left( \frac{1}{3} \frac{\partial^2 p}{\partial x \partial t} + \frac{1}{6} \frac{\partial^2 q}{\partial y \partial t} + 2Bgh \frac{\partial^2 \eta}{\partial x^2} + Bgh \frac{\partial^2 \eta}{\partial y^2} \right) \\ & - h \frac{\partial h}{\partial y} \left( \frac{1}{6} \frac{\partial^2 q}{\partial x \partial t} + Bgh \frac{\partial^2 \eta}{\partial x \partial y} \right) \end{aligned} \quad (3a)$$

$$\begin{aligned} \psi_2 \equiv & - \left( B + \frac{1}{3} \right) h^2 \left( \frac{\partial^3 q}{\partial y^2 \partial t} + \frac{\partial^3 p}{\partial x \partial y \partial t} \right) - Bgh^3 \left( \frac{\partial^3 \eta}{\partial y^3} + \frac{\partial^3 \eta}{\partial x^2 \partial y} \right) \\ & - h \frac{\partial h}{\partial y} \left( \frac{1}{3} \frac{\partial^2 q}{\partial y \partial t} + \frac{1}{6} \frac{\partial^2 p}{\partial x \partial t} + Bgh \frac{\partial^2 \eta}{\partial x^2} + 2Bgh \frac{\partial^2 \eta}{\partial y^2} \right) \\ & - h \frac{\partial h}{\partial x} \left( \frac{1}{6} \frac{\partial^2 p}{\partial y \partial t} + Bgh \frac{\partial^2 \eta}{\partial x \partial y} \right) \end{aligned} \quad (3b)$$

as valid for a wider range of water depths using  $B = 1/15$ .

Bottom friction is modelled using

$$(\tau_x, \tau_y) \equiv \rho \frac{\sqrt{p^2 + q^2}}{C^2 d^2} (p, q) \quad (4)$$

where  $C = Md^{1/6}$  is the Chezy resistance ( $m^{1/2}/s$ ),  $M$  being the Manning number. This formulation is very simplified and does not represent the effect of turbulent interaction between oscillatory boundary layers and the mean flow.

The equation for conservation of mass is unchanged

$$\frac{\partial \eta}{\partial t} + \frac{\partial p}{\partial x} + \frac{\partial q}{\partial y} = 0 \quad (5)$$

## 2.2. Determination of the surface roller

The determination of the surface roller  $\delta(x, y, t)$  (see Fig. 1) is made as described in detail by Schäffer et al. (1992) and summarized below, beginning with the case of only one horizontal dimension.

Breaking sets in when and where the local slope exceeds a certain value  $\tan \phi_B$  and the actual point is taken as the instantaneous toe of a surface roller. At the given instant, the roller is then taken to be constituted by the water above the tangent of angle  $\phi_B$  starting at the roller toe and going in the direction opposite of wave propagation. After incipient breaking the procedure is the same except now decreasing angles  $\phi = \phi(t)$  are used in place of  $\phi_B$ . The system keeps track on the age of each surface roller and applies a value given by

$$\tan \phi(t) = \tan \phi_0 + (\tan \phi_B - \tan \phi_0) \exp \left[ -\ln 2 \frac{t - t_B}{t_{1/2}} \right] \quad (6)$$

Here  $\phi_0$  is the terminal value of  $\phi(t)$ ,  $t_B$  is the time of incipient breaking and  $t_{1/2}$  is the half time for  $\tan \phi(t)$ . The following values were used in all the results presented below:  $\phi_B = 20^\circ$ ,  $\phi_0 = 10^\circ$  and  $t_{1/2} = T/10$  where  $T$  is a typical period of the waves. After the determination of the surface roller in each time step,  $\delta$  is multiplied by a shape factor  $f_\delta$  prior to the inclusion in the governing equations. A value of  $f_\delta = 2$  was used.

In two horizontal dimensions the toe of the roller becomes a curve instead of a single point and the tangent becomes a set of generating lines determined by the instantaneous local angle  $\phi(t)$ . Whereas  $\phi(t)$  in the one-dimensional case is constant within each roller, it is allowed to have a lateral variation in the two-dimensional case. This lateral variation of  $\phi(t)$  within each surface roller must be allowed since, for example, when oblique regular waves break on an alongshore uniform beach both the initial and the final stage of the breaking process will be represented within the same roller. The lateral variation of  $\phi(t)$  is allowed for by keeping track on the surface roller age along the orthogonal to the roller toe curve. Thus, between each pair of generating line used for the roller determination,  $\phi(t)$  decays according to (6).

## 2.3. Solution technique

The differential equations are discretized using a time-centered implicit scheme with variables defined on a space-staggered rectangular grid. The method is based on the Alternating Direction Implicit algorithm. For more details of the solution procedure reference is made to Abbott et al. (1978, 1981, 1984), McCowan (1978, 1984) and Madsen et al. (1991, 1992).

The finite-difference approximation of the spatial derivatives is generally a straight-forward mid-centering. However, in the present work we have treated the nonlinear convective terms somewhat differently. The use of high-order central schemes for the discretization of convective terms is known to introduce non-physical oscillations in regions with large gradients of the convected variable. Typically these appear around corners of structures e.g. at the tip of

**Figure 2** Beach profiles for the rip channel test. (—): along a plane beach section and (- - -): along the rip channel.

a breakwater, in regions of strong wave-induced circulations, and in the bore-like stage in the inner surf zone. The classical first-order upwinding scheme is non-oscillatory, but introduces an unacceptable artificial diffusion. Higher-order upwinding schemes significantly reduce this diffusion, but still overshoots and undershoots may occur in the solution.

A number of oscillation-free schemes have been proposed in the literature, especially within the field of compressible flows with strong shocks. A disadvantage of these schemes is that they increase the computational cost significantly. For this reason a more simple approach has been used here: a first-order upwinding scheme is applied in sharply varying regions, that is in regions where the depth-integrated velocity is non-monotonic, and elsewhere second-order (quadratic) upwinding is applied.

### 3. NUMERICAL SIMULATIONS

In principle, the model can be used for a wide range of coastal phenomena. However, since the inclusion of wave breaking is more or less based on the spilling-breaker assumption, it is primarily suited for mild slopes and rather steep waves.

We have chosen two different situations with waves normally incident on a plane sloping beach but with some alongshore non-uniformity to trigger nearshore circulation. In the first example a rip channel is present while the other concerns a detached breakwater parallel to the shoreline. In both examples the bathymetry has a crossshore line of symmetry. In case of normally incident unidirectional waves the numerical computation was only made in half of the region in question. This reduced the computational cost, but precluded possible instabilities of currents along the line of symmetry.

#### 3.1. A plane beach with a rip channel

The first example is chosen according to laboratory experiments reported by Hamm (1992). The wave basin was 30m by 30m and the bathymetry was a plane sloping beach of 1:30 with a rip channel excavated along the centerline. The profiles of the rip channel and the plane beach is shown in Fig. 2. Two of

**Figure 3** Birds view of the free surface elevation for the rip channel case with regular waves. The surface rollers are shown in white.

Hamm's test cases were modelled numerically. In the first test the waves were regular with a period of 1.25s and a wave height of 0.07m and unidirectional with normal incidence. In the second test the incident waves were multidirectional and irregular and sampled from a JONSWAP spectrum with a peak period of 1.25s and a significant wave height of 0.07m and with a directional spreading corresponding to a  $\cos^6 \theta$ -distribution. In both cases a Manning number of  $72\text{m}^{1/3}/\text{s}$  was used in the bed friction term. The grid spacing was 0.05m and the time step 0.01s.

For the regular-wave case a birds view of the surface elevation (in a sub-domain) is shown in Fig. 3. The surface rollers are shown in white. Due to the increased depth and due to depth refraction by the rip channel incipient breaking occurs comparatively close to shore along the centerline. Here the setup is quite small and the larger setup appearing away from the rip channel gives an alongshore gradient in the mean water surface forcing a current towards the centerline. Here the flows from the two sides join to form a rip current and two symmetrical circulation cells appear.

The effect of the rip current on the wave height counteracts the effect of depth refraction and hence incipient breaking starts locally at the centerline. The rip current also causes a small local oscillation in the wave crest occurring at the same place. These phenomena also show up in a video of the experiment kindly supplied by Hamm.

A vector plot of the depth-integrated velocity averaged over one wave period is shown in Fig. 4. A subdomain is shown in order to focus one of the circulation cells which has developed. A pronounced rip current is seen along the centerline of the bathymetry i.e. at the top of the figure.

Figure 5 shows the cross-shore variation of the rip current computed as the time-average of the velocity below the roller,  $U_0$ . For reasons of symmetry the rip current was bound to be directed exactly perpendicular to the shore. In Hamm's experiments the measured rip current showed a significant deviation from this direction. It is unclear whether this was due to imperfections in the supposedly symmetrical experiment or if instabilities of the rip current could

**Figure 4** Depth-integrated velocity for the situation shown in Fig. 3 focusing on a circulation cell.

**Figure 5** Rip current along the rip channel for the regular-wave case.

be responsible. With regard to the order of magnitude of the rip current speed, agreement was found between the numerical simulation and the experimental results.

Figure 6a shows the wave height at some distance from the rip channel where the beach is a plane slope. A similar plot but along the excavated beach at the centerline is shown in Fig. 6b. The measurements of Hamm are included for comparison and the agreement is quite good. The large variation of the rip

**Figure 6** Comparison of the cross-shore wave height variation for the regular wave case of the rip channel case a) along a plane beach section and b) along the rip channel. (—): numerical simulation, (o): measurements by Hamm (1992).

**Figure 7** As Fig. 3, but for the case of irregular multidirectional waves.

current (see Fig. 5) is seen to cause a pronounced increase in the wave height in Fig. 6b.

Figure 7 shows a birds view of the surface elevation for the multidirectional irregular-wave case. The duration of this simulation was too short to give confidential statistics precluding comparison of significant wave height and average velocities with the experimental values.

### 3.2. *A plane beach with a detached breakwater*

The second example concerns a plane sloping beach of 1:50 with a 300m long detached breakwater placed at a still water depth of 6m i.e. 300m from the shore. Regular, unidirectional waves of normal incidence, a period of 8s and a wave height of 2m were generated at a depth of 10m. The computational domain extended 700m offshore and 600m alongshore from the line of symmetry and the seaward side of the breakwater was treated as land. The grid spacing was 1m and the time step was 0.08s. Bed friction was modelled using a Manning number of  $32\text{m}^{1/3}/\text{s}$ .

A birds view of the elevation is shown in Fig. 8. Again, surface rollers are shown in white. The diffraction around the breakwater gives the expected oscillations in the wave height along the wave crests, see Fig. 9 for the wave height variation. This further results in scattered incipient breaking, but the surface rollers quickly merge extending the breaking process to cover the long crested wave. In the simulation the roller disappears before the waves reach the shore. This is an unwanted side effect of a spatial smoothing which for reasons of stability was applied in the vicinity of the swash zone. Note the nonlinear cross-wave pattern close to the shore in lee of the breakwater.

The depth-integrated velocity averaged over one wave period is shown in Fig. 10. The maximum current speed behind the breakwater is approximately 0.7m/s and it occurs about 80m from the shoreline near the edge of the breakwater. In addition to the expected circulation cell, a local phenomenon resembling thin rip currents appears further away from the breakwater. This is more pronounced in Fig. 11 showing the time-average of the velocity below the roller,  $(U_0, V_0)$ . This velocity field includes the depth averaged undertow. The thin rip currents may be caused by the lateral variation of the wave height as created by the diffraction around the breakwater. However, this remains to be studied further.

### ACKNOWLEDGEMENT

This work has been financed mainly by the Danish National Research Foundation and partly by the Commission of the European Communities, Directorate General for Science, Research, and Development under MAST contract No. MAS2-CT92-0027.

## CHAPTER 188

### ACCURACY AND APPLICABILITY OF THE SPM LONGSHORE TRANSPORT FORMULA

by

J S SCHOONEES\* and A K THERON\*

#### ABSTRACT

The ability to predict the time-averaged longshore sediment transport rate accurately is essential for many coastal engineering applications. Because the longshore transport formula in the Shore Protection Manual (SPM; US Army, Corps of Engineers, 1984) is possibly the most widely used, it is important to know its accuracy. The aim of this paper is therefore to investigate the accuracy and applicability of this formula (the SPM formula). In addition, a number of variations to this formula are presented; these are also tested against a comprehensive data set. Finally, the SPM formula is re-calibrated and guidance is given regarding the use of this formula for coarse bed material.

#### INTRODUCTION

The ability to predict the time-averaged longshore sediment transport rate accurately is essential for the design of breakwaters at harbour entrances, navigation channels and dredging requirements, beach improvement schemes incorporating groynes, detached breakwaters and beach fill as well as for the determination of the stability of inlets and estuaries.

Because the longshore transport formula in the Shore Protection Manual (SPM; US Army, Corps of Engineers, 1984) is possibly the most widely used, it is important to know its accuracy. The aim of this paper is therefore to investigate the accuracy and applicability of this formula (the SPM formula). In addition, a number of variations to this formula have been presented; these will also be tested against a comprehensive data set. Finally, the SPM formula is re-calibrated and guidance is given regarding the use of this formula for coarse bed material.

---

\* Research Engineers, CSIR, P O Box 320, Stellenbosch, 7599, South Africa

The data considered in this paper are only for particulate (non-cohesive) sediment (including sand, gravel and shingle) being transported alongshore from the swash zone across the surf zone to deep water. Only bulk (total rate across the shore) and not local transport rates are considered. These bulk rates include both the bedload and suspended load. Only field data are used because of possible scale effects in laboratory investigations and/or because regular waves were used. Furthermore, the ultimate aim is to be able to predict longshore transport accurately in the field (Komar, 1988).

The data are not meant to provide average long-term data at (a) specific site(s). It is rather assumed that if a longshore transport formula is capable of accurately predicting transport rates for the data sets given herein, it can be used with reasonable confidence at similar sites to determine the long-term longshore sediment budget if representative wave and other input parameters are available. It would of course be even better to have site-specific calibration data before calculating average long-term transport rates.

Previous studies where a few longshore transport formulae have been tested against data are Swart (1976), Fleming *et al.* (1986) and Kamphuis *et al.* (1986). Schoonees (1994) evaluated 51 formulae against an extensive data base. This paper reports the findings of the above-mentioned study with regard to the SPM formula and variations thereof. Two of the most important papers on the development of the SPM formula are Komar and Inman (1970) and Komar (1988). The latter study in which the dependency of the SPM formula on sediment grain size, beach slope and wave steepness was investigated, is partially revised here with a bigger data base.

## DATA

Schoonees and Theron (1993) compiled and reviewed almost all the available field data on longshore transport. They used a point rating system to assess the quality of the data in detail. Two data sets, namely Data Sets 1 and 2, were extracted from the data contained in Schoonees and Theron (1993) together with their point ratings.

Data Set 1 containing 123 data points, consists of data where all the required parameters are available. Table 1 summarizes this data set and gives the point ratings in percentages according to Schoonees and Theron (1993). Data Set 2 includes Data Set 1 and contains other measurements totalling 240 data points. These other measurements are usually where only values of the energy flux factor, the longshore transport rate and the median grain size are available. Table 2 lists the sources of Data Set 2.

It is important to note that the data ranges of the particular Data Set 1 are:

0,058	<	$H_{bs}$ (m)	<	3,400
2,32	<	$T_p$ (s)	<	16,60
0,30	<	$\theta_b$ ( $^\circ$ )	<	35,00
0,0070 (=1/142,9)	<	beach slope	<	0,1380 (=1/7,2)

0,154	<	$D_{50}$ (mm)	<	15,000
600	<	$S$ ( $m^3/year$ )	<	14 793 000

From the above values it is clear that the data ranges of this data set (and therefore also Data Set 2) are quite wide. Most conditions encountered on natural beaches are covered and the data were collected on beaches from a variety of sites from around the world. These give credibility to the conclusions drawn in this comparison with data.

**FORMULAE**

One of the earliest longshore transport formulae and perhaps the best-known method, the **SPM formula** (SPM = Shore Protection Manual) is given in US Army, Corps of Engineers (1984):

$$S = K_1 P_{ls} \quad (m^3/yr)$$

- where  $K_1 = 1289 (m^4/(W.yr))$  for prototype beaches
- $P_{ls} =$  wave energy flux factor using the significant wave height in the calculation. (W/m)
- $= E_b n_b C_b \sin \theta_b \cos \theta_b$

- with  $E =$  wave energy density
- $= \rho g H_{bs}^2 / 8$
- $\rho =$  density of sea water ( $kg/m^3$ )
- $g =$  gravitational acceleration ( $m/s^2$ )
- $H_{bs} =$  significant breaker wave height (m)
- $n_b = 0,5 (1 + (4\pi d_b / L_b) / (\sinh 4\pi d_b / L_b))$

- and  $d_b =$  breaker depth (m)
- $L_b =$  wavelength at the breaker line (m)
- $C_b =$  wave celerity at the breaker line (m/s)
- $= (L_b / T_p)$

- and  $T_p =$  peak wave period
- $\theta_b =$  wave incidence angle at the breaker line

An alternative formulation of the SPM is:

$$I = K_s P_{ls}$$

$$= K_r P_{lr}$$

with  $I =$  immersed weight longshore transport rate  
 $P_r =$  energy flux factor using the root-mean square breaker height  
 where  $K_s = 0,5$  (0,78) = 0,39 if the significant breaker height is used in  $P_s$   
 $K_r = 0,78$  if the root-mean-square breaker height ( $H_{brms}$ ) is used in  $P_r$

Development of the SPM formula was done, among others, by the Scripps Institute of Oceanography (1947), Watts (1953), Caldwell (1956), Inman and Bagnold (1963), Komar (1969), Komar and Inman (1970) and Komar (1988).

Swart (1976) adapted the coefficient  $K_1 = 1289$  to be a function of the median grain size ( $D_{50}$ ). His version of the SPM formula which appears to differ from the SPM formula given above because of several implications, is

$$S = K_2 P_{ls} \quad (m^3/yr)$$

where  $K_2 = 1876 \log_{10} (0,00146 / D_{50})$   
 ( $D_{50}$  in m)

This equation together with a relationship proposed by Bruno *et al* (1981) will be shown later. Komar (1988) maintained that there is no significant relationship between  $K_1$  and  $D_{50}$ . This issue will be discussed further based on all the data.

Kamphuis and Readshaw (1978) and Vitale (1981) investigated whether  $K_1$  is a function of the surf similarity parameter (or Iribarren number)  $\xi_b$ :

$$\xi_b = \frac{\tan \alpha}{(H_{brms} / L_o)^{0,5}}$$

where  $\tan \alpha =$  bottom slope in the surf zone

$$H_{brms} = H_{bs} / \sqrt{2}$$

$$L_o = \text{deep-sea wavelength}$$

Vitale (1981) used a mean wave height (measured in relatively deep water) instead of  $H_{brms}$ . To prevent the need for calculation of the wave height at the breaker line, it was decided to use the relationship proposed by Kamphuis and Readshaw (1978) and Readshaw (1979), namely:

$$K_p' = 0,7 \xi_b \quad \text{for } 0,4 < \xi_b < 1,4 \\ \text{(say for } \xi_b < 1,4)$$

$$1,24 \quad \text{for} \quad \xi_b \geq 1,4$$

with  $Q_s$  (kg/s) =  $K_p' P_{ls} / 2g$

and  $S$  =  $\frac{31\,557\,600 Q_s}{(1-p) \rho_s} \quad (m^3/yr)$

- where  $p$  = porosity of the sediment (assumed to be 0,4 for sand)
- $\rho_s$  = density of the sediment (usually 2650 kg/m<sup>3</sup> for sand)
- and 31 557 600 = number of seconds in one year

**Bailard** (1981) generalized the Bagnold (1963, 1966) energetics-based stream model. After integrating the local time-averaged longshore transport rate, Bailard (1984) obtained the following alternative equation for  $K_1$ , (called  $K_3$ ) valid for both model and prototype applications:

$$K_3 = 0,05 + 2,6 \sin^2 2\theta_b + 0,007 u_{mb} / w$$

- where  $w$  = fall velocity of the sediment grains
- $u_{mb}$  = 0,5  $\gamma (g d_b)^{0,5}$
- and  $\gamma$  = breaker index = 0,8

Bailard (1985) adds another term the equation for  $K_3$ , namely,  $0,0096 \tan \alpha$ . However, choosing a very high value of the beach slope ( $\tan \alpha$ ) of 0,2, it is clear that the estimated maximum value of this term is about 0,0019. For  $\tan \alpha = 0,04$ , a typical value, the term is only 0,00038. Because its contribution to  $K_3$  is negligible, this term was omitted. Furthermore:

$$I = 0,5 K_3 P_{ls}$$

and  $S = \frac{31\,557\,600 I}{(\rho_s - \rho) g (1 - p)} \quad (m^3/yr)$

Watts (1953) empirically related the longshore transport rate to the wave energy flux factor. The **Watts formula** in SI units is:

$$S = 2223 P_{ls}^{0,9}$$

Similarly, **Caldwell** (1956) obtained his formula (given here in SI units):

$$S = 2505 P_{ls}^{0,8} \quad (m^3/yr)$$

## EVALUATION OF FORMULAE

### Method of Testing

The results of the testing of the formulae will be presented in a number of ways in order to facilitate interpretation. These are:

- \* A plot of the predicted longshore transport rates ( $S_p$ ) versus the measured rates ( $S_m$ ).
- \* The relative standard error of estimate ( $\sigma$ ) was calculated (Kamphuis, *et al*, 1986):

$$\sigma = \sqrt{\sum_{i=1}^n \left[ \frac{(\log S_{p,i} - \log S_{m,i})^2}{n-1} \right]^{0.5}}$$

where  $n$  = number of data points  
 $i$  = number of the particular data point

- \* The discrepancy ratio ( $r_d$ ) (Van Rijn, 1984) and its distribution were determined.

$$r_{d,i} = S_{p,i} / S_{m,i}$$

A histogram of the percentage occurrence versus  $r_d$  gives this distribution.

(The residuals ( $e_i = S_{m,i} - S_{p,i}$ ) were computed and plotted against  $S_p$  to check whether there is a systematic trend in the residuals, or not - these are not shown. Refer to Schoonees (1994)).

### Results

Table 3 lists the relative standard error of estimate ( $\sigma$ ) and the percentage occurrence of the discrepancy ratio ( $r_d$ ) within certain limits for the formulae. For example, the percentage of the predicted transport rates for which the discrepancy ratio falls between 0,5 and 2 or between 0,25 and 4 can be read from this table.

Figures 1 and 2 show the predicted longshore transport rates ( $S_p$ ) versus the measured rates ( $S_m$ ) for the SPM and the SPM, Kamphuis and Readshaw formulae respectively. The histogram of the discrepancy ratios for the SPM, Kamphuis and Readshaw formula is contained in Figure 3. Refer to Schoonees (1994) for similar figures of the other formulae. Note that in these figures  $m^3/yr$  means  $m^3/yr$ .

### Discussion

A first impression when examining Figures 1 and 2 and Table 3 is that considerable scatter exists in the predicted longshore transport rates. Based on this particular data set, the SPM, Kamphuis and Readshaw formula gives the best answer of the six formulae over the full range of measured longshore transport rates ( $\sigma=0,515$ ;  $r_d$  between 0,5 and 2: 65,0%). Even so this formula tends to underpredict high transport rates (Figure 2). This is an area of concern because at a particular site, most

of the longshore transport occurs during a few storms so that it is important to predict high transport rates accurately.

It is interesting to note that the SPM formula, perhaps the best known and most used predictor, does not fare very well. Although one can argue that its poor performance at low transport rates (Figure 1) can be attributed to a lack of an incipient motion criterion, it is still clear that it over-predicts in the range  $1,5 \times 10^4 \text{ m}^3/\text{year}$  to  $1,5 \times 10^6 \text{ m}^3/\text{year}$ . What is, however, comforting is that for high transport rates ( $> 1,5 \times 10^6 \text{ m}^3/\text{year}$ ) the SPM predicts transport rates accurately. That is, for the few data points in this range. However, two of the oldest formulae, namely, the Caldwell and Watts methods, also do not have an incipient motion criterion but both appear to be more accurate than the SPM and the SPM and Swart formulae (compare  $\sigma=0,579$  (Caldwell) and  $0,685$  (Watts) to  $0,708$  (SPM) and  $0,720$  (SPM and Swart)). In fact, adapting the SPM formula for grain size (SPM and Swart method) caused a slight decrease in the accuracy of the predictions. The similar answers of these two predictors can, however, merely indicate that most of the data points were collected for grain sizes between  $0,2 \text{ mm}$  to  $0,4 \text{ mm}$  as indeed found by Schoonees and Theron (1993). In this grain size range the SPM and Swart formula gives very similar answers to the SPM formula.

It is interesting to note that the original SPM, Kamphuis and Readshaw formula was only calibrated against laboratory data and therefore no field data of Data Set 1 were used in its derivation. The second-best formula (Caldwell's) only used a few of the data points, especially when compared to the 41 points of Data Set 1 included in the calibration of the SPM formula.

#### FURTHER CALIBRATION OF THE SPM FORMULA

One can argue that the SPM formula is not applicable for coarse-grained sediment which are included in Data Set 1. In addition, the data points for which only  $S$  and  $P_b$  are available, should also be used.

Figure 4 shows the data in Data Set 2 with a distinction being made between fine - ( $D_{50} < 1 \text{ mm}$ ) and coarse-grained ( $D_{50} > 1 \text{ mm}$ ) sediment. It is clear from this figure that except for some minor overlap, two different populations of points are apparent. For the fine-grained sediment (206 data points) the best fit relationship is:

$$I = 0,20 P_b \quad (1)$$

$(R^2 = \text{coefficient of determination} = 0,72)$

Considerable scatter is evident. If the recommendation by Schoonees and Theron (1993) is followed whereby only data in their higher category (point rating 60% and better) is used (Tables 1 and 2), 46 data points are retained. Figure 5 illustrates the result while the equation is:

$$I = 0,41 P_b \quad (R^2 = 0,77) \quad (2)$$

or  $I = 0,82 P_r$  (i.e.  $K_r = 0,82$ )

Unfortunately, the scatter is not significantly reduced and the range of  $P_b$  values is much smaller. In comparing Equations 1 and 2, it is clear that the elimination of the lower quality data, more than doubled the value of  $K_r$ .  $K_r = 0,82$  is an increase of the value of 0,57 proposed by Komar (1988) based on 70 of the data points in Data Set 1. The value in the original formula is 0,78 which is derived from 41 data points (US Army, Corps of Engineers, 1984). Kraus *et al.* (1982) found  $K = 0,58$  based on their data and those of Komar (1969), which are 25 data points. It would of course be even better to have site-specific calibration data before calculating longshore transport rates. The foregoing illustrates the great uncertainties involved in using the SPM formula and in view of this we recommend that the SPM, Kamphuis and Readshaw formula preferably be used.

Both Swart (1976) and Bruno *et al.* (1981) presented relationships between  $K_s$  and  $D_{50}$ . Figure 6 shows these relationships together with the data having median grain sizes below or equal to 1 mm. From this figure it is clear that a single relationship between  $K_s$  and  $D_{50}$  will not explain all the scatter shown in Figures 4 and 6. The same applies if the settling velocity instead of the median grain size is used. Although this correlates with the finding of Komar (1988), the authors believe that a longshore transport formula must contain either  $D_{50}$  or the settling velocity. It is also evident from Figure 6 that neither of the relationships by Swart and Bruno *et al.* are generally valid. The relationship by Bruno *et al.* (1981) almost forms an upper envelope to the values.

Returning to Figure 4, a very approximate line through the coarse-grained sediment is:

$$I = 0,01 P_b \quad (R^2 = 0,11) \quad (3)$$

Because of the considerable scatter in the data and the very low  $R^2$ , this equation should only be used to obtain a rough order of magnitude of the longshore transport rate. For these coarse-grained data as well, no single relationship between  $K_s$  and  $D_{50}$  (figure not shown) will explain all the scatter shown in Figure 4. Clearly, further work is required. For example, an incipient motion criterion (see e.g. Chadwick, 1989, Brampton and Motyka, 1984 and Van Hijum and Pilarczyk, 1982) is necessary.

## CONCLUSIONS

The data ranges of Data Sets 1 and 2 are quite wide and as such, cover most conditions encountered on natural beaches.

Of the six formulae (SPM formula and variations thereof), tested against Data Set 1, the SPM, Kamphuis and Readshaw method fared the best. The standard error of estimate for this method was 0,515 while 65,0% of the time, the discrepancy ratio ( $r_d$ ) fell between 0,5 and 2.

By using only the data from Data Set 2 that fall in the higher (better) category of Schoonees and Theron (1993) - 46 data points -, the best fit relationship for sand ( $D_{50} < 1$  mm) is:

$$I = 0,41 P_{ls} \quad (R^2 = 0,77)$$

Unfortunately, significant scatter is still evident (Figure 5). It was also found that no single relationship between  $K_s$  and the median grain size (or the settling velocity) will explain all the scatter in the data. In view of the uncertainties involved in using the SPM formula it is recommended that the SPM, Kamphuis and Readshaw formula preferably be used.

For coarse grained sediment ( $D_{50} > 1$  mm) 34 data points were available which yielded an approximate relationship:

$$I = 0,01 P_{ls} \quad (R^2 = 0,11)$$

Because of the considerable scatter evident in Figure 4 and very low  $R^2$ , this equation should only be used to obtain an order of magnitude of the transport. Again, no single relationship between  $K_s$  and the median grain size (or settling velocity) will explain all the scatter in the data.

## CHAPTER 189

# FIELD VERIFICATION OF A NUMERICAL MODEL OF BEACH TOPOGRAPHY CHANGE DUE TO NEARSHORE CURRENTS, UNDERTOW AND WAVES

Takuzo Shimizu <sup>1</sup>, Masahito Tsuru <sup>1</sup> and Akira Watanabe <sup>2</sup>

### ABSTRACT

A practical method for estimating the undertow velocity and its direction is developed and verified on the basis of field measurement data. It is found that a simple vector addition of nearshore current and undertow gives a good approximation.

The actual bottom topography change during a year is simulated by the 3-D beach evolution model taking into account the cross-shore sediment transport due to waves and undertow as well as the transport due to nearshore currents. The results of both measurements and calculations show that the sediment transport due to nearshore current is predominant and the contribution of cross-shore sediment transports is cancelled for a long-term beach evolution.

### INTRODUCTION

The sediment transport due to nearshore currents plays a predominant roll on the long-term beach evolution and the contribution of cross-shore sediment transports due to waves and undertow is usually cancelled for a long period beyond approximately a year. In many cases for prediction of long-term beach topography changes due to construction of a coastal structure, only the sediment transport due to nearshore currents is taken into account. The shoreline model based on this concept is also widely used in practice. Therefore, the 3-D beach evolution model which treats only the sediment transport due to nearshore currents, can be regarded as an improved version of the shoreline model, which has

an advantage of predicting the spatial beach topography changes.

In recent years, we have applied the 3-D beach evolution model based on this concept to many practical problems and presented a few attempts to quantitatively demonstrate its field applicability through comparisons with the actual topographical changes around harbors (e.g. Shimizu et al., 1990). It is well known, on the other hand, that the offshoreward sediment transport due to undertow in the surf zone and the onshoreward sediment transport due to sheet flow movement outside the surf zone causes a considerable beach profile change and form a bar during the storm. Most of the previous studies on the undertow and its effects on beach profile changes have been conducted mainly through laboratory experiments and are not thoroughly discussed on the basis of field measurement data.

In this study, at first, we discuss the undertow velocity and its direction through comparisons between the field measurement data and the calculated nearshore currents and, then, discuss their practical estimation method. We also try to simulate the actual bottom topography changes during approximately a year by taking into account the cross-shore sediment transport due to waves and undertow as well as the sediment transport due to nearshore currents.

## FIELD INVESTIGATION

Fig. 1 shows the bottom topography of the investigation site and the calculation area which is 0.9km long in the alongshore direction and 1.0km long in the cross-shore direction with the grid spacing of 12.5m. The field investigation site is located at the end of a sandy pocket beach. The bottom slope is approximately 1/40. A part of the shore is bounded directly by the sea cliff, and the bottom slope is steep near the shoreline. The bottom contours are straight and parallel to the shoreline outside the harbor, and they extend offshoreward like a tongue around the harbor entrance owing to extreme accretion caused by nearshore currents. The seabed material is well-sorted fine sands in the nearshore region where the water depth is less than 10m, and the grain diameter is approximately 0.35mm.

The field observation was carried out over a period of approximately one month during the winter stormy season, in order to obtain the data for verification of the numerical models for estimation of nearshore waves and currents. At Points 1 to 4 with the water depth of about 5m, the mean currents including nearshore currents and undertow and principal wave direction were measured at the level of 0.7m above the bottom by using electro-magnetic current meters. At Points 2 and 4, nearshore waves were also measured by pressure sensors attached to the electro-magnetic current meters. The incident wave conditions were also measured at Point 0 with the water depth of 20m by using a combination of an ultrasonic wave gauge and an electro-magnetic current meter. Data were recorded with the sampling interval of 0.5 seconds during 10 minutes every 2 hours. The pressure fluctuations obtained by a pressure sensor were converted into water

Fig. 1 Bottom topography and calculation area of investigation site.

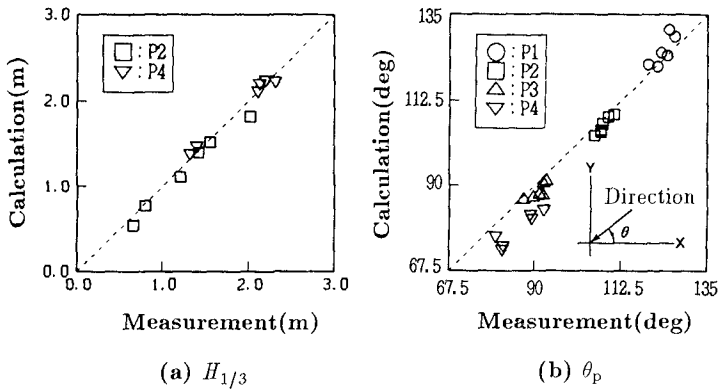

Fig. 2 Comparisons between the measured and the calculated significant wave heights and principal directions.

surface motion on the basis of the small amplitude wave theory. During the observation, storm waves greater than 3m in significant wave height attacked twice. The maximum significant wave height was 4.2m and its period was 9.6s.

## VERIFICATION OF WAVE MODEL

### The Employed Wave Model

The parabolic-type equation model proposed by Isobe(1987) is employed in this study to properly estimate the wave field around the harbor entrance where combined diffraction and refraction occur. This basic equation is derived from the mild slope equation and the energy dissipation term due to wave breaking is included. The parabolic-type equation model has advantages that much computational time can be saved owing to the forward stepping scheme, and then, treatment of multi-directional irregular waves is easy. Random waves are described as a superposition of component regular waves with different frequencies and directions.

In order to improve the accuracy of calculating the wave transformation for a wide range of propagation directions of component waves, a curvilinear coordinate system is introduced. In this model, the curvilinear coordinates are defined from the peak frequency and the peak direction of the directional wave spectrum. In a shadow region, additional wave rays are radiated from the tip of the breakwater. The applicabilities of the model to the actual wave field over complicated bottom topographies were verified through comparisons with field measurement data (Shimizu et al., 1992, 1994).

### Comparison of Wave Height and Direction

In order to compare the calculations with the measurements, the incident wave conditions measured at Point 0 are classified into three cases in accordance with the wave height level ( $H_{1/3}$  (P0):  $\sim 2.0\text{m}$ ,  $2.0 \sim 3.0\text{m}$ ,  $3.0\text{m} \sim$  ) and two cases of wave direction, the righthand side and the lefthand side directions to that perpendicular to the shoreline. For totally six cases of incident wave conditions, the mean values of significant wave height and principal direction were calculated at all measurement points. And these values were adopted as the field verification data. The numerical calculations were also conducted for the mean significant waves of these six cases, using the Bretschneider-Mitsuyasu frequency spectrum and the Mitsuyasu-type directional distribution function.

Fig. 2 (a) and (b) show the comparisons between the measured and the calculated significant wave heights and principal directions. The calculations of both significant wave height and principal direction by the parabolic-type equation model show fairly good agreements with the measurements.

## VERIFICATION OF UNDERTOW AND NEARSHORE CURRENT MODEL

**Field Observation Results**

Fig. 3 (a) shows an example of the comparisons between the measured steady component vectors of near-bottom velocity and the calculated nearshore current vectors under the same wave condition with the significant wave height of 3.5m. The bold vectors are measurements and illustrated in a different scale from the calculated vectors. In calculating the nearshore current field of random waves, the radiation stress is evaluated as for a regular wave with the equivalent wave energy and the principal direction.

During the storm, the wave-induced nearshore circulation develops around the harbor entrance behind the main breakwater. Extreme accretion around the harbor entrance is caused mainly by this nearshore circulation. Around the harbor entrance, the calculated nearshore current field satisfactorily reproduces the observed dominant nearshore circulation.

On the contrary, at Point 4 where there is no influence of diffraction due to breakwater, when the significant wave height becomes larger than 2m and

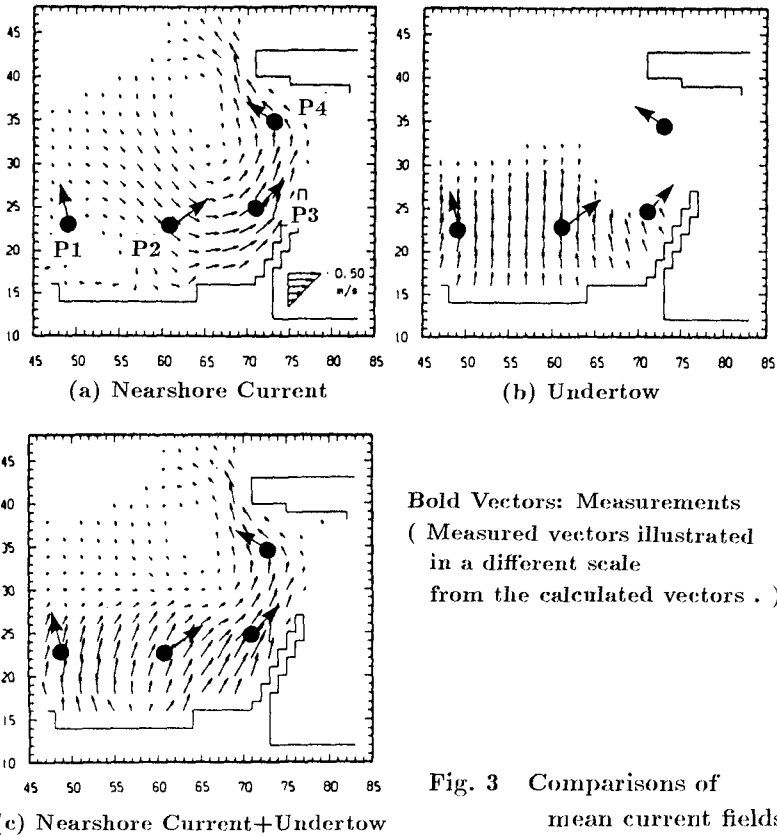

Fig. 3 Comparisons of mean current fields.

the measurement point is involved in the surf zone, the remarkable offshoreward mean currents occur and the velocity becomes larger than 0.3m/s. Even at Point 3 where the nearshore circulation occur, the mean current vector slightly inclines offshoreward. The sensors of the electro-magnetic current meters were installed at the level of 0.7m above the bottom and at the water depth of about 5m and, then, they were always located under the trough level. The observed offshoreward mean current, therefore, seems to be due to undertow.

**Estimation Method of Undertow**

The undertow velocity is estimated as the sum of the return flows compensating for the onshore mass flux due to breaking bores and due to irrotational wave motion and the Eulerian mass transport velocity. We adopt the following rough estimation of the undertow velocity due to breaking bores after Sato et al.(1988).

$$U_b = -A \frac{H^2}{d \cdot T} \tag{1}$$

where  $A$  is a nondimensional coefficient,  $H$  the wave height,  $d$  the water depth and  $T$  the wave period. For random waves, assuming that only breaking waves contribute to generation of return flow,  $H^2$  is replaced by the breaking wave energy  $E_b/(\rho g/8)$ .

$$\frac{E_b}{\rho g/8} = \int_{x_b}^{\infty} H^2 p(\xi) d\xi = H_{rms}^2 \cdot P_b \tag{2}$$

$$P_b = (1 + x_b^2) \exp(-x_b^2) \tag{3}$$

where  $x_b = H_b/H_{rms}$  and  $P_b$  is the probability of wave breaking which is estimated by assuming the Rayleigh distribution for individual waves. The root mean square wave height  $H_{rms}$  is estimated by not taking into account the wave breaking. The breaking wave Height  $H_b$  is evaluated by using the appropriate coefficient value, 0.14 in the wave breaker indices for regular waves proposed by Goda(1970). If the breaking wave energy estimated by this equation becomes larger than that estimated by the parabolic equation model with the additional term of energy dissipation due to wave breaking, the breaking wave energy is set to be the value estimated by the parabolic equation model.

In this study, it is assumed that the near-bottom mean current vector can be estimated by a simple vector addition of the nearshore current vector and the undertow vector after Svendsen and Lorenz(1989). The undertow vectors are given in the opposite direction of the local wave propagation.

**Comparison of Undertow Due to Breaking Bores**

Fig. 4 shows the relationship between the measured undertow velocity due to breaking bores  $U_b$  and the estimated values of  $(H^2/d \cdot T)$ , in order to calibrate the nondimensional coefficient  $A$ . The nearshore current vectors are given by the numerical calculations. The measured undertow velocity due to breaking bores  $\vec{U}_b$  is evaluated by extracting the calculated nearshore current vector  $\vec{U}_c$ , the calculated return flow vector due to irrotational wave motion  $\vec{U}_w$  and the calculated

Eulerian mass transport velocity  $\vec{U}_e$  from the measured steady component vector of near-bottom velocity variation  $\vec{U}_m$ .

$$\vec{U}_b = \vec{U}_m - \vec{U}_c - (\vec{U}_w + \vec{U}_e) \quad (4)$$

The appropriate value of nondimensional coefficient  $A$  is found to be 5.6 through comparisons of the calculations with the measurements. This result is the same as the value obtained by Sato et al.(1988).

Fig. 5 shows the examples of the calculated cross-shore distributions of the significant wave height  $H_{1/3}$ , the breaking wave energy  $E_b$  and the undertow velocity  $U$  under the incident wave conditions with the significant wave height of 2.6m and 3.5m. The calculation results show that the undertow velocity increases exponentially and has a peak in the surf zone. The calculated wave heights and undertow velocities agree well with the measurements at Point 4.

### Comparison of Mean Current

Fig. 3 (a) to (c) show the calculated mean current fields of nearshore current, undertow and the vector addition of both currents. Not only the nearshore circulation around the harbor entrance, but also the measured mean currents due to combined undertow and nearshore current are reproduced well by the simple vector addition. At Points 1 and 2 in the shadow region of the breakwater, the undertow velocity is small. At Points 3 and 4, on the other hand, where the incident waves directly attack, the undertow must be taken into account in order to properly estimate the mean current field during a storm.

Fig. 6 (a) and (b) show the comparisons between the measured and the calculated mean current velocities and between the measured and the calculated mean current directions at all measurement points. The open symbols indicate the calculations of only nearshore current, and the solid symbols indicate the calculations of a vector addition of nearshore current and undertow.

The calculations are the results conducted for the mean values of the incident significant waves observed at Point 0 for six cases in accordance with the incident wave height levels and the principal wave directions. The measurements are the mean values for six cases at each point. By a simple vector addition of nearshore current and undertow, both the calculated mean current velocity and its direction show fairly good agreements with the measured ones. The method for estimating the near-bottom mean current in the surf zone employed in this study is a simple and primitive, but it has enough accuracy for practical use.

## VERIFICATION OF BEACH EVOLUTION MODEL

In order to verify the field applicability of the 3-D beach evolution model. We tried to reproduce the long-term topography changes around the harbor entrance during a year. Before completion of the construction of breakwaters, the bottom contours are parallel, and after the completion, they stretched like a tongue along

Fig. 4 Relationships between the undertow velocity due to breaking bores  $U_b$  and  $(H^2/d \cdot T)$ .

Fig. 5 Distributions of  $H_{1/3}$ ,  $E_b$  and  $U$  (Undertow).

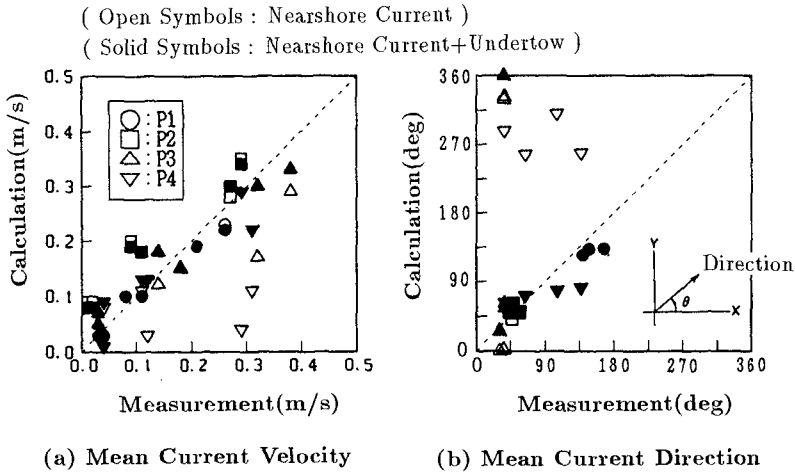

Fig. 6 Comparisons between the measured and the calculated mean current velocities and directions.

the sub-breakwater to the harbor entrance mainly owing to the nearshore circulation.

**Sediment Transport Formula**

The local sediment transport rate formula employed in this study is the formula proposed by Watanabe et al.(1986). The formula for local sediment transport rate under combined wave-current action is formulated so as to be consistent with previous studies on both longshore drift and cross-shore sediment transport. The transport rate  $\vec{q}$  is divided into  $\vec{q}_c$  due to mean currents and  $\vec{q}_w$  due to waves. These formulas are based on the power model concept and assume that the sediments set in motion by the excess shear stress under combined wave-current action are transported with both mean currents and wave motion into the respective directions.

$$\vec{q}_c = A_c(\tau - \tau_c)\vec{U}/\rho g \tag{5}$$

$$\vec{q}_w = A_w F_D(\tau - \tau_c)\vec{u}_b/\rho g \tag{6}$$

where  $A_c$  and  $A_w$  are nondimensional coefficients,  $\vec{U}$  the current velocity vector,  $\vec{u}_b$  the maximum near-bottom orbital velocity vector,  $F_D$  a direction function for wave-induced net transport,  $\tau$  the maximum bottom shear stress in a wave-current coexistent system,  $\tau_c$  the critical shear stress for the onset of the general movement,  $\rho$  the water density, and  $g$  the gravity acceleration.

After Watanabe et al.(1991), the direction function for wave-induced net cross-shore sediment transport is set to be +1 for the onshoreward movements under

the Shields parameter less than 0.2 of the upper limit of bed load and larger than 0.5 of the onset of sheet flow movement, and is set to be -1 for the offshoreward movements of suspended load over ripples under the Shields parameter between 0.2 and 0.5. The bottom shear stress for a wave-current coexistent system is evaluated by the friction law proposed by Tanaka and Shuto(1981). The critical shear stress is calculated from the critical value of the Shields parameter, which is 0.11 for fine sands and 0.06 for coarse sands according to Watanabe et al.(1980).

The coefficient  $A_w$  in the formula for the transport due to wave action is related to another coefficient  $B_w$  in the formula for the wave-induced net sediment transport rate  $q_w$  proposed by Watanabe(1982), which is expressed as follows:

$$\phi = B_w(\psi - \psi_c)\psi^{1/2} \quad (7)$$

where  $\phi = (1 - \lambda_v)q_w/w_0D$  is a dimensionless net transport rate,  $D$ ,  $w_0$  and  $\lambda_v$  are the diameter, settling velocity and porosity of the sediment,  $\psi = \tau/(\rho_s - \rho)gD$  is the dimensionless shear stress or the Shields parameter,  $\rho_s$  and  $\rho$  are the densities of sediment and water, and  $\psi_c$  is the critical value of  $\psi$  for the onset of general movement of sediment.

The coefficient  $A_w$  is related to  $B_w$  as follows:

$$A_w/B_w = w_0\sqrt{f_w/2} / \{(1 - \lambda_v)s\sqrt{sgD}\} \quad (8)$$

where  $f_w$  is the wave friction factor.

In the previous studies under the field conditions conducted by Watanabe et al.(1991), the value of  $B_w$  is considered to be approximately 3.0 to 5.0, though the coefficient must be calibrated in the field application. In this study, the value of  $B_w$  is set to be 2.0 after several tries and errors, and the value of  $A_w$  changes depending on local wave conditions and properties of sea-bed material. The value of  $A_c$  is set by multiplying the value of  $A_w$  by 10.0 after Watanabe et al.(1991).

### Reproduction of Beach Topography Change

The numerical simulation was performed under a simply modelled series of wave conditions by repeating the calculations of waves, mean currents and beach topography changes. The wave conditions during the calibration period of approximately a year were replaced by the simply modelled four series of storms with the significant wave height larger than 2m as shown in Fig. 7. This modelled series of waves have the same occurrence frequency in total as that of the observed wave climate data.

Fig. 8 (a) shows the measured topographical changes and Fig. 8 (b) shows the calculated bottom topography changes by taking into account only the sediment transport due to nearshore currents. Remarkable accretion around the harbor entrance and erosion around Point 3 and at the tip of the breakwater due to nearshore circulation are reproduced satisfactorily. The results of both measurements and calculations show that the sediment transport due to nearshore current is predominant for the long-term beach evolution and that the contributions of

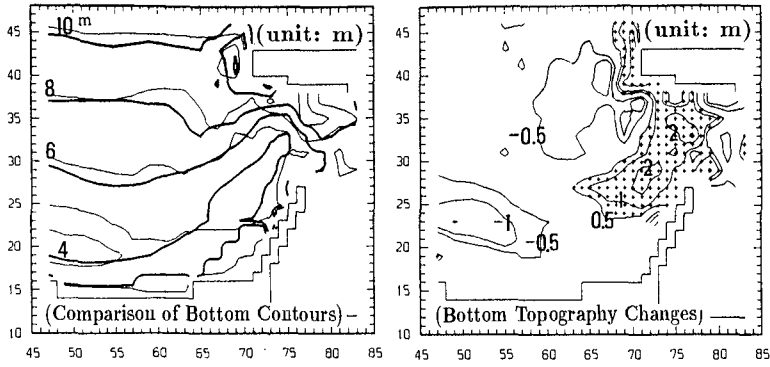

Fig. 7 Simply modelled series of incident wave conditions.

both the offshoreward sediment transport due to undertow and the onshoreward transport due to sheet flow are cancelled for a long-term beach profile change.

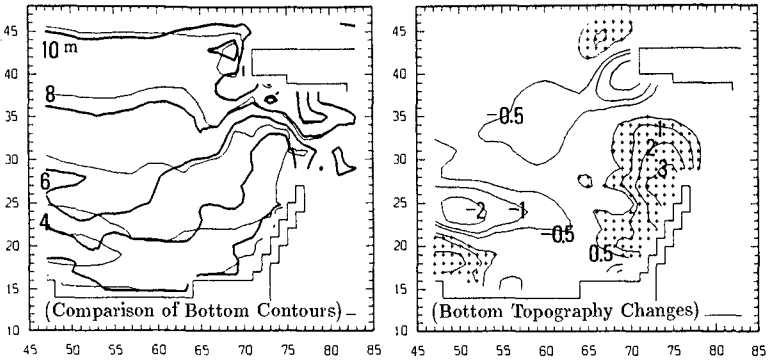

The difference between calculation and measurement is that the calculated result does not show such a sharp extension of the tongue-shaped bottom contours, for example the 4m contour, compared with the measurements. This fact suggests that the nearshore circulation is sharper and the width of fast current is narrower in the field than they are expected. In numerical calculation, however, it is difficult to reproduce such a sharp circulation as observed in the field, owing to the numerical diffusion.

Fig. 8 (c) shows the calculated bottom topography changes by taking into account the cross-shore sediment transport due to waves and undertow in addition to the transport due to nearshore currents. Around the harbor entrance, accretion due to nearshore current is reproduced well. In the area where waves attack directly and the cross-shore sediment transport is active during the storm, however, the measured topography changes are not reproduced well. In numerical calculation, the topographical changes due to cross-shore sediment transport is not cancelled even after a year.

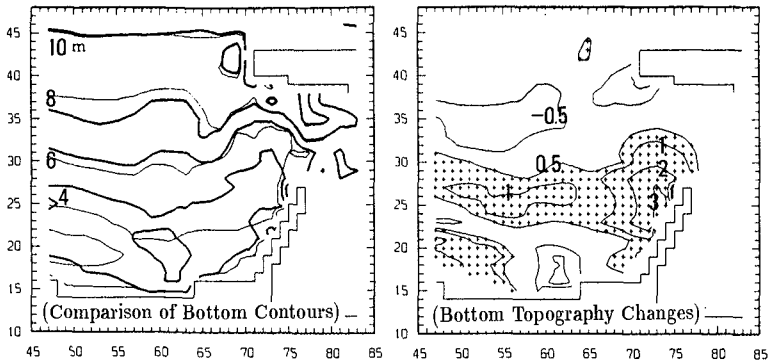

We, therefore, tried to investigate more precisely the calculation results. Fig. 9 shows the examples of calculated bottom topography changes after 3rd to 5th step during the decreasing period of the wave height. The upper figures show changes during each step, and the lower ones show the cumulative changes from the initial topography. The eroded area during 3rd step with the largest wave height is accreted during 4th step. And the eroded area during 4th step is accreted during 5th step. The eroded area near the shore due to severe waves is, thus, gradually buried and the accreted area moves onshoreward during the decreasing period of the storm. These results suggests that the wave-induced transport due to sheet flow and the flow-induced sediment transport due to undertow play an

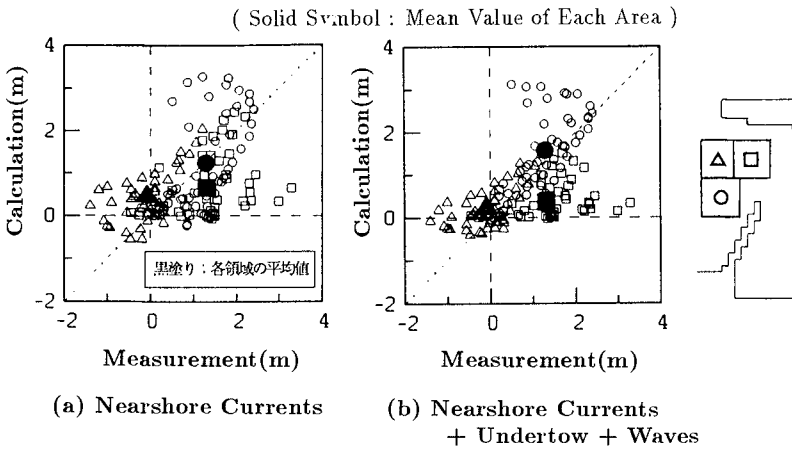

Fig. 10 Comparisons between the measured and the calculated bottom elevation changes.

important role in the short-term beach profile change.

The above tendencies of the actual beach profile change can be reproduced well by numerical simulation. However, the reason for disagreement of final topography after a year is that the modelled series of waves are not given continuously and the duration of each step is not appropriate. In order to properly estimate the beach profile changes due to cross-shore sediment transports, more detailed modelling of the storm is needed.

Fig. 10 shows the comparisons between the measured and the calculated bottom elevation changes. The solid symbols indicate the mean values in each area and the open symbols indicate those at each calculation point. Although the results at each point scatter a lot, the averaged values of each area around the harbor entrance show reasonable agreements in both cases.

## CONCLUSIONS

The results of this study are summarized as follows:

- (1) The parabolic equation model has a fairly good accuracy for estimating the random wave transformation such as combined diffraction, refraction and wave breaking.
- (2) The undertow was clearly observed through the field investigation. A simple vector addition of the nearshore current vector and the undertow vector has enough accuracy for practical use for estimating the near-bottom mean current in the surf zone.
- (3) For a long-term beach evolution, the measurement showed that beach profile changes due to cross-shore sediment transports were cancelled and the beach evolution can be reproduced satisfactorily by taking into account only the sediment transport due to nearshore currents. Further investigations are, however, needed for properly estimating the short-term beach profile changes due to waves and undertow as well as the long-term beach evolution due to nearshore currents.

## CHAPTER 190

### AN ATTEMPT TO MODEL LONGSHORE SEDIMENT TRANSPORT ON THE CATALAN COAST

J.P. Sierra, A. Lo Presti and A. Sánchez-Arcilla <sup>1</sup>

#### Abstract

In this work, the main variables involved in one-line shoreline evolution models have been identified and typical values for them have been found for different zones of the Catalan Coast. These values have been employed in a shoreline evolution model. The model has been calibrated in several points of the Catalan Coast, adjusting the free parameters in a longshore sediment transport formula. Taking into account the quality of the results, the model seems to be an efficient tool for medium term coastal engineering purposes.

#### 1. Introduction

The estimation of longshore transport rates is an important problem in coastal engineering, in order to predict shoreline changes when coastal structures are constructed and to consider shore protection methods without unexpected effects.

Beach changes are controlled by wind, waves, currents, sediment nature and water level among other variables, which are necessary data to estimate these changes. Given the complexity of beach processes, efforts should be made to identify and analyze all relevant physical data needed for an efficient evaluation and interpretation of beach evolution.

Many often these data are not available in the target site. This situation increases the number of unknowns which must be obtained by reasonable estimates or by adaptation and extrapolation from other projects on similar or adjacent coasts. These assumptions should be considered when interpreting computed results because they could induce erroneous or misleading estimated beach changes.

However, sometimes, the methods used for predicting longshore transport rates and beach evolution, over a medium-term period of time (several years),

---

<sup>1</sup> Laboratori d'Enginyeria Marítima (LIM/UPC), Universitat Politècnica de Catalunya. C/ Gran Capitán s/n, mòdul D-1, 08034 Barcelona, SPAIN.

fail in their predictions because the input parameters are not computed for local conditions and corrective procedures are not taken into account.

As an example, the Catalan Coast, located in the Mediterranean Sea, presents distinctive features from other coastal areas like Atlantic or Pacific ones. Among these features, we can mention beach slopes, grain size, tidal range (which is practically negligible) or the wave climate, which presents storms of smaller intensity than other zones due to the limited fetches.

For this reason, the input variables to predict longshore sediment transport rates and shoreline evolution should be expressed in terms of local parameters and conditions.

Therefore, the main goals of this paper are the characterization of input variables for shoreline models in terms of Catalonian coastal features and the application of the obtained results to the Catalan Coast in order to calibrate a shoreline evolution model.

## 2. Data employed

The Catalan Coast has a total length of 580 Km, 270 of them being sandy beaches. The northern part shows a predominance of rocky cliffs and reefs. In the central and southern areas, sandy beaches are dominant.

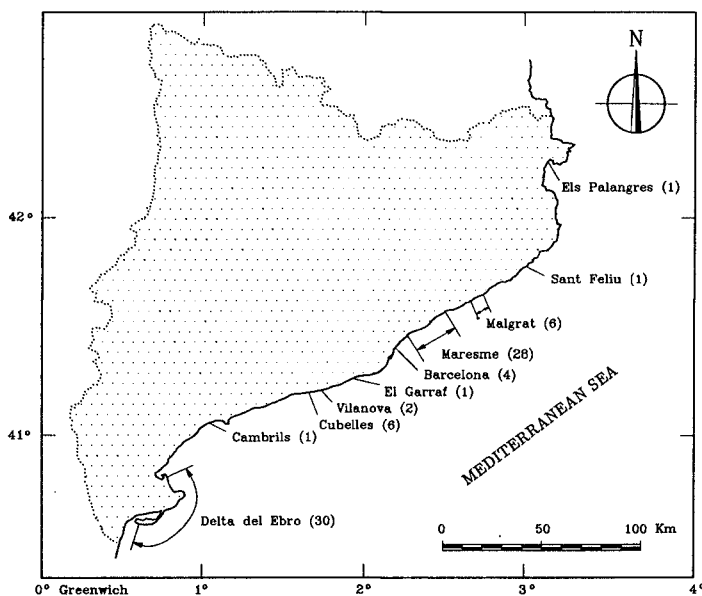

Figure 1. Location of the 82 beach profiles.

In this work, 82 beach profiles from the Catalan Coast have been used. These profiles are representative of 105.2 Km of beach (37.6% of the total length). In figure 1, the profile locations are shown.

The profile data have been obtained from several field measurement campaigns. Some of them are described in Serra et al. (1989, 1990) and Jiménez et al. (1992).

### 3. Variables characterization

The main variables involved in one-line shoreline evolution models are beach profile shape, closure depth, wave climate, sea level changes, sediment size, boundary conditions and interaction with coastal structures.

The boundary conditions and coastal structures will be defined in each individual case to be studied. On the other hand, sea-level fluctuations at geological and intermediate time scales have not been taken into account. Shorter recurrence intervals which are related to climatic effects, as e.g. daily tides, are practically negligible on the Mediterranean Sea, because tidal ranges are very small in this area (order of 20-30 cm). Other episodic events will not be considered either.

In this section, attention will be focused on the other mentioned variables and their characteristics along the Catalan Coast will be analyzed.

#### 3.1. Depth of closure

The depth of closure can be defined as the limit depth for appreciable longshore transport. It is a fundamental parameter in shoreline evolution models but it is difficult to quantify it.

Several expressions for the computation of the closure depth have been proposed. As an example, the Hallermeier (1978, 1981) expression has been widely used since it provides a guidance for the estimated closure depth:

$$d_{,e} = 2.28 H_e - 68.5 \left( \frac{H_e^2}{g T_e^2} \right) \quad (1)$$

where  $H_e$  is the wave height exceeded 12 hours a year,  $T_e$  is the associated wave period and  $d_{,e}$  is the estimated closure depth.

If possible, it would be better to determinate the closure depth from beach profile changes at the site, but the scarcity and accuracy of data is the main difficulty to estimate this parameter which has a statistical nature.

Based on the field measurements available from multiple profile surveys made over a 5 year period through the Catalan Coast, the depth of closure was estimated following a similar approach to the one employed by Kraus and Harikai (1983) on Oarai Beach. In this approach the closure depth was evaluated

Figure 2. Depth changes

plotting the standard deviation of the measured depth values versus the average depth for the overall studied area, as it is shown in figure 2.

It can be observed that the most important deviations occur in depths shallower than 5.5-6 meters. On the other hand, if the closure depth is computed employing the Hallermeier expression (1) fed with the wave data from three existing buoys in the zone (as it will be explained later), the obtained values are of the same order of magnitude, as it can be seen in table 1.

Buoy	$H_e$	$T_e$	$d_{se}$
Tordera	3.5	7.3	6.4
Llobregat	3.2	7.4	5.9
Ebro	3.8	7.0	6.6

Table 1. Closure depths from Hallermeier expression

### 3.2. Beach profiles

The second analyzed variable is the beach profile shape. The aim here is the obtention of an analytical expression which provides the best possible representation of the equilibrium beach profile in the Catalan Coast.

Bruun (1954) based on the analysis of beach profiles for the North Sea and California Coast, developed an empirical equation with a potential function which relates water depth  $h$  and shoreline distance  $y$ .

$$h = A y^B \quad (2)$$

Later on, Bruun and other authors found theoretical justifications for this expression. Dean (1976, 1977), centering his study on linear wave theory and assuming that the ratio of breaking wave height to water depth is constant, justified from three different points of view this potential form for the equilibrium beach profile. He found a value of  $2/5$  or  $2/3$  for the exponent  $B$  and showed that the aforementioned equation with  $B = 2/3$  is consistent with uniform wave energy dissipation per unit volume across the surf zone. Other authors, who also adopted this equation, suggested a potential relationship between the shape parameter  $A$  and the grain size (Moore 1982, Hanson and Kraus, 1989).

The wide spread use of this profile equation, together with its simplicity, led to its application to numerous beaches, which present quite different characteristics from the beaches of United States Atlantic Coast. For this reason, the first step consisted in the evaluation of the Bruun-Dean expression fit to measured data. It was observed that this equation over-predicts depths, specially when the  $A$  parameter values of Moore (1982) are used (see figure 3).

Figure 3. Bruun-Dean profile vs measured data in Ebro Delta area

Considering that the combination of the Bruun-Dean type profile with  $A$  values from Moore (1982) was not suitable for the available data, the following step consisted in the use of an inductive approach to find alternative expressions for the beach profile (Lo Presti, 1994; Sierra et al., 1994). The aim was to improve the fit with respect to the aforementioned equation for the Catalan Coast and to avoid an infinite slope at the shoreline.

This analysis of beach profile shapes was carried out with a purely statistical approach, without any in-depth analysis of the underlying physics. No attempt was made to relate the new profile expressions to the beach morphology or boundary conditions because of the limited number of surveyed profiles. The obtained expressions can be useful in the characterization of beach profiles for site-specific applications. It should be stressed that no attempt is here made to predict the actual beach shape parameters.

The selection of alternative expressions is based on the previous knowledge of general profile shapes. Two alternative expressions have been proposed for the equilibrium beach profile.

i) Exponential equation:

$$e^z = A(y + C)^B \quad (3)$$

ii) Rational equation:

$$z = \frac{y}{A + By} \quad (4)$$

Both equations will be compared with the power-law (potential) expression:

$$z = Ay^B \quad (5)$$

where  $z$  is the water depth,  $y$  the distance to the shoreline and  $A$ ,  $B$  and  $C$  are parameters to be determined.

In order to find the best fit curve, a suitable transformation of variables has been carried out followed by a straight line regression analysis using the least squares method. The curve that provides the best fit to the measured data is the one which shows the minimum vertical distance (or prediction error) to them.

Taking into account the prediction errors of the expressions, in the major part of the 82 profiles it has been observed that both proposed expressions (exponential and rational) fit better to the measured data than power-law equations. Moreover, the differences in fit quality between both expressions are minimal, as it can be observed in figures 4 and 5. These figures show, as an example, the fit of the three expressions to two different measured beach profiles. A potential expression with  $B = 2/3$  has also been plotted and referred with (D). The measured beach profiles are drawn with continuous line.

Figure 4. Fit of one profile in Ebro Delta area

Figure 5. Fit of one profile in Maresme area

### 3.3. Sediment size

The next studied variable was the sediment size. In this case, the aim was to find relationships between the parameters of the analyzed beach profile and

the sediment diameter.

For the exponential equation no predictive relation was found. On the other hand, a poor relationship (with a correlation coefficient  $r = 0.50$ ) between the  $A$  parameter of the potential expression and the gran size appears to exist (see figure 6), while a reasonable relationship ( $r = 0.82$ ) between the  $A$  parameter of the rational equation and the sediment diameter  $D_{50}$  was found (figure 7).

Figure 6. Relationship between  $A$  and  $D_{50}$ . Potential equation.

Figure 7. Relationship between  $A$  and  $D_{50}$ . Rational equation.

### 3.4. Wave data

As it is well known, waves are generally the most important external factor taking part in beach evolution at a short/medium time scale, while the variables before studied are beach parameters which graduate its response to wave action. For this reason, a good definition of waves characteristics in the studied zone is necessary in order to perform an adequate modelling.

In this work, different sets of wave data were used. The monitoring program of the Regional Authorities for the Catalan Coast includes 3 offshore buoys, one of which is directional and began to operate in June 1990. The other two buoys entered in service in May 1984. In figure 8, the three buoys locations are shown. Visual data (since 1950) are available too.

For obvious reasons of space limitation, a detailed analysis of the wave data can not be included here. As a summary of the available information, it can be said that the wave heights recorded by the three buoys present similar trends because the distances among them are relatively short (about 100 km).

Since the Catalan Coast is the West boundary of the Occidental Mediterranean basin, it is opposite to the coasts of France, Italy, Africa and some islands, and as a consequence the maximum fetch on this coast is about 750 Km. Due to this restriction in the fetch magnitude, the waves acting on this zone have a limited energy, as it was mentioned before. The most energetic storms are those coming from NE or E.

The directions of the most frequent waves change along the Catalan Coast. In the southern part, near the Ebro Delta, there are three predominant directions (with almost 80% of the occurrences) according to both visual and recorded data: NW, S and the sector comprised between E and NE. In the northern and central parts, there is no recorded directional information and the only source are visual data. According to this data, the waves are more uniformly distributed in all directions, with two predominant sectors: NE-E (about 40% of the events) and SW-W (about 28%).

## 4. Shoreline evolution modelling

### 4.1 Model description

After all the necessary variables were characterized and their typical values defined, a numerical simulation of beach changes produced by spatial and temporal differences in longshore sediment transport was carried out at several areas of the Catalan Coast. In order to predict the shoreline evolution, a model was developed following Hanson and Kraus (1989). It is an one-line model and therefore it only considers longshore transport.

Several longshore sediment transport expressions have been used in the model. The most frequently employed was the Ozasa and Brampton (1980) one:

$$Q_t = (H^2 C_g)_b \left[ a_1 \sin 2\alpha_{b_s} - a_2 \cos \alpha_{b_s} \frac{\partial H_b}{\partial x} \right]_b \quad (6)$$

in which  $H$  is the significant wave height (in m),  $C_g$  is the wave group celerity (in m/s),  $b$  is a subscript denoting wave breaking,  $\alpha_{b_s}$  is the angle between breaking waves and the local shoreline and  $a_1$ ,  $a_2$  are adimensional parameters given by:

$$a_1 = \frac{K_1}{16 \left[ \frac{\rho_s}{\rho} - (1-p)(1.416)^{5/2} \right]} \quad (7)$$

$$a_2 = \frac{K_2}{8 \left[ \frac{\rho_s}{\rho} - (1-p) \tan \beta (1.416)^{5/2} \right]} \quad (8)$$

where  $K_1$ ,  $K_2$  are calibration parameters,  $\rho_s$  is the sand density,  $\rho$  is the water density,  $p$  is the porosity and  $\tan \beta$  is the average bottom slope from the shoreline to the closure depth.

This formula is a modification of the well-known CERC expression, with an additional term in order to consider wave height gradients alongshore. The free parameters ( $K_1$  and  $K_2$ ) were calibrated as a function of the net volume changes between successive historical coastlines at several beaches on the Catalan Coast. The average shoreline trend for each historical line was estimated, to avoid misinterpretations due to seasonal variability.

Successive analyses were made to characterize sequential order and discretization fineness effects, particularly concerning wave angles. It was concluded that the effect of wave angle variation is very important because of nonlinearities. A small change in wave angle produces greater differences in beach evolution than small changes in wave height.

A sensitivity analysis of the coastline discretization size was carried out too. The importance of both discretizations (spatial and temporal) was analyzed. It was found (within engineering accuracy bounds) that small changes in the spatial discretization parameter ( $\Delta x$ ) do not give rise to significative differences in the results, if the stability condition (given by the Courant number) is satisfied.

On the other hand, changes in the temporal discretization parameter ( $\Delta t$ ) do not originate differences in the results, if the stability condition is preserved and provided that wave directions remain unaltered when a different discretization is adopted.

#### 4.2. Case study

As an example of the model performance, one of the analyzed cases will be

Figure 8. Comarruga-Calafell beach and buoys locations

Figure 9. Wave climate for the simulated beach

described here. It deals with the beach between Comarruga and Calafell whose location is shown in figure 8.

This coastal stretch is a sandy beach with a length of 13 km. Originally it was in a relative dynamic equilibrium and the shoreline was approximately a straight line. The bottom contours were also approximately straight and parallel lines. In this zone, there was a rather large gross longshore sediment transport (about 200,000 m<sup>3</sup>/year) but the net rate of longshore transport was practically negligible (about 10,000 m<sup>3</sup>/year).

In the middle seventies two offshore marinas were constructed here, without taking into account the littoral dynamics and the important gross sediment transport existing in the area. The construction of both marinas induced important changes in the longshore sediment transport conditions and a tombolo was generated between the shoreline and each marina.

Shoreline position data were available immediately before and four years after the construction of the marinas. Using this data set, the one-line model was calibrated simulating the generation of both tombolos.

The main problem was the lack of recorded wave data during the tombolos formation. The necessary wave climate to feed the model was taken from the directional buoy wave data. This directional buoy provides wave parameters (height, period and direction among others) every 3 hours. The available wave data were from the nineties while the simulation period was from the seventies. It is nevertheless hoped that the recorded wave data are representative of average conditions in the zone so that they can be adopted to perform the simulation. A summary of the wave climate is shown in figure 9.

The selected boundary conditions were of pinned-beach type on both sides,

because the simulation bounds were enough far from the studied zone. This means that the transport rate gradients are zero and as a consequence the shoreline at these points does not move.

For other problem variables like closure depth, sediment size and beach profile shape, local values following the methodology described before were adopted. Correspondingly, a closure depth of 6 meters was employed in this case. The adopted grain diameter, obtained averaging several samples was  $D_{50} = 50$  mm. With this value, a profile of the rational type was derived taking into account the curve shown in figure 7. Therefore the only unknowns of the problem were the parameters  $K_1$  and  $K_2$  of the longshore sediment transport expression. These parameters were calibrated following a trial and error procedure. It was found that the more suitable values were  $K_1 = 0.3$  and  $K_2 = 0.7$ .

The value found for  $K_1$  is much smaller than the value of  $K_1 = 0.77$  originally determined by Komar and Inman (1970), although several authors have recommended in more recent works a decrease of the  $K_1$  magnitude. On the other hand, the value of  $K_2$  seems too large. This is probably due to the difficulty in reproducing with accuracy the behaviour of the marinas since they are coastal structures with a complex geometry.

Figure 10. Model calibration in terms of shore-line evolution

The obtained prediction of shoreline evolution is shown in figure 10. A reasonable agreement between measured and predicted shoreline positions can be observed. It is also noticeable that the model reproduces the tomboles at the proper locations.

Finally, a sensitivity analysis of the  $K_1$  parameter was carried out, as shown in figure 11. In this figure, the deviations between measured and predicted

Figure 11. Sensibility analysis of  $K_1$

shorelines for other  $K_1$  values can be seen.

## 5. Summary and conclusions

The essential variables involved in shoreline evolution models have been identified and corresponding typical values have been determined for different zones of the Catalan Coast. The improved description of the relevant physical data in terms of local values is very important in order to reduce the number of unknowns involved in beach evolution simulation.

On the other hand, two new expressions for equilibrium beach profiles have been tested, one of exponential type and the other one with a rational form. Both expressions give an improved fit in most of the measured profiles on the Catalan Coast with respect to other state of the art expressions.

Finally, a shoreline evolution model has been calibrated for different areas of the Catalan Coast, employing local values for the variables involved in the process. The calibration was carried out adjusting the free parameters of a longshore transport formula and finding their most suitable values.

## CHAPTER 191

### EROSION AND OVERTOPPING OF A GRASS DIKE LARGE SCALE MODEL TESTS

G.M. Smith<sup>1)</sup>, J.W.W. Seijffert<sup>2)</sup> and J.W. van der Meer<sup>1)</sup>

#### ABSTRACT

A comprehensive test series at full-scale was performed on a grass dike to obtain quantitative information on the wave loading, erosion rate, residual strength and overtopping under design storm conditions. The purpose was to establish design and assessment criteria for this type of dike, which exists in many places in The Netherlands. The particular dike tested exhibited, in general, a considerable resistance to erosion. However, such a non-homogeneous surface is subject to weak spots which can erode very quickly. The most critical region, where the wave loading is the highest, has been identified. The residual strength of the underlying layer of clay is defined as the time it takes for erosion to progress through the entire layer and expose the sand core of the dike. For the dike tested, the residual strength of the 0.8 m thick clay layer is estimated to be 10 hours under design conditions. Measurements of the average overtopping rate and the volumes per overtopping wave were compared to existing formulae, developed from the results of small-scale tests. The comparison was favourable, indicating that scale effects are not substantial for these quantities.

#### INTRODUCTION

Along many rivers and some sections of sea coast in The Netherlands a grass dike protects the low-lying polder land. Interest in grass dikes is growing, as a result of increasing environmental, economic and aesthetic concerns. In spite of this, no method was available to assess the strength of a grass layer for design or repair

---

1) DELFT HYDRAULICS, P.O. Box 152, 8300 AD Emmeloord, The Netherlands

2) Dutch Ministry of Public Works, Road and Hydraulic Engineering Division, P.O. Box 5044, 2600 GA Delft, The Netherlands

purposes. In recent years the strength characteristics of a grass dike have been systematically studied in order to answer the following questions: Is the strength mostly determined by the grass itself, the root system or the underlying soil? How does the grass layer behave during long-term wave and current loading and how long does it take before the grass layer can be considered to have failed? What is the residual strength of the dike, ie. how long does it take, after failure of the grass layer, until the sand core of the dike becomes exposed?

In 1992 a large-scale testing programme was created in order to answer these questions. By also measuring the overtopping rate, these tests then also provided the opportunity to compare recently derived overtopping formulae with full scale measurements. The aim of the study was:

1. to study the behaviour of the water motion (velocity, pressure distribution, layer thickness and runoff) over the grass slope.
2. to measure the erosion resistance of the grass layer.
3. to measure the average overtopping rate and the overtopping volume per wave, for a wide range of wave and water level conditions.
4. to measure the residual strength of the underlying layer of clay.

The project was commissioned by the road and hydraulic engineering division of the Dutch Ministry of Public Works and was performed by DELFT HYDRAULICS, Delft Geotechnics and the Agricultural University of Wageningen.

The tests were performed in de Delta Flume of DELFT HYDRAULICS. This flume is 250 m long, 5 m wide, 7 m deep. Waves can be generated up to 3 m in height. With this facility waves occurring under design storm conditions for the north coast of Holland could therefore be generated.

## TESTING SETUP

For this project a section of an existing sea dike was excavated and transported to DELFT HYDRAULICS. This was achieved by cutting a total of 16 blocks out of the grass and clay covering layer out of the dike. Each block measured 2.5 m x 2.5 m x 1 m thick (Photo 1).

The dike section was reconstructed in de Delta Flume and consisted of an outer slope (sea side) of 1:4, a 2 m wide crest at a height of 7 m above the flume bottom and an inner slope (land side) of 1:2.5 (see Figure 1 and Photo 2). The grass section of the dike was located in the centre 2.5 m of the flume, with 1.25 m wide concrete sections on either side. The inner slope consisted of grass from the crest down to an elevation of 3.5 m and below that of concrete to a height of 2.5 m. Behind this slope was the overtopping container, which had a capacity of 17 m<sup>3</sup>. The grass was placed only in the middle of the flume for three reasons:

Photo 1 Excavation of sections from the dike

Photo 2 Dike in the Delta Flume prior to testing

Figure 1 Cross-section of the dike in the Delta Flume

1. Fewer sections were needed to be excavated from the dike and placement in the flume was facilitated due to access from the sides. This also reduced the possibility of damage during placement.
2. Instruments could be easily attached to the concrete sections of the slope.
3. The concrete section of the slope served as a smooth reference for wave runup measurements.

In order to prevent interaction of the water on the concrete and grass sections of the dike, 0.45 m high wooden partitions were placed in between and sealed water-tight.

### Condition of the grass in the flume

Approximately 16 m of the dike was located inside the hall of the facility (only part of the flume is located within a hall). The inside section (the outer slope, from the toe to an elevation of 6 m) received therefore less light than would occur under natural conditions. This, in conjunction with relatively high temperatures (25 to 30°C), caused the condition of the grass to deteriorate. In order to minimize this, twenty special 400 Watt lamps were hung 1 m above the grass slope. The lamps burned about 16 hours per day, following the natural day-night cycle. The grass reacted well to this measure and had grown about 30 cm before preparations for the tests were completed. The Agricultural University of Wageningen performed a detailed inspection of the vegetation and root network before testing commenced. The vegetation cover was in good condition and had a high covering density.

## Instrumentation

A large number of instruments was placed on and in the dike. For measurements of the water motion on the slope 6 electro-magnetic velocity meters (EMV's), 2 runup meters (one on the grass and one on the concrete), 3 water layer thickness meters and 30 pressure transducers were used. In order to measure the pore water pressure response in the clay, Delft Geotechnics inserted 32 pore pressure transducers into the clay layer. These transducers were inserted at various depths below the surface via the sides of the grass/clay blocks. In order to measure the rate of erosion due to wave attack the elevation of a large number of points on the grass surface was regularly surveyed.

The overtopping rate was measured via a water level gauge located in the overtopping container. This container consisted of three separate sections to ensure that only the overtopping water from the grass section was accumulated and measured. The number of overtopping waves was determined from the runup meter, which extended to the crest elevation of the dike.

## TESTING PROGRAMME

To achieve the three main aims of the study, three test series were performed: erosion, overtopping and residual strength.

### Erosion tests

This series consisted of seven tests. The purpose of these tests was to obtain information about the behaviour of the water motion on the slope before and after breaking and about the erosion resistance of the grass layer itself.

The first five tests were of short duration and were performed with relatively small regular and irregular waves. These tests were intended to provide information about the water motion without damaging the grass layer. For the interpretation of the measurements of the erosion rate, differentiation was made between the average rate and hole development. On average, the erosion process progresses relatively slowly and is more or less evenly distributed over the surface. Hole development occurs after the erosion has locally progressed through the root layer. The sixth and seventh erosion tests provided information over both types of erosion.

The sixth test was performed with irregular waves having  $H_S = 1,4$  m and  $T_P = 4.7$  s and a water level of 4.8 m (Photo 3). These are the conditions for a design storm along the northern Dutch coast. During the test the waves were interrupted several times for inspections and surveying of the grass surface. After 9 hours of wave attack a hole 0,75 m in diameter and 0,12 m deep was noted 1 m under the still water level (SWL). After 1 more hour of wave attack the hole was measured again and then again after a second hour. The hole had in that time grown to a diameter of 1 m and a depth of 0.15 m (Photo 4).

Photo 3 Erosion test 6:  $H_S = 1.4$  m,  $T_P = 4.7$  s

Photo 4 Erosion test 6: Damage after 11 hours of testing

In order to obtain more information about the average erosion rate, it was decided to continue the test for at least another several hours. To prevent the hole from becoming so large as to affect the other measurements and the subsequent test series, it was repaired and protected from further erosion. After a total of 17 hours of wave loading a second hole had appeared 0.5 m under the SWL. This hole was 0.8 m in diameter and had a depth of 0.11 m. This was the location of the heaviest wave loading, where the most damage was expected to occur. This was the end of the test; the surface was inspected in detail and then repaired and protected for the remaining tests.

The seventh erosion test was performed with small irregular waves ( $H_S = 0.75$  m;  $T_p = 3.4$  s) and a lower water level (3.5 m). This lower part of the slope had not been subjected to much wave loading and was considered to still be in the original condition. The purpose of this test was to obtain information over the influence of the wave height on the erosion rate. The test was carried out in the same manner as test number 6, except the inspections and surveys of the surface were made every 4 hours instead of every hour due to the slower erosion rate. After 20 hours of wave loading the test was stopped. No serious erosion had occurred (Photo 5).

Photo 5 Condition after erosion test 7

The results of the erosion measurements of these two tests led to the definition of 3 erosion zones over the slope. The most erosion (both hole development and the highest average erosion rate) was concentrated to a depth of  $(0.3H_S)$  to  $(0.6H_S)$  under the SWL. This is defined as zone 1 (see Figure 2). Between the SWL and a depth of  $0.3H_S$  (zone 2), the average erosion rate was half of that in the first zone.

No hole development occurred in this second zone. In the third zone, above the SWL, practically no erosion was noted.

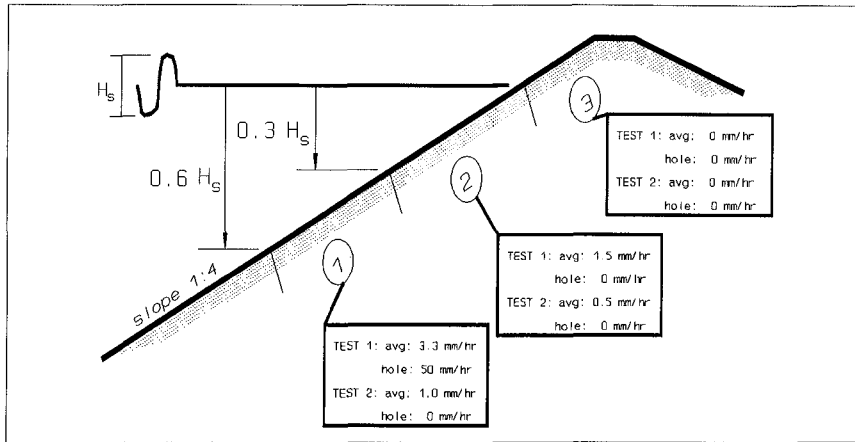

Figure 2 Defined erosion zones

The results showed clearly that the strength of this particular grass dike lay in the root network which was between 5 and 10 cm thick. It was also noted that the average erosion rate was proportional to about the square of the significant wave height (see Figure 3).

Figure 3 Erosion rate ( $E$ ) as function of  $H_s$

Based on these measurements a preliminary model has been developed which allows one to estimate the maximum allowable duration of continuous wave loading before a certain depth of erosion is achieved (Meijer and Verheij, 1994). An example is given in Figure 4 wherein lines of 5 mm and 50 mm erosion are shown. Of course, based on only two tests, this model is very limited. However, more tests have recently been performed with other wave heights on a wide range of different vegetation and subsoil characteristics and it is meant to expand the model with the new information.

Figure 4 Loading duration for erosion of  $d = 5$  mm and  $d = 50$  mm

### Overtopping tests

In this series twelve tests were performed with irregular waves. The purpose was twofold:

1. to give a visual impression of average overtopping rates from 0.1 to 25 l/s/m, under typical conditions for sea dikes (large freeboard and large waves) as well as for river dikes (low freeboard and small waves). A video presentation of the differing conditions was made. During some of the tests an observer stood on the crest of the dike to experience the force of the overtopping water under the various conditions. This was performed for the practical purpose of setting a criterion for the safe performance of dike inspections and repairs during a storm.

2. to compare the predictions of overtopping formulae, developed from small-scale tests, with large scale measurements. Formulae for both the average overtopping discharge and the overtopping volumes per wave and maximum overtopping volume were tested.

The observer on the crest noted that for an average overtopping discharge of 25 l/s/m ( $H_s = 1.8$  m,  $T_p = 4.7$  s and freeboard  $R_c = 1.8$  m) the force of most of the overtopping waves (green water, acting mostly on the observer's legs) was not large enough to cause a loss of balance. However, twice in 15 minutes the spray from the waves (acting over the full height of the observer) did have sufficient force to cause him to lose his balance. If it is also considered that during real storm conditions a high wind speed is also present, it must be concluded that performance of inspection or repair work during these conditions is not possible. This conclusion is also extended to conditions leading to an average discharge of 10 l/s/m.

### Comparison of measurements to existing formulae

#### *Average overtopping rate:*

The most widely applied formula for the average overtopping discharge is (Van der Meer and Janssen, 1994):

$$Q = A \exp(-BR) \quad (1)$$

For this formula the parameters  $Q$ ,  $R$ ,  $A$ ,  $B$  are dependent on the breaker parameter as follows:

for  $\xi_{op} < 2$  (breaking waves):

$$Q_b = \frac{q}{\sqrt{gH_s^3}} \sqrt{\frac{s_{op}}{\tan \alpha}}; \quad R_b = \frac{R_c}{\gamma_f H_s} \frac{\sqrt{s_{op}}}{\tan \alpha}; \quad A = 0.06; \quad B = 5.2 \quad (2a)$$

for  $\xi_{op} > 2$  (non-breaking waves):

$$Q_n = \frac{q}{\sqrt{gH_s^3}}; \quad R_n = \frac{R_c}{\gamma_f H_s}; \quad A = 0.2; \quad B = 2.6 \quad (2b)$$

with

- $Q_b, Q_n$  = dimensionless overtopping discharge [-]
- $b$  = subscript for breaking waves
- $n$  = subscript for non-breaking waves
- $A, B$  = regression coefficients [-]

$q$	= average overtopping discharge, per metre length of dike	$[m^3/s/m]$
$g$	= acceleration due to gravity	$[m/s/s]$
$R_c$	= crest freeboard	$[m]$
$H_s$	= significant wave height	$[m]$
$R_b, R_n$	= dimensionless crest freeboard	$[-]$
$\xi_{op}$	= breaker parameter = $\tan \alpha / \sqrt{s_{op}}$	
$s_{op}$	= wave steepness = $2\pi H_s / (gT_p^2)$	$[-]$
$\gamma_f$	= reduction factor for roughness	$[-]$

Analysis of the runup measurements for the grass slope indicate that the  $\gamma_f$  value is, on average, between 0.8 and 0.9. It is dependent on the length of the grass, etc.

Figure 5 shows that for the higher overtopping rates the measured data points compare favourably to the predicted values.

Figure 5 Measured and calculated average overtopping discharges

#### *Overtopping rates per wave:*

The average overtopping discharge does not give an indication of how much water can be expected to overtop the crest by a particular wave. The maximum volume per wave can be more than 10 times higher than the average discharge. In Van der Meer and Janssen (1994) a formula is presented to calculate the overtopping volumes per wave, based on the probability distribution of the overtopping volumes of individual waves (a Weibull distribution). The volume per wave is based on the

average overtopping discharge. From this approach the maximum overtopping volume from a group of  $N$  waves can be predicted with

$$V_{\max} = a [\ln(N_{ov})]^{4/3} \quad (3)$$

where

$V_{\max}$	= maximum overtopping volume in a single wave	$[m^3]$
$N_{ov}$	= number overtopping waves = $N/P_{ov}$	$[-]$
$N$	= number of incoming waves	$[-]$
$P_{ov}$	= probability of wave overtopping	$[-]$
$a$	= scale factor in the Weibull distribution = $0.84 qT_m/P_{ov}$	$[-]$
$T_m$	= average wave period = storm duration / $N$	$[s]$
$q$	= average overtopping discharge, per m length of dike	$[m^3/s/m]$

The probability of overtopping  $P_{ov}$  can be calculated with

$$P_{ov} = \exp \left[ - \left( \frac{R_c / H_s}{c} \right)^2 \right] \quad (4)$$

The coefficient  $c$  follows from the assumption that the runup distribution follows a Rayleigh distribution. The value of  $c$  can be calculated with

$$c = 0.81 \gamma_f \xi_{op} \text{ with a maximum of } c = 1.62 \gamma_f \quad (5)$$

The relation between the maximum volume in one wave and the average overtopping discharge is shown in Figure 6. In this figure the calculated line is based on a wave height of 1 m. The data points are for differing wave conditions. For average discharges of less than 10 l/s/m the wave heights were all approximately 1 m. For the higher rates the wave heights were approximately 1.5 m, which is why the data points fall above the calculated line.

It can therefore be generally concluded that the formulae developed on the basis of small scale tests are representative of prototype conditions.

### Residual strength test

The residual strength of a dike is defined as the capacity of the underlayers to withstand wave and current loading after the top protection layer has failed. For a grass dike the top protection layer is the top 5 to 10 cm layer where the grass and root network is concentrated. The underlayer is the approximately 1 m thick layer of clay which covers the sand core of the dike. The residual strength is expressed in terms of the time it takes, after failure of the grass layer (the development of a hole), for the sand core to become visible.

Figure 6 Maximum overtopping volume in a single wave as a function of the average overtopping discharge

This last test was performed after all erosion and overtopping tests were completed. The wave conditions for this test were identical to those for the sixth erosion test (design wave conditions). At the location of the wave impact, the grass and root layer had already been fully eroded away during the first two test series. Therefore, this test was considered to give a measurement of the residual strength of the clay layer alone. At the start of the test the clay layer was about 0.8 m thick.

After 4 hours of wave loading an under water inspection of the slope was carried out. It was noted that a large hole 0.4 m deep had appeared just under the still water line, along the edge of the grass/clay section of the dike. After 1 more hour of loading this hole had expanded to the full depth of the clay layer and the test was stopped. Photo 6 shows the results.

The growth of this hole must most likely be attributed to edge-effect and these results cannot be interpreted as the behaviour of a pure clay surface. This can be considered representative, however, for a dike with a transition from grass to a "hard" cover layer such as asphalt or a block revetment. Based on these measurements, the residual strength would be (conservatively) estimated at 5 hours.

Measurements of other sections of the surface that were not disturbed by this hole can be used to get an indication of the erosion rate of the clay. These measurements showed 0.25 m erosion over the 5 hours of testing or 0.05 m/hr. This compares extremely well with the results from erosion tests 6 and 7: the erosion rate, which can be compared to that for hole development, as well as the location of the erosion agreed with the values for zone 1. This value leads to an estimation of the residual strength as being 16 hours. Based on these two results the residual strength of this 0.8 m thick clay layer is estimated to be about 10 hours.

Photo 6 Condition after residual strength test

## CHAPTER 192

# Calculation of Tombolo in Shoreline Numerical Model

Kyung Duck Suh<sup>1</sup>, Associate Member, ASCE, and C. Scott Hardaway<sup>2</sup>

### Abstract

An algorithm is developed that is capable of calculating the formation of a tombolo in the lee of an offshore breakwater in a shoreline numerical model by inversely applying the method proposed in 1985 by Hanson and Kraus for constraining the shoreline not to retreat landward of a seawall. The algorithm is linked to a shoreline numerical model which uses curvilinear coordinates that follow the shoreline. The project of six segmented breakwaters at Chippokes State Park, Virginia is reported. The developed model is applied to the simulation of the shoreline change during the first nine months after construction of the Chippokes breakwaters.

## 1 Introduction

Offshore breakwaters have been used as a means to protect beaches against severe erosion. The wave-induced longshore currents generated behind the breakwaters deposit sediments in the sheltered area to build a new morphological shape called a salient. Sometimes the salient grows until its apex reaches the breakwater to form a tombolo. A number of numerical models has been developed for predicting shoreline change in the vicinity of coastal structures. However, there are few numerical models that can simulate the formation of tombolos. Most of the numerical models stop computation when the computed shoreline reaches the breakwater or predict outgrowth of the salient

<sup>2</sup>Marine Scientist, Department of Physical Sciences, School of Marine Science, Virginia Institute of Marine Science, The College of William and Mary, Gloucester Point, VA 23062, USA.

seaward of the breakwater. Perlin (1979) has proposed a method for handling the formation of a tombolo. Unfortunately, however, he could not find a well-documented data set to test his model for the case of tombolo formation.

In the present study, a numerical shoreline evolution model is developed to permit the formation and growth (or decay) of tombolos in the lee of impermeable offshore breakwaters. Hanson and Kraus (1985) have proposed a method for constraining the shoreline for the case of a seawall in a shoreline numerical model, which corrects the longshore sediment transport rates so as not to allow the shoreline to retreat landward of a seawall. In the present model, the method of Hanson and Kraus is borrowed for the calculation of tombolo formation in the lee of offshore breakwaters, the inverse of the problem of a seawall. The project of six segmented breakwaters at Chippokes State Park, Virginia reported in Hardaway et al. (1988) is summarized, and the developed model is applied to the simulation of the shoreline response during the first nine months after construction of the breakwaters.

## 2 Numerical Model

Advanced knowledge of waves and currents and the resulting sediment transport, associated with the increased capacities of large high-speed computers and improved numerical modeling algorithms, has made it possible to apply such complex models as a multi-line model (Perlin and Dean 1985) or general 3-D topographical change models (Wang et al. 1975; Watanabe 1982) to numerical modeling of shoreline problems. However, due to the relatively accurate prediction of the shoreline change with less computational effort, shoreline models have been widely used. In this section, a shoreline numerical model is developed using the curvilinear coordinates that follow the shoreline, as done in LeBlond (1972), Uda (1983), and Kobayashi and Dalrymple (1986). The use of a curvilinear coordinate system may be more advantageous than the Cartesian coordinate system for the situation in which the shoreline orientation is deviated largely from the straight shoreline as on a tombolo behind an offshore breakwater.

### 2.1 Shoreline change model

The curvilinear coordinate system used in the present model is shown in Fig. 1 along with some other notations. The symbol  $s$  denotes the coordinate following the shoreline whose positive direction points to the right when facing seaward. The coordinate pair  $(x_s, y_s)$  gives the location of an arbitrary point on the curved shoreline in terms of a Cartesian coordinate system.

$$\vec{m} = \left( \frac{\partial x_s}{\partial s}, \frac{\partial y_s}{\partial s} \right) = (\cos \theta, \sin \theta) \quad (1)$$

is the unit tangential vector to the shoreline in the direction of increasing  $s$ ,

Fig. 1. Curvilinear coordinate system and definition of model variables.

$$\vec{n} = \left( -\frac{\partial y_s}{\partial s}, \frac{\partial x_s}{\partial s} \right) = (-\sin \theta, \cos \theta) \tag{2}$$

is the seaward unit normal vector to the shoreline, and  $\theta$  is the angle between  $\vec{m}$  and the  $x$ -axis which is measured counterclockwise from the positive  $x$ -direction. In the figure,  $Q$  is the volumetric longshore sediment transport rate, and  $\alpha_b$  is the breaking wave angle between the wave crest and the  $x$ -axis which is measured counterclockwise from the positive  $x$ -direction.

Assume that the point,  $(x_s, y_s)$ , moves perpendicular to the shoreline, so that

$$\left( \frac{\partial x_s}{\partial t}, \frac{\partial y_s}{\partial t} \right) = e \vec{n} \tag{3}$$

in which  $e$  is the rate of shore-normal movement of shoreline. Using the notation of complex variables,

$$z_s = x_s + iy_s \tag{4}$$

in which  $i = \sqrt{-1}$ , and expressing  $e$  as

$$e = -\frac{1}{D} \frac{\partial Q}{\partial s} \tag{5}$$

(3) can be written as

$$\frac{\partial z_s}{\partial t} = -\frac{1}{D} \frac{\partial Q}{\partial s} \exp \left[ i \left( \theta + \frac{\pi}{2} \right) \right] \tag{6}$$

in which  $D$  is the depth of profile closure at which no measurable change in bottom elevation occurs. If  $\theta$  is very small, the real part of this equation states that the shoreline does not move in the  $x$ -direction and the imaginary part reduces to the sediment continuity equation of traditional shoreline models using the Cartesian coordinate system.

A widely-used expression for the longshore sediment transport rate in places where diffraction dominates is that proposed by Ozasa and Brampton (1980):

$$Q = \Gamma H_b^{5/2} \left[ K_1 \sin(2\delta_b) - K_2 \frac{\partial H_b}{\partial s} \cot \beta \cos \delta_b \right] \quad (7)$$

in which

$$\Gamma = \frac{\sqrt{g}}{16(s_s - 1)(1 - p)\sqrt{\kappa}} \quad (8)$$

and

$$\delta_b = \alpha_b - \theta \quad (9)$$

is the breaking wave angle relative to the shoreline under the assumption that the breakerline and the shoreline are locally parallel, and  $g$  = gravitational acceleration;  $s_s$  = specific gravity of sediment relative to fluid;  $p$  = porosity of sediment;  $\kappa$  = ratio of wave height to water depth at breaking;  $H_b$  = breaking wave height;  $\tan \beta$  = beach slope;  $K_1, K_2$  = empirical longshore sediment transport coefficients. The first term in (7) describes the sediment transport rate produced by obliquely incident waves, whereas the second term describes the transport due to a longshore gradient of breaking wave height, which has been found to be of great importance in cases where diffraction dominates. The beach slope is calculated by the empirical formula proposed by Sunamura (1984) for given breaking wave height, wave period and sand grain size.

A number of studies has been performed to determine the coefficient  $K_1$ . A value of  $K_1 = 0.77$  was originally determined by Komar and Inman (1970), and a decrease from 0.77 to 0.58 was recommended by Kraus et al. (1982). The second transport coefficient,  $K_2$ , has not received great attention of researchers. Ozasa and Brampton (1980) used  $K_2 = 3.24K_1$ . Hanson and Kraus (1989), however, recommended that the value of  $K_2$  is typically 0.5 to 1.0 times that of  $K_1$ .

One of the basic assumptions of shoreline numerical models is that the beach has a constant depth of profile closure throughout the model area, within which erosion or accretion of beach occurs. In this study, the expression proposed by Hallermeier (1983) is adopted with a deep water wave height,  $H_o$ , in place of the extreme wave height for an annual seaward limit of profile change:

$$D = \frac{2.9H_o}{(s_s - 1)^{1/2}} \quad (10)$$

In the model, the greatest  $H_o$  during the simulation period is used for calculation of  $D$ .

## 2.2 Breaking wave model

The sediment continuity equation, (6), can be solved for the shoreline position,  $z_s$ , if the wave heights and angles along the breakerline are given. In the present model, the wave condition (height, period and angle of incidence) at the location of the breakwaters is given as input data and the wave deformation in the lee of the breakwaters is computed. It is assumed that the wave condition is constant along the line connecting the breakwaters and its longshore extensions to the lateral boundaries. This assumption will be appropriate if the offshore bottom topography does not deviate drastically from straight and parallel contours, the offshore distances of the breakwaters are almost constant, and the longshore distance of the model area is not too long.

The three major phenomena which alter the wave in the lee of the breakwaters are refraction, diffraction and shoaling. In the present model, it is assumed that all these wave phenomena occur independently, so that the breaking wave height,  $H_b$ , can be calculated by

$$H_b = K_D K_R K_S H_B \quad (11)$$

in which  $H_B$  = wave height at the location of breakwaters, and  $K_D, K_R, K_S$  = coefficients of diffraction, refraction, and shoaling. The diffraction analysis used in this model is based on the theory of Penney and Price (1952). The method of determining the refraction and shoaling coefficients and the breaking wave angle closely follows that of Kraus (1982).

## 2.3 Finite-difference equations

An explicit finite-difference method is used to solve (6), (7) and (9) numerically for the wave condition computed along the shoreline. The location and orientation of the shoreline and the breaking wave angle are defined at the nodal points, and the longshore transport rate is defined between the nodal points, as shown in Fig. 2. The sediment continuity equation, (6), at the  $i$ th point can be expressed as the following finite-difference form:

$$z'_i = z_{s_i} + \frac{\Delta t}{D} \left[ \frac{Q_{i-1} - Q_i}{\frac{1}{2}(\Delta s_i + \Delta s_{i-1})} \right] \exp \left[ i \left( \frac{\theta_i + \theta_{i-1}}{2} + \frac{\pi}{2} \right) \right] \quad (12)$$

in which  $\Delta t$  is the time step. The prime denotes the quantity being solved for the next time step and the unprimed quantities are known quantities at the present time step. The quantities,  $\Delta s_i$ ,  $\theta_i$ , and  $Q_i$ , are computed by

$$\Delta s_i = \left[ (x_{s_{i+1}} - x_{s_i})^2 + (y_{s_{i+1}} - y_{s_i})^2 \right]^{1/2} \quad (13)$$

$$\theta_i = \tan^{-1} \left( \frac{y_{s_{i+1}} - y_{s_i}}{x_{s_{i+1}} - x_{s_i}} \right) \quad (14)$$

Fig. 2. Finite-difference representation of shoreline and associated transport around  $i$ th point.

and

$$Q_i = \Gamma \left( \frac{H_{b_i} + H_{b_{i+1}}}{2} \right)^{5/2} \cdot \left[ K_1 \sin(2\delta_{b_i}) - K_2 \frac{H_{b_{i+1}} - H_{b_i}}{\Delta s_i} \left( \frac{\cot \beta_i + \cot \beta_{i+1}}{2} \right) \cos \delta_{b_i} \right] \quad (15)$$

in which

$$\delta_{b_i} = \frac{\alpha_{b_i} + \alpha_{b_{i+1}}}{2} - \theta_i \quad (16)$$

The explicit finite-difference scheme becomes unstable for a large time step  $\Delta t$ . As done in Kraus and Harikai (1983) for a Cartesian coordinate system, an approximate stability criterion for small  $\delta_{b_i}$  can be obtained as

$$\Delta t \leq \frac{1}{2} \frac{(\Delta x_s)^2}{\epsilon} \quad (17)$$

in which  $\epsilon = 2K_1\Gamma H_b^{5/2}/D$ . This stability criterion can give the first approximation of the time step for stable solution. If the computed shoreline shows saw-tooth instability, a smaller time step will be needed. Such an instability can be suppressed by smoothing shoreline orientation, longshore transport rate, and shoreline position as done in Uda (1983), but the smoothing process of shoreline position introduces an error in the conservation of sand as  $\Delta x$  increases.

Fig. 3. Illustration of tombolo calculation.

### 2.4 Calculation of tombolo

When the shoreline reaches an impermeable offshore breakwater, its offshore movement should stop there. But a numerical model that does not recognize the presence of the breakwater may calculate shoreline positions located seaward of the breakwater. Thus, at each time step the calculated shoreline position should be examined to determine if any point has moved seaward of the breakwater. If so, the point should be pulled back to the location of the breakwater. Hanson and Kraus (1985) proposed a method to incorporate a seawall constraint in a shoreline numerical model. The method permits a grid point to move landward of the position of a seawall in the initial computation, and then adjusts the longshore transport rates near that point so as to pull it back to the location of the seawall while preserving sediment volume. In the present study their method is applied inversely for the calculation of tombolo formation in the lee of offshore breakwaters.

Consider the discretized shoreline position as shown in Fig. 3. The dashed line denotes the shoreline position at the present time step, and the solid line and dash-dotted line denote the uncorrected and corrected shoreline positions, respectively, at the next time step. In Fig. 3, the  $i$ th point moved seaward of the breakwater to reach the point  $C'(x'_{s_i}, y'_{s_i})$ . We want to pull it back to the point  $C(x_{s_i}, y_{s_i})$ , which is the intersection of the breakwater and the line passing the points  $C$  and  $C'$ . The equation of the breakwater whose tips are located at  $(x_l, y_l)$  and  $(x_r, y_r)$  is

$$y = (x - x_l) \tan \theta_B + y_l \tag{18}$$

in which  $\theta_B$  is the angle between the breakwater and the  $x$ -axis which is measured counterclockwise from the positive  $x$ -direction. The equation of the line passing the points  $C$  and  $C'$  is

$$y = (x'_{s_i} - x) \cot \frac{\theta_{i-1} + \theta_i}{2} + y'_{s_i} \tag{19}$$

in which  $\theta_i$  and  $\theta_{i-1}$  are as defined in Fig. 2, and  $-\cot\{(\theta_{i-1} + \theta_i)/2\}$  represents the slope of the line passing the points  $C$  and  $C'$ . The location of the point  $C$  is then calculated as the intersection of the lines expressed by (18) and (19).

The advance of the shoreline position from  $C$  to  $C'$  results in a fictitious (nonphysical) transport of sand from either one or both sides of the  $i$ th point. The fictitious transport rate of sand,  $\Delta Q_{fic}$ , contributed to move the shoreline position from  $C$  to  $C'$  can be calculated by putting  $z_{s_i}$  for the point  $C$  and  $z'_{s_i}$  for the point  $C'$  in (12) as

$$\Delta Q_{fic} = \frac{D(\Delta s_i + \Delta s_{i-1})}{2\Delta t} \exp \left[ -i \left( \frac{\theta_i + \theta_{i-1}}{2} - \frac{\pi}{2} \right) \right] (z'_{s_i} - z_{s_i}) \quad (20)$$

The amount  $\Delta Q_{fic}$  must be subtracted from the computed transport rates ( $Q_{i-1}$  and/or  $Q_i$ ) depending on their directions as follows:

$$\left. \begin{aligned} Q_{i-1}^c &= Q_{i-1} - \Delta Q_{fic} \frac{Q_{i-1}}{Q_{i-1} - Q_i} \\ Q_i^c &= Q_i - \Delta Q_{fic} \frac{Q_i}{Q_{i-1} - Q_i} \end{aligned} \right\} \text{ if } Q_{i-1} \geq 0 \text{ and } Q_i \leq 0 \quad (21)$$

$$Q_{i-1}^c = Q_{i-1} - \Delta Q_{fic} \text{ if } Q_{i-1} \geq 0 \text{ and } Q_i > 0 \quad (22)$$

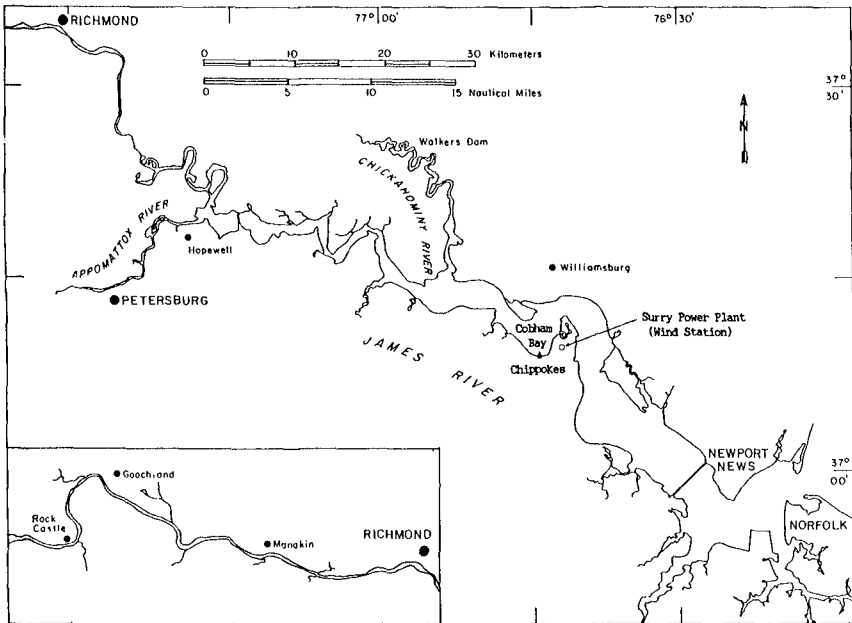

$$Q_i^c = Q_i + \Delta Q_{fic} \text{ if } Q_{i-1} < 0 \text{ and } Q_i \leq 0 \quad (23)$$

The superscript  $c$  denotes the corrected transport rates. The new position of the point  $B$  and/or  $D$  is then calculated using the corrected transport rates. If the new point,  $B$  or  $D$ , is computed to move seaward of the breakwater, it is pulled back to the location of the breakwater using the same procedure as above. Finally, it should be mentioned that in the present model, if any two adjacent shoreline points touch the breakwater, the transport rate between these points is set to zero.

### 3 Chippokes State Park Breakwater Project

The six segmented breakwaters at Chippokes State Park are located on the southern shore of Cobham Bay in the James River, one of the tributary estuaries of Chesapeake Bay, Virginia (Fig. 4). Chippokes is a recreational and historic state park as well as a model farm. The site is characterized by high (12 m) eroding fastland banks composed of a lower unit of shelly, fossiliferous, fine to coarse sand overlain by an upper layer of slightly muddy, fine to medium sand.

The preconstruction beach at Chippokes was a curvilinear strand of sand about 7.5 m wide from MHW to the base of the bank. The beach itself consists of well sorted, shelly sand derived from the eroding bluff. The mean diameter of the beach sand averaged from six sediment samples is 0.44 mm (medium sand). The shoreline at Chippokes faces almost due north and has an average fetch of about 4.8 km. Long fetch exposures of 9.3 km and 14.8 km occur to NNE and NW directions, respectively. Net longshore transport here is eastward but with seasonal fluctuations and on-offshore movement. The seasonal wave climate favors northerly winds in winter and southwesterly winds in summer. Mean seasonal winds generate limited waves across the

**Fig. 4. Location map of Chippokes State Park Breakwaters, Virginia.**

river. Extratropical and tropical storms with the associated storm surges are the main forces causing movement of beach sand and shoreline erosion. Mean tidal range is 58 *cm*.

The goal of the project was to design a system which would permit tombolos to form utilizing the existing volume of sand on the beach such that with time a stable backshore would develop and protect the base of the high banks. A system of six rubble mound breakwaters with a length to gap ratio of 1:1.5 was constructed in June 1987. The crest lengths are 15 *m* and gaps are 22.5 *m*. The centerline of the breakwaters is approximately 9 *m* from the initial MHW line. The water depth below MHW at the location of breakwaters varies between 0.75 and 0.87 *m*.

A baseline (*x*-axis in Fig. 5) was established using a transit. From this, 33 profile lines were determined and surveys performed using a rod and level. Profile measurements were made in July 28 and November 12, 1987 and February 23, 1988. Aerial photography was done every three months between September 2, 1987 and March 9, 1988. The photographs were used along with the profile data to create shoreline position maps.

Fig. 5 shows the measured shoreline change (dashed lines) from June 1987

to March 1988 along with the computed results. The position of MHW was used to track beach changes. Sand began accumulating and migrating toward each breakwater unit as cusped spits formed almost immediately after construction. The characteristic double salients evolved behind each breakwater by September 1987. Sediment for the salients was derived from the adjacent embayments. By March 1988 all the bays showed signs of filling. Especially obvious are the accumulation of sand on the west end of the system and marked loss of sand on the east. One would infer a net west to east movement of sand along this portion of the reach.

## 4 Model Application

The developed numerical model was applied to the simulation of the shoreline change near the Chippokes State Park Breakwaters for the first nine months (from June 1987 to March 1988) after construction.

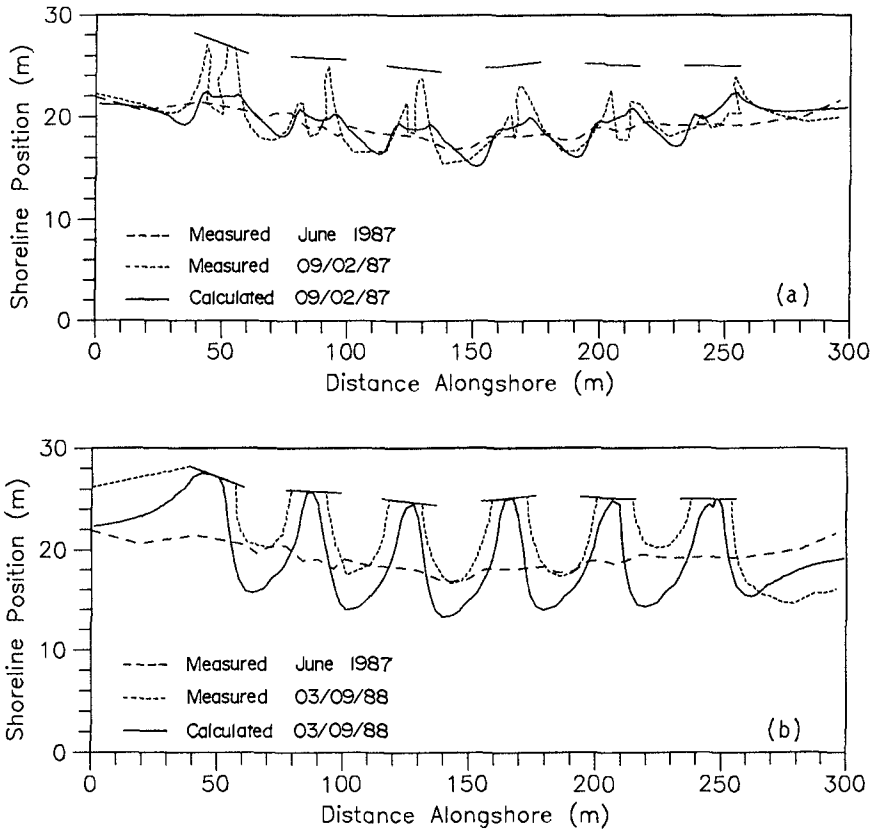

### 4.1 Wave hindcast

There are no available wave data near the project site for the simulation period. Therefore, input wave data at the location of the breakwaters were hindcasted from wind data measured at Surry power plant located about 2.8 km ENE of the project site (see Fig. 4). The wind data included speed and direction every one hour. Assuming that the wave direction corresponds to the wind direction, as seen in Fig. 4, the project site is affected by the wind blowing within the directional window fanning from  $320^\circ$  to  $20^\circ$  measured clockwise from the north. It is also assumed that in order to generate the wave field that affects the shoreline change, wind should blow for more than three hours (i.e., more than three consecutive observations) within the directional window. The average wind speed and direction for the period were calculated by vector-averaging the observations given every one hour. A constant wind field corresponding to the averaged wind speed and direction was assumed for that period.

The significant wave height and period at the location of the breakwaters were computed using the model of Kiley (1989), which is essentially a shallow water estuarine version of the quasi-empirical wind wave prediction model developed by Bretschneider (1966) and modified by Camfield (1977). The model includes variation in water depth, the effect of surrounding land forms on the computation of the effective fetch, wave growth due to wind stress and wave decay due to bottom friction and percolation. The wave angle at the location of the breakwaters is determined by Snell's law assuming that the offshore bottom contours are straight and parallel to the  $x$ -axis and the deep water wave direction (at the center of the river) is the same as the wind direction.

The weight-averaged (by duration of each wave condition) values of significant wave height and period, and wave angle at the location of breakwaters

are 12.2 *cm*, 1.43 *s*, and 1.33°, respectively, indicating very short small waves and net eastward longshore transport rate. The highest wave during the simulation was 21 *cm* high with 2.0 *s* period. Waves of 0.5 to 0.7 *m* height with 2.5 to 3.0 *s* period have been observed on April, 13, 1988. In this area, these types of events occur every two to three years but slightly lesser events occur even more frequently. Total duration of the simulation is 568 hours so that the percent of calm is 90 %.

**Fig. 5. Comparison between measurement and computation of shoreline change near Chippokes State Park Breakwaters, Virginia; (a) September 1987, (b) March 1988.**

## 4.2 Simulation

The initial shoreline in June 1987 in Fig. 5 was discretized by  $\Delta x = 1.524 \text{ m}$  ( $5 \text{ ft}$ ) to give about 10 points behind each breakwater and 195 points ( $296 \text{ m}$ ) for the shoreline reach shown in Fig. 5.  $\Delta t = 90 \text{ s}$  was used. All the water depths and shoreline position in the model are with respect to MHW level, since the shoreline position in the report of Hardaway et al. (1988) is presented in terms of MHW line. The water level was assumed to be fixed at the MHW level. The coordinates of the breakwater tips were taken as the shoreward corners of the bases of the breakwaters.

The shoreline change in the areas far from the project site is not available. Therefore, the model area was extended to both sides by  $100 \text{ m}$  and fixed boundary conditions were used at both ends. The offshore distances of the initial shoreline in the extended areas were assumed to be the same as those at the end points of the initial shoreline in Fig. 5. The shoreline change in the extended areas is not shown in Fig. 5.

The longshore sediment transport coefficient  $K_1 = 0.77$  was used as suggested by Komar and Inman (1970).  $K_2 = K_1$  was used tentatively. The calculated depth of profile closure is  $0.52 \text{ m}$ .

Fig. 5 shows the computed (solid lines) shoreline changes in September 2, 1987 and March 9, 1988 along with the measurement (short-dashed lines). The initial shoreline position is also given by long-dashed lines. The formation of double salients in September 1987 is predicted by the model, even though it is not so clear as in the measurement. The model calculated smaller tombolos and more prominent erosion behind the gaps compared to those in the measurement in March 1988. This may be due to the addition of sediment to the system by runoff and bluff erosion as reported in Hardaway et al. (1988), which was not included in the present model that assumes zero on-offshore transport of sediment.

## 4.3 Decay of tombolos

Sometimes tombolos are built artificially as a means to protect beaches as in Elm's Beach, Maryland (Hardaway and Gunn 1989), for example. If the project is not designed properly, the tombolos can be reduced to salients. In order to test how the model works for such a situation, the model was run for 48 hours of  $H_B = 7.9 \text{ cm}$ ,  $T = 1.16 \text{ sec}$ , and  $\alpha_B = 0^\circ$  (the mildest wave condition used in the previous simulation) with the computed shoreline in March 9, 1988 as the initial condition. The result is shown in Fig. 6. For the mild wave condition, the tombolos reduced to salients and accretion occurred in the embayments.

Fig. 6. Test for decay of tombolos.

## 5 Conclusion

The present study has proposed an algorithm that is capable of calculating the growth and decay of tombolos in the lee of offshore breakwaters in a shoreline numerical model. The algorithm permits a grid point to move seaward of an offshore breakwater in the initial computation, and then adjusts the longshore transport rates near that point so as to pull it back to the location of the breakwater while preserving sand volume. The neighboring shoreline positions are recalculated using the adjusted longshore transport rates. Even though in this study the algorithm was used along with a shoreline numerical model which uses curvilinear coordinates that follow the shoreline, it could be easily modified for the use in traditional shoreline models using Cartesian coordinate system.

The project of six segmented breakwaters at Chippokes State Park, Virginia has been reported. The developed model was applied to the simulation of the shoreline change during the first nine months after construction of the Chippokes breakwaters. The present model, which does not include cross-shore transport, predicted smaller tombolos and more embayment erosion compared to measurement at the Chippokes project site, where sediment was added to the system by runoff and bluff erosion. The model was applied for offshore breakwaters in an estuary with very short small waves, and applications in open coasts may be needed to fully examine the performance of the model.

## CHAPTER 193

### BEACH IMPROVEMENT SCHEMES IN FALSE BAY

by

D H Swart\* and J S Schoonees\*\*

#### ABSTRACT

A physical sediment model was used to design two beach improvement schemes in False Bay near Cape Town. Different layouts of T, L and detached breakwaters were tested to determine their effect on the beach and how they improved bathing conditions. Although caution was exercised to eliminate scale effects, it was found to be necessary to minimize their influences. A method was devised to do so which proved successful. It was found that equilibrium shoreline positions were reached after 4 years (prototype time). Sand feeding after construction will be necessary to minimize the deleterious effects of the breakwaters on the adjacent beaches.

#### INTRODUCTION

False Bay which is a large, partly protected bay (ca 35 km x 35 km) is situated near Cape Town, South Africa (Figure 1). The study site covered about 8 km of coastline from Strandfontein to Kapteinsklip alongshore (Figure 1) and up to the -20 m to mean sea level (MSL) contour. False Bay provides beach recreational facilities for the nearby metropolitan area of Cape Town.

The CSIR was commissioned to undertake studies on recreational schemes proposed for the north shore of False Bay. A tidal pool was built at Strandfontein as Phase 1 of this project. Phase 2 consists of beach improvement schemes at Kapteinsklip and Middelbank. The aim of this latter phase is to provide safe bathing beaches using groynes. At present the major part of the coast is rather unsafe for bathing mainly because of steep

---

\* Division director and \*\* Research engineer, CSIR, P O Box 320, 7599 Stellenbosch, South Africa.

beach profiles. The client laid down specific criteria to ensure safe bathing, e.g. a uniform flat beach slope and the absence of rock and strong rip currents. Further requirements were that a safe bathing beach forms soon after completion of the structures and that the adjacent coastline must not be adversely affected in the long term. This paper deals with the design of these beach improvements schemes using a physical sediment model.

Based on the expected number of visitors and bathers and assuming that 10 bathers per metre distance alongshore can be accommodated, it was stipulated that 1 200 m and 2 000 m of safe bathing beach must be provided at Kapteinsklip and Middelbank respectively.

Waves were recorded in about 20 m of water using two Waverider buoys. During the one year recording period, the mean significant wave height at the Waveriders was 1,2 m with a mean peak wave period of 11,1 s. The tides in the False Bay area are semi-diurnal with a mean spring tidal range of 1,6 m. From quarterly surveys it was found that the average median sand grain size on the beach is 0,45 mm. A best estimate of the gross longshore transport rate is 387 000 m<sup>3</sup>/year while the net longshore transport is eastbound and about 145 000 m<sup>3</sup>/year (CSIR, 1983). More details about the characteristics of the site can be found in Schoonees and Möller (1982) and CSIR (1983, 1988).

The mobile bed model which was about 100 m by 35 m, had a horizontal length scale of 1/20 and a vertical scale of 1/50 (giving a distortion of 2,4). The model sediment was sand with a median grain size ( $D_{50}$ ) of 0,315 mm. Calibration of shoreline evolution was carried out using results from aerial photography. This yielded a sedimentological time scale of 24 h of waves in the model being equivalent to 1 year in prototype. The wave climate was schematized into five cycles comprising quasi-irregular waves from both the westerly and easterly sectors. Schoonees and Möller (1982) and CSIR (1988) discusses the design and calibration of this model in detail.

The values of parameters given below are prototype values unless specified otherwise.

## TEST SERIES

### General

The authorities plan to implement the Kapteinsklip beach improvement scheme first followed by Middelbank some four years later. Because of the

time and cost involved, it was decided to run most of the tests for four years. This was found to be sufficient to reach an equilibrium coastline at the groynes as will be discussed later.

### **Programme**

The groyne layouts for the Kapteinsklip scheme, the A series, are shown in Figure 2a. Figure 2b illustrates the groynes tested in the Middelbank area. T, L and detached breakwaters were modelled. In addition, a zero test (Test A5) was conducted to determine the behaviour of the model without any structures. Having built in the 4 year shoreline condition (of an L groyne) at Kapteinsklip, another zero test (Test B3) was run; in this case for the Middelbank scheme. This test also served the purpose of showing shoreline response over 8 years at Kapteinsklip because the initial shoreline was the 4 year condition.

### **Scale Effects**

The effect of varying the number of cycles of westerly and easterly waves to make up one representative year was investigated. Both 5 and 10 cycles were tested. It was found that there was very little difference in coastline evolution between using 5 or 10 cycles. The easier and cheaper option of 5 cycles was therefore chosen.

Sediment samples were taken during Test B3 at different cross-shore and longshore locations to investigate the variation in  $D_{50}$  over time. No consistent tendencies and therefore scale effects due to sorting were found.

Rocky areas must be accurately represented in the model. Because they limit the availability of sand, rocky areas have a profound effect on coastline evolution if they are present. Care, therefore, should be exercised to survey them in detail so that they can be modelled correctly.

Three different scale effects were present in the results. These are diffraction effects causing the longshore transport to be incorrectly simulated, onshore sediment transport and the formation of cusps. For each of these, a factor was determined such that the shoreline response could be modified to account for these scale effects.

Because it was a distorted model, only refraction or diffraction could be reproduced correctly. Refraction was chosen to be of more importance and thus diffraction had to be corrected for. This was done as follows:

- Diffraction coefficients were determined from diffraction diagrams (US Army, Corps of Engineers, 1977) along a line in the lee of the groynes and parallel to the shore. This was done for the diffraction in the model and for the case where diffraction would have been correctly

simulated. From these, the incident wave characteristics and by assuming Snell's law, the breaker conditions were calculated.

- The longshore transport rates were then computed at different positions along the shore for both diffraction cases. The formulae by Engelund, Hansen and Swart and the SPM adapted by Swart (Swart, 1976a and b) were used. The Schoonees (1986) method was used to account for a gradient in breaker height.
- Volume changes per time were derived from the difference in longshore transport rates. These yielded the diffraction factor,  $k_{dif}$ . Following this procedure for westerly and easterly waves, weighted mean diffraction factors were determined along the beach. These varied around 1,0 (from 0,5 to 2,0). A factor of 1,0 means that the rate of shoreline change was predicted correctly in the model. These factors were almost always positive which means that the model predicted accretion and erosion to occur in the correct locations.

To account for onshore sand transport, mean beach profiles found in the model during Test A5 (a zero test) were computed after 1, 2, 3 and 4 years. A cross-shore sediment transport model (Swart, 1974) was calibrated for both model and prototype beaches. Thereafter the model was used to predict the onshore transport correction factor ( $k_{dwa}$ ) for different wave heights.

$$k_{dwa} = \text{(predicted distance that the coastline changed under model conditions, scaled to prototype size) / (predicted distance that the coastline changed in prototype conditions)}$$

An analysis of the cusps found in the zero tests (Figure 3) yielded a mean cusp factor ( $k_{str}$ ) of 2,0. The ratio of the distance to the apex of the cusp to the distance to the new mean shoreline position without the cusp is  $k_{str}$ . This factor was taken to be 2,0 if a cusp was present or 1,0 if not. This could be done because adaptations of the coastline position were only done at or close to the apex of cusps if they were present.

Adaptation of the coastline changes to account for these three scale effects were done as follows:

$$\begin{aligned} V_m &= V_{dwa,m} + V_{dif,m} \\ \text{and } V_p &= V_{dwa,p} + V_{dif,p} \\ \text{where } V &= \text{volume accreted or eroded} \end{aligned}$$

and subscripts      dwa =      onshore transport

dif = diffraction  
 m = model  
 and p = prototype

Furthermore:  $k_{dif} = V_{dif,m} / V_{dif,p}$   
 $k_{dwa} = V_{dwa,m} / V_{dwa,p}$

Substituting these equations it is possible to obtain  $V_p$  as a function of  $V_{dwa,m}$ ,  $V_m$ ,  $k_{dif}$  and  $k_{dwa}$ . Assuming that the distance over which the shoreline changes horizontally is directly proportional to  $V$  (which model results confirmed) and incorporating  $k_{str}$ , the result is:

$$a_p = a_{dwa,m} \left( \frac{1}{k_{dwa} \cdot k_{str}} - \frac{1}{k_{dif}} \right) + a_m / k_{dif}$$

This relationship was used to modify the measured model responses. It should be noted that the model was designed using preliminary (visually estimated) wave data. While the model was being constructed, the wave recordings were carried out. If the measured wave characteristics are used to compute the vertical scale in the same way as explained in Schoonees and Möller (1982), the vertical scale would have been 1/75 (instead of 1/50) giving a distortion of 1.6. This would definitely affect the cross-shore transport and possibly also the formation of cusps, thus influencing (hopefully reducing) the scale effects in the model.

### Test Results and Discussion

Figures 4a and b show the original model results of Test A4 and the model response of this test corrected for the above-mentioned scale effects respectively. Note that the adaptation of the results were only done in the lee of the L groyne and not to the right of the groyne. The corrected shoreline response of Test B3 which started with the 4 year condition of Test A4, is illustrated in Figure 4c. Shoreline variations over a period of 8 years were thus modelled. From these figures it can be seen that most shoreline changes occurred within 2 or 3 years after construction of the groynes. Equilibrium is reached after 4 years. The same was found of the coastline evolution in the other tests. This is in accordance with what has been found in the field in Israel (Nir, 1982), Japan (Toyoshima, 1976) and Brittain (Barber and Davies, 1985). Thereafter the shoreline fluctuates slightly around the equilibrium position (Figure 4c).

Detailed wave and current measurements were done in order to quantify the improvement in bathing conditions. Figures 5a and b show wave height contours and current velocities for regular westerly waves at the end of Test A6. The comfort of beach users will be improved by the schemes

because the beaches will be wider and will vary less in width over time. Bathing safety will be substantially enhanced because of the reduction in wave action and the associated reduction in current velocities. However, a varying wave climate will be provided along the beach from calm areas to enough wave action for the more adventurous swimmer. In addition, the beach slopes will be flatter and most of the rock will be covered by sand. Rock pinnacles which will still be exposed will have to be removed. To limit the return flow (out of gaps between groynes) due to wave overtopping, it was recommended that the crest height of the groynes be +2 m to MSL. An analysis of prototype schemes around the world and the tidal ranges occurring at those sites, also indicated this crest height to be realistic.

To minimize the effect of the schemes on the adjacent coastline, it was recommended that sand feeding be carried out with compatible sand. This should be done once and up to the equilibrium shoreline position after the construction of the groynes is complete.

Kamphuis (1975) presents an equation to calculate the sedimentological time scale. In this formula the factor  $M$  should be 1 for perfect agreement. By analysing a number of studies he showed  $M$  to vary between 0,35 and 14,6. For this study  $M = 1,48$ , which is in good agreement with the theoretical and empirical values.

### **Proposed Schemes**

Figure 6a presents the proposed scheme at Kapteinsklip. Together with the predicted equilibrium coastline position, areas are shown where additional beaches can be created using sand nourishment. In Figures 6b and c two alternatives are given for the Middelbank scheme. For both the schemes at Kapteinsklip and Middelbank, the required length of safe bathing beach will be obtained. Sand feeding is strongly recommended to minimize the effect on the adjacent beaches. Building each of these schemes in phases in order to limit the initial expenditure, was also considered and found to be viable (CSIR, 1989).

### **CONCLUSIONS**

A physical sediment model is an effective tool to apply to investigations of coastline evolution following the construction of groynes. Clients and designers can see what happens during tests. However, these models are expensive to build and operate.

Scale effects are normally present in studies using mobile bed models. Caution should be exercised to minimise these. In this study the important scale effects were found to be the result of diffraction effects, onshore sand transport and cusps. A method was devised and applied successfully to minimize these scale effects. To achieve this, it is essential to conduct (a)

zero test(s) by which the model behaviour without structures can be quantified. It was also found that rocky areas should be built in accurately because they can have a profound effect on beach evolution.

In accordance with field observations worldwide it was found that most shoreline changes occurred within the first 2 to 3 years after groyne construction. Equilibrium shoreline positions are reached after about 4 years. An independent check on the sedimentological time scale confirmed its accuracy.

The T, L and detached breakwaters proposed for the beach improvement schemes (Figures 6a - c) will improve bathing conditions significantly. Sand feeding after construction is necessary to minimize the deleterious effects of the groynes on the adjacent beaches.

### **ACKNOWLEDGEMENT**

The authors gratefully acknowledge Messrs Frank van Dulm, André Leith, Willie Daniels, Henry Davids and Koos Möller for their meticulous operation of the model.

## CHAPTER 194

# BEACH EROSION IN KUTA BEACH, BALI AND ITS STABILIZATION

Abdul R. Syamsudin<sup>1</sup>, Yoshito Tsuchiya<sup>2</sup>, M. ASCE and Takao Yamashita<sup>3</sup>

### Abstract

Due to the construction of an airport runway, severe beach erosion has taken place on the Kuta beach, a coral-sand beach in Bali. Introducing the most effective wave for beach change in terms of wave transformation on a coral reef, the long-term shoreline change is predicted with changing the positions for the boundary conditions to be used as headlands for stabilizing the beach in the large scale coastal behavior. We could find a possibility of stabilizing the beach against beach erosion by constructing three headlands at the positions found. In this beach, a very small amount of sediment source can only be produced from the activity of sea animals. On the basis of the long-term shoreline change and the theory of the formation of static stable beaches, therefore, a methodology for coral-sand beach stabilization was proposed, and parts of this were constructed. Further improvement for the headlands is needed, but as of 1989, a static stable coral-sand beach has been well-formed between the headlands.

### INTRODUCTION

Acceleration of beach erosion throughout the world is now recognized as being due to the way humans have developed and utilized coastal zones and river basins. Many attempts have been made to control beach erosion, but in the long term none have succeeded in stabilizing sandy beaches that are being eroded. Due to current development of coral reef beaches, severe beach erosion has taken place in coral-sand beaches in Bali. One of them is the Kuta beach as shown in Figure 1, facing the Bali straight. Since, in 1968, an airport runway was constructed on the coral flat in this

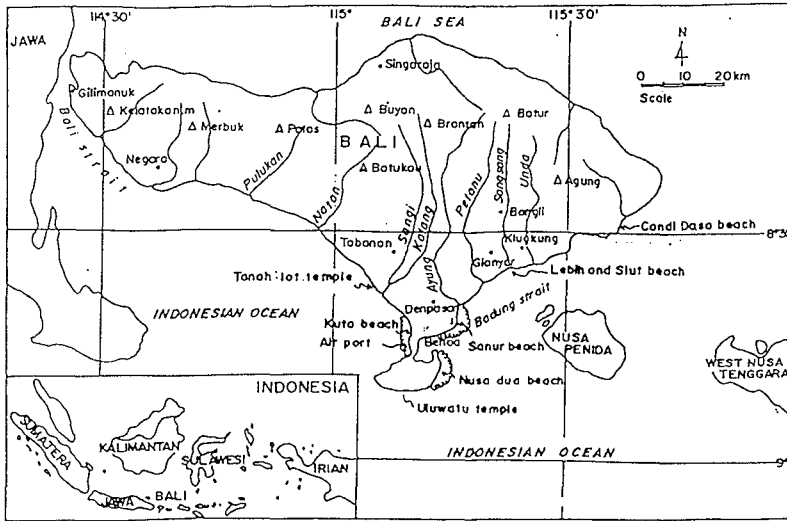

Figure 1. Location of the Kuta beach in Bali island.

beach severe beach erosion began to take place near the runway and has propagated widely on the northern beach (Figure 2 and Photo. 1). Some countermeasures were taken locally, but beach erosion continues to extend northward. In 1975, an UNDP team (Tsuchiya, Yahya and Syamsudin, 1976, and Tsuchiya, 1987) surveyed first the beach erosion problem, and many international advisors also conducted. Recently, an international joint investigation has been carried out with close cooperation between both the Research Institute for Water Resources Development, Agency for Research & Development, Ministry of Public Works of Indonesia and the Disaster Prevention Research Institute, Kyoto University, Japan (Tsuchiya, Syamsudin & Yamashita, 1993). In Figure 1(a), the sorelines measured in 1960, 1977, 1980 and 1987 are shown, and in the figure (b) the distance is taken from the end of the runway in the north direction. Note that severe shoreline retreat has taken place in front of Pertamina Cottages, and that a foreland was formed near the end of runway. Photo. 1

Photo. 1. Severe beach erosion near Pertamina Cottage on the Kuta beach taken in 1975.

also clearly shows severe beach erosion by which trees were fallen near Pertamina Cottages.

In Bali island, two prevailing winds, westerly and easterly exist by which waves are generated. Figure 3 shows refraction diagrams of the wave with a period of 15sec, in which the small bounded area shows the Kuta beach. Due to westerly winds, swells are incident from SW to WSW directions, but no effective waves due to easterly winds. A twin mode appears in frequency distributions of coral-sand on the beach. The sediment sizes decrease northward. Figure 4 shows sedimentation cells in the

Figure 3. Wave refraction diagrams off the southern part of Bali island.

beach, that was schematically shown using coral-sand characteristics, in which the arrows indicate the possible directions of onshore and longshore sediment transport. Before the construction of the runway there existed a sedimentation cell in equilibrium, but after the construction it was changed by the runway. Note that the main sediment source is only due to coral-sand production from the activity of sea

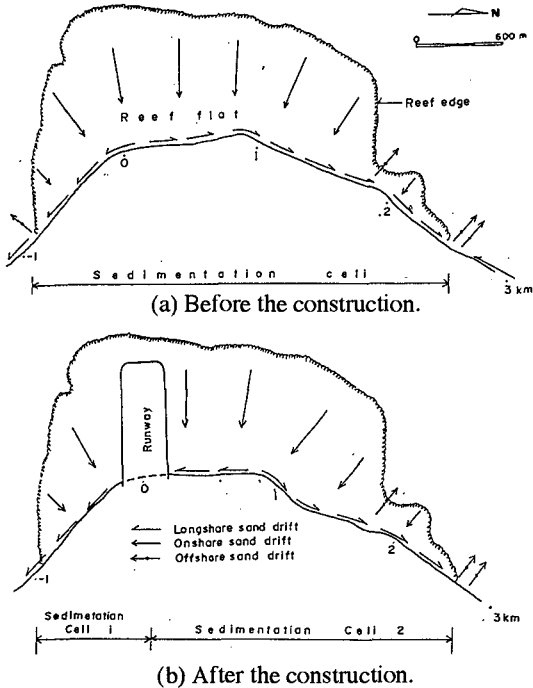

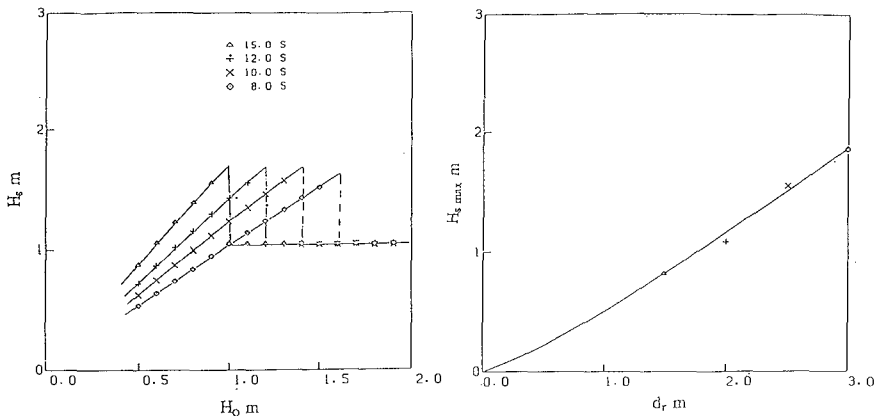

Figure 4. Sedimentation cells formed before and after the construction of the airport runway.

animals and that the northward predominant direction of longshore sediment transport exists. These facts result in severe beach erosion since the airport runway was constructed, especially in the northern area of the beach.

In this paper, we first introduce the most effective wave for beach change in relation to the wave transformation on a coral reef, and second predict long-term shoreline changes with changing the positions for the boundary conditions to be used as headlands for stabilizing the beach against erosion. Third, taking into account an existing small amount of sediment source in the coral-sand beach, a methodology for coral-sand beach stabilization using headlands must be proposed on the basis of long-term shoreline change and the theory of the formation of static stable sandy beaches (Tsuchiya, Chin & Wada, 1993, and Tsuchiya, 1994). Since parts of the proposed headlands were constructed, a coral-sand beach has been well-formed between the headlands. Its plane configuration is compared satisfactorily with the stable one.

### THE MOST EFFECTIVE WAVE FOR BEACH CHANGE

No continuous wave observations in Bali have been carried out and no available wave data can be used. In the prediction of shoreline change, we must specify what wave does effectively influence on the beach change. Incident waves onto coral flats are subjected to the water depth on a coral flat (Takayama, Koyama & Kikuchi, 1977, Tsukayama, Nakaza & Gakiya, 1989, and recently Nelson, 1994) and wave set-up on the flat (Seeling, 1982). Wave transformation in the offshore region on a coral reef can be calculated by the usual method, but on the coral flat we must introduce wave damping due to breaking of the propagating wave and bottom friction. Introducing Battjes' bore model (1974) into the conservation of wave energy flux a wave damping

(a) Dependency to deep water wave height      (b) Dependency to water depth  
 Figure 5. Changes of the wave height at shore with an increase in the deep water wave height and the maximum wave height in relation to the water depth on a coral flat.

model due to breaking is derived and compared satisfactorily with experimental data by Tsuchiya, Syamsudin and Yamashita (1993). Thus, wave transformation on a coral reef was calculated in terms of wave refraction, shoaling, and damping due to breaking and bottom friction to estimate the wave height near the coral-sand beach in

relation to the deep water wave height. Figure 5 (a) shows the relation between the wave height ( $H_s$ ) near the coral-sand beach and the deep water wave height ( $H_0$ ), in which the numerals show the wave period, resulting in clearly a maximum wave height ( $H_{smax}$ ) independent of the wave period. Figure 5(b) shows the relation between the maximum wave height ( $H_{smax}$ ) and the water depth ( $d_r$ ) on the coral flat, that clearly indicates a linear relation independent of the wave period. In the evaluation of the water depth on the coral flat for estimating the maximum wave height, wave set-up must be superimposed on the high tide.

The total rate of longshore sediment transport plays the most important role in the shoreline change. By introducing the longshore sediment transport rate, therefore, the wave height changes were calculated with changing wave period as shown in Figure 6, in which the upper two curves indicate the effective wave heights that representatively were calculated by linear and nonlinear wave theories, and the lower shows the dependency of the relative total rate of longshore sediment transport on the wave period. There exists a maximum total rate of longshore sediment transport at the wave period of about 14sec, but the wave height is nearly constant. The wave having the period and the maximum wave height can be used as the most effective wave in the coral-sand beach process in the Kuta beach. But, the incident angle of the wave should be assumed to be SW in the calculation.

Figure 6. Changes in the maximum wave height and the relative longshore sediment transport rate with the wave period at a central position of the Kuta beach.

## WAVE TRANSFORMATION, NEARSHORE CURRENTS AND LONG-TERM SHORELINE CHANGE

### Wave refraction and nearshore currents on the coral reef

Transformation of the most effective wave respectively was calculated by the usual methods of wave ray and mild-slope equation (Yamashita, Tsuchiya, Matsuyama & Suzuki, 1990). Figure 7 shows the wave ray diagram that was calculated under the high tide condition including an effect of wave set-up. In the figure, the thick line indicates the wave concentration clearly exist at two locations in the northern beach where severe beach erosion has taken place. This fact was understood more exactly in wave height distributions obtained by the method of mild-slope equation (Syamsudin, 1993). Introducing the result of wave fields into the equations of nearshore currents, nearshore currents on the coral flat also were calculated as shown in Figure 8. The result demonstrates that there appear remarkable

Figure 7. Wave ray diagram of the most effective wave in the Kuta beach.

Figure 8. Nearshore currents on the coral flat in the Kuta beach.

nearshore circulation cells that are formed near the end of the runway and locations

where waves concentrate. Unfortunately, we could not find direct influence of the runway on the nearshore circulation. It may be necessary for obtaining more realistic results to change the incident angle of the wave a little southward.

**Prediction of long-term shoreline change under boundary conditions**

As previously stated, we can not estimate the annual duration of the most effective wave. We must investigate whether the beach can be stabilized by some boundary conditions for shoreline change in the long-term shoreline change. In the prediction of long-term shoreline change, therefore, no use of the wave duration is necessary for the prediction.

Applying the long-term shoreline change prediction model (Yamashita, Tsuchiya, Matsuyam & Suzuki, 1990, and Tsuchiya, Yamashita, Izumi & Tottori, 1993), we predict the long-term shoreline changes in the Kuta beach in order to find the most suitable locations of man-made boundary conditions, as headlands for stabilizing the entire beach. The single, two and three boundary conditions respectively are given as headland 1, headland 2, and headland 3, and no wave diffraction by the boundary conditions are included in the prediction. Figures 9 and 10 show the predicted results, in which the solid curves between the headlands indicate shoreline change at intervals of the total run indicated in hours. Figure 10 shows the more detailed expression for the shoreline changes shown in Figure 9. When the single boundary condition was given at the central location of the beach, as shown in Figures 9 (a) and 10 (a), due to

(a) In the case of single boundary condition.

(b) In the case of two boundary condition.

(c) In the case of three boundary condition.

Figure 9. Long-term shoreline changes predicted under the single, two and three boundary conditions, respectively.

northward longshore sediment transport, severe shoreline retreat takes place widely near the end of the runway. In contrast, shoreline accretion occurs severely further down coast. In the case of two boundary conditions, as shown in Figures 9 (b) and 10 (b), little shoreline retreat takes place widely between the end of the runway and the headland 1, but shoreline retreat occurs down coast from the headland 2, resulting in

(a) In the case of single boundary condition.

(b) In the case of two boundary condition.

(c) In the case of three boundary condition.

Figure 10 Detailed expression of long-term shoreline changes predicted under the single, two and three boundary conditions, respectively.

remarkable shoreline accretion further down the coast to the headland 2. If shoreline change is predicted for the coast down the headland 2, shoreline retreat may take place there. If wave diffraction by the headland 2 is included in the prediction, shoreline change rate may reduce down coast.

Finally, when three headlands are given, as shown in Figures 9 (c) and 10 (c), there appears a nearly same tendency of shoreline change as the second case, but magnitude of shoreline change becomes lesser than the second. We recognize that little shoreline change takes place between the headlands 2 and 3, making the shoreline near the headland 3 continued the original one naturally.

## METHODOLOGY FOR CORAL-SAND BEACH STABILIZATION AND ITS APPLICATION

### The principal methodology for coral-sand beach stabilization

Beach erosion takes place locally due to change in the sedimentation cell on a coral reef beach, and extends more widely down coast in the direction of longshore sediment transport. In coral-sand beaches, there exists a natural system of the formation process of coral-sand beaches surrounded by the coral flats. The system is governed biologically and also in the nearshore dynamics on coral flats. The sediment sources are generally due to mainly 1) the activity of coral and other sea animals, producing a very little sediment source into the coral-sand beach, and partially 2) sediment sources from rivers if flowing into the coral flat. As previously stated in the sedimentation cell, the Kuta beach has only the sediment source that are produced from the activity of sea animals. To stabilize the beach against erosion, therefore, we must first consider its formation process of the coral-sand beach and the long-term shoreline change along the entire beach in the large scale coastal behavior. Second, we must investigate whether the beach can be stabilized by some boundary conditions for beach change. When we found the most suitable positions for the boundary conditions necessary for stabilizing the beach in the large coastal behavior, based on the theory of the formation of static stable sandy beaches (Tsuchiya, Chin and Wada, 1993, and Tsuchiya, 1994), we can establish a principal methodology for coral-sand beach stabilization.

As shown in Figure 3, the predominant waves are incident nearly normal to the coral-

Figure 11. A methodology for coral-sand beach stabilization proposed for the Kuta beach.

sand beach. In relation to the formation of the convex coral reef, the coral-sand beach is formed convex offshore by a very little sediment source from the sea animals production (Tsuchiya, 1987). As only a little sediment source maintains the Kuta beach, into which no river flows, static stable beaches must be formed on the basis of the theory of the formation of stable sandy beaches (Tsuchiya, Chin & Wada, 1993, and Tsuchiya, 1994). The theory recognizes that, when two boundary conditions for shoreline change are given at the ends up and down costs, a stable sandy beach can be formed in relation to longshore sediment transport. When no longshore sediment transport is given from up coast, a static stable sandy beach is formed between the boundaries. In other words, no longshore sediment transport exists along the beach formed. Therefore, a series of head-

Figure 12. Temporary change in shoreline at several locations on the Kuta beach.

lands that constitute the boundary conditions for shoreline change can then be spaced suitably so as to produce a series of well-stabilized coral-sandy beaches.

As previously shown in Figures 9 (c) and 10 (c), we have found a possibility for stabilizing the beach against beach erosion by constructing three boundary condition for shoreline change at the specified locations shown in the figure. In other words, when three headlands are constructed at the locations, the long-term shoreline change along the entire beach becomes an equilibrium state, in which a static stable coral-sand beach is formed. We can not construct a mathematical headland having no wave diffraction and deflection. Therefore, we must experience to construct it practically. A methodology for coral-sand beach stabilization was proposed as shown in Figure 11, in which the three headlands are to be constructed, and two others, but smaller may be needed to compensate for the direct effect of the headland 3 on shoreline change. A small groin shown in the figure was constructed before the application of the proposed methodology, to remove a cusped foreland formed near the runway.

### Application of the proposed methodology

Among the headlands, the headlands 1 and 2 had been constructed independently with concrete-filled concrete piles in 1985 and 1988, respectively. The respective headlands are of groin and offshore breakwater type. Due to the local circumstance of Indonesia, therefore, these headlands have too steep slopes to reduce wave reflection. No beach nourishment was carried out between the headlands. Figure 12 shows the shoreline change after the construction of the runway. Referring to Figures 2 and 12,

Figure 13. Shoreline changes after the construction of headlands 1 and 2 in comparison with the shoreline configuration for the static stable sandy beach.

severe shoreline retreat has taken place after the construction of the runway, but after the construction of the headlands the shoreline positions tend to approach equilibrium ones. Figure 13 shows the shoreline change between the headlands, comparing it with the static stable shoreline configuration that was obtained by an empirical relation of equilibrium bay configuration (Hsu, Silvester & Xia, 1987). The shoreline is approaching to the final shape of shoreline. Photo. 2 (a) and (b) show actual views of the formation of coral-sand beach between the headlands 1 and 2, in which (a) and (b) respectively were taken in the north and south directions in 1989. In Photo. 2 (a), there are a number of tetrapods that were placed on for protecting the beach locally about 1978. Waves are breaking at the same time along the beach, not showing a peeling phenomenon. This fact demonstrates that no longshore sediment transport

exists along the beach that has been well-formed as static stable coral-sand beach. In Photo. 2 (b), a tombolo is formed behind the headland 2 of offshore breakwater type, and is connected with the beach shown in Photo. 2 (a) by forming a stable coral-sand

(a) Taken in the north direction.

(b) Taken in the south direction.

Photo. 2 A static stable coral-sand beach is being formed between headlands 1 and 2 in the Kuta beach taken in 1989.

beach. We conclude, therefore, that further improvement are necessary in constructing headlands, but such a static stable beach has been well-formed between the headlands 1 and 2, and that, as shown in Figure 11, the adjacent beach is also well-formed by the headland 3, tending to connect with the natural northern one. We further conclude that, when well-designed headlands are constructed at the most suitable locations for the boundary conditions for shoreline change, a series of static stable coral-sand beaches can be formed in the large coastal behavior.

## CONCLUSION

In coral-sand beaches, sediment sources are mainly due to the sea animals production so that a very little amount can maintain the beach. Since no available wave data exist

in the Kuta beach, Bali, the most effective wave for beach change has been discussed in terms of wave transformation on a coral reef. By the use of the most effective wave, we predicted long-term shoreline changes in the large scale coastal behavior, with changing positions for the boundary conditions for shoreline change. We found the most suitable arrangement of headlands as the boundary conditions for stabilizing the entire beach against beach erosion.

On the basis of this findings and theory of the formation of static stable beach, a methodology for coral-sand beach stabilization was proposed. Since parts of the headlands proposed in the methodology were constructed, a stable beach had been well-formed between the headlands. We concluded that the coral-sand beach had almost approached the final shape of static stable one. Therefore, since the application of the proposed methodology has been examined satisfactorily, this methodology can be applied to other coral-sand beaches.

When Professor Y. Tsuchiya, the second author revisited Bali in 1990, however, the coral-sand beach that had been forming so wonderfully was no longer there. Dr. A. R. Syamsudin, the first author and Professor Tsuchiya who were standing on the groin were angered by the reconstruction of this beach with two big groins to make a marine resort, rather than beach preservation.

### Acknowledgments

Throughout this investigation on beach erosion control in Bali, many individuals have helped us for which we wish to thank; in particular, Ir. Rachmat Tirtotjondro, Former Director, Ir. Soelastris Djennoedin, Immediately Past Director, Institute of Hydraulic Engineering (presently, Research Institute for Water Resources Development) and Dr. Badruddin Machbub, Director, Research Institute for Water Resources Development, Agency for Research & Development, Ministry of Public Works of Indonesia, who kindly provided their supervision and cooperation in carrying out this investigation. Thanks are also due to the Ministry of Education, Science & Culture of Japan for its cooperation.

## CHAPTER 195

# Fundamental Characteristics of a New Wave Absorbing System Using Sand Liquefaction

S. Takahashi, S. Yamamoto, and H. Miura\*)

### Abstract

When a sand bed is liquefied due to a high pore pressure gradient, it significantly reduces the height of waves passing over it. This study investigates the fundamental characteristics of a liquefied sand bed including the wave damping effect.

### 1. INTRODUCTION

Two types of sand liquefaction exist. The first is a well-known phenomenon that occurs during an earthquake, namely, the generation of excess pore pressure caused by the shear deformation of sand, while the second is so-called quick sand or boiling of sand, which is generated by the upward pore pressure gradient of seepage flow in sand. A pore pressure gradient can also be generated by waves, and this causes sinking or settlement of sea structures such as block mound breakwaters.

The primary objective of the present study is to elucidate the fundamental features of a liquefied sand bed. One of its most impressive ones is the wave damping effect; i.e., when a sand bed is liquefied, the sand moves due to wave action and consumes wave energy, which results in generating this unique effect.

A series of model experiments were carried out to investigate the fundamental characteristics of liquefied sand and the wave-damping effect, with this report describing the results of the experiments and some theoretical considerations.

## 2. SAND LIQUEFACTION SYSTEM AND EXPERIMENTAL PROCEDURES

### Sand Liquefaction System

Figure 1 shows the newly developed sand liquefaction system which is comprised of a sand bed and horizontal pipes buried at its bottom. Water is pumped into the pipes to increase the pore pressure in the sand bed and cause so-called boiling of the sand. Basically, a kind of sand liquefaction takes place since the sand behaves like a liquid.

When this phenomenon occurs, the shear modulus of the liquefied sand is significantly decreased, and a large movement of sand occurs due to wave action. Consequently, wave energy is consumed by the resultant friction generated between sand particles during their wave-induced movement.

### Experimental Setup

The experiments were conducted in a small wave flume (30 m x 1 m x 0.5 m). Six cylindrical pipes with an inner diameter of 13 mm and a length of 4 m were horizontally installed at the bottom of the sand bed. Holes were drilled in them to supply water into the sand bed. The pore pressure is changed by adjusting the flow valves.

Two sand bed heights of  $h_s = 20$  and 40 cm were tested. During the experiments, we measured pore pressure, flow rate from the pipes, wave height, and sand movement.

Four types of tests were conducted:

- 1) Permeability tests
- 2) Scouring tests
- 3) Block-sinking tests
- 4) Wave damping tests

Fig. 1 Diagram of the Wave-Absorbing System

### 3. EXPERIMENTAL RESULTS

#### Hydraulic Gradient and Liquefaction

Figure 2 shows the results of the permeability tests, and also the results of a typical permeability test done by Yoshimi (1975). The x-axis is seepage flow rate, while the y-axis is the hydraulic gradient.

In Yoshimi's ordinary permeability test, the proportionality remains until the hydraulic gradient,  $i$ , reaches the critical hydraulic gradient,  $i_{cr}$ , and then even though the seepage flow rate is increased, the hydraulic gradient slightly decreases. This phenomenon in sand is usually called "boiling" or "quick sand." The proportionality of the seepage flow rate with respect to the hydraulic gradient determines the permeability, which is 0.038 cm/s in Yoshimi's test.

Here, however, the proportionality vanishes when the hydraulic gradient is greater than about 0.5, that is, partial boiling is caused by the nonuniform distribution of seepage flow produced by supplying water through the pipes. In this case, the permeability of the sand bed is 0.14 cm/s.

Fig. 2 Results of Permeability Tests

### Ripples and Leveled Sand Surface

A typical feature of a liquefied sand bed is its level surface. It is well known that a sand bed surface normally forms sand ripples due to wave action, whereas a liquefied sand bed always stays level.

Figure 3 shows photographs of these two sand surfaces: ripples in a non-liquefied sand bed and no ripples in a liquefied sand bed. Even if a trench is dug in the liquefied sand surface, it is soon back-filled by the leveling movement.

### Scouring of Sand Bed by Rapid Water Flow

A liquefied sand bed may easily suffer scouring due to rapid water flow over its surface. We therefore directed a water jet at the surface of an ordinary non-liquefied and liquefied sand bed, with Fig. 4 showing the resultant scouring of the liquefied sand bed due to the water jet from the nozzle, shown on the left above the bed. The sand particles are lifted up as indicated. It should be noted that the scoured location is back-filled quickly by the leveling behavior of the liquefied sand, and that the lifting of the sand particles continues.

Sand particles in the non-liquefied sand bed were lifted-up similarly to those in the liquefied sand bed and it becomes small after the sand bed was scoured to a certain depth. This is the significant difference between ordinary and liquefied sand beds.

Our results suggest a difference exists in the scouring mechanism. However, we cannot confirm that a liquefied sand bed suffers scouring more easily in comparison with ordinary beds.

### Sinking of Blocks/Caisson Breakwater

Figure 5 shows a photo of sinking concrete blocks caused by liquefied sand. The blocks appear stable in the upper photo, while in the lower ones, they sink after water is pumped into the pipes.

Figure 6 shows the sinking speed of a concrete block as a function of the hydraulic gradient  $i$  for three water supply methods: constant flow, one-side oscillatory flow, and two-side oscillatory flow. Note that sinking rapidly occurs for each method when the hydraulic gradient is greater than about 0.5.

Sand liquefaction induced by wave action is believed to be a major reason causing the blocks to sink or settle

Fig. 3 Leveling of Sand Surface

Fig. 4 Scouring of a Liquefied Sand Bed

Fig. 5 Sinking of Blocks

Fig. 6 Sinking Speed of a Concrete Block

(Nago (1981), Maeno (1985), Sakai (1992), Zen (1993), Iwagaki (1993)). It is believed that such sinking happens when the pore pressure gradient due to a wave exceeds the critical hydraulic gradient. However, this is not the case, because sinking occurs even when the hydraulic gradient is around 0.5.

Figure 7 shows the settlement of a caisson breakwater into a sand bed after pore water was supplied from its bottom. Although the caisson was expected to quickly sink due to its heavy weight, instead it remained relatively stable. The sand under the caisson is actually not liquefied, although other parts are. Consequently, the toe of the rubble mound begins sinking first.

Due to the caisson weight, the effective stress of the sand under it increases and prevents liquefaction. Wave-induced liquefaction is usually determined by considering the pore pressure gradient  $dp/dz$ . However, instead of employing this parameter, it is presumably better to apply Mohr-Coulomb failure criteria including the effective stress.

Of particular interest, the toe settlement occurring in the mounds of prototype composite breakwaters is very similar to the photographed settlement behavior. This

phenomenon was considered to be a result of scouring damage due to wave-induced water particle velocity. However, wave-induced liquefaction might be another reason for this type of damage, and therefore, proper countermeasures should be taken to mitigate this effect.

It should also be noted that the rubble mound plays an important role in preventing caisson sinking. Actually, owing to the rubble foundation, prototype caissons of composite breakwaters have never suffered from a failure like that shown in Fig. 7. The importance of the rubble mound foundation should be emphasized in the design of sea structures, however, its function has not been fully clarified.

Fig. 7 Settlement of a Caisson Breakwater

#### 4. WAVE DAMPING DUE TO SAND LIQUEFACTION

##### Wave Damping

Wave damping due to soft clay movement is generally known to be high (Yamamoto and Takahashi, 1985). On the other hand, that due to sand movement is much less because of its high shear modulus, though when liquefaction occurs, the sand becomes soft and induces high damping similar to soft clay.

Typical wave records obtained during model experiments are shown in Fig. 8. The sand bed was 40-cm-thick and regular waves with a 1-s period were applied in 25-cm-deep water. As indicated, these wave records were taken at the offshore side, the center of the sand bed, and harbor side. A record of the oscillations of the sand bed surface is also shown.

Note that wave damping clearly occurs after the water supply is started. The wave at harbor side is very small, and its height is reduced by more than 75%. In this case, the sand surface oscillates with an amplitude that is 6% of the incident wave amplitude, having a phase difference of approximately  $50^\circ$ .

Fig. 8 Typical Wave Damping Record

Fig. 9 Wave Transmission Coefficient ( $h_s = 40 \text{ cm}$ )

Fig. 10 Wave Transmission Coefficient ( $h_s = 20 \text{ cm}$ )

In Fig. 9, the wave transmission coefficient  $K_t$  is plotted as a function of the hydraulic gradient  $i$  for three wave conditions and two water depths, where  $K_t$  becomes very small when  $i$  is around 0.5 at  $h = 25$  cm. However, when  $h = 50$  cm, it is not so small, i.e., the damping is slight. Figure 10 is a corresponding graph in which the sand thickness  $h_s$  is 20 cm. Note that wave damping is comparatively much less.

These results indicate that wave damping is large when the soil thickness is deep and the water depth is shallow. It is also apparent that wave damping is large when the sand is partially, not fully liquefied.

Wave Action on a Liquefied Sand Bed

Figure 11 shows the half amplitude of pore pressure due to wave action when  $h = 25$  cm and  $h_s = 40$  cm. The pore pressure increases with an increase in the pressure of the water supplied from the bottom of the sand bed. Due to liquefaction, wave pressure penetrates deeper into the soil.

Figure 12 is a graph showing the amplitude of vertical oscillations of the sand, which increases with an increase in the hydraulic gradient, being about 10% that of the wave height at  $i = 0.5$ . Such large movement was not usually expected.

Fig. 11 Amplitude of Wave-Induced Pore Pressure Variation

Fig. 12 Amplitude of Sand Movement

Fig. 13 Phase of Sand Movement

Figure 13 shows the phase of the sand oscillations, which is actually ahead of the wave profile. As the hydraulic gradient increases, the phase difference approaches closer to zero, being about 10% of the wave period when  $i = 0.5$ . Obviously these differences in amplitude and phase are closely related to damping of wave energy in a liquefied sand bed.

As will be discussed, wave damping is large when the sand movement is large and its phase difference is close to  $90^\circ$ . As the wave pressure on the sea bed increases, the sand movement increases and the phase difference approaches close to  $0^\circ$ . However, wave damping reaches maximum at a phase difference of  $90^\circ$ , vice  $0^\circ$ .

## 5. WAVE DAMPING THEORY

### Biot's Equation

Wave damping in a soil bed has been extensively studied. Application of linear wave theory in conjunction with Biot's theory for soil motion (Biot, 1962) is generally considered useful for describing wave damping in a sea bed, even during the occurrence of sand liquefaction.

Figure 14 illustrates the phenomena of wave damping and soil motion, where  $U_z(0)$ , which is expressed as a complex number, is the amplitude of soil oscillations at the surface. In wave damping theory, the amplitude and phase of  $U_z(0)$  determine wave damping.

Fig. 14 Wave Damping and Soil Motion

Biot's theory, being widely used to describe a sand bed filled with water, employs the equations of motion of the sand and pore fluid (see Yamamoto and Takahashi, 1985).

#### Linear Wave Damping Coefficient

Wave damping on a sea bed can be defined as follows using the linear wave damping coefficient  $D_f$ :

$$K_t = H/H_I = \text{Exp} (D_f x) \quad (1)$$

where  $K_t$  is wave transmission coefficient,  $H$  the wave height at distance  $x$ , and  $H_I$  the incident wave height.

$D_f$  for an infinitely deep soil bed can be defined by the imaginary part of the complex amplitude of the vertical oscillation of sand at the surface, and therefore, it can be expressed using (see Yamamoto and Takahashi, 1985):

$$D_f = \rho_f g \delta^* / (2G^* \cosh^2 k_0 h (1 + 2 k_0 h / \sinh 2k_0 h)) \quad (2)$$

where  $\rho_f$  is the density of water,  $g$  the acceleration of gravity,  $k_0$  the wave number,  $h$  the water depth,  $G^*$  the representative shear modulus, and  $\delta^*$  the equivalent damping factor.

It should be realized that  $G^*$  and  $\delta^*$  are difficult to evaluate. Using the typical wave record in Fig. 8, for example,  $D_f$  is  $0.35 \text{ m}^{-1}$  and the value of  $G^*/\delta^*$  is  $2700 \text{ N/m}^2$ . If it is assumed that  $\delta^*$  ranges from 0.1 to 100, then  $G^*$ s ranges from 27 to 27,000  $\text{N/m}^2$ . However, this value is quite small, and consequently, these parameters should be investigated further.

## 6. CONCLUDING REMARKS

Our major conclusions are as follows:

1) The fundamental characteristics of a liquefied sand bed were experimentally studied, and it was shown that partial liquefaction occurs when pore water is supplied from pipes located at the bottom of sand bed. It was also found that blocks will sink into a sand bed even when a small hydraulic gradient is present. Effective stress analysis using Mohr-Coulomb failure criteria is considered to be better than pore pressure gradient analysis in determining whether a sinking failure will occur.

2) Wave damping due to a liquefied sand bed can be

significant, even at a hydraulic gradient as low as about 0.5. When the water depth is shallow and the sand bed thickness is deep, then wave damping is large. Wave damping can be expressed by Biot's equation using the linear wave damping coefficient.

Our new wave-absorbing system can be employed as a wave barrier designed to produce a calm sea area, and may be especially suitable for damping waves at a harbor entrance. The necessary electrical power for system operation can be supplied from a land-based power generation station or possibly wave power converters. Further work will be directed at researching practical system application.

## CHAPTER 196

### LABORATORY STUDY OF SURF-ZONE TURBULENCE ON A BARRED BEACH

Francis C. K. Ting<sup>1</sup>

#### ABSTRACT

Wave height, wave set-up, undertow, and turbulent velocity on a plane beach and a barred beach were compared in the case of regular waves. The study showed that the presence of an offshore bar altered the turbulent flow in the surf zone by altering the characteristics of the broken waves. It was found that the magnitude of undertow and turbulence intensity were smaller in the inner surf zone on the barred beach. These results suggest that it may be possible to reduce the erosive wave action on beaches by construction of underwater berms in the nearshore zone. Further studies are needed to determine the effects of water depth, berm width and crest elevation on surf-zone turbulence under different wave conditions in order to provide explicit design guidance.

#### INTRODUCTION

This study deals with the characteristics of surf-zone turbulence on a barred beach. The motivation for this work is the effect of offshore bars on beach erosion. It is well known that the dynamic response of a beach under storm wave attack is to sacrifice some beach. Most of the sand removed from the beach are transported offshore and deposited as longshore bars. These bars in turn protect the beach from further erosion. The question which is the basis of this study is how offshore bars protect a beach from erosion. Knowing the how may allow us to develop more effective methods to curb beach erosion. For example, the U.S. Army Corps of Engineers has been using dredged material to construct underwater berms in the nearshore zone (MacLellan 1990, MacLellan and Kraus 1991). Such berms are placed in the form of long linear mounds for the protection of the coastline. It is believed that a berm with sufficient relief will shoal and break the higher erosive waves accompanying storms, forcing the waves to dissipate their energy in the surf zone, and thus reduce the erosive wave action on the beach. In reality, the process is probably more complicated than

---

<sup>1</sup> Oc. Engrg. Program, Dept. of Civ. Engrg., Texas A&M Univ., College Station, TX 77843-3136.

this. Since sediment transport and beach erosion are tied in a fundamental way to the turbulent flow in the surf zone, description of wave characteristics alone will not solve the whole problem. It will be shown that information on flow velocity and turbulence are needed in order to develop explicit design guidance for nearshore berm construction. Moreover, a thorough understanding of mean and turbulent flow characteristics on barred beaches will improve our knowledge of surf-zone dynamics, which is imperative for the development of more reliable coastal models.

There are very few studies which directly address the differences between wave breaking on barred and plane beaches. Smith and Kraus (1991, 1993) studied wave height transformation, reflection, and runup of monochromatic and random waves on barred and plane beach profiles in a wave tank. They found that incident waves with the same characteristics in deep water break differently on barred and plane beaches. For example, some waves that would spill on a plane slope plunge if a bar is present, and some plunging waves on plane slope collapses on a barred profile. Smith and Kraus's study pertained only to macro-features of wave breaking; micro-features of flow velocity and turbulence were not investigated. However, from their description of breaking wave characteristics on plane and barred beaches it may be expected that the presence of offshore bars would alter the turbulent flow in the surf zone by altering the process of wave breaking and turbulence production.

The structure of surf-zone turbulence has a profound influence on sediment transport and beach erosion. Recently, Ting and Kirby (1994) studied the characteristics of mean flow and turbulence in spilling versus plunging breakers. Here, "mean flow" is defined as the organized wave-induced flow which includes the undertow and the orbital wave motion. They found that turbulent kinetic energy was transported seaward under a spilling breaker and landward under a plunging breaker by the mean flow. Considering the common assumption of turbulent energy stirring up sediment and making it available for transport by the mean flow, it may be concluded that the direction of sediment transport would be seaward under spilling breakers and landward under plunging breakers. This is consistent with the field and laboratory observation that spilling breakers tend to result in beach erosion, while plunging breakers produce accretionary beach profiles. It also suggests that the types of beach profiles produced by storm and swell waves are tied in a direct way to the turbulence dynamics in breaking waves, particularly to the relationship between mean flow and turbulent kinetic energy. Because of this, it would be important to compare the mean and turbulent flow characteristics on plane and barred beaches for the same incident wave conditions to determine the effects of offshore bars on the turbulence flow in the surf zone.

In this present study, fluid velocities in a laboratory surf zone were measured using a two-component laser-Doppler anemometer, and surface elevations were measured using a resistance wave gage. Wave height, wave set-up, undertow, and turbulent velocity on a plane beach and a barred beach were compared for the same incident wave conditions. Although experiments were conducted using

both regular and irregular waves, only the results for regular waves are presented here. The structure of turbulent flow in irregular waves will be the subject of a separate paper.

## EXPERIMENTAL PROCEDURE

A schematic diagram of the experimental arrangement is shown in Fig. 1. The experiments were conducted in a two-dimensional wave tank in the Hydromechanics Laboratory at Texas A&M University. The wave tank was 37 m long, 0.91 m wide, and 1.22 m deep with glasswall throughout. It was equipped with a hinged-flap programmable wavemaker. A 1/35 slope false bottom built of marine plywood was installed in this tank to create a plane beach; the slope was sealed to the tank walls with silicone sealant. The coordinate system was chosen with  $x$  measured positive seaward from the shoreline and  $z$  extending positive upward from the still water level. The water depth in the constant-depth section was 45.72 cm. The incident wave height was 12.2 cm and the wave period was 2.0 s. The ratio of deep-water wave height  $H_0$  to deep-water wavelength  $L_0$  was 0.02 based on linear shoaling. The waves broke at a water depth of about 20.0 cm in the form of a spilling breaker. The breaking point was defined as the location where air bubbles began to be entrained in the wave crest.

The barred beach was created by placing a submerged solid triangular-shape object on the sloped false bottom. The geometry of the object was selected based on large wave tank studies and field measurements of bars (see, Larson and Kraus 1989). The dimensions of the bar are shown in Fig. 2; it was 9.6 cm high, 145 cm wide, with a seaward bar angle of  $6^\circ$  and a shoreward bar angle of  $10^\circ$ . The bar was located at the breaking point on the plane beach; the still water depth was 23.1 cm at the seaward toe of the bar, 10.4 cm at the bar crest, and 18.8 cm at the shoreward toe of the bar. In order to determine the incident wave heights it was necessary to measure the reflection coefficients for the plane and barred beaches. Therefore, a wave gage was mounted on an instrument carriage which was moved along the constant-depth section of the wave tank to measure the spatial modulations in wave amplitudes created by the interference of the incident and reflected waves. The reflection coefficient  $K_r$  was determined from the two extreme wave heights  $H_{\max}$  and  $H_{\min}$  of the envelope of amplitudes by  $K_r = (H_{\max} - H_{\min}) / (H_{\max} + H_{\min})$ . It was found that the reflection coefficients for the plane and barred beaches were almost the same and in both cases less than 5%. Hence, the bar did not reduce the wave energy reaching the surf zone. Instead, it caused the waves to plunge into the water ahead, and thus dissipated more energy in the outer surf zone.

Water surface elevations and fluid velocities were measured at three locations in the inner surf zone; their exact locations and water depth are given in Table 1. The following notations are used in this paper;  $\zeta$  is water surface,  $u$  is horizontal velocity,  $w$  is vertical velocity,  $H$  is wave height,  $d$  is still water depth,  $\bar{h}$  is mean water depth, and the superscripts overbar, tilde and acute accent denote time average, phase average and turbulent fluctuation, respectively. Surface elevations were measured using a resistance wave gage. The gage was

**TABLE 1** Locations of Measurements and Water Depths

calibrated in quiescent water, the calibration curve was found by fitting a fourth order polynomial to 15 data points. Water particle velocities were measured using a two-component laser-Doppler anemometer (LDA). Velocity measurements were conducted mainly in the region below trough level and above the bottom boundary layer. The LDA was a backscatter, three-beam system built by Dantec Electronics. It consisted of a 4 W argon-ion laser (Innova 70-5 from Coherent Inc.), transmitting and receiving optics, traverse mechanism, and one frequency tracker and shifter for each velocity component. It was found that the output voltage from the frequency trackers had a non-negligible long-term fluctuation, which could seriously affect the accuracy of time average velocity measurement such as the undertow. Therefore, the output voltage from the frequency trackers in still water condition was recorded in each experiment and used to correct the measured velocity. The estimated error for the undertow was  $\pm 1.0$  cm/s.

Periodic waves were generated for 15 minutes before data were taken. Thus, the measurements corresponded to a steady-state condition in the wave tank. Data were taken by an IBM compatible 486 computer equipped with a Metra-Byte DASH-16(F) data acquisition board. Sampling frequency was 100 Hz for each channel. The measured velocity was first high-pass filtered at 0.1 Hz to remove any long-term fluctuation due to electronic signal drifting. The orbital wave velocity was obtained by phase averaging the filtered velocity over one hundred and two successive waves. The turbulent velocity was found by subtracting the phase average velocity from the filtered velocity. The frequency tracker had a built-in lock detector to record signal drop-out, which was typically less than 5% in these experiments. Nevertheless, velocity data that were obtained during signal drop-out were not used in computing the mean flow and the turbulent velocity.

## RESULTS

Figs 3(a)–3(c) compare the phase average surface profiles at each station on the plane and barred beaches. The control signal to the wave generator has been used to synchronize the surface profiles in different experiments. Table 1 summarizes the major results including wave height and wave set-up. Visual observations showed that the waves broke in the form of a spilling breaker on the plane beach, whereas they plunged into the water shoreward of the bar on the barred beach. It is seen in Figs. 3(a)–3(c) that the waves on the barred beach lagged behind the waves on the plane beach, which is to be expected. The wave set-up was larger on the barred beach but closer to shore the difference became increasingly smaller. On the plane beach, the wave height to water depth ratio  $H/h$  remained constant through the inner surf zone; the measured value of 0.5 is typical of spilling breakers. The ratio of wave height and water depth was somewhat smaller on the barred beach and continued to decrease shoreward. Perhaps the most important difference is that the broken waves on the plane beach had a “saw-tooth” profile which varied only slowly from one station to another, whereas the broken waves on the barred beach had a

secondary crest and the waves reformed through the surf zone. This behaviour has been observed by Smith and Kraus (1991, 1993), but its significance was not recognized. It is seen that the wave profiles were significantly different on plane and barred beaches. This would have a profound influence on the process of wave breaking, and thus the turbulence dynamics in the surf zone. This is because wave breaking originates from instabilities in the water surface therefore the rate of energy transfer from organized wave motion to turbulent motion (i.e. turbulence production) will be related to the details in the broken waves such as wave height and wave shape. Furthermore, since turbulence transport processes such as turbulent diffusion and viscous dissipation are passive processes which can only proceed at a rate dictated by the behaviour of large-scale structure created by wave breaking we should expect that turbulence dynamics in the surf zone will also depend on the wave characteristics. These ideas will be elucidated further when we examine the structure of undertow and turbulence.

Figs. 4(a)–4(c) plot the variations of undertow with distance from mean water level on the plane and barred beaches. The undertow for the plane beach at stations 1 and 2 were taken from Ting and Kirby (1994), which has virtually the same experimental conditions. It is seen that the magnitude of undertow on the barred beach was generally smaller. This is the result of different wave characteristics on the plane and barred beaches. In these experiments, the wave conditions at each station were recorded using a video camera. The video recording showed that wave breaking in the inner surf zone was less intense on the barred beach. Since the undertow is a return current that is created to balance the water carried shoreward by the surface rollers, we should expect that the magnitude of undertow would be smaller under a weaker breaker. Thus, it appeared that by causing the incident waves to form a plunging breaker, the bar changed the way the broken waves evolved through the surf zone which in turn, altered the turbulent flow.

Figs. 5–7 plot the variations of turbulent velocity with distance from mean water level on the plane and barred beaches. It is seen that the horizontal and vertical components of turbulent velocity decreased with increasing distance from the surface, and the vertical velocity remained smaller than the horizontal velocity; these results are to be expected. The important new result is that these figures clearly show that turbulent velocities in the inner surf zone were considerably smaller on the barred beach. If it is assumed that turbulent velocity fluctuations are responsible for keeping sediment in suspension, and the undertow transports the sediment, then the rates of sediment transport from onshore to offshore would be decreased by the formation of offshore bars. This would have a beneficial effect on the beach profile.

## CONCLUSIONS

To examine the effects of offshore bars on wave and turbulence characteristics in the surf zone laboratory experiments were conducted in which measurements of fluid velocity and surface elevation were made on a plane beach and a barred

beach. Some experimental results for regular waves are reported here. The following main conclusions can be drawn from this study:

1. The broken waves reformed on the barred beach, the wave profiles in the surf zone were significantly altered in comparison to the broken waves on the plane beach.
2. The offshore bar reduced the magnitude of undertow in the inner surf zone.
3. Wave breaking in the inner surf zone was less intense on the barred beach.
4. Turbulent velocity in the inner surf zone was considerably smaller on the barred beach.
5. This study shows that undertow and turbulence intensity differ on plane and barred beaches. This behaviour is related to the effect of the bar on wave breaking. It is further shown that description of turbulent flow characteristics on barred beach profiles is important for providing the data base for developing explicit design guidance for nearshore berm construction.

## CHAPTER 197

### BEACH EROSION AROUND A SAND SPIT –An Example of Mihono-Matsubara Sand Spit–

Takaaki Uda<sup>1</sup> and Koji Yamamoto<sup>2</sup>

#### Abstract

Topographic changes around Mihono-Matsubara Sand Spit were studied based on bottom sounding data and aerial photographs. On the Shizuoka and Shimizu coasts located upcoast of the sand spit, erosion waves are generated due to interruption of longshore sand transport by the construction of coastal structures. The propagating velocity of these erosion waves was found to range from 0.5 to 0.8km/yr. This agrees considerably well with the theoretically estimated value of 0.47km/yr. Comparison of beach profiles showed that the dominant beach changes take place at depths shallower than  $-7\text{m}$ , and this provides the closure depth for profile changes on this coast. The longshore sand transport rate was evaluated to be  $1.3 \times 10^5 \text{m}^3/\text{yr}$  at specific locations on the Shizuoka and Shimizu coasts, and it was found that this transported sand discharges into submarine canyons, forming a steep slope of around  $1/2$ , thus resulting in the net loss of sand from this coast.

#### 1. INTRODUCTION

In general, sand spits form where obliquely incident waves are dominant and a large amount of sediment is supplied from rivers or coastal cliffs to the channel or the bay. Johnson (1919) and Zenkovich (1967) studied the formation process of various kinds of sand spits, focusing on the change in shoreline configuration. In their studies, spit forms were well classified, but the consideration of the relationship between spit formation and ambient bottom profiles, which is of vital importance to wave refraction, was not adequate. From this point of view, Uda and Yamamoto (1986, 1988, 1989, 1991) studied the formation process of sand spits along with the deformation mechanism by comparing data obtained from coasts, lake shores and model experiments with particular emphasis on the relationship between sea bottom topography and sand spit formation.

On the western coasts of Suruga Bay there are several well developed sand spits;

<sup>1</sup>D. Eng., Coastal Eng. Div., Public Works Res. Inst., Ministry of Construction, Ibaraki 305, Japan.

<sup>2</sup>Research Engineer, Ditto.

examples are Mihono-Matsubara Sand Spit and Wadabana Sand Spit on the Suruga coast. Mihono-Matsubara Sand Spit is one of the most famous compound spits, being the largest in Japan, together with the Notsukezaki Spit in eastern Hokkaido. This sand spit was originally formed by northward longshore transport carrying a large amount of sediment supplied from the Abe River. The decrease in sand supply from the river as a result of the excavation of the river bed to obtain construction material caused serious beach erosion around the Abe River mouth after 1965. The area of erosion rapidly expanded northeastward after 1977 and reached further downcoast (Shimizu coast) in 1982 (Toyoshima et al., 1981; Toyoshima, 1984). After 1979 various countermeasures against beach erosion were adopted and related construction work is still underway. No fundamental solution to the erosion problem, however, has yet been obtained. Beach erosion has also in recent years started at the tip of the Mihono-Matsubara Spit. Similar beach changes have been commonly observed at other coasts near sand spits in Japan.

In order to solve the above-mentioned coastal erosion problem, it is necessary to fully understand the topographic characteristics and deformation process of the sand spit. Such beach changes are considered to be different from those of straight coastlines with a gentle bottom slope. From this viewpoint, the present study aims at the investigation of beach erosion and accretion around a sand spit, taking the Shizuoka and Shimizu coasts as typical examples. The results of this case study will be useful when considering measures against beach erosion on other coasts suffering from similar problems. For this purpose, the topographic characteristics and beach deformation around the Mihono-Matsubara Sand Spit are studied using bottom sounding data and aerial photographs (Uda and Yamamoto, 1992).

## 2. TOPOGRAPHIC CHARACTERISTICS AND WAVE CONDITIONS

The Mihono-Matsubara Sand Spit, a typical compound sand spit in Japan, is located on the west coast of Suruga Bay (Fig. 1). Within the study site, the area of about 7km from the Abe River mouth to the Takigahara River mouth is referred to as the Shizuoka coast, and the 10km from the end of the Shizuoka coast to the tip of Mihono-Matsubara Sand Spit as the Shimizu coast. Suruga Bay is very deep, having the Suruga Trough in the center, and the bottom slope on each shore of the bay is steep. Narrow continental shelves develop only near the alluvial fans of the Abe and Ohi Rivers. The continental shelf off the Abe River mouth has a water depth of about 100 m at its offshore end.

The sea bottom topography near Mihono-Matsubara Sand Spit is illustrated in Fig. 2. The bottom slope at the tip of the sand spit is very steep; it falls to -400m with a slope of about 1/5, and several submarine canyons exist very close to the shoreline. Between the base of the sand spit and the Abe River mouth a gentle slope is found between -10m and -30m depths. The shape of bottom contours deeper than -50m is complicated, and several submarine canyons develop. Figure 2 also shows the arrangement of survey lines. Point No. 0 is located at the tip of the spit, No. 175 is at the left bank of the Abe River mouth, and the survey lines are arranged at 100m intervals from east to west. It is seen from the figure that the shoreline configuration is convex seaward between No. 0

Figure 1. Location of Shizuoka and Shimizu coasts on the western shore of Suruga Bay.

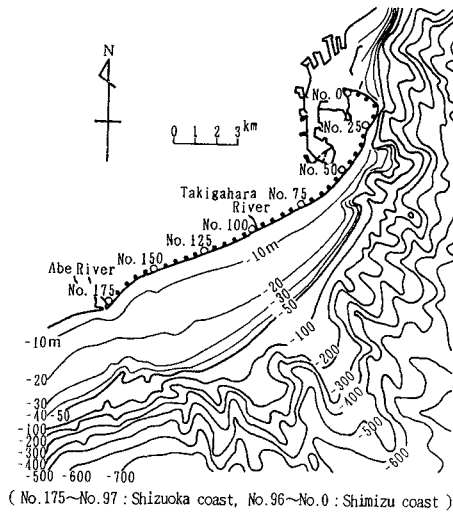

Figure 2. Bottom contours off Shizuoka and Shimizu coasts and alignment of survey lines (No. 0 - No. 175). No. 0 is located at the tip of the sand spit and No. 175 at the left bank of the Abe River mouth.

and No. 75, straight between No. 75 and No. 150, and concave seaward between No. 150 and No. 175.

Since no wave observation is performed off this coast, the distributions of wave directions with the classification of wave height obtained by wave observation off Mochimune Fishery Harbor and Ohigawa Port are shown in Fig. 3. These observatory stations are respectively located about 2.5km WSW and 20km SSW from the Abe River mouth, as shown in Fig. 1. It can be seen from Fig. 3 that the predominant wave direction is SSE at Mochimune Fishery Harbor and SE at Ohigawa Port. The energy-averaged significant wave height estimated from Ohigawa Port data from 1967 to 1979 is 0.82m, the mean period is 9.0s, and the dominant wave direction is SE. The direction of the normal to the coastline on the Shizuoka and Shimizu coasts runs SSE through ESE. Therefore, waves from S to SSE are obliquely incident to the coasts, causing northeastward longshore sand transport. According to foreshore sampling conducted in 1989, beach material has a median diameter in the range of 0.3mm to 20mm and specific gravity between 2.67 and 2.72. As for the tide condition, the mean monthly highest water level is T.P. + 0.806m and the mean monthly lowest water level is T.P. -0.733m, where T.P. is the abbreviation of the Tokyo Peil (mean tide level in Tokyo bay).

### 3. TOPOGRAPHIC CHANGES OF THE COAST

#### 3.1 Long-Term Change in Shoreline Configuration

Long-term change in shoreline position in the study area was investigated by comparing aerial photographs taken in 1948 and 1987 (Fig. 4). Shoreline position was read from the aerial photographs enlarged to the scale of 1/10000. The beach slope near the shoreline is from 1/5 to 1/10, which is steep enough to neglect shoreline change due to change in tide level. On the Shizuoka coast (No. 175 to No. 97) the shoreline retreated

Figure 4. Change in shoreline position between 1948 and 1987 observed from aerial photographs.

approximately 50m on average during the 39 years, while the shoreline apparently advanced on the Shimizu coast located to the east. The shoreline configuration fluctuates considerably between No. 140 and No. 170 because of the accretive effect of the offshore breakwaters built in this area.

The longshore distribution of the annual change in shoreline position determined from soundings off the Shizuoka and Shimizu coasts is shown in Fig. 5, where all soundings were carried out in March unless otherwise indicated in the figure. The longshore distribution of cumulative shoreline change during the entire survey period is also shown at the bottom of the figure. Arrows in the figure indicate the position of the eastern end of the area where wave-dissipating structures were adopted as countermeasures against beach erosion. The area has been extended eastward along the shore from the Abe River mouth.

In 1975, beach erosion began between No. 144 and No. 159. The area where the shoreline retreated moved eastward with time and reached the Shimizu coast in 1983. The mean propagation velocity of the erosion wave, in which the eroded zone propagates downdrift (Inman, 1987), was about 0.8km/yr between 1975 and 1983. In 1988, the eroded area reached the area between No. 59 and No. 80. The propagation velocity of the erosion wave decreased between 1983 and 1988 compared to that between 1975 and 1983, but the area of erosion still extended at a rate of about 0.5km/yr. Inman (1987) suggested that the propagation velocity of the accretion wave, referring to the propagation of the opposite perturbation caused by the sudden release of sand, ranges from 0.5 to 1.5km/yr near Santa Cruz and 0.6 to 1.1km/yr at San Onofre in California. These values are on the same order as in the present study, although the nature of the waves is quite different. It is noted in Fig. 5 that the maximum change in shoreline position at the moving center of mass is around 25m. It should be further noted that, together with the extension of the eroded area, the area covered by the wave-dissipating structures apparently extended. The erosion waves seem to have propagated as a result of the extension of the wave-dissipating measures, but this is not true. In fact, these measures were undertaken at least one year after the onset of beach erosion. This indicates that the countermeasures followed the propagation of the erosion waves.

Figure 5. Longshore distribution of annual change in shoreline position between 1975 and 1988 calculated by bottom sounding data. An erosion wave defined by the longshore propagation of the eroded area (shaded zone in the figure) can be observed and its propagation velocity is about 0.8km/yr in the period between 1975 and 1973, and about 0.5km/yr between 1983 and 1988.

### 3.2 Longshore Changes in Sea Bottom Topography

In order to investigate the topographic features of the Shizuoka and Shimizu coasts, the longshore distribution of the offshore distance from the reference point to 0 to  $-10\text{m}$  contour lines was obtained from the bottom sounding data taken in 1988 and is summarized in Fig. 6.

Between No. 75 and No. 175, the intervals between 0 to  $-5\text{m}$  contour lines are considerably narrow, and the bottom slope of this area is 1/10 to 1/15. The intervals between  $-5$  to  $-10\text{m}$  contour lines further offshore are much wider, the bottom slope being gentler at 1/90 to 1/125. The gentle bottom slope in the offshore zone is considered to have formed as a result of erosion of a region shallower than the closure depth for profile changes, which is associated with shoreline recession. On the other hand, the shoreline configuration is very similar to the shape of contour lines up to  $-7\text{m}$ . This suggests that the beach profiles near the shoreline move in parallel and that the profile

Figure 6. Longshore distribution of offshore distance from a reference point to some contour lines along the study area observed in 1988.

changes are caused by longshore sand transport.

Between No. 35 and No. 75 close to the Mihono-Matsubara Sand Spit, the intervals between 0 to  $-5\text{m}$  contour lines are narrow, similarly to the case of the western coast, and the bottom slope is about  $1/10$ , whereas the intervals between  $-5$  to  $-10\text{m}$  contour lines suddenly decrease from No. 40. The intervals between 0 to  $-10\text{m}$  contour lines at the tip of the Mihono-Matsubara Spit (No. 0 to No. 35) are very short, and the bottom slope is steep at about  $1/5$ .

The comparison of the bottom topography of these three areas with the change in shoreline configuration between 1948 to 1987, as shown in Fig. 4, explains that the topographic features of the sea bottom and the change in shoreline configuration correspond well to each other; that is, a gentle offshore slope is formed between No. 75 and No. 175, where the shoreline retreated in recent years, and a steep slope is formed between No. 10 and No. 20 near the tip of the sand spit, where the shoreline greatly advanced. From these characteristics it should be noted that Fig. 6 shows not only the present topography, but also contains information relating to the topographic changes during beach deformation.

### 3.3 Comparison of Beach Profiles

Two typical profiles along survey line Nos. 122 and 142 on the Shizuoka coast were selected for investigation of long-term profile changes. First, the profile changes at No. 142 are shown in Fig. 7, in which the reference year is selected as 1975. The beach had been severely eroded by 1980 to yield the concave profile upward. Thereafter, sediment accumulated and the beach slope became gentle. Because a group of detached breakwaters was constructed east of this survey line after 1980, eastward longshore sand transport was blocked. This is the cause of accretion on the survey line. Figure 7 indicates that the closure depth for profile changes associated with beach erosion or accretion is about  $-7\text{m}$ .

Figure 7. Temporal changes in beach profiles at No. 142. Beach was eroded severely up to 1980, leading to a concave profile near the shoreline, and beach slope became gentle due to sand accumulation.

Figure 8. Temporal changes in beach profiles at No. 122. This beach was also eroded severely and a concave beach profile was formed.

The profile change at No. 122 located 2km east of No. 142 is shown in Fig. 8. Along this line, erosion progressed rapidly from 1975 to 1982, and the beach profile became concave upward. It is revealed that the location of the shoreline in 1975 was at a depth of 3~4m in 1982 as a result of the erosion. Two profiles, as mentioned above, show the characteristic features of a very gentle slope existing in the offshore zone. Such a flat bottom was formed by the erosional effect of waves, since the water depth over the slope is almost equal to the closure depth for profile changes. Furthermore, when sand accumulates on the beach, the profile near the shoreline becomes convex; it becomes concave when erosion occurs. This agrees well with the profile characteristics around a sand spit obtained in previous studies by Uda and Yamamoto (1986, 1991).

#### 4. ESTIMATION OF THE LITTORAL TRANSPORT RATE AND PROPAGATION VELOCITY OF EROSION WAVES

Figure 5 reveals considerable advance and retreat of the shoreline position west of No. 42 and wide, gentle offshore slopes were well developed below  $-7\text{m}$ . Thus, in these areas the closure depth for profile change is considered to be approximately constant. At the tip of the sand spit, sand discharges into the deep ocean, and it is difficult to define the closure depth. Eight survey lines were therefore selected between No. 42 and No. 161; variation in cross sectional area,  $\Delta A(\text{m}^2)$ , and the change in shoreline position,  $\Delta y(\text{m})$ , were calculated for each profile. The data were examined by means of regression analysis to obtain the following relationship between  $\Delta A$  and  $\Delta y$  with the

correlation coefficient  $R=0.87$ :

$$\Delta A = 11.0 \Delta y - 19.0 \quad (1)$$

The regression coefficient of  $\Delta A$  and  $\Delta y$  gives the characteristic height of beach change,  $h$ , when topographic change is caused by longshore drift. Figure 9 illustrates the definition of the characteristic height of beach change due to longshore sand transport, where  $h_c$  is the closure depth for profile change and  $h_R$  the wave run-up height. The characteristic height is often used in the one-line model for shoreline change to relate the change in cross-sectional area to the change in shoreline position. The characteristic height for this coast is thus evaluated as  $h=11\text{m}$ .

Based on the above definition, the volume change of the beach can be calculated by multiplying the change in beach area by the characteristic height of beach change. Furthermore, the littoral transport rate can be estimated from the temporal change in sand volume taking into account the continuity condition of littoral transport. With reference to Fig. 5, the littoral transport rate is estimated by selecting the area between No. 70 and No. 85, where the eroded region simply extended from 1984 to 1988 and the area between No. 151 and No. 166, where the accretion progressed in the same period, each area having a length of 1,500m. A great number of wave-dissipating structures were installed west of No. 85, so that sand supply from upcoast is considered to be greatly decreased. On the other hand, between No. 151 and No. 166, the discharge of longshore drift is considered to have been interrupted by the group of detached breakwaters and the jetty of the floodway located at No. 151. Figure 10 shows the cumulative change in beach areas of accretion and erosion since 1984. The area of erosion between No. 70 and No. 85 simply increased with time, and the total increase in four years was  $4.5 \times 10^4 \text{m}^2$ . The rate of increase is therefore  $1.1 \times 10^4 \text{m}^2/\text{yr}$ . Similarly, an increase of  $5.2 \times 10^4 \text{m}^2$  occurred between No. 151 and No. 166, the rate of increase being  $1.3 \times 10^4 \text{m}^2/\text{yr}$ . Here

Figure 9. Definition of characteristics height of beach change due to littoral transport ( $\Delta A$ : increase in cross-sectional area,  $\Delta y$ : the change in shoreline position).

Figure 10. Temporal changes in accreted (No. 151–No. 166) and eroded (No. 70–No. 85) beach areas since 1984.

assumptions that the total amount of sand supplied from upcoast is deposited in the accretion zone and that a constant amount of sand discharges out of the erosion zone without any sand supply were made. The rate of change in Fig. 10 multiplied by the characteristic height of beach change then gives the littoral transport rate. Multiplying by  $h=1$  m determined from Eq.(1), the littoral transport rate across No. 70 is evaluated as  $1.2 \times 10^5 \text{m}^3/\text{yr}$  and across No. 166 as  $1.4 \times 10^5 \text{m}^3/\text{yr}$ , the average being  $1.3 \times 10^5 \text{m}^3/\text{yr}$ . These values are very close, and this indicates that no erosion or accretion occurred as long as continuous longshore drift took place in this range of the coast. This also implies that erosion will begin in the future at the tip of the sand spit because of significant decrease in sand supply.

Inman (1987) defined the propagation velocity of accretion or erosion waves,  $V$ , in terms of the longshore sand transport rate  $Q$  ( $\text{m}^3/\text{yr}$ ) and the volume change  $q$  associated with the moving center of mass as

$$V=Q/q. \quad (2)$$

As mentioned above, here,  $Q = 1.3 \times 10^5 \text{m}^3/\text{yr}$  on average. Furthermore, the relation of  $q = h \Delta y_{\text{max}}$  holds where  $\Delta y_{\text{max}}$  is the maximum shoreline change in terms of the moving center of mass. Substituting  $h=1$  m and  $\Delta y_{\text{max}} = 25$  m as obtained from Fig. 5 into this relation, we obtain  $V=0.47$  km/yr, which is comparable to the measured velocity (0.5–0.8 km/yr). As shown in Fig. 6, between Points No. 150 and No. 100 the foreshore width is so narrow that the maximum shoreline retreat ( $y_{\text{max}}$ ) is reduced owing to the restriction of the sea wall. This may cause a higher velocity of erosion waves. On the other hand, between Points No.100 and No.60 the foreshore width is sufficiently wide, and this is a possible reason for the agreement between measured and calculated velocities. It is finally concluded that the extension of the area of erosion can be explained well by introducing the concept of erosional waves.

## 5. BEACH CHANGES IN VICINITY OF TIP OF SAND SPIT

Figure 11 shows sea bottom contours and alignment of survey lines at 100m intervals around the tip of the Mihono-Matsubara Sand Spit. The origin of the survey lines is set at No. 0 at the tip of the sand spit. Steep submarine canyons develop at locations No. 12 through No. 30, No. 36 through No. 44, and No. 48 through No. 54, as shown in Fig. 11, in strong contrast to the development of a wide continental shelf with a gentle bottom slope west of No. 55.

First, the change in shoreline position between No. 47 and No. 71 is shown in Fig. 12 with reference to the shoreline form in 1988. In 1988 the shoreline extended straight north of No.71, where a coastal revetment had been installed to protect the coastline. The shoreline had started to retreat north of this revetment by 1989. The shoreline retreat takes a maximum value at a location beside this revetment, and it gradually decreases eastward with negligibly small change at No. 58. The shoreline change up to 1990 is similar to that measured to 1989, but the shoreline change increased west of No. 62 with a slight recession of the shoreline between No. 50 and No. 58. It is well known that installation of a coastal revetment and wave-dissipating breakwaters at a site updrift of littoral drift simply causes downcoast erosion, requiring further preventive measures

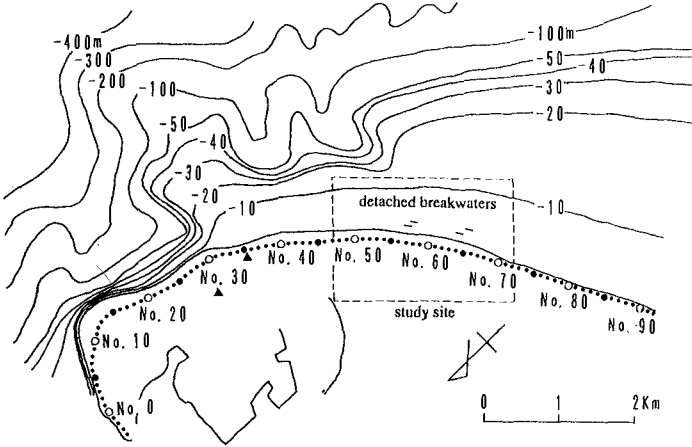

Figure 11. Bottom contours and alignment of survey lines at the tip of the sand spit.

Figure 12. Change in shoreline position between No. 47 and No. 72.

against beach erosion. Recurrence of this process reduces the sandy coastline to an artificial coastline protected by various coastal structures, and the disappearance of natural sandy beaches. On the Shimizu coast, therefore, a method of stabilizing the coastline, in which a set of detached breakwaters is installed in a leap-frog manner at wide intervals, was employed. In 1991 a detached breakwater was installed at No. 65 as part of this plan. Since the detached breakwater blocked northward littoral drift, a step-type shoreline was formed at that location. As expected, downcoast, the shoreline between No. 64 and No. 48 retreated to become triangular. The area of erosion extended eastward about 900m in two years, resulting in the expansion rate of erosion of 0.45 km/yr. This propagation velocity is very close to the value of 0.5 km/yr obtained for the Shizuoka coast between 1983 and 1988, as mentioned earlier. In 1992 two sets of

detached breakwaters with an opening width of 500m were installed. Due to the installation of these detached breakwaters the shoreline between the two sets of detached breakwaters retreated a maximum of about 36m relative to the initial position in 1988, but the recession rate clearly decreased. In contrast the downcoast shoreline retreated in the same manner as the shoreline change observed in 1991.

Here detailed topographic changes around detached breakwaters are investigated. Figure 13 shows the change in sea bottom contours before and after the installation of detached breakwaters. Every contour extended straight alongshore in 1988 before the installation, as shown in Fig. 13(a). The interval between the contours between the shoreline and 4m depth is very narrow, in strong contrast to the gentle slope beyond 5m depth. In 1992 the coastline which was almost straight in the past became step-type form as a result of the installation of detached breakwaters I and II, as shown in Fig. 5(b). Typical topographic features showing the dominance of northward littoral drift can be observed in the vicinity of detached breakwaters I and II. For example, the western shoreline of these detached breakwaters extends straight toward the breakwater, whereas the eastern shoreline has an embayment shape with maximum shoreline retreat at the location beside the detached breakwater.

Mihono-Matsubara Sand Spit protrudes the furthest northeastward at No. 12, as shown in Fig. 11. At this site the sandy beach is very wide, but steep submarine canyons are developed very close to the shoreline. Figure 14 shows the beach profiles measured in 1988 and 1992 along No. 14 through No. 10 in the vicinity of the tip of the spit. At No. 14 sand is deposited up to a depth of 65m to form a steeper slope. A similar feature can be observed at No. 13, showing deposition up to a depth of 65m. The depth of the submarine canyon gradually decreases north of No. 14, and the offshore point of transition of the slope is located at 50m depth at No. 12. Sand is deposited again at No.

Figure 13. Topographic changes around two sets of detached breakwaters I and II between 1988 and 1992.

Figure 14. Change in longitudinal profile between 1988 and 1992.

12, while on upward convex profile is maintained. At No. 11 maximum advance of the shoreline position, 16m, is observed.

At No. 10 the point of transition of the slope becomes shallow, 22m depth, compared to the depth at survey lines located south of this line, and sand is deposited only on the steep slope in a zone shallower than 22m depth. It should be noted that sand is deposited up to 70m depth at maximum and 22m depth at minimum in the five beach profiles located in the vicinity of the tip of the sand spit. This is in marked contrast with the fact that the beach was eroded in a region shallower than 7m depth, as mentioned in section 3.2. In the case of beach erosion the shoreline retreats mainly due to the erosion concentrated in a zone shallower than the closure depth of around 7m on this coast, whereas sand discharges into the very deep region, where depth is one order of magnitude greater than the closure depth in the erosion zone, due to the topographic features of the sand spit. This is a very severe problem for this coast, because the total area of accretion becomes much smaller than the area of erosion in comparison to the areal change of the beach, causing net loss in the area of sandy beaches.

Here the change in sand volume of the beaches in accretion and erosion zones is shown in Fig. 15, taking 1988 as the reference year for comparison. As erosion and accretion zones, the area between No. 47 and No. 72 and the area north of No. 47 are selected on the basis of the recent shoreline changes, as shown in Fig. 12. In the erosion zone  $5.4 \times 10^5 \text{m}^3$  of sand was eroded from 1988 to 1992, resulting in an annual decrease rate of sand volume of  $1.35 \times 10^5 \text{m}^3/\text{yr}$ . This is approximately equal to the rate of littoral drift through No. 47, because the coastline west of No. 72 is totally covered by sea walls with concrete armor units at the foot and detached breakwaters, and therefore sand supply from upcoast through No. 72 is assumed to be negligible. This transport rate is very close to the value obtained further upcoast of Shizuoka coast, as discussed in the

Figure 15. Time change in sand volume in accretion zone north of No. 46 and in erosion zone between No. 47 and No. 72.

previous section.

Total change in accreted sand volume up to 1992 reaches  $6.36 \times 10^5 \text{ m}^3$  which is about 18% greater than total eroded sand volume,  $5.4 \times 10^5 \text{ m}^3$ . However, the correspondence between the two results is considered to be fairly good, taking into account that volumetric calculation in the accretion zone is apt to include large error because of the wide calculation zone and because the sand supply through No. 72 by northward littoral drift is a small but non-negligible value.

## 6. CONCLUSIONS

The principal results of the present study can be summarized as follows.

(1) On the Shizuoka and Shimizu coasts, erosion waves propagated northeastward at a velocity of about 0.8km/yr between 1975 and 1983, and 0.5km/yr between 1983 and 1988. These erosion waves were caused by spatial discontinuity in longshore transport as a result of the installation of various coastal structures. Inman's (1987) method was employed to estimate their propagation velocity as 0.47km/yr, which agrees fairly well with observed values.

(2) A comparison of beach profiles revealed that significant topographic changes occurred in a region shallower than  $-7\text{m}$ , and it was confirmed that this water depth is approximately equivalent to the closure depth for profile changes on this beach. On the other hand, at the tip of the spit, a large amount of sand transported toward the tip of the spit is discharged and deposited up to a depth of 70m, which is one order of magnitude greater than the closure depth of this coast obtained in the erosion zone, forming a very steep slope of 1/2 due to the topographic features of the sand spit. Thus the occurrence of a net loss of sand toward the deep sea is of vital importance for solving beach erosion problems around a sand spit.

(3) The littoral transport rate was evaluated to be  $1.3 \times 10^5 \text{m}^3/\text{yr}$  near No. 70 and No. 166 on the Shizuoka coast from the temporal change in sand volume of the coast. In a recent erosion zone at the tip of the sand spit  $5.4 \times 10^5 \text{m}^3/\text{yr}$  of sand was eroded between 1988 and 1992, resulting in an annual decrease rate of sand volume of  $1.35 \times 10^5 \text{m}^3/\text{yr}$ , which is close to the approximate rate of northward littoral drift through No. 47. Thus the two estimated values are in good agreement.

## ACKNOWLEDGEMENT

The authors would like to express their deepest gratitude to the staff of Shizuoka Civil Engineering Office, Shizuoka Prefectural Government, who provided valuable assistance in collecting various data and information.

## SHORECIRC: A Quasi 3-D Nearshore Model

A.R. Van Dongeren<sup>1</sup>, F.E. Sancho<sup>2</sup>, I.A. Svendsen<sup>3</sup>, and U. Putrevu<sup>4</sup>

**ABSTRACT:** A depth-integrated, short wave-averaged nearshore circulation model is presented, which includes the effects of the 3-D current structure over depth. The model includes the description of time-varying currents such as infra-gravity waves. Two numerical schemes are developed, which will be used for intercomparison in the absence of analytical solutions. An absorbing-generating boundary condition is developed based on the Method of Characteristics in order to allow propagating waves to leave the computational domain with a minimum of reflection while specifying incoming waves at the same boundaries. The model is tested for the time-varying start-up of a longshore current on a cylindrical coast, and the temporal development of both the cross-shore profiles of the longshore current and characteristic samples of the vertical structure of the velocity profiles are given.

### INTRODUCTION

Shoaling, breaking, refraction and randomness of short waves are responsible for larger scale motions such as steady and unsteady currents and low frequency (infragravity) waves. These motions are all described by time-varying nearshore circulation models and can be observed as temporal and spatial variations of the short wave-averaged setup/setdown and longshore and cross-shore currents.

Two classes of models exist to describe these nearshore phenomena: (*i*) models that resolve the instantaneous state of motion, such as models based on the

nonlinear shallow water equations or on the Boussinesq-equations and (ii) time-averaged models that calculate large scale motions due to short wave-induced forcing. The latter class can be further subdivided into two categories. Two-dimensional horizontal (2DH) models describe the depth-mean current and the surface elevation. They are based on the turbulence-averaged, depth-integrated, time-averaged Navier-Stokes equations. The second category, 2DV-models, have primarily been used to study the vertical structure of the cross-shore circulation (Svendsen (1984), Dally & Dean (1984), Stive & Wind (1986), Svendsen *et al.* (1987) and Svendsen & Hansen (1988)). Both types of models are an approximation of the fully 3D case, which until now has not been successfully modeled.

Quasi-3D models were developed to combine the effect of the vertical structure with the simplicity of 2DH models. In the approach by De Vriend & Stive (1987), the current is split into primary and secondary flow profiles based on the assumption that the primary velocity profiles are the same in the cross-shore and longshore direction. In a different approach, Svendsen & Lorenz (1989) determined the vertically-varying longshore and cross-shore currents separately under the assumption of weak dependence. They found that the total vertical current profile has a spiral shape (Fig. 1). Svendsen & Putrevu (1990) formulated a steady-state 3D nearshore circulation model using analytical solutions for the 3D current profiles in combination with a numerical solution of the depth-integrated 2D horizontal equations for a long straight coast. Sánchez-Arcilla *et al.* (1990, 1992) presented a similar concept. They split the current velocity into a depth-invariant component and a component with a vertical variation with zero mean flow integrated over the central layer. Putrevu & Svendsen (1992) and Svendsen & Putrevu (1994a) recognized that the current-current and current-wave interactions neglected in previous investigations induce a non-linear dispersion mechanism, which significantly augments the lateral turbulent mixing and explains the apparent difference in magnitude between the vertical and horizontal mixing.

In the present form, SHORECIRC is the time-dependent extension of the model presented by Svendsen & Putrevu (1994a). This comprehensive model is able to describe a number of nearshore phenomena such as surf-beat, edge waves and longshore currents while allowing for alongshore variations in the hydrodynamical conditions. By including finite amplitudes, random wave forcing, and the effects of the 3D current structure, it extends the description of these phenomena beyond the usual analytical solutions. The topography part of the model is presently configured for a cylindrical coast only, but will later be extended to cover arbitrary bottom topography as well. In the present paper we focus on the form of the 2DH equations, the generating-absorbing boundary condition used, and we test the model performance for a time-varying case of the longshore current on a long, straight beach.

Figure 1: Three-dimensional structure of the current velocities in the surf zone (from Svendsen & Lorenz, 1989).

**GOVERNING EQUATIONS**

The depth-integrated, time-averaged mass and momentum equations read as follows:

$$\frac{\partial \bar{\zeta}}{\partial t} + \frac{\partial}{\partial x_\alpha} \left( \overline{\int_{-h_0}^{\zeta} V_\alpha dz} + Q_{w\alpha} \right) = 0 \tag{1}$$

$$\begin{aligned} &\rho \frac{\partial \bar{Q}_\beta}{\partial t} + \rho \frac{\partial}{\partial x_\alpha} \overline{\int_{-h_0}^{\zeta} V_\alpha V_\beta dz} + \rho \frac{\partial}{\partial x_\alpha} \overline{\int_{\zeta_t}^{\zeta} u_{w\alpha} V_\beta + u_{w\beta} V_\alpha dz} \\ &+ \rho g (\bar{\zeta} + h_0) \frac{\partial \bar{\zeta}}{\partial x_\beta} + \frac{\partial}{\partial x_\alpha} \left( S'_{\alpha\beta} - \overline{\int_{-h_0}^{\zeta} \tau_{\alpha\beta} dz} \right) - \tau_\beta^S + \tau_\beta^B = 0 \end{aligned} \tag{2}$$

where the radiation stress  $S'_{\alpha\beta}$  is given by

$$S'_{\alpha\beta} = \overline{\int_{-h_0}^{\zeta} (\rho u_{w\alpha} u_{w\beta} + \delta_{\alpha\beta} p) dz} - \delta_{\alpha\beta} \frac{1}{2} \rho g h^2 \tag{3}$$

which is equivalent to the definition used by Mei (1983).

In the above,  $V_\alpha$  and  $\bar{\zeta}$  represent the horizontal current velocity and the mean surface elevation, respectively, which is equivalent to the particle velocity

and wave surface elevation if an IG wave is considered.  $u_w$  is the short wave velocity,  $Q_\alpha$  represents the total volume flux and  $Q_w$  is the volume flux due to the short wave motion.  $\zeta_i$  is the elevation of the wave trough,  $\tau_{\alpha\beta}$  is the Reynolds stress,  $h_o$  is the still water depth, while  $\tau_\beta^S$  and  $\tau_\beta^B$  represent the surface (e.g. wind) and the bottom shear stresses, respectively. The overbar denotes short wave averaging and the subscripts  $\alpha$  and  $\beta$  denote the directions in a horizontal Cartesian coordinate system. See Figure 2 for a definition sketch.

Figure 2: Definition sketch.

The form (2) of the momentum equation is written in terms of  $V_\alpha$  which is the current defined in the traditional way: the net velocity at any point below wave trough level and above the purely oscillatory wave motion (i.e.  $\bar{u}_w = 0$ ). For the general case of depth varying currents it is convenient to split this current into a depth uniform and depth varying component:

$$V_\alpha = V_{m\alpha}(x, y, t) + V_{d\alpha}(x, y, z, t) \tag{4}$$

where

$$V_{m\alpha} = \frac{\bar{Q}_\alpha - Q_{w\alpha}}{h} \tag{5}$$

and

$$Q_{w\alpha} = \int_{-h_0}^{\zeta} u_{w\alpha} dz \tag{6}$$

It may be verified that

$$\int_{-h_0}^{\zeta} V_\alpha dz = \bar{Q}_\alpha - Q_w \quad \text{and} \quad \int_{-h_0}^{\zeta} V_{d\alpha} dz = 0 \tag{7}$$

Then (2) may be written as

$$\begin{aligned} & \rho \frac{\partial \bar{Q}_\beta}{\partial t} + \rho \frac{\partial}{\partial x_\alpha} \left( \frac{\bar{Q}_\alpha \bar{Q}_\beta}{h} \right) + \rho \frac{\partial}{\partial x_\alpha} \int_{-h_0}^{\bar{\zeta}} V_{d\alpha} V_{d\beta} dz \\ & + \rho \frac{\partial}{\partial x_\alpha} \int_{\zeta_t}^{\bar{\zeta}} u_{w\alpha} V_{d\beta} + u_{w\beta} V_{d\alpha} dz + \rho g (\bar{\zeta} + h_0) \frac{\partial \bar{\zeta}}{\partial x_\beta} \\ & + \frac{\partial}{\partial x_\alpha} \left( S_{\alpha\beta} - \int_{-h_0}^{\bar{\zeta}} \tau_{\alpha\beta} dz \right) - \tau_\beta^S + \tau_\beta^B = 0 \end{aligned} \quad (8)$$

where  $S_{\alpha\beta}$  is the radiation stress defined by

$$S_{\alpha\beta} = S'_{\alpha\beta} - \rho \frac{Q_{w\alpha} Q_{w\beta}}{h} \quad (9)$$

which is the definition used by Phillips (1977).

The integrals in (8) represent the effects of the depth-varying currents. The rest of the terms are essentially equivalent to the terms found by Phillips (1977) and Mei (1983).

The equations (1) and (8) are solved by finite differences for the time and space variation of  $\bar{\zeta}$  and  $\bar{Q}_\alpha$  in combination with an analytical solution for the current distribution along the vertical, which is given in terms of eigenfunction expansions. This analytical solution includes integration constants that are in turn determined from the numerical solution of the depth-integrated equation (8). The details of this are left out for reasons of space limitation (Svendsen & Putrevu, 1994b and Putrevu & Svendsen, 1994).

## NUMERICAL SCHEMES

Two numerical schemes have been developed: a second order, explicit predictor-corrector method and a second order, ADI staggered-grid scheme. This allows us to compare the two numerical solutions to each other when an analytical solution for the 2DH current pattern is not readily obtained, for instance in cases of random wave forcing or a complicated bathymetry. Both schemes have inherent advantages and drawbacks. While simpler, the explicit method has a Courant-Friedrichs-Lewy (CFL) limitation on its stability, which sets an upper limit on the time-step allowed. Typically we use a Courant number of 0.35 - 0.7. The ADI method, which has no CFL limit, is both more robust and more complicated for the nonlinear terms. Hence it can be operated at even larger Courant numbers, although it loses accuracy if the Courant number is increased too much.

## ABSORBING-GENERATING BOUNDARY CONDITION

In order to be able to model a limited coastal region in an otherwise large ocean, it is necessary to establish boundary conditions along the open ocean-side boundaries that satisfy two criteria:

1. The region outside the computational domain only influences the motion inside through incident (long) waves and currents, which we know and specify along the open boundaries.
2. (Long) waves propagating out of the computational region must be allowed to propagate freely through the open ocean-side boundaries with minimal reflection.

Thus this boundary condition must be able to generate a specified long wave and simultaneously absorb outgoing waves. Such a generating-absorbing boundary condition is derived below based on the Method of Characteristics (Abbott, 1979; Verboom *et al.*, 1981).

We first notice that the open boundaries are established so that near these boundaries the dominating terms in the continuity and momentum equations are the terms corresponding to the nonlinear shallow water (NSW) equations. Introducing  $\bar{u}_\alpha = \frac{Q_\alpha}{h}$ , where  $h$  denotes total water depth, we can thus write (1) and (8) as

$$\frac{\partial \bar{\zeta}}{\partial t} + \frac{\partial h \bar{u}_\alpha}{\partial x_\alpha} = 0 \quad (10)$$

$$\frac{\partial \bar{u}_\beta}{\partial t} + \bar{u}_\alpha \frac{\partial \bar{u}_\beta}{\partial x_\alpha} = -g \frac{\partial \bar{\zeta}}{\partial x_\beta} + f_\beta \quad (11)$$

where  $f_\beta$  represents forcing terms for the motion which include the radiation stress terms, the  $V_{d\alpha}$ -integrals, the bottom and wind shear stresses and the bottom slope term, all included in the original equations.

In characteristic form these equations can be written as:

$$\frac{\partial \beta^+}{\partial t} = -(\bar{u} + c) \frac{\partial \beta^+}{\partial x} - \bar{v} \frac{\partial \beta^+}{\partial y} - c \frac{\partial \bar{v}}{\partial y} + g \frac{\partial h_o}{\partial x} + F_{\beta^+} \quad (12)$$

$$\frac{\partial \beta^-}{\partial t} = -(\bar{u} - c) \frac{\partial \beta^-}{\partial x} - \bar{v} \frac{\partial \beta^-}{\partial y} + c \frac{\partial \bar{v}}{\partial y} + g \frac{\partial h_o}{\partial x} + F_{\beta^-} \quad (13)$$

$$\frac{\partial \gamma}{\partial t} = -\bar{u} \frac{\partial \gamma}{\partial x} - \bar{v} \frac{\partial \gamma}{\partial y} - g \frac{\partial \bar{\zeta}}{\partial y} + F_\gamma \quad (14)$$

where  $\beta^+$  in (12) is the ingoing Riemann-invariant  $\bar{u} + 2c$  and  $c = \sqrt{g(h_0 + \bar{\zeta})}$ .  $\beta^- = \bar{u} - 2c$  and  $\gamma = \bar{v}$  are the Riemann-invariants of (13) and (14). The forcing terms  $F_{\beta^+}$ ,  $F_{\beta^-}$  and  $F_\gamma$  originate from the  $f$ -terms in (11). Because of these terms, the invariants should actually be called *variables*. It turns out that the  $\gamma$ -equation is the  $y$ -momentum equation itself. See Figure 3 for a definition sketch showing the characteristics. Note that the Riemann-variants  $\beta^+$  and  $\beta^-$  are not related to the subscript  $\beta$  used in (1) through (11).

Figure 3: Definition sketch of the characteristics.

From the Riemann variable  $\beta^-$ , which propagates along a trajectory in the negative  $x$ -direction and is updated by (13), we can derive a relationship between the flux of the outgoing wave (subscripted 'r' in the following) and the incoming wave (subscripted 'i'). Assuming linear superposition of these waves

$$\vec{Q} = \vec{Q}_i + \vec{Q}_r \quad (15)$$

and substituting the identities

$$\vec{Q}_i = \vec{c} \zeta_i \quad \vec{Q}_r = -\vec{c} \zeta_r \quad (16)$$

which are valid irrespective of wave theory and only assume constant form, we get

$$|Q_r| (\cos \theta_r + 1) = h_0 \beta^- - |Q_i| (\cos \theta_i - 1) + 2h_0 \sqrt{gh_0} + O\left(\frac{\bar{\zeta}}{h_0}\right)^2 \quad (17)$$

where  $\theta_i$  and  $\theta_r$  are defined as the angles between the normal to the boundary and

the incoming and outgoing waves, respectively. From the  $y$ -momentum equation (14) we then get

$$|Q_r| \sin \theta_r = Q_y - Q_{iy} \quad (18)$$

where  $Q_y = \bar{v}(h_o + \zeta)$ . From (17) and (18) we can find the unknowns  $|Q_r|$  and  $\theta_r$  iteratively. With the incoming wave known through specification, and integrating (13) and (14) in time, the boundary values of total fluxes  $Q_x$  and  $Q_y$ , and the surface elevation  $\bar{\zeta}$ , are determined at the next time step. This boundary condition is essentially a generalized version of the condition derived for the 1-D case by Kobayashi *et al.* (1987).

Two cases have been run to test this absorbing-generating boundary condition. In the first case, linear waves were generated under various angles at the  $x = 0$  and  $y = 0$  boundaries. They were propagated over a flat bottom using the linearized equations and absorbed at the  $x = L_x$  and  $y = L_y$  boundaries. This tests the absorbing capability of the boundary condition. The parameters used were: wavelength  $\lambda = 50 \text{ m}$ , domain lengths  $L_x = L_y = 2\lambda$ ,  $h_o = 1 \text{ m}$ ,  $T = \lambda / \sqrt{g h_o}$ ,  $A = 0.01 \text{ m}$ ,  $\Delta x = \Delta y = \frac{\lambda}{30}$  and  $C_r = 0.6$ . Figs. 4 a-c show the instantaneous water surface for three selected angles  $\theta = 0^\circ, 30^\circ$  and  $75^\circ$ , where  $\theta$  is defined as the angle between the incident wave ray and the  $y$ -axis. Reflections from the boundaries are barely visible.

To calculate the reflection coefficient, a time series was taken at a point on the boundary. Then the domain was extended to be effectively infinite and another time series was taken at the same point. Following Verboom & Slob (1984), the reflection coefficient is then defined as the maximum of the difference of the two time series normalized by the amplitude of the original wave:

$$R = \frac{\max \Delta \zeta(t)}{A} \quad (19)$$

Fig. 4 d shows this reflection coefficient  $R$  (indicated by the dots) as a function of the angle of incidence  $\theta$ .

A comparison is made to the widely-used Sommerfeld radiation condition

$$\left( \frac{\partial}{\partial t} + \frac{c}{\cos \theta_r} \frac{\partial}{\partial x} \right)^n u = 0 \quad (20)$$

where  $n$  indicates the order of the approximation of the boundary condition. For instance, the radiation condition that was introduced by Engquist & Majda (1977) has  $n = 2$ . The theoretical reflection coefficient of this type of condition, which can be calculated as (Higdon, 1986)

$$R = \left| \left( \frac{\cos \theta_r - 1}{\cos \theta_r + 1} \right)^n \right| \quad (21)$$

is shown in Fig. 4d for three values of  $n$ , indicated by the solid lines. The figure shows that the present condition based on the Method of Characteristics has much better absorption capabilities than the Sommerfeld condition. The latter gives large reflection coefficients for large angles and is fully reflecting for waves propagating parallel to the boundary. Note that the reflection, as calculated by (19), includes truncation and other numerical errors, while  $R$ , as calculated by (21), is theoretical only. This probably causes the better performance of the Sommerfeld condition at small angles.

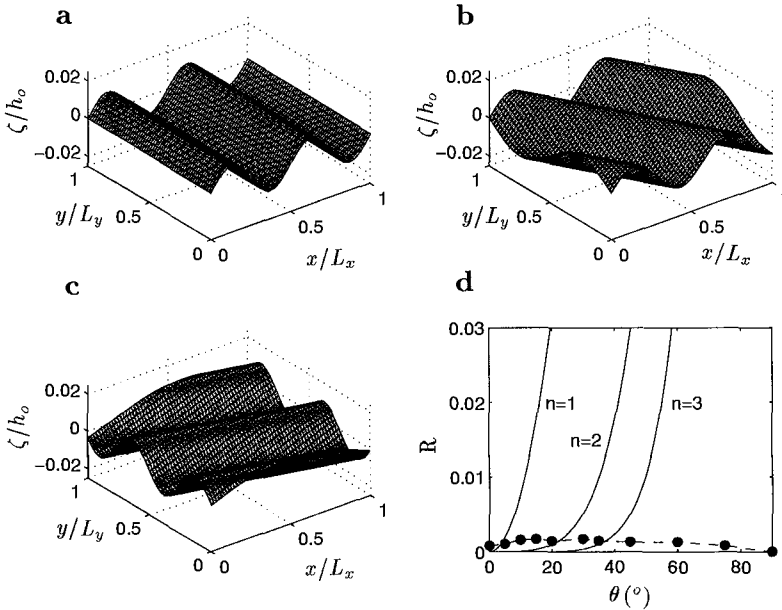

Figure 4: (a) Instantaneous water surface for  $\theta = 0^\circ$ . (b) Same for  $\theta = 30^\circ$ . (c) Same for  $\theta = 75^\circ$ . (d) Reflection coefficients versus angle  $\theta$ , —: Eq. (21),  $\bullet$ : present model.

In a second test, waves are simultaneously generated and absorbed at the  $x = 0$  boundary. From a cold start, waves are generated under an angle of  $0^\circ$  from  $t = 0T - 19T$  and are reflected off a wall at  $x = L_x$ . Parameters used are: wavelength  $\lambda = 50\text{ m}$ , domain lengths  $L_x = 3.3\lambda$  and  $L_y = 0.2\lambda$ ,  $h_0 = 1\text{ m}$ ,  $T = \lambda / \sqrt{g h_0}$ ,  $A = 0.01\text{ m}$ ,  $\Delta x = \Delta y = \frac{\lambda}{60}$  and  $C_r = 0.6$ . Fig. 5a shows the wave propagating in  $+x$ -direction at  $t = 2T$  and Fig. 5b the resulting standing wave. At  $t = 19T$  the incoming wave was turned off instantaneously (causing a minor disturbance wave that is visible in Fig. 5c where a wave propagating in the negative  $x$ -direction is trailed by higher frequency disturbances). The central

part of the time series (taken at  $x = 0$ ,  $y = \frac{L_y}{2}$ ) in Fig. 5d shows the standing wave whose amplitude is equal to the analytical solution within a few percent. It also shows that the transients radiate out with very little reflection. Still-water conditions are reached fairly quickly after the generated waves leave the domain.

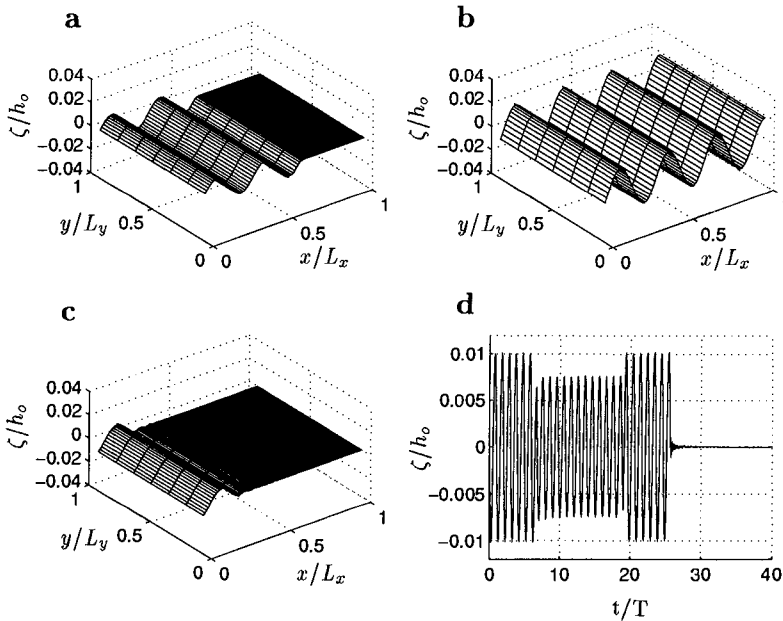

Figure 5: (a) Instantaneous water surface at  $t = 2T$ . (b) Same for  $t = 19T$ . (c) Same for  $t = 25T$ . (d) Time series at  $(x = 0, y = \frac{L_y}{2})$ .

These tests show that the numerical boundaries can be placed close to the regions of interest, which limits the computational time for the model.

### TEST CASE: LONGSHORE CURRENTS

As a formal test of the time-dependent equations (1) and (8), we studied the start-up of a longshore current on a cylindrical coast induced by imposing short wave forcing in a region at rest at  $t = 0$ . The parameters and assumptions used are the same as those in Chapter 4 of Svendsen & Putrevu (1994a), called SP94 in the following, except that here the depth-invariant longshore velocity  $V_0$  (see their (2.6)) is explicitly defined as the depth mean longshore velocity.

Fig. 6a shows the surface elevation versus normalized time for a number of

Figure 6: (a) Surface elevation versus time for cross-shore positions indicated in the figure. (b) Cross-shore variations of the longshore current velocities for different time-steps as indicated in the figure.

points in the domain. The normalizing time-scale  $T$  is defined as the ratio of the surf-zone width to the long wave celerity at the breakpoint. It is also seen that the impulsive application of the short wave forcing at  $t = 0$  initiates a surge in the mean surface elevation. After reflection from the beach, it propagates seawards and is absorbed by the ocean-side boundary condition. The steady-state in the set-up is reached in about  $7T$ . The longshore current evolution in Fig. 6 b, however, does not attain steady-state until about  $50T$ , which indicates a difference in time-scales of cross-shore and longshore motion. In fact, the steady-state is only approached asymptotically as the net forcing of bottom friction and the radiation stress decreases to zero. The figure clearly shows that the turbulent and dispersive mixing,  $\nu_{tx}$  and  $D_c$  (defined in SP94 Eq. (2.22)), cause a spreading of momentum (i.e. longshore current velocity) away from the breakpoint but the momentum spreads relatively slowly, in particular outside the surf-zone.

Figure 7: (a) Three-dimensional current spiral for  $\frac{h_0}{h_b} = 0.24$  at  $t = 0.2T$ . (b) Same for  $t = 4T$ . (c) Same for  $t = 48T$ . (d) Three-dimensional current spiral for  $\frac{h_0}{h_b} = 0.98$  at  $t = 0.2T$ . (e) Same for  $t = 4T$ . (f) Same for  $t = 48T$ .

The slow development in the flow implies that the vertical velocity profiles can be considered a quasi-steady response to the instantaneous forcing, including the gradients of the mean water surface. Thus, using SP94's expressions for the undertow and longshore velocity with time-varying coefficients, we can calculate the change in the 3-D current profiles as time progresses. Figs. 7 a-c show three snapshots of the 3-D current spiral for a position close to shore. Figs. 7 d-f show the spirals at the same times for a position in the surf-zone near the breakpoint. The cross-shore and longshore current profiles are also shown as projections. The current velocities,  $U$  and  $V$ , are normalized by the local wave celerity and  $\xi$ , the vertical position above the bed, is normalized by the still water level  $h_o$ . Figs. 7 a and 7 d for  $t = 0.2T$  show that initially the flow is almost entirely in the cross-shore direction. At  $t = 4T$ , the steady-state in the set-up, and consequently in the undertow profile, is not yet reached and the magnitude of the longshore current is increasing rapidly (Figs. 7 b and 7 e). At  $t = 48T$ , both the undertow and the longshore current have reached steady-state (Figs. 7 c and 7 f). Notice that the longshore current profile in Fig. 7 c is pitched forward, whereas the one in Fig. 7 f is tilted back slightly. This is important since the sign of the vertical gradient of  $V$  indicates a sign switch in the dispersive effect, which is known to control the mixing (SP94). We see that the different time scales for the cross- and longshore motion cause the velocity to change quite significantly during the start-up of the longshore current. With time-varying forcing from random waves, the variation will probably be less dramatic. However, the results for the 2DH case with weak wave groups analysed by Svendsen and Putrevu (1994b) suggest that the vertical currents profiles can vary significantly.

For completeness it is mentioned that these computations were performed with a very short coast to ensure that no instabilities in the form of shear waves developed.

## CONCLUSIONS

A time-dependent, short wave-averaged quasi-3D model is presented that governs nearshore circulation processes as well as infra-gravity waves. An absorbing-generating boundary condition has been developed that allows waves to leave the domain with very little reflection while simultaneously specifying an incoming wave. This makes it possible to choose the model boundaries close to the area of interest, thus limiting the computational effort required. The time-dependent model is tested for the start-up of a longshore current on a long straight coast. The vertical velocity profiles are shown to change significantly as the current evolves.

## CHAPTER 199

# A MODEL FOR BREACH GROWTH IN SAND-DIKES

by

Paul J. Visser<sup>1</sup>

### ABSTRACT

A mathematical model for breach growth in sand-dikes and dunes is presented. The model is based on the five-step breach erosion process as observed in several laboratory and field experiments. A simplified Galappatti (1983) pick up mechanism for sand from the bed is combined with Bagnold's (1963) modified (Visser, 1988) energetics-based sand transport conception to describe the breach erosion. The comparison of the model predictions with the data of the Zwin 89 field experiment shows good agreement.

### 1. INTRODUCTION

The Technical Advisory Committee on Water Defences (TAW) in The Netherlands is completing a probabilistic design method for dikes and dunes (hereafter both named dikes). This method will hold a procedure for the design and control of dikes based on a risk-norm (risk of inundation) instead of on a chance-norm (chance of exceeding a certain water level) as in the present deterministic methods, see Kraak et al. (1994). A risk-norm means that the inundation chance is combined with the consequences of flooding (deaths, loss of property and revenues, repair costs, etc.). To determine the consequences of an inundation, it is necessary to predict both the rate and speed of polder flooding, which are especially governed by the flow rate through the breach in the dike. This discharge rate largely depends on the process of breach growth.

The final aim of the investigation is a mathematical model, that describes the breach

---

<sup>1</sup> Delft University of Technology, Department of Civil Engineering,  
P.O. Box 5048, 2600 GA Delft, The Netherlands

growth and the discharge rate through the breach in case of a dike-burst, as function of the parameters involved. These parameters are:

- cross-section of the dike (height, width, angles of the slopes);
- structure of the dike (dike material, revetments, foundation);
- hydraulic conditions (water level against the dike, wave load).

A first version of the model (Visser, 1988) was especially developed for the huge (about 75 m high) sand-dike of a proposed pumped-storage plant in The Netherlands. Visser et al. (1990) extended the model and confronted it with the data of the Zwin 89 field experiment, yielding reasonable agreement for the first stages of the erosion process. This model version was not yet applicable to the last two phases of the breach erosion process (see section 3). If applied, it would fairly overestimate the breach growth in this final phase.

This paper describes a new version of the model. Its improvements with respect to the previous version are:

- inclusion of a description of the breach erosion in phase IV);
- an improved description of the erosion mechanism in phases I, II and III; these improvements refer to both the physics and the mathematical treatment.

Phase V of the breach erosion process is not yet included in the model. This stage is important since it yields the ultimate breach dimensions. Further the model is still restricted to sand-dikes; effects of clay-layers and revetments have to be included in the near future.

## 2. ENTRAINMENT AND TRANSPORT OF SEDIMENT

Fig. 1 shows a typical cross-section of a sand-dike along the breach axis in the initial phase of the breach erosion process. A coordinate system ( $x, z$ ) is adopted with coordinate  $x$  along the inner slope ( $x = 0$  at the top of the dike) and coordinate  $z$  normal to the slope.  $H_w$  is the water level at sea,  $Z_T$  is the height of the top of the dike in the breach (both  $H_w$  and  $Z_T$  are measured above the base of the dike), and

Fig. 1. Typical cross-section of a sand-dike along the breach axis.

the angles of the outer and inner slope are  $\alpha$  and  $\beta$ , respectively.

The entrainment of sand from the horizontal crown of the dike is very small compared with the pick up from the inner slope, see Steetzel and Visser (1992) and Visser (1994). The pick up of sand starts at the upstream end of the inner slope ( $x = 0$ ). For large values of  $u_* / w_s = C_f^{1/2} u / w_s$  (is of order 10 in the present situation, so suspended load transport will dominate bed load transport), the entrainment and subsequent transport of suspended sediment along the inner slope can be approximated according to Galappatti (1983, see also Galappatti and Vreugdenhil, 1985) by:

$$s(x) \approx \frac{x}{l_a} s_s \quad \text{for } 0 \leq x \leq l_a \quad (1)$$

in which  $s(x)$  is the sediment transport (volumes of particles) per unit width along the slope and  $l_a$  is the adaptation length of the suspended load transport:

$$l_a = \frac{ud}{w_s \cos \beta} = \frac{q_T}{w_s \cos \beta} \quad (2)$$

and  $s_s$  is the capacity of the suspended load transport:

$$s_s = \frac{0.01}{(w_s/u)(\cos \beta)^2} \frac{C_f u^3}{g \Delta} \quad [\text{m}^2/\text{s}] \quad (3)$$

where  $u$  is the depth-averaged flow velocity,  $d$  is the water depth (see Fig. 1),  $w_s$  is the fall velocity of sand in water,  $q_T$  is the discharge flow rate per unit width over the top of the dike,  $C_f$  is the friction coefficient for the bed ( $C_f = g/C^2$ , where  $C$  is the Chézy coefficient),  $\Delta = (\rho_s - \rho)/\rho$ ,  $\rho_s$  is the mass density of sand,  $\rho$  is the water mass density and  $g$  is the acceleration of gravity, see Visser (1988). Equation (3) rests on a modified (Visser, 1988) Bagnold (1963) energetics-based sand transport conception for suspended sediment load. The efficiency factor 0.01 is according to Bagnold (1966).

Equation (3) emerges as the best formula out of 15 sand transport formulae in a test with the flume data of Steetzel and Visser (1992) and the data of the Zwin 89 experiment, with Van Rijn's (1984a, 1984b) formulation finishing second best. Most of the other formulae overestimate the measured sediment transport rates significantly, also those formulae which were developed for sand-water mixture flows at high shear stress (for instance Wilson, 1987) and for sediment transport on steep slopes (for instance Rickenmann, 1991). For the moment this conclusion (and the choice for (3)) holds for the first three phases of the breaching process when the flow is supercritical.

### 3. BREACH EROSION PROCESSES

#### 3.1 Discharge rate

The water discharge rate  $q_T$  per unit breach width is described by a weir formula:

$$q_T = m(2/3)^{3/2} g^{1/2} (H_w - Z_T)^{3/2} \quad (4)$$

where  $m$  is the discharge coefficient ( $\approx 1.0$ ). Equation (4) holds as long as the flow in the breach is not affected by the downstream water level, i.e. for phases I through IV (see paragraph 3.2).

#### 3.2 Erosion of inner slope

The equation for the erosion of the inner slope is:

$$(1 - p) \frac{\partial z_b}{\partial t} + \frac{\partial s}{\partial x} = 0 \quad (5)$$

where  $p$  is the bed porosity,  $z_b$  is the position of the inner slope in  $z$ -direction ( $z$  is the coordinate normal to the inner slope, see Fig. 1). Substitution of (1), (2) and (3) into (5) yields:

$$\left| \frac{\partial z_b}{\partial t} \right| = \frac{0.01 C_f}{(1 - p) g \Delta} \left| \frac{\partial}{\partial x} \left[ \frac{x u^4}{q_T \cos \beta} \right] \right| \quad \text{for } 0 \leq x \leq l_a \quad (6)$$

in which it has been assumed that the friction coefficient  $C_f$  is constant.

If  $q_T$  is constant (that is if  $H_w - Z_T = \text{constant}$ , see equation (4)) and assuming  $\cos \beta \approx 1$ , it follows from (6) that:

$$\frac{\partial}{\partial x} \left| \frac{\partial z_b}{\partial t} \right| > 0 \quad \text{for } 0 < x < l_n \quad (7)$$

since the flow velocity  $u$  increases in positive  $x$ -direction for  $0 < x < l_n$ . So the erosion of the inner slope increases along the slope and the inner slope becomes steeper in  $x$ -direction and in time (see Fig. 2).

For  $x = l_n$  the flow velocity  $u$  approaches the normal value for uniform flows:

$$u_n = \frac{(g d_n \sin \beta)^{1/2}}{C_f^{1/2}} = \frac{(g q_T \sin \beta)^{1/3}}{C_f^{1/3}} \quad (8)$$

Fig. 2. Erosion of inner slope.

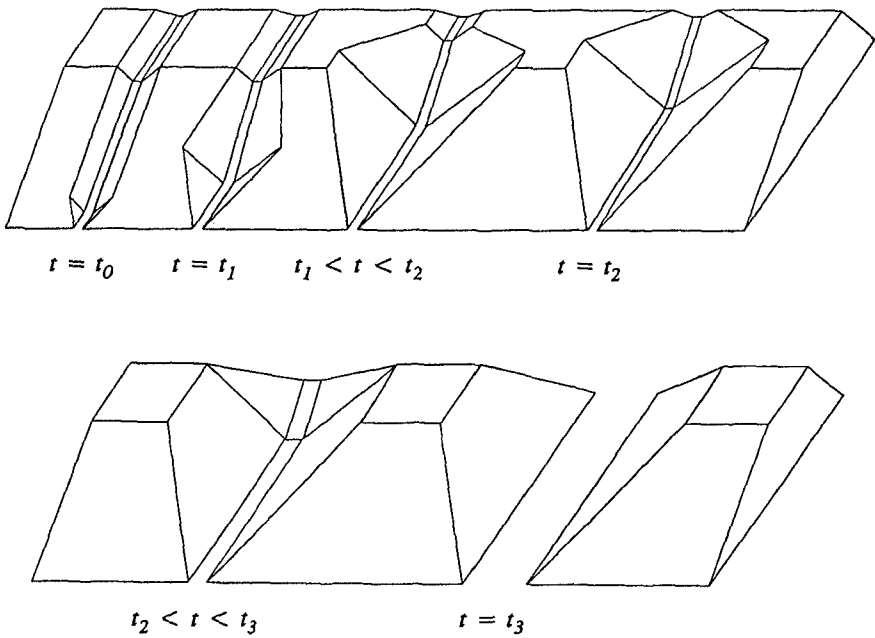

Fig. 3. Process of breach erosion.

Substitution of (1), (2), (3) and (8) into (5) gives:

$$\frac{\partial z_b}{\partial t} = - \frac{0.01}{(1-p)\Delta} \frac{\partial}{\partial x} (x u_n \tan \beta) \quad \text{for } l_n \leq x \leq l_a \quad (9)$$

If  $q_T$  and  $\beta$  are constant then  $u_n$  is constant and (9) becomes:

$$\frac{dz_b}{dt} = - \frac{0.01}{(1-p)\Delta} u_n \tan \beta \quad \text{for } l_n \leq x \leq l_a \quad (10)$$

This means that:

$$\frac{\partial}{\partial x} \left| \frac{dz_b}{dt} \right| = 0 \quad \text{for } l_n \leq x \leq l_a \quad (11)$$

i.e. the erosion of the inner slope is constant for these values of  $x$ , see Fig. 2.

The inner slope becomes steeper for  $0 \leq x < l_n$ . However, the slope angle will not exceed a limit  $\beta_1$ , say  $\beta_1 \approx \phi$  ( $\phi$  is angle of repose). If this limit has been achieved on the entire stretch  $0 \leq x < l_n$  (on  $t = t_1$ ), then the erosion rate becomes constant for  $0 \leq x < l_n$ , as indicated by the lines for  $t \geq t_1$  in Fig. 2.

So, if the breaching process starts at  $t = t_0$  with the flow of water through a small initial channel in the crown and the inner (downstream) slope of the dike, then the following (subsequent) phases can be distinguished in this process (see Figures 2 and 3):

- I. Steepening of the inclination angle ( $\beta$ ) of (the channel in) the inner slope from an initial value  $\beta_0$  up to a critical value  $\beta_1$  at  $t_1$  (see Fig. 1).
- II. Continuation of the erosion of the inner slope resulting in a decrease of the length of the dike-top in the breach for  $t_1 < t < t_2$ ; the inner slope angle remains (in this line of thoughts) at its critical value  $\beta_1$ .
- III. Lowering of the top of the dike in the breach and a subsequent increase of the breach width for  $t_2 \leq t \leq t_3$ .
- IV. After the complete wash-out of the dike in the breach, continuation of the breach growth in both vertical (scour hole) and horizontal direction for  $t_3 < t \leq t_4$ . At  $t_4$  the flow through the breach is critical, i.e. turns from supercritical ( $Fr > 1$  for  $t < t_4$ ) into subcritical ( $Fr < 1$  for  $t > t_4$ ).
- V. Continuation of the increase of the breach width for  $t_4 < t < t_5$ . At  $t_5$  the flow velocities in the breach become so small (incipient motion) that the breach erosion stops.

In phase I the width of the breach remains at its initial small value. At  $t = t_1$  the breach width starts to increase at the downstream side of the crown (so in phase II the breach eats its way into the dike, see Fig. 3). On  $t = t_2$  the width of the breach at the upstream side of the crown also starts to grow. As a first estimation this occurs directly proportional to the breach depth, see Visser (1988). The discharge

rate through the breach starts to increase at  $t = t_2$ . In the period  $t_3 < t \leq t_4$  the scour hole gets its maximal depth. Stages IV and V are the most important stages, since in the period  $t_3 < t < t_5$  most of the water is discharged through the breach and the ultimate dimensions of the breach are determined.

#### 4. MODEL DESCRIPTION

##### 4.1 Steepening of the inner slope (phase I)

The erosion of the inner slope is described by (5) with (1), (2), (3) and an equation for the flow velocity  $u$  follows from (4) and an equation for the non-uniform flow depth along the stretch  $0 < x < l_n$ . Consequently a numerical method is necessary to describe the development of the entire inner slope for  $t_0 < t < t_1$ .

Fig. 4. Horizontal displacements  $dX_t$  and  $dX_T$  due to erosion  $dz_b$  of inner slope.

An analytical solution for stage I is possible along the stretch  $l_n \leq x \leq l_a$ , where equation (10) describes the erosion rate  $dz_b/dt$ . The horizontal displacement  $dX_t$  of the toe of the inner slope can simply be expressed in  $dz_b$  (see Fig. 4):

$$dX_t = \frac{1}{\sin \beta_0} dz_b \quad (12)$$

Substitution of (4), (8), (10),  $\beta = \beta_0$  and  $Z_T = (Z_T)_0$  into (12) yields for  $t_0 \leq t \leq t_1$ :

$$\frac{dX_t}{dt} = -k_0 \sqrt{H_w - (Z_T)_0} \quad \text{for } l_n \leq x_t \leq l_a \quad (13)$$

where  $x_t$  is the  $x$ -coordinate of the toe of the inner slope (see Fig. 4) and:

$$k_0 = \frac{0.0082}{(1-p)\Delta} (m/C_f)^{1/3} g^{1/2} \frac{(\sin \beta_0)^{1/3}}{\cos \beta_0} \tag{14}$$

If  $l_n = L_1$  at  $t = t_1$  then:

$$\int_{t_0}^{t_1} dX_t = -L_t \tag{15}$$

Substitution of (13) into (15) finally yields:

$$t_1 - t_0 = \frac{L_t}{k_0 \sqrt{H_w - (Z_c)_0}} \tag{16}$$

If  $L_1 > l_n(t_1)$  then  $\xi L_t$  as defined in Fig. 5 should replace  $L_t$  in equation (16).

Fig. 5. Erosion of inner slope for relatively high dikes.

#### 4.2 Decrease of crown length (phase II)

At  $t = t_1$  the steepness of the inner slope is at its critical value (angle  $\beta_1$ ). From now on the rate of erosion is constant along the entire stretch  $0 \leq x \leq l_a$ , see Fig. 2. So the erosion of the inner slope for  $t_1 < t < t_2$  is entirely determined by the erosion at the toe of the slope ( $x = L_1$ ) as long as  $L_1 < l_a$ :

$$-L_1(1-p) \frac{dz_b}{dt} = s(L_1) = \frac{L_1}{l_a} s_s(L_1) \quad (17)$$

Generally  $L_1 > l_n$  (see Visser, 1994), so  $u(L_1) = u_n$ . Substituting (2), (3) and (8) with  $\beta = \beta_1$  into (17) yields, in agreement with (10):

$$\frac{dz_b}{dt} = - \frac{0.01}{(1-p)\Delta} u_n \tan \beta_1 \quad \text{for } 0 \leq x \leq L_1 \quad (18)$$

Fig. 4 shows that in the breach the length of the dike-top (initial value  $L_T$ ) decreases for  $t_1 < t < t_2$  due to the erosion of the inner slope. The relation between the decrease of the length of the dike-top ( $dX_T$ ) and the erosion of the inner slope ( $dz_b$ ) is:

$$dX_T = \frac{1}{\sin \beta_1} dz_b \quad (19)$$

Substitution of (4) with  $Z_T = (Z_T)_0$ , (8) with  $\beta = \beta_1$  and (18) into (19) gives:

$$\frac{dX_T}{dt} = -k_1 \sqrt{H_w - (Z_T)_0} \quad \text{for } t_1 < t < t_2 \quad (20)$$

with:

$$k_1 = \frac{0.0082}{(1-p)\Delta} (m/C_f)^{1/3} g^{1/2} \frac{(\sin \beta_1)^{1/3}}{\cos \beta_1} \quad (21)$$

Integration of (20) gives:

$$t_2 - t_1 = \frac{L_T}{k_1 \sqrt{H_w - (Z_T)_0}} \quad (22)$$

Visser (1988) argues that due to the increase of the breach width an extra amount of sand falls into the flow, slowing down the breach erosion in vertical direction (with a factor  $f$  compared with a 2-D situation; to a lesser extent this applies also to phase I). The factor  $f$  will vary from phase to phase. Assuming  $f$  to be constant in each phase, equation (22) becomes for the 3-D situation:

$$t_2 - t_1 = \frac{L_T}{f_1 k_1 \sqrt{H_w - (Z_T)_0}} \quad (23)$$

### 4.3 Decrease of crown level (phase III)

At  $t = t_2$  the top of the dike in the breach starts to drop. The relation between the fall  $dZ_T$  and the rate of erosion  $dz_b$  of the inner slope follows from a simple geometrical consideration (see Fig. 6):

$$dZ_T = \frac{\sin \alpha}{\sin(\alpha + \beta_1)} dz_b \quad (24)$$

Substitution of (4), (8) with  $\beta = \beta_1$  and (18) into (24) yields:

$$\frac{dZ_T}{dt} = -k_2 \sqrt{H_w - Z_T} \quad \text{for } t_2 \leq t \leq t_3 \quad (25)$$

where:

$$k_2 = \frac{\sin \alpha \sin \beta_1}{\sin(\alpha + \beta_1)} k_1 \quad (26)$$

At  $t = t_2$  the width of the breach at the upstream end of the dike-top starts to increase. Visser (1988) argues that the breach width (so also the depth-averaged breach width  $B$ ) increases linearly with the growth of the breach depth  $H_d - Z_T$ :

$$\frac{dB}{dt} = r \frac{d(H_d - Z_T)}{dt} \quad \text{for } t_2 \leq t \leq t_3 \quad (27)$$

where  $r$  is a coefficient with a theoretical value (for sand-dikes) of about 2.2 for the depth-averaged breach width and about 3.8 for the breach width at the top of the dike.

Due to the increase of the breach width an extra amount of sand falls into the flow, slowing down the breach erosion in vertical direction (with a factor  $f_2$  in this stage, see paragraph 4.2). Hence equation (25) becomes:

$$\frac{dZ_T}{dt} = -f_2 k_2 \sqrt{H_w - Z_T} \quad \text{for } t_2 \leq t \leq t_3 \quad (28)$$

in which the factor  $f_2$  is (see Visser, 1988):

$$f_2 = \frac{B + 2q_T/u}{2B} \quad (29)$$

Integration of (28) gives with  $Z_T = 0$  at  $t = t_3$ :

Fig. 6. Relation between  $dZ_T$  and  $dz_b$  in phases III and IV.

$$Z_T(t) = H_w - \left[ \frac{f_2 k_2}{2} (t - t_3) + \sqrt{H_w} \right]^2 \quad \text{for } t_2 \leq t \leq t_3 \quad (30)$$

Substitution of  $Z = (Z_c)_0$  at  $t = t_2$  into (30) gives:

$$t_3 - t_2 = \frac{2}{f_2 k_2} \left[ \sqrt{H_w} - \sqrt{H_w - (Z_T)_0} \right] \quad (31)$$

If the depth of the initial breach  $(H_d - (Z_T)_0)$ , see Fig. 2) is small compared with the dike-height  $H_d$  (so also small compared with  $H_w$ ), then (31) reduces to:

$$t_3 - t_2 = \frac{2}{f_2 k_2} \sqrt{H_w} \quad (32)$$

#### 4.4 Continuation of breach growth (phase IV)

Locally the dike has been completely washed out ( $Z_T = 0$ ) at  $t = t_3$  and the breach continues to grow in both vertical (scour hole:  $Z_T < 0$ ) and horizontal direction for  $t > t_3$ . The equation for the discharge rate  $q_T$  per unit of breach width is for  $t_3 \leq t \leq t_4$ :

$$q_T = m(2/3)^{3/2} g^{1/2} (H_w)^{3/2} \quad (33)$$

The scour hole has an upstream slope ( $\beta_3$ , bed elevation decreasing in flow direction:  $\beta_3$  is not equal to  $\beta_1$ ) and a downstream slope (bed elevation increasing in flow direction). It is assumed that the breach growth in phase IV is determined

by the erosion of the upstream slope of the scour hole. Then equation (10) describes also the erosion in vertical direction in phase IV:

$$\frac{dz_b}{dt} = -\frac{0.01}{(1-p)\Delta} u_n \tan \beta_3 \quad \text{for } l_n \leq x \leq l_a \quad (34)$$

The relation between the increase of the depth of the scour hole  $dZ_T$  and the rate of erosion  $dz_b$  of the upstream slope of the scour hole follows from a simple geometrical consideration (see Fig. 6):

$$dZ_T = \frac{1}{\cos \beta_3} dz_b \quad (35)$$

Substitution of (8) with  $\beta = \beta_3$ , (33) and (34) into (35) and including a factor  $f$  yields:

$$\frac{dZ_T}{dt} = -f_3 k_3 \sqrt{H_w} \quad \text{for } t_3 \leq t \leq t_4 \quad (36)$$

with:

$$k_3 = \frac{0.0082}{(1-p)\Delta} (m/C_f)^{1/3} g^{1/2} \frac{(\sin \beta_3)^{4/3}}{(\cos \beta_3)^2} \quad (37)$$

Integration of (36) gives with  $Z_T = 0$  at  $t = t_3$ :

$$Z_T(t) = -f_3 k_3 \sqrt{H_w} (t - t_3) \quad \text{for } t_3 \leq t \leq t_4 \quad (38)$$

It is assumed that (27) holds also in phase IV; then substitution of (38) into (27) gives the increase of the breach width for  $t_3 \leq t \leq t_4$ . For the initial stage of phase IV this assumption seems reasonable. It is, however, rather obvious that the validity of (38), and consequently also (27), has its limits, otherwise large breach depths are necessary to explain the existence of relatively wide breaches.

One of the aims of a large scale experiment performed October 1994 (Zwin 94 field experiment) has been to solve this uncertainty about the growth of the scour hole and its relation with the increase of the breach width in phase IV. The experimental procedure and results of this field experiment will be presented in a forthcoming publication.

## 5. COMPARISON WITH FIELD DATA

The present breach erosion model is tested to the data of the Zwin 89 experiment. This large scale experiment was performed in the Zwin Channel (an tidal inlet in the south-western part of The Netherlands) in December 1989, see Visser et al. (1990). The dimensions of the sand-dike in the Zwin 89 experiment have been:  $H_d = 2.2$  m,  $L_T \approx 7.5$  m,  $\beta_0 = 18.4^\circ$  and  $\alpha = 39^\circ$ . The 50 m long sand-dike was constructed, exclusively for the experiment, with local sand  $D_{50} \approx 0.22$  mm. A small pilot channel (initial breach), about 9 m long, about 1 m wide and with a depth  $H_d - (Z_c)_0 \approx 0.35$  m was made in the dike-top to ensure breaching near the middle of the Zwin Channel.

The breaching process was both video-taped and photographed. Levelling-staffs in the crown of the dike provided the proper length-scale for the readings from the video-tape and the photographs. The main result of these readings, i.e. the development of the 'depth-averaged' breach width  $B(t)$ , at the downstream end of the crown of the dike, is shown in Fig. 7. These data differ slightly from those in Visser et al. (1990), where breach width  $B(t)$  was given as averaged (both along the breach length and in depth) value of observed breach width.

The comparison of the model prediction with the data of the Zwin 89 experiment

Fig. 7. Comparison of measured (Zwin 89 experiment) and computed breach width  $B(t)$  at the upstream end of the dike-top.

has been done with the following values for the different parameters:  $p = 0.4$ ,  $\Delta = 1.65$ ,  $m = 1.0$ ,  $f_1 = f_2 = f_3 = 0.6$  (estimated with equation (29)),  $C_f = 0.015$ ,  $\beta_1 = 32^\circ$  (see Visser et al., 1990) and  $r = 2.2$  (for depth-averaged breach width). For  $\beta_3$  the value found by Delft Hydraulics (1972) for scour holes has been adopted:  $\beta_3 \approx 12^\circ$  ( $\tan \beta_3 \approx 0.2$ ). This is a very crude assumption since there exists no universal value for this angle.

Setting  $t_0 = 0$ , substitution of these values into (16) with (14) yields  $t_1 = 1.5$  min (in this phase:  $H_w - (Z_T)_0 \approx 0.13$  m), substitution into (22) with (21) gives  $t_2 - t_1 = 5.0$  min (in phase II:  $H_w - (Z_T)_0 \approx 0.17$  m), so  $t_2 = 6.5$  min, and into (31) with (26) gives  $t_3 - t_2 = 1.2$  min (in phase III:  $H_w \approx 2.1$  m), so  $t_3 = 7.7$  min. The increase of the breach width  $B(t)$  is given by (27) with (28) in phase III and by (27) with (36) in phase IV. The result of the model prediction for  $B(t)$  for the Zwin 89 experiment are shown in Fig. 7. The kink for  $t = t_3$  is due to keeping  $\beta$  at  $\beta_1$  for  $t_2 \leq t \leq t_3$  while in reality  $\beta$  will decrease from  $\beta_1$  to  $\beta_3$  in this phase.

The experimental data (flow velocities and water levels measured upstream and downstream from the breach) indicate that  $t_4 \approx 20$  min, see Visser et al. (1990). Hence Fig. 7 shows the development of the breach width  $B(t)$  in phases I through IV.

## 6. DISCUSSION

The agreement between the present breach erosion model and the data of the Zwin 89 experiment is good. It must be emphasized, however, that there still some uncertainties that has to be solved. These uncertainties relate to:

- the development of the scour hole (depth, slope angle  $\beta_3$ ) in phase IV and its effect on the increase of the breach width;
- the magnitude of the factors  $f_1$ ,  $f_2$  and  $f_3$ .

As yet the present version of the model does not describe the breach width in phase V, in which at the end the breach erosion stops and the breach gets its final dimensions.

It is expected that the data of the recent Zwin 94 field experiment (see paragraph 4.4) will significantly contribute to the understanding of the breach erosion process in phases IV and V and to the completion of the breach erosion model in 1995.

## CHAPTER 200

### SCALING EFFECTS ON BEACH RESPONSE PHYSICAL MODEL

Xu Wang<sup>1</sup>, Li-Hwa Lin<sup>2</sup>, and Hsiang Wang<sup>3</sup>

#### Abstract

A modified modeling law based on the comprehensive work by Wang, *et al.* (1990) has been derived with the assumptions that the suspended sediment transport is the dominant mode under storm wave condition inside the surf zone and the wave breaking index is preserved. This, in essence, adds to the constraint that wave height is properly modelled in accordance to the preservation of breaking index instead of simple vertical geometrical scale. Four different scaling laws including the one proposed presently were examined in the laboratory using 2-D wave tank and 3-D basin models. The model results were compared to prototype data from German large wave tank experiment. The model performances under different scaling laws were evaluated separately in the dune region and bar region of the entire model beach profile. Several statistics, including the errors of sand bar location, bar volume, bar profile, dune erosion volume, and dune profile, between model and prototype, were calculated and the result showed that the newly proposed scaling law presented the best overall model performance among the ones compared.

#### 1. Introduction

Beach and dune erosion as well as the shore profile changes that occur under storm waves and high water level are of basic interests in coastal engineering. And, by all means, physical model has been utilized frequently to improve our understanding of the process of beach and dune erosion and provide useful data for numerical models. Numerous papers have been written proposing various similitude relationships for beach response model study. At present there is no general solution which is also practical. Specific modeling laws are usually only applicable to certain restricted conditions. This paper is aimed at evaluating and improving the scaling law for distorted model guided by the modeling theory and through a series of laboratory

---

<sup>1</sup>Graduate Assistant, <sup>2</sup>Research Scientist, <sup>3</sup>Professor, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611, USA.

experiments carried out at different physical scales with the main assumption that suspended sediment transport is the dominant mode in the surfzone.

## 2. Theoretical Approach

Many different scaling laws of beach response model have been proposed in the past. However, there is no clear indication of which is more appropriate than the others. The approach here is to follow the comprehensive work by Wang, *et al.* (1990) but with consideration of a more general wave breaking criterion to determine the proper wave height scale in model. The approach seems adequate since it shows that the modeling law can be established based on the concept accommodating the sediment transport. The theory applied is simple. Based on the equation balancing the spatial change of sediment transport rate and the temporal change of beach profile, the scaling of sediment transport rate can be shown to be

$$N_q = N_\delta N_\lambda / N_t,$$

where  $N$  indicates the ratio of prototype to model quantities such that  $N_q$  is the scale of volumetric sediment transport rate,  $N_\delta$  and  $N_\lambda$  are the vertical and horizontal length scales, respectively, and  $N_t$  is the morphological time scale. Then, by assuming the suspended load mode predominate the sediment transport, the scale of sediment transport rate can be also expressed in a depth average means as

$$N_q = N_\delta N_u N_c,$$

where  $u$  is the sediment transport velocity, and  $c$  is the sediment concentration. By further assuming that  $N_u$  can be determined in preserving the Froude number  $F = u/\sqrt{gh}$ , where  $h$  is the water depth, and  $N_c$  can be obtained from a perceptive model of sediment concentration under wave motion as

$$c \propto \frac{H f(\xi)}{T SW},$$

where  $H$  and  $T$  denote wave height and wave period, respectively,  $f(\xi)$  is a function of the surfzone parameter  $\xi = \tan \beta / \sqrt{H_o/L_o}$ ,  $\beta$  is the beach slope,  $H_o$  and  $L_o (= gT^2/2\pi)$  are the deepwater wave height and wave length,  $S$  is the submerged specific weight, and  $W$  is the sediment settling velocity, a pair of equations can be established:

$$N_T = N_\lambda N_H^{1/2} / N_\delta, \quad N_t = N_\lambda^2 N_W N_S / (N_\delta^{3/2} N_H^{1/2}),$$

under the condition that surfzone parameter is preserved, or  $N_\xi = 1$ , in model.

As a major difference to the concept utilized by Wang, *et al.* (1990), the wave height scale is now assumed here to be not equal to the vertical scale in general. Clearly, in modeling beach profile change, wave height inside the surf zone should be similar between model and prototype. Of course, by treating wave height as a vertical geometrical scale in essence implicitly assumes that wave height is proportional to the local water depth, i.e.,  $H = \gamma_b h$ , with the  $\gamma_b$  a constant value, which was originally proposed by McCowan (1894) and was widely used as breaking criterion. In this paper, however, a more general wave height scaling law is adopted here:

$$N_H = N_\gamma N_\delta,$$

Table 1: Classification of Beach Profile Modeling Laws.

Author	Geometric Distortion	Hydrodynamic Time Scale( $T$ )	Morphological Time Scale( $t$ )
Vellinga (1982)	$N_\delta = N_W^{0.44} N_\lambda^{0.78}$	$N_T = \sqrt{N_\delta}$	$N_t = N_T$
Hughes (1983)	$N_\delta = N_W^{2/3} N_\lambda^{2/3}$	$N_T = N_\lambda / \sqrt{N_\delta}$	$N_t = N_T$
Wang, <i>et al.</i> (1990)	$N_\delta = N_W^{2/5} N_\lambda^{4/5}$	$N_T = N_\lambda / \sqrt{N_\delta}$	$N_t = \sqrt{N_\delta}$
Wang, <i>et al.</i> (present)	$N_\delta = N_W^{2/5} N_\lambda^{4/5}$ $N_H = N_\delta^2 / N_\lambda$	$N_T = \sqrt{N_\lambda}$	$N_t = N_T$

$N$  =prototype to model scale ratio,  
 $\lambda$  =horizontal length scale,  $\delta$  =vertical length scale,  
 $W$ =sediment fall velocity,  $H$ =incident wave height.

where  $N_\gamma$  represents the scale ratio of the breaking index,  $\gamma_b$ .

A guideline on determining  $N_\gamma$  is proposed by examining the functional form of  $\gamma_b$  as developed by various investigators. The breaking index could be affected by both beach slope and deepwater wave steepness, with the latter likely to be minimal inside the surf zone. A general power law of functional form of  $N_\gamma$  is proposed as

$$N_\gamma = \left[ \frac{N_\delta}{N_\lambda} \right]^k,$$

where the value of  $k$  is likely in the range from 0 to 1. In the case of  $k=0$ , the proposed modeling law reduces to that of Wang's (1990). On the other extreme as  $k=1$ , which states that the scale of breaking index is linearly proportional to the scale of local beach slope, or

$$N_r = N_{\tan\beta} = N_\delta / N_\lambda,$$

assuming  $N_T = N_t$ , i.e., the number of incoming waves per unit time is preserved yields another modeling law as

$$N_T = N_t = N_\lambda^{1/2}, \quad N_H = N_\delta^2 / N_\lambda, \quad N_q = N_\delta N_\lambda^{1/2}, \quad N_\delta = (N_S N_W)^{2/5} N_\lambda^{4/5}.$$

Therefore, the modeling laws derived above and by Wang, *et al.* (1990) represent two limiting conditions of the breaking index scale ratio. Table 1 presents four different modeling laws covering the existing scope of the beach profile modeling law which will be tested against laboratory experiments in this study.

### 3. Laboratory Experiments

In order to verify the scaling laws shown in Table 1, a total of 38 laboratory experiments were conducted, with 25 experiments run in a 30 m long wave tank, 10 experiments completed in a 15 m long tilting flume and three experiments in the 12m wide, 30m long 3-D wave basin. The coarse sand with a median size of 0.2mm has been utilized in both wave tank and tilting flume for the distorted model ( $N_\delta \neq N_\lambda$ )

study. Three different horizontal length scales of  $N_\lambda=20, 30,$  and  $40,$  were selected for the experiments as compared to the prototype data from the German large wave tank experiments, which was also known as the GWK experiment (Dette and Uliczka, 1986). The prototype sand has a median size of  $0.33\text{mm}.$  Accordingly, the corresponding sediment settling velocity scale can be approximated by  $N_W=2,$  and the vertical length scales corresponding to  $N_\lambda=20, 30,$  and  $40,$  can be roughly determined to be equal to  $N_\delta=14.5, 20.0,$  and  $25.2,$  respectively, in the models.

As special cases, fine sand with median size equal to  $0.09\text{mm}$  was also replaced in the same  $30\text{m}$  long wave tank for the undistorted model experiments. For this sand,  $N_W = 6,$  as compared with the prototype sand. Three length scales of  $N_\lambda = N_\delta=20, 30,$  and  $40,$  were again selected for the experiments of undistorted model study. The scaling effects were then tested for all the models of different length scales by using different wave periods and wave heights in individual experiments. Three 3-D wave basin experiments were also conducted as to repeat some 2-D wave tank experiments under the same test conditions to examine the three dimensional effects. All the experimental cases tested in this study are summarized in Table 2.

#### 4. Results

The model performance from the experiments was monitored by surveys of model beach profile at different times. In the 2-D wave tank and wave flume experiments, only the center profile is surveyed. In the 3-D wave basin experiments, five profiles, which were evenly spaced across the basin, were surveyed. All the surveys were carried out at times of  $0\text{min}, 5\text{min}, 10\text{min}, 20\text{min}, 40\text{min},$  and  $80\text{min},$  in model. Since the data set is too voluminous to be included in this paper, only reduced information related to the specific study subject is presented. The test results were compared with the GWK prototype data as for evaluating the scaling laws. Of course, the modelled beach should behave closely to the prototype at the points when model wave height and wave period were scaled by a proper modeling law. Figure 1 presents a few typical model and prototype profiles, all shown in the prototype scale, at the final stage of the experiments. The examination of scaling effects will be carried out only for the cases of the distorted model in which the model behavior resembles more to the prototype. For the undistorted model study (Tests A22 to A26), the experiment results were not encouraging, which generally show small scattered bars and insignificant dune erosion as compared to the prototype. The reason is probably due to the fact that wave energy dissipates more quickly over the flatter bed of fine sand in the undistorted model. An example showing the undistorted model profile from Test A22 in the final model stage is presented in Figure 1.

##### 4.1 Evaluation of Scaling Effects

The evaluation of scaling law is performed by investigating the model beach profile changes in separate dune and bar regions instead of the entire profile. The dune region is defined as from the landward end of the profile to the seaward end of the first slope in initial profile and the bar region is defined as from the beginning of the second slope to the seaward end of profile. Figure 2 shows a schematic of the defined dune and bar regions. The scaling effects were evaluated in the dune region

Fig.1: Comparison of model and prototype profiles in equilibrium state.

Fig.2: A schematic of dune and bar profile regions.

by calculating the error of dune erosion volume and the RMS error of dune profile as compared to the prototype. In the model bar region, the errors of bar crest location and bar volume, and RMS error of bar profile were calculated as compared to the prototype. The RMS error of the modelled beach profile is defined as

$$\epsilon = \left[ \frac{1}{n} \sum_{i=1}^n (h_{M,i} - h_{P,i})^2 \right]^{1/2},$$

where  $h_M$  and  $h_P$  are the corresponding profile elevations obtained from model and prototype, respectively. Other errors, including the errors of dune erosion volume, bar location and bar volume, are defined in the dimensionless form as

$$\frac{A_M - A_P}{A_P},$$

where  $A_M$  and  $A_P$ , respectively, are the model and prototype quantities used in the calculation of errors. Figures 3 to 7 show these errors computed and compared against model wave height for different model wave periods from all tested cases with  $N_\lambda = 20$  and  $N_\delta = 14.5$ . These errors were computed based on the survey of model profile at the model time of 40min and the final survey of prototype profile at the prototype time of 273min. This model profile from the survey at the model time of 40min is deemed to correspond to the final prototype profile upon the basis of correct morphological time scale. In Figure 3, a somewhat positive linear relationship between model wave height and error of dune erosion volume is observed. This indicates that greater dune erosion in model is likely to occur under larger waves. However, the effect of wave period upon dune erosion in model is less clear revealing a rather weak relationship between the two. The same patterns are also seen in Figures 5 and 6 for the errors of bar volume and bar location. That is, larger bar volume and further seaward bar location in model are likely to occur in the case of higher waves. In Figures 4 and 7, the RMS errors of modelled profile from the prototype in the dune and bar regions, respectively, were compared against model wave height for different wave periods. In these figures, it is seen that the effect of wave height to the RMS errors is less significant. However, the effect of wave period becomes important since a proper model wave period can result a consistent small RMS error which indicates a better fit of modelled profile to the prototype.

Based on the result of errors compared in Figures 3 to 7, it is clear that a proper modeling law should yield smallest absolute value of errors. That is, the zero crossings appeared in Figures 3, 5, and 6, and the least RMS errors in Figures 4 and 7 should correspond to the best modeling law. In order to examine the performance of the four modeling laws presented in Table 1, the errors corresponding to these modeling laws were also identified and marked in these Figures. Clearly, the modeling law derived in the paper presents the best model result in both dune and bar regions as compared to the prototype.

#### 4.2 Evaluation of Morphological Time Scale

The morphological time scale of a modeling law was evaluated by comparing dune and bar profile properties in model and prototype at different time intervals.

Fig.3: Comparison of error of dune erosion volume.

Fig.4: Comparison of RMS error of dune profile.

Fig.5: Comparison of error of bar volume.

Fig.6: Comparison of error of bar crest location.

Fig.7: Comparison of RMS error of bar profile.

The modelled beach profile results from three experiments, each presented the best fit model profiles to the final prototype data from three different horizontal scale groups, were selected for this evaluation. The three experiments are Test B3 ( $N_\lambda = 20$ ) from the 3-D wave basin experiment, and Tests A18 ( $N_\lambda = 30$ ) and A20 ( $N_\lambda = 40$ ) from the 2-D wave tank experiment. The 3-D model profiles used in the evaluation are those averaged from the survey of five profiles across the basin to eliminate the minor 3-D effect in model. Based on these experimental data and prototype data, three different morphological time scaling laws as of Hughes (1983), Wang, *et al.* (1990) and the present one shown in Table 1 were compared in terms of the temporal changes of dune erosion volume, RMS elevation difference to initial dune profile, bar volume and bar location, and RMS elevation difference to initial bar profile. The RMS elevation difference to initial profile is defined as

$$e = \left[ \frac{1}{n} \sum_{i=1}^n (h_{S,i} - h_{I,i})^2 \right]^{1/2},$$

where  $h_I$  and  $h_S$ , respectively, are the profile elevations from the initial survey and one following survey at a later time. The results of comparison of these errors computed for the three morphological time scaling laws are shown in Figures 8 to 12.

Figure 8 presents the result of time changes of dune erosion volume for all three scaling laws compared. The comparison shows good model result from the 3-D wave basin experiment for  $N_\lambda=20$  but not the 2-D experiment for  $N_\lambda = 30$  and 40. The reason is probably due to poor compaction and dry condition of sand in the dune region in the 2-D experiment. It appears that none of the model results as well as the prototype have reached equilibrium at the end of the run. For the RMS elevation difference to initial dune profile, all three modeling laws appeared to perform reasonably well in Figure 9 as the scaled model values clustered in a narrow range around the prototype result. For the temporal changes of bar crest location, all

Fig.8: Comparison of temporal changes of dune erosion volume.

Fig.9: Comparison of RMS elevation difference of dune profile.

Fig.10: Comparison of temporal changes of bar volume.

Fig.11: Comparison of temporal changes of bar crest location.

Fig.12: Comparison of RMS elevation difference of bar profile.

three modeling laws appeared to give reasonable results for the data compared to the prototype with the exception of those from Test A18. For the bar volume and RMS elevation difference of bar profile, the modeling law derived in the paper apparently showed the best fit to the prototype data than the other two modeling laws compared. Table 3 presents a summary of the model length and time scales computed based on the four modeling laws and those estimated from the best experimental results for the case of  $N_\lambda = 20$  and  $N_W = 2$ . Certainly, the newly derived modeling law shows overall better performance than the others compared.

5. Summary and Conclusions

A new modeling law for distorted beach model was derived by modifying the one proposed by Wang, *et al.* (1990). The new modeling law preserves not only the sediment transport velocity parameter and surf zone parameter but also the wave breaking index in model. This, in essence, adds to the constraint that wave height may need to be modelled differently from the simple vertical geometrical scale.

In order to investigate the scaling effects, a total of 38 beach model experiments were conducted in the 2-D wave tank and wave flume, and 3-D wave basin. The scaling effects were studied by varying the wave height and wave period in individual experiments and the model results were compared to the prototype data from German GWK experiment. Three different horizontal length scales,  $N_\lambda = 20, 30,$  and  $40,$  were selected in the model experiments. Two different sands, with median sizes equal to  $0.09\text{mm}$  and  $0.2\text{mm},$  respectively, were used in model for undistorted and distorted model studies. The prototype sand has a median size of  $0.33\text{mm}.$

Besides the investigation of scaling effects, four different scaling laws including the new one derived in the paper were also tested against the laboratory model results. The evaluation of scaling laws was carried out by examining the changes of modelled

beach profile properties in the separate dune and bar profile regions. Several test parameters, including the errors of dune erosion volume and RMS error of dune profile, bar volume and bar location, and RMS error of bar profile, were utilized to evaluate the model behavior as compared to the prototype. The major conclusions are listed below:

1. Based on the comparison of errors of the model dune erosion volume near the final model stage, greater dune erosion in model is found to occur under larger waves. And, this result is generally not influenced by varying the wave period in model. As comparing the errors of bar volume and bar location, more bar volume and further seaward bar location are found to occur also in the case of larger waves. The smaller absolute value of these errors corresponds to the better cases with the model behavior similar to the prototype. In terms of the RMS errors of modelled beach profile computed in the dune and bar regions, it is seen that the effect of wave height to the RMS errors is less significant. However, the factor of wave period becomes important since a proper model wave period can result a consistent small RMS error which indicates a better fit of modelled profile to the prototype. Accordingly, by applying these results to evaluate the four modeling laws presented in Table 1, the one derived in the present paper appears to have the overall better performance than the other modeling laws.

2. The evaluation of three different morphological time scaling laws, as of Hughes (1983), Wang, *et al.* (1990) and the present one shown in Table 1, by comparing dune and bar profile properties in model and prototype at different times shows that there is less clear which one performs better than the others. In general, all three time scaling laws yield good result to the temporal changes of dune erosion volume and dune profile in model. In terms of bar volume and bar location, the beach model responses seem to develop the bar a little too fast and too large in the initial model stage. However, the results show good agreement to the prototype near the final model stage. It appears that none of the model and prototype profile have reached the equilibrium state at the end of the run.

3. Overall evaluation of the four modeling laws compared in this study shows that the one derived in the present paper performs better than the other three modeling laws. The new modeling law assumes that the fluid motion time scale is the same as the morphological time scale and is equal to square root of the horizontal length scale. The consequences are interesting that both the number of incoming waves per unit time and the deepwater wave length are preserved in model. On the other hand, the new modeling law requires to model the wave height differently from the simple vertical geometrical scale. According to the new modeling law, wave height higher than that from the vertical length scale ratio is needed as to preserve the wave breaking index in the distorted model.

4. The experiments of undistorted model using fine sand of median size of 0.09mm was not successful. The expected bar and dune profile could not be obtained in model. The reason is probably due to the fact that wave energy dissipates more quickly over the flatter bed of fine sand in the undistorted model.

5. The experiments supported the validity of applying distorted model for the prediction of beach and dune erosion in the nearshore zone. However, the present study focuses only on the modeling effects of storm profile. It is necessary to also test the modeling law upon the beach accretion.

## CHAPTER 201

# A NUMERICAL MODEL OF BEACH CHANGE DUE TO SHEET-FLOW

Akira Watanabe<sup>1</sup>, Kazuhiko Shiba<sup>2</sup> and Masahiko Isobe<sup>3</sup>

### ABSTRACT

First a discussion is made on the relation between the time-average of a Boussinesq-type equation and the mean flow equation. Then nonlinear wave transformation on a sloping bed is computed by a set of Boussinesq equations including a breaker-induced energy dissipation term. Comparisons are made between the computations and laboratory measurements for cross-shore distributions of the wave height and mean water elevation, and for time-histories of the near-bottom velocity near and after breaking. Undertow current velocity in the nearshore zone is calculated by a semi-empirical formula and is also compared with measurement data. A beach profile change model is set up by combining the Boussinesq-type equations, a sediment transport rate formula for the sheet-flow proposed by Dibajnia and Watanabe, which incorporates the asymmetric orbital velocity due to wave nonlinearity as well as the undertow current, and a sediment mass conservation equation proposed by Watanabe *et al.*, which includes the effect of local bottom slope. The validity of the model is examined through the comparisons of the computed transport rate distributions and beach profiles with the laboratory data obtained in large wave flume experiments.

### INTRODUCTION

Prediction of beach processes is generally inevitable to develop or protect coastal zones properly. Short-term beach topography changes have usually been predicted in Japan by the numerical model proposed by Watanabe *et al.* (1986) or its improved versions. In this model, however, since the wave computation is performed with linear time-dependent mild slope equations involving breaker-induced energy dissipation, the calculations of the nearshore currents and the mean water elevation should be carried out only through the evaluation of radiation stresses, and hence the wave-current interaction can be treated by the iteration of the computations of waves and of currents. In addition, the effect of

wave nonlinearity on the sediment transport rate has been incorporated on the basis of the simplified semi-empirical formulas.

Dibajnia *et al.* (1992) have performed the prediction of beach profile change applying the formula by Dibajnia and Watanabe (1992) for the sheet-flow transport rate under nonlinear waves. However, since they have employed the linear wave model for the wave computation, a sort of inconsistency has been existing from a theoretical viewpoint.

Prediction of beach profile change under sheet-flow condition is important, because significant short-term beach deformation is caused by large waves, under which the sheet-flow sediment transport is usually predominant. In addition, under such conditions, one cannot discard the asymmetry of near-bottom orbital motion and the presence of undertow particularly in the surf zone. This paper presents a numerical model of beach profile change based on a sheet-flow transport rate formula mentioned above and on Boussinesq-type wave equations, incorporating the effects of asymmetric velocity and the undertow. Comparisons will be made between the numerical computations and measurements.

## BOUSSINESQ EQUATION AND NEARSHORE CURRENT EQUATION

Boussinesq-type equations include nonlinear terms to the order of  $O(a^2)$ , where  $a$  is the wave amplitude. Since nearshore currents (wave-induced mean flow) and wave setup/down are the phenomena of the order of  $O(a^2)$ , they will be evaluated with a Boussinesq-type equation. In this section, we will show that the time-average of the Boussinesq equation that involves vertical velocity distributions becomes equivalent to the governing equation for the nearshore currents, and that thus the concurrent computation of waves and currents becomes possible.

Abbott (1979) has presented the Boussinesq equation involving vertical velocity distributions as follows:

$$\begin{aligned} \frac{\partial \rho u_\alpha}{\partial t} + \frac{\partial}{\partial x_\beta}(\rho u_\alpha u_\beta) + \frac{\partial}{\partial z}(\rho w u_\alpha) + \rho g \frac{\partial \eta}{\partial x_\alpha} \\ = -\rho \frac{\partial^3 \eta}{\partial x_\alpha \partial t^2} \left\{ \frac{(h + \eta)^2 - (h + z)^2}{2(h + \eta)} \right\} \end{aligned} \quad (1)$$

where  $h$  is the still water depth,  $\eta$  the instantaneous surface displacement,  $u$  the horizontal velocity,  $w$  the vertical velocity,  $t$  the time, and  $x$  and  $z$  are the horizontal and vertical coordinates, respectively. The subscripts  $\alpha$  and  $\beta$  take a value of 1 or 2, and the summation convention is adopted.

Boundary conditions on the free surface and the seabed are as follows:

$$\frac{\partial \eta}{\partial t} - w + u_\alpha \frac{\partial \eta}{\partial x_\alpha} = 0 \quad (z = \eta) \quad (2)$$

$$w + u_\alpha \frac{\partial h}{\partial x_\alpha} = 0 \quad (z = -h) \quad (3)$$

Integrating Eq. (1) from the bottom to the free surface and using the boundary conditions, we obtain

$$\begin{aligned} \frac{\partial}{\partial t} \int_{-h}^{\eta} \rho u_{\alpha} dz + \frac{\partial}{\partial x_{\beta}} \int_{-h}^{\eta} \rho u_{\alpha} u_{\beta} dz + \rho g(h + \eta) \frac{\partial \eta}{\partial x_{\alpha}} \\ = -\rho \frac{\partial^3 \eta}{\partial x_{\alpha} \partial t^2} \frac{(h + \eta)^2}{3} \end{aligned} \quad (4)$$

Here we will decompose the horizontal velocity  $u_{\alpha}$  into the time-average (steady) component  $U_{\alpha}$  and the periodic (wave) component  $u'_{\alpha}$ :

$$u_{\alpha} = U_{\alpha} + u'_{\alpha} \quad (5)$$

and define three kinds of mass transport as follows:

$$\overline{\int_{-h}^{\eta} \rho u'_{\alpha} dz} = M'_{\alpha} \quad (6)$$

$$\overline{\int_{-h}^{\eta} \rho U_{\alpha} dz} = \rho U_{\alpha}(h + \bar{\eta}) = M_{\alpha} \quad (7)$$

$$\overline{\int_{-h}^{\eta} \rho u_{\alpha} dz} = \tilde{M}_{\alpha} = M_{\alpha} + M'_{\alpha} = \rho \tilde{U}_{\alpha}(h + \bar{\eta}) \quad (8)$$

where  $\bar{\eta}$  is the mean water displacement,  $M'_{\alpha}$  and  $M_{\alpha}$  are the mass transport due to the orbital velocity and to the mean flow, respectively, and  $\tilde{M}_{\alpha}$  is their summation.

Substitution of Eqs. (6) to (8) into the time-average of Eq. (4) yields

$$\begin{aligned} \frac{\partial \tilde{M}_{\alpha}}{\partial t} + \frac{\partial}{\partial x_{\beta}} \left\{ \tilde{U}_{\beta} \tilde{M}_{\alpha} + \overline{\int_{-h}^{\eta} \rho u'_{\alpha} u'_{\beta} dz} - \frac{M'_{\alpha} M'_{\beta}}{\rho(h + \bar{\eta})} \right\} \\ + \rho g(h + \bar{\eta}) \frac{\partial \bar{\eta}}{\partial x_{\alpha}} = -\rho \frac{\partial^3 \bar{\eta}}{\partial x_{\alpha} \partial t^2} \frac{(h + \bar{\eta})^2}{3} \end{aligned} \quad (9)$$

On the other hand, Eq. (10) gives the governing equation for the nearshore current and the mean water elevation, in which the bottom friction and lateral mixing terms are neglected.

$$\frac{\partial \tilde{M}_{\alpha}}{\partial t} + \frac{\partial}{\partial x_{\beta}} [\tilde{U}_{\beta} \tilde{M}_{\alpha} + S_{\alpha\beta}] + \rho g(h + \bar{\eta}) \frac{\partial \bar{\eta}}{\partial x_{\alpha}} = 0 \quad (10)$$

where  $S_{\alpha\beta}$  is the radiation stress expressed as:

$$S_{\alpha\beta} = \overline{\int_{-h}^{\eta} (\rho u'_{\alpha} u'_{\beta} + p \delta_{\alpha\beta}) dz} - \frac{1}{2} \rho g(h + \bar{\eta})^2 \delta_{\alpha\beta} - \frac{M'_{\alpha} M'_{\beta}}{\rho(h + \bar{\eta})} \quad (11)$$

Comparing Eqs. (9) and (10), we can readily find that their differences exist only in the radiation stress term and on the right hand side. Since the Boussinesq equation holds for shallow water waves, we apply a long wave approximation to the pressure  $p$  in Eq. (11). Abbott (1979) has obtained the following relation for the pressure, in the process of his derivation of Eq. (1):

$$\frac{p(z)}{\rho} = g(\eta - z) + \frac{\partial^2 \eta}{\partial t^2} \frac{(h + \eta)^2 - (h + z)^2}{2(h + \eta)} \quad (12)$$

Substitution of Eq. (12) into Eq. (11) and some manipulations make Eq. (10) become identical to Eq. (9).

It has thus been shown that, as far as the long wave approximation holds good, the time-average of the Boussinesq equation becomes equivalent to the mean flow equation. In other words, solving the Boussinesq equation, we can compute not only the wave field but also the nearshore current and mean water level field, which are obtained by taking the time-average of the solutions for the velocity  $u_\alpha$  and for the surface displacement  $\eta$ , respectively. This means that the wave-current interaction is automatically incorporated in computations.

### COMPUTATION OF WAVES AND MEAN WATER ELEVATION

A set of one-dimensional Boussinesq equations involving a breaker-induced energy dissipation term is expressed in terms of the surface displacement  $\eta$  and the flow rate  $Q$  as follows:

$$\frac{\partial \eta}{\partial t} + \frac{\partial Q}{\partial x} = 0 \quad (13)$$

$$\frac{\partial Q}{\partial t} + \frac{\partial}{\partial x} \left( \frac{Q^2}{D} \right) + gD \frac{\partial \eta}{\partial x} - \frac{h^2}{3} \frac{\partial^3 Q}{\partial t \partial x^2} + M_D = 0 \quad (14)$$

where

$$D = h + \eta, \quad Q = \int_{-h}^{\eta} u \, dz,$$

$u$  is the horizontal velocity and  $M_D$  corresponds to the breaker-induced energy dissipation and is given by (Sato and Suzuki, 1990)

$$M_D = \frac{gD}{\sigma^2} f_D \frac{\partial^2 Q}{\partial x^2} \quad (15)$$

The quantity  $\sigma$  is the angular frequency, and  $f_D$  is the energy dissipation coefficient expressed as (Watanabe & Dibajnia, 1987):

$$f_D = \alpha_D \tan \beta \sqrt{\frac{g}{h}} \sqrt{\frac{\hat{Q} - Q_r}{Q_s - Q_r}} \quad (16)$$

in which the coefficient  $\alpha_D = 2.5$ ,  $\tan \beta$  is the bottom slope around the breaking point,  $\hat{Q}$  is the amplitude of  $Q$ , and  $Q_s$  and  $Q_r$  correspond to  $\hat{Q}$  in the dissipation zone on a uniform slope and in the recovery zone in the constant depth water, respectively, given by

$$Q_s = \gamma_s C h \quad (17)$$

$$Q_r = \gamma_r C h \quad (18)$$

$$\gamma_s = 0.4 (0.57 + 5.3 \tan \beta) \quad (19)$$

$$\gamma_r = 0.4 \left( \frac{a}{h} \right)_B \quad (20)$$

where  $C$  is the wave celerity, and  $(a/h)_B$  is the ratio of the wave amplitude to the water depth at a breaking point.

In order to avoid re-reflection of outgoing waves (reflected from the slope or structures, if any), we should impose such a condition that they can freely pass through the offshore boundary of a computation domain. For this, we express the flow rate  $Q$  on the offshore boundary as the summation of that of the incident waves  $Q_{in}$  and of the outgoing waves  $Q_{out}$ :

$$Q = Q_{in} + Q_{out} \quad (21)$$

The corresponding horizontal velocities are expressed, under the long wave approximation, as:

$$\bar{u}_{in} = \sqrt{g/h} \eta_{in}, \quad \bar{u}_{out} = -\sqrt{g/h} \eta_{out} \quad (22)$$

Using  $Q = \bar{u}(h + \eta)$  and neglecting terms with  $\eta^2$ , we obtain the following relation from Eq. (21):

$$Q = 2C \eta_{in} - C \eta \quad (23)$$

On the other hand, we impose the condition given by Eq. (24) on the shoreward boundary, where  $r$  is the reflection coefficient.

$$Q = (1 - r) \cdot C \eta \quad (24)$$

Using these boundary conditions, numerical computations for Eqs. (13) and (14) will be conducted by the finite difference method with the central difference-staggered mesh scheme.

Computations of wave transformation on a slope have been made and the results have been compared with experimental data obtained by Sato *et al.* (1987). In the experiment, the water surface displacement and the near-bottom orbital velocity were recorded under the conditions that the bottom slope was 1/20 and the incident wave height and period were 6.1cm and 1.18s.

Figures 1 and 2, respectively, compare the cross-shore distributions of the wave height and the mean water surface elevation between the computations and the measurements. Agreement is very good for the wave height even near the breaking point. The mean water level  $\bar{\eta}$  that has been computed by taking the

time average of  $\eta$ , without the computation of the radiation stress, also shows a fairly good agreement with the measurements.

Fig. 1 Comparison of cross-shore distributions of wave height.

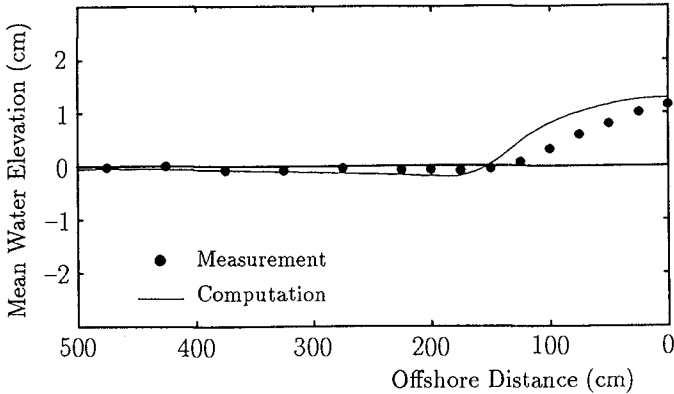

Fig. 2 Comparison of cross-shore distributions of mean water surface elevation.

### CALCULATION OF NEAR-BOTTOM ORBITAL VELOCITY

The orbital velocities were measured at several points 5mm in height above the bottom. By considering the finite water depths in the region, the near-bottom

orbital velocity  $u_b$  has been computed as a function of time at each location by the following equation:

$$u_b = \frac{Q}{h + \eta} \cdot \frac{\cosh(2\pi z'/L)}{\cosh(2\pi h/L)} \tag{25}$$

where  $z'$  is the height of a point above the bottom, and  $L$  is the local wavelength. Figures 3 (a), (b) and (c) show the comparisons of  $u_b$  between the computations and the measurements, for three locations: (a) outside the surf zone, (b) near the breaking point, and (c) in the surf zone.

In previous computations of the orbital velocities based on the small-amplitude wave theory, the method proposed by Isobe and Horikawa (1981) has given fairly good estimates up to the neighborhood of breaking points, but it has failed to evaluate them in the surf zone after breaking. As shown in Figs. 3 (a) to (c), the present model can directly reproduce the near-bottom orbital velocities with a remarkably high accuracy. The above comparisons are for a case of plunging breaker, and it has been found that the present wave model works for cases of spilling breaker as well.

Fig. 3 Comparisons of near-bottom orbital velocities.

## EVALUATION OF UNDERTOW VELOCITY

In the surf zone, the undertow (return flow near the bed) usually develops to compensate the shoreward mass transport accompanying the breakers. Since the concentration of suspended sediment is very high near the bottom, the effect of the undertow on the sediment transport should inevitably be taken into consideration. However, highly reliable models have not yet been established for the prediction of the undertow velocity under general conditions.

In the present study, following Dibajnia *et al.* (1992), we have evaluated the cross-shore distribution of steady flow velocity  $U$  due to the undertow by decomposing it into three components: the return flow velocity  $U_B$  caused by wave breaking, the seaward velocity  $U_W$  compensating the mass transport, and the Eulerian mass transport velocity  $U_E$  at the outer edge of the bottom boundary layer. According to previous studies, the undertow velocity becomes nearly zero near the breaking point. Hence, for simplicity, as a parameter representing the degree of intensity of the breaker-induced large vortex, we have introduced the following function  $K_U$ , whose value is zero before the plunging point  $x \leq X_p$ , being unity after the large vortex development point  $X_i$  and changing linearly between these two points, *i.e.*,

$$K_U = \begin{cases} 0 & (x \leq X_p) \\ \frac{X_p - x}{X_p - X_i} & (X_p < x \leq X_i) \\ 1 & (X_i < x) \end{cases} \quad (26)$$

Then the resultant total undertow velocity  $U$  has been calculated by

$$U = K_U (U_B + U_W + U_E) \quad (27)$$

The first component  $U_B$  has been estimated by the following formula proposed by Sato *et al.* (1987):

$$U_B = -A \frac{H^2}{h \cdot T} \quad (28)$$

where  $H$  and  $h$  are the local wave height and water depth, respectively, and  $A$  is a dimensionless coefficient of the order of unity. In the present study, we have used  $A = 1$ .

Figure 4 shows the comparison of the undertow velocity between the computation and the measurements, indicating a considerably good agreement. However, this only demonstrates the validity of the present method, Eqs. (26) to (28), for a constant slope bed in a wave flume, and its applicability to more general conditions (prototype scale and complicated bottom topography) is still questionable.

Fig. 4 Comparisons of cross-shore distributions of undertow velocity.

**COMPUTATION OF SEDIMENT TRANSPORT RATE AND BEACH PROFILE CHANGE**

Dibajnia and Watanabe (1992) have proposed a sheet-flow sand transport rate formula based on extensive laboratory data obtained in oscillatory flow tank experiments, considering the entrainment and settling processes of suspended sediment during the two successive half wave periods. According to this formula, the net rate of sheet flow transport  $q_{net}$  can be calculated as a function of the root-mean-square amplitudes,  $u_c$  and  $u_t$  and the time durations,  $T_c$  and  $T_t$ , of the onshore and offshore velocity, respectively, and the grain diameter  $d$ , settling velocity  $w_0$ , and porosity  $\lambda_v$  of the sediment, as follows:

$$q_{net} = \text{sign}(\Gamma) \cdot 0.001|\Gamma|^{0.55} \cdot w_0 d / (1 - \lambda_v) \tag{29}$$

$$\Gamma = \frac{u_c T_c (\Omega_c^3 + \Omega'_c{}^3) - u_t T_t (\Omega_t^3 + \Omega'_t{}^3)}{(u_c + u_t) T} \tag{30}$$

where  $\Omega_c$ ,  $\Omega'_c$ ,  $\Omega_t$  and  $\Omega'_t$  are functions of  $u_c$ ,  $u_t$ ,  $T_c$ ,  $T_t$ ,  $d$ ,  $w_0$  and the specific density of the sediment (For details, see Dibajnia and Watanabe, 1992).

Dibajnia, Shimizu and Watanabe (1992) have presented a numerical model for a profile change of a sheet flow predominant beach using the above transport rate formula and the linear time-dependent mild slope equations. In the present study, we have incorporated the effect of wave nonlinearity in the prediction of beach profile change by combining the wave model based on the Boussinesq equation and the undertow model mentioned above as well as the sediment transport rate formula, Eq. (29). The change of a beach profile has been computed from the cross-shore distribution of  $q_{net}$  by the sediment mass conservation equation including the effect of the local bottom slope (Watanabe *et al.*, 1984):

$$\frac{\partial z_b}{\partial t} = -\frac{\partial h}{\partial t} = -\frac{\partial}{\partial x} \left( q_{net} - \epsilon_s |q_{net}| \frac{\partial z_b}{\partial x} \right) \tag{31}$$

where  $z_b$  is the bottom elevation, and a value of 2.0 has been used for the coefficient  $\epsilon_s$ .

In order to examine the validity of the model, we have performed comparisons of the computations with the measurements obtained by Shimizu *et al.* (1985) in their large scale experiments. Table 1 indicates the experimental conditions for the adopted three cases, in which  $d_{50}$  is the median diameter of the sand,  $\tan \beta$  is the initial beach slope,  $T$  and  $H_0$  are the period and height of incident waves.

Table 1 Experimental conditions.

Case	$d_{50}$ (mm)	$\tan \beta$	$T$ (s)	$H_0$ (m)	Breaker type
3-2	0.27	1/20.0	6.0	1.05	Plunging
3-4	0.27	1/20.0	3.1	1.54	Spilling
4-2	0.27	1/33.3	4.5	0.97	Plunging

Although the measurements were made for a total time duration of 30 hours, the computations have been conducted for a duration of 5 or 7 hours only, because the accuracy of the undertow computation may become unsatisfactory as the beach profiles get complicated with time. Figures 5, 6 and 7 show the comparisons between the computations and the measurements of Cases 3-2, 3-4 and 4-2, respectively, for the wave height distributions, the net rates of the sediment transport, and the beach profiles.

These figures demonstrate considerably good agreement between the computations and the measurements, indicating the overall validity of the present model that includes the nonlinear wave equation, the formulas for the near-bottom orbital velocity and for the undertow velocity, and the sheet flow transport rate formula.

## CONCLUDING REMARKS

This paper has presented a numerical model for beach profile change, which incorporates the asymmetric orbital velocity due to wave nonlinearity as well as the undertow current. By using the Boussinesq equation, the iteration of computations for the waves and for the mean flow and mean water level has become unnecessary, and the computational accuracy of the near-bottom orbital velocities has been highly improved. A beach profile change model has been established by the combination of the wave model based on the Boussinesq equation and the sediment transport rate formula for the sheet flow proposed by Dibajnia and Watanabe (1992). An overall validity of the present numerical model has been examined through the comparisons of the computed sediment transport rate distributions and beach profiles with the laboratory data obtained in large wave flume experiments by Shimizu *et al.* (1985). A better method will be required for the prediction of the undertow velocity distribution under general conditions so as to make the present model more practical and useful.

## Field Tests of Radiation-Stress Estimators of Longshore Sediment-Transport

Thomas E. White <sup>1</sup>

### Abstract

Surfzone measurements of longshore sediment-transport with optical backscatter sensors and current meters are compared to transport estimates from offshore wave data. Several methods from the Shore Protection Manual for computing longshore sediment transport from waves are compared and correlated. Some formulas work well some of the time. Circumstances of which equations perform well/poorly under which conditions are specified, and reasons for poor performances are speculated upon. Advice is given for placement of wave gages and methods of analysis, which would increase the probability of obtaining good estimates of longshore sediment transport from directional wave data.

### Introduction

Comprehensive arrays of 43 sensors were deployed to measure waves, currents, tides, and sediment transport at a long straight beach with gently-sloping plane parallel contours near a river outlet, Colorado River, Texas. (See inset map in Figure 1.)

Several state-of-the-art instruments were deployed: a trawler resistant Directional Wave Gage (DWG), a puv gage of colocated pressure and current sensors, Optical Backscatter Sensors for suspended-sediment concentrations, electromagnetic current meters for velocities, a new cable with internally imbedded pressure sensors for surfzone waves, and Acoustic Doppler Current Profilers for inlet currents and sediment flux.

This project of monitoring the behavior of the jetty system had several objectives, only one of which was estimation of longshore sediment transport from the offshore wave gages, the topic of this paper. Table 1 lists the major objectives (hypotheses) of the monitoring project and the means by which various functions

---

of the sediment transport ( $Q$  in volumetric terms) would be used to test the hypotheses. In addition to the engineering objectives in Table 1, there were several science objectives as well. The surfzone data are being used to test suspended-load transport theories at a point, in order to find the best ones to use in CERC's numerical models. This paper will describe only the results of the final objective: using the offshore wave data to predict longshore transport.

Figure 1. Colorado River location map (inset) and river mouth plan view. The weir section is underwater and allows some sediment to pass.

The purpose of this paper is to compare longshore sediment transport, as determined from both shoaled radiation stress and from transport measurements in the surfzone. For this reason, two sets of measurements were necessary: the offshore directional wave field and the sediment transport in the surfzone.

## HYPOTHESES ..... METHODS

### 1. Weir-Jetty System Hypotheses:

- Weir-trapping efficiency is high ..... Compute  $\frac{Q_{trapped}}{Q_i}$  (Impoundment/Transport)
- Weir length should be 1000 feet ..... Compute minimum of  $Q(x)$
- Weir is in proper cross-shore location ..... Compute  $\frac{\partial Q}{\partial x}$
- Impoundment area is large enough ..... Compute  $\int Q dt$
- Anticipated dredging frequency is reduced by design ..... Compute Required Dredging Frequency =  $\frac{Q_{trapped}}{V_{trap}}$
- Weir should be east of inlet .....  $Q_+ \gg Q_-$
- Jetty length should be 1500 feet ..... Bypassing efficiency =  $1 - \frac{Q(x_{inlet})}{Q_{TOTAL}}$

### 2. Sediment-Transport Hypotheses:

- $I = KECn \sin(\alpha) \cos(\alpha)$  ..... Compute Correlation Coefficient (absolute) and Confidence Interval (relative)
- $K = 0.7$  ..... Compute ratio of Predicted to Predictor
- Offshore wave gage predicts I ..... Correlations of  $S_{xy}$  and measured I

## Radiation Stress Method

The offshore wave field was measured at 10m depth at approximately 3.2km offshore. As seen in Figure 2, the topography is quite linear (plane parallel contours) with very gentle slopes. When designing this project, it was hoped that if shoaled wave energy could be used to predict transport, the method ought to work better here than at many other sites, because of the gentle topography. Of course, it's always better to measure the waves close to where the data are needed (in this case, the breakpoint). But a very shallow gage deployment would have been unlikely to remain stationary over a long period, due to the stresses and topographic changes which are relatively large at 3m depth compared to 10m. Also the area is heavily trawled for shrimp, so gages were deemed more likely to survive in the area of offshore towers, which is where the gages were placed.

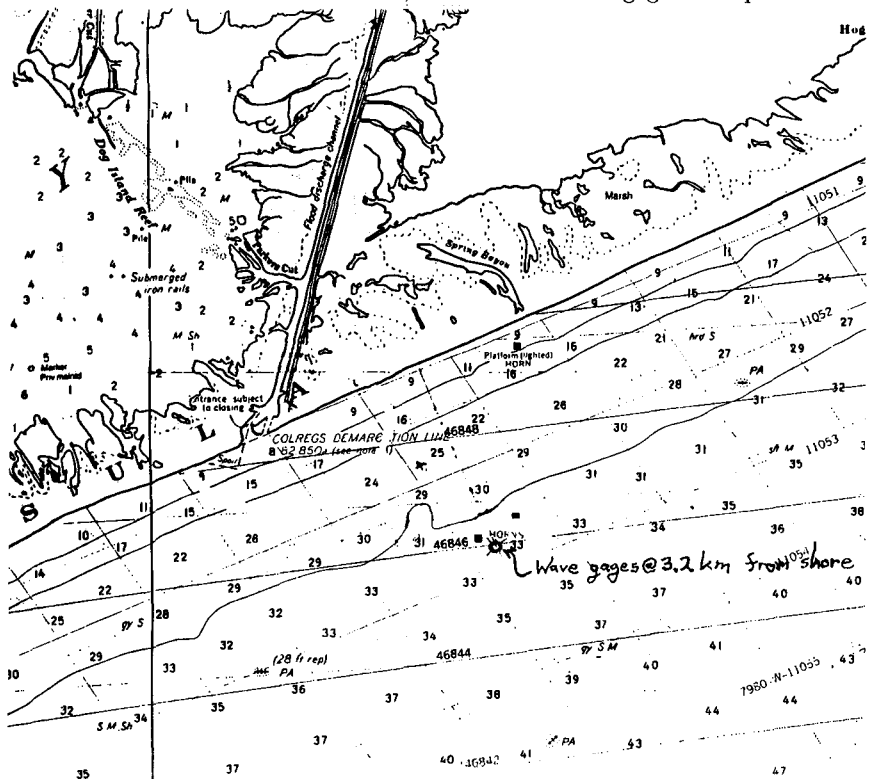

Figure 2. Topographic map of the region offshore of the jetties, with wave gage site marked at 3.2km offshore and 10m depth (from NOAA/NOS Chart #11316, dated 31 May 1980).

The total-load alongshore sediment flux is determined by shoaling the ra-

radiation stress measured at offshore directional wave gages. The offshore directional wave field was measured by both "puv" collocated pressure and current sensors and by a new three-pressure-sensor Directional Wave Gage (Howell, 1992). For both sensor types, the measured wave data were first surface-corrected with the standard  $\cosh k(z+h)/\cosh kh$  factor and then used to compute energy/frequency/direction spectra with the standard methods of Longuet-Higgins, Cartwright, and Smith (1963).

Once the direction/energy spectra are determined, they are used to estimate longshore sediment transport through the radiation-stress concept:

$$I_l = K C S_{xy} \quad (1)$$

where  $I_l$  is the immersed-weight longshore sediment flux,  $K$  is a coefficient (not necessarily constant, White and Inman, 1989),  $C$  is the wave phase speed, and  $S_{xy}$  is the longshore component of the cross-shore momentum flux, as determined from:

$$S_{xy} = E n \sin \alpha \cos \alpha \quad (2)$$

where  $E$  is the wave energy,  $n$  the ratio of group to phase speeds, and  $\alpha$  is the angle of wave approach relative to beach normal.

The energy was then shoaled over the topography using the most common technique of placing the energy summed over the spectrum into the peak band. Using Snell's Law, the direction of propagation was then altered at each 3m horizontal progression of the energy along the beach-profile rangeline between the gage and the breakpoint.

The procedure given above, using equations (1) and (2) and then shoaling the energy to the breakpoint, is equivalent to the "exact" method listed in the Shore Protection Manual (1984) as its Equation 4-40 (although the listed requirement for *deep* water wave angle, rather than the angle at the location where transport is desired, is apparently a mistake.) In addition to this exact method and three other functionally equivalent forms listed as equations 41, 42, and 43 in the Manual, there are four approximate methods for computing volumetric transport  $Q$ . These can be translated to immersed-weight transport  $I$  that we use, under the assumptions of constant densities, constant void ratios, and standard sand densities and voids, via  $I[N/s] = Q[yd^3/yr]/4356$ .

$$Q = 0.884 \rho g^{3/2} H_{sb}^{5/2} \sin 2\alpha_b \quad (3)$$

$$Q = 0.05 \rho g^{3/2} H_{so}^{5/2} (\cos \alpha_o)^{1/4} \sin 2\alpha_o \quad (4)$$

$$Q = 0.00996 \rho g^2 T H_{so}^2 \sin \alpha_b \cos \alpha_o \quad (5)$$

$$Q = 1.572 \rho g (H_{sb}^3/T) \sin \alpha_o \quad (6)$$

where  $\rho$  is fluid density,  $g$  gravity,  $H_s$  significant wave height,  $\alpha$  wave angle,  $T$  wave period,  $o$  the deep-water value, and  $b$  the breakpoint value. We also employed these four methods to compute longshore transport, using shoaled values (at "b") when the equations called for them. These four methods and the exact method were all compared to the sediment transport measured *directly* in the surfzone.

## Direct Method

The surfzone transport was measured by cross-shore integration of the point measurements from three synoptic multi-sensor platform arrays of Optical Backscatter Sensors (OBSs) (Downing, Sternberg, and Lister, 1981) and Electromagnetic Current Meters (ECMs), sonars, and pressure sensors. Figure 3 shows a plan view of the site with various platforms of gages drawn in the general areas where they were deployed.

### MCCP COLORADO RIVER, TEXAS

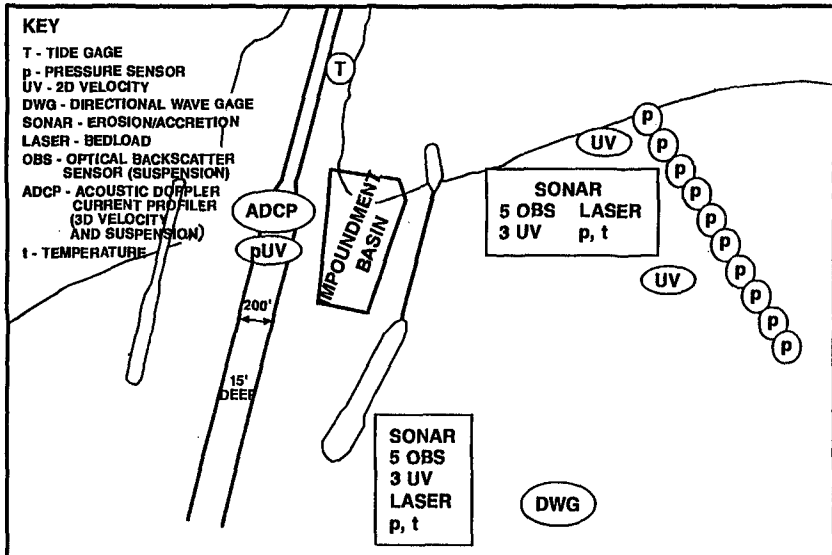

Figure 3. Areas of deployment of each gage type. Gage platforms are not to scale, but for visualization are drawn very large relative to the jetties. The lasers were replaced by micro-OBS gages for bedload.

The sediment concentration was measured with OBS2 optical backscatter sensors, which were each calibrated in a flow tank over a wide range of transport values. The sand from the site was sampled prior to each experiment and generally had a median size of 130 microns, with a size distribution that was always single-peaked. The sand from the site was used in the laboratory to calibrate the sensors over a wide range of transport values (from 1 to 300 grams per liter), both prior to and after each of the three experiments.

The currents were measured with standard 1-inch diameter Marsh-McBirney electromagnetic probes, calibrated just prior to use. Pressure sensors were used to determine the range of vertical integration for each platform, and also to determine when uppermost sensors were out of the water and thus not to be used.

The longshore sediment transport is the direct integration of the product of these two types of calibrated-sensor outputs, as measured in the surfzone:

$$I_l = (\rho_s - \rho)gN_o \int_0^{X_b} \int_0^n v(x, z)c(x, z)dzdx \tag{7}$$

where  $\rho_s$  is the sediment density,  $\rho$  the fluid density,  $g$  the acceleration of gravity,  $N_o$  the solids density (one minus porosity),  $v$  the longshore fluid velocity,  $c$  the sediment concentration, and the integral is taken over both the vertical surf depth and the cross-shore surfzone width.

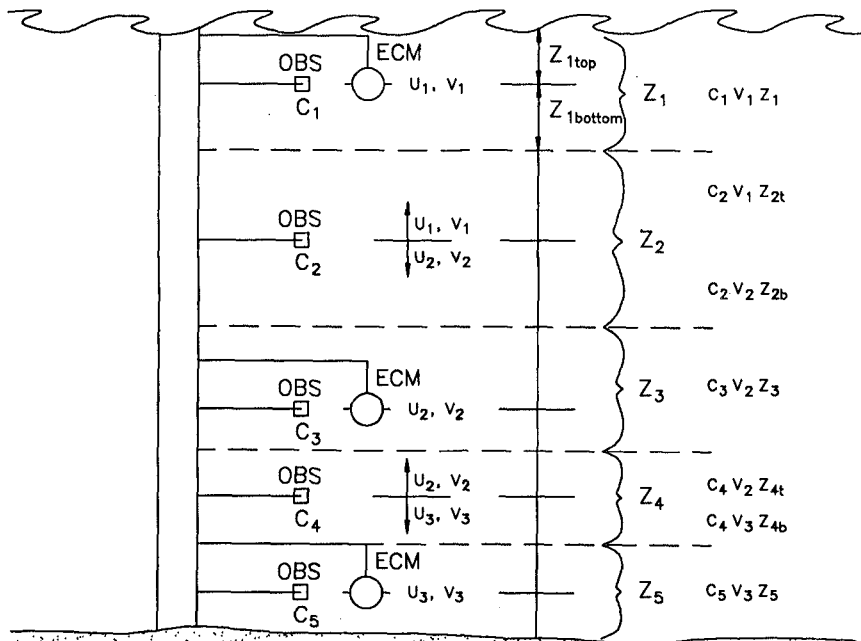

Figure 4. Regions of vertical integration of local sediment transport. Mid-points (dashed lines) between each gage of each type (both ElectroMagnetic Current meters and Optical Backscatter Sensors) separate each region.  $c$  = concentration,  $v$  = longshore velocity,  $z$  = vertical distance.

The above integration is first accomplished in the vertical at each platform location by vertically integrating the values of concentration  $c$ , longshore velocity  $v$ , and vertical range  $z$ , as shown in Figure 4. It is important to note that the vertical integration is performed at each time step of 0.2 seconds, and is thus unaffected by phenomena with longer time periods, such as bursts of sediment out of the boundary layer. Each sensor measures at one instant, and all the

instantaneous products of  $c$ ,  $v$ , and  $z$  are vertically summed before moving to the next 0.2s time step.

The direct measurements are also being used to test theories of suspended-load and total-load sediment transport, which will be done in other publications. These theories of sediment transport relate fluid forcing of waves or velocities to sediment flux on a "local" or point basis. The theories are tested by comparing the predicted transport from the theories with the measured surfzone transport.

## Results

The longshore transport rates from the exact method, the four approximate methods, and the direct method were all computed for the one-week experiments, during which the surfzone platforms were deployed. The rates are listed in the following two tables for the June 1991 and January 1992 experiments. Note the considerable difference in transport values between the different methods. Individual estimates often differ as to the *direction* of transport. It is obvious that the different methods cannot be relied upon to produce comparable results for any specific set of wave conditions. But this is not generally what coastal engineers want to know. The more pertinent question is whether on a long-term basis (years), the wave-based methods can produce comparable transports to the real (measured) rates. The accumulation of the transport over months and years is the sand next to jetties, in navigation channels, or in impoundment basins, such as in Figure 1. Means of coping with this integral of the transport over time are what must be engineered.

Correlations over the 26 time periods in Table 2 and the 24 time periods in Table 3 were computed between the radiation-stress methods and the measured transport. Simple linear regression of the form  $y = mx + b$  was used, where  $x$  are the radiation-stress methods, and  $y$  the measured values. Standard deviations were computed using N weighting, and thus the correlations are simply  $r = m\sigma_x/\sigma_y$ . Negative values represent anti-correlation. The  $r^2$  values are the fraction of the total variance in the data explained by the method.

All the results of this paper are summed up in Table 4. One can reach different conclusions as to the effectiveness of a particular method, depending on which data set one examines. The July 1991 data show that *all* radiation-stress methods poorly predict measured rates. (The  $r^2$  values are quite small.)

On the other hand, the January 1992 data show that all but one method do very well. All but one of the  $r^2$  values are very high. For the method that did poorly, there are a couple possible explanations. It is the easiest method to use, because it does not require shoaling the wave data, but uses only deep-water values and ignores the topography. Another possible explanation, as noted in the table's footnote, is that conservative data-acceptance criteria were applied, whereas all the other methods used all measured data.

In the methods that did well (explained a high fraction of the variance, as

indicated by  $r^2$ ), note that some represent *anti*-correlations, meaning they indicate the right variation, but the wrong longshore direction. In the preparation of this paper, considerable time was spent trying to find any errors in sign. But the signs reported in the table appear to be correct. In fact, it is easy to see by examining individual spectra, that the signs of the correlations are valid. For example, note the reversal in sign between Eq 4-47 and the other methods, for the very large transport rate during a storm, on 18 Jan 1992 (the bottom line in Table 3.) That method agrees with the measured transport direction, whereas the others do not. However, all agree that transport was very large. Thus the correlations agree with conclusions that can be reached by looking at individual data points in Tables 2 and 3.

The bottom half of Table 4 correlates the exact method with one of the approximate methods. Since we are no longer comparing to the measured transport, this allows us to use *all* the offshore wave data, increasing by two orders of magnitude the number of data points (and the sampling of different wave climates throughout the year.) In contrast to the short experiments, these large data sets *consistently* show the same results, no matter which year's data are applied. For the years shown, the  $r^2$  is always about 0.40, so each method contains 40% of the variance of the other method. This low value is not encouraging, since it is the hope of engineers using the Shore Protection Manual that they will obtain roughly the same results, regardless of which method they use.

Modifications to the SPM transport equations may be extracted from Table 4. The slope  $m$  would be a modification to the coefficient  $K$  (Eq. 1) via  $K = 0.7 m$  (since 0.7 was our  $K$  value used in this rms-wave-height data set). For example, Eq. 6 performs well in the Jan 92 data set, so a new  $K$  could be  $K = 0.7 m = 0.7(0.6668) = 0.47$ , *provided* a  $y$ -intercept were also added to the equation. So one might compute  $I$  from the original formula, and then  $I_{new} = mI_{old} + b$ , and in our example  $b$  is negative.

## Conclusions

**The method of computing radiation stress** is clearly of first-order importance, as illustrated by the discrepancy in output from the five methods examined.

**Predicting transport by shoaling the radiation stress** sometimes works very well in predicting transport, and at other times does quite poorly. The possible reasons for this are numerous, and we can only speculate. The wave gage could have been malfunctioning during one of the experiments. But since there are means for testing the reasonableness of the data, it is more likely that sometimes there are processes operating in the surfzone not represented by offshore waves, but at other times these processes are small (e.g., wind, river flow rates, river silt load, etc.).

**Not shoaling the energy over the topography** (just using the deep-water values directly) may worsen the predictive capabilities. Evidence the poor performance of Eq 4-45 (our Eq 4).

**To obtain accurate estimates** of sediment transport, one must do something more than place wave gages offshore. Measuring the transport directly is preferred, but this is tedious and expensive. The different methods of measuring a transport rate, such as tracers, electronic sensors, or extensive beach profiling, all have the same order of magnitude in cost. Spending time and money on means to reliably obtain directional wave data very close to the breakpoint would seem a worthwhile effort. The shoaling process is likely to represent a large portion of the accumulated error in the radiation-stress method.

**Individual transport estimates cannot be reliably performed.** Although certain methods produce reliable results *over many occurrences*, use of an individual wave spectrum to estimate sediment transport can result in huge error, frequently even predicting the wrong direction of longshore transport.

In another study, the main factor not included in the SPM equations that was found to improve *local* estimates of transport, was inclusion of a sediment threshold-of-motion criterion (White, 1987; White, 1989). "Local" refers to predictions and measurements at essentially one point in the horizontal, as opposed to the "global" methods tested in this paper. In comparing predictions of different local transport theories with transport measured by sand tracer, it was found that agreement on direction of transport improved from 70% to 100% of the experiments, once a threshold criterion was added to the theory. It would be interesting to see if this were also true of the "global" equations tested in this paper.

Table 2: Measured and Computed Longshore Transport Rates: July 1991

All transport values are total  $I_l$  in Newtons per second.

Positive transport is upcoast (roughly ENE) on heading 65 degrees geographic.

For low waves and very large wave angles, King set transport to zero in his method using Eq 4 (SPM 4-45).

The computed transports are reported with far more significant digits than the method justifies, in order to retain digits until the rounding of the final result.

## Acknowledgments

The considerable efforts in obtaining the large field data set at Colorado River were performed by the capable staff of the Prototype Measurement and Analysis Branch of CERC, including Bill Grogg, Doug Lee, Rhonda Lofton, Bill Kucharski, Chuck Mayers, Debbie Shafer, and Kerry Taylor. The data-collection systems were designed and built by Ralph Ankeny, Bill Grogg, Gary Howell, and J. Rosati. The analysis of the surfzone time-series data and computation of measured transport were completed by Joon Rhee. The computations of transport potential using deep-water methods (SPM Eq. 4-45) were provided by David King. All other transport computations, including the extensive work in shoaling the wave data, were performed by Rhonda Lofton. Without her considerable efforts in data analysis, this paper would not have been possible.

The tests described and the resulting data presented herein, unless otherwise noted, were obtained from research conducted under Monitoring Completed Coastal Projects (Colorado River, Texas), Coastal Research (Field Tests of Sediment-Transport Theories), and Coastal Inlets Research Programs of the US Army Corps of Engineers at the Waterways Experiment Station. Permission was granted by the Chief of Engineers to publish the conference Abstract. Clearance for the full paper was requested, but has not been received as of the submission date. Thus this paper should be considered a private submission.

## CHAPTER 203

### Suspended Sediment Concentration Profiles under Non-breaking and Breaking Waves

Rattanapitikon Winyu and Tomoya Shibayama <sup>1</sup>

#### Abstract

Simple formulas to predict time-averaged suspended sediment concentration are formulated using steady diffusion equation. Empirical formulas are developed to compute reference concentration (boundary condition) and diffusion coefficient. For suspended sediment concentration in the field, the same formulas with regular wave condition can be applied by using root mean square wave height and average wave period. Total 139 data sets are used for calibration of empirical formulas and 175 data sets are used for verification.

#### Introduction

The need for reliable prediction of sediment transport and beach profile change is increasing due to an increasing of human activity on the coast. In order to predict the suspended sediment transport rate, it is necessary to predict the vertical distribution of sediment concentration and fluid velocity accurately. This study focuses an attention on the sediment concentration distribution. Sediment concentration is important not only for computing sediment transport rate but also for significant effect on the water quality for domestic and industrial use. From the last few decades, a number of models and experimental investigation have been performed to draw a clearer picture of suspended sediment concentration. Considerable amount of knowledge has been accumulated so far. However, it has not reached a satisfactory level. This is resulted from the unclear knowledge of movable sand layer and diffusion coefficient. At the present stage of knowledge, any type of model must be based on empirical or semi-empirical formula calibrated from the experimental results. For the prac-

---

<sup>1</sup>Dept. of Civil Eng., Yokohama National University, Hodogaya-ku, Yokohama 240, Japan

tical purposes, simple formulas may be more suitable than the complex ones (if it yields the accuracy in the acceptable range).

Based on wide range of wave and sediment conditions, Shibayama and Winyu (1993) proposed simple formulas to predict time-averaged concentration profiles under both non-breaking and breaking waves. The present study mainly focusses on the application and verification of the formulas. The measured surf zone concentration profile in prototype scale wave flume of Kajima et al. (1983) and in the field of Nielsen (1984) are used in this study. For some background information, a brief introduction of the formulas is also presented.

### Governing Equation

The vertical distribution of suspended sediment is calculated by the diffusion equation. By considering time averaged value of concentration and neglecting convection and horizontal diffusion, the diffusion equation can be written as:

$$cw_s + \epsilon_s \frac{\partial c}{\partial z} = 0 \quad (1)$$

where  $c$  is the time averaged sediment concentration;  $w_s$  is the falling velocity;  $\epsilon_s$  is the diffusion coefficient; and  $z$  is the vertical coordinate. To solve the diffusion equation, concentration at reference level should be given as a boundary condition, and the diffusion coefficient should also be known.

### Reference Concentration under Non-breaking and Breaking Waves

The reference concentration is defined at the level where the concentration can be measured without disturbance to the bed formation. The formula for predicting reference concentration is derived by applying transport rate formula of Watanabe (1982) and dimensional analysis (for more details, see Shibayama and Winyu, 1993). Total thirteen sources of published experimental results, totally 139 experiments, are used to calibrate the formulas. Table 3.1 shows the experiments which are used in formula calibration. As a result, the formula for computing reference concentration is given as:

$$c_r = \frac{10 (\psi - 0.05)\nu}{3 r \sqrt{(s-1)gd}} \quad (2)$$

where  $c_r$  is the reference concentration at  $z = r$ ;  $r$  is the reference level; The reference level is equal to half of ripple height above the ripple crest for vortex ripple case and equal to a hundred times of sand diameter above the mean bed for flat bed (i.e., breaking wave case);  $\psi$  is the grain Shield parameter;  $s$  is the relative density of sediment;  $d$  is the sand diameter and  $\nu$  is the fluid kinematic viscosity. The comparison between measured and computed reference concentration,  $c_r$ , is shown in Fig. 1. Figure 1 shows that about 80 percent of the predicted ones are within factor two.

### Concentration Profiles under Non-breaking Waves

Under non-breaking waves, high concentration areas of suspended sand are usually confined within the thin layer above the bottom, the thickness of which is usually about three ripple-heights or a few hundred times of grain diameter above the bed in laboratory tests and field measurements. Most of the previous experimental results show that if very small concentrations are neglected, the time averaged concentration profile fits well with the exponential form which is derived from steady diffusion equation (Eq. 1) under the assumption that the diffusion coefficient,  $\epsilon_s$ , is independent of vertical coordinate,  $z$ . After the integration of Eq. 1, the analytical solution is expressed as:

$$c(z) = c_r \exp\{-w_s(z - r)/\epsilon_s\} \quad (3)$$

Equation 3 shows that the relation between  $\ln(c)$  and  $z$  is the straight line with the gradient of  $-w_s/\epsilon_s$ .

At present, the knowledge of diffusion coefficient,  $\epsilon_s$ , is very limited, an application of empirical formula cannot be avoided. The difficulty of this approach is to find out the way to relate the diffusion coefficient with flow and sediment properties. From the previous empirical formulas of Sleath (1982), Skafel and Krishnappan (1986), and Nielsen (1988), we may assume that the diffusion coefficient  $\epsilon_s$  is a function of the following quantities:

$$\epsilon_s = f(u_b, A_b, \nu, w_s, d, s, f_w, \eta) \quad (4)$$

where  $f$  is the function;  $u_b$  is maximum orbital velocity;  $A_b$  is the orbital amplitude;  $f_w$  is the wave friction factor;  $\eta$  is the ripple height.

Experimental data of non-breaking wave cases, which shown in Table 1 (totally 108 cases), are used to calibrate the empirical formula. From dimensional analysis, using the experimental data of non-breaking wave cases in Table 1, the following formula is fitted well with the measured ones (see Fig. 2).

$$\epsilon_s = 0.21 u_* A_b \left(\frac{w_s}{u_*}\right)^2 \left(\frac{\eta}{d}\right)^{0.5} d_*^{-1.5} \quad (5)$$

where  $u_*$  is the maximum bed shear velocity; and  $d_* = d(sg/\nu^2)^{1/3}$  is the particle parameter. Eq. 5 is kept in the dimensionless form as in the analysis. Since  $u_*$  can be canceled out,  $\epsilon_s$  is not reverse proportional to  $u_*$ .

Figure 2 shows that about 80 percent of predicted diffusion coefficient,  $\epsilon_s$ , are within factor 1.5. Examples of measured and computed concentration profiles under non-breaking waves are shown in Fig. 3.

It should be mentioned that the exponential form of suspended concentration profile is valid within the thin layer (about few hundred times of sand diameter above the bed). As a results, Eq. 3 can be used to predict only the high concentration near the bed.

Figure 2: Comparison between measured and computed diffusion coefficient for non-breaking wave cases (legend see Table 1).

Figure 3: Examples of measured and computed concentration profiles under non-breaking waves of each data source.

### Concentration Profiles under Breaking Waves

The turbulence generated by the breaking waves causes a significant increase in the amount of suspended sediments compare to non-breaking waves of the same wave conditions and water depth. Moreover, the effect of turbulence due to breaking waves changes the shape of concentration profile (see Nielsen, 1978, Fig. 5) and the exponential form of concentration profile is not found. Thus, in breaking wave cases, we can not assume that the diffusion coefficient is constant as we assumed in non-breaking wave cases.

According to the experimental results, Okayasu (1989) suggested the linear distribution of eddy viscosity,  $\epsilon$ , as the function of the rate of energy dissipation due to wave breaking,  $D_B$ . By assuming diffusion coefficient proportional to the eddy viscosity of the flow and incorporating the diffusion coefficient caused by shear in wave field, the total diffusion coefficient,  $\epsilon_{sb}$ , is expressed as:

$$\epsilon_{sb} = [k_a u_* + k_b (D_B / \rho)^{1/3}] z \quad (6)$$

where  $k_a$  and  $k_b$  are the constants and  $D_B$  is the rate of energy dissipation. From the bore model, we can set  $D_B = \rho H^3 g / (4Th)$ .

After integration of the diffusion equation (Eq. 1), the analytical solution of concentration profile can be written in the following form:

$$c(z) = c_r \left( \frac{r}{z} \right)^M \quad (7)$$

$$M = \frac{w}{[k_a u_* + k_b (D_B / \rho)^{1/3}]} \quad (8)$$

From the best-fit technique, using breaking wave data in Table 1 (totally 29 data sets), the following constant parameters are recommended.

$$k_a = 0.04, \\ k_b = \begin{cases} 0.144 & \text{spilling breaker,} \\ 0.216 & \text{spilling-plunging transition breaker,} \\ 0.450 & \text{plunging breaker.} \end{cases}$$

Figure 4 shows the measured and computed parameter  $M$ . Examples of measured and computed concentration profiles under breaking waves are shown in Fig. 5.

It should be noted that Eq. 6 is valid if the turbulent due to the breaking waves can uplift the sediment throughout the water depth. Equation 5 should be used with care for coarse sand (i.e.,  $d > 0.55$  mm) and certainly it can not be used in gravel bed material. Also it can not be used to compute concentration at the bed ( $z = 0$ ).

Figure 4: Comparison between measured and computed parameter  $M$  (legend see Table 1).

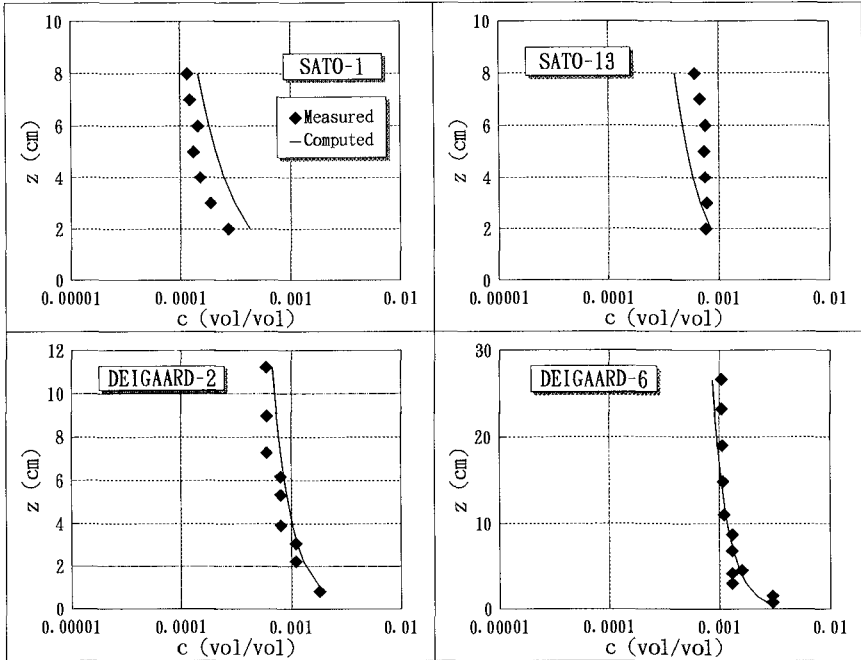

Figure 5: Predicted concentration profiles under breaking waves in comparison with the laboratory data of Deigaard et al. (1986), Sato et al. (1990).

### Verification with Prototype Scale Measurements

In order to confirm an empirical formula, wide ranges of experimental results are necessary in the calibration or verification. The objective of this section is to modify and examine the validity of the Shibayama and Winyu (1993) formulas by using the measured surf zone suspended concentration of a prototype scale wave flume which were performed by Kajima et al. of Central Research Institute of Electric Power Industry (CRIEPI) in 1983. The CRIEPI experiments were carry out under regular wave motion in a large wave flume (205 m long, 3.4 m wide, and 6 m deep). The CRIEPI experimental conditions that used in this section are shown in Table 2. The suspended concentrations were measured, by suction type concentration meter, at various sections along the flume. However, not many points were measured in the vertical direction of each section. Also lowest measuring level is not very near to the movable bed. This may because of the difficulty to measure the concentration very near to the bed accurately. The data may difficult to be used in formula calibration but can be used for formula verification.

The proposed formula assumed that  $\epsilon_{sb} \propto (D_B/\rho)^{1/3}$  and  $D_B$  is computed from the bore model which valid only inside the surf zone (full developed surface roller). Therefore if we use bore model to compute the rate of energy dissipation,  $D_B$ , near the recovery zone where the surface roller is not fully developed, the predicted  $\epsilon_{sb}$  is expected to be over-estimated and also it will yield the over-estimation of suspended concentration at the level above the reference level. To avoid this problem, energy dissipation may be computed from the measured wave height transformation, based on linear wave theory, as:

$$D_B = -\frac{\partial(Ec_g)}{\partial x} \quad (9)$$

where  $E = \rho g H^2/8$  is the wave energy;  $c_g$  is the group velocity; and  $x$  is the horizontal coordinate in wave direction.

Question may be asked that whether energy dissipation computed from bore model and from Eq. 9 are the same or not (in the case of no reformation zone). For verification, measured wave height transformation inside the surf zone (no reformation zone) of Hansen and Svendsen (1984), Okayasu et al. (1988), Sato et al. (1988 and 1989) are used. Figure 6 shows that energy dissipation computed from bore model and Eq. 9 give approximately the same results. Therefore the energy dissipation rate computed from the measured wave height, based on linear wave theory, will be used in the following analysis. However, due to the fluctuation of measured wave heights, the computed energy dissipation rates in some points are negative. So, in the present study, the fluctuated wave heights are smoothed before using for computing energy dissipation rates from linear wave theory.

For diffusion coefficient caused by breaking waves inside the transition zone, the eddy viscosity (or diffusion coefficient) at the breaking point cannot be

incorporated with the same manner as in the inner zone (Okayasu, 1989). From the analysis of undertow data of Nadaoka et al. (1982) and Okayasu (1988) (based on eddy viscosity model), the coefficient of turbulent eddy viscosity,  $K$ , increases linearly from 0.3 at the breaking point to 1 at the transition point. By assuming no vortex ripple occur in the surf zone, the final formula for computing sediment concentration profile can be expressed as:

$$c(z) = \frac{10}{3} \frac{(\psi - 0.05)\nu}{100d\sqrt{(s-1)gd}} \left( \frac{100d}{z} \right)^{w/[0.04u_* + 0.144K(D_B/\rho)^{1/3}]} \quad (10)$$

where  $K$  is the coefficient varies linearly from 0.3 at breaking point to 1 at transition point;  $D_B$  is the energy dissipation computed from measured wave height based on linear wave theory (Eq. 9).

The verification results for all of the measuring points, totally 149 sets, 645 points, are shown in Fig. 7. The examples of topography, wave height and concentration profile variations along the cross-shore direction are shown in Figs. 8-11. Fig. 7 shows that about 80 percent of predicted concentrations are within the factor 3, which can be considered to be well estimation in the field of sediment concentration profile. Since the accuracy of computed reference concentration is within the factor 2 (see reference concentration section), about 2/3 of error in Fig. 7 is expected to be caused by the formula that used for computing reference concentration. The left 1/3 is expected to cause by the formula for computing the distribution of concentration (parameter  $M$ ). Based on the above consideration, for excellent prediction of concentration profiles, the formula for computing reference concentration should be the main target of improvement for the next step.

Table 2: Experimental conditions and number of data sets for verification.

### Verification with Field Measurements

Although, the Shibayama and Winyu (1993) formula is developed from the data measured in laboratory, it may also be used to predict the sediment concentration in the natural beach. The objective of this section is to apply Shibayama and Winyu (1993) formula to predict surf zone sediment concentration in the natural beach. Nielsen (1984) measured sediment concentration and hydraulic properties on several beaches and locations in Australia. Total 26 concentration profiles are measured under breaking wave conditions. For each measuring location, 7 elevations suction type is used to measure sediment concentration and the sampling time is about 3 minutes. The selected working depth is about 1.5 m and the measurement started from about 1 cm above the bed. For more details of measured concentration, hydrodynamic and sediment data, please see Nielsen (1984).

By assuming all of the measured locations are within the inner surf zone and there is no vortex ripple, the formula for predicting sediment concentration profiles can be expressed as:

$$c(z) = \frac{10}{3} \frac{(\psi - 0.05)\nu}{(100d)\sqrt{(s-1)gd}} \left( \frac{100d}{z} \right)^{w/[0.04u_* + 0.144\{H^3g/(4Th)\}^{1/3}]} \quad (11)$$

where all variables are calculated based on linear wave theory.

To compute concentration profiles, under irregular wave, from Eq. 11, representative wave height and wave period should be specified. By trial and error of various representative wave height and wave period, root mean square wave height (assuming Rayleigh distribution) and average wave period gives a good prediction on concentration profiles. The comparison between measured and computed sediment concentration for all of the measuring points (26 data sets) is shown in Fig. 12. Examples of predicted concentration profiles are shown in Fig. 13. Fig. 12 shows that about 70 percent of predicted concentrations are within the factor 3, which can be considered reasonably well estimation for the field measurements. However, the number of experimental results may not enough to confirm the ability of the present formula. In the further study, more field experimental results are required to check the ability of present formula.

### Conclusion

Empirical formula of Shibayama and Winyu (1993) has been applied to compute surf zone concentration profiles in prototype scale wave flume experiments of Kajima et al. (1983) and in the field experiments of Nielsen (1984). The computed results show reasonable agreement with the experimental results.

## CHAPTER 204

### Mass Transport and Orbital Velocities with LAGRANGEian Frame of Reference

Stefan Woltering<sup>1</sup> and Karl-Friedrich Daemrich<sup>2</sup>

#### Abstract

Measurements of surface elevations and horizontal orbital velocities in regular waves and two component wave groups were performed to prove the experimental validity of periodic wave theories for regular waves, and empirical engineering methods for calculations in irregular waves. Besides the traditional wave theories a LAGRANGEian approach was introduced. With this LAGRANGEian method for waves of finite height, based on the geometry of orbital paths given by STOKES wave theories, it is possible to extend the region of validity of STOKES theories over a wider range of wave parameter. The use of a superposition method with LAGRANGEian approach and the application to two component wave groups, results in the appearance of non linear interaction components in surface elevations and horizontal orbital velocities, which are in fair agreement as well with a 2nd order approach for irregular wave surface elevation as with the measurements of surface elevation and horizontal orbital velocities.

#### Introduction

Orbital velocities and mass transport velocities are important e.g. for the prediction of forces on coastal structures and the verification of transport models in the near shore region. Traditional wave theories (e.g. STOKES, DSFT-Dean Stream Function Theory etc.) and empirical calculation methods (e.g. modified potential theories) are used for theoretical treatment of regular waves and as a basis for simulation methods for irregular waves (e.g. linear superposition). A point of controversy is the selection of calculation methods to give best results and how to interpret mass transport velocity measurements, especially in wave flumes. Measurements of orbital velocities and mass transport velocities in a wave flume are compared with DSFT and calculations based on STOKES wave theories in different ways of interpretation. A LAGRANGEian approach is introduced by the authors.

---

<sup>1,2</sup> both University Hannover, SFB 205, Franzius Institut, Nienburger Straße 4,  
30167 Hannover, Germany.

Experimental Set-up

The research program was carried out in the Large Wave Flume (Großer Wellenkanal - GWK, University Hannover / Technical University Braunschweig - Length 324m, width 5m, water depth up to 5m) and the Wave Flume "Schneiderberg" (WKS - Length 120m, width 2m, water depth up to 1,2m) of the Franzius-Institute / University Hannover. The investigations were concentrated on waves in intermediate water depth. The measurements were taken with electromagnetic type velocity probes located in fixed positions below the still water level, and also with a velocity probe fixed to a Movable Instrument Carriage (MIC). The MIC follows the water surface with the velocity probe in a constant position below the moving surface. The waves were generated with a piston type wave maker using modified higher order control signals to reduce free parasitic wave components.

The LAGRANGEian approach

For simplicity the introduced LAGRANGEian approach is explained using the linear description of orbital paths. Figure 1 shows a principal sketch for the LAGRANGEian approach surface elevation. Figure 2 gives a detailed information concerning wave kinematics calculation for a fixed probe position below the deepest wave trough. During the calculation process the centre of the orbital path of the respective water particle will be determined for every time step  $\Delta t$  by linear iteration, using the formulas for  $\eta$  and  $\zeta$  given by the respective order of the theory (Equations 1, 2 for linear wave theory).

$$\zeta(x_0, z_0, t) = -\frac{H}{2} \cdot \frac{\cosh 2\pi(z_0 + d) / L}{\sinh 2\pi d / L} \cdot \sin 2\pi \left( \frac{x_0}{L} - \frac{t}{T} \right) \quad (1)$$

$$\eta(x_0, z_0, t) = \frac{H}{2} \cdot \frac{\sinh 2\pi(z_0 + d) / L}{\sinh 2\pi d / L} \cdot \cos 2\pi \left( \frac{x_0}{L} - \frac{t}{T} \right) \quad (2)$$

where  $\zeta(x, t)$  = horizontal location of water particle;  
 $\eta(x, t)$  = vertical location of water particle;  $L$  = wave length;  
 $H$  = wave height;  $x_0, z_0$  = still water position;  $T$  = wave period

The surface elevation results from the particle motion of the most upper water particles. The LAGRANGEian surface elevation for first order particle motion and deep water conditions contains higher harmonic components, which are nearly in the same magnitude, as calculated with STOKES higher order theories. For more shallower water STOKES higher order descriptions of orbital paths are used for the LAGRANGEian method. The calculation procedure is the same as outlined before. As the surface elevation results directly from the water particle movement, the kinematic free surface boundary condition is satisfied.

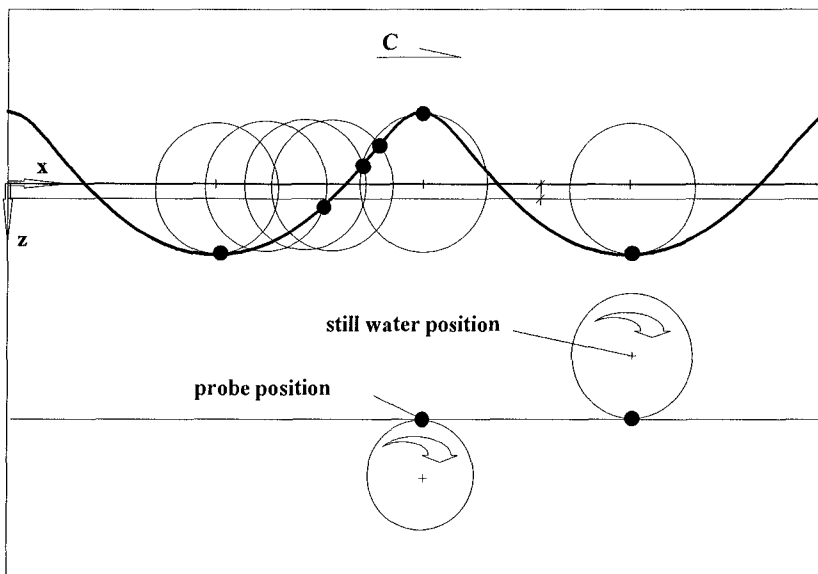

Figure 1. Principle sketch of LAGRANGEian surface elevation

Figure 2. Principle sketch of LAGRANGEian method for the calculation of orbital velocities

The orbital velocity is calculated for the actual position of a water particle along its orbital path at the location of the probe for each time step. The velocity below wave crest results from the smaller orbit below the velocity probe, the velocity below wave trough relates to the wider orbital path above the probe position, and in the same way for all time steps between crest and trough. Figure 3 shows the time series of horizontal orbital velocity for a theoretical calculated example of 1st order LAGRANGEian approach in comparison to linear wave theory. Figure 4 is the amplitude spectrum for the difference curve of the both methods.

Figure 3. Time series of horizontal orbital velocity  
( $T=1.13s$ ,  $H=0.35m$ ,  $d=1.00m$ ,  $z=-0.20m$ )

Figure 4. Fourier transformation of difference time series

The Fourier analysis of the theoretical time-series (e.g. motion on orbital paths according to linear theory) results in higher harmonic components and shows a slight decrease of the basic component. In addition a negative dc-value (mean velocity) for the horizontal orbital velocity appears. This negative mean velocity is not to be interpreted as a constant velocity in the opposite direction of wave travel. The LAGRANGEian time series has to be corrected to zero mean, which is in fact the superposition of the mass transport velocity. This again gives a clear argument, that linear wave theory already contains mass transport.

The LAGRANGEian approach can be transferred to irregular waves, by using the superposition method for the particle motion on orbital paths of the linear components of a spectrum, however, effects of mass transport and back flow have to be determined separately. Figure 5 shows an amplitude spectrum of a wave group for a theoretical calculated deep water example.

Figure 5. Amplitude spectrum of surface elevation  
 1st order LAGRANGEian approach - 2nd order MANSARD et al. (1986)  
 ( $f_1=1.01\text{Hz}$ ,  $f_2=1.09\text{Hz}$ ,  $H_1=H_2=0.1\text{m}$ ,  $d=1.00\text{m}$ )

The components of the wave group spectrum according to 2nd order are in the same magnitude for both methods, and for the 1st order LAGRANGEian approach in addition components higher than 2nd order are clearly visible. This non-linear interactions are automatically appearing using the described superposition method for the orbital motion of the two linear components of the surface elevation spectrum. The formulation of  $\eta$  and  $\zeta$  for the two linear components is simply added during the iteration procedure.

Figure 6 shows a comparison of super harmonics by the LAGRANGEian approach with the transfer function  $G^{+nm}h$  for the 2nd order frequencies of the linear components as given by MANSARD et al. (1986). In deep water a 1st order LAGRANGEian approach gives same results as 2nd order theory. For more shallow water a 2nd order description of particle motion is needed for the LAGRANGEian approach to achieve fair agreement with MANSARD's approach.

Figure 6. Comparison of 2nd order MANSARD et al. (1986) with LAGRANGEian approach for  $f_n+f_n$  and  $f_m+f_m$

Figure 7 shows the transfer function  $G^{+nm}h$  for the higher harmonic component at frequency  $f_m+f_n$ .

Figure 7. Comparison of 2nd order MANSARD et al. (1986) with LAGRANGEian approach for  $f_m+f_n$

The value of the transfer function depends on the relative spacing of the linear components in frequency domain  $f_n/f_m$ . For deep water the 1st order LAGRANGEian approach shows fair agreement with the 2nd order theory of MANSARD et al. (1986). In more shallower water the LAGRANGEian approach of higher order is not able to calculate the  $f_m+f_n$  higher harmonic amplitude in that order of magnitude, however, differences between LAGRANGEian approach and Mansard's approach are not to big for intermediate water depth. In addition it has not yet been defined clearly to what extend a 2nd order theory is suitable to shallower water conditions. As shown in Fig. 5 LAGRANGEian approach results are of higher than 2nd order.

#### Comparison with measurements

Figure 8 shows measured mean velocities and mass transport velocities for one example of regular waves plotted as depth distribution. For the fixed measurements a fair agreement with the EULERian backflow considered as constant over depth can be seen. The analysis is done in a time window without reflecting waves. The mean velocities from the movable probe can be interpreted neither as backflow nor as real mass transport velocity according to STOKES 2nd order theory. Only by a LAGRANGEian analysis of the data, a fair agreement of the data with real mass transport velocity, superposed by a backflow to a zero-net mass transport in the closed wave channel, can be achieved.

Figure 8. Measured and calculated mass transport velocity and backflow ( $T=3.20s$ ,  $H=1.20m$ ,  $d=4.00m$ )

The constant EULERian backflow is considered in all theoretical calculations. It is known, that the constant profile of the backflow is only an approximate value, which neglects any influence of viscosity in the boundary layer. The analysis of the data shows that variations of the backflow profile due to the influence of viscosity appear, however, outside the time window chosen for velocity analysis.

Figure 9 shows measured surface elevations in comparison to 5th order DSFT and 3rd order LAGRANGEian approach for a wave in intermediate water depth with  $d/L = 0.1$ . Small differences are appearing in the crest region, which can be related mainly to a not quite perfect wave generation. It can be assumed, that a certain amount of free wave is superposed on the stable wave, however, both theories show a good overall agreement with the measured time series.

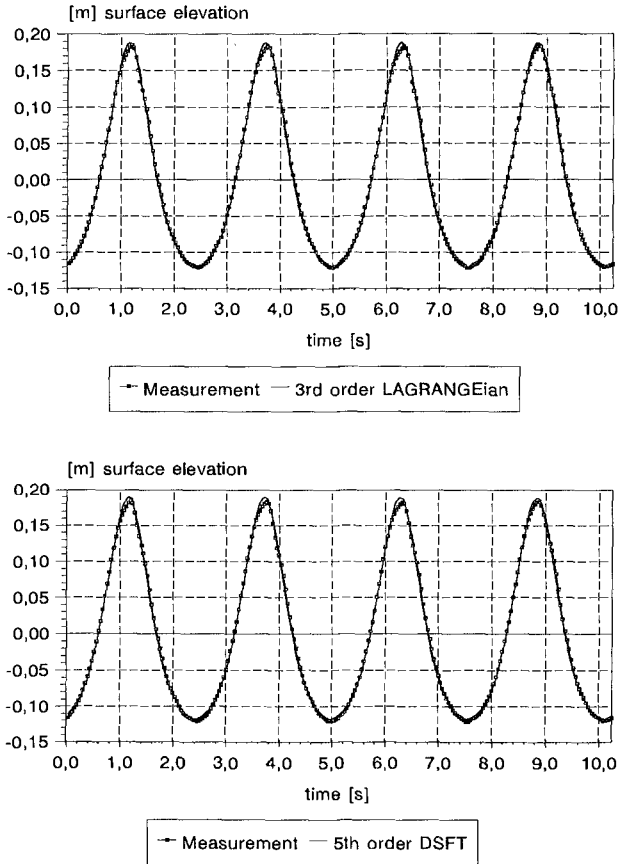

Figure 9. Comparison of measured and calculated surface elevation (T=2.56s, H=0.30m, d=1.00m)

Figure 10 shows comparison of measured and calculated horizontal orbital velocities below the wave crest for the above shown wave case.

Figure 10. Horizontal orbital velocities below the wave crest  
( $T=2.56s$ ,  $H=0.30m$ ,  $d=1.00m$ )

1st order LAGRANGEian approach and 1st order STOKES theory show a clear underestimation of the measured velocities near the wave crest. Velocities below the deepest wave trough are well predicted using 1st order LAGRANGEian approach. As outlined before, the surface elevation was in fair agreement with 3rd order LAGRANGEian approach and 5th order DSFT, and as the surface elevation is a result of the particle movement on their respective orbits, it is consequent to use this higher order theories also for velocity prediction. Comparison of the data with this approaches show good agreement. 2nd and 3rd order STOKES theory used in EULERian way tend to overpredict the near crest velocities slightly.

The same tendencies also hold for the horizontal orbital velocity below the wave trough, as can be seen in Figure 11. The 3rd order LAGRANGEian approach and the 5th order DSFT fit the measurements, 2nd and 3rd order STOKES theory calculate too high negative velocities, as well as 1st order LAGRANGEian approach and linear wave theory.

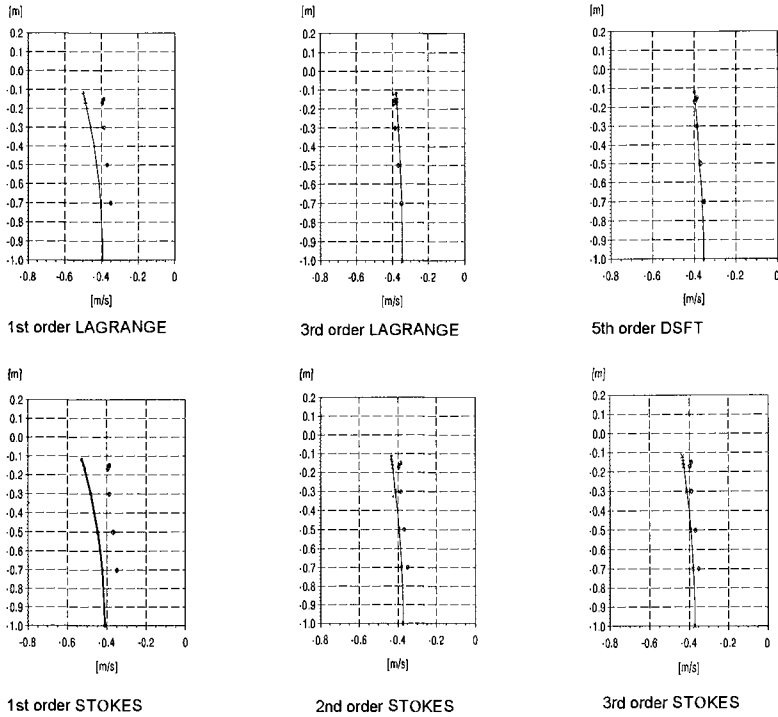

Figure 11. Horizontal orbital velocities below the wave trough (T=2,56s, H=0.30m, d=1.00m)

Results of measurements of horizontal orbital velocities in wave groups and comparison with various engineering methods and with LAGRANGEian approach are shown in Figures 12 to 15. Two wave groups with wave parameter listed in table 1 are considered for this paper.

	$f_m$ [Hz]	$f_n$ [Hz]	$H_m$ [m]	$H_n$ [m]	$d$ [m]
group 1	0,78	0,86	0,07	0,07	1,00
group 2	0,78	0,86	0,12	0,03	1,00

Table 1. Wave parameter of the wave groups

Figure 12 shows a comparison of measured horizontal orbital velocities with the theory as scatter plots for wave group 1. The measurement is done below the deepest wave trough at  $z=-0.10m$  with a fixed velocity probe. The Linear Transfer Function Method (LTFM) shows the known tendency of overprediction of the crest velocities.

WHEELER's stretching method gives slightly better results below the wave crest, but there is a small tendency of underprediction of the velocities below the wave troughs. The complementary method shows similar tendencies as the LTFM. The stretching after DEAN and LO (1986) under predicts the crest velocities as well as the velocities below the wave troughs. DONELAN's superposition method (1992) shows good results, and finally a 2nd order LAGRANGEian approach fits the measurement best.

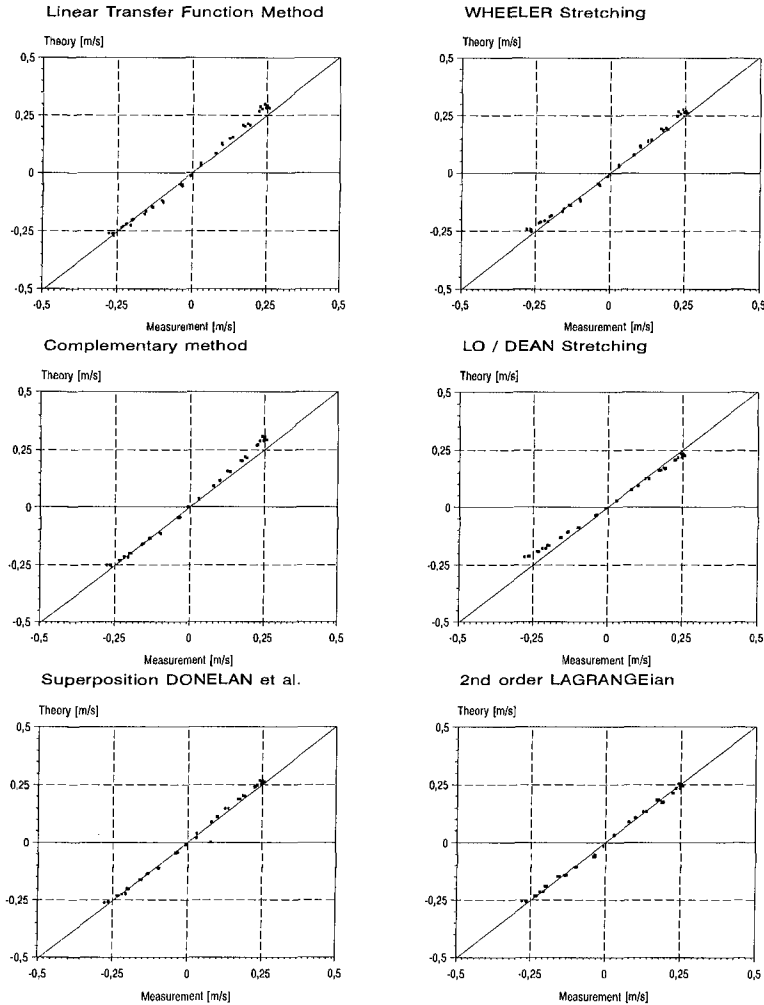

Figure 12. Comparison of measured and calculated horizontal orbital velocity at  $z=-0.10\text{m}$  for wave group 1

The tendencies outlined before also hold for wave group 2 in figure 13, however, there are stronger deviations in the results of LTFM and DONELAN's superposition method.

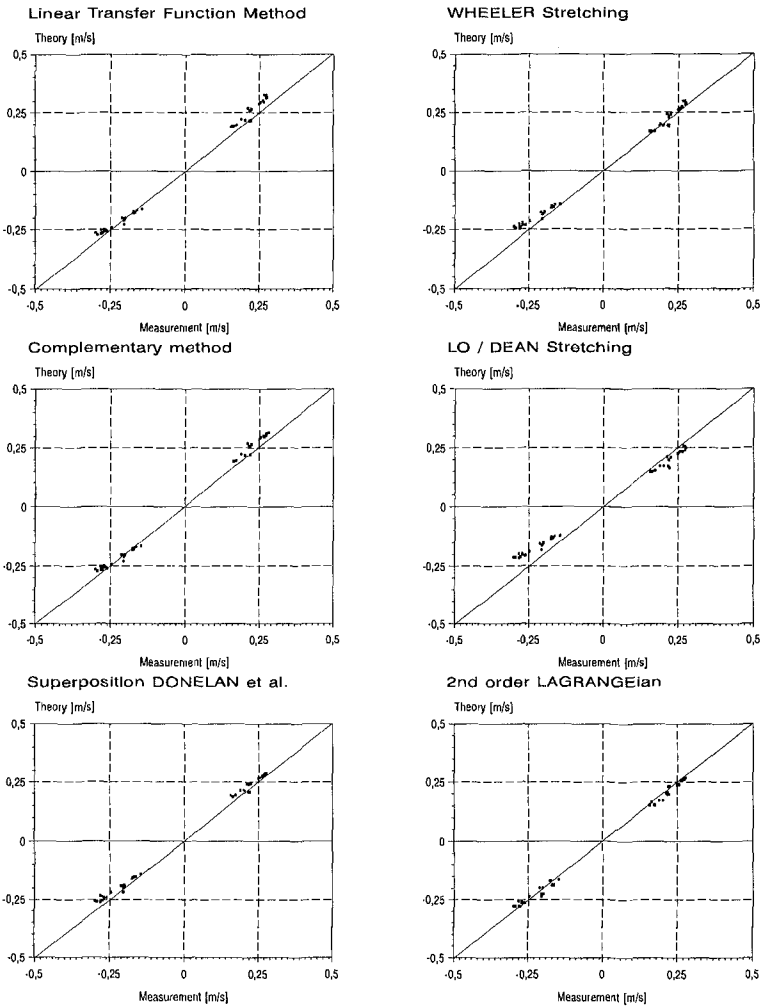

Figure 13. Comparison of measured and calculated horizontal orbital velocity at  $z=-0,10\text{m}$  for wave group 2

The reason for the mentioned tendencies becomes more clear looking to the comparison of the calculated and measured velocity components in frequency domain.

Figure 14 gives the measured and calculated values according to 2nd order theory for wave group 1. LTFM calculates too high basic components of the horizontal orbital velocity as well as too high 2nd order super harmonics. WHEELER's stretching counteracts this concerning the linear components, the higher harmonic components, however, are over predicted. DONELAN's superposition method calculates too high linear velocity components, the super harmonics are better predicted than by the two before mentioned methods. Finally, the 2nd order LAGRANGEian approach gives fairly good results concerning the linear components and also concerning the higher harmonic components of the horizontal velocity, which in this example are relatively small. For the velocity at frequency component  $f_n - f_m$  it can be stated, that, except DONELAN's superposition method, all methods calculate the velocity in the same magnitude and in disagreement with the measurement. This will not be discussed in detail, since this is state the of actual research work. It is assumed, that the misinterpretation of the bound long velocity component belongs to interaction of mass transport velocity and back-flow in the wave channel and the resulting free long wave. The analysis of the data shows, that the deviations between the theoretically calculated and measured long wave velocity is not the reason for the before mentioned tendencies.

Figure 14. Amplitude spectrum of measured and calculated horizontal orbital velocity according to 2nd order for wave group 1,  $z=-0.10\text{m}$

A main reason for the failure of the engineering methods in prediction of orbital velocities in irregular waves is the misinterpretation of the higher harmonic components. In figure 15 measured and calculated profiles of the horizontal orbital velocity below the highest wave crest and the deepest wave trough are plotted for both wave groups. The overprediction of the higher order velocity components using the higher order components of the surface elevation as linear input for the LTFM, increases rapidly above still water level. Complementary method and also DONELAN's superposition method counteracts this tendency, but clear deviations are visible. Only LAGRANGEian approach, which uses the basic components of the surface elevation as input, fits the measurement near the surface. The opposite tendency of underpre-

diction of the trough velocities is for all methods the same. LAGRANGEian approach is in fair agreement with the measured values.

Figure 15. Measured and calculated horizontal orbital velocities below the highest wave crest and below the deepest wave trough (A : wave group 1 | B : wave group 2)

Conclusions

Measurements of surface elevations and horizontal orbital velocities in regular waves and in two component wave groups are compared with various calculation methods. A LAGRANGEian approach, which bases on the geometry of orbital paths given by STOKES 1st, 2nd and 3rd order theory was introduced by the authors.

Following conclusions can be achieved after presentation and discussion of the results:

- The periodic wave theories of the respective order show good agreement with measured regular wave kinematics as well as with regular wave surface elevations.
- The introduced LAGRANGEian approach gives good results concerning surface elevations and orbital velocities and needs a lower order for calculation than other periodic wave theories.
- Using LAGRANGEian approach on the basis of STOKES wave theories, the application range of the STOKES theory can be extended over a wider range of wave parameter.
- Stretching techniques and engineering methods on the basis of linear wave theory seem to be not the right physical tool for the calculation of wave kinematics in irregular waves. The main reason for the failure of these methods is the linear treatment of the super harmonics of the surface elevation.
- Using a superposition method with the LAGRANGEian approach, nonlinearities are automatically appearing. Especially in deep water a 1st order LAGRANGEian approach allows to calculate higher order irregular wave kinematics as well as higher order irregular surface elevations in a mathematical and physical conclusive way.

#### Acknowledgement

The investigation described in this paper was carried out as part of the research programme of the Sonderforschungsbereich 205 (SFB 205) at the FRANZIUS-Institute for Hydraulic Research and Coastal Engineering, University of Hannover. The authors gratefully acknowledge the Deutsche Forschungsgemeinschaft (DFG) for their financial support throughout the investigations.

## CHAPTER 205

### CROSS-SHORE PROFILE MODELLING UNDER RANDOM WAVES

Yongjun WU<sup>1</sup>, Hans-H. DETTE<sup>2</sup> and Hsiang WANG<sup>3</sup>

#### Abstract

This paper presents part of the test results conducted in the Large Wave Flume (LWF) for 2D beach profile response under random wave input as well the numerical modelling effort to simulate the laboratory data. The tests were conducted with various input wave spectra, initial profiles and for both erosional and accretional cases. The numerical model is a 2DV(two dimensional vertical) beach profile model. It couples a sediment transport model with a random wave model. The sediment model is a modified version of the SBEACH model developed by Larson and Kraus (1989) for regular waves. The input wave condition is a time-series of irregular waves simulated from a given wave height probability density function, here selected as the Rayleigh distribution. The final profile is then computed from the cumulative changes due to each randomly occurring individual wave.

#### Introduction

In the last few decades, many studies have been carried out for modelling beach profile evolution under storm wave conditions. Most of these efforts, whether physical or numerical, have been for regular waves and for beaches under the state of erosion. It is only natural to extend the effort for cases of random waves. Therefore, since 1987, a systematic series of experiments were carried out in the Large Wave Flume (LWF) located in Hannover, Germany to study the beach response under random wave inputs. The tests were conducted for various types of input wave spectra, with different initial slopes and for both accretional and erosional conditions. In a parallel effort, attempts were made to simulate the laboratory results with numerical model. The numerical model is largely built upon existing modeling techniques.

Two different approaches have evolved in the past decades for beach evolution modelling. One approach is to establish the mechanics of sediment mobilization and transport first on micro-scale; transport models are then constructed at integrated temporal and spatial scales. This approach is referred to as mechanics approach or fine-scale approach. This type of model could yield better temporal and spatial resolution but may not be practical for long term or large spatial scale simulation. The other approach avoids the details of the mechanics of sediment transport and simply attempts to relate sediment transport to flow properties on a macro scale. The commonly inferred flow properties are temporal and spatially averaged wave energy, wave energy flux or rate of wave energy dissipation. Sediment transport models of this kind ignore the details and bypass the basic sediment mechanics; they are, more or less, heuristic and mainly based upon physical reasoning and/or empirical evidence. This approach is referred to as heuristic approach or macro-scale approach. Since models of the latter type deal with integrated flow properties they are usually more suitable for long term simulation. At present, most of the workable models are of the latter type. And, as mentioned they are mostly restricted to 2D, regular wave input and erosional case. In principle, extending these models for irregular wave application presents no fundamental difficulty, although different approaches can be taken. Indeed, various efforts have been made towards this extension. One of the major handicaps has been the lack of adequate data for calibration and verification.

One of the objectives of the present study is to develop and test a 2DV numerical model that simulates the changes of cross-shore profile under random wave action. The model like most of its kind is composed of a sediment transport model driven by a hydrodynamic model. The beach profile change is then computed by use of conservation of sediment mass. The model is intended for engineering application. The aim is to keep the basic characteristics of the model simple, but still reliable and realistic. Generality and mathematical rigor are, at times, compromised.

### **Laboratory Measurements and Results**

The experiments were carried out in the LWF located in the University of Hannover, which is 320 m long, 5 m wide and 7 m deep and is capable of generating waves up to 2 m high. Beach profile response tests under random waves inputs were carried out in four test series in 1986/87, 90, 91 and 93, respectively. The 1986/87 test was concentrated on dune erosion under regular and irregular waves. The same initial profile were exposed to both regular waves and irregular waves with height of 1.5 m and period of 6 sec. In 1990 and 1991, the main concern of the experiments was to measure the energy dissipation and the sediment transport with an initial equilibrium profile. In 1993, experiments were carried out to study both erosional profile evolution under short waves and accretionary profile evolution under long waves. The effect of water level variations due to tide effect was also examined. The test conditions are given in Table 1.

Table 1 GWK TEST SCHEDULE

Spectrum type	Initial Profile	$H_s$ (m)	$T_p$ (sec)	Water Depth,	Duration (hr)	Response Type
JONSWAP (1987)	$m=1:20$ , $D_{50}=0.33$ (mm)	1.5	6	5 m	9.8	Erosion
PM(1990)	$h=Ax^{2/3}$ , $A=0.08$ $D_{50}=0.22$	0.8	6 - 8	2 m	9.0	Equilibrium
TMA (1991)	$h=Ax^{2/3}$ ; $A=0.08$ $D_{50}=0.33$	0.9-1.04	6 - 8	2.5 m	9.6	Equilibrium
TMA (1993)	Uniform slope $m=1:30$ $D_{50}=0.22$	1.2	5-10	4.5 m	23.5 (no tide) 84.0 (with tide)	Erosion and Accretion

Detailed results can be found in Wu (1994). Only a selected sets of results from 1993 tests were given here. The 1993 test was a long sequential experiment of 3 phases. Phase I was regular waves of erosional(short wave period)-accretional(long wave period)-erosional(short wave period) sequence. It was followed by Phase II test of irregular wave input with short period waves followed by long period wavesl. Phase III has the longest test period with irregular wave input coupled with water level variations, consisting of 45 hrs of short period wave test followed by 39 hrs of long period wave. The test conditions are summarized in Table 2.

Table 2 Summary of Test Conditions, 1993

## PHASE I. REGULAR WAVE

H=1.2 M; T=5 SEC	H=1.2 M; T=10 SEC	H=1.2 M; T=5 SEC
17 HRS	15.75 HRS	7.33 HRS

## PHASE II. IRREGULAR WAVE, NO TIDE

$H_s=1.2$ M; $T_p=5$ SEC	$H_s=1.2$ M; $T_p=10$ SEC
13 HRS	10.5 HRS

PHASE III. IRREGUAR WAVE, WITH TIDE	
$H_s=1.1 \text{ M}; T_p=5 \text{ SEC}$	$T_s=1.1 \text{ M}; T_p=10 \text{ SEC}$
45 HRS	39 HRS

Figure 1 shows the end profiles of Phase I tests. In the first 17 hrs. of phase I-1, the 5 sec waves built a bar 0.75 m high. Then under 15.75 hrs. action of 10 sec waves in phase I-2, the bar moved about 3 m in onshore direction. In the next 17 hrs. of short waves, an the bar moved offshore again and a smaller inner bar was developed. The change in the dune region took place mainly in the 2 short-wave phases.

Figure 1. Profile Evolutions in Phase I test, 1993

Figure 2 shows the end profiles of Phase II tests. It is quite apparent that the initial bar-trough profile was smoothed into a foreshore tarrace during the short period wave test. In the subsequent long-period wave test, onshore sediment motion was observed. Different from the regular wave case, the bar was much lower and broader. The bed changes in the inner surf zone were also more rigious and rapid. The results of Phase III test are given in Fig. 3. In this Phase, water surface variations due to tide (12-hr period) were also simulated in addition to the irregular wave input.

During the short-period wave test, the variation of water depth appeared to aid in offshore sediment movement causing the bar to move further offshore. In the subsequent long-period wave test, the development of the profile was very gradual as the bar was flattened and moved inshore.

Figure 2. Profile Evolutions in Phase II test

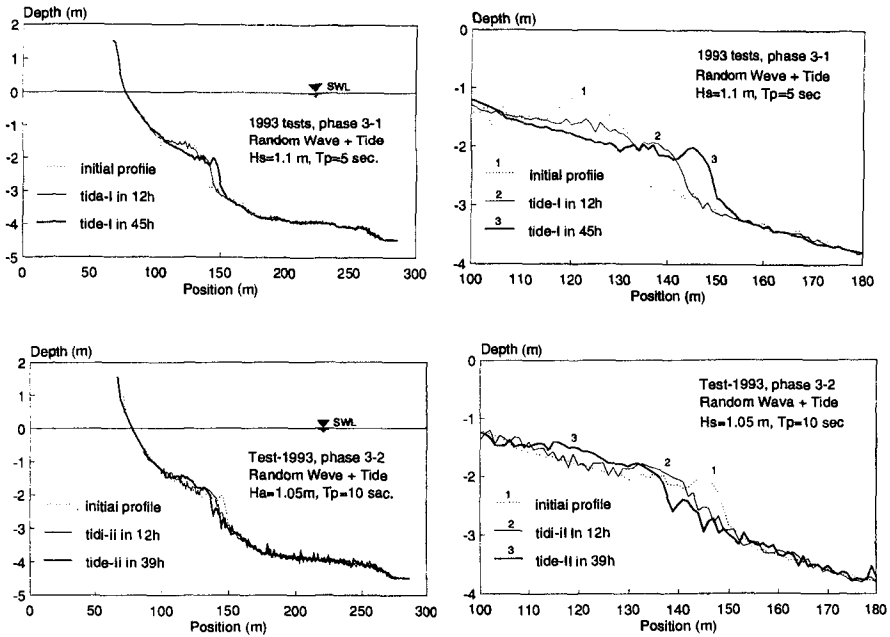

Figure 3. Profile Evolutions in Phase III test

## Numerical Modelling With Random Waves

The profile response model consists of two major parts: the wave input model and the sediment transport model. Conceptually, the randomness should be entered in both parts. At present the randomness can be incorporated in the input wave only.

### (1) Random Wave Model

There appear to be three basic approaches for treatment of random wave transformation in shoaling water and through the surf zone: They are: (1). Using a deepwater random wave time series as input and transforming each individual wave in the series as if it were a regular wave component with a distinct wave amplitude and period. (2). Carrying out a spectral transformation first from deepwater into shallow water. A time series is then created from the shallow water spectrum for further shoaling and surf zone transformation of each individual wave. The first step is equivalent to transformation of Fourier components under the constraint of energy conservation. Numerous numerical models can be used to accomplish this transformation. (3). Conducting a "parametric" type transformation of deepwater random wave directly into surf zone. The surf zone wave properties are then expressed as significant wave parameters and, sometimes, with associated distribution functions. Each approach presented above can be considered for random wave input information. Approach (1) and (2) are conceptually the same except that another layer of model is required in (2) to carry out shallow water wave transformation. The third approach yields local wave information inside the surf zone but it is difficult to reconstruct a continuous spatial variations of each wave which is required in some of the sediment transport models.

The wave model used here was based on approach (1) for its directness. The essential assumptions are: shoaling and breaking are not affected by wave-wave interaction, reflection is weak and the waves are unidirectional. The method is called as the "time dependent discrete pdf method". As an initial attempt the input wave is assumed to be uni-directional and narrow-banded in wave period with the deepwater wave heights following Rayleigh distribution.

First, a random wave height series is generated by the Monte-Carlo method. If  $\rho$  is a uniformly distributed random number with a value between zero and one, the Rayleigh distributed wave height corresponding to this level of probability is given ;

$$H_p = H_{rms} \sqrt{\ln(1/\rho)} \quad (1)$$

in which  $H_p$  is the wave height that is exceeded by  $\rho N$  waves,  $\ln$  is natural logarithm and  $H_{rms}$  is root-mean-square wave height. The  $H_{rms}$  value is the only required input.

Each wave height from this random series is treated as a regular wave in one profile simulation time-step and is transformed through the computational space by the wave

decay models of Dally et al. (1984). The number of waves used in one simulation run is determined by comparing the simulated wave height distribution with the target Rayleigh distribution. Since Rayleigh distribution has no upper bound, the function must be truncated in high wave end (for example, cutoff at  $H/H_{rms}=2.5$  or 2.0) to avoid unrealistically high waves. To save computational time, the distribution is also truncated at the low wave end to cutoff small waves that make no contribution to sediment transport. Figure 4 shows an example of the simulated time series and the comparison of the wave height histogram from 500 waves with the target Rayleigh distribution. Numerical experiments showed that approximately 100 waves are needed to produce a reasonable Rayleigh distribution and 500 waves will produce a very good one.

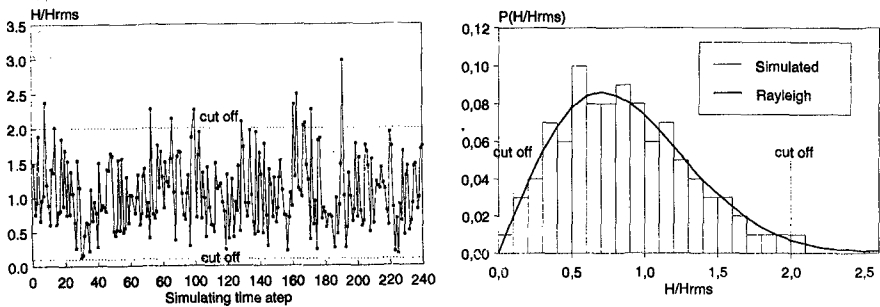

Figure 4 Example of Simulated Random Waves from Rayleigh Distribution

## (2) Sediment Model

The selected sediment transport model is one of the macro-scale type which is based on the energy dissipation concept as used by Moore (1982), Kriebel and Dean (1985) and Larson and Kraus (1989). The reason for selecting this type is that the numerical results from the SBEACH model (Larson & Kraus, 1989) appear to yield the best overall agreement with our own laboratory experiments for regular waves. Their model is modified for random wave inputs.

The SBEACH model is expressly developed to incorporate the offshore bar formation and movement produced by storm waves and water levels. Bar formation and movement produced by breaking waves are satisfactorily simulated. In essence, the model is an extension of Kriebel and Dean's approach. The sediment transport model is patterned after Kriebel and Dean but empirically adjusted from large wave tank test results to insure bar formation and movement. The sediment transport is partially restricted to the equilibrium beach profile in the inshore zone of profile evolution. The sediment transport formulae proposed in this model is one of the possibilities of extending Dean's equilibrium beach profile concept to bar-berm profiles. The basic formation is delineated in the following schematicst:

**Schematics of Sediment Transport Model**

This scheme is almost the same as the SBEACH with the exceptions that most of the coefficients have been adjusted. Also, the definition of the swash zone in the original model is defined in terms of controlling depth whereas in the present model it is defined in terms of percentage of the total surf width to produce more realistic nearshore profile. For detail see Wu (1994).

**Model Sensitivity and Stability**

Systematic sensitivity analysis to assess the influence of model parameters and empirical coefficients has been performed, with both regular wave and random wave. This allows us to examine the physical implications of the model parameters and their effects. It is also serves to explore the applicability of the model beyond the range for which it was calibrated.

Related to time scale of simulation, with increase of total simulating time in both regular and random wave cases, the change of profile will reach quasi equilibrium form. Regular waves are not sensitive to the size of time step,  $dt$ , which regulate the number of iterations. But for random waves, the time step (used  $dt: 5T_p - 80T_p$ ,  $T_p$ : peak period) must be small enough to include a sufficient number of sample waves (at least 100 waves) to represent the Rayleigh distribution. Model sensitivity to wave height  $H_o$  or  $H_b$ , wave period  $T$  or  $T_p$ , change of water level, and breaker index were analyzed. The profile evolution is significantly affected by the change of wave height, **Fig. 5**, but it is not sensitive to the wave period. Under given wave condition, beach erosion always increases with increasing water level as the surf zone moves inshore with increasing water level, **Fig. 6**. The influence of sediment transport model

(a) Regular Waves

(b) Irregular Waves

Fig. 5. Effects of Wave Height on Profile response

parameters, i.e. the sediment diameter  $D_{50}$ , fall velocity  $w$  and coefficient of equilibrium beach profile  $A$  were evaluated. As expected, a finer sand will produce flatter beach slope and coarse sand a steep profile. The influence of the coefficient of sediment transport rate  $K$  only affects the rate of transport but has very little effect on the final profile.

Figure 6. Effect of Water Level Changes on Profile Response

**Comparison Between Numerical and Experimental Results**

The model simulations are compared with limited cases of experimental results from the Large Wave Flume. Fig. 7 shows the comparison between the numerical simulation and the experiments of 1987. As can be seen, the step-type profile is fairly well represented so is the transport rate. In the 1990 and 91 experiments, the initial profile was shaped in accordance to an equilibrium form (Dean, 1977) with  $A=0.07$ . Both numerical and experiment results showed only small changes. The results

indicate that the method is capable of simulating equilibrium profile shapes under random wave conditions.

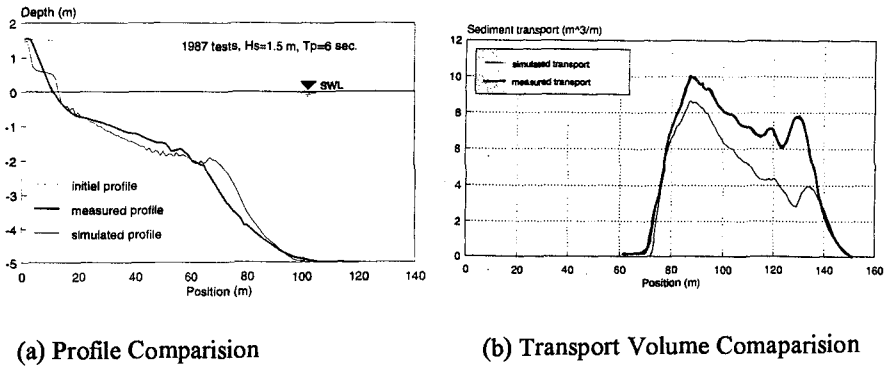

Figure 7. Model Simulations, 1987 Random Wave Test

**Figure 8** shows the comparison of numerical simulation with the experimental result of tests in 1993. The model simulation for phase I test is shown in **Fig. 8a**. The test consisted of a combined erosional cycle with an accretional cycle with regular wave input. It is evident that the numerical model was not successful for the accretional cycle. In the phase II test of irregular waves, the numerical model was reasonably successful for the erosional cycle as shown in **Fig. 8b**. The surf zone became broader, the bar decreased and its position moved in onshore direction. Near the shore line, the dune erosion is somewhat over estimated by the model. Again, the simulation was unsuccessful in the accretional cycle (not shown). In test phase III-1, random waves of 5 sec period were run with change of water level. The model simulation was successful for this erosional cycle. The measured final profile was well represented by the simulated one and it approached to an equilibrium form, **Fig 8c**. In the phase III-2, longer waves were run, which produced onshore sediment movement. The model, again, failed to simulate this case partly because the onshore-offshore criterion used in the model by Larson and Kraus (1989) suggests offshore transport for  $H_{1/3} = 1.1$  m and  $T_p = 10$  sec whereas in the experiment the sediment was clearly onshore. The criteria from Dean (1973), Hattori and Kawamata (1980) also indicate offshore sediment transport; only the criterion from Sunamura and Horikawa (1975) indicate onshore sediment transport. For the specific case simulated, one actually found that the absolute magnitude of transport volume measured in the laboratory was about the same order as that predicted by the numerical model, **Fig. 8d**.

### Conclusions

A systematic series of experiments have been carried out in the LWF to study the beach profile response under random wave conditions. A 2DV numerical model was also developed based on the SBEACH model. The study was aimed at documenting the laboratory observation as well as evaluating numerical modelling capabilities. It was found that:

Under erosional condition, berm profiles were generated under random wave instead of the bar profile under regular waves.

Beach recovery was difficult without water level changes and random wave input.

Beach profiles appeared to be able to reach quasi-equilibrium under both erosional and accretional cases and for both regular and irregular waves of constant conditions. At times, the profile appeared to have reached an equilibrium only to become active again due to unknown causes; it will then reach an equilibrium the second time which was usually more stable.

The numerical model adequately predicted the proper shapes of the profile for both regular and irregular waves under erosional condition in both profile shape and rate of erosion. The model as presented in the present study responds well to changes in water level and is numerically stable. The original SBEACH model, at occasions, becomes unstable. The numerical model as presented was not capable of reproducing the profile under accretional condition.

The current erosional and accretional criteria as proposed by various authors should be re-examined.

Further development of the profile model is required, possibly by (1) extending the model for simulation of beach accretion or combined beach erosion-accretion; (2) extending the present "discrete pdf" to a joint wave height and period distribution to accommodate the broad banded random sea; (3) taking the nonlinear wave transformation into account.

## CHAPTER 206

# MULTIPLE BAR FORMATION BY BREAKER-INDUCED VORTICES: A LABORATORY APPROACH

Da Ping Zhang<sup>1\*</sup> and Tsuguo Sunamura<sup>1</sup>

**ABSTRACT:** Using a two-dimensional wave flume and a two-video-camera system, mechanism and process of multiple bar formation were investigated in the light of breaker-induced vortices. A fixed-bed experiment revealed that (1) the vortex formed at the wave break point can be classified into three: oblique, A-type horizontal, and B-type horizontal vortices; (2) the vortex formed in the surf zone is always oblique; and (3) the location of a vortex reaching bottom can be described by wave properties and the bottom slope, and its water depth can be expressed by breaker height alone. A movable-bed experiment indicated that bars are initiated by the vortices reaching bottom in the surf zone; the number of bars formed coincides with the number of such vortices. Suspension of the bottom sediment due to vortex action and the mean-drift-velocity pattern can play an important role in multiple bar formation; mechanism for break-point bar formation is "convergence", while that for inner bar formation is "congestion". Two major modes for the development of multiple bars were found: simultaneous and successive: these depend on the interaction of vortex action and topography in the surf zone. Multiple-bar features such as trough spacing and crest depth could be explained from vortex features found through the fixed-bed experiment.

## INTRODUCTION

Major hypotheses regarding multiple bar formation are: the wave breaking hypothesis (e.g., O'Brien, 1968; Dhyr-Nielsen and Sorensen, 1970; Exon, 1975; Dolan and Dean, 1985; Sunamura and Takeda, 1993), and standing wave hypothesis (e.g., Suhayda, 1974; Short, 1975; Bowen, 1980; Katoh, 1984; Aagaard, 1991). In both hypotheses, no clear explanation on multiple bar formation has been provided

**Fig. 1 Three vortex types**

based on sediment dynamics.

With the recent progress of measuring techniques of flow velocity, studies from a micro-scopic point of view have been conducted with the purpose of elucidating the nearshore hydrodynamics. Nadaoka et al. (1987, 1988) found the presence of "oblique vortex" in the surf zone under spilling breaker conditions, and reconfirmed that this oblique vortex induced sediment suspension in the surf zone. Although they have not noted the interaction of the oblique vortex and bar formation, it is suggested that such sediment suspension could influence the net sediment movement in the surf zone resulting possible bar formation.

This study, conducted in the laboratory from the standpoint of the breaking-wave hypothesis, attempts to investigate the possibility of vortices induced by breaking waves to form multiple bars.

**FIXED-BED EXPERIMENT ON BREAKER-INDUCED VORTICES REACHING BOTTOM**

In order to examine the characteristics of vortices produced by breaking waves, an experiment was conducted setting up a 1/10 or 1/20 uniform steel bottom in a wave flume (12 m long, 0.2 m wide, and 0.4 m deep) equipped with a regular-wave generator. The period of waves ranged from 0.6 to 2.4 sec and the height of

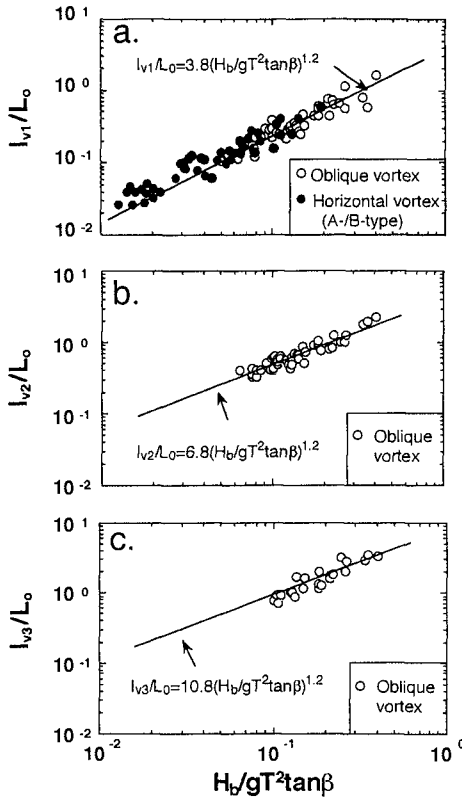

**Fig. 2 Development of triple vortices reaching bottom**  
 $(H_b=11\text{cm}, T=1.2\text{s}, \tan \beta =1/20)$

breaking waves from 5.0 to 14 cm. To examine the characteristics of vortices developed in the whole surf zone, two video cameras were set up beside the flume. One was placed normal to the side of a glass window of the flume, and the other was installed with an angle of 30 degrees at the offshore side of the wave break point. The three-dimensional characteristics of vortices were examined on reproduced video pictures using both breaker-induced air bubbles and neutrally buoyant particles (1.2mm in diameter) as tracers.

Vortices formed just after wave breaking are classified into three types according to the direction of vortex axis: oblique vortex and two types of horizontal vortex, i.e., A-type and B-type horizontal vortices (Zhang and Sunamura, 1990). The oblique vortex is like a tornado that has an obliquely stretched axis of rotation (Fig. 1a). The B-type horizontal vortex looks a cultivator that has a horizontal axis of rotation (Fig. 1c). The A-type horizontal vortex is a hybrid between horizontal and

**Fig. 3** Definition sketch of location of vortices reaching bottom

**Fig. 4** Relationship between  $H_b/gT^2 \tan \beta$  and  $l_{vn}/L_0$

oblique vortices (Fig. 1b). Namely, the horizontal vortex forms first in the upper part of water column and then it changes to the oblique vortex. Considering that a vortex which is stretched to reach bottom play a very important role in sediment motion and resulting topographic change, we focused on this kind of vortices.

The experiment showed that the vortices reaching bottom are not only formed at the wave break point, but also in the whole surf zone depending on experimental conditions. Figure 2 is an example of a sequence of video-pictures that show developmental processes of the triple vortices reaching bottom. The time between one stage to the next is 0.3 sec. The first oblique vortex develops at Stage 2 just after wave breaking (spilling breaker) and it touches the bottom as indicated by the arrow at Stage 3. As the bore propagates, the second oblique vortex develops inshore and reaches bottom at Stage 4, and finally the third oblique vortex reaching bottom forms further inshore at Stage 6 as indicated by the arrow. The vortex strength tends to decrease with increasing distance from the wave break point.

Results obtained through the present experiment indicate that the first vortex, i.e., the vortex formed just after wave breaking, is an oblique vortex or an A-type or a B-type horizontal vortex depending on experimental conditions, but the vortex or vortices in the surf zone are always oblique. It was also observed in this experiment that the vortices not reaching bottom appeared when the breaker height was extremely small.

The location and water depth when the first vortex touches the bottom were almost constant with time, whereas those of vortices reaching bottom in the surf zone slightly fluctuated with waves. Average location and depth were measured by reproducing video-pictures for six consecutive waves.

The average horizontal distance from the break point to the location of the vortex reaching bottom, counting from the first vortex ( $n=1$ ), is denoted as  $l_{vn}$  (Fig. 3). Data were analyzed using three dimensionless quantities,  $l_{vn}/L_o$ ,  $H_b/gT^2$ , and  $\tan \beta$ , where  $L_o$  is the deep-water wavelength,  $H_b$  is the breaker height,  $T$  is the wave period, and  $\tan \beta$  is the bottom slope. These three quantities are the same that Sunamura (1985) used to analyze the data of the location of the deepest penetration of breaker-produced bubbles in the surf zone.

Figure 4 shows the result of analysis. From the equation written beside the straight line in each graph, it is anticipated that the location of the  $n$ -th vortex can be described by

$$l_{vn}/L_o = A(H_b/gT^2 \tan \beta)^{1.2} \quad (1)$$

where  $A$  is a dimensionless coefficient that varies with the value of  $n$  as shown in Fig. 4. To obtain the relationship between  $A$  and  $n$ ,  $A$  is plotted against  $n$  in Fig. 5; the line in this figure can be expressed by

$$A = 3.98 n^{0.86} \quad (2)$$

One obtains the following relation:

$$l_{vn}/L_o = 3.98 n^{0.86} (H_b/gT^2 \tan \beta)^{1.2} \quad (3)$$

Fig. 5 Relationship between  $A$  and  $n$

Fig. 7 Relationship between  $B$  and  $n$

Fig. 6 Relationship between breaker height and water depth for vortex reaching bottom

Fig. 8 1/10 uniform and six non-uniform beach profiles used as the initial boundary condition for movable-bed experiment

This equation allows us to predict the position of multiple vortices which can touch the bottom.

Denoting the water depth of the  $n$ -th vortex reaching bottom as  $h_{vn}$  (Fig. 3), Fig. 6 shows the relationship between breaker height and water depth of 1st, 2nd, and 3rd vortices. It is easily anticipated from the equations in this figure that the case of the  $n$ -th vortex can be described by

$$h_{vn} = B H_b \quad (4)$$

The values of  $B$  are plotted against  $n$  in Fig. 7, and the line in this figure is given by

$$B = 0.69 n^{-1.44} \quad (5)$$

The following relation can be written:

$$h_{vn} = 0.69 n^{-1.44} H_b \quad (6)$$

Prediction of the water depth of multiple vortices reaching bottom is possible by the use of this equation.

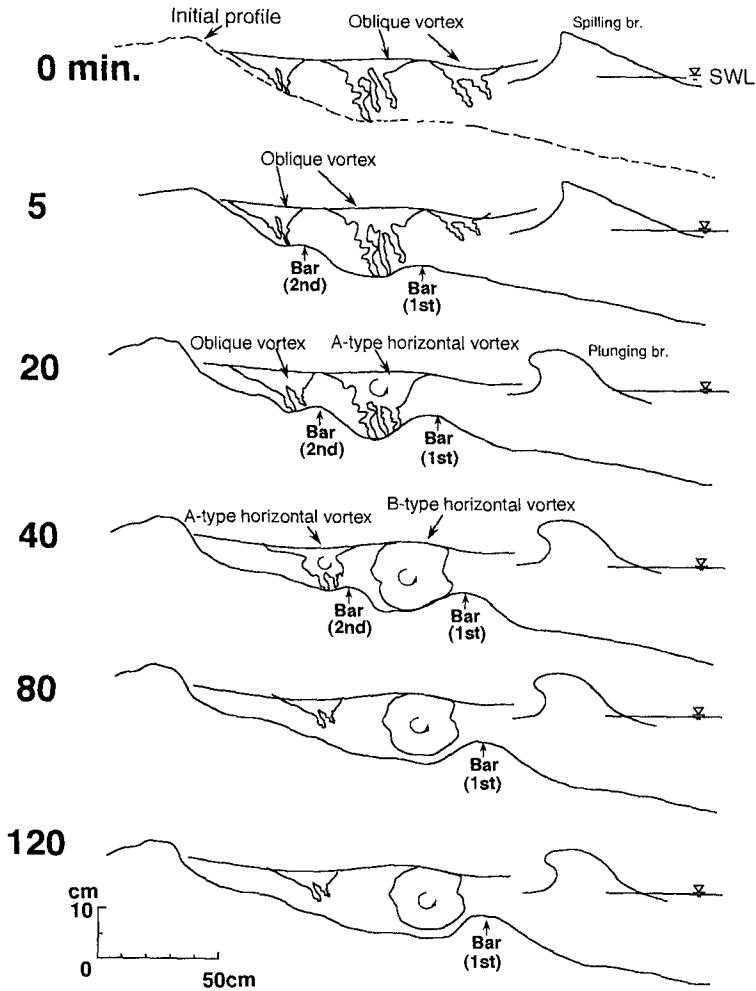

### MOVABLE-BED EXPERIMENT ON BAR FORMATION DUE TO BREAKER-INDUCED VORTICES REACHING BOTTOM

An experiment was conducted using 1/10 uniform beach profile and six kinds of non-uniform profiles as the initial boundary condition set up in the same wave flume as used before. Figure 8 is a schematic illustration of the seven initial beach profiles, of which "1/10" and "shallow shelf" were artificial and the remaining five were formed by waves (Zhang, 1994). To examine the vortex characteristics and vortex-topography interaction, the two-video camera system was again used. Changing the combination of these initial beach slopes, the grain size of beach material (0.22, 0.69, 1.3, and 2.4 mm), wave period (0.7, 0.8, 0.9, and 1.0 sec), and breaker height (5.0~10cm), 61 experiment runs were conducted. As the breaker height, the value measured at the initial stage where no significant topographic change occurred was adopted in this study. Waves continued to act until no significant development of the break-point bar occurred. This stage is defined as the equilibrium; the time required for it ranged from thirty minutes to two hours depending on experiment runs. The beach topography was measured at the center of the flume by an automatic profiler every five minutes as a general rule.

The result showed that multiple bars were formed depending on the experiment conditions. It was found that (1) the bar formation is closely associated with the action of vortices reaching bottom, (2) the number of bars formed coincides with that of such vortices, and (3) the shape of initial morphology greatly affects the mode of multiple bar formation. Two major modes will be illustrated below.

#### Simultaneous and Successive Modes for Multiple Bar Formation

Figure 9 shows an example of simultaneous mode of double bars. The initial morphology was a berm profile. During the first 5-minute wave action, two bars started to form at the same time by two oblique vortices reaching bottom,

**Fig. 9 An example of simultaneous development of double bars**

respectively. The breaker-point bar, located offshore, grew to a large bar; then the breaker type changed from spilling to plunging, which resulted in the change of vortex type from the oblique vortex to the A-type and finally to the B-type horizontal after 40-minute wave action. At the same time, the vortex type near the inner bar changed from the oblique to the A-type horizontal vortex. After 80 minutes, the breaker-point bar attained the equilibrium with the B-type horizontal vortex having no significant force to further scouring of the trough, because the trough was too deep for the vortex to reach bottom any more. The inner bar disappeared after 80

**Fig. 10** An example of successive development of quadruple bars

minutes due probably to the decrease in force of the inshore vortex, which has already changed from the A-type to the oblique vortex at the stage of 80 minutes. In the present experiment, this type of bar development, i.e., simultaneous occurrence of bars, was observed in the cases in which the initial morphology was a berm or a berm-step. Simultaneous occurrence of multiple vortices acting on the bottom is

**Fig. 11** Formative processes of inner and break-point bars at the initial stage. (a) Average drift velocity profile in the surf zone; (b) different patterns of sediment transport by the action of vortices; and (c) formation of inner and break-point bars

necessary for simultaneous bar development.

Figure 10 shows an example of successive development of four bars. The initial morphology had a profile of a shallow shelf. During the first 5 minutes, the break-point bar was formed by the B-type horizontal vortex due to plunging breakers, and the second bar was formed inshore almost simultaneously by the action of oblique vortex produced by the strong shear flow of rushing bores induced by splash of the plunging breakers. At 20 minutes, the third bar appeared by the action of oblique vortex occurred further inshore. At 40 minutes this oblique vortex changed to the A-type horizontal vortex, which finally changed to the B-type horizontal vortex at 80 minutes. At the same time the second breakers were observed above the third bar. At this stage, the fourth bar was formed most landward by the oblique vortex. Finally, the equilibrium state of four bars was achieved when most vortices did not touch the bottom. This type of bar growth was observed in the cases in which the initial morphology was a shallow shelf.

As illustrated in Fig. 10, the multiple bars are formed successively from the wave break point to the inshore zone due to the coupling between the vortex action and nearshore topography. As the third bar clearly indicates, the order of change in vortex type occurring there is from oblique to A-type and finally to B-type horizontal vortices due to the interaction between bar growth and change in breaker type.

The present experiment showed that the second bar, as shown in this case (Fig. 10), was initiated by the vortex action induced by splash of plunging breakers, and it was always located deeper than and closer to the first bar. This type of bar is called a "splash inner bar" in this paper. A splash inner bar often occurred when plunging breakers acted on the beach.

### **Difference in Formative Processes Between Inner and Break-point Bars**

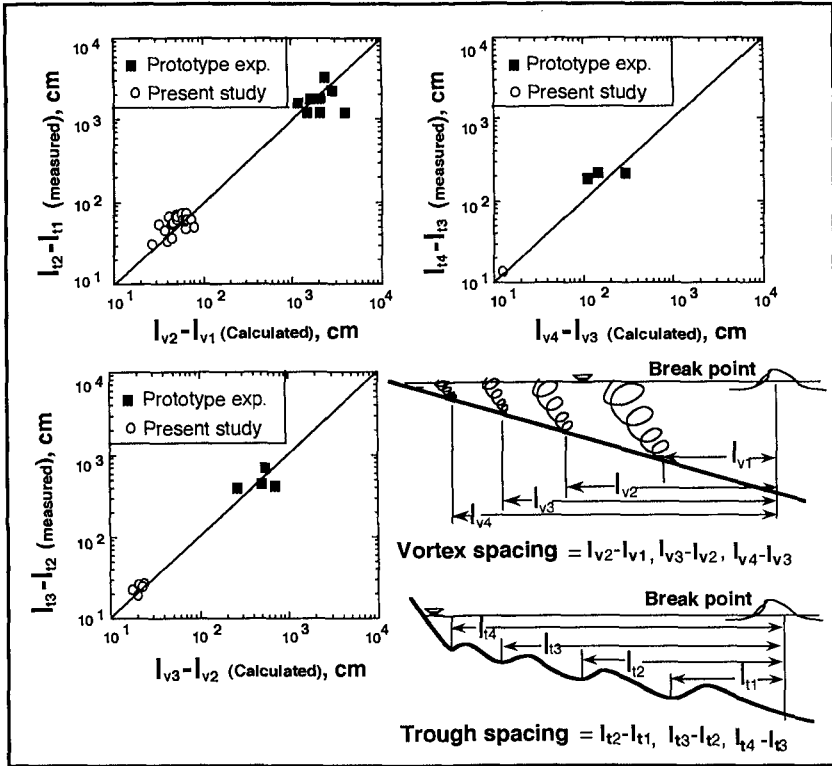

Figure 11a shows the average drift velocity profile in the surf zone induced by spilling breakers which may form bars; this result is obtained from the result of float observation in this study and supplemented by the results of studies by Pae and Iwagaki (1984), Svendsen (1984), and Wang et al. (1984). The average velocity is found to direct onshore in the upper layer of water column, and offshore in the middle to bottom layers within the surf zone, where the middle layer has higher offshore velocity than the bottom. The onshore velocity occurs near the bottom in the offshore zone including the break point.

Figure 11b shows two modes of net sediment transport under the action of vortices. One is the "congestion" in the surf zone. Sediment particles lifted by the vortex occurring inshore are more rapidly transported by the higher offshore velocity, whereas the sediment particles located adjacent to the vortex but not lifted by the action of the vortex are transported by the lower offshore velocity without suspension. The difference in sediment particle velocities directed offshore causes congestion. The other mode of sediment transport is the "convergence" near the wave break point. Sediment particles suspended by the action of the breaker-induced vortex are transported offshore by offshore-directed drift velocity, whereas sediment particles rested on the bottom seaward of the break point may be transported onshore by the onshore-directed drift velocity near the bottom. Convergence of transported sediments occurs immediately seaward of the place where the vortex acts on the bottom.

Figure 11c illustrates the inner bar formation by congestion, and the break-point bar formation by convergence. Sediment grain size that controls the height of suspension is also important in multiple bar formation. Sediment particles suspended by the surf-zone vortex would be transported to the break point to form the break-point bar, if the fall velocity of the sediment is too low to settle down immediately seaward of the vortex. In this case no inner bars would form.

### **RELATIONSHIPS BETWEEN CHARACTERISTICS OF MULTIPLE VORTICES AND MULTIPLE BAR FEATURES**

Figure 12 shows the relationship between vortex spacing (defined in this figure) calculated using Eq. (3) and the observed trough spacing using bar-profile data of small-scale experiments (the present experiment and Yokotsuka, 1985) and

**Fig. 12 Comparison of calculated vortex spacings and measured bar-trough spacings**

the existing prototype experiments (Sunamura and Maruyama, 1987; Kraus and Larson, 1988), except the "splash inner bar". This figure illustrates that the calculated value of vortex spacing is almost equal to the observed value of trough spacing. In the calculation using Eq. (3), a problem is how to evaluate  $\tan \beta$  for the case of non-uniform beach profiles. Considering that the wave breaking is crucial for multiple bar formation, the average beach slope shoreward of the wave break point,  $i$ , was used for  $\tan \beta$ . The average slope  $i$  is defined as

$$i = 2h/l \tag{7}$$

where  $h$  and  $l$  are the average water depth and the width of the surf zone (from the wave break point to the still-water line), respectively. The average depth  $h$  is given by

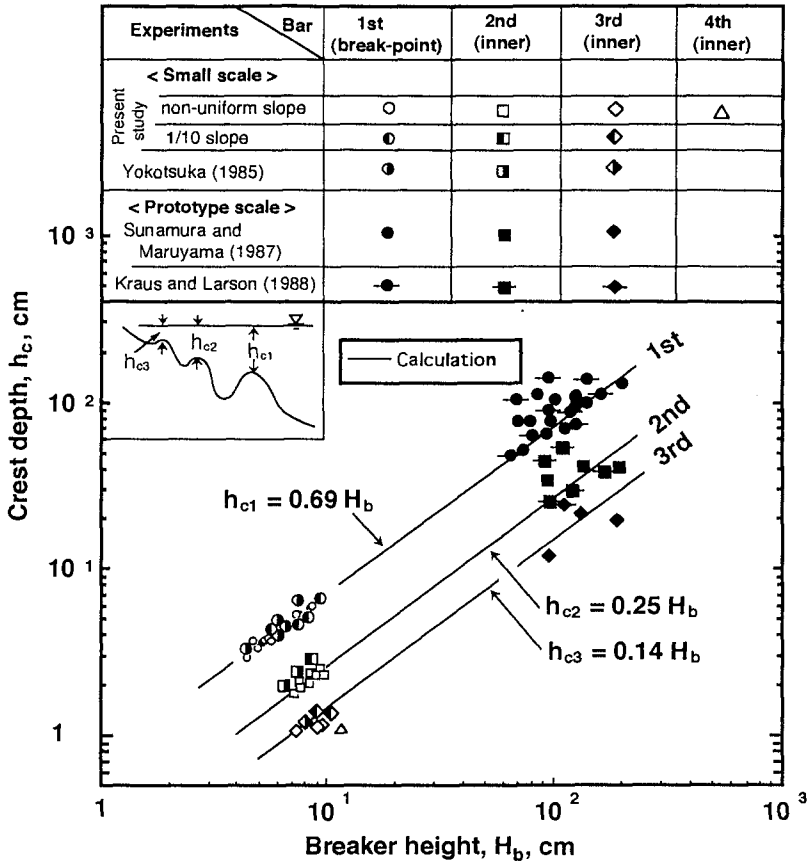

Fig. 13 Relationship between bar-crest depth and breaker height

$$h = \frac{1}{l} \int_0^l h(x) dx = S/l \tag{8}$$

where  $S$  is the cross-sectional area of the surf zone. From Eqs. (7) and (8), we have

$$i = 2S / l^2 \tag{9}$$

The relationship between the breaker height and the water depth at the crest of

n-th bar is shown in Fig. 13, using data of the above-mentioned small-scale and prototype experiments; data of the "splash inner bar" were again excluded. It was found that the water depth of bar crest is independent of time and is almost equal to the water depth where the vortex reaches bottom at the initial stage (Zhang, 1994). Assuming that the water depth of vortex reaching bottom is equal to the water depth of bar crest, the following equation is obtained from Eq. (6):

$$h_{cn} = 0.69 n^{-1.44} H_b \quad (10)$$

where  $h_{cn}$  is the water depth of n-th bar crest. The straight lines in this figure are the result of calculation by use of this equation substituting  $n=1, 2,$  and  $3$ . It is seen that calculation and experiment are in fairly good agreement.

## CONCLUSIONS

- (1) Bars are only formed by the vortices reaching bottom; the number of bars formed coincides with the number of vortices reaching bottom. The occurrence of vortices reaching bottom in the surf zone is crucial for the multiple bar formation.
- (2) Average drift velocity and sediment suspension due to vortex action can play an important role in bar formation. The mechanism for break-point bar formation is "convergence"; however, that for inner bar formation is "congestion"(Fig. 11).
- (3) Multiple-bar features such as trough spacing and crest depth can be explained from vortex features found through a fixed-bed experiment (Figs. 12 and 13).

## CHAPTER 207

### IDENTIFICATION OF SOME RELEVANT PROCESSES IN COASTAL MORPHOLOGICAL MODELLING

Hakeem Johnson<sup>1</sup>, I. Brøker<sup>1</sup>, J.A. Zyserman<sup>1</sup>

**ABSTRACT:** This paper presents a coastal morphology modelling system based on an explicit forward time integration scheme for the morphological evolution involving the following stages: a) Initialisation, b) Sediment transport computation using a deterministic sediment transport model, c) Wave computation using an arbitrary wave model, d) Hydrodynamic computation assuming a mobile bed evolving at  $\partial z/\partial t$ , with optional use of a module to determine the apparent roughness in combined wave-current motion and e) Bed level update scheme using an improved second order Lax Wendroff scheme. A series of numerical tests is performed with the aim of evaluating the effect of space-varying hydraulic roughness in combined waves and current, choice of wave modelling approach and of directionality of the waves on the morphological evolution. A detached breakwater is used as test case.

#### INTRODUCTION

The numerical modelling of morphological evolution in coastal areas has experienced an important development in recent years and is becoming a feasible alternative to physical modelling. The morphological modelling system considered here

---

<sup>1</sup>) Danish Hydraulic Institute, Agern Allé 5, DK 2970 Hørsholm, Denmark

consists of a wave module, a depth-integrated hydrodynamic module (in which the two horizontal dimensions are taken into account), a quasi-3D sediment transport module (Deigaard et al., 1986) and a modified second order Lax-Wendroff scheme for updating the bed level. A module for accounting for the effect of wave-related bed roughness on the current (Fredsoe, 1984) is also included in the modelling system. In the morphological model, the way in which the different modules are coupled is user-specified; for example, the influence of currents on wave refraction (influence of current module on wave module) may be accounted for or not; the same applies to the influence of waves on the apparent bed resistance for currents (influence of wave module on current module).

While the flow of information among the different modules and the inherent stability of such a modelling system have been discussed in detail (de Vriend, 1987 and de Vriend et al., 1993), an assessment of the influence of relevant parameters related to practical aspects of morphological modelling is still lacking. A series of numerical tests has therefore been devised in order to identify relevant parameters from the point of view of coastal area morphological modelling. The following aspects have been considered:

- The type of wave model used to simulate the propagation and transformation of the nearshore wave field
- The influence of directional spreading of the waves
- The influence of accounting for the apparent (wave-related) bed roughness on the current field, and consequently on the sediment transport field and the rates of bed level change.

The use of the model complex in practical engineering situations is further illustrated by investigating the morphological evolution behind a detached breakwater using different layouts and wave parameters.

## DESCRIPTION OF THE MODELLING COMPLEX

The modelling of the morphological response in the coastal zone, both on a natural coast and a coast influenced by structures, requires in principle simultaneous simulation of waves, currents and sediment transport, as the bathymetry develops.

Considering the various time scales which are involved, an explicit approach has been developed with sequential calculations of waves, currents, sediment transport and rates of bed level changes. The first version of the present model was described in Andersen, et al. (1988).

A block flow chart, showing the morphological modelling scheme, is illustrated in Figure 1. This figure is explained as follows: Given the initial bathymetry and

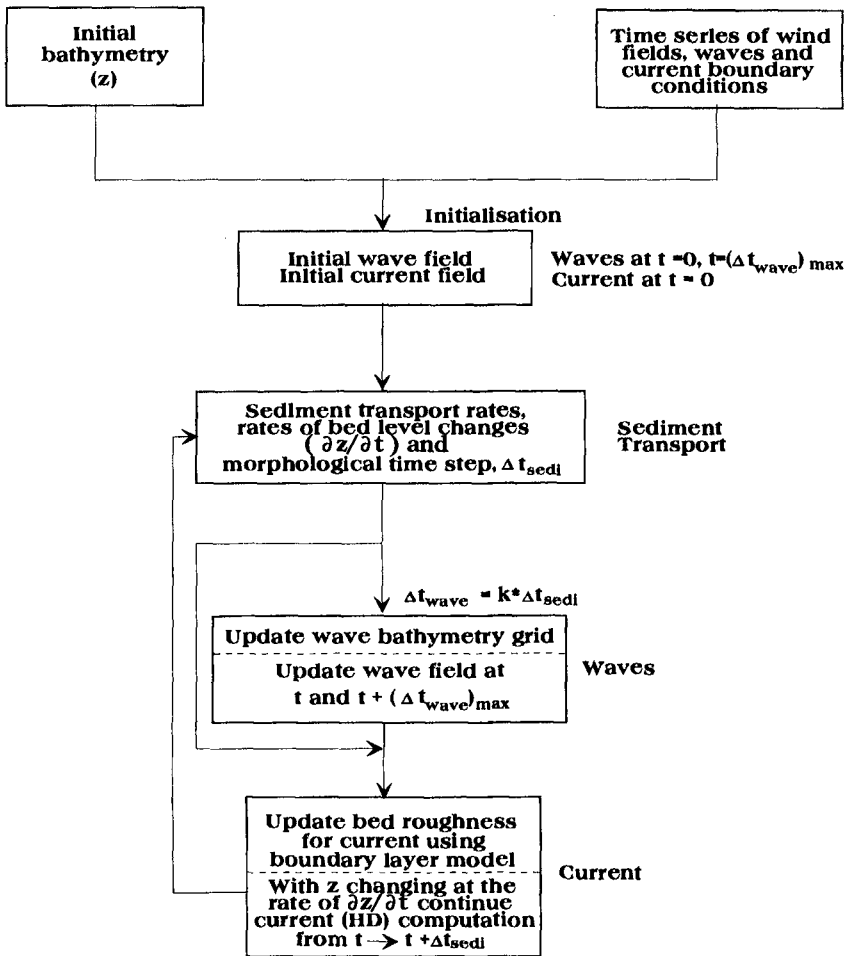

Figure 1. Block flow chart for morphological model.

time series of boundary wave and current conditions, the initial wave and current fields are first computed before entering the morphological loop. Then the loop is entered and the sediment transport, the rates of bed level changes  $\partial z/\partial t$  and the allowable maximum morphological time step,  $\Delta t_{\text{sedi}}$  (based on the stability condition for the bed update scheme) are computed. Next the wave field is updated

if necessary (since this is done every  $k$ -th update of the sediment transport field, where  $k$  is an integer  $\geq 1$ ). Next the bed resistance map is updated taking into account the apparent roughness in combined wave-current motion using a boundary layer model, and lastly the hydrodynamic calculation is continued from present time,  $T$ , to  $T+DT_{\text{sedi}}$ , where the sediment transport field is updated. Using the calculated  $\partial z/\partial t$ , the bed level is gradually updated during the hydrodynamic computation. The whole process is then repeated in a cyclical loop until the prescribed length of simulation is completed.

In the sections below, the modules in the modelling complex are described.

### Wave Models

The wave models presently built into the morphological complex are: an elliptic mild slope model, MIKE 21 EMS, a parabolic mild slope model, MIKE 21 PMS and a spectral nearshore wind wave model, MIKE 21 NSW.

MIKE 21 EMS is a linear refraction-diffraction wave model including back-scattering and wave breaking. The model solves the mild slope equation (Berkhoff, 1972), and includes a general formulation of radiation stresses which applies in crossing wave trains and in areas of strong diffraction. Of the three models, this is the most accurate for monochromatic linear waves under the test conditions chosen and is selected as our reference model. However, it is the one with the largest computational requirements.

MIKE 21 PMS is based on a simplification of the mild slope equation assuming wave propagation in one predominant direction ( $x$ -dir), neglecting diffraction in this direction and back-scattering in the opposite direction. Using the approach of Kirby (1986), this model is made to allow large-angle (up to 60 deg.) propagation to the  $x$ -dir. Furthermore, MIKE 21 PMS includes the effect of a frequency spectrum and directional spreading. The model is extremely cost-efficient and requires a very low computational effort, being approximately 50 times faster than the elliptic mild slope model for the same setup.

MIKE 21 NSW is a stationary directionally decoupled parametric model based on the wave action conservation equations as formulated by Holthuijsen et al. (1989). It describes the propagation, growth and decay of short-period waves in nearshore areas. The model takes into account the effects of refraction and shoaling due to varying depth as well as wind generation, energy dissipation due to bottom friction and wave-breaking plus the effect of current on these phenomena. Although this model does not include diffraction (an important effect behind the breakwater), it is nevertheless included in the analysis to illustrate the relative importance of this limitation.

In the three wave models, wave-breaking is formulated using the theory of Battjes and Janssen (1978).

#### Flow Model

The hydrodynamic module in the morphological modelling complex is MIKE 21 HD, which solves the vertically integrated equations of conservation of mass and momentum in two horizontal dimensions. The rate of bed level changes  $\partial z/\partial t$  has been included in the equation for conservation of water mass. The methods of solution are described in Abbott et al. (1973, 1981, 1988).

The hydrodynamic model is capable of operating with a space- and time-varying hydraulic roughness. The theory of Fredsøe (1984) for the apparent roughness in combined waves and currents has been implemented. The apparent roughness is updated every morphological time step.

The hydrodynamic model uses fluxes or levels as boundary conditions. In cases where the boundaries cut through the surf zone, the conditions are found from the radiation stress gradients assuming quasi-stationary flow.

#### Sediment Transport Model

A deterministic intra-wave period model for non-cohesive sediment is applied. A detailed description is given in Deigaard et al. (1986) It is noted that the model covers the range from pure current to combined current and waves (breaking or non-breaking). It is a basic assumption in the present model complex that the transport capacity is a function of the local conditions only, ie. no time and space lag effects are included.

#### The Bed Level Changes $\partial z/\partial t$

The rates of bed level change are described by the equation of continuity:

$$\frac{\partial z}{\partial t} + \frac{1}{1-n} \frac{\partial q_x}{\partial x} + \frac{1}{1-n} \frac{\partial q_y}{\partial y} = 0$$

where  $x$ ,  $y$  and  $z$  are horizontal and vertical space coordinates, respectively;  $t$  is time,  $n$  is porosity and  $q_x$ ,  $q_y$  are sediment transport rates in  $x$ - and  $y$ -directions. A second-order accurate explicit finite-difference method is applied. The truncation errors are eliminated by applying a modified Lax Wendroff scheme, see Abbott (1978). The solution is kept stable by adjusting the morphological timestep so that the maximum Courant number, reflecting migration rates of bed forms, is  $\leq 1$ .

## THE CHOICE OF WAVE MODEL

The most appropriate wave model must be chosen depending on the dominating phenomena in the area to be studied using the morphological model. Morphological modelling requires many repetitive calculations of the wave field. Consequently, there is a need for finding the optimal balance between accuracy and computational effort.

The problem has been investigated by calculation of the initial wave, current and sediment transport fields behind an offshore breakwater for normally incoming waves with the three wave models available in the morphological complex: the elliptic mild slope model, EMS, the parabolic mild slope model, PMS, and the spectral wind wave model, NSW.

The phenomena shoaling, depth refraction and breaking are all well described by the three models. Diffraction is best described by the elliptic model, approximately by the parabolic model and not at all in the spectral wind wave model. To compensate for the lack of wave energy penetration behind the breakwater in the case of the spectral wave model, this model was run with directional spreading of the incoming waves.

The studied configuration is a 300 m long shore-parallel breakwater located 280 m from the shoreline on a plane sandy beach with a slope of 1:50. The wave height ( $H_{\text{RMS}}$ ) and period are 2m and 8s, respectively, at 10 m water depth. The sediment is sand with a median grain size of 0.25 mm and a gradation  $\sigma_g$  corresponding to  $(d_{84}/d_{16})^{1/2} = 1.1$ .

A grid spacing of 5m was used in the EMS and PMS models. Furthermore, the front face of the breakwater is assumed to have zero reflection in the EMS model. This is achieved by placing a 5-line sponge layer inside the breakwater. The incident wave field is assumed to be monochromatic and unidirectional in the EMS and PMS models. For the NSW model, the grid spacing was chosen as  $DX=2\text{m}$ ,  $DY=10\text{m}$  and a  $\cos^2$  directional spreading function was used. The bed roughness in the wave models was chosen as 1.5mm.

The radiation stresses from the wave models are interpolated to a square grid with  $DX=DY=10\text{m}$  used for the hydrodynamic simulations. The hydrodynamic time step is 6 s and a bed roughness corresponding to a Manning number (in the Strickler sense) of 32 is used.

Figure 2 shows the contours of wave heights, wave-induced currents and sediment transport vectors from the three models.

Although the NSW model does not include diffraction, some wave energy can be observed behind the breakwater due to the use of a broad-banded ( $\cos^2$ ) directional

spectrum. However, the computed NSW wave heights in the diffraction zone are much smaller than corresponding EMS waves, while the PMS wave heights are generally closer to the EMS waves.

All three models drive two eddies between the breakwater and the shoreline. The maximum current speed in the EMS model is slightly greater than 1m/s, which is nearly the same as obtained with the PMS model. However, the current speeds are generally lower for the NSW model, the maximum in this case being about 0.8m/s. The difference in wave-induced currents between NSW and the others is partly due to directional spreading in NSW: the directional spreading results in a smoothing of the radiation stress field, and hence in a reduction of the radiation stress gradients.

The combined wave and current fields are used for calculating the sediment transport rates. As can be expected from a comparison of the waves and current fields, the sediment transport rates computed using the NSW model are about a factor 3 smaller than those calculated using the EMS model. In contrast, the PMS model results are generally much closer to the EMS values, except for the alternating high and low transport rates computed close to the shoreline behind the breakwater which arise from alternating bands of high and low wave heights (constructive/destructive interference) which are well described by the EMS model, but only partially modelled in the PMS model.

It is concluded that the PMS model is an optimal choice for computing the sediment transport field and hence the morphology response behind the offshore breakwater, since it gives comparable results to the EMS model at a much lower cost.

The NSW model is found to be unsuitable for computing sediment transport rates for the test setup selected in which diffraction is an important phenomenon.

## EFFECTS OF DIRECTIONAL SPREADING

The effects of directional spreading of the waves on the flow field and on the sediment transport field have been investigated with a similar setup as used for the discussion of types of wave model. The parabolic mild slope model has been applied and the direction of the waves at 10m depth is  $10^\circ$ . Furthermore, the distance from the shoreline to the breakwater is now 200m. Simulations have been made with unidirectional waves and with directional spreading. Five (5) directional components have been used to resolve the directional energy spectrum which at 10m water depth is described as  $\cos^5(\theta - \theta_{\text{mean}})$ .

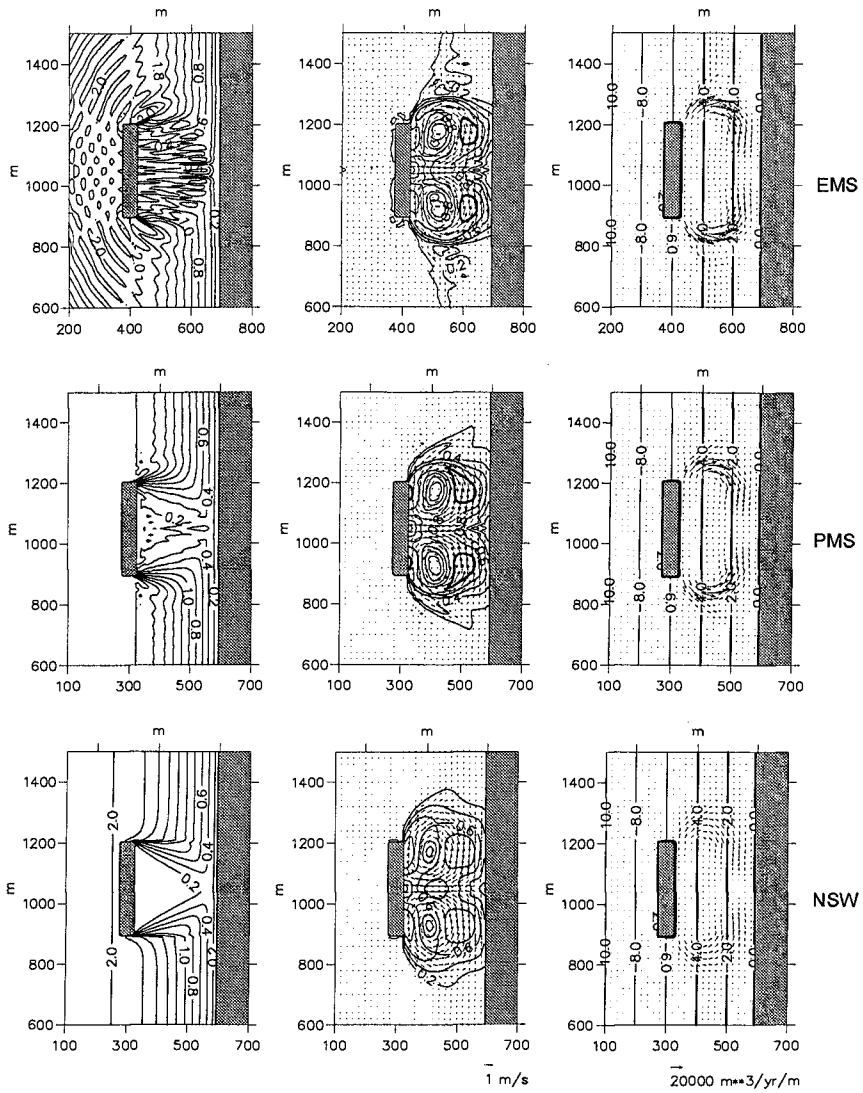

Figure 2. Contours of wave heights (a), current speeds (b) and sediment transport field (c).

The calculated initial wave, current and sediment transport fields are shown in Figure 3.

The comparison of the two wave heights fields shows an increase of  $H_{RMS}$  behind the breakwater in the case of directional waves compared to unidirectional waves. The longshore currents and the littoral drift are both decreased along the open coast due to the directional spreading. However, the sediment transport into the area behind the breakwater has increased with the directional spreading, both from 'updrift' and from 'downdrift'. This is also seen from the comparison of longshore sediment transport shoreward of the breakwater.

The different changes in the transport along the open coast and behind the breakwater indicate that the directional spreading also influences the morphological response.

### EFFECT OF APPARENT ROUGHNESS

The effect of the apparent hydrodynamic roughness due to the presence of a turbulent wave boundary layer on the morphological evolution is evaluated by comparison of initial current and transport fields calculated using a constant hydraulic roughness,  $k_N = 0.625$  mm (grain roughness) and an apparent roughness,  $k_w$ , respectively.  $k_w$  is calculated according to Fredsøe (1984). The data for these tests is as follows: length of the breakwater is 100 m, distance from shoreline is 200m, beach slope is 1:50 out to 10m depth, grain size ( $d_{50}$ ) is 0.25, gradation ( $\sigma_g$ ) is 1.1, wave height  $H_{RMS}$ , direction, period (at 10 m depth) are respectively 2.0 m,  $10^\circ$  and 8s. The waves are unidirectional and the model used is MIKE 21 PMS.

The two sets of results are compared in Figure 4. The presence of the wave boundary layer increased the hydraulic roughness by a factor of 5 to 10 in the area most relevant with respect to sediment transport. This leads to reduction of current speeds with a factor of about 0.6 and reduction of the sediment transport with a factor of 0.3 - 0.5.

From the comparison of littoral drift shoreward of the breakwater shown in Figure 4, it appears that apart from an obvious difference in time scale of the morphological response the non-linearities will lead to a different erosion/deposition pattern when the space-varying roughness is included.

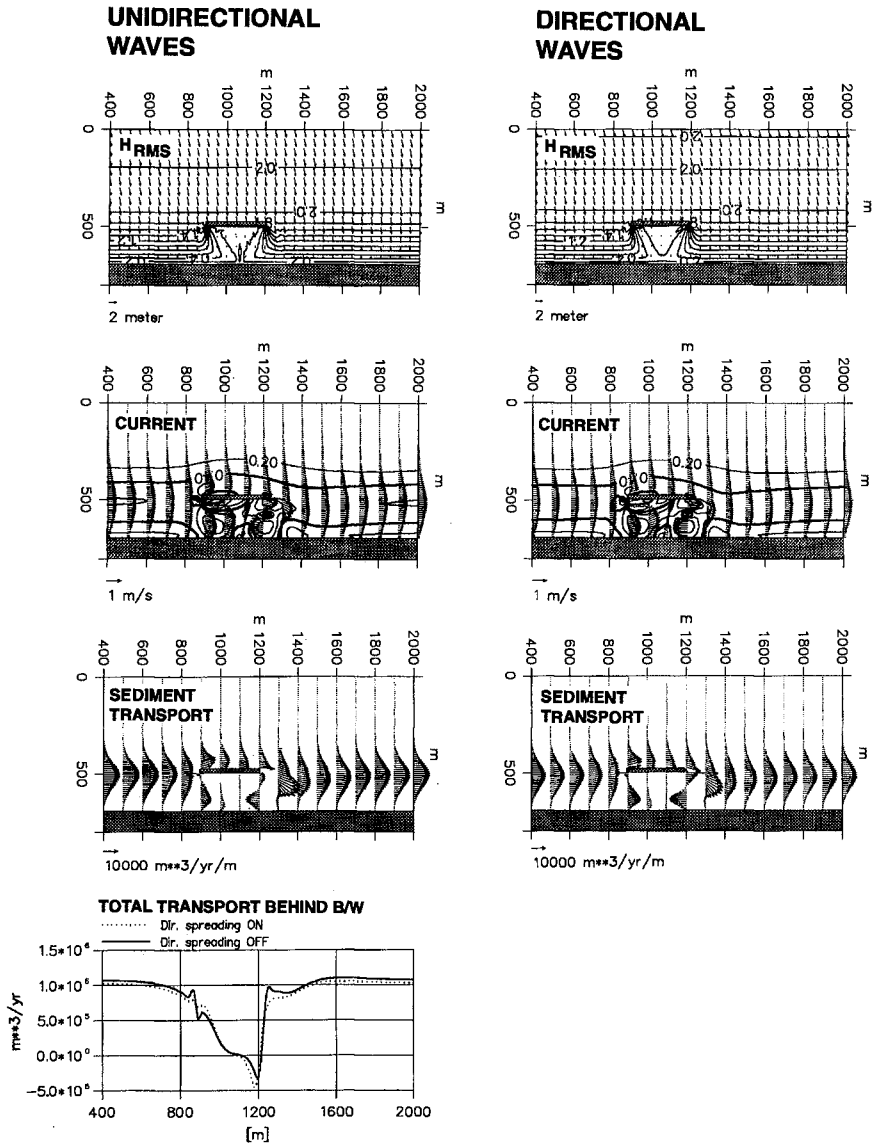

Figure 3. Wave, current and sediment transport fields for unidirectional and directional waves. Comparison of longshore sediment transport.

Figure 4. Roughness distribution and current- and sediment transport fields for constant and wave-enhanced roughness. Comparison of longshore sediment transport.

## ON THE EFFECTS OF SHORE-PARALLEL BREAKWATERS

The overall purpose of discussing morphological models is to produce tools to guide and support the design of coastal structures.

Although the present modelling complex does not include all relevant processes, a first attempt at a systematic study of the effects of shore-parallel breakwaters on sandy beaches has been initiated.

The initial conditions for all the presented simulations are a plane beach with a slope of 1:50 extending out to a depth of 10 m. The coastline is a fixed boundary which cannot be eroded. The incoming waves have been kept constant in time along the offshore boundary. The morphological evolution has been simulated for different dimensions of the breakwater and different incoming waves. The applied model setup is as previously described. The wave module applied is MIKE 21 PMS and the waves have been taken as unidirectional.

In Figure 5, the bed contours after a certain period of time are shown for varying angle of the incoming waves, varying wave height, varying distance from the shore to the breakwater and varying length of the breakwater. For the four different comparisons all other parameters are kept constant. (Note that in Figure 5, areas between the 0.5m contour and the shoreline are black. This is only to make the illustration clear).

The simulations indicate that localised scour occurs around the heads of the breakwater and a double or single-peaked salient forms behind the breakwater.

With increasing angle of the incoming waves the pattern changes from being localised redistribution of sediment to a trap for the littoral drift followed by downdrift erosion.

The salient peak 'updrift' decreases, while the 'downdrift' peak increases and is shifted further downdrift with increasing angle.

Sand ridges oriented at an obtuse angle to the shoreline are also seen for the simulations with large angle of incidence. The reason for the occurrence of this ridges is still under investigation.

As the distance of the breakwater to the shoreline decreases, there is a reduction of the scour around the breakwater heads and a greater tendency of tombolo formation.

With decreasing wave height, the surf zone becomes narrower, accompanied with a decreasing total littoral drift and a slower overall morphological response. However, it is noted that the deposition close to the shoreline is slightly increased for

the smaller waves due to the fact that the trapped littoral transport in this case is trapped in the very narrow surf zone close to the shore, as opposed to being distributed over a wide surf zone as for the high waves.

The length of the breakwater and the distance from shore both influence the development of the salient, and determine whether it is single or double-peaked.

These first results are only indicative and future long simulations and detailed quantitative analysis are expected to contribute considerably to the established knowledge of design of breakwaters.

### **CLOSING REMARKS**

The effects of a number of relevant processes in coastal morphological modelling have been investigated in this paper. The processes considered are: (1) the choice of wave model, (2) effect of directional spreading, and (3) the influence of wave boundary layer on the hydraulic roughness used in flow modelling. It is concluded that the above processes influence the results of the morphological modelling.

Using the presented model complex, the morphological response of a single detached breakwater subject to different wave conditions was investigated. A qualitative description of the effects of various layouts and wave conditions is also presented. The occurrence of sand ridges downdrift of the breakwater for large angle of wave incidence is noted, however this subject is still under investigation.

Overall, these first results are indicative and future work is expected to contribute considerably to the established knowledge on morphological modelling and the design of offshore breakwaters.

### **ACKNOWLEDGEMENT**

This work has been carried out as a part of the G8 Coastal Morphodynamics research programme. It was funded jointly by the Danish Technical Research Council (STVF) within the frame of the 'Marin Teknik' programme and the Commission of the European Communities, Directorate General for Science, Research and Development, under contract no. MAS2-CT92-0027.

## CHAPTER 208

### Experimental Shoreface Nourishment, Terschelling (NL)

J.P.M. Mulder<sup>1</sup>, J. van de Kreeke<sup>2</sup>, P. van Vessem<sup>1</sup>

#### Abstract

An experimental shoreface nourishment was implemented at Terschelling, the Netherlands in 1993. The effectiveness of this nourishment will be evaluated in the framework of an EU sponsored project NourTEC.

The design of the Terschelling nourishment including the objectives and alternatives, are described in detail. Preliminary monitoring results lead to a cautious optimism with regard to the performance of the nourishment.

#### NourTEC: evaluation of innovative nourishment techniques

Full scale experiments with alternative coastal nourishment techniques, including shoreface nourishments, are being carried out in three countries around the North Sea: at the island Terschelling in the Netherlands, at the island Norderney in Germany and at the closed barrier coast near Torsminde Tange in Denmark (Fig. 1; Table 1). A comparative analysis of all these experiments is planned within the project NourTEC.

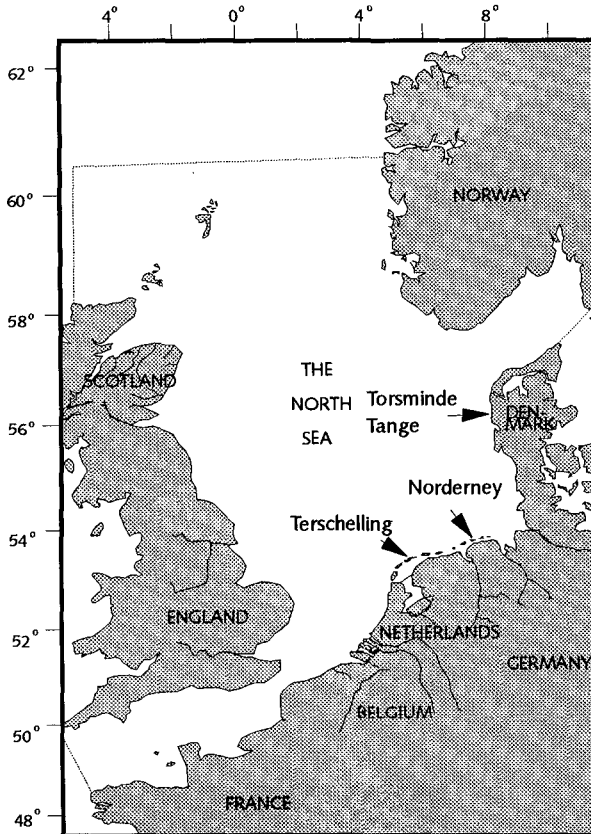

Fig. 1 Location of the three NOURTEC test sites

NOURTEC locations	nourishment type	total amount ( Mm <sup>3</sup> )	averaged volume ( m <sup>3</sup> /m )	year
Terschelling (Netherlands)	- shoreface	2	450	1993
Norderney (Germany)	- combined shoreface- and beach	0.45	250	1992
Torsminde Tange (Denmark)	- shoreface	0.25	250	1993
	- beach	0.25	250	1993

Table 1 Characteristics of nourishment experiments in the NOURTEC project

In particular, Nourtec aims at generalized conclusions on the design, the effectiveness and the feasibility of shoreface nourishment techniques in different coastal environments.

In general, shoreface nourishments can be used to attain one, or a combination, of the following design objectives (i) coastline stabilization, (ii) coastal protection, (iii) creating or maintaining a recreational beach. Although each of the Nourtec nourishment experiments has a specific design objective - i.e. coastal protection for Torsminde and Norderney and coastline stabilization for Terschelling - within the framework of Nourtec each will be evaluated for all of the above design objectives. The final report is due in 1996.

Each nourishment experiment is accompanied by an extensive monitoring program including frequent bathymetric surveys and monitoring of the offshore wave climate and nearshore tidal current field. In addition to this special process-oriented field programs are carried out (Hoekstra et al., 1994; Kroon et al., 1995).

This paper will focus on the design of the Terschelling nourishment (Nourtec, 1994) and some initial results of the monitoring program.

### Coastal defense policy in the Netherlands

About three-quarters of the Dutch coast consists of dunes and beaches. Together they offer a natural, sandy defence to the North Sea. Under the influence of nature, this barrier is constantly changing; advancing at one location, receding at another. In 1990 the Government and Parliament of the Netherlands instituted a new national coastal defence policy: dynamic preservation of the 1990 coastline. This policy is based on the concept of a standard or reference coastline, the so-called basal coastline (BKL). Whenever the actual coast line tends to move to a position landward of the basal coastline, the beaches will be restored.

The main method in the Netherlands, to preserve the 1990 coastline is beach nourishment. On a yearly basis 5 to 7 million m<sup>3</sup> of sand is added to the (dry) beaches.

### Definition of coastline

To arrive at a uniform measure for the overall change in a cross-shore profile, a critical region 0 - indicated by the hatched area in Fig. 2 - is defined. In the vertical direction the critical region extends between the elevation of the dune foot and a depth corresponding to twice the vertical distance between Mean

Fig. 2 Definition sketch of the BKL zone and the Momentary Coastline

Low Water (MLW) and the elevation of the dune foot. In the landward direction the critical region is bounded by a vertical line. The location of this line is sufficiently landward so that erosion is not encountered. This critical region is called the BKL - zone.

Making use of the concept of the BKL - zone, the momentary coastline is defined as a line located at a horizontal distance  $B$  seaward of the dune foot. The magnitude of  $B$  follows from  $B = O / (2H)$ . Note that in general the momentary coastline does not coincide with MLW. To document the position of the coastline, once a year cross-shore profiles spaced 200 - 250 m apart are measured along the entire Dutch coast. For each cross-shore profile, the values of  $O$  and  $B$  are calculated and the position of the coast line is referenced to fixed survey monuments.

To account for yearly fluctuations, a transient coastline (TKL) is defined. The TKL for a given year follows from the linear trend of the momentary coastline during the preceding ten years. As an example, in Fig. 4 the TKL for 1992 is indicated, based on coast line data over the period 1982 - 1991.

The TKL for 1990 was defined as the basal coastline.

#### Coastline retreat at Terschelling

The project site is located on the central part of the island of Terschelling; see Fig. 3. As an example of

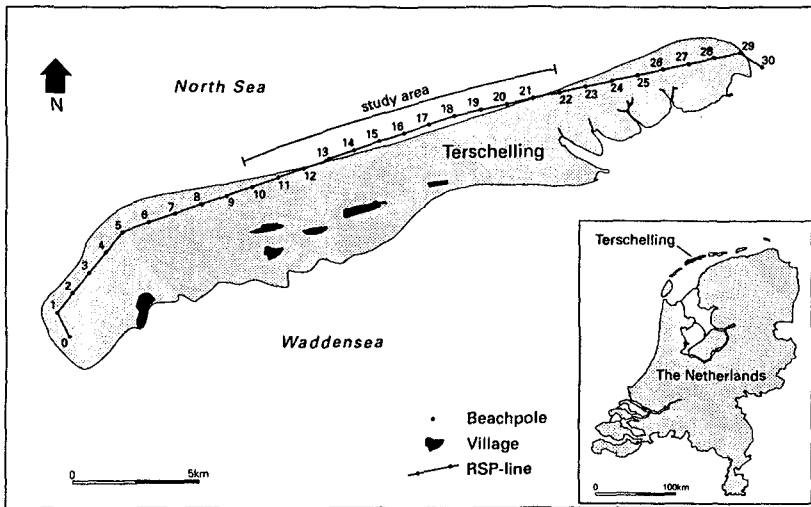

Fig. 3 Location of nourishment at Terschelling; the numbers correspond with km-positions of the cross-sectional profiles along the coast

coastline retreat the position of the coastline over the period 1965 to 1991 at km 16.00 is plotted in Figure 4. In the same figure the position of the basal coastline (BKL) and the transient coast line (TKL) for 1992 are presented. The transient coast line suggests that at km 16.00, the TKL 92 will soon retreat to a position landward of the BKL. Calculations showed that for 68 % of the profiles between km 13.70 and 17.80 the TKL 92 had already crossed the BKL. On this basis it was decided that for this stretch of the Terschelling coast the coast line had to be restored by means of a nourishment. Because of the west to east direction of the littoral drift, the project area was extended to km 18.20.

To calculate the amount of sand required to assure that the TKL for the next ten years remains landward of the BKL, the erosion rates were determined from the trend lines of the various profiles. Erosion rates for the project area range between 1- 5 m /year. This corresponds to a loss of approximately 110 thousand cubic meters per year. If this trends continues, 1.10 million cubic meters of sand will have been removed out of the BKL-zone in the next ten years.

Fig. 4 Coast line development at km 16.00; indicated are the Transient Coastline (TKL) for 1992 derived from the period 1982 - 1991, and the Basal Coastline (BKL). Note the remarkable positive trend after the nourishment (Nov 1993 - June 1994).

### Design objectives

The design objectives are to return the TKL to a position seaward of the BKL and to assure that the TKL will not retreat landward of the BKL during the next ten years. Maintaining a sufficiently wide recreational beach and protecting the low-lying polderland landward of the dunes from storm surge are not acute problems and therefore are not part of the design objectives.

### Pertinent physical parameters

At the location of the project, the width of the surf zone ranges between 1600 m and 2000 m. The morphology is characterised by three long-shore bars. Typically, the distance between the bar crests, measured in the cross-shore direction, varies between 100 m and 400 m. The vertical distance between trough and landward crest can be as large as 4 m. Using bathymetric data of the past 26 years, Ruessink (1992) showed that bars tend to originate between the high water and low water line, migrate in an offshore direction and fade out at a depth of 8-11 m below MSL or about 2000 m offshore; see Fig. 5.

The total sequence takes approximately 10-15 years. Although less pronounced than the offshore directed movement, there is also a long-shore movement of the bars. The area is in general very dynamic with a considerable transport of sediment.

Fig. 5 Typical example of migration of longshore bars

The wave climate at the project site is characterised by an annual average significant wave height of 1.2 to 1.5 m. Tides are semi-diurnal with neap tidal range of 1.5 m and a spring tidal range of 2.1 m. The amplitude of the tidal current at the nourishment site is estimated at 0.4 m/sec. There are indications that the residual current is from west to east. The sand present in the nourishment area has a median grainsize of 155 - 165  $\mu\text{m}$ .

### Principles of shoreface nourishment

Shoreface nourishment involves placement of sand on the shoreface rather than on the beach. The principle of the shoreface nourishment is based on the observation that erosion of the shoreface leads eventually to erosion of the beach and the dunes. Conversely, it is expected that nourishment of the shoreface might stop or retard the erosion of the beach.

There are two types of shoreface nourishments: a stable berm and a feeder berm. A stable berm is constructed in deeper water. It's function is to attenuate storm waves and to reduce the wave energy expanded on the beach. For Terschelling this is not a viable design alternative because there is no initial

contribution of sand to the BKL-zone, implying that the TKL will remain landward of the BKL, and subsequent transport of sand to the BKL-zone is, by definition, not expected. A feeder or nearshore berm is constructed in relatively shallow water and therefore part of it could be in the BKL - zone. It serves as a dissipator of incident wave energy and is expected to gradually provide additional sand to the BKL-zone.

Both types of shoreface nourishments have been constructed since 1935. Only the more recent projects were accompanied by monitoring programs. With regard to the feeder berm projects the monitoring results showed a gradual movement of sand in the landward direction and consequently a movement of the coastline in the seaward direction. In addition, the following general conclusions can be reached:

- the estimated cost of a shoreface nourishment is half of that of a beach nourishment;
- sand should be placed as high as possible in the profile to assure landward transport, a depth of less than 10 m is recommended;
- the length of the nourishment in the along-shore direction should be several times the average local wavelength to minimize the potential for wave focusing.

Obviously, more monitoring is needed to verify performance and to quantify the physical benefits of shoreface nourishments.

Roelvink (1989) carried out a desk study to determine the effect of a shoreface nourishment on the coast. In particular he focused on

- depth of placement
- volume of the nourishment
- influence of sea level rise.

He defined the effectiveness of the shoreface nourishment as the increase in volume of a specified part of the cross - shore profile, for example the BKL - zone, expressed as a percentage of the nourished volume. The autonomous development of the profile is not taken into account.

The main conclusions of Roelvink's study are that

- shoreface nourishments become more effective when placed close to shore; for the Dutch coast nourishments placed landward of MSL -7 m have a definitely favourable effect on the beaches; the nourishment has little or no effect when placed seaward of MSL - 10 m;
- the volume of a specific part of the beach profile and therefore the effectiveness increases linear with the volume of the nourishment;
- the effectiveness is little influenced by an

increase in the rate of sea level rise. Parameter values used in the calculations by Roelvink pertain to the Dutch coast. Conclusions are valid within this parameter range and should not be extended beyond this range.

Partly in response to Roelvink's study, Hillen et al. (1991) carried out a feasibility study for shoreface nourishment including methods of construction and cost. One of their conclusions was that for nourished volumes of 1-10 million cubic meter, distances to the borrow area of 15-20 km and a nourishment depth of less than MSL -7 m, only nourishments carried out by small to medium size split barge hopper dredges lead to a price per cubic meter of sand that is substantial lower (50 %) than that of a beach nourishment. Furthermore, using the results of Roelvink they calculated how much sand is expected to be in the BKL-zone as a function of time and depth of placement. The results showed that a shoreface nourishment placed between MSL -5 m and MSL -7 m has an effectiveness of 35% to 60 % after 5 years. It was concluded that, compared to a beach nourishment (effectiveness estimated at 90 %), twice the volume of sand is needed for a shoreface nourishment to arrive at the same volume of sand in the BKL-zone after 5 years. In view of the 50 % reduction in the price of a cubic meter of sand in place, it follows that the total cost of a beach nourishment and a shoreface nourishment, which would guarantee the same volume of sand in the BKL - zone after 5 years, are about the same.

Hillen et al. (1992) emphasize that estimates of cost and effectiveness of the shoreface nourishments used in their study are conservative; this to not create false expectations. However it seems clear that the method has potential, and ultimately could lead to substantial savings considering the annual budget of 60 million Dutch guilders (28 million Ecu) spent in The Netherlands to combat erosion. In view of this it was decided for Terschelling to select the option of a shoreface (feeder berm) nourishment.

#### Design of the shoreface nourishment

Further specification of the feeder berm design was largely based on experience with earlier nourishments and on theoretical results. Unfortunately, state-of-the-art models turned out to be of limited use as a design tool. For the shoreface nourishment to meet the design objectives stated above, a total of (2 \* 1.10 million = ) 2.20 million cubic meter of sand is required. Sand should be placed as high as possible in the profile. However an upper limit of MSL - 5 m was imposed by the smallest

available hopper dredge. This depth is still available within the BKL - zone which extends to NAP - 5.24 m at the project site. This allowed at least a fraction of the sand to be placed initially in the BKL - zone.

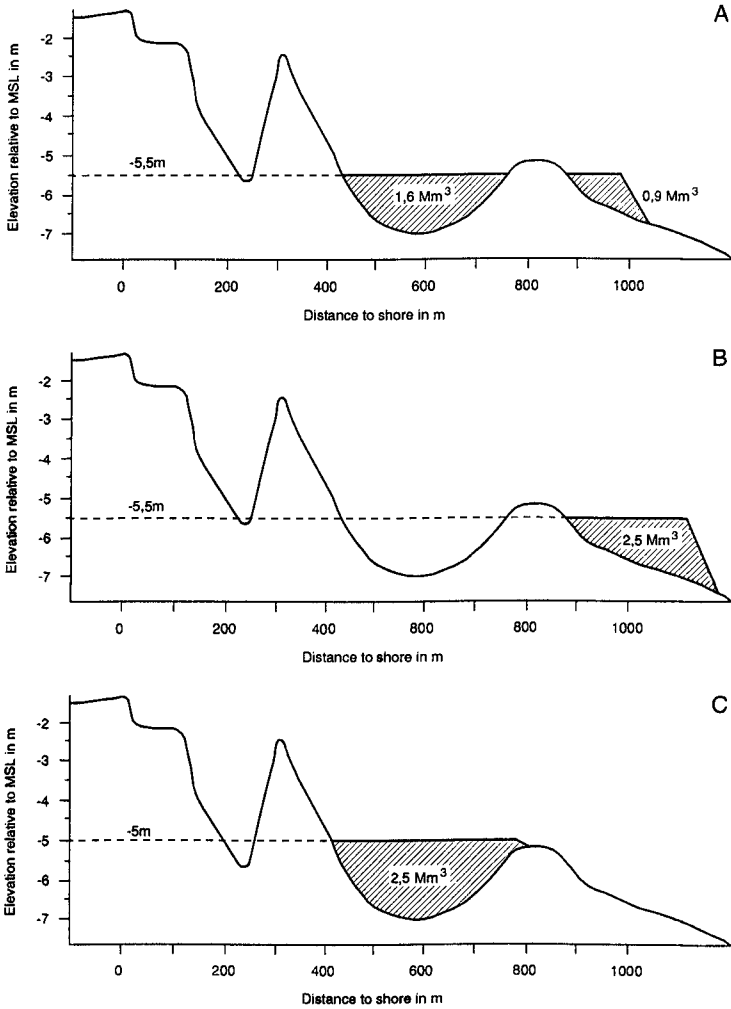

Fig. 6 Design alternatives for a shoreface nourishment at Terschelling

Three possible designs for a shoreface (feeder berm) nourishment were considered; see Fig. 6. To reiterate, the design objectives or functional requirements to be

met by each of the designs were

- After placement of the sand the TKL should be seaward of the BKL everywhere at the project site;
- The TKL should not retreat landward of the BKL during the next ten years.

Furthermore the design should allow adequate monitoring (this in view of the experimental character of the nourishment). The optimum design is the one that meets the functional requirements at a minimum total cost.

Calculations with a 3-LINE model (Bakker, 1995), which included the actual geometry with the three bars, suggested that nourishment seaward of the outer bar, as in designs A and B, could not sufficiently compensate for the landward movement of the coastline of about 1-5 m per year during the next ten years. The nourished volume seaward of the outer bar would act as a breakwater, however, with little effect on the natural erosion of the coast. For design C, the model indicated that the nourishment would prevent the TKL from retreating behind the BKL in the next ten years. It should be emphasized however, that the calculations were of an exploratory nature.

For designs A and B sand loss during dumping could be substantial due to the relatively large depth and tidal current speed. For design C, losses during construction were expected to be minor due to the placement of the sand between two bars. Consequently, the cost per cubic meter sand in the profile was expected to be lowest for design C. In design C a substantial fraction of the sediment is initially placed in the BKL-zone. From a monitoring point of view both designs B and C were acceptable. Design A was less attractive because it consists essentially of two parts.

It follows that design C is the only design that meets all design criteria and it has the lowest cost. Therefore, this design was selected as the final design. Because of financial constraints the total volume of sand was somewhat reduced to 2 million cubic meters. The nourishment stretched between km 13.6 and km 18.2; see Fig. 3. Originally a volume of 0.3 million cubic meter was placed in the BKL zone.

The type of sand to be selected for the nourishment should closely resemble the native sand to avoid additional complications and to facilitate interpretation of the behaviour of the shoreface nourishment. If it is different, the sand should preferably be coarser than the native sand. This will lead to less loss of sediment during and immediately after placement and will lead to an extended life span of the nourishment. Borrowing of sand in the Dutch territorial waters is limited to the

zone offshore of the 20 m isobath. A good source of sand resembling the native sand was found 10 km of the project site at the 22 m depth contour with a median grain size in the range of 183 - 212  $\mu\text{m}$ .

The nourishment was implemented using three suction split hull hopper dredges with hopper capacities ranging between 1200 and 2100 cubm. The draft of the vessels ranged between 4.50 to 5.30 m. To provide access to the project site, an entrance channel was dredged through the most seaward bar at km 16.30. The channel depth was 6.50 m below NAP. The nourishment area was divided into 9 dump sections each with a width of approximately 500 m. The dumping started simultaneously at the west and east side of the project area. Depending on the direction of the tidal current, the dredges placed the sand in the outermost east or west section. At the end of the construction the entrance channel was closed. For execution of the project an accurate electronic positioning system was used. Total construction time was 6 months (May - November 1993). Due to an unexpectedly high frequency of unfavourable swell conditions hindering manoeuvring of the dredges between the bars, the total operation took 65 instead of the planned 36 weeks of shipping time.

The contractor was reimbursed based on results of bathymetric surveys rather than volumes of sand transported by the hopper dredges. It appeared that the transported volumes were about 30% larger than the bathymetrically observed volumes.

### Monitoring results

Since the completion of the nourishment in November 1993, bathymetric surveys have been carried out at regular intervals. Based on these surveys the position of the coastline was calculated for various cross-sections. As an example, for km 16.00 the positions of the coastline since the nourishment have been added to Fig. 4. Between the nourishment and the last survey during June 1994 the coastline has advanced by 50 m. In Fig. 7, the change in volume of the BKL-zone since the start of the nourishment in May 1993 is indicated. As per June 1994, the volume in the project area (between km 13.60 and km 18.20) has increased by 0.9 million cubic meter. Originally only 0.3 million cubic meter of sand was placed in the BKL zone. The additional 0.6 million cubic meter was transported landward by wave action, leading to cautious optimism with regard to the performance of the shoreface nourishment.

Fig. 7 Volume changes in the BKL zone after implementation of the shoreface nourishment over the period May 19, 1993 to June 20, 1994.

#### Acknowledgements

NOURTEC is a joint Dutch-German-Danish effort co-sponsored by the Commission of the European Communities under the Marine Science and Technology Programme (MAST-II), contract number MAS2-CT93-0049. Partners on the Dutch side are Rijkswaterstaat - National Institute for Coastal and Marine Management (RIKZ) and Utrecht University - Institute for Marine and Atmospheric Sciences (IMAU), on the German side the Coastal Research Station Norderney and on the Danish side the Danish Coastal Authority.

In the Netherlands the fruitful co-operation is acknowledged with the Rijkswaterstaat Directorates Noord Nederland and Noord Holland. Special thanks are due to mr. Edwin Biegel who was largely responsible for the analysis of the bathymetric monitoring data and for illustrating this contribution.

## CHAPTER 209

### IMPORTANCE OF PERMEABILITY IN THE SEDIMENTATION CONSOLIDATION PROCESS

A. Alexis<sup>1</sup>, P. Thomas<sup>1</sup>

#### ABSTRACT

This paper first presents a literature review of permeability laws. A link between hydraulics and geotechnics formulations is pointed out. Second, reduced permeability expressions are discussed from experimental data available in literature. An extended exponential expression of reduced permeability is proposed.

#### 1. INTRODUCTION

In coastal engineering, sedimentary transports and harbour silting are governed by the sedimentation-consolidation process.

The current modellings are based on:

- hydraulics laws for very low concentration soils (less than 100 g/l) applicable to sedimentation and using the settling velocity

- soil mechanics laws for high concentration soils (greater than 500g/l) applicable to consolidation and using permeability and effective stress.

Sedimentation-consolidation process is complex. Its settling velocity parametrisation has important limits, because of the lack of distinction between effective stress and permeability influences, and also because of the lack of account of consolidation.

On the other hand, we observe that the flow law is at the core of the confrontation between hydraulics and geotechnics approaches.

It is interesting to use an important flow law parameter : the permeability.

So, the topic of this paper is the analysis and the suitability of the permeability concept with the sedimentation-consolidation process.

We will select a main parameter which will allow us to use sedimentation and consolidation results.

---

<sup>1</sup>Civil Engineering Laboratory E.C.N.I.U.T. St NAZAIRE BP 420, F 44606 St-NAZAIRE CEDEX (FRANCE)

So, permeability is infinite and we can see, here, the great interest of a parametrisation by means of reduced permeability which remains finite.

So, we obtain a link between geotechnics and hydraulics, that is between consolidation and sedimentation, by means of reduced permeability.

Most representative theories for modelling sedimentation-consolidation process are Richardson's law and Kozeny's law.

First, the empirical Richardson's law corresponds to the beginning of the phase called hindered settling.

The settling velocity is linked to Stokes' velocity  $v_o$  and porosity  $n$ , which is a function of void ratio ( $n=e/(1+e)$ ):

$$v_s = v_o \cdot n^{4,65}$$

In this case, we deduced reduced permeability  $k_r$  as a power law of porosity :

$$k_r = k_{ro} \cdot n^{4,65}$$

Second, Kozeny's law corresponds to a porous media.

Permeability is a function of specific area  $a$ , viscosity and porosity :

$$k = \frac{\gamma_w}{h_k a} \cdot \frac{n^3}{2 \eta (1-n)^2}$$

It appears the Kozeny's constant  $h_k$ , which depends on grain shape and tortuosity of the flow between grains.

Usually,  $h_k$  equals 4.5.

For spheric grains, we obtain a formulation of reduced permeability with porosity :

$$k_r = \frac{\gamma_w d^2}{36 h_k \eta} \cdot \frac{n^3}{1-n}$$

Using Stokes' reduced permeability, we deduce a new relation between reduced permeability and porosity :

$$k_r = \frac{k_{ro}}{9} \cdot \frac{n^3}{1-n}$$

So, we can compare these 2 theories by means of the formulation of reduced permeability in function of porosity.

So, the reduced permeability  $k_r$  is the basic parameter which enables the link between hydraulics and geotechnics.

We compare the results of Kozeny's law and Richardson's law (fig.1)

It appears differences for values of porosity higher than 90% in the extremal condition of very low

concentration  $k_r$  remains finite for Richardson's law while  $k_r$  is infinite for Kozeny's law.

For porosities lower than 90%, the 2 curves are rather close.

Fig.1 Comparison of Kozeny's and Richardson's laws

So, for the middle concentrated mixtures which are the most interesting, we can consider that the hydraulics analysis of Richardson and the geotechnics analysis of Kozeny give quite similar results.

**3. INVENTORY OF EXPERIMENTAL LAWS AND CHOICE**

The experimental flow laws are numerous in litterature, as every experimenter, according to his speciality and the range of his measurements , looks for a particular shape , both simple and representative which is able to synthesize his values.

So, there is a lot of permeability laws with a lot of parameters.

We propose a methodology consisting in choosing main parameters, such as reduced permeability  $k_r$ , permeability  $k$  and void ratio  $e$  and then in translating settling velocity, porosity and concentration in terms of  $k_r$ ,  $k$  and  $e$ , and at last in gathering different laws to show the links and particular cases.

For this specific work, we are going to propose an original tree-shaped diagram (fig.2) showing the links between the different types of laws.

We are also going to propose new generic laws.

Two main families of experimental laws can be distinguished :

- power laws for reduced permeability in the upper part of this scheme.

- and logarithmic laws for permeability in the lower part of this scheme.

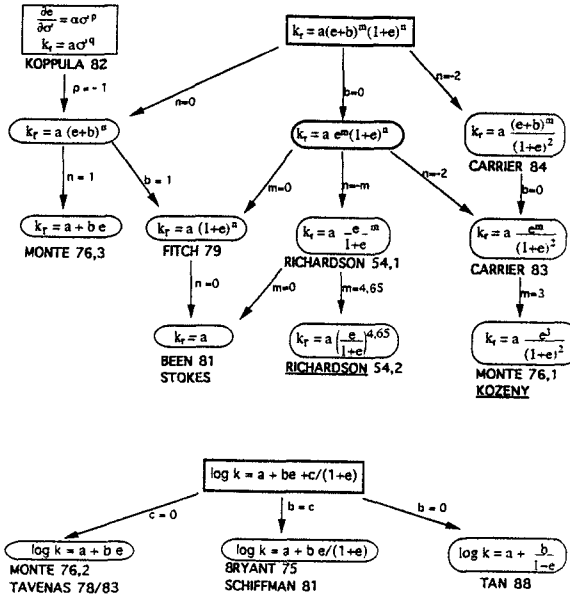

Fig.2: Synthetic arborescent scheme of reduced permeability laws

The name of each parametric constant  $a$ ,  $b$ ,  $m$ ,  $n$ , is only generic, for instance we have always named  $a$  the first parametric constant.

Each law is presented with his author and the year of its publication.

For gathering all this laws, we propose new generic laws (in bold). These new generic laws allow a general linkage between all the experimental laws.

In our representation, each stage corresponds to a number of parametric constant. So, we presents 16 laws with 1, 2, 3 or 4 parametric constants.

Once mathematical shapes are compared, we also compare the representative curve of these laws (Fig. 3).

For that, we choose an experimental data set with values of void ratio between 1 and 6 (these values are issued from experiments on clay ey-silt by YONG, 1982).

We study the 10 previous laws with 1 or 2 parameters.

For each law, we obtain the value of each parameter by means of a best fit method of regression on these experimental data.

Fig.3: Comparison of reduced permeability laws

In fig.3, experimental values are represented by dots, and each curve corresponds to 1 law.

Corresponding to Stokes'law, BEEN's law is not representative for our problem, neither Richardson 2, Kozeny, Monte 3 laws

We remark that TAN and BRYANT laws give the same curve.

Among these 10 laws, we have written, in the legend, five laws which seem to be representative.

Among these 5 best laws, Carrier's and Richardson 1's laws are the only ones that give a permeability zero where void ratio is zero.

So, we will choose these 2 most representative laws.

To conclude this comparison of curves, we can use 3 criterions :

- representativity
- adequacy with extremal conditions of Stokes with infinite value of void ratio, that is initial sedimentation.
- adequacy with extremal conditions of zero value of void ratio and permeability, that is final consolidation.

Carrier's law seems to be the most representative, but the law of Richardson 1 with 2 parameters has a better adequacy with the extremal condition of Stokes.

CRITERIONS	CARRIER'S LAW	RICHARDSON 1'S LAW
REPRESENTATIVITY	++	+
STOKES EXTREME (e infinite)	-	++
$k_r = 0$ (e=0)	++	++

Tab. 1 : Synthesis of comparison of curves.

#### 4. VALIDATION

The previous comparison allowed a first sorting of the laws of reduced permeability. These selected laws have to be validated over a much wider range. The bibliographic study reveals a lack of experimental data covering this range (down to a concentration of 50 g/l).

So, we are going to exploit a very large range of cohesive sediment data from different authors, for values of void ratio between 1 and 50 (concentrations between 1300g/l and 50g/l).

The conversion law of settling velocity into reduced permeability during pure sedimentation is :

$$v_s = \frac{\gamma'_s}{\gamma_w} k_r = 1.65 k_r$$

$$(\gamma_s = 26.5 \text{ kN/m}^3)$$

Figure 4 represents the reduced permeability data in function of void ratio.

Toorman's tests were expressed in terms of settling velocity, they have been continued until the beginning of consolidation, where the relation  $v_s$  equals  $1.65 k_r$  is not valid.

So, the previous conversion implies a left shift for the lowest dots of each set.

The regularity of the evolution confirms the concept of continuous process of sedimentation-consolidation.

So, we will keep 2 sets of experimentation data (set1 = Toorman 1 + Pane 1, Set 2 : Toorman 2 + Yong).

Previous figure (fig.4) was interesting but we have no continuous wide-distributed set of measurements.

In order to validate the laws in a wide field, we propose now to synthetise the 2 previous sets of experimentations.

By means of these coherent data sets, we will compare for each set :

- 3 theory-based laws (Richardson 1 and 2 and Kozeny)
  - and 2 selected laws (Richardson 1 and Carrier)
- Dots are experimental data of set 1 for figure 5 and set 2 for figure 6.

Fig.4: Evolution of experimental reduced permeability with void ratio

These 2 figures show again clearly that the one parameter laws (Richardson 2 and Kozeny) are not convenient.

The curve of Richardson 1 law (here with a power about 20) is not enough representative.

Carrier's law is well representative, and its shape is quasi-linear on this graph.

So, we propose a more simple power-typed law, for the whole range of void ratio between 1 and 50 (or concentration between 50 and 1 300 grains per liter) :

$$k_r = a e^b$$

Fig.5: Proposed law and other laws of reduced permeability with Set 1.

Fig.6: Proposed law and other laws of reduced permeability with Set 2.

## 5. CONCLUSION

The flow law is essential for the modelling of the sedimentation-consolidation process. We have shown the interest of the reduced permeability which links hydraulics and geotechnics.

We have described and compared theory-based laws. We have proposed a tree-shaped synthesis scheme which allows a gathering of laws, which are various as for their origins as for their shapes, and we have proposed new generic laws.

We have achieved a first selection of laws by means of one data set issued from bibliography in which void ratio is between 1 and 6. We have selected two laws, close to the theoretical ones by their shapes.

Then, we have validated by means of extended data sets in which void ratio is between 1 and 50. The position of the dots tends to confirm the continuity of the sedimentation-consolidation process. We have suggested to express the reduced permeability as an exponential law of the void ratio. We have thus extended the validity range of the reduced permeability concept and the concentration field of the modelling.

## 6. ACKNOWLEDGEMENTS

The present research on consolidation is undertaken as part of the MAST European program Coastal Morphodynamics (contract n°035).

## CHAPTER 210

### WAVE-CURRENT INTERACTION WITH MUD BED

Nguyen Ngoc An<sup>1</sup>  
Tomoya Shibayama<sup>2</sup>

#### ABSTRACT

A series of wave flume experiments for wave-current-mud system has been performed. The results reveal that the rate of wave attenuation increases in the opposing currents and decreases in the following currents. The results are the same with the waves on the fixed bed. Another important result is that the mud mass transport velocity increases in the opposing currents and decreases in the following currents. The visco-elastic-plastic model which was proposed by Shibayama and An (1993) for wave-mud interaction has further been extended to the wave-current-mud system by taking a wave deformation effect into considerations. The extended model succeeds in predicting the laboratory results. The model shows that due to pressure gradient in wave propagating direction, the largest mud mass transport velocity occurs in the strongest opposing current and the smallest one in the strongest following current.

#### INTRODUCTION

The wave-current interaction is a phenomenon of considerably practical interest. Also waves traveling on mud bed is another important phenomenon because these results in high wave attenuation (Gade, 1958 and Tubman and Suhayda, 1976) and large mud mass transport (Sterling and Strohbeck, 1973).

---

<sup>1</sup> D. Eng., Department of Civil Engineering, HCMC University of Technology

<sup>2</sup> D. Eng., Associate Professor, Department of Civil Engineering, Yokohama National University

The wave-current interactions on fixed bed have been studied through both laboratory experiments and mathematical analyses (Brevik and Aas, 1980, Thomas, 1981, etc.). And it is known that currents introduced into wave field make change of wavelength and wave height. The wave-current interactions on the mud bed have not yet been studied well, and therefore their effects on the mud mass transport velocity and the wave attenuation remain unclarified. In order to evaluate wave attenuation rate under this condition, Nakano et al. (1989) tried to include current effect to their multi-layered viscous fluid model (Tsuruya et al., 1987). But the results are not well compared with their own laboratory data.

These interactions among wave, current and mud will be investigated through both laboratory experiments and the numerical model in the present study.

## **THEORETICAL CONSIDERATIONS**

It is understood that the pressure gradient of water waves is much more important than shear stress at the interface between the water layer and the mud layer in creating movement of mud in the mud bed. In the mathematical formulation, it is assumed that the wave attenuation process will take place after waves are deformed due to the currents. This means that the mud bed responds only to the deformed waves resulting by the wave-current interaction. This assumption will be later justified with the laboratory experiments. It is also assumed that the current itself has no effect on the mud mass transport in the bed layer. The experimental results of Otsubo and Muraoka (1986a) can be used to justify the latter assumption. It was found that when currents flow over mud bed, sediments are transported only in the water layer by the current if they are suspended or if the bed surface is massively destroyed. No mass transport in the mud layer was reported. In the followings, two models which describe the two processes will be present.

### **Model of Wave Deformation due to Current**

In this process, no energy loss is taken into account while formulating the model of wave deformation due to the currents. Two main parameters of deformed waves are the wave height and the wavelength. The accuracy in

predicting the wavelength variation using the dispersion relation has been verified (Thomas, 1981). The accuracy in predicting the wave height variation, however, depends on the nature of currents. Several models are available. Longuet-Higgins and Stewart (1961,1964) assumed that the current was irrotational and its profile was uniform over depth. Jonsson et al. (1978) solved for rotational currents by assuming current with constant vorticity. Thomas (1981) numerically solved for more general case by considering current to be a function of elevation from bottom. In a simple case where the depth-averaged velocity was used, he found that the model well predicted the wavelength and wave height variations.

Under steady condition following Thomas (1981) for the simple case, the conservation equation for wave action is (Bretherton and Garrett, 1969; Whitham, 1974; Brevik and Aas, 1980)

$$\frac{E}{\sigma}(U + C_{gr}) = \text{const.} \quad (1)$$

where  $E$  is the wave energy,  $\sigma$  is the relative angular frequency defined by  $\sigma = \omega - kU$ ,  $\omega$  is the absolute angular frequency,  $U$  is the mean depth-averaged current velocity,  $k$  is the wave number, and  $C_{gr}$  is the group wave velocity. Because the wave energy is proportional to the square of wave height,  $H$ , Eq. (1) can be rewritten as:

$$\frac{H^2}{\sigma}(U + C_{gr}) = \text{const.} \quad (2)$$

The wavelength variation is obtained from the usual irrotational dispersion relation as follows:

$$(\omega - kU)^2 - gk \tanh kd_i = 0 \quad (3)$$

where  $d_i$  is the water depth. Following Thomas (1981), in order to use Eqs. (2) and (3), it is necessary to specify a reference level to define the constant in Eq. (2). The reasonable choice of reference level is the values with no current. This introduces the quantities  $H_0$  and  $L_0$ , corresponding to the wave height and the wavelength respectively when no current exists.

### **Model of Wave-Current Interaction on the Mud Bed**

The model of wave-mud interaction which was developed by Shibayama and An (1993) is used. In this process, the model of wave-mud system is extended

to the wave-current-mud system by taking the wave deformation effect into consideration. For example, the free surface displacement is given by  $\eta_1(x,t) = a_1 \cdot \exp[i(kx - \sigma t)]$ , where  $a_1$  is the deformed wave amplitude due to the current and determined by Eq. (2).

The rheological equation and the governing equations are modified here while making use of new parameters.

(1) Rheological equations are the followings:

$$\sigma'_{ij} = 2\mu_e e'_{ij} \tag{4}$$

$$\text{where } \mu_e = \begin{cases} \mu_1 + \frac{iG}{\omega} & \left( \frac{1}{2} \sigma'_{ij} \sigma'_{ij} \leq \tau_y^2 \right) \\ \mu_2 + \frac{\tau_y}{\sqrt{4|\Pi_e|}} & \left( \frac{1}{2} \sigma'_{ij} \sigma'_{ij} > \tau_y^2 \right) \end{cases} \tag{5}$$

and  $\sigma'_{ij}$  and  $e'_{ij}$  are stress and strain tensors, the prime indicates the deviator of these two tensors, the dot indicates derivative with time.

(2) Governing equations are the followings:

$$\frac{\partial \hat{u}_j}{\partial x} + \frac{\partial \hat{w}_j}{\partial z} = 0 \tag{6}$$

$$\frac{\partial \hat{u}_j}{\partial t} = -\frac{1}{\rho_j} \frac{\partial \hat{p}_j}{\partial x} + \nu_{e,j} \left( \frac{\partial^2 \hat{u}_j}{\partial x^2} + \frac{\partial^2 \hat{u}_j}{\partial z^2} \right) \tag{7}$$

$$\frac{\partial \hat{w}_j}{\partial t} = -\frac{1}{\rho_j} \frac{\partial \hat{p}_j}{\partial z} + \nu_{e,j} \left( \frac{\partial^2 \hat{w}_j}{\partial x^2} + \frac{\partial^2 \hat{w}_j}{\partial z^2} \right) \tag{8}$$

where  $\hat{u}$  and  $\hat{w}$  are the horizontal and vertical components of orbital velocities,  $\nu_{e,j}$  is the kinematic viscosity of mud and  $\hat{p}$  is the dynamic pressure.

(3) The solutions are put to be the following forms:

$$\hat{u}_j(x,z,t) = u_j(z) \exp[i(kx - \sigma t)] \tag{9}$$

$$\hat{w}_j(x,z,t) = w_j(z) \exp[i(kx - \sigma t)] \tag{10}$$

$$\hat{p}_j(x,z,t) = p_j(z) \exp[i(kx - \sigma t)] \tag{11}$$

## EXPERIMENTAL SET-UP AND METHODOLOGY

### Set-up

The experiments were carried out in a flume at the Department of Civil Engineering of Yokohama National University, Japan. The length of the flume was 17m, the width was 0.6m and the total depth was 0.55m. The still water depth was 30cm during experiment on the fixed bed and 26.3 cm on the mud layer of 8cm. Figure 1 shows the experimental set-up with the mud bed.

### Instrumentation

Wave heights were measured by means of electric capacitance wave gauges. Two sensors with distance of 50cm were installed at the movable carriage to measure water elevations at every half meter along the flume. The signals from the sensors were amplified and digitally recorded for 1030 records at the frequency of 20Hz. Using the technique introduced by Goda and Suzuki (1976), the incident and reflected waves were estimated.

Horizontal component fluid velocities were measured with a Fiber-Laser Velocimeter. Steady current velocity at one point was taken as an average value of all data recorded in certain duration.

Table 1: Wave damping coefficients in wave-current condition.

Run No.	$T$ (s)	$H$ (cm)	$U$ (cm/s)	$d_t$ (cm)	$k_i$ (1/m)	Remarks
W1	1.01	3.49	0.00	30.0	0.0036	fixed bed

WC4	1.01	2.98	16.65	30.0	0.0027	fixed bed
WC5	1.01	4.48	-19.11	26.3	0.1032	mud bed
WC6	1.01	4.48	-9.00	26.3	0.0840	mud bed
WW7	1.01	4.48	0.00	26.3	0.0718	mud bed
WC8	1.01	4.48	8.10	26.3	0.0624	mud bed
WC9	1.01	4.48	18.64	26.3	0.0543	mud bed

Mud mass transport velocities were measured from movement of colored mud used as a tracer. The technique introduced by Sakakiyama and Bijker (1989) was adopted.

### **Experimental conditions**

Table 1 shows the experimental conditions of waves and currents. The mixture of 158% water content of commercial kaolinite and fresh water was used for the bed material when the experiments on the mud bed were conducted.

## **RESULTS**

### **Wave height variation due to current**

(1) Measurement of wave heights on fixed and mud beds.

Firstly, the reference values of wave amplitude were measured. A problem arose when the location for references was selected to ensure the condition of Eq. (2). On the fixed bed, there is no problem since the wave attenuation is expected to be small. On the mud bed, however the wave attenuation rate is rather high. In this experiment, the location for references  $x=0$ , was chosen at front edge of the mud layer. This selection was based on the assumption that the high wave attenuation is supposed to start when the waves come to the mud bed.

Currents were generated and the velocity profiles were measured. These currents were superimposed with progressive waves produced by the wave generator. The input data of wave period  $T$ , wave height  $H$ , and water depth  $d_1$  were the same for all runs. The actual wave amplitudes were then measured at  $x=0$  for various current velocities. The measured values of  $H$  and the corresponding predicted value of  $L$  are listed in Table 2, where the subscript 0 here indicates the condition without current generation.

(2) Results.

The experimental results on the wave height variation are shown in Table 2. Figures 2 and 3 show the wave height variation for various current speeds on the fixed bed and on the mud bed, respectively. It was seen that the strongest opposing currents yielded the biggest wave heights on both the fixed and mud beds.

Table 2: Wave height variation due to currents.

Run No.	$U$ (cm/s)	$H$ (cm) Measured	$H$ (cm) Predicted	$H/H_0$ Measured	$H/H_0$ Predicted	$L_0$ (cm)
WC2	-16.0	3.72	3.88	1.25	1.30	113
WC1	-7.34	3.23	3.32	1.08	1.11	128
W2	0.00	2.98	2.98	1.00	1.00	139
WC3	5.58	2.78	2.79	0.93	0.93	147
WC4	16.65	2.66	2.48	0.89	0.83	162
WC5	-19.1	6.00	6.21	1.34	1.39	104
WC6	-9.00	4.91	5.11	1.10	1.14	121
WW7	0.00	4.48	4.48	1.00	1.00	134
WC8	8.10	4.07	4.07	0.91	0.91	145
WC9	18.64	3.64	3.66	0.81	0.82	159

The comparisons of the measured and predicted wave heights are showed in Table 2 and in Figs. 2 and 3. Good agreements are seen. The assumption in which the mud bed responds only to deformed wave are therefore justified.

#### Wave attenuation due to interaction with current

To estimate the wave attenuation quantitatively, a first approximation is to assume an exponential decay law of wave height:

$$H = H_{x=0} \exp(-kx) \quad (12)$$

where  $H_{x=0}$  is the initial wave height at  $x=0$ ,  $H$  is the wave height at  $x$  and  $k$ , is the wave attenuation rate (or wave damping coefficient). This approximation is similarly supported by theoretical and experimental investigations of Keulegan (1950) and Iwasaki and Sato (1972). Although, this is only a first approximation, it turned out to be well fitted in representing present laboratory data both on the fixed and mud beds.

#### (1) Wave attenuation on the fixed bed by current interaction.

Although the present work mainly deals with the mud bed, one test with fixed bed was first conducted. The purposes of this test were given as follows. The first purpose was to check the wave attenuation rate with the ones obtained in previous works. The second one was to estimate a magnitude of wave attenuation rate from which the effects of currents and the effects of mud bed can be easily distinguished in the later experiments over the mud bed.

The experimental results on the wave attenuation rate,  $k_i$ , for the case  $T=1.01$ s and  $H_0/L_0=0.021$ , are shown in Fig. 4 and in Table 1 for several values of current speed. The values of  $k_i$  were determined on the basis of regression analysis. The vertical line lengths represent standard deviations. The small standard deviations mean that the reliability is high in evaluating the wave attenuations.

There is a clear tendency in which  $k_i$  is the greatest in the strongest opposing currents and decreases slowly with the following currents. As long as the bottom boundary layer is laminar, the increase of wave number will result in the increase of energy dissipation rate. The opposing currents made the wavelength shorter. The wave number therefore increased and the higher wave attenuation rates were seen. On the other hand, the following currents made the wavelength longer. The wave number, therefore, decreased and the lower wave attenuation rates were seen.

It should be noted that the values of  $k_i$ , around  $0.004 \text{ m}^{-1}$ , obtained in the present experiment are close to the theoretical value about  $0.002 \text{ m}^{-1}$  given by Hunt (1952). These values are, however, relatively small compared to the ones of  $0.02 \text{ m}^{-1}$  obtained by Iwasaki and Sato (1972) and of  $0.01 \text{ m}^{-1}$  by Brevik (1980). The reason for this difference can be explained as follows. The incident wave heights were used in the present work to analyse wave attenuation. The closeness of present values to the theoretical ones is reasonable as long as only progressive waves are concerned.

The results of runs W1 and W2 given in Table 1 show that the same wave attenuation rates were obtained with different wave heights. Examination of the wave conditions in these tests indicated that the bottom boundary layers were laminar because the maximum Reynolds number of 3215 in the tests was smaller than the critical one of  $1.26 \times 10^4$  (Jonsson, 1966). The wave attenuation rates should, therefore, be same because they do not depend on the initial wave heights as long as the bottom boundary layers are laminar (Ippen, 1966).

## (2) Wave attenuation on the mud bed due to interaction with current.

The effect of currents on the wave attenuation is again considered in this part.

Figure 1: Sketch of experimental set-up.

Figure 2: Wave height variation due to currents on the fixed bed.

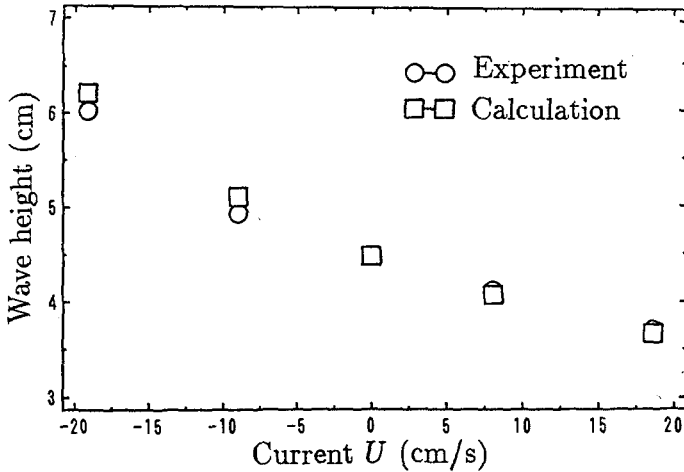

Figure 3: Wave height variation due to currents on the mud bed.

Figure 4: Effect of currents on wave attenuation on the fixed bed.

The experiments were carried out on the mud bed. Similarly, the experimental results of  $k_i$ , for the case  $T=1.01s$  and  $H_0/L_0=0.013$ , are shown in Fig. 5 and Table 1 for several values of current velocity. The wave attenuation rate is the highest in the strongest opposing currents and decreases in the following currents, in the same manner with the waves on the fixed bed. Although the same tendency of wave attenuation are found for waves on the fixed bed and the mud bed, the magnitudes of wave attenuation for waves on the mud bed are one order of magnitude greater than the ones for waves on the fixed bed. It was confirmed again that the mud bed enhances wave attenuation.

These laboratory results are now utilized to verify the numerical model. The comparison between the laboratory data and the computed ones are shown in Fig. 5. The model predicts the highest wave attenuation rate in the strongest opposing currents and the lowest wave attenuation rate in the fastest following currents, in the same manner with the wave attenuation which varied with the current speeds observed in the experiments. In terms of the absolute magnitudes, the model also predicts well the wave attenuations in all cases of various current speeds except in the case of strongest opposing current where the model gives underestimation. The strongly nonlinear wave pattern in the strongest opposing current might be the reason for this underestimation because the model is based on the linear waves.

Figure 5: Effect of currents on wave attenuation on the mud bed.

### Mud mass transport velocity under wave-current interaction

#### (1) Measurements.

The mud mass transport velocity is the average velocity obtained from the measured displacement over the duration of experiment. The duration time, therefore, was a decisive factor in determining the mud mass transport velocity. A long duration would render the mud surface slope tilted at the onshore end and less mud mass transport might be resulted. On the other hand, if a very short duration was applied, the effect of inertial force and thixotropy effect would become profound. By trial and by carefully observing the formation of mud surface slope, the proper duration was selected to be from 65 s to 75 s. For each run, the mud mass transport was measured at the location of 1.0 m downstream of the front edge of the mud layer.

#### (2) Mud mass transport velocity.

A series of five runs with various current speeds was performed in order to analyse the effect of currents on the mud mass transport velocity.

Before comparisons are made between the calculated results with the laboratory data some parameters used in calculation are explained here. The parameters  $\mu_1$  and  $G$  were given by Shibayama and An (1993). The values of  $\mu_2 = 4.5 \text{ N s/m}^2$  and  $\tau_y = 17.0 \text{ N/m}^2$  are chosen by being fitted to mud mass transport velocity and wave attenuation rate in the case of no current, and then

Figure 6: The comparison between the experimental and calculated results on mud mass transport velocity. a) Run WC5: $T=1.01s$ ,  $U=-19.1 \text{ cm.s}^{-1}$ , b) Run WC6: $T=1.01s$ ,  $U=-9.0 \text{ cm.s}^{-1}$ , c) Run WW7: $T=1.01s$ ,  $U=0$ , d) Run WC8: $T=1.01s$ ,  $U=+8.1 \text{ cm.s}^{-1}$ , e) Run WC9: $T=1.01s$ ,  $U=+18.6 \text{ cm.s}^{-1}$ .

applied them for other calculations with currents.

The results of mud mass transport velocity at  $x=1.0\text{m}$  in five runs are shown in the Fig. 6. There is a trend that the mud mass transport velocity is biggest in the strongest opposing current and decreases with increasing current in the positive direction. This trend can also be predicted by the numerical model. The good agreement between the experimental results and the computed ones confirms that the numerical model on the wave-mud interaction can further be extended to predict the wave-current-mud interaction by taking wave deformation effect into consideration. The effect of currents on mud transport can be explained by the wave deformation due to current as follows. In the opposing currents, the water pressure gradient at the water-mud interface becomes great as the wave height increases and the wavelength decreases, and this change causes to yield large mud transport. In the following currents, the pressure gradient becomes small as the wave height decreases and the wavelength increases and this results small mud transport.

## CONCLUSIONS

From the present study, some conclusions on the wave-current-mud interaction are drawn as follows.

- (1) Usage of the incident wave height improves the reliability of analysis of wave attenuations significantly.
- (2) Wave attenuation increases in the opposing currents and decreases in the following currents on both the fixed and mud bed.
- (3) Wave height variation due to wave-current interactions on the mud bed can be predicted well by a simple model of irrotational slowly-varying current.
- (4) The mud mass transport velocity increases in the opposing currents and decreases in the following currents.
- (5) The numerical model for the wave-mud interaction has further been extended for the wave-current-mud interactions by taking a wave deformation effect into consideration. The extended model succeeded in predicting the

laboratory results that the largest mud mass transport velocity and highest rate of wave attenuation occur in the strongest opposing current and the smallest and lowest ones in the fastest following current.

## CHAPTER 211

### On Residual Transport in Shallow Tidal Basins <sup>1</sup>

Andrea Balzano <sup>2</sup>

#### Abstract

In the paper the influence of some physical and numerical effects on computations of residual transport in shallow tidal basins is analysed. Investigations deal with: i) the Coriolis acceleration, ii) the specification of the tidal forcing, iii) the diffusion coefficient, iv) a time weight in a standard implicit numerical scheme. The analysis has been carried out by means of intratidal mathematical models with reference to three schematic basins, with the tide being the only forcing of the system. These are typical conditions in which critical environmental events like anoxia occur. Usual assumptions in mathematical modeling of 2D flows in shallow basins regarding the above effects are tested both in the short and long term. The different importance of that effects depending on both the time scale of processes and the basin morphology is shown. Results are presented in terms of turbulence-time-averaged circulation patterns, Lagrangian residual circulation patterns, distributions of relative differences induced in the latter by including or not the investigated effects, and convection-dispersion of a passive solute.

#### 1. Introduction

Environmental modelling of a tidal basin generally requires long-term hydrodynamic and transport simulations. For such a task, either *intratidal* and *intertidal* mathematical models could be seen as proper tools from a cost-benefit point of view, depending on the actual time extent of the simulations required for the specific problem to be solved (weeks, months, years, etc.). However, whatever the model used, one is essentially interested in the net (residual, *intertidal*) transport over a time extent of the order of the period of a representative tidal component - typically, 12-24 hours - rather than in a detailed description of the motions occurring at a smaller (*intratidal*) time scale.

It is well known that residual transport is strongly influenced by the nonlinearities acting in water motion (Van de Kreeke, 1976; Zimmermann, 1979)

---

<sup>1</sup>Research carried out with the financial support of Sardinia Regional Authorities.

<sup>2</sup>Research Engineer, CRS4, Centro di Ricerca, Sviluppo e Studi Superiori in Sardegna - Centre for Advanced Studies, Research and Development in Sardinia, Via Nazario Sauro 10, 09123 Cagliari, Italy, E-mail: balzano@crs4.it.

and usually at least one order of magnitude smaller than the tidal excursion. Thus, typical schematizations that are commonly accepted - and acceptable, indeed - when dealing with turbulence-time-averaged quantities could no longer be so when, based on the relevant, intratidal, velocity fields, computations of residual fields are to be performed. This, as long as results may be seriously influenced by effects - either physical or numerical - that are minor factors at smaller time scales.

Many studies about residual circulation can be mentioned, concerning fields of quite different characteristics: harbours (Falconer, 1985), estuaries (Cheng and Casulli, 1982), open sea (Maier-Reimer, 1977). A great deal of research work has been done on Mediterranean lagoons, even with environmental safeguard purposes (O' Kane et al., 1990; Avanzi e Fiorillo, 1983; Cioffi e Gallerano, 1990; Dejak et al., 1990; Cioffi et al., 1994; Defina e D'Alpaos, 1994). Indeed, such water bodies are particularly liable to environmental hazards due to their relatively weak refreshment capability. However, fewer studies of their long term dynamics by field-verified mathematical models exist.

As a preliminary step to the implementation of a water quality forecasting system for eutrophic water bodies in the island of Sardinia, the influence of some of the above mentioned effects on residual transport has been analysed by means of intratidal mathematical models. Since the system is to be applied primarily to relatively small and shallow lagoons, the analysis has been carried out on schematic tidal basins whose geo-morphological characteristics resemble those of such natural water bodies. However, several mediterranean tidal basins match these general features as well. The present investigation is then to be seen as a specific contribution, strictly significant for the particular class of water bodies mentioned above.

Moreover, at this stage particular environmental conditions are considered like those eventually determining anoxia in the water body. These are essentially high temperature and the absence of wind, the latter being of major importance for the setup of residual circulations. Results are then to be intended as realistic for time extents not longer than, say, one month, in the summer season.

## 2. Description of numerical experiments

In the numerical experiments the three prototypes shown in fig. (1) have been considered, namely: (a) a completely flat, 1 m deep, basin with a 400 m long by 800 m wide inlet, whose axis coincides with the symmetry axis of the basin, sided by two expansions whose dimensions are 4000 x 4000 m; (b) a similar basin, in which the central, 800 m wide, strip is occupied by a 5 m deep channel; (c) a basin in which the depth varies gradually from 5 m in the central strip to 1 m at the lateral borders of the expansions. The tidal range at the entrance of the inlet is assumed of the order of 1 m; a latitude of 45° is considered. For the three prototypes and for the various effects investigated, comparisons have been made between either the two-dimensional, depth averaged, Lagrangian residual circulation fields and the results of a stochastic convection-dispersion model based on the random-walk technique.

The influence of the following factors on residual transport has been investigated: i) the Coriolis acceleration; ii) the specification of the tidal forcing at the basin inlet; iii) the diffusion coefficient,  $K$ , in the equation of motion; iv) the time weight,  $\alpha$ , of the finite difference implicit scheme for both the divergence of fluxes in the equation of continuity and the gradient of the free surface elevation in the equation of motion.

For the computations of the intratidal velocity fields a 2D finite difference, Eulerian-Lagrangian, hydrodynamic model was employed. This is based on the usual shallow water equations

$$\frac{\partial \eta}{\partial t} + \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} = 0$$

$$\frac{\partial U}{\partial t} + \frac{\partial(uU)}{\partial x} + \frac{\partial(vU)}{\partial y} + gh \frac{\partial \eta}{\partial x} - K \nabla^2 U - \frac{\tau_{sx}}{\rho} + g \frac{\sqrt{U^2 + V^2}}{k_s^2 h^{7/3}} U - fV = 0 \quad (1)$$

$$\frac{\partial V}{\partial t} + \frac{\partial(uV)}{\partial x} + \frac{\partial(vV)}{\partial y} + gh \frac{\partial \eta}{\partial y} - K \nabla^2 V - \frac{\tau_{sy}}{\rho} + g \frac{\sqrt{U^2 + V^2}}{k_s^2 h^{7/3}} V + fU = 0$$

where  $x, y$  are the cartesian coordinates in the horizontal plane;  $t$ , the elapsing time;  $u, v$  and  $U, V$ , respectively the mean velocity and unit width discharge components in the  $x$  and  $y$  directions;  $g$ , gravity acceleration;  $\eta$ , free surface elevation above a datum;  $h$ , total depth;  $K$ , the horizontal diffusion coefficient;  $\tau_{sx}$  and  $\tau_{sy}$ , respectively the  $x$  and  $y$  components of the surface stress;  $\rho$ , the density of water;  $k_s$ , the Strickler roughness coefficient ;  $f = 2\omega \sin \varphi$ , the Coriolis parameter;  $\omega$ , the angular speed of the earth's rotation;  $\varphi$ , latitude.

A fourth order Lagrangian method for the treatment of the convective terms and a real bidimensional solution of propagation ensures the correct representation of the velocity fields even in the presence of a dramatically irregular bathymetry (Benqué et al., 1982; Balzano, 1993). Lagrangian residual velocity fields were computed on the basis of the following definition (Cheng and Casulli, 1982)

$$\mathbf{v}_{lr}(\mathbf{x}_o, t_o) = \frac{1}{T} \int_{t_o}^{t_o+T} \mathbf{v}[y(\mathbf{x}_o, t), t] dt \quad (2)$$

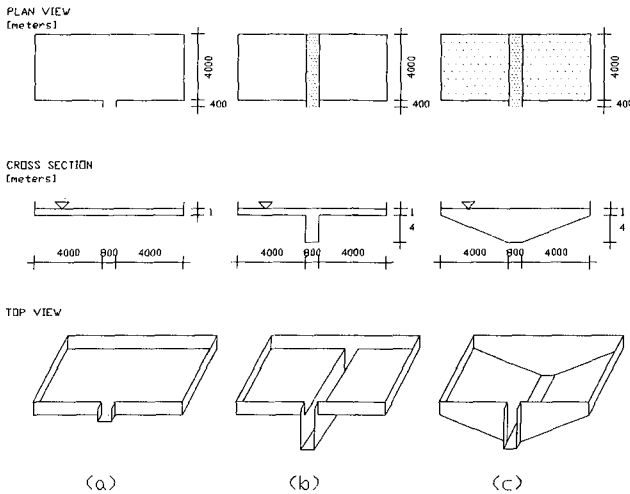

Figure 1: Schematic test basins

where  $\mathbf{v}_{lr} \equiv (u_{lr}, v_{lr})$  is the Lagrangian residual velocity computed in the point of coordinates  $\mathbf{x}_o$  for the tidal phase  $t_o$ ;  $T$  is the tidal period;  $\mathbf{v}(\mathbf{x}, t) \equiv (u, v)$  the eulerian velocity;  $\mathbf{y}(\mathbf{x}_o, t)$  the coordinates of the trajectory of a passive tracer released in the point  $\mathbf{x}_o$  at time  $t_o$ . In the numerical integration (2), the time step was assumed as  $\Delta t = \min \left\{ \frac{\Delta x/n}{u}, \frac{\Delta y/n}{v} \right\}$ , with  $n = 5 \div 10$  and  $\Delta t \leq 10 \div 30$  s. Numerical convergence of the residual velocity fields required time steps down to  $60 \div 120$  s in the hydrodynamic model, corresponding to values of the Courant number  $Cr=0.7 \div 3$ . Incidentally, it is remarked that this suggests the feasibility of resorting to explicit or ADI models for this kind of problems. This, particularly in the case that developments on parallel computers are foreseen to achieve higher computational speed.

In the stochastic transport model a mass of passive solute is represented as a "cloud" of mutually independent particles, subject to the resultant of the deterministic mean flow velocity and random fluctuations (Ghoniem and Sherman, 1985; Maier-Reimer and Sundermann, 1982)). Gaussian random displacements, uncorrelated in the directions normal and tangent to the trajectory were assumed. These are computed on the basis of the relevant longitudinal and transverse components of the dispersion tensor,  $K_l$  and  $K_t$ , as given by Elder formulas, i.e.  $K_l = 5.93 u^*h$ ,  $K_t = 0.23 u^*h$ , where  $u^*$  is the shear velocity. Thus, also dispersion due to vertical shear is represented. Computed values of the above diffusion coefficients are in agreement with those obtained by others with subgrid scale energy techniques for similar water bodies (Pfeiffer et al., 1988).

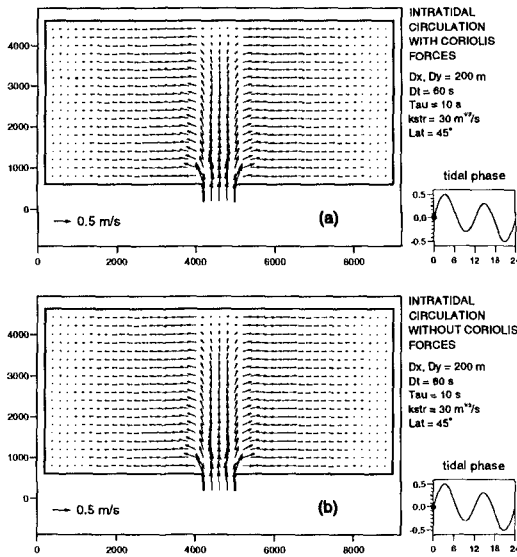

Figure 2: Intratidal circulation velocity field in a flat, 1 m deep, tidal basin with a central, 5 m deep, channel, computed (a) with and (b) without the Coriolis forces

3. Results

3.1 Coriolis acceleration

Classical order of magnitude analysis of the governing equations shows that Coriolis forces are negligible compared to convective terms whenever the Rossby number,  $Ro = \frac{v^*}{2\omega L^*}$ , is large,  $v^*$  and  $L^*$  being a characteristic velocity and length (Pedlosky, 1987). Moreover, they can be small compared to bottom friction in the presence of relatively small water depth and large bottom roughness. As a matter of fact, Coriolis forces are usually regarded as a minor factor in lagoons on the basis of the above arguments (Morandi Cecchi, 1989) and therefore neglected in real case studies (Chignoli e Rabagliati, 1977; Volpi e Sguazzero, 1977; Umgiesser et al., 1988, 1993; Rosso et al., 1993; Cioffi et al., 1994). If only intratidal fields are required, for a number of practical applications it can be agreed upon this choice. As an example, in fig. (2) the instantaneous (i.e. turbulence-time-averaged) velocity fields at mean flood tide in the basin with channel, computed (a) with and (b) without the Coriolis terms included, are shown. For a significant comparison Strickler roughness coefficients down to  $k=30 \text{ m}^{1/3}\text{s}^{-1}$  were assumed in the computations. Indeed, this value corresponds to a rather rough bottom and results from calibrations of models with field data (Umgiesser et al., 1988). In order to avoid problems arising when a uniform level is directly imposed in the presence of the Coriolis forces (Cheng e Walters, 1982), the same symmetrical time series of discharges has been imposed at the inlet as common boundary condition. This was deduced from preliminary computations with the Coriolis terms not included, for a reference mixed tide of 1 m of range. This is composed of a semidiurnal component of amplitude  $a_s = 0.4 \text{ m}$  and a diurnal component  $a_d = 0.141 \text{ m}$  with the same phase.

Clearly, hardly significant differences can be perceived between the two patterns, even in details. Even though differences are more evident near the high and low tide, nonetheless it is agreeable that a reliable description of the instantaneous circulations can be obtained without the inclusion of the Coriolis terms. However, residual velocity fields based on intratidal fields computed including or not the Coriolis terms show significant differences for all the three prototypes, particularly for the flat and the channeled basin. In the former (see fig. (3)), quite different locations of the centers of the macro-vortexes can be observed, while in the latter (see fig. (4)) a large zone of close recirculation is not reproduced without the inclusion of the Coriolis terms. This occurs also in the third basin, but with narrower recirculating eddies. It is to be noted that not only the test basins are given a remarkable roughness, but also they are much smaller than the real water bodies for which Coriolis effect was assumed as negligible in the references previously quoted, i.e. the Venice lagoon ( $550 \text{ km}^2$ ).

A quantitative analysis has been carried out, resulting in curves of the cumulative frequencies,  $F(S)$ , of the relative differences,  $S$ , between the values of the residual velocity components in the grid nodes as computed in the two cases. These are plotted for various tidal phases, to which Lagrangian residual quantities are sensitive (phase 0 = flood, mean tide). Also, these curves are plotted for different threshold values,  $\Theta$ , of the velocity components in order to point out whether large relative differences affect even the greatest velocity components in the residual field. In symbols:

$$S_w(\Theta) = \left| \frac{w_{i,j}^a - w_{i,j}^b}{w_{i,j}^a} \right| \quad \text{with} \quad w_{i,j}^a \geq \Theta \text{ OR } w_{i,j}^b \geq \Theta ; \quad w = u_r, v_r$$

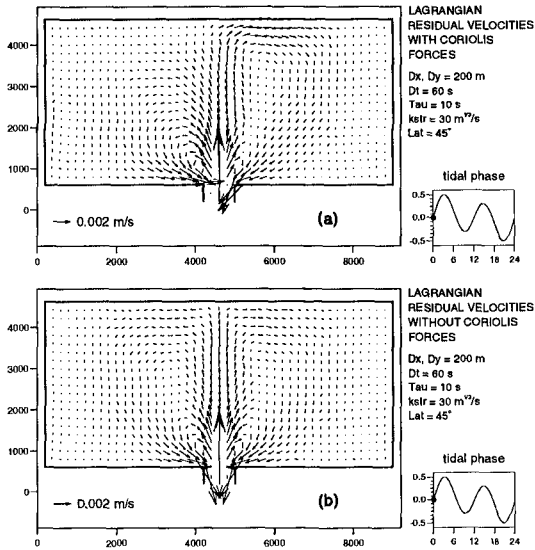

Figure 3: Lagrangian residual circulations in a flat, 1 m deep, tidal basin computed (a) with and (b) without the Coriolis forces

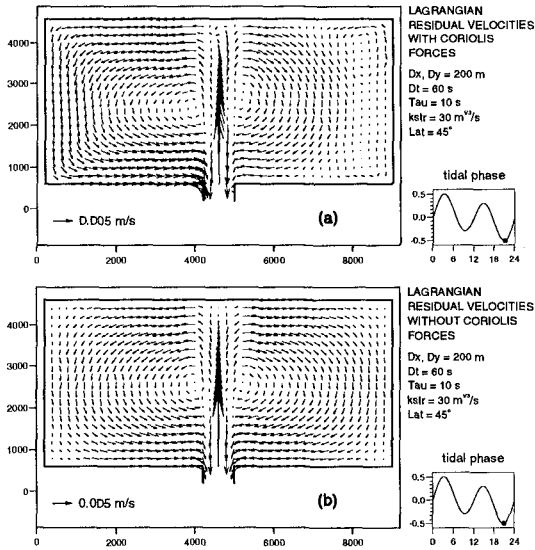

Figure 4: Lagrangian residual circulations in a flat, 1 m deep, tidal basin with a central, 5 m deep, channel, computed (a) with and (b) without the Coriolis forces

In fig. (5a-c) such curves computed for the three basins in the cases that Coriolis forces were included or not are shown. For instance, for the flat basin (fig. (5c)) it is seen that not only the about 1100÷1350 values of residual velocity components greater than 0.0001 m/s – whatever the tidal phase – but also the 26 values greater than 0.002 m/s – for the 0/8 tidal phase – still exhibit significant relative differences, i.e. even greater than 100%. More impressive

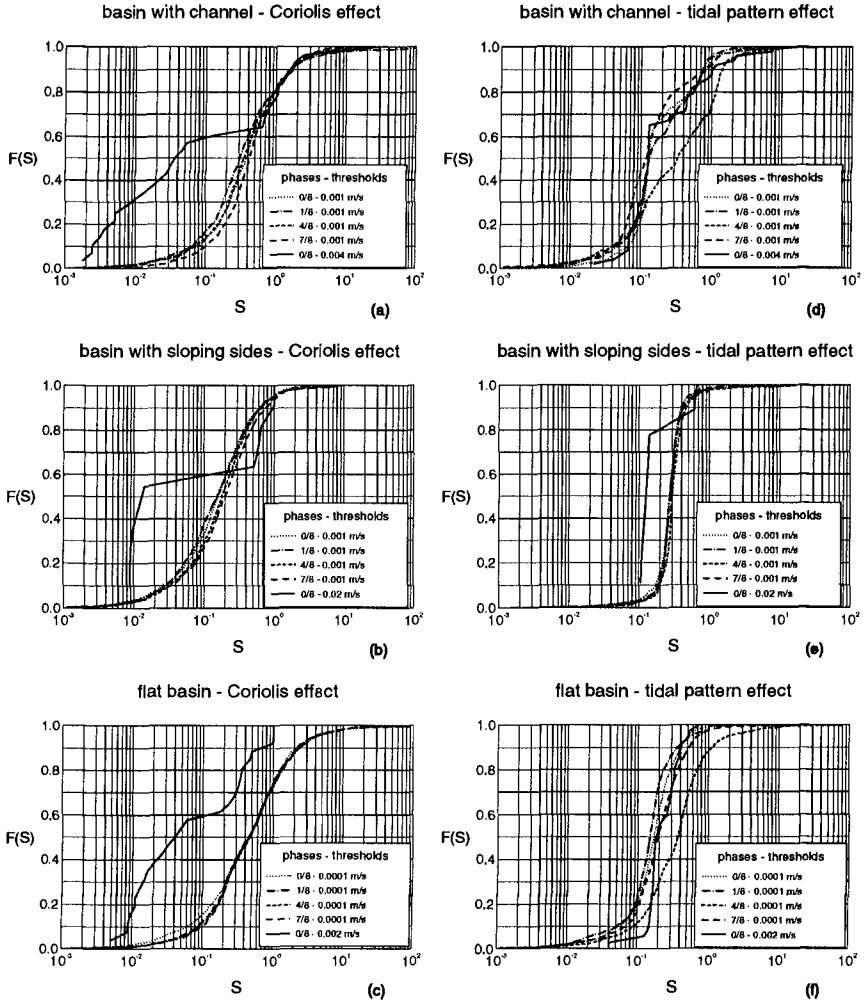

Figure 5: Curves of the cumulative frequencies,  $F(S)$ , of the relative differences,  $S$ , between residual velocities components computed for the three test basins (a-c) with the mixed tide including or not the Coriolis terms and (d-f) with the Coriolis terms considering the semidiurnal or the mixed tide

results obtained with the stochastic transport model will be shown further on, together with analogous results from analysis of the effect of the tidal pattern.

### 3.2 Specification of tidal wave at open boundaries

The second comparison has been carried out between the specification of a semidiurnal and a mixed tide (see fig. (6c,b)) as boundary condition of the hydrodynamic model. Indeed, the latter is the basic pattern of a possibly more complicated real tide like that shown in fig. (6a). This general behaviour can be observed at Mediterranean coasts, as well as at many other sites in the world. However, in literature cases can be mentioned in which, given a real irregular pattern, the semidiurnal one is assumed either, generically, for the sake of simplicity or since it is assumed that very refined results should not be expected when a necessarily rough specification is given as to any other parameter or forcing – typical is the case of wind – included in the model (Cheng and Casulli, 1982). It seems then useful to elucidate what the consequences of this choice might be if a less rough description of residual circulation is desired in the case that no other important external forcing is acting on the field. As mentioned earlier, this is not an unacceptible abstraction since these are exactly the conditions in which, e.g. anoxia phenomena occur in an eutrophic water body. However, the present investigation is, in turn, somewhat simplified in that the tidal amplitude variability in the syzygial period is not taken into account. The present investigation may then be regarded as a first attempt to define a suitable representative tidal pattern to be used in practical applications to approximate the real behaviour in the intertidal approach.

The mixed tide to be approximated is the one already mentioned in section 3.1 and shown in fig. (6b). At first, results obtained with tides of equal amplitude  $a = 0.5$  m (fig. (6c)) have been compared. Then, tentative alternative specifications of the semidiurnal tide have been tried, namely: i) the single semidiurnal component extracted from the mixed tide ( $a = a_s = 0.4$  m); ii) the semidiurnal tide whose mean energy equals that of the mixed tide ( $a = \sqrt{a_s^2 + a_d^2} = 0.424$  m), mean tidal energy over the period,  $T$ , being defined as

$$E = \frac{1}{T} \int_T \eta^2 dt$$

In no case significant improvements were obtained as to the similarity of numerical results. In fig. (5d-f) the curves of cumulated frequencies of relative

Figure 6: Simplification of tidal patterns: (a) typical real behaviour of a Mediterranean tide, (b) mixed pattern, (c) semidiurnal pattern

differences computed for the three basins for the comparison to the semidiurnal tide of equal range are shown.

### 3.3 Simulations of convection-dispersion

Numerical simulations of convection-dispersion of a passive solute released in various points of the basins confirmed the significance of the previously mentioned differences.

In the flat basin the spreading of the tracers is very weak and regular. Indeed, according to the simple gaussian model of dispersion (Adams and Baptista, 1987), the second central moment of the mass distribution

$$D_{sq}^2 = \frac{1}{N} \sum_{i=1}^N (x_i - x_c)^2 + (y_i - y_c)^2$$

where  $x_i$ ,  $y_i$  are the coordinates of the  $i$ -th particle of the ensemble of  $N$  particles, and  $x_c$ ,  $y_c$  are the coordinates of the center of mass, was found to be fairly linearly proportional to the elapsed time for a specified tidal phase, at least after a sufficiently long time from the release. This is shown in fig. (7) for the release point No. 1 of fig. (8), in the presence of both mixed tide and Coriolis forces. Although the alternate stretching and contracting behaviour of the cloud is governed essentially by the mean velocity gradients, the order of magnitude of the ratio  $D_{sq}^2/2t$  is as that of the intratidal diffusion coefficients considered in the simulation of random fluctuations.

Under the above conditions of regularity of diffusion, exclusive reference can be made to the position of the center of mass for the comparison of the effects of the tidal pattern and the Coriolis forces. Results are shown in fig. (8) for three points of release of the mass of solute and for the four possible combinations of the above factors. Trajectories followed by the centers of mass over a time extent of 20 days are plotted with a time step equal to the period of the relevant tidal pattern, so that tidal excursion is not resolved. It is apparent that

Figure 7: Ratios  $D_{sq}^2/(2t)$  computed at fixed tidal phases for a cloud of passive solute transported in the flat basin under the effect of both the mixed tide and the Coriolis forces - release point No. 1 of fig. (8)

neglecting of the Coriolis forces leads to a much more unrealistic simulation of the transport phenomenon compared to the approximation of the mixed tide by the semidiurnal one.

In the channeled basin, depending on the location of the release point, intratidal dispersion can be completely dominated by the spread induced by noticeable mean velocity gradients. Indeed, in that zones intratidal dispersion is only responsible for the initial, near field, displacement from which the second factor leads to a spread of a greater order of magnitude. In fig. (9a-f) the displacements of clouds of solute after four days from the release in two points of the basin are shown. Depending on the location of the point of release, a different relative importance of the Coriolis forces and the tidal pattern in the convection-dispersion process can be perceived. In particular, near the shore, just like in the flat basin, considering the Coriolis forces is much more important than exactly specifying the tidal pattern. However, in the proximity of the channel both factors must be properly represented for a correct reproduction of the dispersion process.

It is apparent that the reason of this behaviour is to be found in the major role played by the channel in the whole dynamics of the water body, it being able to produce a circulation that is one order of magnitude stronger than in the flat basin. Apparently, the Coriolis forces act more as a direct driving factor of the circulation in the flat areas of both basins. Instead, in the areas influenced by the channel their role is mainly that of inducing different interactions between the expansions and the channel itself, whose presence, along with the associated strong velocity gradients, is indeed responsible of the important convection and dispersion at the intertidal scale. If boundary conditions like the tidal wave are changed, then the low hydraulic conductivity of the flat areas - in particular, of the inlet - causes the effects of the changes to be damped as well. Instead, the major conductivity of the channel causes the features of an important driving mechanism, and so the resulting features of circulation, to be remarkably modified too.

The basin with sloping sides behaves essentially like the channeled one, as far as analogous conditions at the inlet are involved. This is shown in fig. (10a-f) for the same points and initial tidal phases of release as for the channeled basin. In particular, for the release in the proximity of the channel, while considering the mixed pattern makes only a small part of the particles to be out of the domain after four days, none of them remains within it if the semidiurnal tide is considered, regardless of the inclusion of the Coriolis terms.

### 3.4 Diffusion coefficient and numerical time weight

Let us consider the following simplified form of the x-momentum equation drawn from system (1):

$$\frac{\partial U}{\partial t} + gh \frac{\partial \eta}{\partial x} + \gamma U = 0 \quad (3)$$

where  $\gamma U$  is the linearised bottom friction term. This can be discretised on a fully staggered, Arakawa-C grid as

$$\frac{U_{i+1/2,j}^{n+1} - U_{i+1/2,j}^n}{\Delta t} + \alpha \left( gh_{i+1/2,j}^{n+1} \frac{\eta_{i+1,j}^{n+1} - \eta_{i,j}^{n+1}}{\Delta x} \right) \quad (4)$$

Figure 8: Pathlines of the centers of mass of clouds of a passive solute dispersing in a flat, 1 m deep, tidal basin under different forcing conditions

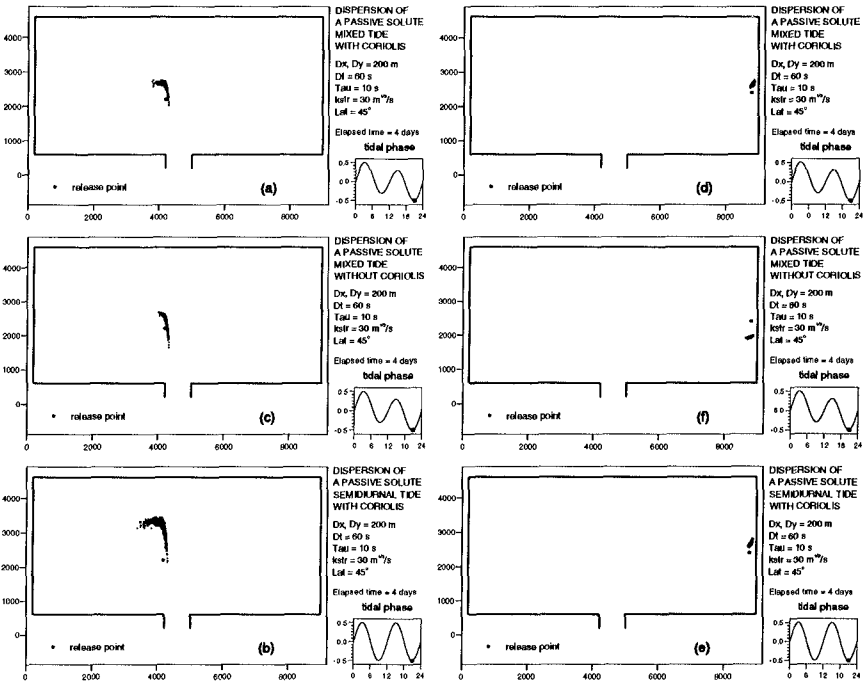

Figure 9: Advection-dispersion of a passive solute in a flat, 1 m deep, tidal basin with a central, 5 m deep channel, four days after release in two points, computed for a mixed tide (a,d) with and (b,e) without the Coriolis forces, and (c,f) for a semidiurnal tide of equal range with the Coriolis forces

$$+ (1 - \alpha) \left( g \bar{h}_{i+1/2,j}^n \frac{\eta_{i+1,j}^n - \eta_{i,j}^n}{\Delta x} \right) + \gamma U_{i+1/2,j}^{n+1} = 0$$

where  $\alpha = 0.5 \div 1$  is required for a stable discretization. Analysis of the relevant truncation error shows that using scheme (4) in numerical computations equals solving

$$\frac{\partial U}{\partial t} + gh \frac{\partial \eta}{\partial x} + \gamma U = - \left[ \left( \frac{1}{2} - \alpha \right) \frac{\partial^2 U}{\partial t^2} + (1 - \alpha) \gamma \frac{\partial U}{\partial t} \right] \Delta t + O(\Delta t^2, \Delta x^2, \Delta y^2)$$

regardless of the method used for the linearisation of the barotropic pressure gradient. This holds also for a fully non-conservative analog of equation (3), involving velocity components alone. In the absence of bottom friction, the scheme can be made of second order in time by letting  $\alpha = 0.5$ , while values greater than 0.5 provide a damping effect (Casulli and Cattani, 1993). Since this effect, even though not remarkable, is nonetheless clearly perceivable at the intratidal time scale, a check on its importance at the intertidal scale has been done.

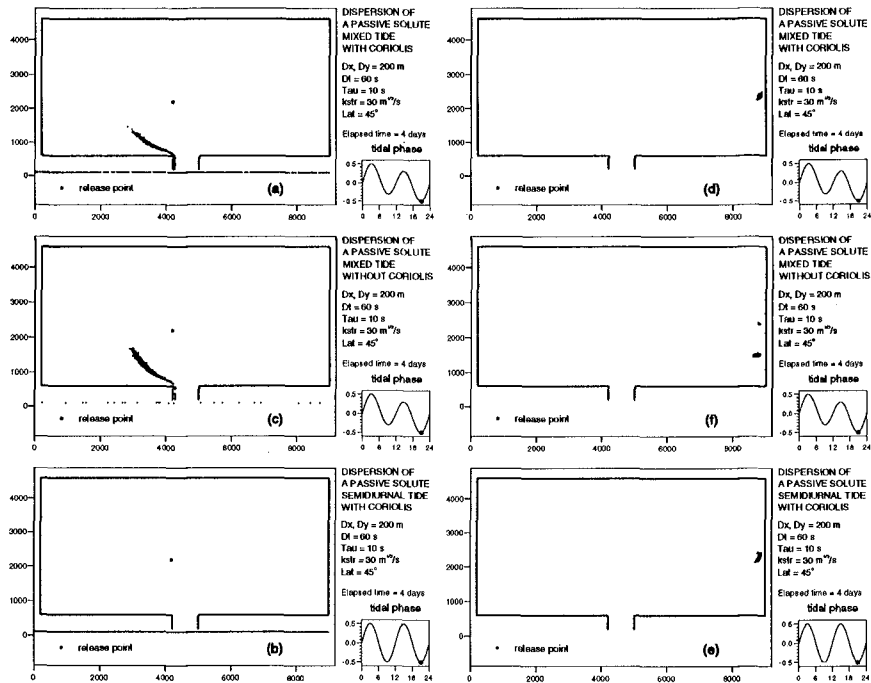

Figure 10: Advection-dispersion of a passive solute in a tidal basin with a central, 5 m deep, strip and sloping sides, four days after release in two points, computed for a mixed tide (a,d) with and (b,e) without the Coriolis forces, and (c,f) for a semidiurnal tide of equal range with the Coriolis forces

The effect of diffusion terms in equations (1) is also often considered negligible in current simulations in lagoons, provided that sufficiently small space and time scales are considered in the computations (Pfeiffer et al., 1988; Rosso et al., 1993; Umgiesser et al., 1993).

As far as regards the parameter,  $\alpha$ , and the diffusion coefficient,  $K$ , comparisons have been carried out, for the channeled basin only, between results obtained in a reference case (the above mixed tide of 1 m of range,  $K=0$ ,  $\alpha=0.5$ , i.e. Crank-Nicholson scheme), and two cases differing respectively by  $K=1 \text{ m}^2/\text{s}$  and  $\alpha=1$  (fully implicit scheme). These values represent a strictly upper limit value for the latter parameter and a reasonable one, though roughly estimated, for the former, depending on the characteristics of both the basin and the motion. In fig. (11a,b) the relevant curves of relative differences are shown. Though the channeled basin was expected to be, among the three, the most sensitive to changes in the above mentioned parameters, results are apparently much less significant compared to the cases of Coriolis forces and tide specification.

4. Conclusions

Some features of long term transport in shallow and relatively small lagoons under a relatively weak tidal forcing alone have been analysed. Results are then applicable to Mediterranean tidal basins in the absence of wind, i.e. in conditions like those eventually leading to anoxia in the water body.

It has been shown that the usual assumption of neglecting Coriolis forces in this kind of basins is acceptable only for the purpose of determining the general characteristics of intratidal circulation. Indeed, this factor proved essential to the correct simulation of long term transport in all the three prototypes considered. Potentially dangerous mistakes of practical interest in applications have been shown. A mixed tidal pattern proved well approximated by a semidiurnal one of equal range in a flat basin in which the tidal range is substantially damped at the inlet, as well as in the peripheral, shallower areas of basins in which propagation of the tidal wave is allowed to a larger extent. In the latter, a more realistic tidal pattern is required for a correct simulation of convection-dispersion in areas

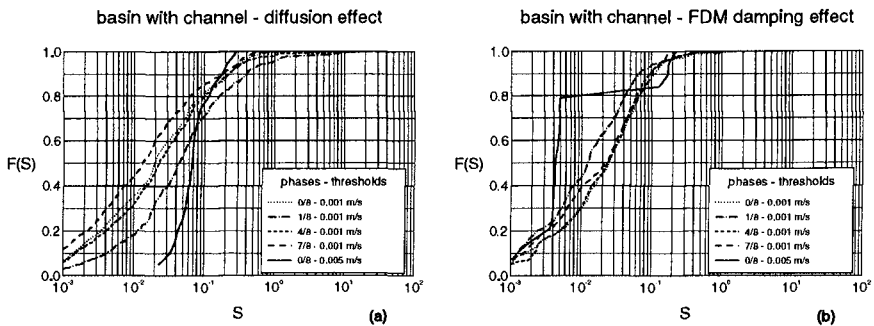

Figure 11: Curves of the cumulative frequencies,  $F(S)$ , of the relative differences,  $S$ , between residual velocities components computed for the basin with channel with the mixed tide and Coriolis forces (a) including or not the diffusion terms with  $K = 1 \text{ m}^2/\text{s}$  and (b) selecting  $\alpha = 0.5$  and  $\alpha = 1$  in the numerical discretization (4) of the propagation terms

characterized by relatively strong velocity gradients in the hydrodynamic field.

Though numerical results should always be regarded with caution even when an accurate check is done on numerical convergence and a robust and accurate model is employed, particularly in the presence of a highly irregular bathymetry (D'Alpaos et al., 1992), nonetheless it seems that, if not exactly the numerical entity of the mentioned differences, at least the remarkable differences shown as to the circulation patterns should be regarded as really meaningful.

On the basis of the above results, it seems that a representation of the long term transport due to a real tide of variable amplitude in the syzygial cycle in terms of residual fields for semidiurnal tides of correspondingly varying amplitudes can be tried for basins like the flat one considered in this study.

On the other hand, residual circulation seems to be less sensitive even to reasonably high values of the diffusion coefficient, which, however, could not be assigned an accurate value at the start of the art. Even less significant is the effect of the numerical time weight  $\alpha$ , of a standard implicit discretization scheme for spatial derivatives, whose smoothing effect when equal one is not so much important on tidal waves compared to short and high-frequency ones.

## CHAPTER 212

### THE EXTENT OF INLET IMPACTS UPON ADJACENT SHORELINES

Kevin R. Bodge, Ph.D., Member ASCE<sup>1</sup>

#### Abstract

*The erosional impacts of improved inlets upon adjacent shorelines may be best estimated by first computing the volume of material removed from the littoral system and then examining the adjacent shorelines to identify the length along which this volumetric impact has been manifest. This contrasts with the traditional approach whereby erosion is identified along a finite reach of shoreline and attempts are then made to link the erosion to a plausible cause. The length and volume of inlet-related erosion at two inlets considered herein are significantly greater than that traditionally ascribed to the inlets. Both feature near-field and far-field downdrift erosion signatures separated by stable shoreline.*

#### INTRODUCTION

Improved ocean inlets are becoming increasingly recognized for their role in effecting beach erosion along adjacent shorelines. Such inlets include those which have been created or stabilized by dredging and/or by structures for purposes of navigation, water quality, flood control, etc. The total extent of these projects' influence upon the adjacent shorelines is not presently certain and is the subject of considerable debate. In the United States, perhaps the first examination of the topic was prepared for the U. S. Army Chief of Engineers in 1938 (Blackman, 1938). More recent discussions include those of Dean and O'Brien (1987), Fields *et al.* (1989), Work and Dean (1990), Bodge (1993), Bruun (1994), among others.

This paper considers the proposition that the littoral impact of inlets (and similar coastal perturbations) may be much greater than previously suspected. The reasons for this could be that (1) the littoral impacts are more closely related to interruptions of the gross transport rates (rather than the net transport rates), and (2) that the traditional identification of downdrift shoreline change may be a poor indicator of an inlets' total volumetric impact. Because the paper examines the degree to which man-made coastal projects impact the shoreline's littoral drift regime, its applicability need not be limited to ocean inlets. That is, the principles considered herein should be applicable to coastal perturbations in general which act as a sediment sink; e.g., marinas, breakwaters, long groins, nearshore dredging, etc.

#### GENERAL CONSIDERATIONS OF INLET IMPACTS

**The Influence of Gross vs. Net Transport.** An inlet's littoral impact is often expressed in term of its "interruption of the *net* littoral drift." While this is a useful

---

<sup>1</sup> Senior Engineer, Olsen Associates, Inc. 4438 Herschel St., Jacksonville, Florida 32210 U.S.A. (904) 387-6114; Telefax (904) 384-7368.

concept to help explain inlet impacts to laymen, it is a significant simplification of littoral processes -- and risks marked underestimation of an inlet's actual impacts.

For example, it is known that a perturbation (such as a groin) placed along a beach with large gross transport but negligible net transport will, indeed, induce changes to the adjacent shorelines. The degree to which the beach will be erosional or accretional on each side may depend upon the state of the transport regime or the overall supply of sediment at the time the perturbation is introduced. Thus it is recognized that the *gross* components of transport may be central in characterizing the response of shorelines to perturbations. This idea is not new (Galvin, 1990, among others), but perhaps is increasingly overlooked.

An improved inlet represents such a shoreline perturbation, and in particular, is often a sediment sink in response to gross transport processes (e.g., Bruun and Battjes, 1963; Dean and Walton, 1975; Walton and Adams, 1976). Consider, for example, a shoreline with component drift rates of +100 and -20 units, yielding a net drift rate of +80 units, along which is constructed a stabilized inlet (Figure 1). If all or part of the transport directed toward the inlet on its downdrift side leaks into the entrance channel, then the net downdrift erosion stress could be as much as 100 units instead of 80. Similarly, if all or part of the transport directed toward the updrift side is sunk to the channel or permanently impounded, there will be up to 20 units of localized erosion well updrift of the inlet. The total potential erosional impact would thus be 120 units (the gross transport rate), not 80 units (the net transport rate).

**Figure 1:** Potential effect of an inlet upon a shoreline with gross transport rate components of 100 and 20 units. By introducing the inlet, the potential downdrift and updrift erosional impacts are 100 units and 20 units, respectively. Consideration of only the net drift rate leads to the erroneous conclusion that erosional impacts are limited to 80 units on the downdrift side.

**Mechanisms of Inlet Impacts.** The general mechanisms by which inlets impact the adjacent shorelines are known: Material is removed from the littoral system by impoundment against the inlet's terminal structures and by transport through, over and around leaky terminal structures (i.e., jetties which are too short, porous, or low). That

material which is transported past the structures is then deposited into tidal shoals or along the channel seabed. Dredging and subsequent offshore disposal further removes some of this material from the system. Even recent efforts to restore the suitable dredged material to the system are not 100% effective because the beach material which deposits in the channel often mixes with ambient silts and clays -- making the material unsuitable for nearshore recovery (i.e., beach or nearshore berm disposal).

The volumetric sum of these components (impoundment, shoal formation, and dredge disposal out of the system), measured relative to natural conditions, represents the inlet's littoral impact. Through consideration of the conservation of mass, this must also represent the total erosional impact of the inlet upon the adjacent beaches.

**Approach.** A reasonable approach to estimate an inlet's littoral impacts may therefore be to *first* identify the volume of sand removed from the system by the inlet, and *then* examine the adjacent shorelines to identify the extent of the shoreline along which this volume has been realized. This approach contrasts with that conventionally employed to determine inlet impacts; i.e., where one first estimates volumetric erosion along a finite length of beach and then attempts to link the erosion to a plausible cause.

#### APPLICATION: PORT CANAVERAL, FLORIDA

As an example of the approach outlined above, the case of Port Canaveral, Florida, will be considered. Port Canaveral is located on the Atlantic coastline of the southeastern United States in the state of Florida (Figure 2). The port's inlet is presently

Figure 2: Location map of Port Canaveral, Florida.

maintained to a depth of -14 m MLW. Dual rock jetties which extend about 275 m and 70 m seaward of the pre-inlet MHWL bound the channel entrance to the north and south, respectively. There are no tidal shoals associated with the inlet because the port has always been hydraulically isolated from inland waters by a navigation lock or berm, and the inlet's tidal currents are weak. The dominant drift direction is southerly.

The inlet was artificially established by dredging through a sandy barrier island in 1950-52. The pre-inlet shoreline was regular, though arcuate, and accretive. Subsequent to the inlet construction, the shorelines north and south of the new inlet rapidly advanced and eroded, respectively. Despite the placement of almost 1.8 MCM of beach fill in the mid-1970's, the present shorelines north and south of the inlet are offset by over 280 m.

**Updrift Impoundment.** The volume of sand impounded by the inlet's north jetty was estimated by comparing historical shoreline records prior to and after construction. The shoreline changes were converted to volumetric changes through an approximate, fixed multiplier of  $8.23 \text{ m}^3$  per m of change per m of shorefront. (This is a conservative value; i.e., it may underestimate the volume change. Comparison of the limited profile data historically collected along this beach suggested a value 20% greater than  $8.23 \text{ m}^3/\text{m}/\text{m}$ .) The computed volume changes were then expressed as *cumulative* volume change updrift of the inlet -- annualized over the years between shoreline surveys (Figure 3a).

**Figure 3:** Cumulative annualized volume changes updrift of Port Canaveral developed from (a) discrete shoreline change records and (b) the average signals of the pre- and post-inlet shoreline change records. The difference between the pre- and post-inlet signals is the inlet effect.

The volume change data expressed in this way clearly fell into two groups corresponding to pre- and post-inlet conditions, respectively. The average of the cumulative curves in each of the two groups was computed to yield the approximate pre- and post-inlet rates of updrift volume change as a function of distance from the inlet. The difference between these two averages represents the net updrift effect of the inlet (Figure 3b). The updrift extent of the impoundment signal -- suggested by the maxima in the curve -- is noted about 3.3 to 5.0 km updrift of the inlet. The magnitude of the impoundment signal over this distance is about 152,500 m<sup>3</sup>/yr ( $\pm 37,500$  m<sup>3</sup>/yr). Over the first 40 years since the inlet was constructed, this represents about 6.1 ( $\pm 1.5$ ) million cubic meters (MCM) of impoundment.

**Dredging.** Only a portion of the sand which is transported toward the north jetty is impounded. The jetty is low and porous, and is now too short relative to the accreted shoreline. The south jetty is likewise low and porous. Sand which is transported over, through and around the jetties deposits in four well-defined, consistent shoals at the landward and seaward ends of the structures. Diving, core-boring, and dredging inspection reveals that these shoals are composed of sand from the adjacent beaches. From "condition" surveys of the inlet entrance collected quarterly over the past few years, these shoals re-appear after dredging at a combined, average annual rate of about 150,000 m<sup>3</sup>/yr. Over a 40 year period, this amounts to 6.0 MCM. The latter value agrees well with independent estimates of the sand volume thought to have been dredged from the inlet. Specifically, dredging records and geotechnical data (which reveal a consistent lower depth to the local surficial sand lens) suggest that about 6.0 MCM of the 38 MCM of material dredged from the inlet over its first 40 years was beach-quality sand which was removed for purposes of maintenance and placed in deep water, offshore.

Over the inlet's first 40 years since construction, then, about 6.1 ( $\pm 1.5$ ) MCM of sand have been impounded by the north jetty beyond pre-inlet trends, and about 6.0 MCM have been dredged and disposed of out of the littoral system. The total, about 12.1 ( $\pm 1.5$ ) MCM, represents the inlet's littoral impact to the beaches over 40 years.

**Impact to Shorelines.** It has been historically assumed that the inlet's effects extended only about 3 km downdrift -- an area over which the post-inlet shoreline has been severely erosive (Figure 4). South of this distance (for a length of about 4 km), the shoreline has been stable to accretional. It is important to note, however, that the rate of accretion along this reach has been less than in pre-inlet conditions, and the beach south of this area has exhibited erosion.

Erosion along the downdrift 3 km of shoreline was estimated in a similar manner as for the impoundment signal on the updrift side of the inlet. Historical shoreline change data were converted to volumetric equivalents (using a multiplier of about 5.8 m<sup>3</sup>/m/m based upon typical profile comparisons), and expressed as average annual, cumulative volume change downdrift of the inlet. The effects of two beach fills during 1972-1975 were approximately removed by subtracting the placed volume from the post-fill data along the placement area. Like the updrift volume changes, the results fall into two groups corresponding to pre- and post-inlet timeframes (Figure 5a). The difference between the average of the two groups yields the inlet's effect (Figure 5b).

**Figure 4:** Historical shoreline changes south (downdrift) of Port Canaveral Entrance for pre- and post inlet conditions.

The inlet's primary erosive effect is evident within about 3.3 km south of the inlet (i.e., the point at which the cumulative volume change curve "levels out" in Figure 5b). Over this reach, the inlet's effect has been equivalent to about 75,000 m<sup>3</sup>/yr of erosion, on average. Over the first 40 years since the inlet's construction, this represents about 3.0 MCM of erosion. The inlet's total littoral impact, however, is computed as about 12.1 ( $\pm 1.5$ ) MCM -- which leaves another 9.1 ( $\pm 1.5$ ) MCM of impact unaccounted for. It is possible, but not certain, that 1.3 MCM of inlet-related impact may be associated with erosion north of the inlet's impoundment fillet. Such updrift erosion is predicted by the sediment budget (see below). Impacts further updrift are improbable; therefore, by deduction, the inlet's remaining 7.8 ( $\pm 1.5$ ) MCM of erosional impacts are likely associated with the beaches beyond 3.3 km south of the inlet. The inlet's total downdrift impact is thus estimated as about 10.8 ( $\pm 1.5$ ) MCM (Figure 6).

Cumulative volume changes along the beach downdrift of the inlet were computed beginning at the inlet for pre- and post-inlet conditions (Figure 7). An erosional volume of 10.8 MCM, accounting for pre-inlet processes is noted between 31 and 42 km south of the inlet. The  $\pm 1.5$  MCM uncertainty in the volume impact increases this range to between 22 and 53 km. Recent independent estimates of beach nourishment requirements within 42 km south of the inlet total 5.6 to 8.8 MCY (USACE 1992; Coastal Tech. Corp. 1992). Another 2.8 MCM of beach fill have already been placed herealong during the period of study. When this 2.8 MCM is added to the existing requirements, the total restoration requirement is 8.4 to 11.6 MCM. These values corroborate the author's findings; i.e., that the inlet's total downdrift impact, based upon a sediment budget, is 10.8 ( $\pm 1.5$ ) MCM.

**Sediment Budget.** The sediment budget developed for the inlet in pre- and post-project (existing) conditions is illustrated in Figure 8. The results are based solely

Figure 5: Cumulative annualized volume changes downdrift of Port Canaveral developed from (a) discrete shoreline change records and (b) the average signals of the pre- and post-inlet shoreline change records. The difference between the pre- and post-inlet signals is the inlet effect.

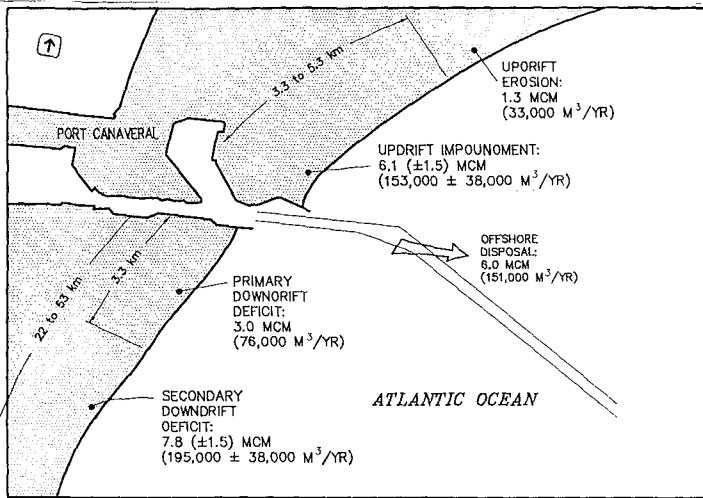

Figure 6: Overview of volumetric impacts attributed to Port Canaveral over the 40 years since the inlet's construction.

**Figure 7:** Cumulative change in beach volume estimated as a function of downdrift distance from Port Canaveral Entrance. The upper pair of curves refers to "observed" changes since the inlet's construction. The lower pair refers to changes since the inlet's construction -- relative to the local pre-inlet accretional trend. The range between the curves in each pair reflects error bars associated with transforming shoreline change data to volumetric estimates.

**Figure 8:** Gross sediment budget computed for Port Canaveral Entrance. The arrows and values represent longshore sediment transport rate in thousands of cubic meters per year.

upon interpretation of (i) measured shoreline changes north and south of the inlet, (ii) maintenance dredging records, and (iii) assumed values of the gross southerly and northerly transport rates incident to the inlet. The selection of the latter values was guided by refraction and GENESIS modelling results, and early studies of shoaling at the newly cut inlet (USACE 1961, 1992).

The pre-project, net littoral drift rate across the inlet entrance is estimated to have been 184,000 m<sup>3</sup>/yr to the south. From the sediment budget, however, the inlet's net impact is estimated to be 302,500 m<sup>3</sup>/yr. The 64% difference in these values is attributable to the sink effect of the inlet. Along the south beach in particular, the sand which chronically leaks through the south jetty (about 88,000 m<sup>3</sup>/yr) is lost from the beach and is no longer available for southerly transport during the predominant wave climate. At Port Canaveral, the result is an apparent *reversal* in the net transport direction downdrift of the inlet. This example illustrates the potential underestimates of inlet impact when *net* transport rates are considered in lieu of *gross* transport rates.

#### APPLICATION: SOUTH LAKE WORTH INLET, FLORIDA

South Lake Worth Inlet, Florida, is another example of a case where traditional examination of the downdrift erosion signature fails to reveal the extent of the inlet's littoral impacts. The inlet is located along the Atlantic coastline of Florida, about 150 km south of Port Canaveral, in Palm Beach County. The inlet was artificially cut through a sandy barrier island in 1927 for the purposes of improving water quality within the southern half of Lake Worth. Dual jetties stabilize the entrance channel, which reduces to 41 m width and 3 meters depth at its smallest point. The net littoral drift is southerly-directed. Despite the operation of a sand bypassing plant at the inlet's north jetty (which discharges sand to the downdrift shoreline south of the inlet), the beach to the south of the inlet has exhibited chronic erosion. The shoreline within about 2 km south of the inlet has been authorized as the site of a Federal shore protection (beach restoration) project.

**Sediment Budget.** The major sediment transport paths at the the inlet were identified as shown in Figure 9. The net volume of sand reaching the inlet's north shoreline ( $Q_1$ ) is impounded at the north beach ( $Q_2$ ), lost to the ebb shoal or offshore ( $Q_3$ ), lost to the inlet interior ( $Q_4$ ), naturally bypassed via the inlet's bar ( $Q_5$ ), and/or mechanically bypassed ( $Q_6$ ). The net volume of sand which is transported away from the inlet's south shoreline ( $Q_9$ ) includes sand which is naturally and artificially bypassed ( $Q_5$  and  $Q_6$ ), placed upon the south beach from interior dredging ( $Q_7$ ), and/or eroded from the south shoreline within about 2 km of the inlet ( $Q_8$ ). That is,

$$Q_1 = Q_2 + Q_3 + Q_4 + Q_5 + Q_6 \quad (1)$$

$$Q_9 = Q_5 + Q_6 + Q_7 + Q_8 \quad (2)$$

Estimates of six of the nine components in Eqs. 1 and 2 were developed for a number of time intervals using available data, including shoreline change records,

**Figure 9:** Net sediment transport components identified for South Lake Worth Inlet.

surveys of the ebb and flood tidal shoals, aerial photography, sand bypassing and dredging records. Using the values for these components, estimates of the natural bar bypassing rate ( $Q_5$ ) and the net drift rate leaving the inlet area ( $Q_9$ ) were computed from Eqs. 1 and 2 for net littoral drift rates incident to the inlet ( $Q_1$ ) ranging from 135,000 to 173,000  $m^3/yr$ . In this way, it was estimated that over the period 1927-90 (the first 63 years since the inlet's construction), about 28% to 36% of the incident net drift was bypassed mechanically ( $Q_6$  and  $Q_7$ ) while about 37% of the incident net drift was bypassed naturally ( $Q_5$ ). (See Figure 9.) Thus, only about 65% to 73% of the net drift incident to the inlet's north beach has been transported across the inlet to the beaches south of the inlet -- implying that the inlet has removed a volume of sand from the area's littoral system equal to about 27% to 35% of the incident net drift rate. This material has been diverted to interior shoals (much of which was dredged and used for upland fill along Lake Worth's shoreline), and the formation of an ebb shoal/bypassing bar platform and updrift impoundment fillit.

Considering the incident net drift rate to be on the order of 154,000  $m^3/yr$  (Watts, 1953; Bruun et al., 1966), the inlet is therefore estimated to have diverted as much as 2.6 to 3.4 MCM of sand from the littoral system over its first 63 years. On the

other hand, shoreline change records (including those which were incorporated to the sediment budget analysis) suggest that the shoreline within about 2 km south of the inlet has eroded by only about 2% of the net drift rate incident to the inlet's north side -- or about 0.2 MCM over the inlet's first 63 years.

**Obfuscation of Downdrift Impact.** In the case of South Lake Worth Inlet, the downdrift erosion signature along the 2-km (+/-) reach of coastline thought to be most severely impacted by the inlet potentially underestimates the inlet's littoral impact by a factor of 16. The reason may be related to the significant degree to which the downdrift shoreline has been artificially manipulated through armoring (seawalls), the construction of groins, and the placement of sand (sand bypassing). In such cases, the shoreline's response to erosional stress may be extraordinarily obscured.

By simple inspection of the nautical charts and historical aerial photography, there can be no doubt that the construction of South Lake Worth Inlet has removed from the littoral system far more than the 0.2 MCM of sand indicated by the immediate downdrift shoreline. The erosional stress that the inlet placed upon the shorelines (coupled with imprudent development in some cases) resulted in significant shoreline armoring adjacent to the inlet. This armoring limits the erosional signal of the beach, and/or precludes its identification from shoreline change data (which describe shoreline positions, not beach volumes). Reliance only upon the "near-field" downdrift shoreline history to deduce inlet-related impacts can result in significant underestimation of the inlet's impacts in those cases where the shoreline has been artificially manipulated. Additionally, in those cases where the adjacent shoreline(s) has (have) been stabilized against erosion, the inlet's erosional impacts must -- by deduction -- extend particularly far afield.

## DOWNDRIFT EXTENT OF INLET-RELATED EROSION

**Theoretical Considerations.** In the two example applications presented above, it was noted that the inlets' littoral impacts may extend far from the inlets, despite their young age. In both cases, however, the apparent *limit* of the erosion was traditionally thought to be about 2 km or less downdrift of the inlets; i.e., on the order of about 10 jetty lengths downdrift. Pelnard-Considére (1956) presented now-classical solutions for shoreline change adjacent to a sediment-trapping structure. At the time at which the structure becomes filled to capacity and begins to bypass sand, according to his solution, the shoreline recession ( $y$ ) at a distance ( $x$ ) downdrift of the structure is

$$\frac{y}{Y} = [\exp(-u^2) - \sqrt{\pi} u \operatorname{erfc}(u)] \quad (3)$$

where

$$u = \frac{x}{Y} \frac{1}{\sqrt{\pi}} \tan(\alpha_p) \quad (4)$$

where  $Y$  is the structure length, and  $\alpha_b$  is the wave breaking angle (assumed to be quasi-steady). Both  $y$  and  $Y$  are measured relative to the no-structure shoreline. Figure 10 presents solutions to Eq. 3 for various values of the wave breaking angle. For typical angles on the order of 4 to 8 degrees, shoreline recession on the order of 5% of the structure's length might be anticipated between 15 and 30 jetty lengths downdrift.

**Figure 10:** Shoreline recession predicted from Eq. 3 as a function of structure length and distance downdrift of the structure. The condition corresponds to the time at which sand begins to bypass the structure.

In the case of Port Canaveral, the average-annual breaking wave angle south of the inlet (as computed from hindcast data refracted to shore) is about 4 degrees. Taking  $Y = 275$  m (the length of the north jetty measured from the pre-inlet shoreline), downdrift recession on the order of 5 m over the inlet's history is predicted to occur about 37 jetty lengths downdrift, or about 10 km. (Recession less than about 5 m over 40 years is generally perceived as negligible in this locality.) When one considers that the updrift impoundment represents only half of the inlet's estimated impacts (the other half is dredging related), then the appropriately predicted distance may be twice as great -- or about 20 km. This length agrees in general magnitude with that estimated by the method presented in this paper. In any case, it is considerably greater than the 3 km shoreline reach along which the inlet's erosion is traditionally attributed.

In the case of South Lake Worth Inlet, the lineal extent of the inlet's impacts to the adjacent shorelines is not entirely clear. Considering that the estimated volumetric impact is 2.6 to 3.4 MCM over 63 years, and that typical observed erosion rates in the area are on the order of 0.5 m/yr or less (or about 2.75 m<sup>3</sup>/m/m/yr), the length of effected shoreline may be on the order of 15 to 20 km. The actual length is probably much greater -- and/or perhaps the volume of sand removed by the inlet has never been fully mitigated by erosion of the adjacent beaches -- because long reaches of the adjacent shorelines are armored by seawalls which significantly reduce observed shoreline and volumetric erosion of the beach.

**"Near-field" and "Far-field" Impacts.** The primary reason that the inlet impact associated with Port Canaveral was considered as only 3 km was that the shoreline south thereof (for a distance of a few km) appears stable to accretional. Indeed, this shoreline remained accretional after inlet construction -- but the rate of accretion was about two-thirds less than pre-inlet rates. Bodge (1994) demonstrates through a large-scale sediment budget that it is possible to have net shoreline accretion in the midst of an otherwise erosive regime downdrift of the Port Canaveral inlet. In any case, the overall picture is one of a severe "near-field" erosion wave within a few km of the inlet and a less dramatic "far-field" erosion wave separated from the former by a relatively short reach of stability or accretion. Bruun (1994) discusses numerous examples of this phenomenon and examines possible migration rates of these two erosion features downdrift of inlets. Bruun concludes that the "downdrift shoreline development at a littoral drift barrier may in general, but not always, be described by a short (local) as well as a long distance effect which both move downdrift at various rates, the long distance movement being 2-3 times faster than the short distance, or about 0.5 km/yr versus 1 to 1.5 km/yr.... The short distance effect is a coastal geomorphological feature, the long distance a materials deficit feature."

The appearance of the stable area between the near- and far-field erosion areas may be due to localized shoreline stability (rock outcrops, etc.), local refraction effects (such as those related to the ebb shoal across the inlet mouth), or far-field refraction effects. Local refraction effects and the shoreline attachment of the inlet's bypassing bar are responsible for a short reach of stability/accretion at South Lake Worth Inlet (Bodge, Olsen and Savage, 1990). Far-field refraction effects -- induced by Bull Shoals south of Cape Canaveral -- are apparently responsible for the reach of stability south of Port Canaveral Entrance (Bodge, 1994).

## CONCLUSION

The erosional effects of improved inlets upon adjacent shorelines may be best estimated by first computing the volume of material removed from the littoral system (beyond that which would have been removed naturally in the absence of the improvements) via consideration of the inlet-related (1) impoundment fillets, (2) flood and ebb shoal development, and (3) disposal of maintenance dredged, beach-type material outside of the littoral system. One next examines cumulative beach volume changes along the adjacent shorelines -- beginning at the inlet -- to determine the up- and downdrift-extent along which the inlet's volumetric impacts may be manifest. This fundamental approach contrasts with that conventionally employed to determine inlet

impacts; i.e., where one first estimates volumetric erosion along a finite length of beach and then attempts to link the erosion to a plausible cause. The latter approach is shown to be potentially deficient because (1) the length of the downdrift shoreline classically selected for examination may be much shorter than the actual length which has been affected by the inlet, and (2) downdrift shoreline changes may obfuscate erosion impacts via the effects of coastal armoring, beach reclamation, and other works which have been undertaken in defense against erosion.

The mechanisms by which the inlet's littoral impacts occur illustrate the behavior of many improved inlets as a sediment sink – and the importance of adequate terminal structures to limit sink behavior. It is likewise illustrated that an inlet's impacts are not necessarily limited to interruption of the *net* littoral drift rate, but can extend to the area's *gross* drift rate.

The methodology presented above for deducing inlet-related impacts should also be important to the development of regional sediment budgets. In such regional budgets, the volume of sand removed from the littoral system by an inlet must be accounted for as a deficit within the system as a whole. Barring changes in the wave climate or the natural expansion or appearance of an external sand source, this effect must be manifest as (1) a volumetric erosion of the adjacent beaches, and/or (2) a decrease in the littoral drift rate which reaches the adjacent, downdrift inlets.

For the two example cases presented, the extent of the inlet's littoral impacts is considerably greater (by a factor of 15 to 20) than has been traditionally thought. For the first 40 years after construction of Port Canaveral entrance, the downdrift impact of the inlet is estimated to be 12.1 ( $\pm$  1.5) MCM -- affecting between 31 and 42 km ( $\pm$ 10 km) of shoreline south of the inlet. Traditionally, the effect has been thought to be limited to about 3 km of shoreline, along which only 4 MCM of erosion is detectable. Likewise, for the first 63 years after construction of South Lake Worth Inlet, the inlet's impact is estimated as 2.6 to 3.4 MCM as compared to only 0.2 MCM of impact which is detected from shoreline changes observed along the first 2 km (approx.) south of the inlet. Both inlets feature "near-field" and "far-field" erosion signatures -- separated by a relatively short reach of stable to accretional shoreline. For the two cases examined, the appearance of the latter is related to local and offshore wave refraction effects respectively induced by inlet-related and non-inlet related bathymetries.

## CHAPTER 213

### The Spreading of Dredging Spoils During Construction of the Denmark-Sweden Link

Ida Brøker<sup>1</sup>, John Johnsen<sup>1</sup>, Morten Lintrup<sup>1</sup>,  
Anders Jensen<sup>1</sup>, and Jacob Steen Møller<sup>1</sup>

#### Abstract

An overview of the model complex, including a combined Lagrangian and Eulerian approach to simulation of sediment transport, developed to study spreading of dredging spoils in connection with off-shore earth works necessary for construction of the Denmark-Sweden Link is provided; - together with in-depth descriptions of two particular work topics: (a) Model representation of flow friction to allow application of an inherently depth-integrated model system to a partially stratified environment, and (b) overall design of the model complex to make it fit as a versatile tool at several stages of this large project.

#### Introduction (Location and Scope)

In connection with the planned Link between the Danish capital Copenhagen and Malmoe in Sweden along the Drogden Sill, see Figure 1, dredging of clay and chalk is necessary for flow compensation as well as for direct construction purposes since it is required that the net water and salinity exchange through the Sound must not be affected. The dredging results in release of substantial amounts of fine material within an area, which is both environmentally perceptible and hydraulically complicated since the sill in combination with an approximately 25 PSU longitudinal salinity difference between Kattegat to the north and the Baltic to the south induces a mobile and variable mixing front over a fairly stable salinity interface normally extending southwards only to Drogden Sill.

The model setup and calibration have been supported by laboratory and field experiments. The model complex is verified by comparison with data from test dredgings totalling 64,000 m<sup>3</sup> of moraine clay and chalk, of which 8,200 m<sup>3</sup> were spilled. During these tests spill percentages and variability for different types

---

<sup>1</sup>Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark.

of operations were specifically evaluated. The actual dredgings are expected to approach 7 mill.  $m^3$  after early planning had indicated dredging requirements to be twice that amount.

Figure 1. Location Map (left) and Model Areas (right).  
The large area indicates extent of main model. The small area corresponds to a fine resolution model used in calibration/verification of material specific parameters.

The scope of the present study was to establish a numerical model complex for simulating the spreading of fines, notably determining shading effects associated with dredging plumes and the eventual fate of spilled material. This should be done so as to facilitate subsequent planning of actual dredging operations as well as to prepare a tool useful in the implementation of an actual dredging spill control strategy.

Administrative objectives as well as legal requirements for dredging operations primarily focus on instantaneous spill rates, specified by area and season. These limitations have been derived from maximum acceptable concentrations by inverse interpretation of results obtained with the model complex described in this paper. An effective dredging period of almost 4 years is anticipated.

Overall, an upper limit to the average spill rate of 5% (implying a total spill of up to 350,000  $m^3$ ) will be imposed. A dredging control strategy should aim at monitoring during the entire operation that actual spill rates allow compliance with this target. Since economical dredging practice dictates operating with a variable spill rate, this implies comparison of measured spill to an *a priori* planned and contractually agreed spill budget.

### Background, Physical Processes and Model Complex Overview

The seabottom material along the planned link consists of hard chalk (limestone), partly overlaid by moraine clay. Construction works include dredging operations for a submerged tunnel along half the crossing length, foundation of bridge piers (approx. tot. 4.5 mill. m<sup>3</sup>) and compensation dredging to maintain the present water and salinity exchange through the Sound (approx. 2.3 mill. m<sup>3</sup>).

The spreading of fine particulates from dredging spoils is a function of currents, wave action and sediment properties. Immediately after the release spreading takes the form of narrow plumes which can be observed far away from the source due to generally appreciable current speeds. Parts of the material settles and deposits on the bottom where a consolidation process takes place.

The settling velocity - which is one of the most important parameters - depends on the material in question, salinity, temperature and biological activity due to flocculation. However, preliminary simulation results indicated application of straight values of 0.00018 m/s (moraine clay) and 0.00021 m/s (chalk/limestone) to be satisfactory in this case.

If bed shear stresses are increased above a critical value, resuspension takes place. This resuspension is a function of the degree of consolidation, see Mehta et al. (1989), whose formulation has generally been followed in the modelling.

All relevant processes are represented in a comprehensive setup of numerical models, comprising (H=Horizontal):

- 2-D(H) hydrodynamic model
- 2-D(H) discrete spectral wind wave model
- Particle model (random walk (x,y,z)-tracer technique) for the initial spreading around the source
- 2-D(H) advection-dispersion model for spreading in the far field

Furthermore, these models have been linked to an associated ecological model, describing growth and distribution of benthic vegetation notably eelgrass, *Zostera marina*. The ecological model is also an integrated part of the EIA (Environmental Impact Assessment) and anticipated dredging control procedures, and it is reported elsewhere, Bach et al. (1991).

The source/sink term in the advection-dispersion model represents the link between transporting agents and in-the-bottom processes. A multi-layer representation of shear strength of the bed and consolidation in the bed are included.

The study concept has been to apply nested far-field and near-field models (two, with resolutions of 500 m and 100 m, termed ØRESUND and LINK modelling areas, respectively, see Figure 1) and to couple wave, current and sediment models as shown in Figure 2. Sediment models must be run separately for both moraine clay and chalk, and result fields added, as needed.

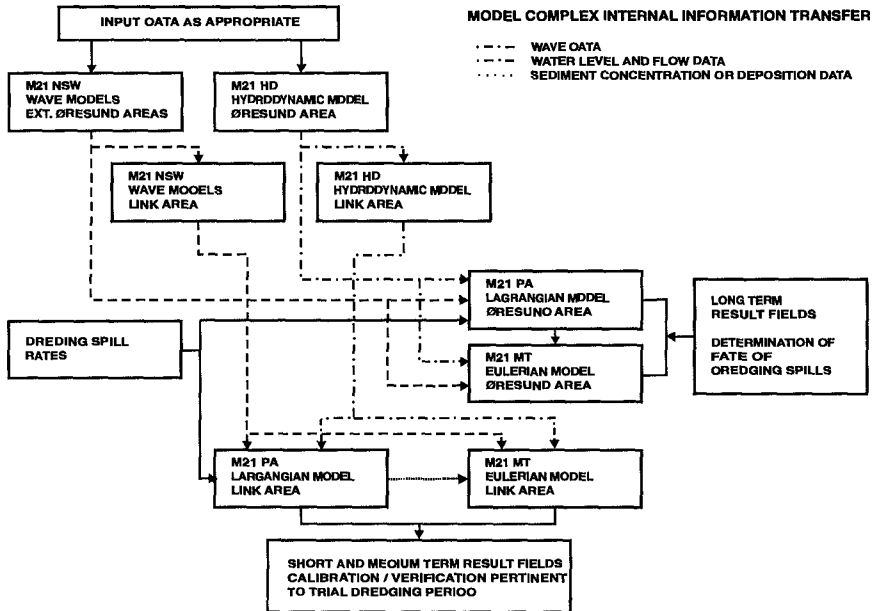

Figure 2. Sediment Spreading Model Complex. Overview emphasizing internal structure and input/output of data on transport/deposition rates.

The two nested models have to some extent served different objectives. The finer model has been sufficiently detailed to allow model calibration and verification to test data from field experiments covering a three months period with respect to material specific parameters; - whereas the coarser model has proved useful for repeated, several-year-long simulations covering a larger area in support of operations planning.

Two coupled sediment models have been applied; the first having a Lagrangian modelling approach. In addition to savings in execution time and computer storage, two main advantages are achieved over traditional, direct Eulerian modelling:

Numerical dispersion due to "poor" resolution is avoided even though a relatively coarse grid is maintained for the current, i.e. model concentra-

tions of suspended matter reach realistic high values very close to the source. This is important for subsequent modelling of eelgrass growth.

Most dredging spoils are released near the surface, ie. the areal spread and time lag before it is justified to assume a standard vertical concentration profile is considerable. This adaptation takes place within the Lagrangian model.

After a certain period the sediment is then transferred to an advection-dispersion model comprising a more refined description of bed consolidation and resuspension effects. The transfer period is basically a matter of technical judgment and compromise; here values in the range 3-6 hours have been found to work satisfactorily.

The *sediment transport module* needs input of settling velocity of flocs depending on degree of flocculation, whereas the *bottom process module* needs input of critical bed shear stresses for erosion and deposition for description of reentrainment and erosion and parameters for description of the consolidation process. Parameters in the sediment transport and bottom process modules are derived from laboratory and field experiments.

In-situ settling experiments using an Owen settling tube to determine settling rates were carried out. In the laboratory the resuspension as a function of shear stress and degree of consolidation were investigated in an annular flume. Consolidation rates were studied in the annular flume and in settling tubes.

Flow conditions in the laboratory are stationary and the biological activities are minimized. Those experiments have therefore been supplemented with field experiments where a test area ( $20 \times 10 \times 0.25 \text{ m}^3$ ) was constructed in the Sound close to the Link alignment. The test area was covered by chalk similar to the finest fractions ( $<63\mu$ ) of dredging spoils. All experiments and the sediment model calibration process including actual selections of parameters are described in detail in Johnsen et al. (1994).

The wave climate in Øresund has been demonstrated to be effectively fetch-limited and dominated by locally generated waves. As a result, conditions are generally mild with waves in the range  $H_s=0.2$  to  $0.6 \text{ m}$ . This has justified a simplified wave modelling approach based on a number (36) of stationary simulated wave fields (12 wind directions times wind speeds 5, 10, and 15 m/s), from between which instantaneous wave fields as input to sediment models were interpolated using measured wind conditions.

The flow is modelled dynamically with bathymetry, bed resistance, eddy viscosity, wind and boundary water levels as the main defining input. The latter are derived from four water level stations - two each north and south of the Sound;

two lying on the Danish and two on the Swedish side. An entire year of registered currents at two stations were available for verification of the flow model. A detailed description of the bed resistance input is provided in the following section.

In Figure 3 is shown an example comparison of plumes observed, respectively simulated on basis of the combined wave, current and sediment models.

Figure 3. Comparison of Observed and Simulated Plumes for Model Verification (example)

The verified model has been run for a full year, Sept. '92 - Aug. '93, to simulate the fate of spoils from the test dredgings. That same year has then been designated as design period for subsequent EIA-studies.

With respect to spoils from test dredgings it appears that final deposition areas are mainly along the Danish coastline, and there is only a minor difference between spreading of moraine clay and chalk because settling characteristics are very similar and both types of spoil consolidate relatively quickly after deposition. It is estimated that 90% of moraine clay and 80% of chalk spoils are deposited within the Sound, the majority less than 20 km from the spill site.

### Model Representation of Flow Friction

In order to use the DHI MIKE 21 hydraulic modelling system - which assumes a "homogenous" (one-layered) current regime - to simulate the normally stratified environment in the Sound north of Drogden sill, a correction procedure has been developed and applied to the flow friction; expressed in the model in terms of a Chezy no.,  $C$ , which is reciprocally defined in relation to current velocities.

For homogenous flow a logarithmic velocity profile is assumed. When the water column is stratified, the velocity profile will be contorted and for identical head losses result in a higher water discharge. In other words, stratification may be seen as a lubricant for the current. The principal differences between homogenous and stratified (two-layered) current regimes may be visualized as in Figure 4.

Figure 4. Definition sketch for homogenous (left) and two-layered (right) current regimes

The reduced energy loss caused by the stratification can be incorporated in a homogenous one-layer calculation by introducing an *equivalent (reduced) bottom friction*. This is done on the assumption that the current is dominated by barotropic effects, ie. pressure gradients caused by water level differences are (much) more significant than those caused by density gradients in the flow momentum equation. Then, the momentum equations may be written as:

$$gh_1 I = \frac{\tau_i}{\rho_R}$$

$$gh_0 I = \frac{\tau_b}{\rho_R} - \frac{\tau_i}{\rho_R}$$

where  $g$  ( $9.81 \text{ m/s}^2$ ) is gravity,  $h$  (m) is the thickness of a layer (index 1 is for the upper layer, and 0 for the lower),  $I$  is the energy gradient,  $\tau$  ( $\text{N/m}^2$ ) is the friction (index b is for the bottom, and i for the interface), and  $\rho_R$  ( $1010 \text{ kg/m}^3$ ) is a reference density. Shear stresses are determined by

$$\frac{\tau_i}{\rho_R} = (1-c) \frac{f_i}{2} \frac{1}{4} (V_1 - V_0)^2 + c \frac{f_b}{2} V_1^2$$

$$\frac{\tau_b}{\rho_R} = (1-c) \frac{f_b}{2} V_0^2 + c \frac{f_b}{2} V_1^2$$

where  $f$  is the friction factor, and  $V$  (m/s) is the mean velocity in a layer. The factor  $c$  has been introduced to the equations in order to transfer bottom shear stress directly to the surface layer when bottom layer thickness,  $h_0 = H - h_1$ , decreases to a value comparable to the equivalent bottom roughness,  $k$ :

$$c = \frac{h_1}{H} \exp \frac{-(H-h_1)}{\alpha k}$$

The equivalent bottom roughness is typically 0.3 m in the Sound. The  $h_0/k$  aspect ratio,  $\alpha$ , has been roughly estimated as  $\alpha=2$ . It is noted that the equations lead to the traditional one-layer formulation when the thickness of either of the two layers approaches zero.

Dividing the momentum equations, an equation regarding the ratio of the upper and lower layer velocities,  $V_1/V_0$ , is obtained: The ratio shows a higher velocity in the upper layer than in the lower as shown in Figure 4 and measured

in Øresund. In the velocity ratio equation, the ratio between the friction factors,  $f_t/f_b$ , is present. This ratio is evaluated to be 1/3.

Adding the momentum equations it is seen that the total pressure is balanced by the bottom friction, which in the considered case is a function of both the lower and upper layer velocity (the right side of next equation). To model the two layer system as a one-layer system we need to relate the bottom friction to the depth mean velocity by defining an equivalent bottom friction factor ( $f_e$ ):

$$\frac{f_e}{2} \cdot \left( \frac{h_0 V_0 + h_1 V_1}{h_0 + h_1} \right)^2 = \frac{f_b}{2} \left( (1-c) V_0^2 + c V_1^2 \right)$$

Thus, by applying the equivalent bottom friction factor in the flow simulations the correct depth mean velocity is obtained.

The relation between a friction factor and its corresponding Chezy no,  $C$ , is taken as:

$$C = \left( \frac{2g}{f} \right)^{1/2} \Leftrightarrow \frac{f}{2} = \frac{g}{C^2}$$

Following calibration of the model a constant "homogenous" reference Chezy no.,  $C_b$  of 35 m<sup>1/2</sup>/s has been used, corresponding to  $f_b=0.016$ . By applying an equivalent Chezy no.  $C_{eq}$  instead of  $C_b$  for calculations north of Drogden Sill the lubricating effect of stratification on current has been accounted for in the modelling. In Figure 5 is seen how the equivalent Chezy no. (corresponding to a reference Chezy no. of 35 m<sup>1/2</sup>/s) varies with the position of the interface for different total water depths. The importance of the stratification as a lubricant is evident from the figure.

Figure 5. Equivalent Chezy no. as a function of interface depth for total depths 5, 10, 15, and 20 m.

### Model Complex Applications with Example Results

In this section it is demonstrated how the developed model complex has been and continues to be a useful tool in several, at least three, cases (a)-(c), stages of the project planning and execution.

Particularly, it is noted how the modelling complex may provide results with a statistical character since it is comprehensive, yet operationally manageable for extensive and/or repetitive calculations. Thus the complex is especially likely to be useful in connection with criteria, objectives, requirements etc. that are cast in statistical terms.

Additionally, it is noted that results may be obtained by inverse as well as direct interpretation of results.

**(a)** A number of relatively short simulations were made corresponding to four typical key dredging and deposition activities, two different dredging (spill)

intensities, and two types of hydrographic conditions, summer calm and autumn variable (incl. storm) conditions.

Results from these simulations were compared to conservatively estimated empirical tolerances with respect to bathing water quality, eider and swan forage (1), mussel beds (2), mussel larvae settling (3), and herring migration (4). Tolerances were expressed as concentration maximum exceedance time (1), max. weekly sedimentation (2), sedimentation rate max. exceedance time (3), and max. concentration (4), - all concerning specific areas and seasons. From the comparison a number of restrictions on dredging activities expressed as maximum spill rates (kg/s) were identified, and in some cases it was demonstrated that conflicts were unlikely to occur.

In Figure 6 is shown an example result field of calculated  $6 \text{ g/m}^3$  concentration percentage exceedance time pertaining to herring migration tolerance.

**(b)** Based on experiences from (a) above a complete realistic dredging scenario was worked out for EIA purposes assuming that two backhoe dredgers and one cutter suction dredger will be employed. This preliminary scenario consists of 26 individual dredging (and deposition) activities and spans the period October '95 to April '99. Scenario resolution is daily production rates.

By recursive application of the design year period EIA background simulations for the entire dredging operation could be made. The associated ecological (eelgrass) module was similarly applied.

The model complex has been further refined for this application to include movable sources along piece-wise linear transects in the sediment modules.

As an example and to illustrate the areal impact of the entire operation is shown in Figure 7 the calculated distribution of net accumulation after four years. It is noted that expected maximum accumulation is just over  $5000 \text{ g/m}^2$ .

Presently, EIA is an ongoing process actively in support of project planning and development rather than just a passive instrument for legal acceptance.

**(c)** It is anticipated that the model complex will be applied also at later stages in connection with implementation of control procedures for actual dredging operations, but the exact role(s) and extent of its use remains to be defined.

Figure 6. Example results pertaining to Migration of Herring. Depth averaged concentration of 6 g/m<sup>3</sup>, Percentage Exceedance Time.

### Conclusion

A general and figurative outline of the entire complex developed for modelling of spreading of dredging spoils during construction of the Denmark-Sweden Link, - mainly composed of already existing individual modules, - but with some customizations to fit special requirements and make it a versatile tool in connection with several project stages, - has been given.

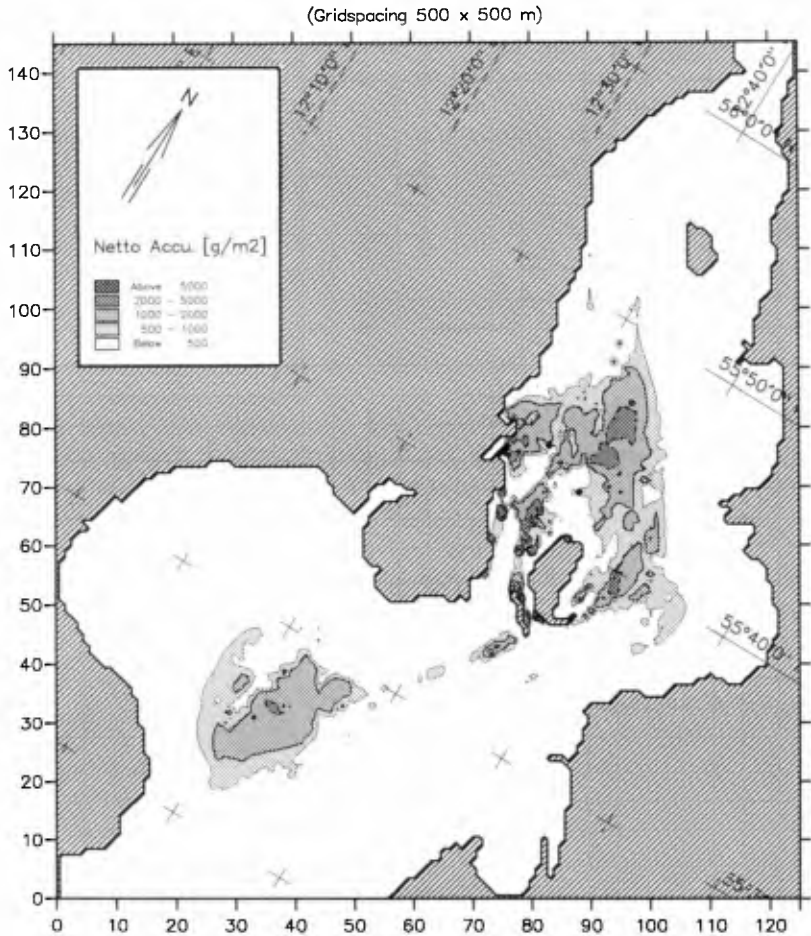

Figure 7. Calculated Net Accumulation from Entire Dredging Operation, 951001-990930.

The main innovation is the use of a relatively fast and practical Lagrangian (random walk particle tracer) sediment model to describe spreading very close to the source, rather than an Eulerian (2-D advection-dispersion) model, which becomes very unwieldy when a high resolution is required.

It has been demonstrated how - given the right circumstances - a depth-integrated hydraulic model system may be adapted for application to a stratified

environment by the introduction of an equivalent (reduced) bottom friction calculation.

Furthermore it has been demonstrated how overall design of the model complex is made to fit requirements for EIA-purposes as well as anticipated procedures for control of dredging spill compliance with strict administrative and legal requirements.

More generally, the model complex allows generation and presentation of results in a statistical form. Thus, whenever biological criteria, administrative objectives, legal requirements, etc. are cast in statistical terms the complex is likely to be a useful tool.

### Acknowledgments

The Sound model complex was implemented under contract to the Øresundsconsortium. The cohesive sediment models were developed as part of the G8 Coastal Morphodynamics programme (contract no. MAS2-CT-92-0027).

## CHAPTER 214

### EXPERIMENTAL STUDIES ON THE EFFECT OF THE DREDGING ON CHANG-HWA RECLAMATION AREA, TAIWAN

Tai-Wen Hsu<sup>1</sup> and Hsien-Kuo Chang<sup>2</sup>

#### ABSTRACT

The effects of offshore dredging at Chang-Hwa reclamation area, Taiwan, are investigated by using movable bed model tests. A practical scale relation for the design of movable bed model is presented. It takes the advantage to give more flexibility for the selection of model sediment. The scale relations of wave conditions in the model test are obtained based on the similitude of two parameters: wave steepness and mobility number. Time scale of sea bottom changes is determined by longshore sediment transport rate. Experimental results show that the proposed scale relations are able to reproduce beach changes in nature. Topographical changes before and after dredging are predicted in model tests. Special attention was made to study the location of erosion and accretion of sea bed configuration owing to offshore dredging.

#### INTRODUCTION

In recent years the utilization of coastal zone has been increased for human activities due to the growth of economics and population and the limited land. The land reclamation project was steadily executed at Chang-Hwa Coast, located on the west coast of central Taiwan (see Fig. 1), to obtain an industrial area. The method of dredging from offshore sea bed is considered as one of the sources of sand supply for

Figure 1 Geographical location of Chang-Hwa industrial area in Taiwan

Figure 2 Schematic diagram of Chang-Hwa reclamation area

reclamation. The reclamation regions at Chang-Hwa Coast shown in Fig. 2 covers a length of 12 kilometers from north to south and extends 3.5 to 4.5 kilometers offshore. The planned layout is divided into three districts (Fig. 2) with a total area of 3643 hectares to accommodate heavy industries such as machinery, steel, power and petrochemistry. Generally the topographical changes in the coastal region tend to reach a dynamic equilibrium for a long term period without significant interference. However, a new sea bottom formed after dredging may lead to changes of coastal process and result in beach erosion. An assessment of coastal environment impact for this project becomes important in engineering practice.

It is recognized that field survey, physical hydraulic model and numerical modeling are three dominant methods to solve coastal problems. Among them, the physical hydraulic model is an alternate means of replacing governing equation with complicated initial and boundary conditions and permit examination in controlled conditions of coastal processes and effects due to gravity waves and other environmental forces.

Satisfactory reproduction of sandy shore and nearshore regions in a movable bed model can provide a valuable tool to the coastal engineering. Design and operation of moving bed models are a difficult task involving complex considerations of hydraulics and sedimentation. The aim of this paper is to investigate the effects of offshore dredging on reclamation area by movable bed tests. A practical scale relation for the design of movable bed model is presented. Predictions of topographical changes after dredging and countermeasures against beach erosion are discussed.

## MODEL SIMULATION

### **1. Scale Relationships**

A practical scale relationship for the design of movable bed test is proposed to reproduce physical features of sediment transports in prototype. Two parameters of wave steepness and mobility number were selected as the important factors of beach changes:

$$\left( \frac{H_0}{L_0} \right)_m = \left( \frac{H_0}{L_0} \right)_p \quad (1)$$

$$\left( \frac{U_*^2}{\gamma' g D_{50}} \right)_m = \left( \frac{U_*^2}{\gamma' g D_{50}} \right)_p \quad (2)$$

where  $H_0$  and  $L_0$  are the wave height and wave number in deep water, respectively.  $U_*$  is the bottom friction velocity,  $\gamma'$  the submerged specific gravity of sediment,  $g$  the

gravitational acceleration, and  $D_{50}$  the median diameter of sand grain. The subscript m and p represent physical quantities of model type and prototype, respectively.

According to the former scale laws [3,4,6,7], the sediment in the model can not be chosen freely that makes the scale laws inapplicable in most of cases. The present scale give more flexibility for the selection of model sediment.

Based on the similitude of Eqs. (1) and (2), the scale relations for wave height and wave period are found as follows

$$N_{H_0} = \left( N_v^{1/2} N_{D_{50}}^{1/2} N_f^{-1/2} N_v^{2/3} \right)^{6/7} \quad (3)$$

$$N_T = \left( N_v^{1/2} N_{D_{50}}^{1/2} N_f^{-1/2} N_v^{2/3} \right)^{3/7} \quad (4)$$

where N denotes the ratio of parameter of model to prototype,  $N_v$  is the vertical scale, f the friction factor.  $N_f=10.4$  was adopted in the present study. The conversion of wave height and wave period between the model and nature was obtained on the basis of Eqs. (3) and (4).

Tidal variation should be considered in model test because it causes sediment movement significantly in Chang-Hwa area. This area has a maximum tidal change of 4.5m and its temporal variation has been modeled. The similitude of Froude number was applied for simulating tidal variations:

$$N_{Fr} = \frac{N_u}{\sqrt{gN_v}} = 1 \quad (5)$$

in which u indicates tidal velocity. From Eq. (5) the tidal period scale ratio is obtained

$$N_{td} = N_h^{1/2} \quad (6)$$

The equation of sediment conservation is

$$\frac{\partial h}{\partial t} = \frac{1}{1-\lambda} \frac{\partial q_y}{\partial y} \quad (7)$$

where h is the water depth, t the time,  $\lambda$  the sediment porosity,  $q_y$  the littoral transport per unit width. It is assumed that both model and prototype have the same value of  $\lambda$ , then Eq. (7) is reduced to

$$N_t = N_v N_h N_{q_y}^{-1} \quad (8)$$

in which  $N_h$  is the horizontal length scale and  $N_{qy}$  is the littoral transport scale. The time scale for sediment transport is obtained from Eq. (8) based on littoral sediment transport formula proposed by Le Mehaute[6]:

$$N_t = N_h^2 N_v^{-1} N_\gamma^{1/2} N_{D_{50}}^{-1/2} \quad (9)$$

Its inappropriate for apply Eq. (9) for the case of a topographical changes induced by typhoon waves. Hughes [3] suggests an empirical relation of time scale

$$N_t = N_v^{1/2} \quad (10)$$

## 2. Preliminary tests of the distorted ratio

The distorted ratio was determined by the preliminary tests performed in a  $60\text{m} \times 1\text{m} \times 1.2$  wave flume. Three selected beach slopes  $\tan\beta=1/30$ ,  $1/40$ , and  $1/50$  were placed with fine sand of  $0.12\text{mm}$  median diameter under the action of monsoon and typhoon wave conditions. The vertical scale is calculated on the basis of the distorted ratio and horizontal scale. These geometric scales were chosen in order to let model be similar to the prototype in sea bed changes.

Fig. 3 shows the time history of standard deviation of beach profile changes for different beach slopes and wave steepnesses  $H_0/L_0$ . It is seen that the minimum standard deviations are occurred  $\tan\beta=1/50$  for all  $H_0/L_0$  on the exception of  $H_0/L_0=0.047$ . Since the averaged beach slope in the prototype is  $1/300$ , this implies that the proper distorted ratio is 6.

Based on scale ratios mentioned above, all physical quantities are calculated and listed in Table 1. Table 2 gives the time scale of topographical changes during monsoon and typhoon .

## MODEL TESTS

Planar movable bed model tests were conducted in a wave basin of  $50\text{m} \times 16\text{m} \times 0.8\text{m}$ . Four wavemakers wave been installed in the basin to generate regular waves from deep water. The board of each wavemaker is  $4\text{m}$  in length and is motivated by a  $20\text{HP}$  motor. A total number of wave conditions have been tested for sea bottom changes under the conditions of (1) the present condition; (2) dredging at  $-15\text{m}$  water depth; (3) countermeasures for shore protection after dredging. These test cases are presented in Table 3.

Coal ash was used as bed material which has a median diameter of  $0.12\text{mm}$ , with a submerged specific gravity of  $1.02$ . The field sand has a median diameter of  $0.24\text{mm}$  with a submerged specific gravity of  $1.65$ . All relative physical quantities in model and prototype are given in Table 1.

Figure 3 Time history of beach profile changes

Table 1. Physical quantities in model and prototype

physical quantity	scale	prototype		model
horizontal length	1/600	24.0km		40m
vertical length	$\frac{1}{100}$	water depth	+3m~-2.0m	+3cm~-2.0cm
		tidal level	+2.38m - -2.13m	+2.86cm~-2.56cm
wave height	$\frac{1}{74.3}$	monsoon wave	2.60m	3.35cm
		typhoon wave	4.50m	6.90cm
wave period	$\frac{1}{8.62}$	monsoon wave	7.76sec	0.90sec
		typhoon wave	11.20sec	1.38sec
Tidal period	$\frac{1}{10}$	12.42hr		1.242hr
submerged specific gravity	$\frac{1}{1.62}$	1.65		1.02
median diameter	$\frac{1}{2}$	0.24mm		0.12mm

Table 2. Time scale of topographical changes

quantities wave	scale	prototype	model
monsoon wave	1/5267.4	0.6 year	1.0 hr
typhoon wave	1/10	10 hr	1.0 hr

Sea bottom topography was measured at 30 minutes time interval by five point gauges set up on a moving vehicle. Ten traps were buried at the middle position of the model to measure littoral transport across surf zone. Fig. 4 depicts the distribution of littoral transport from laboratory observations. The summation of all traps gives the total longshore sediment transport. Fig. 5 presents temporal variations of longshore sediment transport. We notice that longshore sediment transport tends to become a constant value after 3 hours.

## RESULTS AND DISCUSSION

### **1. Sea bed changes under present conditions**

Using the time scale obtained in the previous section, the monsoon and typhoon waves were respectively generated for 10 hours in the model for the equivalent of 6 years and 10 hours in the nature. The topographical changes under the action of monsoon and typhoon waves in NNE direction are shown in Fig. 6 and Fig. 7. In both cases, the region of the existence of longshore current caused sea bed changes owing to limited sand supply from upstream. Erosion of the sea bottom occurs around seawall of each reclamation area. A remarkable recession of the shoreline appears at area 1 .

### **2. Sea bed changes after dredging**

The industrial area shown in Fig. 8 and Fig. 9 was reclaimed by sand materials. The method of dredging from offshore sea bottom at -15m water depth is considered as one of the sources of sandy supply for reclamation. It extends to 1.5km offshore and the water depth becomes -16m at the dredging area. All sides of industrial area were protected by seawalls to prevent beach erosion from wave attack.

From Fig. 8, we can see that severe erosion takes place along new seawalls. The wave conditions are the same with those without dredging. The figures show the wave energy is not attenuated due to a deeper bathymetry. The interaction between incoming waves and reflected waves forms a very complicated distribution of longshore sediment transport. In Fig. 9, it is evident that on-offshore sediment is dominated for topographical changes. Most of sands were carried offshore and deposit at deep water.

Figure 7 Sea bed changes due to storm wave action (the present condition)

Figure 8 Sea bed changes due to monsoon wave action (new reclamation area after dredging)

Figure 9 Sea bed changes due to storm wave action (new reclamation area after dredging)

### 3. New reclamation area protected by groins

Model tests reveal that erosion occurs along the segment of coast from area 1 to area 2. Accretion takes place in the north of Koshui river (area 3). The most important effect due to dredging can be found as shoreline recession and beach erosion in the vicinity of seawalls. To decrease the influence of dredging, the erosion of reclamation area was designed to be protected by groins. The groins in the model were made of small armour units as shown in Fig. 10 and Fig. 11.

The topographical changes for the case of monsoon and typhoon wave attack are illustrated in Fig. 10 and Fig. 11. The wave conditions in these cases are the same as the previous cases. It is noted that the system of groins almost protected the shore from erosion and accordingly the accretion around the shoreline where erosion occurred was stopped.

## CONCLUSIONS

The effects of dredging on Chang-Hwa reclamation area have been studied by movable bed model tests. The scale relations of wave conditions in the model design are obtained based on the similitude of wave steepness and mobility number. Time scale of topographical changes is determined by longshore sediment transport rate. The present scale law provides a useful tool in practical applications. It takes the advantage to give more flexibility for selection of model sediment.

Several test cases have been carried out including (1) tests for determination of time scale; (2) tests for sea bottom changes under present conditions; (3) tests for sea bottom changes after dredging at -15m water depth; and (4) tests of countermeasures for shore protection after dredging. The most important influence on the position of erosion has been found. The method of construction of groins was considered to decrease beach erosion. It is shown that the proposed groins protect the shore from erosion quite well.

## CHAPTER 215

### OSCILLATIONS INDUCED BY IRREGULAR WAVES IN HARBOURS

C.R. Chou \*, W.Y. Han \*\*

#### ABSTRACT

An approach for predicting the harbour oscillations induced by unidirectional irregular waves in a harbour of arbitrary shape and variable water depth is presented. Effects of partial reflection along harbour and breakwater boundaries were considered by involving an energy dissipation coefficient in boundary conditions. Numerical results on wave heights within a rectangular harbour were presented and a realistic harbour geometry was selected for trial computations. The results of the computations were verified through hydraulic model experiments.

#### 1. INTRODUCTION

One of the major objectives in harbour engineering is the maintenance of a relatively undisturbed water surface within regions of interest. The most effective way to achieve this is to reserve some area in a harbour for natural dissipation. However, almost all the harbours, especially the fishery harbours, in Taiwan have insufficient space to allow for wave energy dissipation. An alternative way is to dispose the vertical dissipating quays in harbours, as many examples are found both in Taiwan and in Japan. However, the choice

---

\* Professor, Dept. of Harbour and River Eng., National Taiwan Ocean Univ.,  
Taiwan, R.O.C.

\*\* Graduate student, ditto.

of the most suitable location and length of the dissipating structure in a harbour is rather problematic. To solve this problem, engineers have usually relied on model experiments in the past, but numerical methods have also been developed. With the increasing speed of performance and lowering cost for acquisition of modern computers, numerical analyses seem to provide a potentially more economical alternative than model experiments.

Many investigators have studied various aspect of the harbour oscillation problem. Miles and Munk(1961) used a point source method to analyze harbour oscillations associated with radiation effects that expand from harbour entrance to offshore. They found the phenomenon of harbour paradox. Ippen and Goda(1963) used Fourier tranformation to analyze a rectangular basin with impermeable veritical wall. Hwang and Tuck (1970) used a boundary integral method which involves the distribution of wave sources along the harbour boundary to calculate oscillations in harbours of constant depth and arbitrary shape. Lee(1971) applied Weber's solution to solve Helmholtz equation and analyzed harbour oscillation of arbitrary shape with constant water depth. Chou and Lin (1986) used a boundary element method to analyze wave-induced oscillations in a harbour of arbitrary shape, together with rigid quays in variable water depth.

The above studies, however, suffer a deficiency, in other words, they are applicable to complete reflection at the harbour boundaries. In fact, reflecting boundaries are not always fully reflecting. In order to treat this problem, Chou and Lin (1989) applied a boundary element method involving an energy dissipating coefficient  $\alpha(= \sqrt{1 - Kr^2})$  based on the theory of energy conservation in arbitrary reflecting boundary to analyze oscillations in a harbour of arbitrary shapes with constant water depth. Chou and Han (1993) also applied a boundary element method to analyze oscillations in a harbour of arbitrary shapes with variable water depth.

All of the above studies can be applied only to small amplitude waves. However, waves in seas are one of the most complex and changeable phenomena in nature. In this paper, an extended model for unidirectional irregular waves will be presented. For verification, model experiments were carried out and compared with numerical predictions.

2. THEORETICAL ANALYSIS

2.1 Regular Wave

Fig.1 schematically shows a harbour configuration under consideration. A Cartesian coordinate system is employed, the origin of which is located at  $o$  with the  $z$ -axis vertically upwards. As shown in the figure, the flow field is divided into two regions by a pseudo-boundary surface  $\Gamma_1$ : Region I is an open sea region with constant depth, and Region II is a harbour basin bounded by  $\Gamma_1$  and the harbour and breakwater boundaries, with variable water depth.

Fig. 1 Definition sketch

Usual assumptions of the fluid being inviscid and incompressible and the flow being irrotational are adopted here. We consider linear waves, having angular frequency  $\sigma (= 2\pi/T, T$  is the wave period) and amplitude  $\zeta_0$  incident from the open sea at an angle of  $\omega$  against the  $x$ -axis. Fluid motions in both the regions will then have velocity potentials as follows:

$$\Phi(x, y, z; t) = \frac{g\zeta_0}{\sigma} \cdot \phi(x, y, z) \cdot \exp(-i\sigma t) \tag{1}$$

where  $g$  is the gravitational acceleration, and  $\phi(x, y, z)$  must satisfy the Laplace equation  $\nabla^2 \phi = 0$

Applying Green's law(Chou and Han(1993)), the potential function for any point in Region I can be calculated from the following integral equation:

$$cf^*(x, y) = \int_{s_1} \left[ \left( \frac{i}{4} H_0^{(1)}(kr) \right) \frac{\partial}{\partial \nu} f^*(\xi, \eta) - f^*(\xi, \eta) \frac{\partial}{\partial \nu} \left( \frac{i}{4} H_0^{(1)}(kr) \right) \right] ds \tag{2}$$

where  $f^*(\xi, \eta)$  is the potential function specified by the geometric condition of the boundaries in Region I,  $\partial f^*(\xi, \eta)/\partial \nu$  is its normal derivative with  $\nu$  the

local normal coordinate to the boundary taken outwards.  $H_0^{(1)}(kr)$  is the zeroth order Hankel function of the first kind, and  $r = [(x - \xi)^2 + (y - \eta)^2]^{1/2}$  is the distance between a point under consideration and the boundary. The factor  $c$  equals to unity within the boundary, but will have a value of  $1/2$  on boundaries.

In the numerical analysis, the boundary  $S_1$ , where  $c=1/2$ , is discretized into  $M$  segments, each having a constant element. Equation (2) is then rewritten in a matrix form as

$$\{F^*\} = [K^*]\{\bar{F}^*\} \quad (3)$$

where  $\{F^*\}$  and  $\{\bar{F}^*\}$  are the potential function and its normal derivative on the pseudo-boundary  $S_1$ , and  $[K^*]$  is a coefficient matrix related to the geometric location of  $S_1$ .

According to Green's second identity law, velocity potential  $\phi(x, y, z)$  at any point within Region II can be determined as

$$c\phi(x, y, z) = \int \left[ \frac{\partial\phi(\xi, \eta, \zeta)}{\partial\nu} \left(\frac{1}{4\pi r}\right) - \phi(\xi, \eta, \zeta) \frac{\partial}{\partial\nu} \left(\frac{1}{4\pi r}\right) \right] dA \quad (4)$$

where  $r = [(x - \xi)^2 + (y - \eta)^2 + (z - \zeta)^2]^{1/2}$ . As before,  $c$  is unity for points inside the region and is equal to  $1/2$  on smooth boundaries.

To proceed with numerical calculation, surfaces of the boundaries  $\Gamma_1$  through  $\Gamma_4$  are divided into  $N_1$  to  $N_4$  discrete segments with constant elements.

For the case that  $c=1/2$ , Eq.(4) is readily expressed as

$$\{\phi\} = [K]\{\bar{\phi}\} \quad (5)$$

where  $\{\phi\}$  and  $\{\bar{\phi}\}$  are the potential function and its normal derivative on the boundaries  $\Gamma_1$  through  $\Gamma_4$ .  $[K]$  is a coefficient matrix related to the geometry of the boundaries.

The boundary conditions required for the case under consideration are summarized as follows:

(i) The free surface condition:

For constant air pressure, the kinematic boundary condition for the free water surface is expressed as:

$$\bar{\phi} = \frac{\sigma^2}{g} \cdot \phi \quad , \quad z = 0 \tag{6}$$

(ii) Boundary condition on impermeable sea bed:

For an impermeable sea floor, the flow is zero in the normal direction:

$$\bar{\phi} = 0 \tag{7}$$

(iii) Boundary condition on the pseudo-boundary at open sea:

The requirement of continuity for mass and energy fluxes between Region I and Region II at the pseudo-boundary  $\Gamma_1$  leads to the expression:

$$\bar{\phi}_0(\xi, \eta, z) = \bar{\phi}(\xi, \eta, z) \tag{8}$$

$$\phi_0(\xi, \eta, z) = \phi(\xi, \eta, z) \tag{9}$$

(iv) Boundary condition on a quay or breakwater

Assume the boundaries of the quays or breakwaters  $\Gamma_3$  are impermeable and have an arbitrary coefficient of reflection  $K_r$ . Since waves are reflected only partially, based on the theory of energy conservation, these constructions can therefore be treated, conceptually, as having a energy dissipating coefficient  $\alpha$  indicated by Chou and Lin(1989) reads

$$\alpha = \sqrt{1 - K_r^2} \tag{10}$$

The boundary condition on  $\Gamma_3$  can be expressed conveniently as:

$$\bar{\phi}(\xi, \eta, \zeta) = ik\alpha\phi(\xi, \eta, \zeta) \tag{11}$$

Substitution of Eqs.(6),(8),(9) and (11) into Eq.(5), a little algebra lead to

$$\begin{bmatrix} [K_{11} - CRK^*Q] & \frac{\sigma^2}{g} K_{12} & ik\alpha K_{13} \\ K_{21} & \frac{\sigma^2}{g} K_{22} - I & ik\alpha K_{23} \\ K_{31} & \frac{\sigma^2}{g} K_{32} & ik\alpha K_{33} - I \end{bmatrix} \begin{bmatrix} \bar{\phi}_1 \\ \phi_2 \\ \phi_3 \end{bmatrix} = \begin{bmatrix} R[F^o - K^*\bar{F}^o] \\ 0 \\ 0 \end{bmatrix} \tag{12}$$

where  $C = k/(N_0 \sinh kh)$ ,  $\{F^o\}$  and  $\{\bar{F}^o\}$  are the potential function and its normal derivative of the incident wave, [R] and [Q] are coefficient matrices given by Chou and Han (1993).

By solving the above equation, the potential functions on boundaries  $\Gamma_2$  are obtained. The wave height ratio,  $K_d$ , defined as the ratio of the wave height in Region II to the incident wave height, can be calculated from

$$K_d = |\phi_2| \quad (13)$$

## 2.2 Irregular Wave

The approach for the oscillations of unidirectional irregular waves in the harbour of arbitrary shape with dissipating quays is based on the spectral resolution method (Nagai (1972)), where each component wave is known. Assuming that incident component waves are small amplitude waves, the oscillations of these regular waves can be obtained by numerical method in section 2.1, then the water surface oscillations for irregular waves can be obtained through linear superposition method.

In this paper, the Bretschneider spectrum (Bretschneider(1968)) was used. In order to simplify the process of numerical analysis, the incident spectrum was transformed into dimensionless type as follows:

$$S^*(f^*) = af^{*-5} \exp[-(bf^{*-4})] \quad (14)$$

$$a = b/4$$

$$b = 0.675/0.9^4 = 1.0288$$

To obtain the component waves, the dimensionless spectrum is discretized into  $m$  parts, each with the same energy  $\Delta E$  (each part under the spectrum having the same area), then, the representative frequencies  $f_{cn}^*$  of each component wave can be written as

$$f_{cn}^* = \sqrt{\frac{8am\sqrt{\pi}}{\sqrt{b}} \left[ \operatorname{erf} \left( \sqrt{2 \ln \left( \frac{m}{n-1} \right)} \right) - \operatorname{erf} \left( \sqrt{2 \ln \left( \frac{m}{n} \right)} \right) \right]} \quad (15)$$

where  $a$  and  $b$  are the coefficients of the dimensionless Bretschneider spectrum;  $n=1,2,\dots,m$ ; and  $\operatorname{erf}(x)$  is the error function given as

$$\operatorname{erf}(x) = \int_0^x \frac{\exp(-z^2/2)}{\sqrt{2\pi}} dz \quad (16)$$

2.3 Wave height ratio  $K_D$  and period ratio  $K_T$  due to irregular waves

From section 2.1, the wave height ratio  $K_d$  due to regular component waves can be obtained, then the wave height ratio  $K_D$  and period ratio  $K_T$  due to irregular waves can be obtained by following equations.

$$K_D = \frac{H_{1/3}}{(H_{1/3})_o} = 4.0 \sqrt{\int_0^\infty S_D^*(f^*) df^*} \tag{17}$$

$$K_T = \frac{T_{1/3}}{(T_{1/3})_o} = \sqrt[3]{\pi b} \sqrt{\frac{\int_0^\infty S_D^*(f^*) df^*}{\int_0^\infty f^{*2} S_D^*(f^*) df^*}} \tag{18}$$

$$S_D^*(f^*) = K_d^2 S^*(f^*) \tag{19}$$

where  $S_D^*(f^*)$  is the spectrum in the harbour induced by the incident spectrum  $S^*(f^*)$ , subscript "o" means the values in off-shore.

3. DETERMINATION OF THE REFLECTION COEFFICIENT

To proceed with the analysis numerically, the energy dissipation coefficient  $\alpha$  in Eq.(11) must be determined. In other words, the reflection coefficient of the dissipating structure in Eq.(10) must be found empirically. This was done in a 2-D wave flume, shown schematically in Fig.2. The reflection coefficients can be obtained as shown in Fig.3, where the dotted curve shows the best fit of the experimental data in a least squares sense. Reflection coefficients for different frequencies determined from this empirical function were used in the subsequent calculations.

Fig. 2 Setup of 2-D wave flume & dissipating quay

Fig. 3 The reflection coefficient of dissipating quay

4. EXAMPLE

Table 1. Cases of square basin

	S1	S2	S3	remarks
case I	x	x	x	x:impermeable quay
case II	o	o	o	o:dissipating quay
case III	x	o	x	
case IV	o	x	o	

Fig. 4 Definition sketch for square harbour

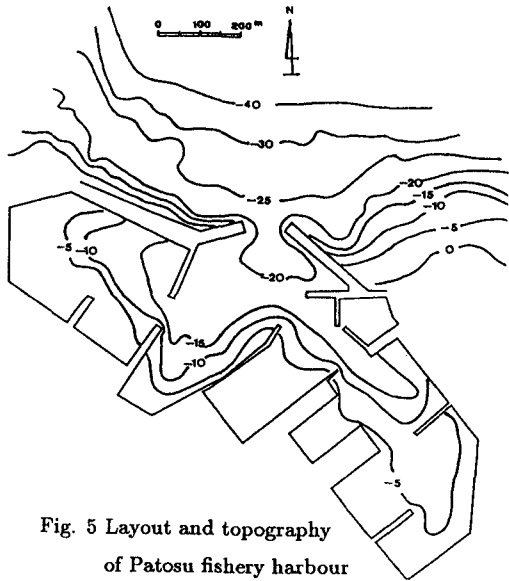

Fig. 5 Layout and topography of Patosu fishery harbour

Calculations were first carried out for a square basin with a width equal to  $10h$ , ( $h$  is the water depth of the open sea) and an opening width  $b=5h$  at the center of the basin, as shown in Fig.4. The same dissipating quays as those in the two-dimensional wave flume experiment were assumed and uniform water depths in both the Regions I and II.

In the numerical analysis, the surfaces of the boundaries are divided into 1056 discrete areas with constant element ( $N_1=104, N_2=720, N_3=52, N_4=180, M=2$ ). Waves propagating perpendicular toward the harbor entrance were used. Distributions of wave heights for dimensionless frequencies  $\sigma_{1/3}^2 h/g = 1.206$  ( $T_{1/3} = 1.0$  second) was determined. Table 1 shows the conditions used for the calculation.

Computations were also performed for an example of the Patosu fishery harbour built 3 years ago in the northern part of Taiwan. The layout and topography of the harbour are given in Fig.5. Quays and breakwaters of this fishery harbour are dissipating structures (PERFORCELL), whose reflection coefficient is estimated approximately at 0.75, the energy dissipation coefficient being 0.661. In the numerical computation, water depth larger than 40

m was regarded as constant, and the boundary surfaces were divided into 1988 discrete segments with constant elements ( $N_1=152, N_2=1329, N_3=176, N_4=331$  and  $M=2$ ). Distributions of wave heights were calculated for incident waves propagating from  $23.5^\circ$  north-northeast ( $\omega = 66.5^\circ$ ) toward the harbour entrance with dimensionless frequencies of  $\sigma_{1/3}^2 h/g = 1.611$  ( $T_{1/3} = 1.0$  second).

In the numerical analysis, the dimensionless spectrum is discretized into 12 segments ( $m=12$ ), then the representative frequency  $f_{cn}^*$  of each component wave can be calculated by Eq.15, and the wave height ratio  $K_D$  and period ratio  $K_T$  can be obtained by Eq.17 to 18.

## 5. LABORATORY EXPERIMENT

Experiments were carried out in a 3-D wave basin. The wave basin is 30 m long, 24 m wide and 1 m deep. The programmable wave generator is capable of generating regular and irregular waves. Water depth was kept to be 0.3m throughout the experiments. Water surface displacements were measured with capacitance-type wave gauges.

## 6. RESULTS AND DISCUSSION

Fig.6 shows the wave height distributions for irregular waves obtained both by the present numerical method and experiments for case I and case II of square basin with significant wave period  $(T_{1/3})_0 = 1.0$  second. From these figures, a general increase of wave height in case I due to reflection effects and decrease of that in case II due to the effects of disposing dissipating quays were found. The tendencies of wave height distributions predicted by the present numerical model are confirmed by the experiments.

Fig.7 shows the period distributions  $K_T$  for irregular waves obtained both by the present numerical method and experiments for case I and case II of square basin with significant wave period  $(T_{1/3})_0 = 1.0$  second. The spatial variation of  $K_T$  is increasing in the range of 20% in the square basin, and the spatial similarity between numerical solutions and experimental results are reasonable.

Fig.6 Wave height distributions  $K_D$  for irregular wave  
 $(\sigma_{1/3})^2 h/g=1.206$ ,  $t=1.0$  sec,  $h=30$  cm,  $\omega = 90^\circ$

Fig.7 Wave height distributions  $K_T$  for irregular wave  
 $(\sigma_{1/3})^2 h/g=1.206$ ,  $t=1.0$  sec,  $h=30$  cm,  $\omega = 90^\circ$

Fig.8 shows the comparison of wave height distributions in square basin by numerical model to regular waves with period  $T=1.0$  second and to irregular waves with significant period  $(T_{1/3})_0 = 1.0$  second for case I to IV respectively. For both regular and irregular waves, the oscillations in case II to IV is apparently reduced because of disposing dissipating quays. Compared the difference of wave height distributions induced by regular and irregular waves, it can be found that the wave height distributions induced by irregular waves are, in general, more stable than those induced by regular waves. The wave motions by irregular waves generally consist with those existing in nature sea-water surface.

Fig.9 shows the distribution of wave height  $K_D$  for irregular wave obtained by the numerical method and experiments for the Patosu fishery harbour with  $\alpha = 0.661$ , wave direction of  $23.5^\circ$  north-northeast and wave period  $(T_{1/3})_0 = 1.0$  second. Compared the difference of these figures with Fig.10, the same phenomena in square basin mentioned above that the wave height distributions induced by irregular waves are more stable than those induced by regular waves was found. The spatial similarity between numerical solutions and experimental results are reasonable too.

Fig.10 shows the period distributions  $K_T$  for irregular waves obtained both by the present numerical method and experiments for the Patosu fishery harbour with significant wave period  $(T_{1/3})_0 = 1.0$  second. The spatial variation of  $K_T$  is increasing in the range of 20% in the numerical results. Because the wave heights in the inner region of the harbour are too small to measured, the significant wave period in that region can not be obtained in the laboratory.

## 7. CONCLUSION

The effects of dissipative quays and/or breakwaters are modeled using a coefficient for energy dissipation in the boundary condition. Comparisons of calculated and measured results for both a square basin and a real harbour are shown. From the examples presented above show that the spatial similarity between numerical solutions and experimental results are reasonable. It is conjectured that, given the correct coefficient, the most suitable position for dissipating quays in a harbour could be estimated by the present method.

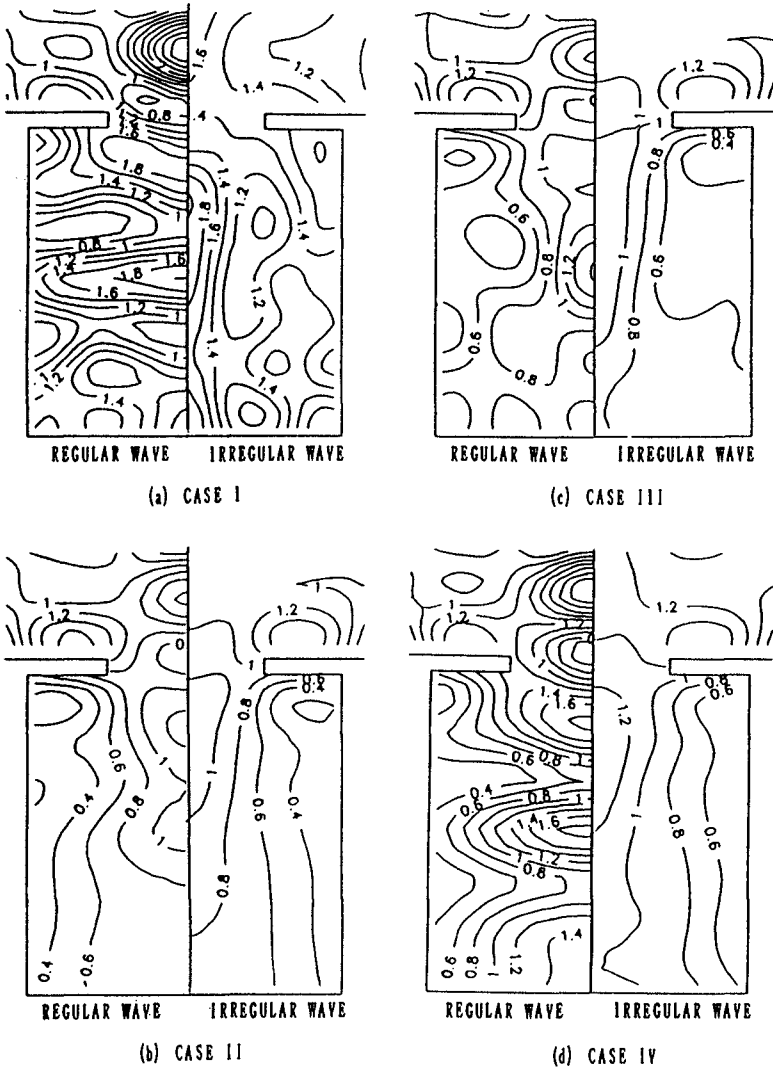

Fig.8 Wave height distributions for regular wave ( $T=1.0$  sec.)  
and irregular wave ( $T_{1/3}=1.0$  sec.)

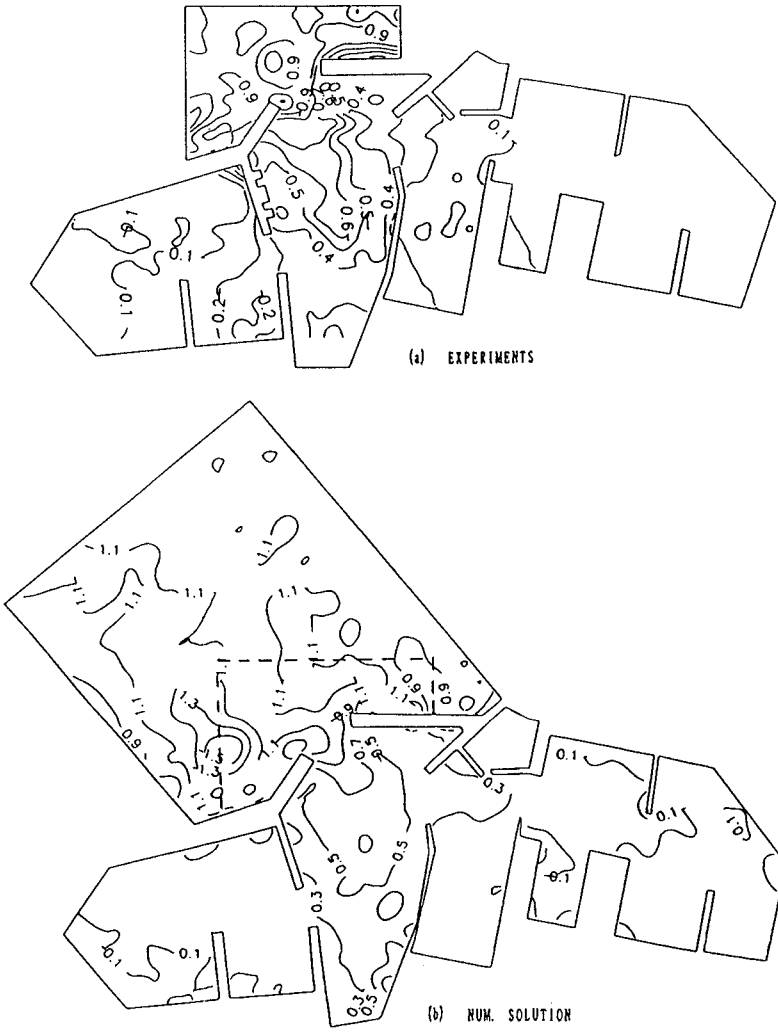

Fig.9 Wave height distributions  $K_D$  for irregular wave in Patosu fishery harbour, ( $T_{1/3}=1.0$  sec.)

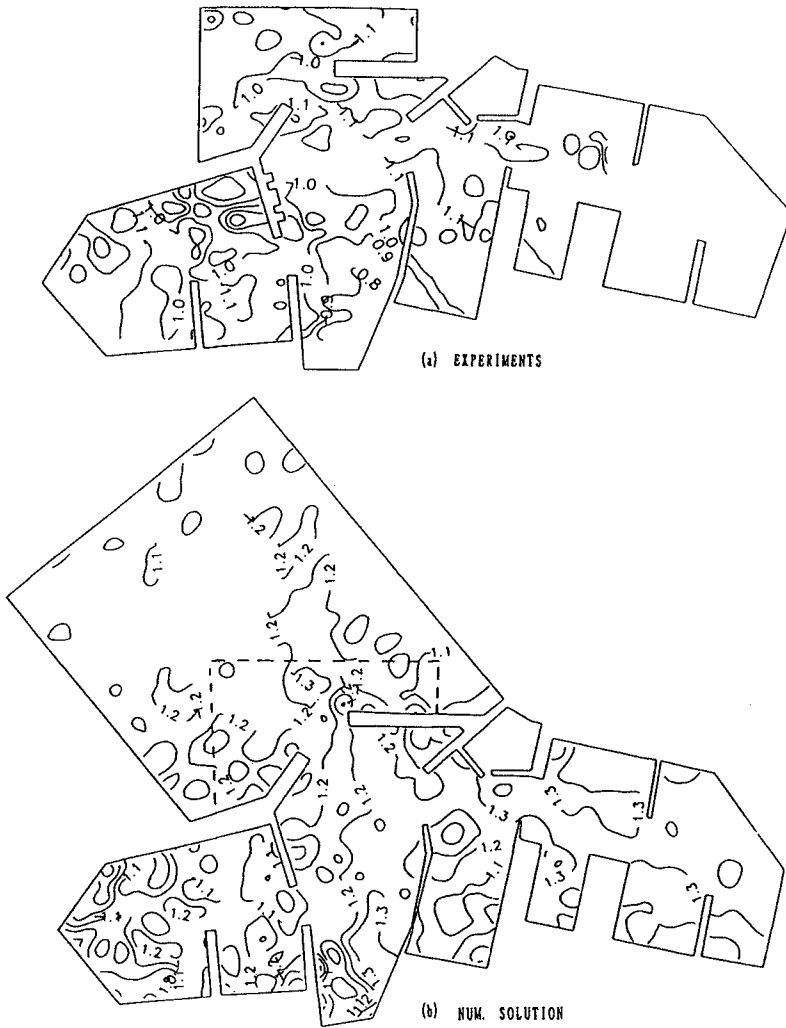

Fig.10 Wave period distributions  $K_T$  for irregular wave in Patosu fishery harbour, ( $T_{1/3}=1.0$  sec.)

Though only the Bretschneider spectrum as incident wave spectrum was used in this paper, other spectrums such as Pierson Moskowitz spectrum or JONSWAP spectrum can be applied by this method also.

It is thus concluded that the present numerical method can be used to study problems related with harbour oscillations.

## CHAPTER 216

### Mechanism and estimation of sedimentation in Bangkok Bar Channel

Ichiro DEGUCHI<sup>1)</sup>, Toru SAWARAGI<sup>2)</sup>, Masanobu ONO<sup>3)</sup>  
and Sucharit KOONTANAKULVONG<sup>4)</sup>

#### ABSTRACT

Mechanism of sedimentation in Bangkok Bar Channel in Thailand is investigated by using the periodically measured water depth around channel, dredged volume and the relation between discharged sediment concentration and discharged velocity measured at the river mouth of Chao Praya. Simple numerical simulations for predicting sedimentation volume in the channel are also carried out. The results show that both discharged sediment from the river and sedimentation around Bangkok Bar caused by waves and current play an important role in the sedimentation in the channel.

#### Introduction

The city of Bangkok has been developed along the Chao Praya River. The Bangkok Harbor plays very important role in economic and social activities of Thailand. Bangkok Bar Channel is a unique approach channel to Bangkok Harbor that is the representative river port constructed along the river mouth of the Chao Praya, Thailand. Various facilities are scattered along the both sides of the river between the river mouth and the bridge located about 50km upward (see Fig.1). Due to the heavy sedimentation discharge from the river and severe sedimentation around the bar, the channel is barely maintained its fair way through the continuous dredging of about 5million m<sup>3</sup>/year.

Some reports have already been published about the sedimentation of the channel by NEDECO(1963), Port Authority of Thailand and so on. They reported many important and interesting phenomena and fact about hydraulics of the river mouth and characteristics of the bed material

The aim of this study is to investigate the mechanism of sedimentation in Bangkok Bar Channel and to estimate the volume of sedimentation in the channel through the statistical analysis of measured time history of river discharge, dredged volume and bottom profiles during August 1989 and August 1991 together with the results mentioned in the above-mentioned reports. In 1992, we also carried out field measurements of velocity and silt concentration at river mouth.

1),2) and 3) Associ. Prof., Prof and Research Associ., Dept. of Civil Engineering, OSAKA University, Yamadaoka, Suita, Osaka 565, Japan 4) Associ. Prof., Dept. of Water Resources Engineering, CHULALONGKORN University

For the estimation of siltation volume in the channel, we conducted some numerical simulation of non-equilibrium sediment concentration caused by waves and current that crossed the channel. It is generally recognized that there are two modes of silt transport that is transport by mud flow and that by suspension. Here, we only evaluate the sedimentation volume in latter mode.

### Outline of Bangkok Bar Channel

The construction of the channel began in 1951 and was completed in 1954. The volume of capital dredging was about 16million  $m^3$ . The length of the channel is 18km and the channel crosses Bangkok Bar, the depth of which is less than 2m at low tide. Figure 1 shows a plane view of the Bangkok Bar Channel. A mean depth of the channel is about -8.5m under the mean sea level and the width of the channel varies from 100m (at straight part) to 200m (at the bend).

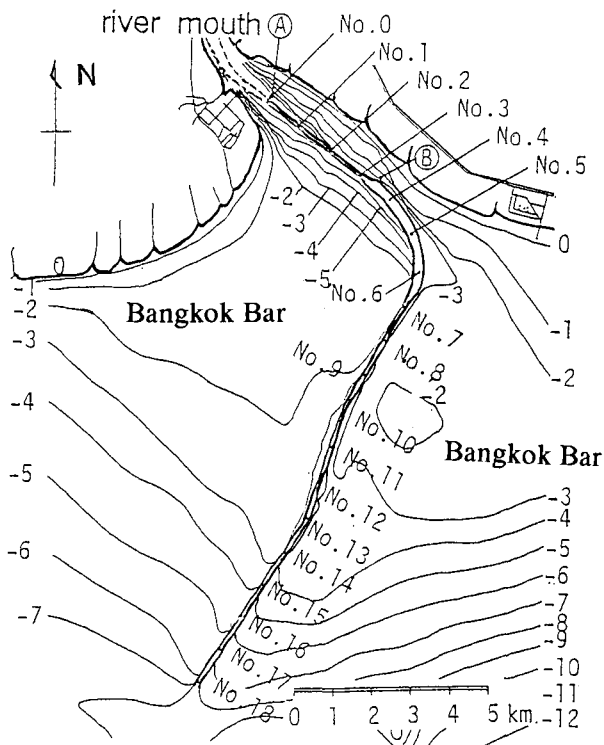

Fig.1 Plane view of Bangkok Bar Channel

There is a couple of possible causes for the sedimentation around the channel, such as sedimentation of discharged silt from the river, sedimentation caused by waves and tidal current, that caused by waves and wave-induced current around the

bank, and so on. There are also some mode of sediment transport, such as suspended sediment transport, bed load transport, mud flow, and so on. Among them, we firstly evaluated the volume of discharge sediment from the river based on the depth averaged discharge velocity and siltation concentration measured in May and in August 1991. Then, the amount of sedimentation due to suspension around the Bangkok Bar caused by waves and tidal current was predicted through the numerical simulation.

### Characteristics of River discharge and Monsoon

Sedimentation around the channel seems to deeply depend on the river discharge and wind waves generated by monsoon. In usual, the maximum discharge is more than  $3000\text{m}^3/\text{s}$  that took place at rate September to October that will be shown in Fig.5(b) later. However, in the objective period (from August, 1989 to August, 1991), the discharge was far less than the usual year as will be shown in Fig.6(b).

Figure 2 is the time series of wind direction and wind velocity measured at the Bangkok during objective period.

Fig. 2 Time series of wind direction and velocity during objective period

NE monsoon and SW monsoon seasons usually begin at November and May, respectively. In the objective period, each monsoon seasons began first than usual. The mean wind velocity is about 0.5m/s to 3.0m/s and a little bit strong wind blows in SW monsoon season.

The direction that brings significant wind waves is from south to south-west. From May to July in 1990, both discharged flow from the river and wind waves caused by the monsoon might affect sedimentation in the channel. Only the discharged flow was the sedimentation agency in channel from October to December in 1989 and only waves and tidal current caused sedimentation in the channel from May to July in 1991.

#### Sedimentation volume in the channel

Sedimentation volume in the channel was estimated from measured channel topography and records of dredged volume. Sounding of the channel has been carrying out by Port Authority of Thailand twice a month at distances of 200m in the offshore (transversal) direction and 5m in the longitudinal direction. We express the measured depth in the following way:

$$h(x, y, t) = h(i\Delta x, j\Delta y, k\Delta t) \quad (1)$$

$x$  : transversal direction,  $\Delta x = 200m, 1 \leq i \leq 91$

$y$  : longitudinal direction,  $\Delta y = 5m, 1 \leq j \leq 61$

$\Delta t = month/2$

Sedimentation volume was calculated by the following relation:

$$\Delta V(i, j, k) = \{h(i, j, k) - h(i, j, k + 1)\} \Delta x \Delta y \quad (2)$$

We define the total sedimentation volume  $\Delta TV$  as a sum of  $\Delta V$  and dredged volume  $\Delta V_d$ . We obtained there data through the courtesy of the Port Authority of Thailand.

The characteristics of the time and spatial variation of the sedimentation volume is investigated by comparing the time histories of river discharge and wind data.

Figure 3 illustrates the temporal and spatial distribution of the total siltation volume of the channel. The vertical axis is the distance from the river mouth and the horizontal axis is the month.

It can be seen that dark parts centered around 3 to 8km from the river mouth. This section of the channel corresponds to the bending part. Especially, from August to October and April to July, large volume of sediment deposited. These two duration corresponds to the two peaks of river discharge (see Fig.6(b)). However, there are another dark parts in the bend during February and August in 1991 (south-west monsoon season) when there was only small river discharge.

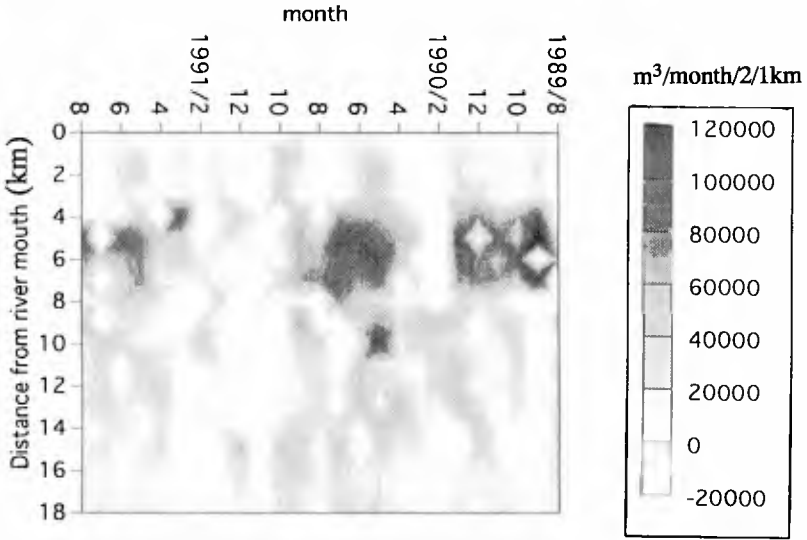

Fig.3 Temporal and spatial distribution of the total sedimentation volume

Figure 4 illustrates the variance of the change in water depth  $\Delta h_{vr}(i,j)$  that means the magnitude of the topographic change in the channel.

Fig.4 Variance in water depth around the channel

The variance is calculated by Eq.(3).

$$\Delta h_{vr}(i, j) = \sum_k \{h(i, j, k) - \overline{h(i, j)}\}^2 / 25 \quad (3)$$

where  $h(i, j)$  is the averaged water depth during the objective period.

The vertical axis is again the distance from the river mouth and the horizontal axis is the longshore distance. It is found that change in water depth is large in the bend and the slope of the channel where the non-equilibrium property of suspended sediment is strong.

Figure 5 shows the comparison of the averaged river discharge and the averaged total siltation during 1957 and 1963. The averaged total siltation volume is calculated in upper section (from 0km to 6km from the river mouth), middle section (from 6km to 12km from the river mouth) and lower section (from 12km to 18km from the river mouth) separately in the following way and are shown by a solid line, a dotted line and a broken line, respectively.

$$\Delta TV_l(k) = \sum_{i=(l-1)*30}^{l*30-1} \sum_j \Delta TV(i, j, k), \quad (4)$$

$l=1$ : upper section,  $2$ : middle section,  $3$ : lower section

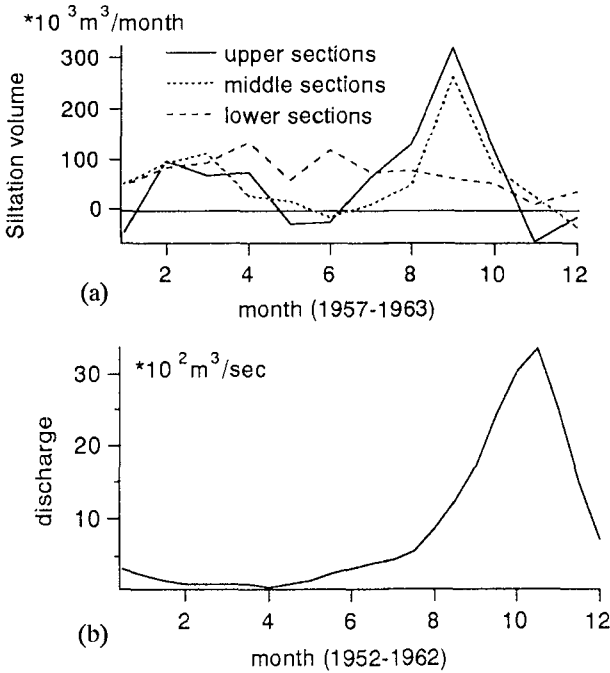

Fig. 5 Comparison of the seasonal changes of averaged total sedimentation volume and river discharge

River discharge has a peak at middle of October and the total siltation in the upper and the middle sections have peaks at middle of September that correspond to the peak of river discharge. They also indicate large values during February and April when the river discharge becomes minimum. The total siltation in the lower sections dose not show any significant seasonal change.

From these results, we can judge that sedimentation in the upper and the middle sections is mainly caused by river discharge and in the lower sections river discharge has little influence. Waves and current also play an important role in sedimentation in dry SW monsoon season in the upper and middle sections and in the lower sections they become unique agitation and transporting agency of bed material to deposit in the channel.

Figure 6 shows the comparison of time histories of the total siltation and river discharge during August 1989 and August 1991. In this duration there are three peaks in river discharge and again there are increases in the total siltation in the upper and the middle sections. However, the correspondence is not so clear as the former figure due to the scattering of the data because these are the raw and unsmoothed data.

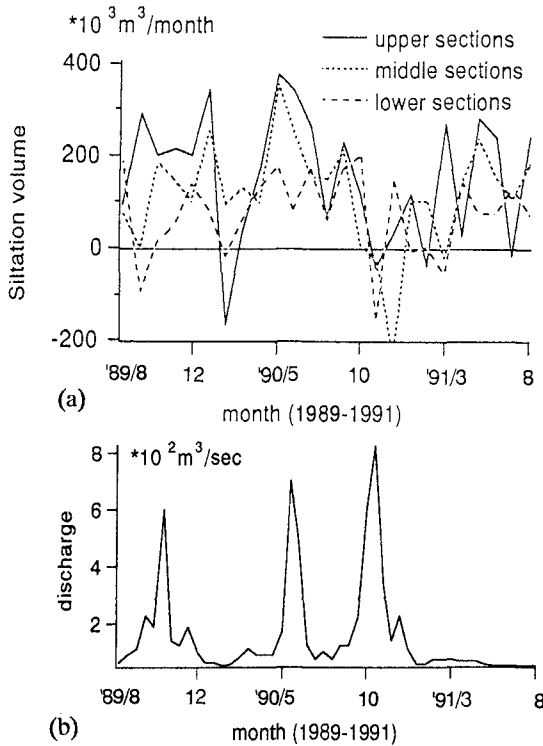

Fig.6 Comparison of time histories of total siltation volume and river discharge during the objective period

Estimation of sedimentation volume discharged from the river

We carried out field measurement of discharged velocity and silt concentration in May and August 1992 at two point near the river mouth. Here, we roughly estimated the siltation volume using the measured results. Figure 7 illustrates the relation between the mean discharged velocity and mean silt concentration presented in the report of NEDECO (1963). The open circles in the figure are the result of our measurements.

Fig.7 Relation between depth averaged discharge velocity and silt concentration at the river mouth

As you know well, the mean silt concentrations in the beginning of the discharge and in the descending period of the discharge are not the same. Generally it is lower in the later period. However, we assume that the mean silt concentration is a unique function of the mean velocity. Then we have the relation between them from the figure in the following form:

$$C[ppm] = 400U[m/s] \tag{5}$$

Let the discharged volume and sectional area of the flow at the river mouth be  $Q$  and  $A$ , then the discharged silt volume  $Q_s$  is expressed as:

$$Q_s = AUC = 400Q^2/A * 10^{-6} [m^3/s] \tag{6}$$

Further we assume that the time history of the river discharge is expressed by the triangle with the peak value of  $3000m^3/s$  and continues for two months as shown in Fig.8 and the sectional area of the river mouth be  $2000m^2$ . Then the total siltation volume discharged from the river is calculated by the integration

Fig.8 Assumed hydrograph

$$Q_{total} = \int_0^{two-month} Q_s dt \quad (7)$$

that gives  $1.6 \cdot 10^6 m^3/year$ . The value is about a half of the annual averaged total annual siltation volume.

**Estimation of sedimentation volume caused by waves and tidal current**

In this section, siltation volume due to waves and current, an another sedimentation agency in the channel is evaluated by a simple numerical simulation.

For the sake of simplicity, and to grasp the rough figure of the sedimentation in the channel, we assume that the waves and current cross the channel at right angle as shown in the lower figure. X-axis is taken in the direction of wave propagation and we simulate the flow and sedimentation in 2-D phenomena (see Fig.9).

In such case, sever sedimentation will take place due to the non-equilibrium suspended sediment transport caused by the existence of channel. In the numerical simulation, we have to reproduce the non-equilibrium state of the suspended sediment concentration adequately.

Fig.9 Coordinate system

A governing equation of suspended sediment concentration  $c$  is an advection-diffusion equation that is expressed by Eq.(8).

$$\frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} - W_f \frac{\partial c}{\partial z} = \epsilon_x \frac{\partial^2 c}{\partial x^2} + \epsilon_z \frac{\partial^2 c}{\partial z^2} \quad (8)$$

where  $u$  is the mean current velocity that has a vertical distribution,  $\epsilon_x$  and  $\epsilon_z$  are the diffusion coefficients in  $x$  and  $z$  direction and  $W_f$  is the settling velocity of bed material.

It has been recognized that it is generally difficult to numerically solve the advection-diffusion equation with high accuracy because it contains two mathematically and physically different terms, i.e., advection term and diffusion term. Recently, highly accurate numerical procedures for solving the advection-diffusion equation have been developed by Komatsu et.al.(1985) that is called a split operator approach.

We applied two procedures to simulate non-equilibrium suspended sediment concentration. Eq.(8) is solved by using a split-operator approach in Method-1 and in Method-2, an advection-dispersion equation Eq.(9) instead of Eq.(8) is solved to obtain sediment concentration. Equation (9) is derived by taking depth average of Eq.(8).

$$\frac{\partial C}{\partial t} + U \frac{\partial C}{\partial x} + V \frac{\partial C}{\partial y} = \kappa_x \frac{\partial^2 C}{\partial x^2} + \kappa_y \frac{\partial^2 C}{\partial y^2} + \Delta Q_s \quad (9)$$

$$\Delta Q_s = \left\{ C_0 u^* (1 - W_f / u^*) - W_f C \right\} / h \quad (10)$$

$$\gamma = 1, \quad u^* / W_f \leq 1, \gamma = 0, \quad u^* / W_f > 1$$

where  $U$  and  $V$  are the depth averaged mean current velocity in  $x$  and  $y$  directions,  $C$  is the depth averaged concentration of suspended sediment,  $\kappa_x$  and  $\kappa_y$  are the dispersion coefficients in  $x$  and  $y$  directions,  $u^*$  is the bottom shear velocity caused by waves and current  $C_0$  is the reference concentration at the bottom and  $h$  is the water depth.

In Method-1, the advection-diffusion equation is split into the advection and the diffusion equations Eqs.(11) and (12).

$$\frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} - W_f \frac{\partial c}{\partial z} = 0 \quad (11)$$

$$\frac{\partial c}{\partial t} = \varepsilon_x \frac{\partial^2 c}{\partial x^2} + \varepsilon_z \frac{\partial^2 c}{\partial z^2} \quad (12)$$

These two equations are transformed to a pair of finite difference equations by using 6-point and 5-point methods, respectively. The difference equations are calculated iteratively at grid points. The boundary condition for concentration is given at the upstream end and at the bottom.

After obtaining the steady solution, we can evaluate suspended sediment flux (Eq.(13)) and the rate of topographic change by Eq.(14).

$$q_s(x, z) = \int c(x, z) u(x, z) dz \quad (13)$$

$$\frac{\partial h(x, t)}{\partial t} = \frac{1}{1 - \lambda} \frac{\partial q_s(x, t)}{\partial x} \quad (14)$$

In Method-2, a depth averaged advection-dispersion equation (Eq.(9)) is solved by using an Alternating Direction Implicit method. The boundary condition for the depth averaged concentration is given at the upstream end and at the bottom. The change in water depth is calculated by using vertical sediment flux  $\Delta Q_s$  as follows:

$$\frac{\partial h}{\partial t} = \frac{-\Delta Q_s}{1 - \lambda} \quad (13)$$

We have already developed this method for the simulation of topographic change in coastal region. We apply the procedure to calculate topographic change of channel section. About 20 times as much as CPU time is required in Method-1 when compared with that required in Method-2.

We carried out numerical simulations of channel topography change of two cases as shown in Fig.10. In both cases, the depth of the fairway was 8.5m. The depth at the channel approach was 3m in Case-1 and 5m in Case-2. The non-equilibrium property of suspended sediment is stronger in Case-1 than in Case-2.

Fig.10 Channel section of numerical simulation

Height and period of incident waves were 1.5m and 6s. According to the report of the Port Authority of Thailand, waves of such magnitude would occur more than 30hrs per year. The mean current velocity was determined to be 0.3m/s that was a mean tidal current that crosses the channel. The settling velocity of bed material was 0.12cm/s that included the effect of flocculation (NEDECO, 1963).

In the numerical simulation, we first calculated waves and current based on equations of wave energy conservation and depth averaged momentum conservation where the bottom shear stress were evaluated from the turbulent boundary layer equation (Deguchi, 1995). In Method-1, the vertical distribution of mean current was determined from the depth averaged mean current velocity by using the kinematic eddy viscosity as a function of bottom shear velocity.

Figure 11 illustrates flow charts of both methods. We used the same value as the kinematic eddy viscosity for the diffusion coefficient in Method-1. The dispersion coefficient in Method-2 was given as a function of the product of the bottom shear velocity and the water depth.

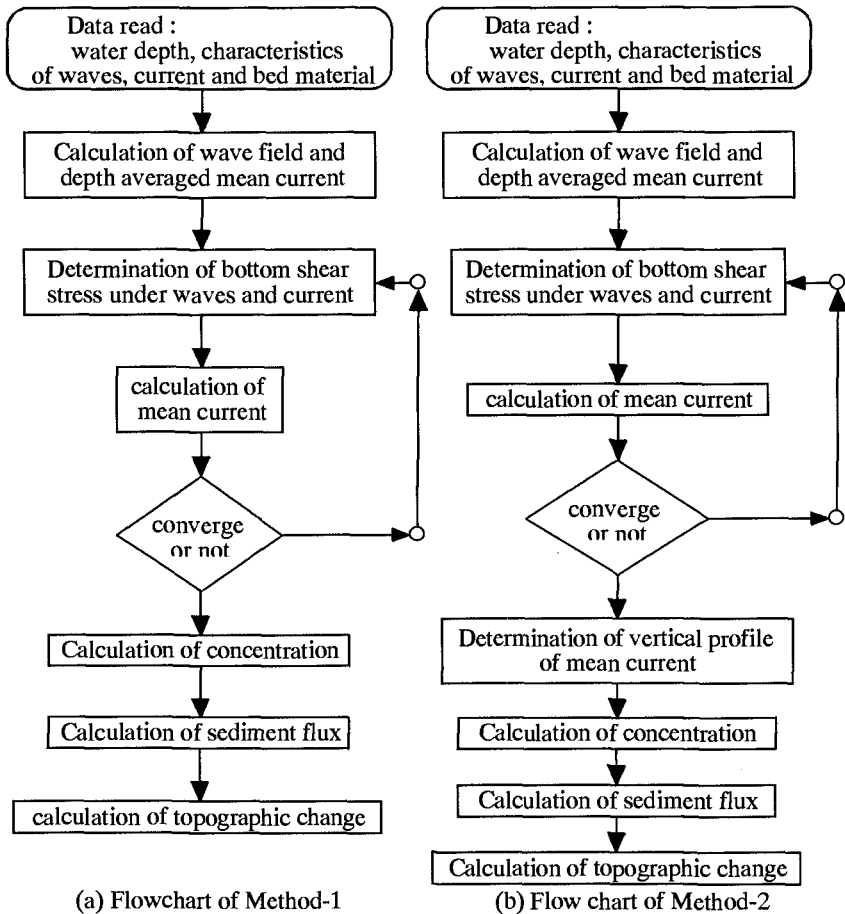

Fig.11 Flow chart of numerical simulation

Figure 12 shows the comparison of predicted changes in water depth at two representative channel sections by two methods. Although there are significant difference between the simulated results by the two methods, we can judge that we can not neglect the effect of the waves and current in the sedimentation in channel. In Case-1 (Fig.(a)), the predicted decrease in water depth in channel by Method-1 is larger than 20cm per one hour. On the other hand, the decrease of the depth in Case-2 (Fig.(b)) is only 6cm per hour in average.

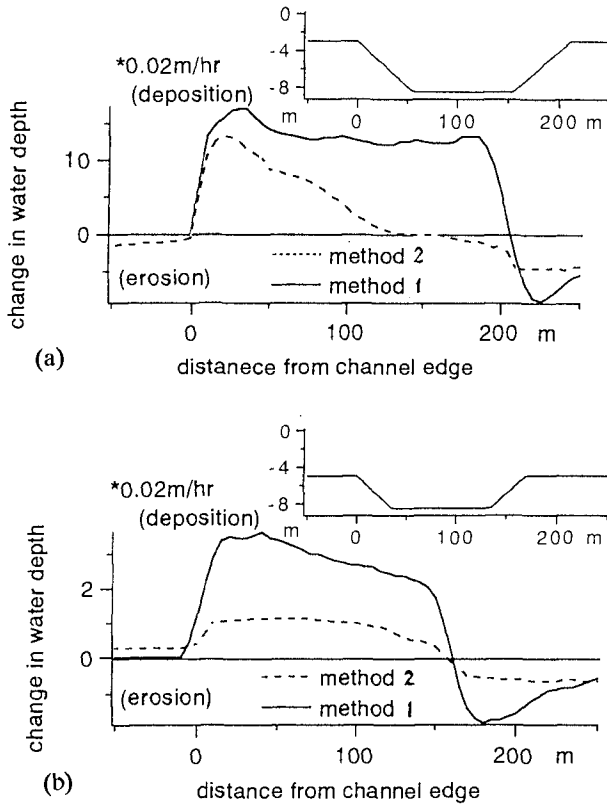

Fig.12 Change in water depth across channel  
 ((a):Case-1, (b):Case-2)

According to the calculated change in water depth by Method 2, volumetric change per unit length per one hour of the channel is about  $17\text{m}^3/\text{m}/\text{hour}$  that will be about  $500\text{m}^3/\text{m}/\text{year}$ . When we assume that this amount of siltation take place along the middle sections 6km (From No.6 to No.12) where the depth of approach is about 3m, the total amount of sedimentation will be  $3 \times 10^6\text{m}^3/\text{year}$  that is the same order of the siltation volume due to river discharge.

From these results the amount of sedimentation caused by waves and current is estimated to be about  $3 \times 10^6\text{m}^3/\text{year}$  that is the same order of the sedimentation volume discharged from the river.

### Conclusions

Through the statistical analysis of the topographic change in the channel, it is found that sedimentation in the upper and the middle sections of the Bangkok Bar Channel is mainly caused by the river discharge. In the lower sections, the river discharge has little influence. Waves and tidal current also play an important role in sedimentation in the middle and lower sections and they become a unique agitation and transporting agency of bed material to deposit in the channel of lower sections.

From the results of simplified numerical simulation of the sedimentation in the channel, we can judge that the order of the amount of sedimentation caused by waves and current in the middle sections is almost the same as that brought about by the river discharge.

## CHAPTER 217

### Turbidity and Suspended Sediment Associated With Beach Nourishment Dredging

Daniel M. Hanes<sup>1</sup>, Member A.S.C.E

#### Abstract

A field observation program was carried out to measure natural and man-induced fluctuations in suspended sediment and turbidity in connections with a beach nourishment project. The project was carried out at Longboat Key, on the west coast of Florida. The analysis of the manual turbidity, sedimentation, and wave data revealed several significant facts concerning the differences between the hard bottom sites and control sites and the interactive dynamics between these three phenomena. The sedimentation measurements indicate that the sand sedimentation rates are highly variable, particularly with time. In contrast, the fines sedimentation rates are relatively less variable with respect to both location and time. It is evident from the examination of the sedimentation data that the sand sedimentation rates at the hard bottom sites were approximately 2.5 times higher than those of the control sites. The statistical analysis indicated that there is less than a 10% probability that this difference is due to chance. In contrast, there were no significant differences in fines sedimentation rates between the hard bottom and control sites. The manual turbidity measurements indicate high variability in space and time. Based on approximately 15 measurement dates, following nourishment the hard bottom sites experienced approximately 50% less turbidity than the control sites. The variations in sand sedimentation rates are believed to be directly related to the hydrodynamic forces resulting primarily from waves. The wave height was approximately 33 % greater at the hard bottom sites.

#### Introduction

Turbidity, a measure of light scattering due to particles or impurities suspended in solution, is important to underwater visibility and light transmission.

Periods of high turbidity significantly stress some underwater communities such as coral. Suspended sediment contributes to turbidity and independently stresses corals through the deposition of sediment. Turbidity and suspended sediment concentration vary substantially in the nearshore region under natural conditions. Natural variations in these quantities may be significantly enhanced by engineering activities such as beach nourishment dredging.

A field observation program was carried out to measure natural and man-induced fluctuations in suspended sediment and turbidity in connections with a beach nourishment project. A large scale beach nourishment project was carried out at Longboat Key, Florida, during the period of observations. Sedimentation, turbidity, and wave climate were measured over a two year period. Figure 1 is a time line of these activities.

Figure 1: Time Line of Nourishment and Monitoring Activities

The monitoring locations (see Figure 2) include four stations at hard bottom study sites along Longboat Key and three control stations on adjacent Siesta Key, Anna Maria Island and Long Key. Table 1 provides the names, locations and mean lower low water depths of each site during the period of wave measurements. Sedimentation rates and turbidity measurements were obtained at all seven sites. Wave sensors were deployed at the Long Key and Siesta Key control sites and the Longboat Key #34 and Longboat Key #2 hard bottom sites.

Table 1: Monitoring Locations

Site	Latitude	Longitude	Depth
Siesta Key - SK	27°15'40" N	82°33'09" W	4.6 m
Longboat Key #6 - LBK6	27°23'21" N	82°38'43" W	4.5 m
Longboat Key #2 - LBK2	27°23'38" N	82°38'57" W	5.6 m
Longboat Key #43 - LBK43	27°25'28" N	82°40'34" W	4.6 m
Longboat Key #34 - LBK34	27°25'19" N	82°40'42" W	5.3 m
Anna Maria Island - AM	27°30'47" N	82°43'33" W	4.6 m
Long Key - LK	27°42'27" N	82°44'39" W	4.5 m

**Figure 2:** Location Map of Monitoring Sites

### Sedimentation Monitoring

Sediment traps are deployed in order to measure the relative amounts of sand sized sediments and fine sediments suspended in the water column. The sediment trap used in this study is shown in Figure 3. The traps function by capturing suspended sediment which have sunk into the trap opening due to the tendency for sediment to settle downward due to gravity. Once inside the trap, sediments are presumably not resuspended or eroded. Thus the measured sedimentation rates are actually a measure of the product of the concentration of suspended sediments and the settling velocity of the sediments. The sedimentation rates are not a measure of deposition rates upon the bed. In fact, high sedimentation rates can sometimes indicate low deposition rates, because the sediment is suspended above the bed and advected away by currents.

After the initial deployment in October, 1992, field trips to retrieve the samples were scheduled for the first week of January, 1993 and approximately every four weeks thereafter during nourishment. After the completion of nourishment, field trips were scheduled at a maximum of every six weeks.

**Figure 3:** Sediment Trap and Mounting  
 deployment) were then averaged to provide the best estimate of the sedimentation rate for that site during the measurement period.

Each sample was separated into sub-samples of sand and fines by wet sieving with a 63 micron sieve. These sub-samples were then dried at 110° C and weighed to determine dry weight of the sand and fines portion. Finally, the samples were ashed at 500 ° C for two hours and re-weighed to determine the weight of organic matter. Sedimentation rates, given in milligrams per centimeters squared per day, were calculated by dividing mass by the area of trap entrance and Julian days between deployment and retrieval. The sedimentation rates for multiple traps at each station (for each

Table 2 shows the average sand sedimentation rates of the four hard bottom sites off Longboat Key and of the three control sites for each deployment. Of the nearly 350 sedimentation samples, there were three cases in which one of the three sediment traps was significantly different from the other two traps at the same location. For these cases the deviant measurement was discarded. The bottom row is the average of all of the hard bottom samples and all of the control samples over all deployments.

6/12/94	7/18/94	7.9	11.4
7/18/94	8/25/94	14.8	11.7
<b>OVERALL AVERAGES</b>		21.4	20.6

The sand sedimentation rate data is punctuated by high sedimentation rates for the deployment retrieval dates of 4/7/93, 11/10/93, 12/22/93, 2/16/94, 3/22/94 and 8/25/94. These coincide with periods of high waves, as is discussed further in the wave data analysis. There is a pronounced difference in sand sedimentation between the hard bottom and the control sites. It seems evident that the sedimentation rate is much higher for the sites at Longboat Key. This result is partially explained by the spatial variations in wave climate, which is presented later.

In contrast, the difference in fines sedimentation rates between hard bottom and control sites is small. These data reflect high values for the deployments retrieval dates of 4/7/93, 11/10/93, 12/22/93, 2/16/94, and 3/22/94. However, the increase in fines sedimentation rates during these times was not as dramatic as for sand sedimentation. The sedimentation rates for the fine material is essentially similar at all study locations, particularly relative to the enormous variations measured for the sand sedimentation rates. The overall mean and standard deviation of the fines sedimentation rate are 21.1 and 15.9 mg/cm<sup>2</sup>/day, respectively. The means of each site are well within one standard deviation of the overall mean.

The sedimentation rates can be compared before, during, and after nourishment. Because the nourishment project occurred over a period of approximately 6 months, the beach upland of each hard bottom site was nourished at different times as the project progressed along the coast. Rather than subjectively determining "before, during, and after" dates for each site, we choose rather to apply the same dates to all sites, as described in the introduction to this report. This allows for the grouping of hard bottom sites and control sites, as will be statistically justified in the following section on statistical analysis. Table 4 gives the average sand and fines sedimentation rates for hard bottom (HB) and control sites (Con) before, during and after nourishment. These values are given in mg/cm<sup>2</sup>/day. The average value of the ratio HB/Con is also given. The hard bottom sites have sand sedimentation rates which are approximately 2.5 times the control sites, but the fines sedimentation differ only slightly at the hard bottom and control sites.

	Sand Sedimentation Rates			Fines Sedimentation Rates		
	HB	Control	HB/Con	HB	Control	HB/Con
Before	2.5	1.8	1.7	19.6	18.3	0.8
During	85.0	27.0	2.5	23.8	20.0	1.3
After	51.0	20.3	2.5	22.7	19.6	1.1

**Table 4:** Average sedimentation rates before nourishment (1/2/93 and 2/6/93 retrieval dates), during nourishment (4/7/93 to 8/25/93 retrieval dates) and after 9/29/93 to 8/25/94 retrieval dates). Values are given in mg/cm<sup>2</sup>/day.

In summary, the study period was characterized by moderate sedimentation through the first nine months with the notable exception of the hundred year storm in March, 1993. In contrast, sedimentation in the Fall/Winter of 1993/1994 and again in Summer of 1994 were marked by significant activity, especially at the hard bottom sites. There is a notably greater sand sedimentation rate for the hard bottom sites. Finally, the data shows that fines sedimentation rates are less variable than sand sedimentation rates.

A statistical analysis of these data indicate that there were no significant differences within the hard bottom sites and also no significant differences within the control sites. The sites were therefore combined into two categories: hard bottom and control. These data were then paired for comparison during the nourishment project and following the nourishment project. The comparison was made using the Binomial Sign test. The Sign test provides the probability that the number of positive differences is greater (or less) than random chance (50 % of the values). For the sand sedimentation rates measured during the nourishment project, the results of the Sign test indicate  $P=0.094$ . For the sand sedimentation rates measured after the nourishment, the results of the Sign test indicate  $P=0.087$ . There is less than a 10% probability that the differences between the hard bottom and control sites in sand sedimentation rate both during and following nourishment occurred by chance.

### Manual Turbidity Monitoring

Manual measurements of turbidity were obtained through the use of SCUBA divers during each field trip. Divers obtained a water sample near the surface, mid-depth, and near the bottom of the water column. The surface and bottom samples were generally obtained approximately two feet from the surface or bottom. The water samples were then sub-sampled on board the boat and inserted into an H-F Scientific Model DRT-15C portable turbidimeter for reading.

Table 5 shows the average manual turbidity readings for hard bottom and control sites and presents the ratio of hard bottom to control turbidities (HB/Con) for the nourishment and post nourishment periods.

**Table 5: Manual Turbidity Readings (NTU), During and After Nourishment**

	level	Hard Bottom	Control	HB/Con
During Nourishment	surf.	4.6	2.9	1.6
	mid	5.8	4.0	1.5
	bot.	7.5	5.5	1.4
After Nourishment	surf.	2.8	4.4	.64
	mid	3.2	5.5	.58
	bot.	4.4	9.2	.48

On the whole, the manual turbidity readings are relatively low compared to the 29 NTU standard. It must be noted here that the turbidity values represent discrete readings and that this sampling cannot be considered random. The manual turbidity samples were taken only when weather permitted. Obviously weather is a very significant forcing mechanism for turbidity. Thus, in all likelihood, these values underestimate actual time-average turbidity levels.

Table 5 clearly illustrates three facts. First, the turbidity at the hard bottom sites was larger than at the control sites during nourishment. Secondly, the turbidity at the hard bottom sites decreased significantly after nourishment. Finally, the turbidity of the hard bottom sites is significantly less than the control sites after the nourishment. These average values are based on seventeen sampling dates.

### Wave Sensors

Two instrument package designs were deployed for the turbidity and wave climate monitoring. These packages are referred to as system I and system II. Both systems were self contained, with on-board power and data storage capabilities. The waves were measured using Transmetric pressure sensors.

System I consisted of two model 1 Optical Backscatterance Sensor (OBS), a pressure transducer, and a Marsh McBirney Electromagnetic current meter. This package was used almost exclusively at the Longboat Key #2 hard bottom site. The system I samples at one hertz for 1024 seconds every two hours. The 12V power source required renewal approximately every month. A spare system I was employed until it was damaged in the field during the fifth deployment. The system II package consisted of one model 3 OBS and a pressure transducer. These packages were deployed at the Long Key, Siesta Key, and the Longboat Key #34 hard bottom sites. System II samples turbidity and waves at one hertz for 512 seconds every two hours. The 1Mb RAM is filled approximately every month but the 12 V power source lasted approximately three months. Therefore, the initial plan was to download the data in the field every deployment and perform complete maintenance, which included battery change, every three months. A spare system II was also employed as a backup. The field configuration of the system II package is presented in Figure 4.

All of the instruments required calibration for interpretation. The calibrations of the pressure sensor and current meter are straight forward, and were performed in some cases by the instrument manufacturer. In some cases we also calibrated these instruments at the Coastal Engineering Laboratory at The University of Florida. Turbidity is measured in Nephelometric Turbidity Units (NTU's). Calibration is accomplished using formazin in the laboratory. For the manual turbidity measurements, a HF Scientific model DRT 15C portable turbidimeter is utilized. The OBS calibration is somewhat more problematic. We calibrated the sensors in

the laboratory using a formazin solution. Formazin is the turbidity standard accepted by National Institute of Standards Technology. Each time the OBS are removed from the water for cleaning (approximately once per month), they are recalibrated. However, upon deployment in the field, these calibrations were not always accurate.

**Figure 4:** System II Package Field Configuration

The instrument deployment began August 25, 1993 and the preliminary plan was to schedule deployments every month thereafter. However, due to severe biofouling and unforeseen package damage, the deployments were interspersed as conditions demanded. A time line of the wave data coverage for the monitoring project is given in Figure 5. Lapses in coverage were largely due to equipment damage and maintenance.

**Figure 5:** Time Line of Wave Data Coverage

Figure 5 points to two main lapses in wave data coverage. These interruptions occurred from 11/1/93 to 12/1/93 and from 1/11/94 to 2/16/94. The first incident was due to the unexpected severity of the biofouling of the OBS's. The packages were taken back to the coastal lab for maintenance, data offload and recalibration. System I packages suffered extensive damage in the field during the fifth and eighth deployment due to crab traps. The crab traps and buoy lines tended to collect around the instrument package, often becoming entangled in it, and extensive damage was incurred as the crab fishermen retrieved the traps. One system

I package was damaged beyond repair. Each of the sensors on the package was sheared off. In the case of the second system I package, the repairs required almost two months of work. The spare system II was utilized in its place at the Longboat Key #2 site. Even after the repairs to the system I package, the current meter was no longer functioning and much of the OBS signal was unsatisfactory.

As can be seen, maintaining the instrument packages in the field proved to be very demanding. This can be attributed to severe biofouling and field damage to the packages. The biofouling on the face of the OBS was more troublesome than anticipated. It served to block out the OBS signal after a few days in some cases.

The performance of the OBS's was dismal and our painstaking efforts to correct the problem were generally ineffective. Biofouling was anticipated before the initial package deployment and the OBS face was painted with an anti-biofoulant. The OBS were subsequently painted whenever the packages were removed from the field. It was evident that the severity of the fouling was grossly underestimated. As a result, we attached commercially available caustic hoods to the OBS. The manufacturer of these hoods claimed that they would keep OBS's clean of growth and fouling for 2 to 3 months at the project site. Although the hoods did somewhat decrease the amount of fouling, the effect of the hoods were not significant enough to improve the OBS signal. Our next plan of attack was to simply remove the packages more frequently to repaint the OBS face. The system II packages were eventually removed monthly for this purpose. Unfortunately, this provided disappointing results as well. Eventually, we tried underwater field cleaning of the OBS face biweekly. We found that we were not able to obtain valid turbidity data for more than a maximum of seven days after the OBS faces were painted with anti-biofoulant and for more than three days after cleaning with a nonscouring pad in the field. Although this seemed unproductive, we had no recourse. This presented an opportunity to increase the frequency of manual turbidity readings, which were gaining in importance due to the ineffectiveness of the OBS's. By the eighth deployment, we designed and implemented an 'OBS wipe' instrument which was mounted to the OBS to mechanically clean the face of the OBS every hour. Once again, this proved ineffective. Our final decision was to discard the OBS data.

The average values of the depth ( $D_{av}$ ), significant wave height ( $H_{m0}$ ) and peak period ( $T_p$ ), as well as the number of days of wave data coverage within the period are summarized in Table 6. For purposes of comparison, the averages in Table 6 were calculated to correspond to the sedimentation data periods. These values represent the averages of the available wave data within these periods. The average values in the last row and column are weighted to reflect the varying days of coverage within periods and monitoring sites.

### Discussion

The relatively higher sand sedimentation rates measured at the hard bottom sites relative to the control sites can be explained by examining the wave conditions at the sites. Table 7 compares the average wave characteristics between the hard bottom and control sites. It is evident from this table that the hard bottom sites have experienced larger waves than the control sites.

**Table 7: Average Wave Data Characteristics**

Characteristic	Hard Bottom	Control
Average Depth, $D_{av}$	5.47 m	4.58 m
Significant Wave Height, $H_{mo}$	.29 m	.22 m
Peak Period, $T_p$	5.17 s	5.17 s

In addition to time average data, an examination of discrete storm events provides valuable insight. An examination of the five largest, measured, storm events is presented in Table 8. The maximum significant wave height ( $H_{mo(max)}$ ) and maximum peak period ( $T_{p(max)}$ ) for the storm events are given for each of the sites. The largest waves of our monitoring were recorded at LBK2 and LBK34 from 1/3/94 and to 1/5/94. The most recent storm event beginning on 8/13 and subsiding on 8/18/94 was tropical storm Beryl.

**Table 8: Maximum Height and Period for Five Storm Events**

Event Date		SK	LBK2	LBK34	LK
10/29/93 to	$H_{mo(max)}$		1.78 m	1.99 m	1.42 m
11/1/93	$T_{p(max)}$		10.7 s	10.7 s	10.7 s
12/14/93 to	$H_{mo(max)}$	1.28 m	1.40 m	1.43 m	1.11 m
12/17/93	$T_{p(max)}$	9.1 s	9.8 s	9.1 s	9.1 s
1/03/94 to	$H_{mo(max)}$	1.84 m	2.23 m	2.15 m	1.62 m
1/05/94	$T_{p(max)}$	10.7 s	11.6 s	12.8 s	10.7 s
3/1/94 to	$H_{mo(max)}$	1.43 m		1.63 m	1.61 m
3/5/94	$T_{p(max)}$	10.7 s		10.7 s	10.7 s
8/13/94 to	$H_{mo(max)}$	1.26 m	1.51 m	1.72 m	
8/18/94	$T_{p(max)}$	8.0 s	7.5 s	8.0 s	

Table 8 illustrates two important facts. First, this data shows that in every case, the hard bottom sites recorded larger maximum significant wave heights for these storm events. Secondly, these five storm events occurred during the periods of highest sand sedimentation rates.

In order to demonstrate the relationship between significant wave height and sand sedimentation rate, Figure 6 displays the deployment averaged measurements for both the hard bottom sites and the control sites. Plotted on a log-log scale, Figure 6 shows that the sand sedimentation rate is an increasing function of the significant wave height. Furthermore, the hard bottom sites and the control sites plot with approximately the same trend. This supports the conclusion that the difference in sand sedimentation rate is largely due to the differences in significant wave height.

Figure 6: Log-Log plot of sand sedimentation rate versus significant wave height.

### Conclusions

The analysis of the manual turbidity, sedimentation, and wave data revealed several significant facts concerning the differences between the hard bottom sites and control sites and the interactive dynamics between these three phenomena.

The manual turbidity measurements indicate high variability in space and time, and were probably under-sampled and biased toward low wave conditions. During the monitoring period, turbidities exceeding 29 NTU were measured only at sporadic locations on 11/10/93, 12/22/93 and 2/16/94. Based upon three measurement dates, the manual turbidity measurements during the nourishment indicate that the hard bottom sites experienced approximately 50% higher turbidity than the control sites. However, based on approximately 15 measurement dates, following nourishment the hard bottom sites experienced approximately 50% less

turbidity than the control sites. Statistical analysis confirmed that the lower turbidity at the hard bottom sites relative to the control sites following nourishment is statistically significant at the 0.05 probability level.

The sedimentation measurements indicate that the sand sedimentation rates are highly variable, particularly with time. In contrast, the fines sedimentation rates are relatively less variable with respect to both location and time. It is evident from the examination of the sedimentation data that the sand sedimentation rates at the hard bottom sites were approximately 2.5 times higher than those of the control sites. The statistical analysis indicated that there is less than a 10% probability that this difference is due to chance. In contrast, there were no significant differences in fines sedimentation rates between the hard bottom and control sites.

The variations in sand sedimentation rates are believed to be directly related to the hydrodynamic forces resulting primarily from waves. During periods that included large waves, correspondingly large sand sedimentation rates were measured. Wave forcing also partially explains the trend for higher sand sedimentation rates at the hard bottom sites relative to the control sites. The wave height was approximately 33 % greater at the hard bottom sites. This higher wave height results in the wave energy being approximately 75% higher at the hard bottom sites relative to the control sites. The increased wave energy at the hard bottom site is probably the reason for the relatively higher sand sedimentation rates. Because a high sedimentation rate is an indication of high concentration of suspended sediment, these findings indicate that sand deposited at the hard bottom sites is most likely resuspended into the water column during periods of large waves.

#### Acknowledgments

## CHAPTER 218

### SOIL MECHANICS OF SHIP BEACHING

N.-E. Ottesen Hansen<sup>1</sup>, B.C. Simonsen<sup>2</sup>, and M.J. Sterndorff<sup>3</sup>

#### Abstract

When a ship hits a soil or gravel slope it will create a large transient pore pressure in the soil which will force the ship bow upwards. At the same time the pore water will cause ruptures in the soil which influences the lifting forces on the ship bow. Methods of analysis are presented for the pore water build up, the soils rupture and the resulting reactions on the ship bow for frictional soils. Soil slopes with low permeability (sand in connection with a scour protection) generates large reactions on an impacting ship with the result that the ship will ride up on the surface of the slope and be brought to a stop by friction . Soil slopes with high permeabilities as pebbles or quarry run generate smaller reactions, and the ship will plow itself into the slope. It will then be stopped by a combination of friction and passive soils pressure. The analytical results are compared with test results made in a hydraulic laboratory and by full scale testing in nature of a ship sailed into a beach. Good agreement was found between the theoretical findings and the test results.

#### Introduction

In many places structures are placed adjacent to heavily trafficked navigation channels. The ship traffic is supposed to stay in the main navigation channel. Some ships, however, do loose their way or their steering and may ram the structure. One method to protect against the impact is to surround the structures with works built in fill materials. An example of this is the protective works for the side span

---

<sup>1</sup> Ph.D. Director, LICEngineering A/S, Ehlersvej 24, DK-2900 Hellerup, Denmark.

<sup>3</sup> Ph.D. Chief Engineer, Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm. Denmark.

piers of the Great Belt suspension bridge in Denmark. They are designed to stop all ships with a displacement greater than 4000 tonnes before they reach the bridge foundations, figure 1. The impact of smaller ships can be sustained by the bridge piers themselves.

Such protective works will have the effect that they either force the ship to ride up the slope and absorb the energy of the ship by friction or they will absorb the ship impact inside the soil skeleton as passive soil pressure. An accurate calculation of the stopping length of the ship will therefore be important. Typical marine structures to protect are bridge foundations or immersed tunnel elements.

Figure 1. Protective work for one side span foundation of the Great Belt suspension bridge, Denmark.

### Mechanics of Ship Grounding

The stopping force acting on a beaching ship is the result of ruptures in the soil at the areas of contact between bow and soil. The mechanics of this rupture is complicated. This is illustrated by an example where a ship with cylinder bow with vertical sides is rammed horizontally into a submerged slope of sand of 1:6, Figure 2. The bow has a semi-circular shape with a radius of  $r = 378$  mm. The bottom is flat. The sand is very uniform in gradation with a mean diameter of 0.125 mm, permeability coefficient  $9 \cdot 10^{-5}$  m/s and frictional angle of  $39^\circ$ . The ship is rammed with constant velocity and it is locked in the horizontal position such that it cannot heave or pitch.

In figure 2 the horizontal forces and vertical forces for different impact velocities are presented as a function of horizontal position for a ship with cylindrical bow rammed into a slope of 1:6. The soil reaction is shown for tests in both dry sand and submerged slopes of different impact velocities.

The horizontal resisting force and the lifting force as the bow depends on the velocity. The force is 10-20 times larger than the resisting force for the identical tests performed out of water where the bow is rammed into the same slope of dry sand, figure 2.

Figure 2. Force on ship bow.

Therefore the porewater flow generated by the bow during the impact must have great influence on the behaviour of the ship. The porewater flow creates strong effective stresses in the soil which act on the hull both as normal stresses and as tangential stresses. It is then the question of how these effective stresses are generated. There seem to be two possible mechanisms to choose:

1. At the rupture the sand will dilatate and thereby create a large suction in the pore water in the rupture zones. This suction will result in a just as large effective stresses in the grain skeleton.
2. At the impact the sand will be compressed and pore water will be squeezed out in the compression zone creating an additional pore water flow. This pore water flow will build up large effective stresses in areas of the grain skeleton.

In other areas liquified zones will be formed.

Which of the two mechanisms are correct can be decided by investigating the vertical lift on the ship bow. This lift must partly be caused by friction on the front and partly of the pore water pressure at the bottom of the model ship. From figure 2 it can be seen that there is a relatively large lift on the bow. Consequently there must be an excess pore pressure underneath the bow. This indicates that the impact follows the mechanism, 2, where the sand skeleton is compressed and the pore water squeezed out.

The pressure generated by the porewater has further been demonstrated by establishing a vertical downwards directed pore water flow through the sand (originally made to compact the laboratory sand), figure 3. This drainage will reduce the initial pore pressure with depth. Figure 3 shows the difference between the lift on the ship bow with and without the additional vertical pore water flow. The important finding is that even though the initial pressure underneath the bottom of the model ship is reduced, still a lift is generated. This proves that excess pore pressures are generated by the impact.

Figure 3. Variation in lifting force for various drainage conditions in the soil.

### Method of Analysis

The analysis of the soils forces acting on an impacting ship must be made with some simplifications in order to obtain a result.

Ships with bulb- and V bows have a narrow keel such that the foot print into the slope becomes oblong, figure 4. Hence the soils resistance can locally be calculated by two-dimensional methods.

Figure 4. Principle of strip calculation model.

- a) The division of the slope into elements.
- b) Soils movement and porewater flow lateral to ship movement in a strip.

The slope is divided into a series of strips. Within these strips the soil deformation and porewater movement are calculated using a two-dimensional solution, figure 4. Using this reference frame the deformation of the slope can be described in detail and it is possible to determine which strips are in contact with the bow, furrow geometry etc.

The total soil reaction is found by summing up the soil reaction force from

each of the soil strips in contact with the bow. This provides a normal force perpendicular to the slope and a frictional force parallel with the slope. They can be used for the equations of motion of a beaching ship. The ratio between the frictional force and the normal force is defined as the effective frictional coefficient.

Thus the system is reduced to a two-dimensional system which is easier to analyse.

The cylinder bow mentioned as an example in the preceding paragraphs can be approximated with strips along the periphery of the bow in the vertical plane.

### Basic Assumptions

In order to explore the impact on the soil the basic one-dimensional case of the cylinder bow is considered

Figure 5. Basic case of impact of cylinder bow.

For an impulsively started motion at  $t = 0$  to  $U$ , a pressure wave with celerity,  $c$ , is sent out. Joukowski's law then gives for the horizontal force,  $F_H$

$$F_H \sim \rho c U h \quad , \quad c \approx \sqrt{\frac{E}{\rho}}$$

$\rho$  is the density of saturated soil and  $E$  the Young's modulus of dry sand. The ratio between effective stresses from pore water flow and inertia force are decided by the soil permeability,  $k$  and given by

$$\frac{\rho_w g h U}{\rho k c^2}$$

This means that the forces from the pore water for normal sand dominates over the inertial forces.

From the expression for  $F_H$  it can be seen that the stresses at the impact in this example will be very high ( $\sim 100 \text{ kN/m}^2 - 500 \text{ kN/m}^2$ ). This is extremely high. So high that a soil rupture must occur. The rupture force will depend on how large vertical stresses can be generated by friction against the ship hull.

Hence in the following the inertia forces can be neglected, and calculations can be treated as a quasi steady soil rupture problem even though it is an impact problem.

### Equilibrium Equations for an Element of saturated Soil in Rupture

In order to analyse the rupture problem, the approximation of using a series of circles as rupture lines is used. The rupture figure are then kinematically allowable and will produce stresses which are slightly higher then the correct stresses. The method is an adaption of the equilibrium method of Brinch Hansen, 1953.

The stress conditions for soil elements in a circular rupture line are shown in figure 6. There is a flow of pore flow through the element which generates tangential and radial pressure gradients

The shear stress,  $\tau_r$ , along the circular rupture line in frictional soil is given by the Kötter equation, Brinch Hansen, 1953:

$$\frac{\partial \tau_r}{\partial v} + 2 \tan \varphi \tau_r + \gamma' r \sin(v + \varphi) \sin(\varphi) - \sin^2(\varphi) r \frac{\partial p_p}{\partial r} + \sin(\varphi) \cos(\varphi) \frac{\partial p_p}{\partial v} = 0$$

$r, v$  are the polar coordinates and  $\gamma'$  is the submerged weight of the soil.  $\varphi$  is the frictional angle of sand.  $P_p$  is the pore water pressure.

The normal stress,  $\sigma_r$ , is found from the Coulomb relationship

$$\tau_{rv} = \tan \phi \sigma_r$$

With the known boundary conditions and pore water pressure field,  $p_p$ , this equation can be integrated to give the effective shear stress,  $\tau_{rv}$ , along the considered rupture line.

Figure 6. Effective stresses and pore water pressures on a soil element in a circular rupture line.

### Soil Reaction on a Strip of the Bow

To demonstrate how the soil reaction is calculated, one strip on the slope (see figure 4) is considered. Normal velocity and acceleration of the bow at the considered strip is  $u_b$  and  $\dot{u}_b$ , respectively, figure 7a.

The first simplification of the problem shown in figure 7a is achieved by assuming that the penetrating bow can be modelled by a plate of width  $B$  corresponding to the immediate width of the bow in the plane of the slope, figure 7a,b.

Initially the grain skeleton is compressed elastically and a pore water flow is generated. When the force reaches a certain level soil rupture will develop. During beaching of a ship the deformations of the soil are sufficiently large to develop complete rupture.

The geometry of the rupture body can be approximated by a circular arc with its center placed off the surface of the soil in  $(x,y) = (a,b)$ , figure 7. This is the most simple approximation. A better approximation would be to use a number of

consecutive circles. For an impact problem this additional accuracy is not warranted. The procedure is now to choose  $a, b$ , and the unknown force on the bow,  $F$ , such that the rupture body is in both horizontal, vertical and moment equilibrium.

Figure 7. Assumed circular rupture below a bow penetrating saturated soil. Equivalence between bow and flat plate.

The total loads,  $T$ ,  $N$  and  $M$ , on a given rupture body are the resultants of the effective stresses,  $\tau_{rv}$ ,  $\sigma_r$  in the rupture line, the pore water pressure,  $p_p$ , along the edge of the rupture body, the submerged weight of the soil in the rupture body and the load from the bow,  $F$

The effective stresses,  $\tau_{rv}$ ,  $\sigma_v$  and  $\sigma_r$  in the rupture line can be calculated from the Kötter equation, if the pore water pressure,  $p_p$ , and the boundary conditions for  $\tau_{rv}$  are known.

In the general case the pore water pressure cannot be found without considering the kinematics of the grains. However, in this case of modest penetration of a bow it can be assumed that the displacements of the grains are small compared with that of the pore water. The pressure field,  $p_p$ , can then be

found by use of Darcy's law and the of continuity equation for water.

The solution can be written, Lamb, 1932

$$\frac{P_p(x,z)}{\gamma'' \frac{B}{z}} = z' \sqrt{z'^2 + \frac{1}{2}(1-x'^2-z'^2)} + \sqrt{z'^2 + \frac{1}{4}(1-x'^2-z'^2)^2}$$

$$\gamma'' = \frac{\rho g u_b}{k} + \frac{(1+e)}{e} \dot{u}_b$$

$$x' = \frac{x}{B/2} = \frac{a}{B/2} + \frac{r}{B/2} \sin \nu, \quad z' = \frac{z}{B/2} = \frac{b}{B/2} + \frac{r}{B/2} \cos \nu$$

in which  $\rho_w$  is the density of the pore water,  $g$  the gravity acceleration,  $e$  the void ratio, and  $k$  the permeability coefficient.

Inserting these equations into the Kötter equation the variation of  $\tau_{rv}$  along the rupture line is expressed in terms of the non-dimensional parameters.

$$\frac{\gamma'}{\gamma''}, \frac{r}{B/2}, \frac{a}{B/2}, \frac{b}{B/2}, \nu, \varphi$$

The boundary conditions for  $\tau_{rv}$  and the angle,  $\nu_0$ , of the rupture line at point P are, figure 7

$$\tau_{rv}(P) = 0$$

$$\nu_0 = \pi/2 - \varphi/2$$

Using the approximation of a circular rupture there will not be sufficient degrees of freedom to satisfy all boundary conditions. However, the second condition can be neglected without losing too much accuracy, Brinch Hansen, 1966.

If boundary condition for the shear stress is used in the solution of the Kötter equation negative effective stresses will occur in an area around P. They cannot exist. Therefore there is liquefaction in this area and no contribution to the resistance. Therefore the boundary condition is  $\tau_{rv} = 0$  from P to the point in the

rupture line where the shear stress can grow towards positive values, see for instance figure 9. This point is characterized by

$$\frac{\partial \tau_r}{\partial v} = 0$$

The effective stresses and the porewater pressure acting on a given rupture body at a given value of  $\gamma'/\gamma''$  can be calculated. The resulting values of  $\gamma'/\gamma''$ , a,b,F are the ones which result in equilibrium for both horizontal and vertical forces and for the moment. The results of the analysis are presented in figure 8 in which the force F on the plate is expressed as a function of  $\gamma'/\gamma''$  for soils with a frictional angle of  $\phi = 32^\circ$ .

Typical values for the parameters in  $\gamma'/\gamma''$  are  $\rho_w = 10^3 \text{ kg/m}^3$ ,  $\gamma' = 10^4 \text{ N/m}^3$ ,  $u_b = 1 \text{ m/s}$ ,  $k = 10^{-4} \text{ m/s}$ ,  $\dot{u}_b = 0 \text{ m/s}^2$  giving a typical value of  $\gamma'/\gamma''$

$$\gamma'/\gamma'' = \frac{k}{u_b} = 10^{-4}$$

Figure 8. Non-dimensional rupture load for different values of  $\gamma'/\gamma''$  for  $\phi = 32^\circ$ .

For values of  $\gamma'/\gamma''$  below 0.1 the nondimensional total force, F, is seen to be approximately constant

$$\frac{F}{\gamma''(B/2)^2} \approx 2$$

Thus for  $\gamma'/\gamma'' < 0.1$  the model does not predict an upper level for the soil reaction - it is simply proportional to

$$\gamma'' \left( \frac{B}{2} \right)^2$$

The pore water pressure gives a vertical reaction which is included in the above total force. The pore water contribution,  $F_{pw}$ , is

$$\frac{F_{pw}}{\gamma'' (B/2)^2} = \frac{\pi}{2} \approx 1.57$$

Therefore in this example of  $\phi = 32^\circ$ , the effective stresses between plate and soil only account for approximately 20% of the total load for small values of  $\gamma'/\gamma''$ .

Figure 9 shows the rupture body and the effective stresses on the rupture body for  $\gamma'/\gamma'' < 0.01$ .

Figure 9. Rupture body and effective stresses in the rupture line for small values of  $\gamma'/\gamma''$  ( $\gamma'/\gamma'' < 0.01$ ).

For such small values of  $\gamma'/\gamma''$  the rupture load is carried by very large effective stresses directly below the bow, figure 9.

Knowing the effective soils normal force,  $F$ , on the bow at the considered strip, the tangential force,  $T$ , is simply taken as

$$T = \mu \cdot (F - F_{pw})$$

$\mu$  is usually set to 0.38.

Knowing the soil reaction in each strip in contact with the bow, the total soil reaction is found by summing up forces vectorially. Inserting this expression into the equation of motion for the ship, the beaching course can be calculated.

For V-bows similar expressions can be developed. Instead of using a flat plate-approximation, a wedge approximation is used.

### COMPARISON WITH TESTS

The results of the soil reactions have been compared with both laboratory tests and with full scale tests. Parameters such as apparent coefficient of friction and calculated and measured stopping lengths were compared.

The laboratory tests were performed with a ship model corresponding to a 20,000 DWT ship in scale 1:60. The ship was forced into a sand slope inclined 1:6. Both fine and coarse sand were considered. Various bow types were considered.

Figure 10. Comparison between theory and test results for effective coefficient of friction.

The measured effective coefficients of friction were compared with the corresponding calculated values, figure 10. This effective coefficient of friction is the ratio between the tangential and normal components of the soil and pore water reaction.

It is interesting to note that the effective coefficient of friction is in the order of 0.6 - 1.0 whereas the coefficient of friction between fill and ship plating is 0.38 (for the effective soils stresses).

The full scale tests were performed with a condemned 300 DWT fishing vessel which was rammed into an island built of the same materials as will be used for the protective works of the Great Belt suspension bridge. The vessel had a V-bow. The tests were made with velocities up to 10 knots. The stopping length and ship motions were recorded. Further, the foot prints in the slope were surveyed. The tests were repeated for various impact energies and various slopes.

Figure 11 shows a comparison between the calculated and the measured stopping length.

It is seen that the agreement is satisfactory. The measured furrow depths on the in-situ tests further show good agreement with the calculated furrow depth.

Figure 11. Measured stopping length depicted as function of calculated stopping length for a 300 DWT fishing vessel rammed into sand

slopes varying between 1:6 and 1:11.

### ACKNOWLEDGEMENTS

The authors wish to express their gratitude to the Great Belt Link Company for permission to publish the test results.

### Abstract

To investigate the angle effects on the initial mixing processes of the buoyant jet under wave action, the flow visualization and concentration measurements based on laser-induced fluorescence are employed in this study. The dilution improvement of the effluent in the co-wave and opposing-wave is mainly caused by the velocity gradient increasing due to the opposite wave flow and the wave tractive mechanisms resulted from the onshore and offshore wave motion. When orthogonally discharged into wave motions, the effluent is increasingly diluted by the formation of wake vortex and trajectory deflection curved by the wave flow. From the quantitative measurement of tracer concentration, the dimensionless dilution rate shows a function linearly increasing with the dimensionless wave parameter whose coefficient in the orthogonal discharge is above 33% higher than the other two cases. For practical design, it suggests that the orientation of the nozzle should be orthogonal to the propagation of principal wave motion.

### Introduction

Ocean outfall has been a feasible alternative of sewage disposal to diminish water pollution problems in most coastal cities. The primary parameter in practical design is the initial dilution rate which should meet the environmental legislation for public health and biological considerations. For the engineers, a simple but accurate method in initial dilution predictions of jet flow discharged into the ocean has been longing for decades. In the past, most relevant researches were theoretically and experimentally conducted in stagnant fluid. However, domestic sewage in the initial mixing processes is affected by oceanographic influences such as currents, density gradients, natural convective processes and wave action. Among these factors, the interaction of jet flow with surface waves is a very fascinating phenomenon in hydrodynamics and also important in the practical design of ocean outfalls.

The subjects concerning the kinematic and dynamic behaviours of jet flow under wave actions were not initiated until Shuto & Ti (1974). It shows that the dilution

rate of buoyant plumes in long waves is proportional to the ratio of the discharge velocity to a characteristic horizontal velocity of wave motion, and inversely proportional to the square of the ratio of the water depth to the nozzle diameter. Based on limited experimental results, Ger (1979) suggests that the axial dilution in shallow water waves linearly increase with the dimensionless horizontal distance when it is less than 12. Sharp & Power (1985) observed the dispersion patterns in short waves and long waves respectively, and qualitatively concluded that the short wave would change the jet flow when approaching the surface. The mixing pattern in long waves was obviously affected as soon as the effluent left the nozzle. The above investigations support insufficient information needed in the practical design since most ocean outfalls locate in the intermediate water depth. From the experimental and computational results of Chin (1987) and Chin (1988), the ratio of the initial dilution rate in intermediate water waves and in still water is shown to be linearly increasing with the ratio of  $L_q/Z_m$ .  $L_q$  is the spatial scale where the nozzle geometry influences the jet behaviour and  $Z_m$  is the length scale required for the wave-induced momentum to be on the same order of the jet momentum. Because of experimental wave conditions being similar to the field situations, the prediction equation proposed is more practicable for the design engineers.

Under the consideration of practicality, however, the interaction mechanisms between the jet flow and surface waves has not been thoroughly understood in the past. Hwung & Chyan (1990) and Chyan & Hwung (1993) investigate a pure momentum jet vertically discharged from the bottom of wave flume and identify the interaction mechanisms, *i.e.*, *jet deflection, wake vortex structure and wave tractive mechanism*, which are responsible for the increase of initial dilution. It also concluded that the jet has a higher dilution ratio when orthogonal to the propagation direction of surface waves. The interaction angle between jets and waves should be an important factor influencing the interaction mechanisms that occur and the sewage dispersion that improves. The purpose of this paper is to investigate discharging angle effects on the mechanisms and the initial dilution of horizontal buoyant jets interacting with surface waves. Avoiding the interference from the direct sampling instruments, the qualitative and quantitative experiments are conducted by an optical method based on laser-induced fluorescence.

### Theoretic Considerations

The dilution rate of jet effluents in wave motion is function of the control parameters of the buoyant jets and surface wave, respectively, which includes the factors of the kinematic and dynamic behaviours of buoyant jets such as momentum flux,  $M = QV_o$ ; buoyancy flux,  $B = Qg_o$  (effective gravity,  $g_o = \frac{\Delta\rho_o}{\rho_o}g$ ); volume flux,  $Q = \pi/4D^2V_o$ ; and discharging depth,  $H$ . In the mentioned parameters,  $\Delta\rho_o$  denotes the initial density differences between the effluent and the ambient and  $\rho_o$  represents the initial density

of the effluent. The parameter groups describing the motion of surface waves are water depth,  $h$ ; wave amplitude,  $a$ ; wave period,  $T$ ; and gravity,  $g$ . There are two more variables describing the relative spatial relationship between the buoyant jet and the surface wave, which are the discharging angle relative to the horizontal plane,  $\theta_1$ ; and the discharging angle relative to the the direction of wave propagation,  $\theta_2$ . From these control parameters, the characteristics of dilution rate is, then, described as

$$S = f(M, B, Q, H, h, a, T, g, \theta_1, \theta_2) \quad (1)$$

Chin (1987) suggests that the dominant mechanisms influencing the dilution of the effluent may be more easily characterized by formulating the dimensional variables in terms of length scales. As proposed by Fischer *et. al.* (1979), the definitions of appropriate length scales are

$$L_q = \frac{Q}{M^{1/2}} = (A)^{1/2} \quad (2)$$

$$L_m = \frac{M^{3/4}}{B^{1/2}} \quad (3)$$

$$Z_m = \frac{M^{1/2}}{U_{max}} \quad (4)$$

where  $L_m$  is the length scale beyond which the buoyancy dominates the plume flow;  $A$  denotes the area of the nozzle cross section; and  $U_{max}$  is the amplitude of the horizontal wave particle velocity. From the small amplitude wave theory,  $U_{max}$  is defined by

$$U_{max} = -\frac{agk}{\sigma \cosh kh} \quad (5)$$

$\sigma = \frac{2\pi}{T}$  and  $k = \frac{2\pi}{L}$  are the angular frequency and the wave number, respectively. From the Buckingham  $\pi$  theorem and Eq.(2)~Eq.(4), non-dimensionalizing Eq. (1) with the dilution rate of buoyant jets in still water,  $S_o$ , yields

$$\frac{S}{S_o} = f\left(\frac{H}{L_m}, \frac{L_m}{L_q}, \frac{Z_m}{L}, \frac{h}{L}, \theta_1, \theta_2\right) \quad (6)$$

which contains the non-dimensional variable groups characterizing the dilution enhancement of the effluent under wave action. In most practical conditions,  $H \gg L_m \gg L_q$ , which indicates that the effluent will be plume-like very quickly after leaving the nozzle. According to the observations of Sharp & Power (1985) and Chyan & Hwung (1993), no strong interaction between the jet flow and wave motion occurs when the axial jet momentum being weak. In fact,  $H/L_m$  and  $L_m/L_q$  are important dimensionless

parameters influencing  $S_o$ , however, they become minor in the dilution improvement effect of wave motion on buoyant jets when  $H \gg L_m \gg L_q$ . In the present study,  $\theta_1=0$  and Eq. (6) can be simplified as

$$\frac{S}{S_o} = f\left(\frac{Z_m}{L_q}, \frac{h}{L}, \theta_2\right) \quad (7)$$

Chin (1987) suggests that the relative depth,  $h/L$ , does not play a significant role in the dilution enhancement. From Eq. (5),  $Z_m/L_q$  is not independent of  $h/L$ , then, the effect of the latter in the dilution enhancement is implicitly involved in the former. From the experiments conducted by Chin (1987), the relation of Eq. (7) is demonstrated to be a linear function

$$\frac{S}{S_o} = 1 + C_s \frac{L_q}{Z_m} \quad (8)$$

where  $C_s$  is a coefficient depending on the interaction angle between the buoyant jet and surface wave. From the quantitative measurement,  $C_s$  can be determined to evaluate the characteristics of the angle effect.

### Experimental Setup

The nature of surface waves is an unsteady kinematical phenomenon. Optical method based on laser-induced fluorescence (LIF) is employed to carry out the flow visualization and the concentration measurements. The technique of LIF avoids distorting the interaction flow of jets and surface waves, and is sensitive up to tracer concentration of 0.19 pb. The experiments are conducted in a wave tank of  $12m \times 0.5m \times 0.6m$ . A piston type wave maker is installed on one end of the wave flume and a wave absorber locates on the other side to diminish the wave energy. Supplied by a constant head assembly, the effluents mixed with tracer is discharged by a nozzle of diameter of 0.33 cm at middle part of wave flume. Three discharge angles of jet flow relative to the propagating wave direction, *i.e.*,  $0^\circ$  (co-wave),  $180^\circ$  (opposing wave),  $90^\circ$  (orthogonal discharge), are selected to investigate the angle effects on the initial dilution processes. In case of orthogonal discharge, the nozzle is located nearby the side wall and otherwise in the centerline of the flume.

### Flow Visualization—

Drexhage (1973) found that the dye, Rhodamin 6G ( $C_{28}H_{31}ClN_2O_3$ ), could emit yellow fluorescence (wavelength=570 nm) when stimulated by an Argon-ion laser (wavelength = 514.5 nm). If the effluent contains with fluorescent dye, the flow pattern and vortex structures of the jet flow under wave action could be visualized by a sheet of laser light. The installation of flow visualization is shown in Fig. 1 where the laser beam is

Fig. 1 Experimental layout of flow visualization for cases of (a) orthogonal discharge  
(b) co-wave or opposing-wave

transformed to a light sheet by an optical system. In order to understand the flow pattern related to the wave phase, signals from the wave gauge and the electrical shutter of the camera are simultaneously collected by the data acquisition system. As shown in Table 1, three cases (Case 1 ~ Case 3) with a lower Reynolds number ( $Re = 772$ ,  $F_d = 7.05$ ) is employed to clearly visualize the vortex structures. Especially, there is no buoyancy in Case 2 because of the necessity for the observation of wake vortex formed in the interaction process. Strong density difference will seriously distort the image. If the location of laser light sheet is in the zone of flow establishment, pure momentum jet can be employed to simulate the interaction of buoyant jet with surface waves since the momentum force rather than the buoyant force is the dominant force of the flow field.

#### Quantitative Measurements—

The principle of LIF is also applicable to the quantitative measurements. According to the Lambert–Buoguer–Beer law in Yoe & Koch (1957), the fluorescent intensity,  $F$ , can be described by the Taylor series,

$$F = K_1 I_o \left[ 2.3ecd - \frac{(-2.3ecd)^2}{2!} - \frac{(-2.3ecd)^3}{3!} - \dots - \frac{(-2.3ecd)^n}{n!} \right] \quad (9)$$

where  $K_1$ =proportional coefficient;  $I_o$ =intensity of incident laser beam;  $e$ =molar extinction coefficient;  $c$ =tracer concentration; and  $d$ =length of test section. If the tracer concentration is low enough to the have the higher order terms neglected in the equation, the intensity of fluorescence with fixed  $K_1$ ,  $I_o$ ,  $e$  and  $d$  will be a linear function of tracer concentration. A calibration process is able to quantify this characteristic function which, in the following quantitative measurements, transforms the voltage signals from photo-detector into concentration data. Fig. 2 shows an example of calibration

curves. Three cases, such as pure water ( $\rho = 998\text{kg/m}^3$ ,  $20^\circ\text{C}$ ); water-alcohol mixture (1:5.33); and pure alcohol (95%,  $\rho = 808\text{kg/m}^3$ ,  $20^\circ\text{C}$ ), are employed to investigate the effect of compositions. It shows that the slopes are the same except the intercept caused by different system error. Before conducting the concentration measurement in a new test point, the background level of tracer concentration has to be determined to rid data of system error. The correlation coefficient of each calibration curve is larger than 0.999 and the standard deviation is lower than 0.1 ppb.

Most ocean outfalls usually locate in the intermediate water depth where the depth-to-wavelength ratio,  $h/L$ , ranges from 0.05 to 0.5. On the consideration of prac-

Fig. 2 Calibration curves of different compositions

tical applications, all of experimental conditions are in this range as shown in Table 1. Suitable *Reynolds No.* ( $Re > 2450$ ) and *Froude No.* ( $18.9 < F_d < 23$ ) are also selected to keep the simulated flow pattern similar to that of the diffusers. According to Chin (1987), the blocking layer of a buoyant jet with a poor dispersive ability is about 10% of the discharge depth. The measuring plane including 5 ~ 7 points locates 5 cm under the still water surface. The water surface variations induced by surface waves may block the fluorescence emitted from the measuring point while moving toward a higher test level. With the appropriate experimental conditions, the quantitative measurements of a buoyant jet under the action of surface waves can be proceeded. The data acquisition system collects signals from photo-detector and wave gauge in a sampling rate of 100 Hz and sampling duration of 60 sec. The initial dilution of different interaction cases can be determined from the experimental data, therefore, quantitative assessment of angle effects can be obtained and applied in the practical design of ocean outfalls.

## Results and Discussions

### Flow Visualization—

The flow visualization results of buoyant jet in co-wave are shown in Photo 1 where the flow pattern in still water is also pictured in Photo 1(a) for comparison. The trajectory in still water near the nozzle remains horizontal in the momentum-dominant domain, however, it gradually bends as the buoyant force getting stronger. During the ascending period, the effluent mixes with the ambient water and the boundary

(a)

spreads simultaneously. Obviously, the vortex resulted from the velocity gradient plays an important role in lateral mass transfer and concentration dilution. Concerning the buoyant jet in wave motion, it is classified according to the temporal duration of wave crest and wave trough. The effluent experiences a co-stream flow induced by wave motion in the former while it interacts with an opposing flow in the latter. In case of wave-induced opposing flow, as shown in Photo 1(b), it is interesting to observe that the spreading rate of jet boundary in the neighborhood of the nozzle is larger than that in still water. The horizontal distance from the nozzle to the location where the plume ascending completely upward is shorter in Photo 1(b) than that in Photo 1(a). It shows that the effluent interacts with an opposing and inclining flow induced by wave motion. A greater velocity gradient and the opposing flow explain the formation of an increasing spreading rate and shorter excursion distance. There are many slender and inclining strips of jet fluid near the nozzle. According to Chyan & Hwung (1993), this structure is closely connected to the wake vortex. Due to the buoyancy and the upward wave flow being the same direction, the former will accelerate the formation of wake vortex even if the latter is small. As shown in Photo 1(e) where the opposing wave flow still influencing the effluents, there doesn't exhibit similar structures. It is because that the buoyant force prohibits the formation of wake vortex. From the above discussion, it explains the reason that, as shown in Photo 1(b) ~ Photo 1(e), the slender strips of the effluent always occur in the offshore side of the buoyant jet. This mechanism also changes the symmetry of profile distribution of the buoyant jet. However, these phenomena imply the mechanisms responsible for the increase of dilution rate.

On the phase of wave crest ( $t/T = 0.25$ ), as shown in Photo 1(c), the wave flow near the nozzle is parallel to the jet flow. It results in a smaller velocity gradient which depressing the formation of vortex and spreading rate. When  $t/T = 0.49$ , the inclining flow contains an upward velocity component, it will be against the ascending tendency of the effluent. As shown in Photo 1(d), there is a region where the trajectory is almost horizontal. Compared to the buoyant jet of the same trajectory characteristics in still water, the length scale in horizontal direction is longer and the spreading rate is smaller. From the observation of the effluent influenced by the co-stream of wave motion, the wave flow during the phase of wave crest seems to diminish the dispersion ability of the buoyant jet. In fact, there is an additional mechanism of dilution improvement during the interaction of co-stream and opposing flow on the effluent. As mentioned in the above discussion, the excursion distance will be shortened by the opposing and upward wave flow and stretched by the co-stream and downward wave flow. When the velocity of buoyant jet being too low to interact with surface waves, the plume will merely oscillate with wave motions which can not change the relative position within the effluent. Sharp & Power (1985) and Chyan & Hwung (1993) had observed the same phenomena. The effluent plumes ascending in the stretched excursion of wave

crest phase will enclose a large volume of ambient water with the following plume in the shortened excursions of wave trough. Therefore, a few patches of fresh water can be found in the ascending effluent plume as shown in Photo 1(b) ~ Photo 1(e). This additional mechanism provides a new chance of dilution and is similar to the wave tractive mechanism found by Chyan & Hwung (1993).

The flow visualization results of buoyant jet oppositely discharged into the wave motion would not be discussed herein since it shows a qualitatively similar result obtained in the co-wave case. Photo 2 depicts the formation cycle of wake vortex on the plane 1.1 cm away from the nozzle in the orthogonal discharge case. Within the momentum dominating domain of buoyant jets, it is acceptable to employ a pure momentum jet to simulate the momentum interaction of buoyant jets with surface waves for observing the inside structures of wave vortex. As shown in Photo 2(a) ( $t/T = 0$ ), the appearance of the effluent has been upwardly distorted into a horseshoe by the cross-flow induced by waves. The vertical velocity of intermediate wave is usually smaller than the horizontal velocity. During the wave phase of  $t/T = 0$  and  $t/T = 0.5$  when the vertical velocity dominates, the vortex induced by wave motion can not develop completely. A pair of counter-rotating vortex are not formed until the cross-flow of wave motion is large enough, as shown in Photo 2(b). As shown in Photo 2(a) ~ 2(f), the axes of vortex pair also rotates clockwise as the wave flow vector does except that the vortex around the phase of  $t/T = 0$  or  $t/T = 0.5$  is relatively immature. The formation of wake vortex certainly increases the dilution rate due to additional forced entrainment.

In order to investigate the buoyancy effect on the wake vortex formation, the flow visualization experiments of Photo 2 repeat again except the substitute of the pure momentum jet with a buoyant jet. The experimental results are shown in Photo 3 whose images are obscured by the density gradient. From the appearance of the flow structures, the wake vortex can still be found in Photo 3(c). The interacted structures are more sophisticated than that of the momentum interaction as depicted in Photo 2. A curved vortex tail following the wake vortex is observed and it mainly results from the vortex occurred before the test section. From the above observations, it suggests that the buoyancy effect will enhance the unsteadiness of the jet flow. The dispersion area of the effluent is enlarged by this effect, which implies the increase of dilution rate. In fact, the flow field of buoyant jet orthogonally discharged into the wave motion is a very complex but interesting flow phenomenon. In addition to the formation of wake vortex, the jet trajectory deflects in a status of 3-dimensional while a 2-dimensional deflection was observed by Chyan & Hwung (1993). Generally, the jet is onshore and offshore deflected in wave phase of  $t/T = 0.25$  and  $t/T = 0.75$ . In phase of  $t/T = 0$ , the ascending process of the effluent occurs earlier because of the upward vertical wave velocity while the horizontal domain of the trajectory will be stretched in phase of

(f)

Photo 2 Formation cycle of wake vortex in orthogonal interaction (Case 2)  
 $t/T =$  (a) 0, (b) 0.21, (c) 0.30, (d) 0.44, (e) 0.65, (f) 0.81.

$t/T = 0.5$ . Due to the periodic deflection induced by wave motion, the shape of the effluent plume is no longer a circle, however, the mixing area of the effluent will be increased by the deflection mechanism and wake vortex structures.

From the above discussions, it suggests that the mechanisms improving the dilution rate of the buoyant jet in cases of co-wave and opposing wave result in the velocity gradient increase and wave tractive mechanism. The deflection mechanism and wake vortex structure play an important role in the enhancement of dilution rate when the buoyant jet orthogonally discharged into the wave motion. Concerning the contribution of these mechanisms to the dilution increases, it can only be evaluated by the quantitative measurements which will be discussed in the following.

#### Dilution Measurements—

From the elaborate measurements of  $S$  and  $S_o$ , the data obtained was processed according to Eq. (8) and the results of interaction angles,  $0^\circ$ ,  $180^\circ$ , and  $90^\circ$ , are shown in Fig.3. The regression relationships of  $S/S_o$  and  $L_q/Z_m$  are linear as proposed by Eq. (8) which are

$$\text{co-wave} \quad : \quad \frac{S}{S_o} = 1 + 4.21 \frac{L_q}{Z_m} \quad (10)$$

$$\text{opposing-wave} \quad : \quad \frac{S}{S_o} = 1 + 4.16 \frac{L_q}{Z_m} \quad (11)$$

$$\text{orthogonal discharge} \quad : \quad \frac{S}{S_o} = 1 + 5.55 \frac{L_q}{Z_m} \quad (12)$$

with the correlation coefficients being 0.90, 0.93, and 0.91, respectively, while the standard deviations are 0.10, 0.08, and 0.10. Positive slopes indicate the wave action increasing the dispersion of the effluent. From the flow visualization identifying the similar interaction mechanisms in cases of co-wave and opposing wave, it results in the coefficient,  $C_s$ , almost equivalent in both cases. As shown in Fig. 3, Chin (1987) suggests a higher estimate of  $C_s = 6.15$  which may be because of the sampling method and the calibration relation. The mechanisms, *i.e. wave deflection and wake vortex*, formed in the orthogonal discharge obviously play a more effective role in the dilution enhancement. In coastal water, the propagation of surface waves is not unidirectional so that the orientation of the diffusers can only be designed to be orthogonal to the principal direction which will provide the highest initial dilution. To estimate the dilution rate increased by wave action, the data obtained in different interaction angles is collected in Fig. 4 which shows  $C_s = 4.87$ .

#### Conclusion

The mechanisms improving the initial dilution processes of jet flow in co-wave and opposing wave are identified as the velocity gradient increase induced by the opposite

Fig. 4 Estimate of initial dilution increase

wave flow and the wave tractive mechanism stemmed from the onshore and offshore wave flow. When orthogonally discharged into wave motion, the effluent is affected by different interaction mechanisms, such as wake vortex and wave deflection. The concentration measurements show that the increase of the initial dilution is comparable in cases of co-wave and opposing wave. However, a higher increasing tendency is found in the orthogonal discharge whose  $C_s$  is 33% larger than that of the other cases. It

implies that the orthogonal discharge is a more effective orientation in the enhancement of mixing efficiency. Considering the field situation in coastal water, an average value of  $C_s = 4.87$  is suggested to estimate the dilution rate increase of the buoyant jet under the wave action.

## CHAPTER 220

### STUDY ON THE BEHAVIORS OF COHESIVE SEDIMENT IN THE YANGTZE ESTUARY

Xiaochuan Zeng<sup>1</sup>, Yixin Yan<sup>2</sup>, Kai Yen<sup>2</sup>

#### Abstract

In order to study the deposition and erosion behaviors of the cohesive sediment in the navigation channel through the bar of the Yangtze Estuary, a series of experiments have been made with a standard settling tube and Ubbelodhe viscometer. The tests show that the flocculation and rheological behaviors of the cohesive sediment differ from the clay mineral contained in the fine sediments. Different clay mineral aggregates or flocs have their apparent volume due to the thin layer of water surrounding the aggregates or water entrained in the flocs. The Bingham relative viscosity and yield stress are obtained:  $\mu_r = (1 - KC_v)^{-2.5}$ ,  $\tau_y = 0.13K \exp(7kc_v)$ . The suspended load transport rate and depositional behavior of the cohesive sediment have been studied with rotating annular channel. It is shown that there is a certain silt carrying capacity for a certain flow condition. The equilibrium silt concentration can be expressed:  $C_{\infty q} = A(\tau_b - \tau_1)$  and the concentration-time relation is  $C = C_{\infty q} + (C_0 - C_{\infty q}) \exp(-\alpha \omega t / 2H)$ . Using the above formulas and tidal velocity analysis the yearly average dredging amount in the the navigation channel can be calculated.

#### Introduction

The Yangtze River is the largest river of China. It carries annually  $924 \times 10^9 \text{ m}^3$  of runoff and  $470 \times 10^6 \text{ t}$  of sediment

- 
1. Instructor, Hohai University, Nanning 210024, China
  2. Professor, Hohai University, Nanning 210024, China

into the sea. The yearly average suspended concentration is  $0.544 \text{ kg/m}^3$ . The grain size of suspended load is generally greater than  $5 \phi$ , 30% of which are clay particles. Most of the sediment is deposited on the estuarine area, causing shoaling of navigation waterway, thus greatly affecting the traffic capability of port Shanghai and other port along the lower reaches of the River. The grain size of the materials deposited in the navigation channel is of the same order magnitude as that of suspended sediment (Chang Zhizhong, 1981). Extensive dredging has to be carried out to maintain the required water depth of the navigation channels, particularly the approach channel to the sea. Therefore regulation works have to be carried out in combination with dredging to cope with such adverse situation. For this purpose study was made, among others, on the behaviors of cohesive sediment of the Estuary, which is necessary for the planning and design of the regulation works, as well as for the disposal of the dredged materials in the dredging operation. The deposition and erosion of the cohesive sediment of the navigation channel in the Yangtze Estuary is affected by various factors, such as tidal current, runoff, wave, salinity, pH value etc.. The floc size and floc strength of cohesive sediment are important factors affecting deposition and erosion. In this paper the rheological behaviors of the cohesive sediment are studied from the test results with Ubbelodhe viscometer for different clay mineral composition and mediums. Transportation and deposition tests for Yangtze Estuary clay were conducted in the annular rotating channel. For deposition the concentration versus time relationship is obtained and could be used for calculating dredging amount in the navigation channel.

#### Experimental Study on the Rheological Behavior of Cohesive Sediment

On silty coast and estuaries the fine sediment usually consists of mixture of clay, silt, fine sand and occasionally some organic matters. Previously it was taken that there is no difference in behaviors between the clay minerals and the primary minerals except their grain size. In reality, the clay particles of the cohesive sediment carry electric charge which causes flocculation and deflocculation of the sediment. Size distribution analysis with a setup of settling tube is shown in Table 1. Different clay mineral particles have

different ratio of width to thickness and the flocculation sized of different clay mineral varies appreciably from each other in different mediums, but for fine silt particles of quartz there is no significant difference in the flocculation size  $d_{50}$  in different mediums. For example, kaolinite can be flocculated in distilled water but montmorillonite cannot.

Table 1.  $d_{50}$  of quartz, kaolinite and montmorillonite in different mediums

Minerals  Mediums	Non clayey sediment	Clay minerals		Remarks
	Quartz silt	Montmoril- lonite	Kaolinite	
Distilled water	0.010	0.0024	0.038	1. Unit : mm 2. Quantity of [NaPO <sub>3</sub> ] <sub>6</sub> added: 0.5N. l.c.c. / g.
Water with salinity 10‰	0.015	0.027	0.040	
Distilled water+[NaPO <sub>3</sub> ] <sub>6</sub>	0.011	0.0021	0.0032	

The modes of particle (aggregate) association are of great importance to the essential behaviors of the flocs, such as settling, shearing, swelling etc., and are affected by factors such as pH value, concentration of electrolyte and sediment as well as composition of mineral etc. . Under normal conditions edge to face association is the principal mode of association, which leads to voluminous card-house structures and entrains a large amount of water. The aggregates or flocs will increase their apparent volume due to the thin layer of water surrounding the aggregates or water entrained in the flocs. The degree of association will change with different mediums. Along coast of China, the major clay minerals are illite, kaolinite, montmorillonite and in the Yangtze Estuary the clay mineral consists mainly of illite. The optimum salinity for flocculation is about 10~15‰. With this salinity the apparent volume and settling velocity of the flocs attain a maximum.

In order to investigate the erosion of sediment and movement of fluid mud, the rheological behavior tests of cohesive sediment are conducted with Ubbelodhe viscometer for different clay mineral suspension and mediums (Yen, Kai, et al, 1989), as shown in Fig. 1. It is clear that for the same

concentration the relative viscosity of montmorillonite suspension is larger than that of kaolinite suspension with salinity of 10%. For the same clay mineral, the relative viscosity in salinity medium is larger than that of suspension with peptizer. The degree of volume expansion K, which can be

Fig. 1  $\mu_r$ - $C_v$  curves of montmorillonite and kaolinite suspended in different mediums: 1-montmorillonite suspension with salinity of 10 %. 2-montmorillonite suspension with peptizer. 3-kaolinite suspension with salinity of 10%. 4-kaolinite suspension with peptizer.

expressed by the ratio of the volumes after and before expansion, may be obtained from the formula

$$\mu_r = (1 - KC_v)^{-2.5} \quad (1)$$

In this formula  $\mu_r$  is the relative viscosity coefficient and  $C_v$  the volumetric concentration. The volume expansion K for different clay mineral and mediums are given in Table 2.

Table 2 Value K obtained by Ubbelodbe viscometer

Minerals	Saline water with salinity 10%	Distilled water + peptizer of $[\text{NaPO}_3]_s$	Remarks
Montmorillonite	37.0	15.3	Quantity of $[\text{NaPO}_3]_s$ added: 0.5N, 0.5c.c./g
Kaolinite	7.8	1.5	

The Bingham yield stress is a measure of the number and the strength of the links in card-house (Van Olphen, 1977). The magnitude of Bingham yield stress is closely related to the size of flocs and to volume of the entrained water in the

flocs, as shown in Fig. 2. When peptizer is added into the suspension, the card-house structures are completely dissociated, and the Bingham yield stress will tend to disappear. The formula of Bingham yield stress for Yangtze Estuary clay is:

$$\tau_y = 0.13K \exp(7KC_v) \quad (2)$$

Fig. 2 Equivalent yield stress of montmorillonite and kaolinite suspension

For the Yangtze Estuary clay, which consists mainly of illite, the values of volume expansion K in Equ. (1) and Equ. (2) are given in Table 3.

Table 3. Value d in Different Salinity Mediums

Salinity	2%	5%	10%	20%	25%
n	5.9	6.3	5.0	6.0	5.6

Comparison of  $\mu_r$  values between experimental and calculated by Equ(1) is shown in Fig. 3 and comparison of Bingham yield stress between experimental and calculated by Equ. (2) is shown in Fig. 4. It shows that Equ. (1) and Equ. (2) conform with experimental data.

All the above tests show that the composition of clay minerals is of great importance to the essential properties of flocs.

Fig. 3 Comparison between experimental and calculated  $\mu_r$  values

Fig. 4 Comparison between experimental and calculated Bingham yield stress

### Deposition Behavior of Cohesive Sediment

A series of deposition tests with different clay mineral composition and the Yangtze Estuary clay in sea water were conducted in an annular rotating channel to study the relation between the deposition behavior of cohesive sediment and the bed shear stress (Zeng Xiaochuan, 1985). Fig. 5 shows the results of test for kaolinite. It can be seen that there is a critical critical shear stress  $\tau_1$  below which the flocs of the

cohesive sediment will be all deposited on the channel bed, and when the bed shear stress  $\tau_b$  is greater than the critical shear stress  $\tau_1$ , the suspended sediment will attain a state of equilibrium with concentration  $C_{eq}$ . The relation between equilibrium concentration  $C_{eq}$  and bottom shear stress  $\tau_b$  for different initial concentration  $C_0$  can be divided into single-valued stage (along  $\tau_1$ ) and the multi-valued stage (on the right of  $\tau_1$ ) respectively. At the single valued stage  $C_{eq}$  versus  $\tau_b$  is independent on the initial concentration  $C_0$ . That is, there is a certain silt carrying capacity for a certain flow condition. At this stage  $C_{eq}$  varies with  $\tau_b$  in a straight line relation. For a give water depth it can be written

$$C_{eq} = A(\tau_b - \tau_1) \quad (3)$$

where  $A$  is a coefficient and  $\tau_1$  the critical shear stress, both depend on the salinity of water and kind of clay mineral. On the right of curve  $\tau_1P$ , the values of  $C_{eq}$  vary with initial concentration  $C_0$  for a constant flow condition. At this stage there is no marked siltation on the bed. On the bare fiber glass channel bed there could be no exchange between bed load and suspended load. When a large amount of sediment is deposited on the bed, free exchange between suspended load and bed load occurs, thus obtaining the relation as shown by the curve  $\tau_1P$ .

For clay suspension in the Yangtze Estuary, equilibrium  $C_{eq}$  versus differential motor speed  $\Delta n$  between ring and channel is shown in Fig. 6. This could also be seen from Equ. (3). The values  $A$  and  $\tau_1$  in different salinity mediums are shown in Table 4. Making use of equation (3), we analysed sediment

Table 4. Value  $A$  and  $\tau_1$  in Different Salinity Mediums

Salinity	$A$	$\tau_1$ (dyne/cm <sup>2</sup> )
5%	11.28	0.72
10%	10.67	0.90
20%	10.99	0.76
30%	10.79	0.82

concentration data (average over semitidal period) in Yangtze Estuary during spring or neap tide in both high flow and low flow seasons. Both laboratory test and field data show that equation (3) well describes the relationship between suspension concentration and bed shear stress.

Fig. 5 Equilibrium concentration  $C_{eq}$  versus bed shear stress  $\tau_b$  for kaolinite

Fig. 6  $C_{eq}$  versus differential motor speed  $\Delta n$  between ring and channel for Yangtze Estuary Clay

No matter at which stage, the vertical concentration distribution can be expressed by the diffusion equation (Ren, Ru-shu et al, 1987), from which the settling velocity can be calculated. The curve  $\omega_s$  versus  $\tau_b$  can be expressed by equation

$$\omega_s = \omega_o \exp [-b(\tau_b - \tau_1)] \tag{4}$$

$\omega_o$  and  $b$  depend on salinity and depth of water and kind of clay mineral. It can be seen that the settling velocity of the flocs decreases exponentially with increase of the bed shear stress, indicating that cohesive sediment is very sensitive to the dynamic actions of flow, as shown in Fig 7. For Yangtze Estuary clay, the settling velocity in turbulent flow is much smaller than that in still water and reduces with increasing bed shear stress, the values  $\omega_o$  and  $b$  in different salinity water are shown in Table 5.

Table 5 Value  $\omega_o$  and  $b$  in Different Salinity Mediums

Salinity	$\omega_o$	$b$
5‰	$2.17 \times 10^{-2}$	0.63
10‰	$3.64 \times 10^{-2}$	0.90
20‰	$3.45 \times 10^{-2}$	0.76
30‰	$1.13 \times 10^{-2}$	0.46

In order to forecast the dredging amount in navigation channel, which is needed for the planning of regulation works and determining the required capacity of dredging equipment, the depositional behavior of the cohesive sediment in turbulent flow was studied in the annular rotating channel. For a given flow condition, the sediment movement equation can be written as:

$$\frac{\partial(AC)}{\partial(QC)} + \frac{\partial t}{\partial x} + \alpha \beta \omega (C - C_{eq}) = 0 \tag{5}$$

where  $A$  is cross-sectional area,  $Q$  is discharge,  $B$  is channel width, and  $\alpha$  is the probability of sediment siltation. For the annular rotating channel,  $x = \bar{v}t$ , where  $\bar{v}$  is mean velocity, then Equ. (5) can be written as:

Fig. 7  $\omega_s$  versus bed shear stress  $\tau_b$  (lower layer)

$$2 \frac{\partial(HC)}{\partial t} + \alpha \omega (C - C_{eq}) = 0 \tag{6}$$

where H is the water depth, we have

$$C = C_{eq} + (C_0 - C_{eq}) \exp(-\alpha \omega t / 2H) \tag{7}$$

where  $C_{eq}$  can  $\omega$  could be calculated by Equ. (3) and Equ. (4). Equ. (7) conforms well to the experimental data.

The siltation thickness p in the navigation channel for steady flow can be obtained from:

$$P = \frac{H}{r_0} (C_0 - C_{eq}) (1 - \exp(-\alpha \omega T_d / 2H)) \tag{8}$$

where  $r_0$  is the dry specific weight of deposited sediment,  $T_d$  is the time of current passing through the channel.

For unsteady flow, the thickness p of deposited sediment can be written as:

$$P = \beta \frac{H}{r_0} (C_0 - C_{eq}) (1 - \exp(-\alpha \omega T_d / 2H)) \tag{9}$$

where  $\beta$  is a coefficient.

### Conclusions

a. The mineral composition and its content are of great importance to the hydrodynamic behaviors of fine cohesive sediment.

b. The transportation of cohesive sediment can generally be divided into three stages. At single valued stage  $C_{eq}$  is independent of  $C_0$ .

c. The vertical concentration distribution of sediment can be expressed by diffusion equation. The settling velocity in turbulent flow is smaller than that in still water.

d. The relation of suspension concentration versus time in turbulent flow can be obtained from tests with an annular rotating channel, formula (7) could be used for calculating the yearly dredging amount.

Apart from the factors mentioned above, there are also many other factors affecting the hydrodynamic behavior of cohesive sediment.

## CHAPTER 221

### Dispersion of pollution in a Wave Environment.

R. Koole<sup>1</sup> & C. Swan<sup>2</sup>.

#### Abstract.

This paper concerns the wave-induced mixing of a discharged contaminant, and presents the results of a two-part laboratory investigation in which both a two-dimensional and a three-dimensional jet were discharged beneath a series of progressive gravity waves. In each case the measured data is compared to an identical discharge in a quiescent ambient. This comparison suggests that the oscillatory wave motion generates a region of intense fluid mixing which cannot be predicted by the existing integral solutions. Comparisons with a Lagrangian model, first proposed by Chin (1988), highlights the importance of the "apparent" mixing associated with the wave-induced deflection of the jet-axis. This provides a convincing explanation for both the non-Gaussian distributions observed by Sharp (1986), and the multi-stage structure of the centre-line decay (Chyan et al., 1991). Furthermore, quantitative comparisons with the Lagrangian model suggest that in addition to the wave-induced deflection, the oscillatory motion produces a significant increase in the rate at which ambient fluid is entrained into the emerging jet.

#### 1. Introduction.

The design of coastal outfalls, and in particular the estimate of pollutant concentrations, is usually based upon a simplified steady state or quasi-steady state analysis. In the near-field region, close to the outlet orifice, the velocity and concentration profiles are typically described by some form of integral solution based upon the concentration of mass, momentum and, where appropriate, species concentration. Although these solutions were originally developed for buoyant

---

<sup>1</sup> Research assistant & <sup>2</sup> Lecturer. Department of Civil Engineering, Imperial College of Science Technology and Medicine, London, United Kingdom. SW7 2BU.

discharges in a quiescent ambient (Morton et al., 1956), subsequent research has shown that they may also be applied to a range of quasi-steady flows. This extension of the existing theory is, however, only valid if the unsteadiness of the ambient fluid has a time-scale which is significantly larger than the time-scales of the turbulent fluctuations within the emerging jet. As a result, a quasi-steady solution (based upon a modified integral solution) may be used to describe the discharge of pollution in a tidal flow, but should not be used to model the near-field mixing which arises when pollution is discharged into a wave environment. In this latter case the typical wave periods are similar to the eddy time-scales (of the order of seconds), and consequently there may be significant coupling between the turbulent fluctuations and the unsteadiness of the surrounding flow.

Indeed, previous qualitative studies (Shuto and Ti (1974), Ger (1979), Sharp (1986) and Chyan et al. (1991)) suggest that the oscillatory motion associated with the propagation of the surface gravity waves has a significant effect upon the local mixing characteristics. In particular, the wave motion appears to produce a large increase in the dilution immediately downstream of the discharge orifice. This region, which is usually referred to as the "zone of flow establishment", is characterised in a quiescent ambient by a gradual transition from a top-hat velocity profile at the exit to an approximately Gaussian distribution further downstream. This latter state marks the beginning of the so-called "zone of established flow" within which the integral solutions are valid. Recent quantitative measurements presented by Chyan and Hwung (1994) and Koole and Swan (1994) have shown that the "zone of flow establishment" is considerably shortened by the wave motion; and that a region of intense fluid mixing arises, the characteristics of which cannot be predicted by the existing integral solutions.

For example, there is both qualitative (Sharp, 1986) and quantitative evidence (Chyan and Hwung, 1994) to suggest that in some circumstances the radial distribution of both the axial velocity and the "pollutant" concentrations are no longer Gaussian. These observations are interpreted as providing evidence for a new wave-induced mixing mechanism (referred to as the "wave tractive mechanism") which involves the "entrapment" of large volumes of uncontaminated (ambient) fluid into the central area of the jet. Furthermore, Chyan and Hwung (1994) conclude that the axial variation in both the centre-line velocities and the concentrations no longer follow a typical exponential decay. Indeed, they provide evidence of a multi-stage decay in which three specific mechanisms of wave-induced mixing are identified.

The present paper will consider the nature of the mixing processes within the near-field region, and will, in particular, examine the occurrence of non-Gaussian distributions within the "zone of established flow". Section 2 commences with a brief outline of the experimental apparatus in which two widely differing discharges were considered. The first concerns a two-dimensional, non-buoyant, jet discharged in a horizontal plane; while the second concerns a three-dimensional, buoyant (thermal) discharge orientated in a vertical plane. In both cases two sets of measurements were undertaken so that the mixing and dilution of the jet in a wave environment can be

directly compared with an identical discharge in a quiescent ambient. In section 3 the velocity and temperature data are compared with both the existing integral solutions and a simplified Lagrangian model. This latter solution was first proposed by Chin (1988) and further developed by Koole and Swan (1994). Evidence to support the various wave-induced mixing mechanisms is examined, as is the multi-stage structure of the centre-line decay. Finally, some conclusions regarding the effectiveness of the additional wave-induced mixing are made, and the practical implications for outfall design assessed.

## 2. Experimental apparatus.

### Case 1: Two-dimensional, non-buoyant jet.

The first experimental study was undertaken within a narrow wave flume located in the Civil Engineering Department's hydraulics laboratory at Imperial College. This facility has good optical access, and is equipped with a numerically controlled random wave paddle located at one end of the wave flume. A large block of poly-ether foam is positioned at the opposite end to provide passive wave absorption. Typical reflection coefficients within this facility are less than 3%. The tank is 25m long, 0.3m wide, and has a working depth of 0.7m. The two-dimensional jet was introduced through a horizontal slot ( $D=1\text{cm}$ ) located at mid-depth at the downstream end of the wave flume (figure 1a). The present results correspond to an exit velocity of 0.75m/s, and include measurements undertaken within a quiescent ambient and beneath a progressive regular wave train in which the wave amplitude was 30mm, and the wave period 1.04s.

The resulting flow field was measured using a two component laser Doppler anemometer in a forward scatter configuration. A 35mW helium-neon laser was used to create a three beam arrangement with cross polarisation. This apparatus allows the simultaneous measurement of two velocity components within a measuring volume which was estimated to be  $0.5\text{mm}^3$ . After seeding the flow with milk (added in the ratio of approximately 100ppm), a data rate in excess of 2kHz was achieved so that the velocity components could be sampled at 500Hz with a measuring accuracy of  $\pm 2\%$ . Further details of these experimental observations are given by Koole and Swan (1994).

### Case 2: Three-dimensional, buoyant jet.

The second set of measurements were undertaken in a larger wave flume which is also located in the hydraulics laboratory at Imperial College. This facility is 65m long, 2.75m wide, and is also equipped with a numerically controlled random wave paddle. At the downstream end of this flume the wave energy is dissipated on a 1:20 sloping beach. Under the present test conditions (see below) this produced a reflection coefficient of 4%. The "pollutant" was introduced in the form of a hot water discharge, through a 1cm diameter nozzle located on the bed of the wave flume. The initial jet was orientated in a vertical direction, and was positioned along the centre-line of the wave flume some 25m downstream of the wave paddle (figure 1b).

## 1(a). Two-dimensional, non-buoyant jet.

## 1(b). Three-dimensional, buoyant jet.

Figures 1a-1b. Experimental apparatus.

Although a wide range of test conditions were investigated, the present paper is only concerned with one specific data set in which the discharged "pollutant" was  $35^{\circ}\text{C}$  above the temperature of the ambient fluid. The results presented in section 3 correspond to an exit velocity of  $0.55\text{m/s}$ . Once again, measurements were undertaken in a quiescent ambient, and beneath a progressive wave train in which the wave amplitude was  $30\text{mm}$  and the wave period was  $1.0\text{s}$ . Due to the restricted access and the physical dimensions of this facility a second laser Doppler anemometer was used to measure the velocity field. This system is based upon a  $10\text{mW}$  helium-neon laser which is used to create a two beam arrangement from which one component of the flow field could be determined. The beams were passed down a fibre-optic cable, and emerged through a converging lens to focus  $60\text{mm}$  from the fibre head. The intersection of the beams was observed in a back-scattered configuration. With careful seeding of the flow (using Trimiron Supersilk, MP-1005) an accuracy and data rate

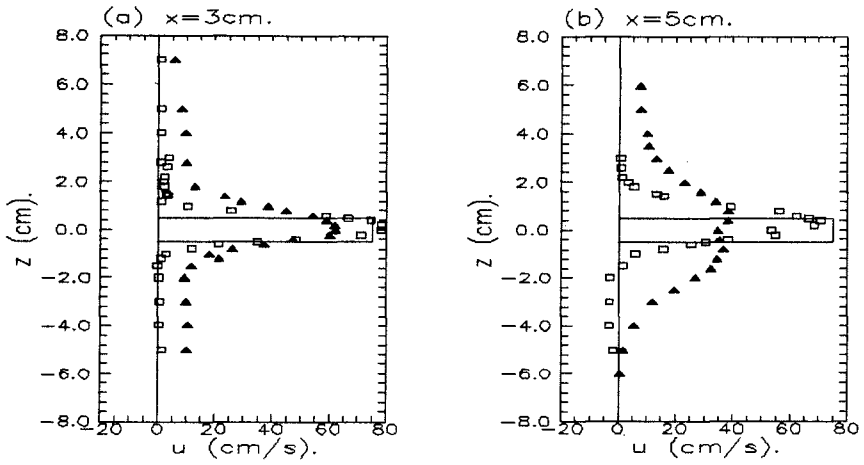

similar to that noted above were achieved. The temperature variations within the developing plume were measured using an array of 8 K-type thermocouples. These were manufactured at Imperial College using teflon coated wire with a diameter of 3 microns. Calibration tests indicated that these probes have an accuracy of  $\pm 0.05^\circ\text{C}$  with a response time of 0.05s. This was sufficient to measure the temperature fluctuations within a wave cycle, and to assess the mixing and dilution of the jet at differing wave phases.

### 3. Measured data.

The axial velocity measured within the "zone of flow establishment" in Case 1 (described above) is shown on figures 2a-2b. In each of these figures, and many of the subsequent figures, two data sets are presented. The first, indicated by the open squares, corresponds to a discharge in a quiescent ambient; while the second, indicated by the solid triangles, corresponds to a discharge in the relevant wave conditions. Within the "zone of flow establishment" the mean jet velocity ( $U$ ) in Case 1 is significantly larger than the wave-induced fluid motion ( $u,v$ ), and thus there is little wave-induced displacement of the jet-axis. The experimental data presented on figures 2a-2b suggest that there is significant mixing of the jet immediately downstream of the nozzle, and that the "zone of flow establishment" (or the region over which a Gaussian distribution evolves) is significantly shortened. A similar pattern is observed in figures 3a-3b which describe the evolution of the three-dimensional discharge outlined in Case 2.

Figures 4a-4b concern Case 1, and present the variation in the axial velocity within the "zone of established flow" ( $x > 5\text{cm}$ ). It is within this region that the integral solutions discussed previously are applicable. However, since the mean jet velocity is now of a similar magnitude to the wave-induced velocity (ie  $U/v_{\text{max}} \approx 1$ ), the jet will undergo considerable lateral displacement. As a result the laboratory data, which corresponds to measurements undertaken at a number of points fixed in space and time-averaged over an integer number of wave periods (typically 40), will reflect both the dilution of the jet and its lateral displacement. In consequence, the velocity data gathered in a wave environment are very different from the integral solutions (indicated by a solid line on figures 4a-4b), whereas the measurements undertaken in a quiescent ambient are in good agreement with the existing theory. A similar sequence of results also arises in Case 2. In figures 5a-5b the average temperature profiles are presented within the so-called plume region (ie. that region of the flow where the buoyancy effects are important). Once again the influence of the wave motion is clearly apparent.

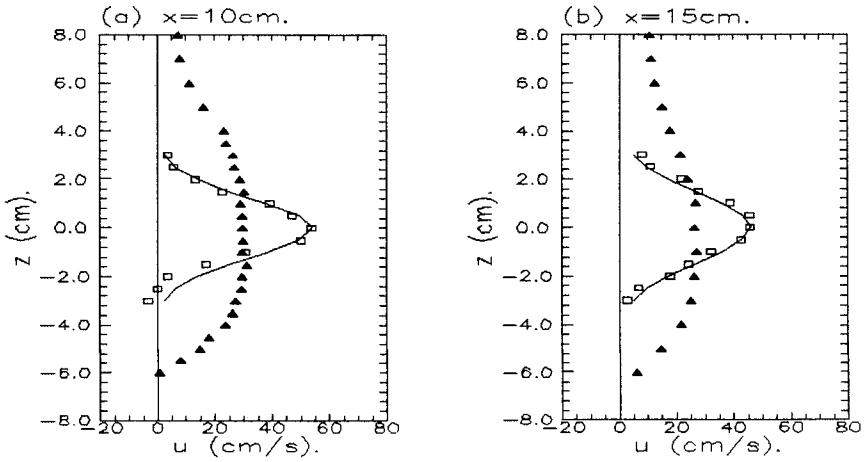

These results suggest that in both Case 1 and Case 2 the standard integral solutions are unable to describe the time-averaged laboratory data if the pollutant is discharged in a wave environment. However, the extent to which this change is due to the lateral displacement of the jet or the occurrence of additional wave-induced mixing remains unclear.

#### 4. Discussion of Results.

To examine the relative importance of the jet displacement a simplified Lagrangian model similar to that proposed by Chin (1988) was adopted. This solution considers a succession of fluid elements discharged at regular intervals throughout a wave cycle. Each element is tracked, in both space and time, and the entrainment characteristics are based upon the velocity of the jet relative to the surrounding fluid. The conservation equations appropriate to Case 1 are given by:

$$\frac{\partial}{\partial \xi} \int_{-\infty}^{+\infty} U(\xi, \eta) \cos(\gamma) \partial \eta - 2\alpha U(\xi, 0) \cos(\gamma) + \beta |U(\xi, 0) \sin(\gamma)| \quad (1)$$

$$\frac{\partial}{\partial \xi} \int_{-\infty}^{+\infty} [U(\xi, \eta) \cos(\gamma)]^2 \partial \eta - 0 \quad (2)$$

where  $(\xi, \eta)$  represent the local cartesian co-ordinates in which the  $\eta=0$  corresponds to the instantaneous jet-axis,  $U$  is the velocity of the fluid element relative to the surrounding flow (figure 1a), and  $\gamma$  is the angle between  $U$  and the jet-axis. In Case 2 the conservation equations (including a heat flux relation) are best expressed in local polar co-ordinates  $(\xi, r)$ , where the  $\eta=0$  once again represents the instantaneous jet-axis:

$$\begin{aligned} \frac{\partial}{\partial \xi} \int_0^{\infty} 2\pi r \rho(\xi, r) W(\xi, r) \cos(\gamma) \partial r - 2\pi b \rho_0 \alpha W(\xi, 0) \cos(\gamma) \\ + 2b \rho_0 \beta |W(\xi, 0) \sin(\gamma)| \end{aligned} \quad (3)$$

$$\frac{\partial}{\partial \xi} \int_0^{\infty} 2\pi r [W(\xi, r) \cos(\gamma)]^2 \rho(\xi, r) \partial r - \int_0^{\infty} 2\pi r [\rho_0 - \rho(\xi, r)] g \cos(\gamma) \partial r \quad (4)$$

$$\frac{\partial}{\partial \xi} \int_0^{\infty} 2\pi r [W(\xi, r) \cos(\gamma)] T(\xi, r) \partial r - 0 \quad (5)$$

In this case  $W$  represents the velocity of the fluid element relative to the surrounding flow (figure 1b),  $\rho(\xi, r)$  is the variable density within the jet,  $T(\xi, r)$  is the corresponding temperature, and the subscript 0 refers to the ambient conditions within the surrounding fluid. In both cases (equations 1 and 3)  $\alpha$  defines the coefficient of radial entrainment which is based upon the velocity component in-line with the instantaneous jet-axis ( $U \cos(\gamma)$  or  $W \cos(\gamma)$ ). In contrast,  $\beta$  is the coefficient of forced entrainment which defines the proportion of the laterally impinging flow ( $U \sin(\gamma)$  or

$W\sin(\gamma)$  which is entrained.

Having identified an appropriate set of initial conditions, and made an assumption regarding the radial distribution of the velocity, density, and temperature, the conservation equations may be integrated to yield a Lagrangian solution for one fluid element released at a given phase of the wave cycle. If these calculations are repeated for a succession of fluid elements released at small increments of the phase angle, the resulting data may be time-averaged in the spatial domain to give a solution which is consistent with the laboratory measurements outlined above.

If the Lagrangian solution is based upon the entrainment coefficients appropriate to discharges in a quiescent ambient (ie.  $\alpha=0.052$ ,  $\beta=0$ ) a comparison with the existing integral solutions highlights the importance of the wave-induced displacement of the jet-axis. Calculations of this type suggest that there is significant wave-induced mixing. However, the reduction in the time-averaged velocities and/or concentrations does not in this case represent a "real" mixing process, but merely reflects the fact that under certain wave conditions the "pollutant" discharge only occupies some spatial locations for a small fraction of the wave cycle. Nevertheless, these results are important since they provide a qualitative explanation for two important features of the flow field which have been misinterpreted by previous researchers.

**(a) The occurrence of non-Gaussian distributions.**

Previous studies by Sharp (1986) and Chyan and Hwung (1994) have commented on the occurrence of "flat-topped" and, in particular, "bi-peaked" velocity and concentration profiles. These distributions have also been noted in the present study as indicated by the temperature data (Case 2) presented on figure 6. However, previous researchers have sought to explain this effect via an additional wave-induced mixing mechanism (referred to as an "enclosing mechanism") which involves the "entrapment" of ambient fluid within the interior of the jet. In contrast, the present calculations suggest that these non-Gaussian distributions may be directly explained by the lateral displacement of the jet and the time-averaged analysis of the data.

Figure 6. Radial variation in temperature data.

For example, if the length scale ( $l$ ) of the wave-induced displacement is large in comparison to the width ( $b$ ), the characteristics of the wave motion are such that the "residence-time" of the jet at any one spatial location increases with distance from the time-averaged centre-line. This may be demonstrated by considering the displacement of a Gaussian distribution at equal intervals throughout a wave cycle (Case 2 on figure 7a). This indicates that since the wave-induced horizontal velocity reduces to zero (as part of the cyclic reversal) at the extremities of the lateral displacement, the jet spends a larger proportion of one wave period at these locations. This, combined with the method of time-averaging in a fixed spatial domain (or, indeed, data collection from a probe fixed in space), produces a bi-peaked velocity and concentration profile (figure 7b). Furthermore, if the ratio of  $l/b$  is varied, then other non-Gaussian profiles such as the flat-topped velocity distributions shown on figure 7c may be explained.

Figure 7a. Lateral displacement of a Gaussian distribution.

(b)  $l > b$ .

(c)  $l > b$ .

Figures 7b-7c. Time-averaged radial distributions.

**(b) The structure of the centre-line decay.**

If the time-averaged velocity and concentration data is measured along the mean jet-axis a decay curve similar to that indicated by the data points in figure 8 (Case 2) results. Once again, this pattern has been observed by previous researchers including Chyan et al (1991) and Chyan and Hwang (1994). Indeed, measurements of this type have been used to classify a three stage decay in which (with increasing distance from the nozzle) the so-called "deflection region" is characterised by a rapid dilution; the "transition region" by a steady or small rise; and the "developed region" by a gradual decay. Unfortunately, the nature of the mixing mechanisms within these layers remains unclear. In particular, no previous explanation has been offered for the increase in both the axial velocity and the pollutant concentrations with increasing distance from the nozzle (ie. within the "transition region").

Figure 8. Decay of centre-line velocity (Case 2).

However, it is difficult to envisage how the dilution of the jet could in some way reduce (ie. for the fluid to effectively become un-mixed). As a result, a more probable explanation lies in a reduction in the "apparent" dilution. In other words, at some height above the nozzle, the wave-induced displacement of the jet-axis is reduced. The Lagrangian solution outlined above predicts exactly this effect. Figure 9 describes the trajectory of successive fluid elements released at equal intervals throughout a wave period. In this case, it is clear that the maximum lateral displacement of the fluid elements, and hence the maximum "apparent" dilution, occurs at a height of 12cm above the nozzle. Beyond this point the displacement first reduces and then increases. The present calculations suggest that this intermediate stage will produce an increase in both the predicted time-averaged velocity and concentration. Indeed, the solid curve indicated on figure 8 corresponds to the present Lagrangian solution. This appears to be in good qualitative agreement with the experimental data. In particular, it provides a convincing explanation for the multi-stage structure of the centre-line decay.

Figure 9. Trajectory of fluid elements (Case 2).

Unfortunately, good quantitative comparisons with the experimental data are, as yet, difficult to achieve because of the uncertainty in the entrainment coefficients ( $\alpha$  and  $\beta$ ). For example, the Lagrangian solution presented on figure 8 was based upon a three-fold increase in the coefficient of radial entrainment ( $\alpha=0.156$ ). This suggests that in addition to the so-called "apparent" mixing (associated with the displacement of the fluid elements), the wave motion also produces a "real" increase in the dilution of the discharged pollutant. This point is further emphasised in figures 10a-10b. Figure 10a describes the mean centre-line velocity (Case 1), and compares the data with a number of potential solutions. The uppermost curve (indicated by a dashed line) represents an integral solution based upon the standard entrainment coefficients ( $\alpha=0.052$  and  $\beta=0$ ); while the second curve corresponds to a Lagrangian solution in which the forced entrainment is maximised ( $\beta=1.0$ ), but the coefficient of radial entrainment remains unchanged ( $\alpha=0.052$ ). The difference between these curves indicates the cumulative effect of the forced entrainment and "apparent" mixing. However, neither curve provides a good description of the experimental data. Indeed, a sensitivity study conducted by Koole and Swan (1994) showed that the best fit to the measured data was achieved by altering the initial conditions to shorten the "zone of flow establishment", and increasing the coefficient of radial entrainment to  $\alpha=0.156$ . This solution is presented on figure 10b. However, the present study (including the data presented on figure 8) suggests that these values ( $\alpha=0.156$  and  $\beta=1.0$ ) are not universally applicable. Indeed, the entrainment coefficients appear to be critically dependent upon the flow conditions at the discharge orifice. In particular, the relative balance between the momentum flux of the jet and that of the wave-induced motion at the discharge orifice appears to be very important.

Figure 10a-10b. Non-dimensional centre-line velocity (Case 1).

## 5. Concluding remarks.

The present paper has presented the results of a two-part experimental study in which a two-dimensional non-buoyant jet (orientated in a horizontal direction), and a three-dimensional buoyant jet (orientated in a vertical direction) were discharged beneath a progressive regular wave train. In both cases the mean flow characteristics (including the temperature distribution in Case 2) were compared with an identical discharge in a quiescent ambient. These comparisons confirm that the oscillating wave kinematics have a significant effect upon the near-field mixing and dilution. In particular, the experimental data suggests that a region of intense fluid mixing arises immediately downstream of the discharge orifice, and that this results in a significant shortening of the "zone of flow establishment". This occurrence cannot be predicted by the existing integral solutions which form the basis of present near-field design

calculations.

In contrast, a Lagrangian solution similar to that proposed by Chin (1988) provides a good qualitative description of the experimental data. In particular, it highlights the importance of the "apparent" mixing associated with the wave-induced displacement of the instantaneous jet-axis, and provides a plausible explanation for the non-Gaussian distributions of both the axial velocity and temperature. Indeed, it also explains the non-exponential decay of the mean centre-line characteristics. In particular, the apparent increase in both the velocity and concentration observed by previous authors (notable Chyan and Hwung, 1994) may be explained by the lateral displacement of the jet, and the time-averaged analysis of the laboratory data. Unfortunately, quantitative comparisons between the laboratory data and the Lagrangian solution are, as yet, difficult to achieve because of the uncertainty in the entrainment coefficients ( $\alpha$  and  $\beta$ ). However, the measurements suggest that in addition to the "apparent" mixing the wave motion also produces a significant increase in the rate at which ambient fluid is entrained into the jet. In the two-dimensional case a three-fold increase in the radial entrainment coefficient was recorded. However, comparisons with the three-dimensional data suggest that this increase is insufficient to predict the measured dilution. Indeed, it seems very unlikely that one universal entrainment coefficient will be applicable to all cases of wave-induced mixing.

Finally, although the present paper has only considered wave effects within the near-field region, one should not lose sight of the fact that these solutions provide the "initial" conditions for the random walk formulations used to calculate the dispersion of pollution in the far-field. As a result, the wave-induced mixing identified in the present paper may potentially have a significant effect upon the concentration contours predicted in the far-field.

## CHAPTER 222

### Model of Bivalve On/offshore Movement by Waves

Hisami Kuwahara<sup>1</sup>

Junya Higano<sup>2</sup>

#### Abstract

This study aimed to develop a numerical method of calculating bivalve movement by waves, and to consider the validity of this model with comparison between the calculated distribution of bivalves and real sampled data.

The distribution of bivalves calculated by this numerical method coincided well with the real sampled data. This numerical method can predict the difference of distribution according to shell length, specific gravity of bivalve, shape of bivalves and so on. Thus, this method will be able to explain the mechanism of zonation of bivalves.

#### Introduction

It has been generally thought that the fishing productivity is low for sandy beach facing the open sea. However, only a few studies about the fishing productivity of sandy beaches have been performed in Japan because of severe sea conditions such as the surf zone. Therefore, almost no technology exists to develop the sandy beaches as fishing grounds.

Many bivalves live in the dissipative exposed sandy beach. These include species commercially important as fishery resources, for example, *Meretrix lamarckii*, *Gomphina melanaegis*, *Pseudocardium sachalinensis* and so on. We believe that the movement of bivalves by waves is closely related to the formation of grounds for their fishing. Therefore, it is very important to study the movement of bivalves for the development of fishing grounds.

On the other hand, recently, the development of

waterfronts has attracted our attention in Japan and many kinds of artificial facilities have been constructed. Those facilities change the physical environment around them, such as wave velocity, wave direction and so on. It means that bivalves incur risks of being moved to other places where the environment is undesirable for them. We need to predict how such facilities will affect the movement of bivalves, if we are afraid of destruction of the coastal ecosystem.

The study on the movement of bivalves by waves is important not only for the improvement of fishing ground but also for environmental conservation of the sandy coastal zone.

Since 1986, we have studied the relationship between the beach profile and the distribution of bivalves in the surf zone utilizing the pier of the Hasaki Oceanographic Research Facility (HORF) of the Port and Harbor Research Institute. From numerous investigations, we found the following:

1. Passive movement by waves is more important for the distribution of bivalves than their own motility.
2. The distribution of bivalves is related to physical conditions, such as waves, the beach profile, the bivalve and so on.

Therefore, it is considered possible to analyze the mechanism of bivalve movement numerically, based on civil engineering methods.

From these points of view, this paper proposes a numerical method that predicts the movement of bivalves by waves. The wave field is calculated with a time-dependent mild slope equation. The bivalve model is expressed by specific gravity, shell length, coefficient of mass force and drag force and so on. The moving distance is calculated for bivalves at any place and time. After that, we consider the validity of the numerical method with comparison between the calculated distribution of model bivalves and the real sampled data at HORF. The field survey of distribution of bivalves has been carried out by both the National Research Institute of Fishery Engineering and the Port and Harbor Research Institute.

### Numerical Method

This numerical method consists of three calculation steps as follows:

- 1) of the wave field.
- 2) of the distance a bivalve is moved by one wave.
- 3) of the distance a bivalve is moved by cyclic waves.

Through these steps, we can predict the moving distance is calculated for bivalves at any place and time.

### Wave Field

We calculated the wave field in the on/offshore including the surf zone at an optional beach profile with the time-dependent mild slope equations as follows (Watanabe and Maruyama, 1984).

$$\frac{\partial Q_x}{\partial t} + c^2 \frac{\partial \zeta}{\partial x} + f_b Q_x = 0 \quad (1)$$

$$\frac{\partial \zeta}{\partial t} + \frac{1}{n} \frac{\partial (n Q_x)}{\partial x} = 0 \quad (2)$$

where  $Q_x$  denotes  $\int u dz$  ( $u$ : horizontal component of wave orbital wave,  $z$ : vertical coordinate),  $\zeta$ : water surface elevation,  $c$ : wave celerity,  $n$ :  $1/2(1+2kh/\sinh 2kh)$ ,  $k$ : wave number,  $h$ : water depth,  $f_b$ : damping coefficient by wave breaking,  $x$ : horizontal coordinate,  $t$ : time.

The determination of wave breaking point depends on the ratio of orbital velocity and celerity of the wave (Isobe, 1986).

The wave orbital velocity on the seabed is shown as follows. This equation is given by the small amplitude theory.

$$u_{bv} = k Q_x \sin(\sigma t + \epsilon_x) / \sinh(kh) \quad (3)$$

where  $\epsilon_x$  denotes phase difference,  $\sigma$ : angular frequency ( $= 2\pi/T$ ,  $T$ : wave period).

In the surf zone, the flow in the offshore direction, the undertow, occurs when the breaking waves generate mass flux in the onshore direction. Eq.(4) denotes the undertow velocity calculated by Sato et al.(1987). It is assumed that the distribution of undertow is the largest value at the making point of bore and decreases linearly from this point to 10 times breaking water depth in the offshore direction. Eq.(5) shows the distance between the wave breaking point and the making point of bore (Okayasu et al., 1990). Eqs.(4) and (5) are experimentally obtained.

$$U_{br} = A \frac{H^2}{hT} \quad (4)$$

$$l_t = \left( \frac{1}{5 \tan \beta} + 4 \right) h_b \tag{5}$$

where A denotes experimental constant, H: wave height,  $h_b$ : breaking water depth,  $\beta$ : beach slope near breaking point. In this calculation step, we aim to calculate the wave and flow on seabed which acts on the bivalve.

Bivalve Movement by One Wave

Figure 1 shows the bivalve movement model. For bivalves with shell length D on the seabed with slope  $\beta$ , the bivalves move at velocity  $u_s$  due to the wave bottom velocity  $u_b$ . It is assumed that bivalves are passively moved by waves and move on the surface of the bottom by sliding. The components of forces acting on the bivalve are also shown in Figure 1.

- 1) the force caused by the pressure gradient of waves:  $mdu_b/dt$
- 2) the mass force caused by the relative movement between bivalve and fluid:  $C_M m (du_b/dt - du_s/dt)$
- 3) the drag force caused by the relative velocity:  $1/2 C_D \rho_w A (u_b - u_s) |u_b - u_s|$
- 4) the component of gravity parallel to the seabed surface:  $g(M-m) \sin \beta$
- 5) the frictional resistance force caused by sliding of the bivalve on the seabed:  $-\mu_f g(M-m) \cos \beta u_s / |u_s|$ .

where M denotes mass of bivalve ( $1/6 \pi \rho_s D^3$ ,  $\rho_s$ : specific gravity of bivalve), m: mass of water ( $1/6 \pi \rho_w D^3$ ,  $\rho_w$ : specific gravity of water),  $C_M, C_D$ : coefficient of apparent mass force and drag force respectively, A: area of the bivalve that projects,  $\mu_f$ : the frictional resistance coefficient. However,  $\mu_f$  in this numerical method is

Figure 1. Bivalve Movement Model By Wave.

defined as the coefficient of the degree of movement, which includes the effect of burrowing, rough ripple and so on. Thus, we assumed that the bivalve was moved by the balance of these forces.

The resulting equations of motion of bivalve by wave are shown as follows. These equations are able to express Lagrangian analysis of bivalve movement, when the orbital velocity on the seabed is precisely given at the moved position of bivalve.

$$\frac{dX(t)}{dt} = u_s(t) \quad (6)$$

$$\begin{aligned} M \frac{du_s(t)}{dt} = & m \frac{du_b(X, t)}{dt} + C_d m \frac{d(u_s(t) - u_b(X, t))}{dt} \\ & + \frac{1}{2} C_D A \rho_w |u_b(X, t) - u_s(t)| (u_b(X, t) - u_s(t)) \\ & - (M - m) g \sin \beta - \mu_f g (M - m) \cos \beta \frac{u_s(t)}{|u_s(t)|} \end{aligned} \quad (7)$$

The bivalve starts to move when the total of the drag force and the mass force exceeds the total of the gravity and the frictional resistance force. The bivalve stops when the velocity of the bivalve becomes zero. In addition, the frictional resistance coefficient used is the static one when the bivalve stops and is the dynamic one when the bivalve moves. These equations are calculated by the Runge-Kutter-Gill method. In this calculation step, the distance the bivalve is moved by one wave is calculated at each position of the whole beach.

#### Bivalve Movement by Cyclic Waves

The number of cyclic waves and the position and the number of bivalve individuals are given. The bivalve movement by the cyclic waves is able to be calculated by piling the moving distance by one wave which is given at the previous calculation step.

#### Method of Field Survey & Conditions of Numerical Calculation

The investigation was carried out at the HORF research pier. This pier is on the Hasaki coast in Ibaragi Prefecture, Japan (Figure 2). The total HORF length is 427m and the deck width is 2.5m. This pier juts out into the surf zone. The distribution of bivalves has been investigated at intervals of 10m along HORF once a month since 1986 by means of the Smith-McIntyre grab (22×22cm). This investigation

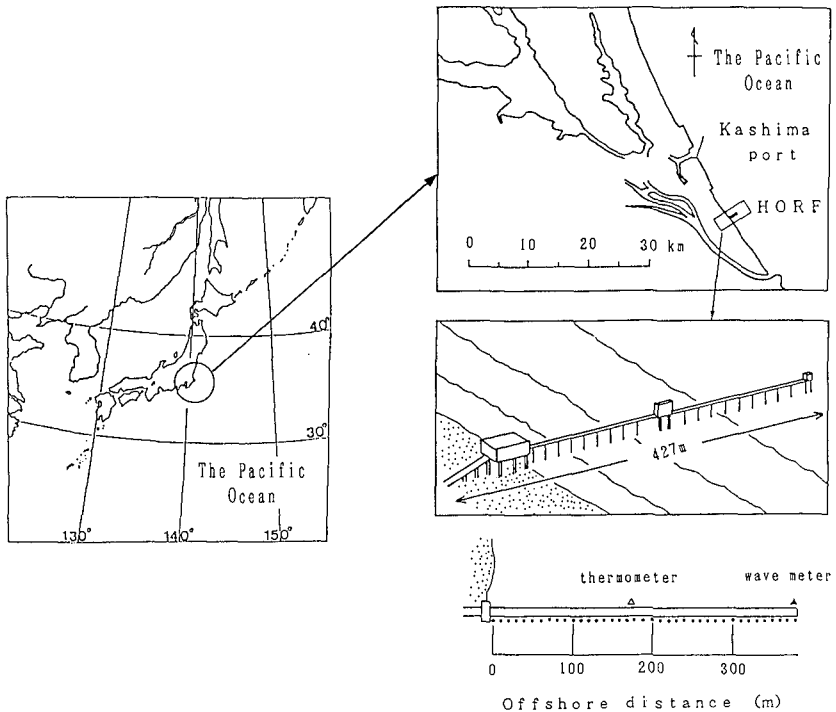

Figure 2. Study Site of Field Survey. The coast consists of exposed sandy shores facing the Pacific Ocean. Location of Hasaki Oceanographical Research Facility (HORF), water temperature meter, wave gages and sampling stations of bottom sediments(\*) are shown.

method and results were described in detail by Higano et al. (1993a).

The following conditions were used in the numerical calculation. The beach profile used the field data at HORF and the tidal level used the value of the observation at 15:00, June 23, 1987. The physical characteristics of waves and bivalves were used the following values.

$H_0=1.5\text{m}$ ,  $T=7.0\text{sec}$

$D=20\text{mm}$ ,  $\rho_s=1.8$ ,  $C_M=0.5$ ,  $C_D=0.5$ ,  $\mu_{fs}=1.0$ ,  $\mu_{fd}=0.5$

The specific gravities  $\rho_s$  of *Macra crossei*, *M. lamarckii* and *G. melanaegis* are 1.3, 1.6, and 1.8, respectively (Higano et al., 1993b).

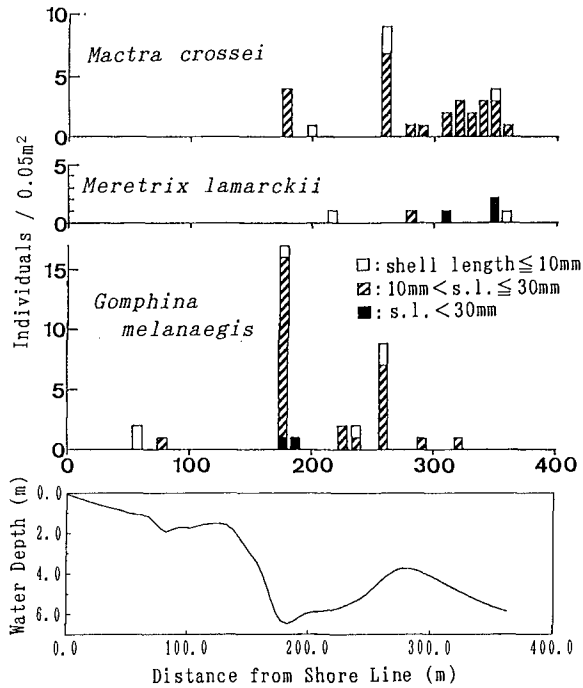

Figure 3. Beach Profile and Distribution Density of Bivalves (columns) at HORF on June 23, 1987.

## Results and Discussion

### Results of Field Survey (June 23, 1987)

Figure 3 shows the distributions of three bivalve species and the beach profile at HORF, on June 23, 1987. The beach profile indicated the trough largely scoured by a storm a few days previously. The onshore side of the trough became remarkably steep. *G. melanaeigis* were accumulated extremely densely at 180m from the shoreline. *M. lamarckii* tended to distribute on the offshore side of the bar. *M. crossei* distributed mainly on the zone farthest offshore.

Photograph 1 shows the bivalves sampled in this field: *G. melanaeigis*, *M. lamarckii* and *M. crossei*, in order from left. These physical characteristics (for example, specific gravity, shape, roughness of bivalve surface and so on) are varied. It is considered that the physical differences of bivalves form the zonation of bivalves as shown in Figure 3.

Photo 1. Bivalves Sampled at HORF. ( Left: G. melanaegis, Center: M. lamarckii, right: M. crosseii )

#### Results of Numerical Calculation

Figure 4 shows the results of calculation of the wave field. The offshore wave is assumed to have  $H_0$  of 1.5m and  $T$  of 7.0sec.

Figures 4 (a), (b) and (c) show the distributions of the wave height, the wave orbital velocity on the seabed and the undertow velocity, respectively. These horizontal axes show the distance from the shoreline.

The wave breaking occurred at 157m from the shoreline. The wave height, wave orbital velocity and undertow velocity were maximum near the breaking point and were damped drastically at the onshore side of the trough.

We exerted the wave orbital velocity and undertow velocity on the model bivalve and calculated the bivalve movement. Figure 5 shows the bivalve's movement by waves. The model bivalve assumed the physical characteristics of G. melanaegis. Figure 5 (a) shows the distribution of the distance moved by one wave. The vertical axis shows the moving distances of bivalves, which are taken to be positive in the onshore direction and negative in the offshore direction. Figure 5 (b) shows the movement of bivalves by the cyclic wave. The vertical axis is the passage of time. Each model bivalve was placed on the seabed at intervals of 10m along the on/offshore line in the initial condition.

Although bivalves on the offshore side of the bar and on the onshore side from 100m showed almost no movement, they moved in the onshore direction from the top of the bar to the bottom of trough and in the offshore direction on the

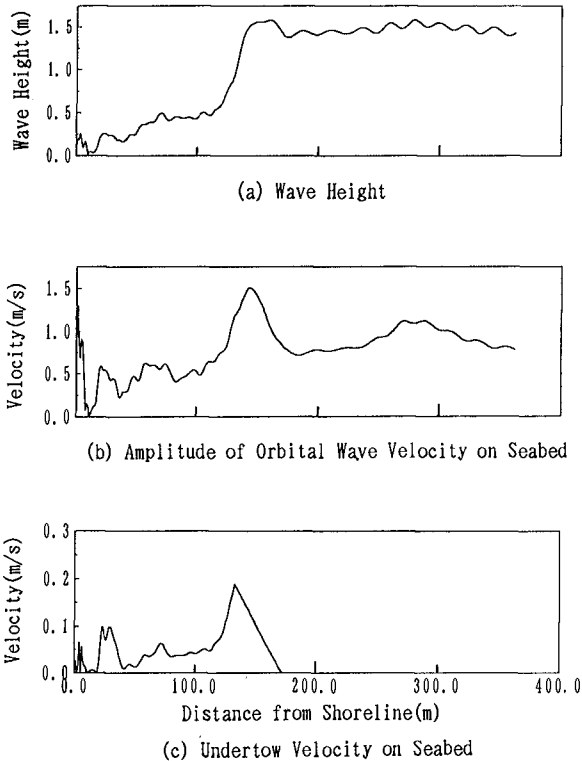

Figure 4. Results of calculation of Wave Field. ( The beach profile is shown in Figure 3. The offshore wave are  $H_0=1.5\text{m}$  and  $T=7.0\text{sec}$ . )

onshore side of the trough. Bivalves were extremely densely accumulated at 180m by cyclic waves, which is the bottom of trough. This tendency was the same as the field survey in Figure 3.

After that, we varied the physical characteristics of the waves and the bivalves and tried to calculate model bivalve distributions. Figure 6 shows the results of calculated distribution of the model bivalves. Figures 6 (a), (b) and (c) show the effect of wave characteristics, shell length and specific gravity of the bivalve, respectively. Individual bivalves were counted in each section at an interval of 10m. The distributions after 10,000sec were shown.

In Figure 6 (a), although bivalves hardly moved when the wave height was 0.5m and the wave period was 5.0sec, they

Figure 5. Bivalves Movement by Waves. The model bivalves assumed the *G. melanaegis*. (  $D=20\text{mm}$ ,  $\rho_s=1.8$ ,  $C_M=0.5$ ,  $C_D=0.5$ ,  $\mu_{fs}=1.0$ ,  $\mu_{fd}=0.5$  )

accumulated in the trough when the wave height was 1.5m and the period was 7.0sec and on the top of the bar when the wave height was 2.5m and the period was 9.0sec. In Figure 6 (b), the model bivalves with shell length 5mm accumulated at 150m and 170m. Those of shell length 20mm accumulated at 180m. However, those of shell length 40mm hardly moved. In Figure 6 (c), the distribution of model bivalves of specific gravity 1.6 had the same tendency as those of specific gravity 1.8. These model bivalves accumulated at 180m. The model bivalves of specific gravity 1.3 accumulated at 150m and 170m. These calculated results coincide well with the real sampled data for *G. melanaegis* of 10 to 30mm in diameter accumulated at the bottom of trough. But this calculated result cannot explain *M. crossei* in the offshore side of the bar. The reason why the results don't coincide may be that the initial distribution of bivalve at the real beach was different from that of the numerical study.

Figure 6. Relation between Distributions of Model Bivalve and Physical Characteristics of Waves and Bivalves.

### Conclusion

In this study, we developed the numerical method of calculating bivalve movement by waves, and we considered the validity of this model with comparison between the calculated distribution of bivalves and the real sampled

data at HORF.

As a result, the following main findings were obtained from this study:

- 1) This numerical method can predict the difference of distribution given the shell length, the specific gravity and so on. Thus, this method will be able to explain the mechanism of zonation of bivalves.
- 2) This numerical method explains the tendency which the bivalves accumulate in the trough. The result coincides well with the real accumulation of G. melanaegis.
- 3) But, this numerical method cannot explain the accumulation of M. crosseii on the offshore side of the bar.
- 4) The bivalves throughout the area start to move and accumulate remarkably when the waves become severe.

As mentioned above, we found that this numerical method was useful in predicting the bivalves' movement by wave. We are conducting experimental study with the 2-dimensional wave tank. We are trying to give this numerical method more precision. This numerical prediction method will be able easily to be applied to bivalves' horizontal movement by waves. With this numerical method, we hope to contribute to the development of fishing grounds and the conservation of coastal zones.

## CHAPTER 223

### INITIAL GAP IN BREAKOUT OF HALF-BURIED SUBMARINE PIPE DUE TO WAVE ACTION

Adrian W.K. Law<sup>1</sup> and Mostafa A. Foda<sup>2</sup>

#### ABSTRACT

An analytical formulation is presented for the analysis of the breakout of a half-buried submarine pipe due to wave action. The formulation accounts for the contact between the pipe and the soil due to the horizontal hydrodynamic force. An asymmetric gap geometry is described that incorporates a second order expansion in the gap opening due to the pipe rise. Results with this formulation demonstrate the existence of an initial gap of the order 1 mm in the breakout experiments. With this initial gap, the gap flux dominated the influx of water into the gap from the beginning of the breakout process.

#### 1.0 INTRODUCTION

Breakout of a partially buried pipe under severe wave action is one of the possible mechanisms for the pipe to detach from the sea bed (Foda, 1985). The configuration is schematically sketched in Figure 1. Experiments were performed by the authors to investigate the breakout of a half-buried pipe in the laboratory, and the results were previously reported in Foda et al. (1990).

<sup>2</sup> Hydraulic and Coastal Engineering Division, Department of Civil Engineering, University of California at Berkeley, Berkeley, CA 94720, USA

The bulk of the Foda et al. (1990)'s paper dealt with the analysis of the pressure and displacement measurements from the breakout tests. An uniform lift analytical model using the poro-rigid bed assumption was also presented in that paper. This uniform lift model is based on the consideration of the action of the net lift force on the pipe. This net lift force induces an uniform liftoff of the pipe in the vertical direction, thus creating a symmetric gap geometry as well as symmetric gap suction pressures about the vertical axis of the semi-circular trench. However, further considerations of the effect of the oscillatory horizontal hydrodynamic force reveal that this uniform liftoff conceptualization may not be fully representative of the physical breakout process. These considerations are discussed in the followings.

Through analysis of the measurements on the hydrodynamic forces and the resultant forces by the gap suction pressures, we demonstrated in Foda et al. (1990) that the pipe was always in contact with the soil. In essence the pipe was bouncing back and forth against the sides of the soil's semi-circular interface. In doing so, the gap distribution would become asymmetric with respect to the vertical axis. There would be some finite opening on one end of the semi-circular trench whereas on the other end the gap would be closed by the contact between the pipe and the soil. This asymmetric gap distribution, however, is not reflected in the symmetric gap assumption in the uniform lift model.

The asymmetric gap distribution also poses differences in the pressure boundary conditions on both ends. On the opening edge the gap pressure is subjected to the positive pressure buildup due to the stagnation point in front of the pipe, whereas on the other side the contact between the pipe and the soil isolates the suction pressures inside the gap to the ambient pressure above. The situation in terms of the pressure boundary conditions is thus closer to the tilted lift case than the uniform lift case in Mei et al. (1985). With the differences in the gap pressure distribution about the vertical axis, the resulting horizontal force will be reinforcing the horizontal hydrodynamic force in the first harmonic. This is indeed what was observed in our analysis of the laboratory measurements on the horizontal force balance. The above discussion demonstrates that an asymmetric gap model can better represent the physical situation than the uniform lift model.

With these considerations, we set out to develop an asymmetric gap formulation that incorporates the effect of the oscillatory horizontal hydrodynamic force. Subsequently, based on this formulation, we will address the existence of some initial gap opening in the beginning of the breakout process. However a brief summary of the laboratory experiments is first presented in the next section.

## **2.0 EXPERIMENTAL SETUP**

The experimental setup consisted of a 0.22 m diameter PVC pipe half-buried in a sand basin inside a wave flume under 0.61 m water depth. The sand was a well-sorted medium sand with  $d_{50}$  of 0.32 mm and with permeability approximately equal to  $0.85 \times 10^{-11}$  m. The half-buried pipe was subjected to monochromatic waves of approximately 3 second wave period and 0.15 m wave height until breakout from the sea bed occurred.

Submerged weight of the pipe was used as a control parameter to generate different net lift forces on the pipe thus producing different breakout times. The vertical displacement of the pipe was monitored using a hermetically sealed sensor installed inside the pipe. Pressures around the pipe were also recorded. Additional descriptions of the experimental setup can be found in Foda et al. (1990).

A typical vertical movement history of the half-buried pipe in the experiments is shown in Figure 2. As can be observed in the figure, after the half-buried pipe was exposed to the monochromatic waves, the pipe started to rise with a steady but very slow rate (of the order of 2.5 mm/min in the experiments). No significant soil erosion around the pipe was observed. Minor oscillatory motion of the pipe was also recorded superimposing on the net vertical movement. The net rising rate gradually increased near the breakout time. Subsequently, at the breakout time a sudden and rapid release of the pipe from the sea bed occurred.

## **3.0 PORO-RIGID MODEL WITH ASYMMETRICAL GAP DISTRIBUTION**

In this section, an analytical formulation is presented for the analysis of the breakout of a half-buried pipe from sea bed due to wave action. First, the movement of the pipe during one wave cycle is examined as shown in Figure 3. The pipe oscillates horizontally with respect to the underlying trench due to the wave-induced horizontal force. This horizontal oscillatory motion of the pipe produces a mirror image setting between the two halves of a wave period. With this mirror image and in a quasi-steady manner, it is postulated that the situation can be analyzed as if the pipe is subjected to a steady lift force  $F_L$  and an unidirectional steady horizontal force  $F_h$  (Figure 4) of the following magnitudes based on the Morrison equation:

$$\text{horizontal} \quad F_h = \frac{2}{T} \int_0^{T/2} \rho \left[ C_M \frac{\pi D^2}{4} \frac{\partial u}{\partial t} + \frac{1}{2} C_D D u |u| \right] dt \quad (1a)$$

vertical 
$$F_L = \frac{1}{T} \int_0^T \frac{1}{2} \rho C_L D u^2 dt \quad (1b)$$

where  $T$  is the wave period,  $\rho$  the water density,  $D$  the pipe diameter,  $u$  the wave-induced horizontal velocity at the mud line, and  $C_L$ ,  $C_M$  and  $C_D$  the lift, added mass and drag coefficients for a half-buried pipe respectively. In our experiments the value of  $C_L$  was measured to be 2.55.

At this point, to facilitate further analysis we introduce a conformal mapping to transform the geometry of the seabed to a full half plane without indentation:

$$\zeta = \frac{1}{2} - \frac{1}{2D} \left( z + \frac{D^2}{4z} \right) \quad (2)$$

where  $z = (x,y)$  = the physical plane with coordinate orientation as shown in Figure 4;  $\zeta = (\xi,\eta)$  = the mapped domain. From a geometrical standpoint, the asymmetric gap induces by the rise of the pipe while maintaining contact with the soil can be approximated as:

$$\Delta(\theta, t) = \Delta_o(t) \left( \sin \theta - \frac{\delta}{2} \cos \theta (1 - \cos \theta) \right); \quad \delta = \frac{\Delta_o(t)}{R} \quad (3)$$

where  $\Delta$  is the gap thickness,  $\Delta_o$  the midgap thickness, and  $R$  the pipe radius. The gap distribution is shown in Figure 5. The asymmetry of the gap is thus only in the second order, or  $O(\delta^2)$ . However this second order asymmetry properly accounts for the expansion in the gap opening due to the pipe rise, and thus is necessary for computing the growth of the gap flux which is the supply of ambient water through the gap opening at  $\xi = 1$ . In the mapped plane, this gap distribution becomes:

$$\Delta(\xi, t) = \Delta_o(t) f(\xi); \quad f(\xi) = \left( 2\sqrt{\xi - \xi^2} + \delta(t)\xi(2\xi - 1) \right) \quad (4)$$

We will now follow the poro-rigid bed approach in Mei et al. (1985) to formulate the governing equation for the flow inside the gap between the pipe and the soil. In this approach, the soil is assumed to be poro-rigid and Darcy's law is assumed for the pore water flow. Lubrication theory is used to analyze the flow along the gap between the pipe and the soil. Following the analysis of Mei et al. (1985) and with an further assumption of a no-slip boundary condition at the surface of the porous bed, we obtain the following water budget equation for the expanding gap:

$$\xi D \frac{d\Delta_o}{dt} = \frac{k}{\mu\pi} \int_0^1 \frac{p}{\eta - \xi} d\xi + \frac{\partial p}{\partial \xi} \frac{\Delta^3 \sqrt{\xi - \xi^2}}{6\mu D} \quad (5)$$

where  $\mu$  is the viscosity,  $k$  the intrinsic permeability of the porous bed, and  $p$  the dynamic pressure in the gap. Taking  $\xi = 1$ , the left-hand side of Eq. 5 then represents the first order, or  $O(\delta)$ , expansion rate of the gap volume. The first term on the right-hand side gives the contribution to such expansion from the pumping of pore water into the gap, which is given in terms of a Cauchy principle-value integral. The last term of Eq. 5 gives the gap flux. It should be noted that the gap flux term will not vanish at  $\xi = 1$  despite its appearance. This is because both  $\Delta(\xi = 1)$  and  $\left. \frac{\partial p}{\partial \xi} \sqrt{\xi - \xi}^2 \right|_{\xi=1}$  have finite non-zero values at this edge of the semi-circular trench where the ambient water is drawn into the gap.

Next, the balance of forces before the breakout is considered. With the asymmetric gap distribution, the resultant force from the gap suction pressures in the horizontal direction will be reinforcing the horizontal hydrodynamic force. Together they will then be resisted by a reaction force from the soil. In the vertical direction, the balance of forces yields:

$$F + D \int_0^1 p \, d\xi = 0 \quad (6)$$

where  $F$  is the net lift force = time-averaged hydrodynamic lift  $F_L$  minus the pipe submerged weight  $F_s$ . The horizontal force balance in the first harmonic and the vertical force balance in the zero harmonic were both observed in the experimental results.

At this point, we need to address the pressure boundary condition at the gap opening  $\xi = 1$ . Due to Bernoulli's effect, there will be positive pressure buildup with the stagnation point in front of the pipe. This positive pressure can be calculated in a quasi-steady manner as:

$$p_o = \frac{1}{T} \int_0^T \frac{1}{2} \rho u^2 dt = \quad (7)$$

The formulation of the asymmetric gap model is now completed. We will further convert the governing equations into nondimensional form by introducing the following variables:

$$P = \frac{pD}{F}; \quad \sigma = (Dk)^{-1/3} \Delta_o; \quad \tau = \frac{Fk^{2/3}}{\mu D^{7/3}} t \quad (8)$$

The two governing equations, Eqs. 5 and 6, become:

$$\xi \frac{d\sigma}{d\tau} = \frac{1}{\pi} \int_0^1 \frac{P}{\eta - \xi} d\xi + \sigma^3 \frac{\partial P}{\partial \xi} \frac{\sqrt{\xi - \xi^2}}{6} f^3(\xi) \quad (9)$$

$$\int_0^1 P d\xi = -1 \quad (10)$$

Eqs. 9 and 10 permit numerical computation in a manner as suggested in Mei et al. (1985). However it should be emphasized that closely spaced numerical grid will be required near  $\xi=1$ . This is to avoid introducing arbitrary large opening for the computation of the gap flux in the numerical algorithm. For example, following the mid-point computation approach in Mei et al. (1985) with  $N+1$  nodes (resolution  $\varepsilon = N^{-1}$ ), the volume of the gap flux in Eq. 9 will be computed as  $\frac{P_{at\xi=1} - P_{at\xi=1-\varepsilon}}{6\sqrt{\varepsilon}/2} \sigma^3 (\sqrt{2\varepsilon} + \delta)^3$ . Since this flux term should be proportional to  $\sigma^3 \delta^3$ , it is thus required that  $\varepsilon < \frac{\delta^2}{2}$ . Typically  $\delta \sim O(10^{-2})$  when the gap flux becomes significant, and thus the requirement would then be  $\varepsilon \sim O(10^{-4})$  or  $N \sim O(10^4)$ . This is a stringent requirement since the computation will then involve finding the inverse of a large  $N \times N$  matrix, a task that is both time-consuming and error-prone.

Note that if indeed the finite gap opening at the edge of the trench is due only to the second order expansion due to the pipe rise, it would be more appropriate to use another time scale,  $T_b = \frac{\mu D^{8/3}}{Fk^{5/6}}$ , based on the balance of terms in Eq. 5 at  $\xi = 1$  of  $\frac{D^2 \delta}{T_b} \sim \frac{kF}{\mu D} \sim \frac{FD \delta^6}{\mu}$ . However whether the gap opening is realistically second order in nature will be discussed in the following section on the existence of an initial gap.

#### **4.0 INITIAL GAP**

As shown in Figure 2, the pipe typically rose with a net constant rate during the initial stage in the breakout process. These initial rates of rise,  $R \frac{d\delta}{dt}$ , were of the order of 2.5 mm/min (0.04 mm/s) in the laboratory experiments. The gap volume expansion due to this vertical rise of the pipe should be balanced by the combined pore water and gap fluxes. In the following section we will discuss the implication of these measured rates on the initial gap geometry base on the derived governing equations.

Numerical computation using Eqs. 9 and 10 without the gap flux term shows that the initial rate of rise,  $\frac{d\sigma}{d\tau}$ , due to the pore water flux alone is approximately 0.85. This is slower than the corresponding rate with the uniform lift model which can be determined analytically to be equal to  $8/\pi$  (see Mei et al. (1985)) but in the same order of magnitude.

With  $D = 0.22\text{m}$  and  $k = 0.85 \times 10^{-11} \text{ m}^2$  in our experiments, the non-dimensional length scale will then be  $(Dk)^{1/3} = 0.12 \text{ mm}$ . The breakout time scale,  $T_b$ , was of the order of  $O(10^2)$  in the breakout tests. The measure rate of rise of approximately  $0.04 \text{ mm/s}$  thus represents a nondimensional rate of rise of around 30. This measured rate is an order of magnitude higher than the predicted rate supported by the pore water flux. Despite the fact that there were possible variations in some of the experimental parameters such as the soil permeability, the differences were judged to be too large to be explained by these variations. Clearly this points to the existence of an initial gap in the beginning of the breakout process. In addition, it also shows that in our experiments the pore water flux, though always important in relieving the negative pressures near the contact ( $\theta \cong 0$ ) where the gap width is always small, was insignificant in terms of expanding the gap volume and allowing the pipe to rise.

Physically, this initial gap can be due to the imperfect contact between the pipe and the soil. Another mechanism of generating this initial gap in the soil region around the two ends of the semi-circular trench would be through plastic deformations. In the first half of the wave cycle, one end of the soil trench will be compressed as the horizontal force and the resultant force from the gap pressures together push the pipe against the soil. This compression will subsequently be released in the second half of the wave cycle when the pipe moves to rest against the opposite side. It is possible that the soil skeleton in these areas is weakened by the periodic compression and relaxation, allowing plastic deformations to take place.

We will first use a scaling analysis to examine the magnitude of this initial gap. Let  $\bar{\Delta}$  be a characteristic length scale for the initial gap. Comparing the two terms in the RHS of Eq. 5 for  $\xi = 1$  suggests that the balance between the pore water and the gap fluxes will be of the order of  $O\left(\frac{kD}{\bar{\Delta}^3}\right)$ . This implies that  $\bar{\Delta}$  should be much larger than  $\sqrt[3]{kD}$ , or  $0.1 \text{ mm}$  in this case.

The initial gap geometry in reality can be very complicated, and will also depend to some extent on the processes how the pipe was half-buried. To get an general assessment on the order of magnitude of the initial gap in our experiments, we assume a simple constant gap geometry as follows:

$$\Delta = \Delta_i \quad \text{for} \quad 0 < \theta \leq \pi \quad (11)$$

where  $\Delta_i$  represents an initial constant gap. Ignoring the pore water flux term, Eq. 5 can be simplified in the physical plane to be:

$$R^2(1 - \cos \theta) \frac{d\delta}{dt} = \frac{\Delta_i^3}{12\mu R} \frac{\partial p}{\partial \theta} \quad (12)$$

Substituting the constant gap geometry into Eq. 12 and integrating yield:

$$p = p_o - \frac{12\mu R}{\Delta_i^3} \frac{d\delta}{dt} (\pi - \theta + \sin \theta) \quad (13)$$

Finally, substituting Eq. 13 into 6 in the physical plane, the initial rate of rise can then be estimated as:

$$R \frac{d\delta}{dt} = \frac{(F + 2p_o R)\Delta_i^3}{18\pi \mu R^3} \quad (14)$$

With  $R = 0.11$  m,  $\mu = 10^{-3}$  kg/ms,  $p_o \sim O\left(\frac{F}{R}\right)$  and  $F \sim O(10)$  in our experiments, the measured initial rate of rise of the order of 0.04 mm/s would represent an initial gap  $\Delta_i$  of the order of 1 mm in the beginning of the breakout process.

## 5.0 CONCLUSION

An asymmetric gap model is presented for the analysis of the breakout of a half-buried pipe from sea bed due to wave action. The model accounts for the contact between the pipe and the soil due to the horizontal hydrodynamic force. An asymmetric gap geometry is described that incorporates the second order expansion in the gap opening due to the pipe rise. Quasi-steady vertical force balance is assumed. The resultant horizontal force from the distribution of the gap pressures reinforces the horizontal hydrodynamic force in the first harmonic which is consistent with the experimental observations. Calculations with this asymmetric gap model demonstrate the existence of an initial gap of the order of 1 mm between the pipe and the soil in the breakout experiments. This initial gap is postulated to be due to imperfect contact between the pipe and the soil and possible plastic soil deformations due to periodic compression and relaxation of the soil skeleton around the pipe. With this initial gap, the gap flux is found to dominate the influx of water from the beginning of the breakout process. The pore water flux, though important in relieving the negative pressures near the

contact where the gap width is always small, was insignificant in terms of expanding the gap volume and allowing the pipe to rise. The role of the initial gap and the soil deformation around the pipe to the breakout process will be further examined in the future.

## CHAPTER 224

# ANALYTICAL SOLUTION FOR THE WAVE-INDUCED EXCESS PORE-PRESSURE IN A FINITE-THICKNESS SEABED LAYER

Waldemar MAGDA \*

### ABSTRACT

This paper presents the analytical solution to the wave-induced excess pore-pressure oscillations in permeable seabed sediments, derived for the case of limited thickness of the seabed layer. In order to show the utility of the analytical solution, a wide parameter study has been performed with a special emphasis to the relative compressibility of the two-phase (soil skeleton – pore-fluid) medium. The results of example computations are discussed with respect to the accuracy of the ‘finite-thickness’ analytical solution for the pore-pressure.

### INTRODUCTION

The excess pore-pressure oscillations in permeable seabed sediments, induced by regular surface waves, have been the subject of several investigations and theoretical considerations over the last 40 years.

For many purposes in soil mechanics, it is permissible to uncouple the soil and fluid parts of any analysis in order to treat them separately. However, it may also be desirable on occasion to analyse the true coupled performance of a composite continuum, in which the two phases interact. Examples of practical importance would involve external loads which vary in time, and structure-foundation interaction analyses where the generation of foundation pore-pressure is completely dependent upon the relative stiffness of the components of the system. That is, a stiff or inhomogeneous structure causes different pore-pressures from a flexible or homogeneous one.

In many practical problems appeared in the coastal engineering, there are many subsoil stratifications and hydro-engineering structures that can be treated as vertically two-dimensional. Assuming also that the seabed is loaded by harmonic waves characterized by long crests parallel to each other, then as a result the seabed is deformed under plain strain conditions. Under these conditions, the following two equations, describing elastic deformations, together with the 'storage' equation constitute the coupled problem and can be written as:

$$G \left( \frac{\partial^2 u_x}{\partial x^2} + \frac{\partial^2 u_x}{\partial z^2} \right) + \frac{G}{1-2\mu} \frac{\partial}{\partial x} \left( \frac{\partial u_x}{\partial x} + \frac{\partial u_z}{\partial z} \right) = \frac{\partial p}{\partial x} \quad (1a)$$

$$G \left( \frac{\partial^2 u_z}{\partial x^2} + \frac{\partial^2 u_z}{\partial z^2} \right) + \frac{G}{1-2\mu} \frac{\partial}{\partial z} \left( \frac{\partial u_x}{\partial x} + \frac{\partial u_z}{\partial z} \right) = \frac{\partial p}{\partial z} \quad (1b)$$

$$\frac{k_x}{k_z} \frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial z^2} - \frac{\gamma n \beta'}{k_z} \frac{\partial p}{\partial t} = \frac{\gamma}{k_z} \left( \frac{\partial u_x}{\partial x} + \frac{\partial u_z}{\partial z} \right) \quad (1c)$$

where:  $p$  is the wave-induced excess pore-pressure,  $u_x$  and  $u_z$  are the horizontal and vertical displacements of soil skeleton, respectively,  $G$  is the shear modulus of the soil skeleton,  $\mu$  is the Poisson's ratio,  $k_x$  and  $k_z$  are the coefficients of permeability of soil in horizontal and vertical direction, respectively,  $\gamma$  is the unit weight of the pore-fluid,  $\beta'$  is the compressibility of the pore-fluid,  $n$  is the porosity of soil,  $x$  and  $z$  are the horizontal and vertical coordinates of the Cartesian system, respectively.

The problem described in Eqs. (1a) to (1c) is very often called as a 'storage' problem because the third is based on the 'storage' equation given by Verruijt (1969), as the governing equation for flow of a compressible fluid in a homogeneous compressible porous medium.

The earlier simplified theoretical solutions give only approximated values for the pore-pressure response. Others, more advanced theories (*e.g.*: Madsen, 1978; Yamamoto *et al.*, 1978; Okusa, 1985) seem to be enough developed in order, at least, to describe the governing problem by introducing additional, meaningful parameters giving thereby a possibility of wide analyses of real soil-water conditions. All these three theories have the same physical background and they differ from each other in the applied method of deriving the particular solution. Okusa (1985), as a first one, discussed also the problem of phase-lag (time-shift) phenomenon existing in a gas-laden sediment for the wave-induced pore-pressure and stresses. The theoretical values calculated from the 'storage' theory lie far away from the 'potential' solution, originally presented by Putnam (1949) and based on the assumptions of incompressible pore-fluid and soil skeleton. These rigorous assumptions differ strongly from the realistic conditions of the soil and pore-fluid two-phase medium. The differences between the 'storage' solution and the 'consolidation' solution proposed by Moshagen & Tørum (1975) and assuming compressibility only for the pore-fluid, are not so drastic

but they might become meaningful especially when a relatively compressible soil (*e.g.*, loose sand) is concerned.

### 'FINITE-THICKNESS' ANALYTICAL SOLUTION

The solutions obtained from the 'potential' problem and 'consolidation' problem approximate roughly the pore-pressure response. Both of these solutions can be used in a feasibility study. More precise information on the pore-pressure attenuation and phase-lag distribution with depth can be obtained at the preliminary or detailed design level where the both components of two-phase system (*i.e.*, soil skeleton and pore-fluid) are considered to be compressible.

The appropriate analytical solutions for the pore-pressure response in case of a homogeneous, poro-elastic, semi-infinite seabed were derived by many authors (*e.g.*: Madsen, 1978; Yamamoto *et al.*, 1978; Okusa, 1985) and obtained in terms of the pore-pressure and effective stresses in seabed sediments. Analytical solutions of the 'potential' and 'consolidation' equation for the case of limited thickness of the seabed layer are also well known (*e.g.*, Moshagen & Tørum, 1975). Using the general solution presented by Madsen (1978), Magda (1989, 1992) derived a particular solution for the wave-induced excess pore-pressure under the assumption of a finite thickness of the seabed layer. A 'finite thickness solution' has a very important bearing on further analysis and verification of laboratory test results but would also have a wide application to several engineering problems where natural soil-water conditions exist.

#### Boundary conditions

The boundary conditions at the surface of the seabed require that both the vertical wave-induced effective stress  $\sigma_z$  and the wave-induced shear stress  $\tau$  are zero, and additionally, the pore-pressure  $p$  at the seabed surface is induced by the hydrodynamic bottom pressure. Therefore, one has to fulfil the following boundary conditions at the surface of the seabed ( $z = 0$ ):

$$p = P_0 \exp[i(ax - \omega t)] \quad (2a)$$

$$\sigma_z = 0 \quad (2b)$$

$$\tau = 0 \quad (2c)$$

Field investigations frequently prove the existence of a limited thickness of permeable and isotropic seabed layer or layers with different properties in the upper boundary of seabed. In such cases, the soil profile may look like a sand layer, possibly with permeable sub-layers, a few metres thick overlaying an impermeable clay stratum.

If a finite, permeable layer overlaying a stiff and impermeable base is considered the boundary conditions at the bottom of permeable seabed layer ( $z = -d$ ) have to be specified. And thus,

$$u_z = 0 \quad (2d)$$

$$\frac{\partial p}{\partial z} = 0 \quad (2e)$$

$$u_x = 0 \quad \text{completely rough base} \quad (2f)$$

$$\tau = 0 \quad \text{perfectly smooth base} \quad (2g)$$

where:  $p$  is the wave-induced excess pore-pressure,  $\sigma_z$  is the wave-induced effective vertical stress,  $\tau$  is the wave-induced shear stress,  $u_x$  and  $u_z$  are the horizontal and vertical displacements of the soil skeleton, respectively,  $z$  is the vertical coordinate of the Cartesian system, and  $d$  is the thickness of a permeable seabed layer.

### Finite thickness solution

Below, a solutions for the instantaneous wave-induced excess pore-pressure in the seabed sediments is presented whereas the problem is considered in terms of the wave response of a single layer resting on a stiff impermeable base. The solution derived in order to obtain the response of a single layer, can be successfully used for the case of a multi-layered seabed; however, the number of mathematical manipulations will increase substantially.

Taking the general solution for the wave response together with the boundary conditions for a finite layer overlaying a perfectly smooth, stiff and impermeable base, a set of six linear and complex-valued equations is obtained. This system of equations can be solved either in its complex form or in form of real values; this would induce however twelve equations involved in the solution procedure.

An implementation of the six boundary conditions leads to a system of six coupled linear equations. Because of rather lengthy form of each of 36 constant coefficients accompanied by unknowns  $Y_{1,\dots,6}$ , the calculation procedure has been programmed. The matrix representation of the equation system is as follows:

$$[\mathbf{D}]\{\mathbf{Y}\} = [\mathbf{B}] \quad (3)$$

where each of these three matrices can be written as:

$$\mathbf{D} = \begin{bmatrix} D_1^{(1)} & D_2^{(1)} & D_3^{(1)} & D_4^{(1)} & D_5^{(1)} & D_6^{(1)} \\ D_1^{(2)} & D_2^{(2)} & D_3^{(2)} & D_4^{(2)} & D_5^{(2)} & D_6^{(2)} \\ D_1^{(3)} & D_2^{(3)} & D_3^{(3)} & D_4^{(3)} & D_5^{(3)} & D_6^{(3)} \\ D_1^{(4)} & D_2^{(4)} & D_3^{(4)} & D_4^{(4)} & D_5^{(4)} & D_6^{(4)} \\ D_1^{(5)} & D_2^{(5)} & D_3^{(5)} & D_4^{(5)} & D_5^{(5)} & D_6^{(5)} \\ D_1^{(6)} & D_2^{(6)} & D_3^{(6)} & D_4^{(6)} & D_5^{(6)} & D_6^{(6)} \end{bmatrix} \tag{4}$$

$$\mathbf{Y} = \begin{Bmatrix} Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \\ Y_5 \\ Y_6 \end{Bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ -P_0 \\ 0 \end{bmatrix} \tag{5,6}$$

Matrix **D** contains constant coefficients accompanied by proper unknowns in equations of the boundary value problem. And thus,  $D_j^{(i)}$  represents a set of constant coefficients related to  $j$ -th unknown in  $i$ -th equation. There are six equations where  $i$ -equation ( $i = 1, \dots, 6$ ) relates to the boundary condition (Eqs. 2f, 2d, 2b, 2c, 2a, and 2e, respectively). Matrix **Y** represents unknowns  $Y_j$  ( $j = 1, \dots, 6$ ), and matrix **B** is composed of free term in each expression for the boundary condition problem. The 36 coefficients of matrix **D** can be computed using the following relationships (Magda, 1992):

$$D_1^{(1)} = \exp(-ad) \tag{7.1a}$$

$$D_2^{(1)} = -d \exp(-ad) \tag{7.1b}$$

$$D_3^{(1)} = \exp(ad) \tag{7.1c}$$

$$D_4^{(1)} = -d \exp(ad) \tag{7.1d}$$

$$D_5^{(1)} = \exp(-\bar{k}ad) \tag{7.1e}$$

$$D_6^{(1)} = \exp(\bar{k}ad) \tag{7.1f}$$

$$D_1^{(2)} = \left( a^3 - X_2a + X_3 \frac{1}{a} \right) \exp(-ad) \tag{7.2a}$$

$$D_2^{(2)} = \left( 3a^2 - a^3d - X_2 + X_2ad - X_3 \frac{ad+1}{a^2} \right) \exp(-ad) \tag{7.2b}$$

$$D_3^{(2)} = -D_1^{(2)} \exp(2ad) \tag{7.2c}$$

$$D_4^{(2)} = \left( 3a^2 + a^3d - X_2 - X_2ad + X_3 \frac{ad-1}{a^2} \right) \exp(ad) \tag{7.2d}$$

$$D_5^{(2)} = \left( \bar{k}^3 a^3 - X_2 \bar{k}a + X_3 \frac{1}{\bar{k}a} \right) \exp(-\bar{k}ad) \tag{7.2e}$$

$$D_6^{(2)} = -D_5^{(2)} \exp(2\bar{k}ad) \quad (7.2f)$$

$$D_1^{(3)} = X_1 a^4 - X_1 X_2 a^2 + X_1 X_3 + X_5 ia \quad (7.3a)$$

$$D_2^{(3)} = 4X_1 a^3 - 2X_1 X_2 a \quad (7.3b)$$

$$D_3^{(3)} = D_1^{(3)} \quad (7.3c)$$

$$D_4^{(3)} = -D_2^{(3)} \quad (7.3d)$$

$$D_5^{(3)} = X_1 \bar{k}^4 a^4 - X_1 X_2 \bar{k}^2 a^2 + X_1 X_3 + X_5 ia \quad (7.3e)$$

$$D_6^{(3)} = D_5^{(3)} \quad (7.3f)$$

$$D_1^{(4)} = a + X_1 ia^4 - X_1 X_2 ia^2 + X_1 X_3 i \quad (7.4a)$$

$$D_2^{(4)} = 1 + 3X_1 ia^3 - X_1 X_2 ia - X_1 X_3 i \frac{1}{a} \quad (7.4b)$$

$$D_3^{(4)} = -D_1^{(4)} \quad (7.4c)$$

$$D_4^{(4)} = D_2^{(4)} \quad (7.4d)$$

$$D_5^{(4)} = \bar{k}a + X_1 \bar{k}^3 ia^4 - X_1 X_2 \bar{k} ia^2 + X_1 X_3 \frac{i}{\bar{k}} \quad (7.4e)$$

$$D_6^{(4)} = -D_5^{(4)} \quad (7.4f)$$

$$D_1^{(5)} = X_7(a^4 - X_2 a^2 + X_3) + X_4 ia + X_6 \frac{a}{i} \quad (7.5a)$$

$$D_2^{(5)} = 2X_7 a(2a^2 - X_2) + 2X_6 \frac{1}{i} \quad (7.5b)$$

$$D_3^{(5)} = D_1^{(5)} \quad (7.5c)$$

$$D_4^{(5)} = -D_2^{(5)} \quad (7.5d)$$

$$D_5^{(5)} = X_7(\bar{k}^4 a^4 - X_2 \bar{k}^2 a^2 + X_3) + X_4 ia + X_6 \frac{\bar{k}^2 a}{i} \quad (7.5e)$$

$$D_6^{(5)} = D_5^{(5)} \quad (7.5f)$$

$$D_1^{(6)} = D_1^{(5)} a \exp(-ad) \quad (7.6a)$$

$$D_2^{(6)} = (D' + D'') \exp(-ad) \quad (7.6b)$$

$$D_3^{(6)} = -D_1^{(5)} a \exp(ad) \quad (7.6c)$$

$$D_4^{(6)} = (D' - D'') \exp(ad) \quad (7.6d)$$

$$D_5^{(6)} = D_5^{(5)} \bar{k} a \exp(-\bar{k}ad) \quad (7.6e)$$

$$D_6^{(6)} = -D_5^{(5)} \bar{k} a \exp(\bar{k}ad) \quad (7.6f)$$

The above presented set of coefficients is derived to solve the pore-pressure problem with the assumption of rough basement under the permeable seabed layer. Principally, the same procedure is applied for a finite layer overlaying a completely smooth base. The only difference is that the boundary condition (2f) has to be replaced by the relation (2g) which is foreseen for the smooth base condition. It means that the sub-set of constant coefficients  $D_j^{(6)}$  is built up using constant coefficients of Eq. (2g). All the elements in the other two matrices (i.e.,  $\mathbf{X}$  and  $\mathbf{B}$ ) stay unchanged. Equations (7.6a) to (7.6f) were derived for the case of perfectly rough basement. If a perfectly smooth basement is assumed Eqs. (7.6a) to (7.6f) have to be replaced by the following set of equations in the computational procedure, respectively:

$$D_1^{(7)} = X_6(a + X_1ia^4 - X_1X_2ia^2 + X_1X_3i) \exp(-ad) \tag{7.7a}$$

$$D_2^{(7)} = X_6 \left[ 1 - d + 3X_1ia^3 - X_1dia^4 - X_1X_2ia + X_1X_2dia^2 - X_1X_3 \frac{i(ad + 1)}{a} \right] \exp(-ad) \tag{7.7b}$$

$$D_3^{(7)} = -D_1^{(7)} \exp(2ad) \tag{7.7c}$$

$$D_4^{(7)} = X_6 \left[ 1 + d + 3X_1ia^3 + X_1dia^4 - X_1X_2ia - X_1X_2dia^2 + X_1X_3 \frac{i(ad - 1)}{a} \right] \exp(ad) \tag{7.7d}$$

$$D_5^{(7)} = X_6(\bar{k}a + X_1i\bar{k}^3a^4 - X_1X_2i\bar{k}a^2 + X_1X_3\frac{i}{a}) \exp(-\bar{k}ad) \tag{7.7e}$$

$$D_6^{(7)} = -D_5^{(7)} \exp(2\bar{k}ah) \tag{7.7f}$$

where:

$$D' = X_7(5a^4 - 3X_2a^2 + X_3) + X_1X_3X_6 + X_4ia + 3X_6\frac{a}{i} \tag{8a}$$

$$D'' = -X_7ad(a^4 - X_2a^2 + X_3) + X_1X_3X_6 - X_4ia^2d - X_6\frac{a^2d}{i} \tag{8b}$$

$$X_1 = \frac{2(1 - \mu)k_z}{a\omega\gamma \left( n\beta + \frac{1 - 2\mu}{G} \right) + i(k_z - k_z)a^3} \tag{8c}$$

$$X_2 = a^2 + \frac{[k_z(1 - 2\mu) + k_z]a^2 - i\omega\gamma n\beta(1 - 2\mu)}{2k_z(1 - \mu)} \tag{8d}$$

$$X_3 = a^2 \left( a^2 \frac{k_z}{k_z} - \kappa^2 \right) \tag{8e}$$

$$X_4 = -\frac{(1-\mu)E}{(1+\mu)(1-2\mu)} \quad (8f)$$

$$X_5 = \frac{\mu}{1-\mu} \quad (8g)$$

$$X_6 = -G \quad (8h)$$

$$X_7 = X_1(X_4X_5 + X_6) \quad (8i)$$

Solution of the coupled linear equations' system [Eq. (3)], obtained in terms of coefficients  $Y_1, \dots, 6$ , constitutes simultaneously an explicite solution to the pore-pressure (and also to the wave-induced effective stresses and strains) within the seabed layer of finite thickness. The pore-pressure solution can be written as:

$$p = -\left(\sigma_z + \frac{1}{ia} \frac{\partial \tau}{\partial z}\right) \quad (9)$$

where:

$$\sigma_z = X_4(T_1 + X_5T_2) \exp[i(ax - \omega t)] \quad (10)$$

$$\begin{aligned} \frac{\partial \tau}{\partial z} = & X_6[2Y_2a \exp(az) + (Y_1 + Y_2z)a^2 \exp(az) \\ & - 2Y_4a \exp(-az) + (Y_3 + Y_4z)a^2 \exp(-az) \\ & + Y_5\bar{k}^2a^2 \exp(\bar{k}az) + Y_6\bar{k}^2a^2 \exp(-\bar{k}az) \\ & + T_2ia] \exp[i(ax - \omega t)] \end{aligned} \quad (11)$$

$$\begin{aligned} T_1 = & ia[(Y_1 + Y_2z)a^2 \exp(az) + (Y_3 + Y_4z)a^2 \exp(-az) \\ & + Y_5\bar{k}^2a^2 \exp(\bar{k}az) + Y_6\bar{k}^2a^2 \exp(-\bar{k}az)] \end{aligned} \quad (12)$$

$$\begin{aligned} T_2 = & X_1\{4Y_2a^3 \exp(az) + (Y_1 + Y_2z)a^4 \exp(az) \\ & - 4Y_4a^3 \exp(-az) + (Y_3 + Y_4z)a^4 \exp(-az) \\ & + Y_5\bar{k}^4a^4 \exp(\bar{k}az) + Y_6\bar{k}^4a^4 \exp(-\bar{k}az) \\ & - X_2[2Y_2a \exp(az) + (Y_1 + Y_2z)a^2 \exp(az) \\ & - 2Y_4a \exp(-az) + (Y_3 + Y_4z)a^2 \exp(-az) \\ & + Y_5\bar{k}^2a^2 \exp(\bar{k}az) + Y_6\bar{k}^2a^2 \exp(-\bar{k}az)] \\ & + X_3[(Y_1 + Y_2z) \exp(az) + (Y_3 + Y_4z) \exp(-az) \\ & + Y_5 \exp(\bar{k}az) + Y_6 \exp(-\bar{k}az)]\} \end{aligned} \quad (13)$$

in which:

$$\bar{k} = \sqrt{\frac{k_x}{k_z} - \frac{\kappa^2}{a^2}} \quad (14)$$

and

$$\kappa^2 = i \frac{\omega \gamma \{n\beta' + (1 - 2\mu)/(2(1 - \mu)G)\}}{k_z} \quad (15)$$

where, additionally to the formerly described parameters:  $a$  is the wave number,  $\omega$  is the wave angular frequency, and  $i$  is the imaginary unit.

Having the formula for the pore-pressure  $p$  distribution with depth  $z$ , which is written in a complex-number form, the formulae describing the amplitude,  $|p|$ , and the phase-lag,  $\delta$ , of the pore-pressure oscillated in seabed sediments, with respect to the phase of bottom pressure oscillations, can be easily obtained.

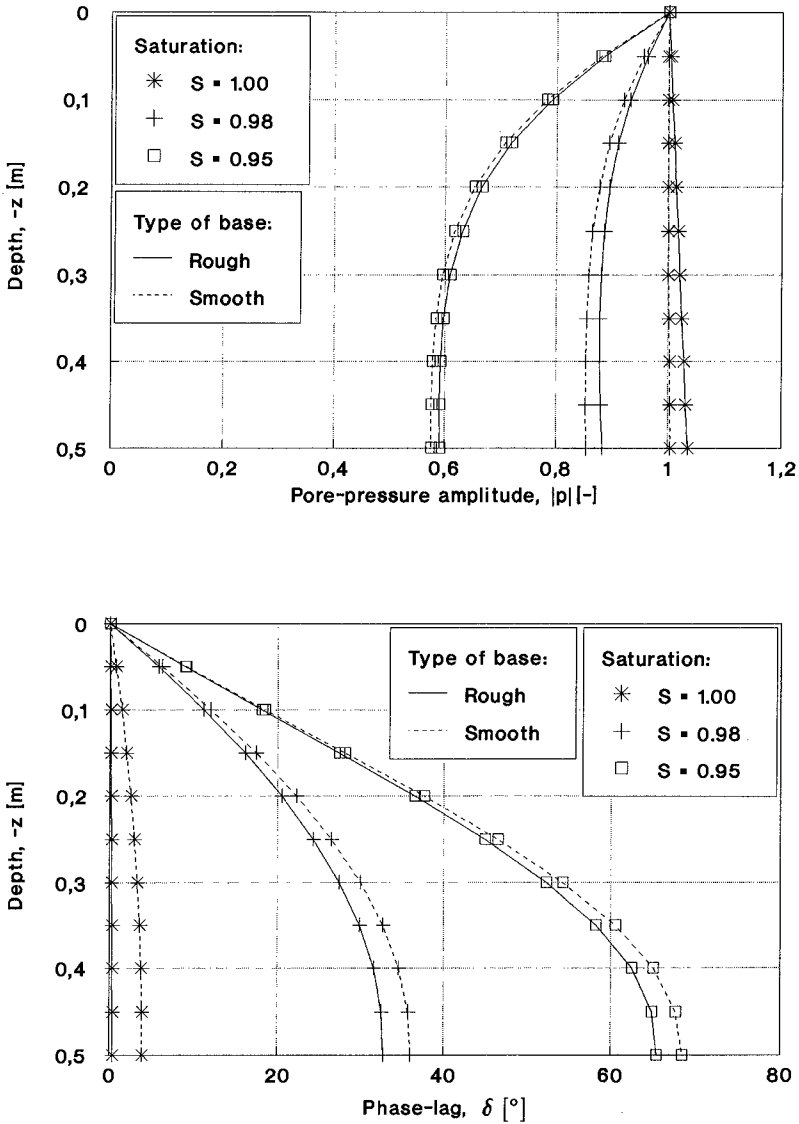

### RESULTS OF EXAMPLE CALCULATIONS

In order to perform illustrative calculations the following input data were used:

- coefficient of isotropic permeability:  $k_x = k_z = 0.0001$  m/s
- porosity of soil:  $n = 0.4$  (loose sand),  $n = 0.36$  (dense sand)
- Poisson's ratio:  $\mu = 0.3$
- Young's modulus of soil:  $E = 10^4$  kN/m<sup>2</sup> (loose sand), and  $E = 10^5$  kN/m<sup>2</sup> (dense sand)
- degree of saturation: from  $S = 1.00$  (fully saturated soil conditions) to  $S = 0.95$  (unsaturated soil conditions)
- seabed layer of finite thickness:  $d = 0.5$  m (smooth or rough basement)
  - wave period:  $T = 6$  s
  - water depth:  $h = 4.5$  m

Using the analytically derived finite-thickness layer solution (Magda, 1989, 1992), two different boundary conditions assumed at the bottom of the permeable seabed layer [Eqs. (2f) and (2g)] were introduced in order to simulate either rough ( $u_x = 0$ , *i.e.* no movement of the soil skeleton) or smooth ( $\tau = 0$ , *i.e.* no friction and free movement) surface of a rigid and impermeable basement underneath the permeable seabed layer.

The results of pore-pressure response in a permeable seabed layer of finite thickness, overlaying either a smooth or rough impermeable stiff base, are given in Fig. 1 (the solid-line denotes the rough base condition and the dashed-line denotes the smooth base condition) in terms of the pore-pressure amplitude and phase-lag as functions of depth in the seabed. Different soil saturation conditions ( $S = 0.95 - 1.00$ ) as well as different compressibilities of soil skeleton, *i.e.*:  $E = 10^5$  kN/m<sup>2</sup> for dense or semi-dense sandy sediments (see Fig. 1), and

**Figure 1.** Pore-pressure amplitude and phase-lag distribution with depth for different saturation conditions and type of impermeable basement (finite-thickness-layer solution,  $E = 10^5 \text{ kN/m}^2$  – dense sandy sediments)

$E = 10^4 \text{ kN/m}^2$  for loose sandy sediments (the results are not presented here in graphical form) were introduced into computations.

In case of dense sandy sediments (Fig. 1), the difference between the rough and smooth base is relatively small. The influence of introduction of the smooth base is magnified when loose sandy sediments are considered. In both cases (*i.e.*, loose and dense sediments) the smooth base condition makes the pore-pressure attenuation as well as the phase-lag larger with respect to the rough base condition. Although the pore-pressure gradient is more inconvenient (more dangerous for the stability of seabed sediments) when the smooth base is assumed, although the rough base condition seems to be more natural.

Performing comparative calculations and wide parameter studies, it was found that fully saturated soil conditions ( $S = 1.00$ ) and a finite thickness of the seabed layer cause some unexpected disturbances in the pore-pressure distribution with depth, namely, the pore-pressure value at the impermeable base exceeds the value of inducing hydrodynamic pressure at the seabed surface (see Fig. 1) which normally – from the physical point of view – should not appear. This phenomenon can be explained if the value of relative compressibility of both components in the two-phase system (*i.e.*, soil skeleton and pore-fluid) as well as the boundary condition choice are investigated carefully.

It is believed that the discrepancy between the calculated and logically expected (*i.e.*, a vertical-profile distribution with depth) values of the pore-pressure amplitude might be caused by:

- ill-conditioned coefficient matrix  $\mathbf{D}$  (numerical problem), or
- unrealistic boundary conditions assumed at the surface of seabed sediments (boundary-condition problem), or
- interaction of both of them (mixed problem).

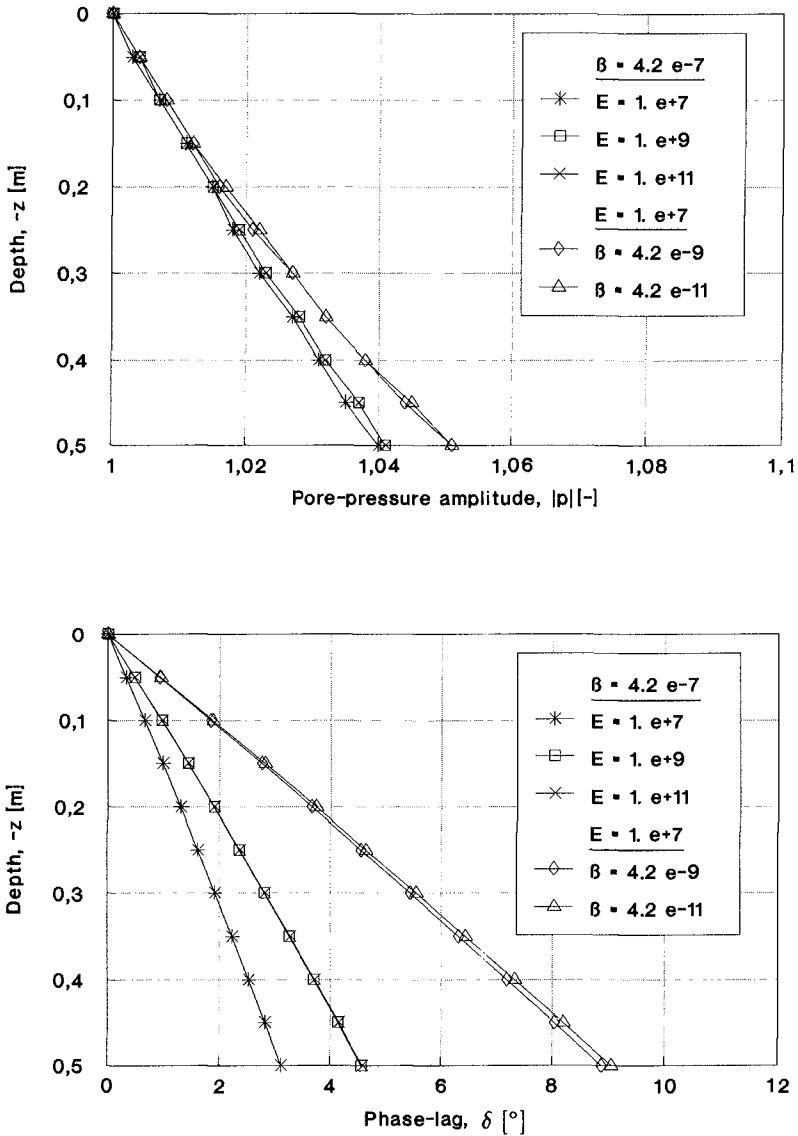

In order to get more detailed insight into the problem, some additional computations were performed where the influence of different extreme values of the relative compressibilities of the two-phase medium was studied (Figs. 2 and 3).

The ratio between the absolute smallest and largest values in the coefficient matrix  $\mathbf{D}$  differs in order between  $10^{14}$  and  $10^{22}$ , in the case analysed and presented in Fig. 3. On the other hand, it is commonly known that the matrices like this one are ill-conditioned and can very often cause some serious numerical problems.

In direct methods of solution, roundoff errors accumulate, and they are magnified to the extend that the governing matrix is close to singular (Press *et al.*, 1989). In spite of the Gaussian elimination method, the following three methods, dealing with sets of equations that are either singular or else numerically very close to singular, were applied:

- LU decomposition,
- iterative improvement of a solution,
- singular value decomposition (SVD).

**Figure 2.** Test on numerical accuracy – pore-pressure amplitude and phase-lag distribution with depth for fully saturated soil conditions ( $S = 1.00$ ) (finite-thickness-layer solution, rough basement,  $\beta' E = 4.2 \times 10^0 (2)(4)$  and  $\beta' = 4.2 \times 10^{-7} \text{ m}^2/\text{kN}$  or  $E = 10^7 \text{ kN/m}^2$ )

**Figure 3.** Test on numerical accuracy – pore-pressure amplitude and phase-lag distribution with depth for fully saturated soil conditions ( $S = 1.00$ ) (finite-thickness-layer solution, rough basement,  $\beta^i E = 4.2$  (const) and  $\beta^i = 4.2 \times 10^{-7(-9)(-11)} \text{ m}^2/\text{kN}$ )

Although performing all computations in a double-precision mode, neither of these methods could avoid the numerical problems discovered in Fig. 1, confirmed in Fig. 2 and strong emphasized in Fig. 3.

Figure 2 illustrates that by assuming a constant value of one of the compressibility parameters (*i.e.*, the compressibility of pore-fluid  $\beta' = 4.2 \times 10^{-7} \text{ m}^2/\text{kN}$  or Young's modulus of soil skeleton  $E = 10^7 \text{ kN/m}^2$ ) and enlarging a value of the second one, the numerical problems do not lead to a dramatical increase of both the pore-pressure amplitude and the phase-lag, which show to be coherent and vary: amplitude – from 1.04 to 1.05, phase-lag – from  $3^\circ$  to  $9^\circ$ , computed at the bottom of seabed layer. A simultaneous increase of both the compressibility parameters (see Fig. 3), however, brings both the pore-pressure amplitude and the phase-lag onto an enormous and unrealistic level (amplitude – from 1.04 to 5.5, phase-lag – from  $3^\circ$  to  $80^\circ$ , computed at the bottom of seabed layer).

## CONCLUSIONS

Taking into account the results of the above presented analysis, it is a rather lucky coincidence that the realistic values of compressibility of the pore-pressure and soil skeleton are:  $\beta' \geq 4.2 \times 10^{-7} \text{ m}^2/\text{kN}$  and  $E \leq 10^5 \text{ kN/m}^2$ , respectively. These conditions guarantee that the order of maximum ratio between the absolute smallest and largest value in the coefficient matrix  $\mathbf{D}$  will be always less than  $ca 10^{14}$ . Only by a near-incompressible system (*i.e.*,  $\beta' = 4.2 \times 10^{-7} \text{ m}^2/\text{kN}$  for fully saturated soil conditions  $S = 1.00$ , and  $E = 10^5 \text{ kN/m}^2$ ) some numerical problems are expected as indicated in Fig. 1. It was shown, however, that even in this case, the difference between the computed pore-pressure amplitude and the logically expected values (*i.e.*, a vertical-profile distribution with depth) have no practical meaning and can be neglected.

There is, however, another method that helps to solve the governing problem, correctly, omitting simultaneously the above mentioned numerical problems when solving the system of coupled linear equations. This method, based on a finite-element approximation of one-dimensional model for wave-induced excess pore-pressures and displacements in the soil skeleton, allows to omit a bit artificial boundary conditions (*i.e.*,  $\sigma_z = 0$  and  $\tau = 0$ ) assumed at the seabed surface, and gives more realistic picture of the pore-pressure field in permeable seabed sediments. The results of such a numerical analysis was published by Magda (1991, 1992).

The preparation of all elements [Eqs. (7.1a) to (7.6f)] from the coefficient matrix  $\mathbf{D}$  in the analytical solution requires much more mathematical operations with relatively small and large values before the equations system is solved. This complicated and superfluous procedure is omitted in the finite-element solution where the elements of coefficient matrix are computed using less mathematical operations.

## CHAPTER 225

# Response Characteristics of River Mouth Topography in Wide Time Scale Range

A. Mano<sup>1</sup>, M. Sawamoto<sup>1</sup> and M. Nagao<sup>2</sup>

### Abstract

Based on the observations, response characteristics of sand barrier and flood terrace for the Abukuma River mouth are analyzed in wide time scale range spanned from several hours to half century. We propose some measures representing magnitude of the deformation and the external forces to find quantitative relationship between them. The analyses deal with breaching in the flood process, development of the sand barrier, alternation of the barrier side, and the formation and decay of flood terrace, together with their time scales. There will be also shown interaction between the barrier and the terrace.

### 1 Introduction

The final goal in the study of river mouth topography is to predict it in the near and far future, and to make control, if necessary, for the flood passage, voyage, or coastal sedimentation. Stable prediction generally requires both qualitative analyses and quantitative evaluation of long-term history.

The complexity of the topographical deformation in the river mouth area would be produced by complication of the external forces, i.e. duality of river flow and waves, and their fluctuating characteristics, and by influences from the topography itself and man-made structures, which are also changing.

The key to resolve these entangling situation is time scale of each process. Sawamoto and Shuto(1988) have found various time scales on the topographical change around the Abukuma River mouth based on the observations. The time scales range from several hours of flood process to half century of the alternation of the sand barrier side. This paper develops their findings by collecting further observation data on both the deformation and the external forces, and

<sup>2</sup>Department of Civil Engineering, Ashikaga Institute of Technology, Ashikaga 326, Japan

by connecting them. To perform the analyses, we introduce some new measures representing their magnitude, that enables some quantitative evaluations.

Further new findings is the existence of the interaction between the sand barrier and the terrace, especially in the stage when the deformation of the terrace is proceeded. This is added to patterns of the deformation.

At the end of this paper, will be presented a diagram summarizing each deformation stage and time scale.

## 2 Outline of the river and data collection

The Abukuma River is the first class river, with the catchment area of 5,400 km<sup>2</sup> and the main channel length of 239 km, managed by the Ministry of Construction in Japan. The river has a mouth opened eastwards to flow into the Pacific Ocean (Fig. 1). At the mouth, the annual mean discharge of the river is about 120-180 m<sup>3</sup>/s, which is comparable with the mean tidal discharge in the half cycle of 50 - 130 m<sup>3</sup>/s. Therefore, the channel at the mouth is usually maintained by both the river and tidal flow. The incident waves, there, having dominant direction, ESE, produce littoral drift from the south to the north macroscopically.

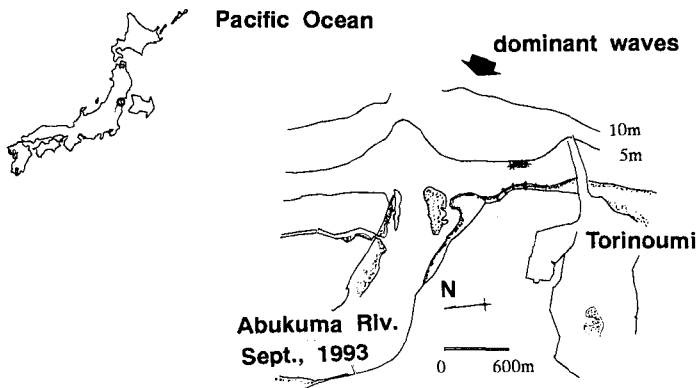

Fig. 1: Geography around the Abukuma River mouth.

There are some man-made structures near the mouth. The large saline barrier called Abukuma Ohzeki, which locates 10 km up the river mouth and was constructed in 1982, prevents the sediment transport for usual flow, that is, except floods. Training jetties have been established, not at the Abukuma river mouth, but at the entrance of Torinoumi lagoon which is an old mouth of the river. They were in construction in 1954 - 1980 to be lengthened to about 400 m. In order to prevent erosion between the entrance and the mouth, a detached break-water and groins were set up in 1986 - 1992 and 1974 - 1976 respectively. The effect of these coastal structures on the river

mouth topography is not so clear, because the river has function as a sediment source also.

The circumstance of observations is given in the Table 1. Depth sounding, river discharge, and aerial photograph have half century's history, while our observations for the sand barrier are relatively new, but the period of the observations covers short to middle term change. Especially, the flood process in 1985 was recorded on the video tape. The aerial photographs have been taken by the U.S. military, and the Geographical Survey Institute and Tohoku Regional Construction Bureau, the Ministry of Construction.

The discharge is observed at Iwanuma, located 7.8 km up the mouth. Since the floods are most influential on the response among the river flow, we have collected hydrographs of major floods, as well as daily mean discharge in the long period. They are utilized in the examination of the new measure. The maximum flood in the peak discharge occurred in 1986. Its flush and the recovery process have been observed by ourself as well.

The wave observation is performed off the Sendai Harbour locating about 26 km NNE of the mouth and has relatively short history corresponding to the construction of the harbour.

### 3 Response of sand barrier

#### 3.1 long-term change

The history of sand barrier in the long time span is shown in Fig. 2 which is edited from the aerial photographs. The oldest plate of 1947 indicates the barrier in the right side, which is dominant due to the macroscopically prevailing direction of the littoral drift. The shoreline position of the barrier is more seaward than recent one is.

Then, switch of the side to the left is recognized in the plate of 1969 and this side continues until the plate of 1979, with the thickness getting very thin. Again, the barrier in the right side appears in the plate of 1984 to last up to now. The recent two plates of 1992 and 1993 show quite different shape of the barrier from

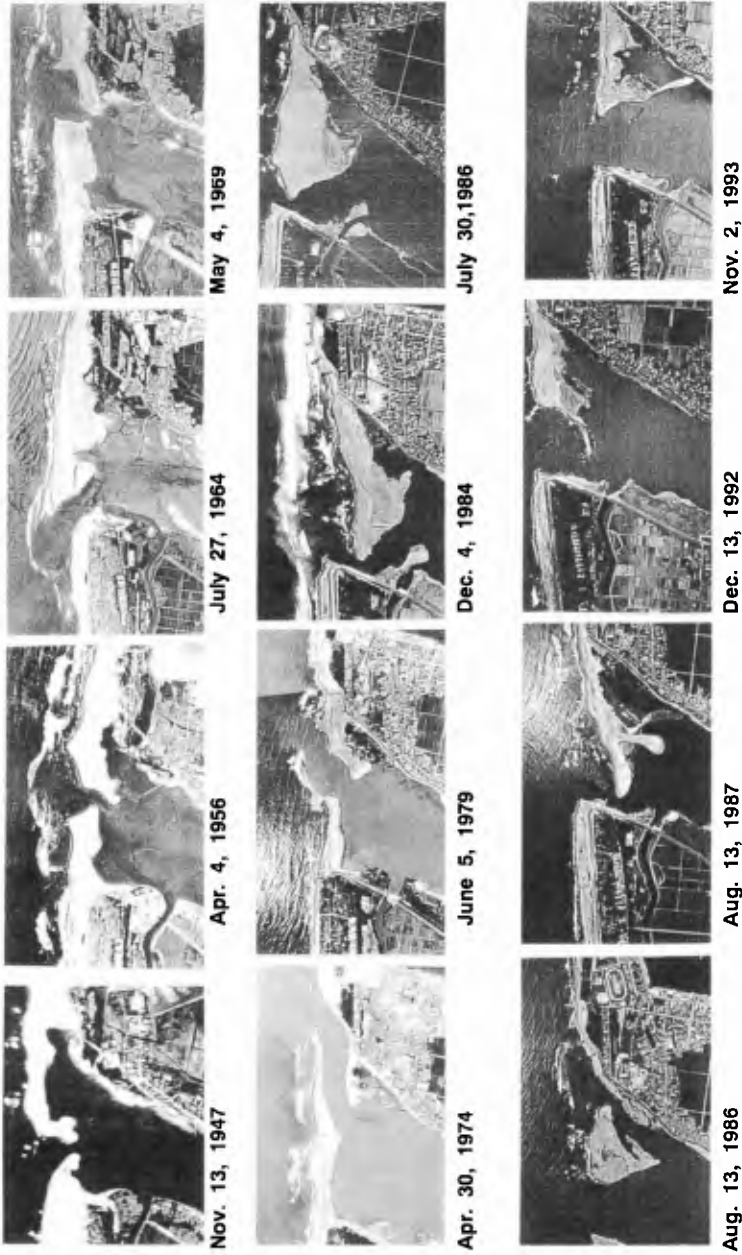

Fig. 2: History of the sand barrier. The photographs of 1947 and 1956 were taken by the U.S. military; 1964, 1969, 1974, 1979, and 1984 by the Geographical Survey Institute; 1986, 1987, 1992, and 1993 by Tohoku Regional Construction Bureau.

Fig. 3: History of the floods.

any other one. This will be analyzed in Section 5.

Here, let us focus on the long term change, that is the alternation of the side. This is corresponding to the activity of the floods. Figure 3 shows the whole history of the major floods observed. The ordinate indicates the total discharge, integrated in one flood, which is a new measure and will be discussed in the next subsection.

Long-term fluctuation exists, that is, in 1940s and 1950s there occurred many floods in huge magnitude, which caused serious disasters. The flood in 1941 is the biggest in the total discharge. In the following two decades; 1960s and 1970s, the flood activity calmed down and then in 1980s and 1990s floods are again active. The flood in 1986 is another representative having the biggest peak discharge in the history. The time scale of the long-term fluctuation is about half century.

The alternation of the side to the left would be triggered by the overhang of the right side barrier in 1964, because this is unstable for the flood passage. Backwater induced by the resistance of the overhang would cause the overflow somewhere around the lower part of the barrier to make a new channel there. The channel at the mouth is usually maintained strait by the flush due to floods in appropriate period. The calmness of the flood activity in 1960s promotes the overhang. Once the side is changed to the left, the supply of the littoral drift to the barrier is prevented by the flow in the channel. Hence the barrier becomes thin, that is corresponding the barrier shape in 1960s and 1970s. Although thin barrier is unstable for the flood passage, the left side barrier continued until 1979, that is more than 10 years. This continuation is also assisted by the calmness of the flood in this period.

Therefore the long-term deformation of the side alternation synchronizes with the fluctuation of the flood activity, through the mechanism provoked by the calmness in the flood intensity.

3.2 short-term change

The opposite extreme in the time scale range would be flood process. The breaching of sand barrier during the flood of 1985 was recorded by the video tape and analyzed by Sawamoto et al.(1988). Here we will examine about the measure of the flood relating with the breach. Figure 4, showing the change of the minimum channel width at the mouth , $B$ , during the flood, indicates that significant change occurs even after the peak of the discharge has passed. Therefore the terminal channel width  $B_T$  after one flood passage should be related to the quantity representing the whole flood.

Fig. 4: Breaching process.

Fig. 5: Runoff characteristics.

Another examination is about the relationship between the peak discharge,  $Q_{max}$ , and the total discharge(Fig. 5). In a short period, these two quantities are on one linear relationship, but in the long time span the gradient apparently

changes. The border of the change is in 1960s and 1970s, which are not clear because of the absence of the huge floods in the period. The change would be resulted from the channel improvement of the Abukuma River after the serious disasters in 1940s and 1950s. Decrease of the gradient corresponds to decrease of the resistance in the channel. The flood in October, 1991 has special hydrograph with two peaks which are produced by the twin typhoons. Filled diamond in Fig.5 is the plot of half of the total discharge for this flood. This is still on the recent relationship.

Since the total discharge is a simple and invariant quantity including the information of the whole flood, we adopt it as a measure of magnitude of the flood relating with the breach. The dependence of the terminal width on the total discharge is given by the linear relationship(see Fig.6). The flood in 1991 is also included in this figure and on the relationship. The flood in 1992 is the exception, that is, the channel was widened for relatively small amount of total discharge. Although the thin barrier at the tip(see Fig.2)is the direct cause, it will be shown later that the influence of the deformation of the flood terrace with different time scale is more original cause.

Fig. 6: Terminal channel width after the flood passage.

### 3.3 middle-term change

The breaching follows the recovery process of the sand barrier. The change of the channel width and the area of the sand barrier are plotted in Fig. 7, where the region accounting the area is defined in the left plate. After the flood, the littoral drift is spent to fill up the channel deepened by the flood. Therefore the change of the width is not evident. Then, the channel width starts to decrease rapidly to reach the stationary value of 50 - 60 m. The time scale of the decrease is 4 to 12 months depending on the scale of breaching. The stationary state is maintained by the dynamic equilibrium between the traction by the flow and deposition by waves, that is shown by Aota and Shuto (1980).

Fig. 7: Middle-term deformation of sand barrier.

Fig. 8: Barrier development rate.

Even though the equilibrium at the channel is reached, the shape of the sand barrier is still thin. The thickening process of the barrier continues, which is indicated by the increase of the area. In this figure the daily mean discharge of the river and the wave energy flux are also shown. The flux is calculated by the equation;

$$F = \frac{1}{32\pi} \rho g^2 H^2 T \cos \theta$$

where,  $H$  and  $T$  are the wave height and period, respectively,  $\theta$  is the wave direction measured clockwise with the origin at the direction normal to the macroscopic coastline. These three quantities are all measured off Sendai Harbour. This figure shows the response characteristic that the channel width decreases sensitively for even minor flood, but the change of the area is more gradual. Hence, we evaluate the mean increase rate of the area in the three regions bounded by the major floods in 1986 and 1989 to correlate with the energy flux ( Fig. 8).

It is shown that the increase rate of the area,  $dA/dt$ , is directly proportional to the wave energy flux,  $F$ . This relation gives the time scale of the recovery of the sand barrier. Since the flood in 1986 flushed the area  $0.01 \text{ km}^2$  out of  $0.11 \text{ km}^2$ , the recovery would require 7 years for the energy flux of the ordinal sea condition,  $1.0 \times 10^{11} \text{ J/year/m}$ , that is  $3.2 \text{ kW/m}$ .

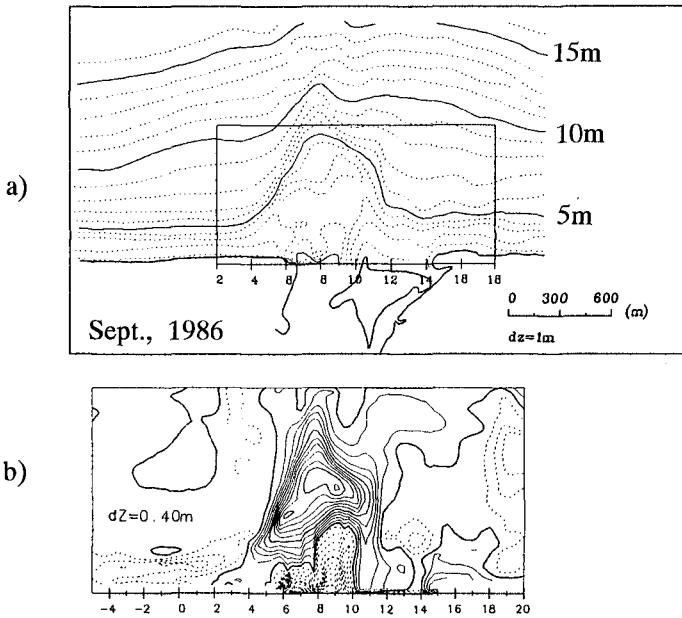

Fig. 9: Formation of flood terrace in 1986.

#### 4 Formation and decay of flood terrace

Figure 9 a) shows the flood terrace produced by the flood in 1986 and b) the distribution of deposition (solid line) and erosion (dashed line) obtained by taking difference of the two bathymetry charts sounded before and after the flood in the interval of six month. The terrace is about 4 m in depth and very flat. The maximum deposition is 4 m in height and locates the distance 800 m offshore of the shoreline. The channel at the mouth, the sand barrier, and its front area were

eroded by the flood. The volume of the erosion estimated to be about 60 % of that of the deposition by Mano et al.(1993). Hence, the rest would be due to the transport in the river. For any kind of sediment, the formation of flood terrace requires work transporting a large quantity of sediment by the long distance from the mouth.

Here we adopt the total kinetic energy in one flood at the mouth, *T.K.E.* as a measure of the flood magnitude relating to the terrace formation. The assumptions introduced to compute the quantity are; 1) the flood flow is critical at the mouth, 2) the channel width changes, linearly in terms of time, from the initial width to the terminal width. Where for the floods before 1982, we used 50 m and the terminal value shown in Fig. 6. as these width respectively. The energy is written as follows;

$$T.K.E. = \int \rho g^{2/3} \frac{Q^{5/3}}{2B^{2/3}} dt$$

where,  $\rho$  is density of water,  $g$  gravitational acceleration,  $Q$  the discharge,  $B$  the channel width. The integration is taken over one flood. While the measure on the terrace formation is also necessary. Since we can not extract precise information from the old bathymetry chart, we define  $L_5$  as the longest distance from the macroscopic shoreline near the mouth to the contour line of 5 meter depth. The changes of these two measures in half century time span are well corresponding (Fig.10). The threshold of the external force for the big terrace formation would be given by the value,  $1.3 \times 10^{13} J$ . The figure shows that major floods are of 1941, 1948, 1858, and 1986. In the case of 1986 flood, sediment near the mouth also contributed to the terrace formation.

Fig. 10: Terrace formation and T.K.E.

The bathymetry chart sounded just before the 1986 flood still shows small terrace. From the interval of major floods, the time scale of disappearance of the big terrace would be given by more than 27 years.

## 5 Interaction

The last two plates in Fig. 2 show the recent sand barrier. The formation of big arc at the barrier tip in the plate of December, 1992 shows the wave direction approximately normal to the shoreline, which is different from the offshore wave direction. The effect of wave refraction becomes important. Although there exist some small arcs at the tip before, they would not be influential. The wave direction at the arc in 1992 prevents the development of the barrier toward the tip to result in the thin tip and to change the response characteristics of terminal width in Fig. 6. The plate of November, 1993 shows more advanced stage. Two strait shoreline facing the sea and river would be formed by waves refracted near the mouth. In this stage, the channel width is kept open.

The characteristics of the wave refraction is shown in Fig. 11. Wave rays, given by the numerical integration of the ray equation, see, for example, Mei(1983),pp. 66, are plotted for the bathymetry of 1993. The wave condition is for the dominant wave; direction of ESE and period of 8 s.

Fig. 11: Refraction characteristics.

The caustic is stably formed at the hollow on the flood terrace for the various offshore directions and the periods. The wave rays refracted at the hollow approach the barrier from ENE, that is, two dominant wave directions exist at the sand barrier. As stated above, these waves change significantly the barrier shape and various response characteristics.

This hollow would be formed by the river flow, mainly by the passage of floods after 1986. The time scale on the hollow formation is about 6 years.

## 6 Concluding remarks

We have shown various deformation of the river mouth topography and its time scales, and their interactions. Figure 12 shows the summarizing diagram mainly for the right side barrier. The lines with arrow indicate the direction of the change with the cause, which is distinguished by the type of lines. The right direction

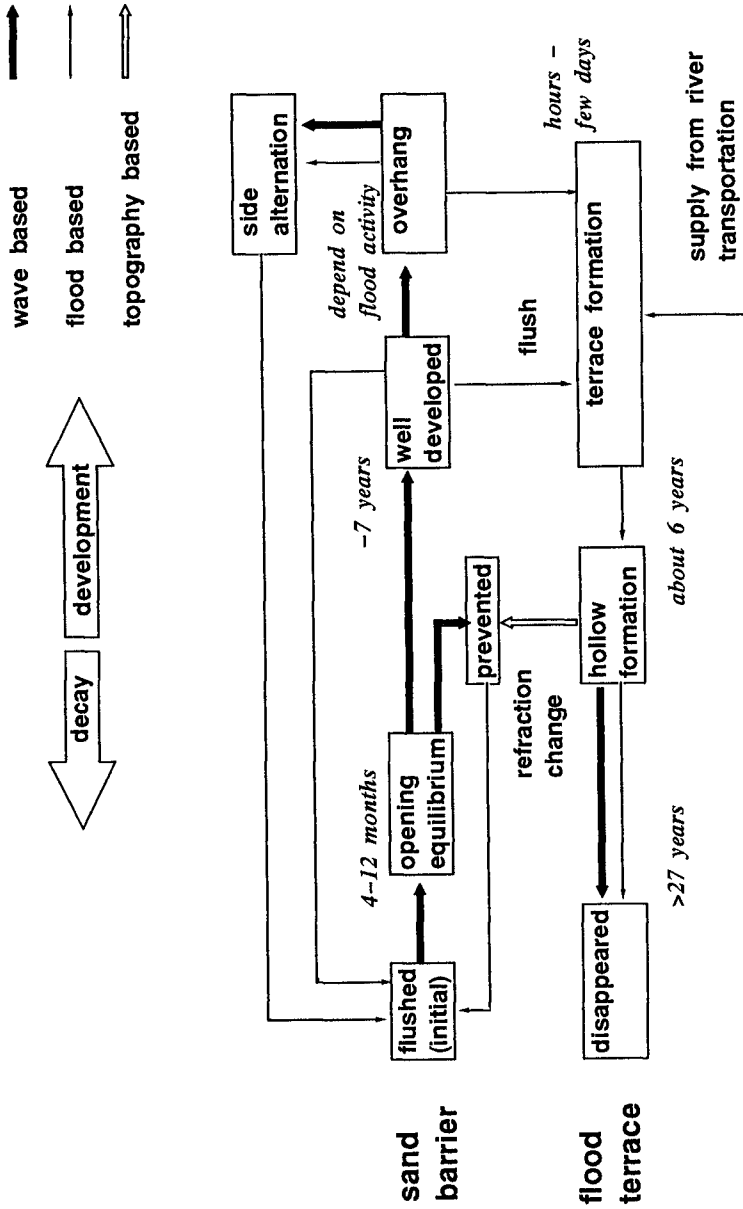

Fig. 12: Deformation stage and time scale.

corresponds to development and vice versa. Each box shows the stage of the deformation. The italic numbers are time scales based on the recent observations. The initial condition of the sand barrier is flushed state by the flood. Then it changes into equilibrium at the opening channel, well developed state, and overhang, depending on the flood activity. Although the main cause for the terrace formation is flood, sediment at the barrier contributes as well. Once the hollow is formed, it changes the refraction characteristics to prevent the development of the barrier. Depending on the timing, the barrier may not reach the equilibrium.

### Acknowledgement

The authors wish to express their gratitude to the Ministry of Construction and the Ministry of Transport for allowing to access the observed data. They also wish to express their thanks to the River Environment Fund by the Foundation of River & Watershed Environment Management and to Tohoku Regional construction Bureau, the Ministry of Construction for the sponsorship to this study. Acknowledgement also is due to the Ogawa Memorial Fund for the financial support for the publication.

## CHAPTER 226

### Half-Life Period of Sedimentation - Model Test on a Scale 1:1

Helmut Manzenrieder<sup>1</sup>

#### Abstract

In the framework of an extension plan for a large cargo handling berth, it is necessary for one alternative to build an artificial approach. The bottom of this dredged channel will lie approx. 6 m under the natural seabed level. The run of the axis is unfavourable since it is perpendicular to strong tidal currents which reach 2 m/s in the 705 cycles per year. In a model test, re-sedimentation for a volume of approx. 210,000 m<sup>3</sup> was observed indirectly in the standard procedure with repeated measurements by echo sounding as well as with a direct method using a sand-surface-meter combined with wind, tide, current and wave measurements.

#### History

The most important entrepot for energy in the Federal Republic of Germany is Wilhelmshaven. Its recent but nevertheless highly varied history began late - in 1853 - when a large Prussian naval port was established, the tradition of which continues up to the present time. In the year 1889, King William I of Prussia named the town after himself, i.e. Wilhelmshaven. Starting in 1957, the settlement of various oil companies and chemical concerns with their respective cargo handling installations including four large piers (Fig. 1) was influenced by the favourable natural conditions along the shore, especially water depth. Although no maintenance dredging had been carried out for a period of more than 10 years (1944 - 1957), a navigational depth of 11 m was still encountered. This can be attributed to the natural scouring force of the tidal current.

With the constantly increasing size of oil tankers, the navigation channel has been further deepened over several stages. The present target depth is between 18.5 and 20.0 m below chart datum so that fully laden tankers of 250,000 D.W.T. can put in at Wilhelmshaven under the right tidal conditions. The deep water region of

---

<sup>1</sup> Consulting Engineering Office Dr. Manzenrieder and Partner, Brookweg 29, D-26127 Oldenburg, Germany

Wilhelmshaven is located on the Jade which is a large arm of the sea on the coastline on the south side of the North Sea. The bay (555 km<sup>2</sup>) has very little fresh water flow, so most of the deterministic and stochastic parts of the energy in the regime are transferred only from the North Sea into the Jade which differs from the situation in a typical river estuary.

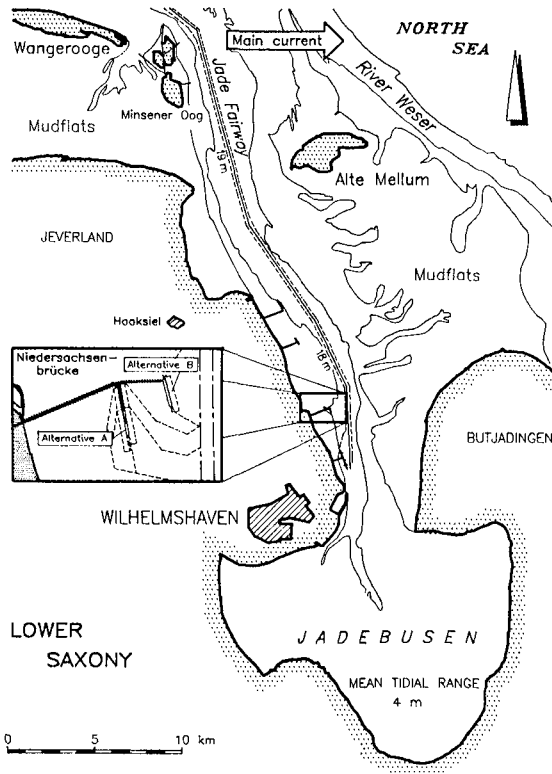

Figure 1. The Jade with the fairway and four cargo handling berths

Situation and Methods

The regular semi-diurnal tidal range of close to 4 m reaches its maximum all along the German coast. During one tide, approx. 1 billion cubic meters of salt water move into and out of the Jade, 705 times a year. As a rough estimate, approx. 6 million cubic meters of solid material is carried into the regime during this period. This process in combination with the artificial water depth in the fairway is the reason for recurrent dredging activities of up to 10 million cubic meters per year. In the framework of a current extension plan for a large cargo handling berth (called

"Niedersachsenbrücke") on the inner part of the Jade, there are two alternatives. For one alternative it is necessary to build an artificial approach between the berth and the navigation channel (see Fig. 1). The bottom of this dredged channel with a length of approx. 1 km will lie 6 - 7 m below the natural seabed level (12 - 13 m). The run of the axis is unfavourable since it is perpendicular to strong tidal currents which reach 2 m/s and have a high suspension load.

In view of this background, the simple but also substantial question for a cost-benefit calculation is the amount of maintenance dredging that will be needed to equal the sedimentation rate for a defined span of time in such an underwater depression. Also, because of the increasing importance of environmental aspects concerning the disposal of the material, a most critical point in design is the estimation of quantity in maintenance dredging which can be summarized in the question: *How many m<sup>3</sup> should be expected per year?*

Since we intuitively feel that the quantity of maintenance dredging will be related to the channel geometry, a prediction of this maintenance dredging will be necessary in order to complete the evaluation of particular alternatives. On the other hand, the prediction of such sedimentation is an extremely complex problem in itself and the classical sediment transport formulas will not be sufficient for predicting the bottom changes in a marine approach channel. In the example (Fig. 2), the deepening from 9.8 to 11.3 m is the reason for an increased shoaling rate of more than 200 %. However, a few untested methodologies for predicting channel shoaling do exist (SPM/I 1984, Galvin 1983, Bijker, Massie 1986).

Figure 2. Mass dredging curve (from CERC, 1984)

The quality of powerful numerical models for such sophisticated questions are at a research level and far from adequate for forecasting engineering practice. The condition is much the same for simple models, for example, combining suspension

load and sink velocity. To meet the requirements, valid data on the physical processes in the specific area will be needed as input for calibration and checkup.

For the assessment of the different alternatives, the potential of sedimentation in the area is important. For the evaluation of these values, different methods are used (Basinski, 1989):

- Contained water samples
- Pumping samples in vertical profiles
- Turbidity profiles
- Stationary traps on the bottom
- Sand gauges (Sand-Surface-Meter)
- **In-situ model test on a scale 1:1**

One important result during regular tides was the quantity of sediment in suspension which was measured at approx. 15 t per hour and unit meter or about 100,000 t in the channel during the flood and ebb tide current. The local flow and wavefield has a rather high influence on this transport capacity.

#### Results of the Model Test in a Scale 1 : 1

In the framework of the investigation, a model test was set up at this stage since there was an independent requirement for a volume of approx. 210,000 m<sup>3</sup> of sand on land. After checking the physical parameters of the sandy soil ( $d_{50} = 0.25$  mm and  $d_{60}/d_{10} = 2.3$ ), a large underwater depression was dredged in the center of the designed approach with a maximum depth of approx. 22 m below chart datum (Fig. 3).

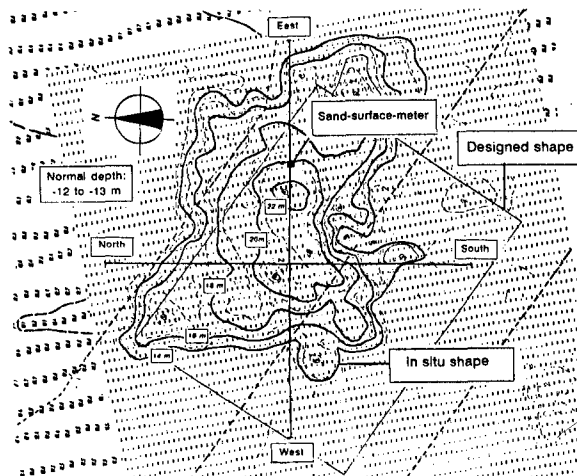

Figure 3. Test dredging - in situ shape in the initial stage

Subsequently, re-sedimentation was observed indirectly by the standard procedure with repeated measuring by echo sounding as well as with a direct method using a so-called Sand-Surface-Meter (SSM) in the deep center area of the dredged structure over a two month period (Manzenrieder, Witte 1986, Erlingsson 1990). Re-sedimentation and/or rearrangement within the structure started already during the dredging activities. The results of repeated precise echo sounding give information on the development in quantity over a period of one year. In table 1, all numerical values are listed.

Table 1: Re-sedimentation in an artificial depression  
(<sup>a</sup> Days after the end of-dredging )

Sounding No.	Sounding Date	Duration of Sedimentaion <sup>a</sup>	Max. Depth	Artificial Volume
0	31.01.1991	-	13,0 m	0 %
1	09.02.1991	2	22,5 m	100 %
2	12.02.1991	5	22,3 m	98 %
3	21.02.1991	14	22,0 m	95 %
4	05.03.1991	26	21,8 m	93 %
5	04.04.1991	56	20,9 m	83 %
6	03.05.1991	85	20,2 m	76 %
7	05.06.1991	118	19,2 m	65 %
8	10.07.1991	153	18,2 m	55 %
9	11.09.1991	216	17,8 m	51 %
10*	13.11.1991	279	17,8 m	51 %
11*	16.01.1992	343	16,9 m	41 %

\* Uncertainty in the echo sounding execution

In Fig. 4, the development of the bottom shape which was taken by echo sounding is given up to sounding No. 9. The right-angled axis is shown in Fig. 3. The tidal currents cross the depression in the North-South direction with velocities up to 2 m/s. In Fig. 5, the remaining value at the end of the dredging period is assigned to time. The analysis of the information from the soundings indicate an average sedimentation rate of 2.4 cm per day.

To get more detailed information on the processes in the dredged structure, a Sand-Surface-Meter (SSM) was installed in the center area of the depression. Modern instruments such as this were used in addition to the classical areal sounding method which of course only give continuous data on the relative bottom position for a single point but during all sea conditions (Manzenrieder, Snippe 1991). The necessity for this instrument is shown in Fig. 6.

Figure 4. Cross-sections in the center area

Figure 5. Re-sedimentation in the depression

Figure 6. Uncertainty in the Interpretation of Soundings

In Fig. 7, a sketch of such specific measurements under water should give an impression how such devices give a sort of microscopical view of the complex processes. The newest generation of these instruments is also qualified to observe transport processes above the bottom (bed load). In its application for observing sedimentation in the introduced dredging contour, the constant time interval was 60 minutes, the range of measuring 1.5 m and it was supported by diver inspections. One system exchange was necessary. For a period of approx. two months, digital information was collected continuously and the original results are displayed in Fig. 8. Sedimentation in the first two weeks was almost linear. After that, some discontinuous steps were measured. Between the following linear gradients, two periods without significant sedimentation are conspicuous. The average sedimentation rate over the two month period was calculated at 4.1 cm/day.

Combined with wind, tide, current and wave measurements, direct observation of the boundary layer especially provided deeper insights (Fig. 9). During a strong gale of up to Bft No. 8, the sedimentation rate increased to 18 cm/day. After the event there was a period without significant sedimentation. This remarkable process during a higher energy level in the watercolumn is an indication for the sedimentation potential on the bottom which is mobilized during such periods in the form of a suspended charge. Afterwards, the bottom in general showed an over-proportional absorption capacity before reaching standard conditions of "normal" sedimentation.

Figure 7. Field Measurements with a Sand-Surface-Meter (schematic)

Figure 8. Sedimentation in the Center Area (Continuous Observation with Sand-Surface-Meter)

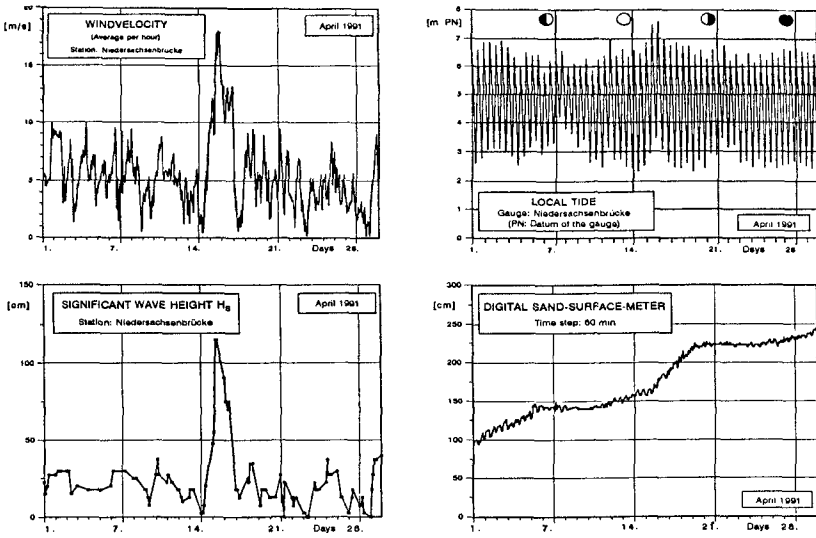

Figure 9. Assignment for the Sedimentation Processes

Theoretical Approach

All present observations and the results of investigations on erosion of beach nourishments (Führböter 1974, 1991) support a non-linear nature for the material on the balance sheet. Führböter based his approach on the assumption that the local, long term wave climate is constant and mentioned the same exponential law known in nuclear physics using the definition of a half-life period. In relation to the erosion processes close to the surface, sedimentation in artificial underwater structures (e.g. channels) is influenced by water depth. Especially due to this hydraulic filter in deeper regions, the assumption of a more constant local transport regime could be supported. Taking a sediment-laden current crossing a channel into consideration, the abrupt change in hydraulic conditions will cause time dependent morphological changes in the channel. The supposed function over time is given schematically in Fig. 10.

Under the assumptions stated above for an analytical expression of the sedimentation processes, the dredged volume  $V$  below the natural horizon at time  $t$  is the initial information. In the next time step  $\Delta t$ , this artificial volume will be reduced due to sedimentation by an amount of  $\Delta V$ .

$$- \frac{\Delta V}{\Delta t} = \lambda V \text{ or } \Delta V = - \lambda V \cdot \Delta t \tag{1}$$

Figure 10. Sedimentation in an Artificial Underwater Depression (schematic)

The negative sign deals with the sedimentation tendency. Very little knowledge is available on the range of sedimentation parameter  $\lambda$ . One step for the evaluation of this value is a part of this paper.

In equation (1), the assumption is included that volume  $V$  is constant during time-step  $\Delta t$ , so that the relation will be stabilized with increasing time between each sample (sounding). The transition for the gradient of the secant  $\Delta V, \Delta t$  to the differential form (gradient of the tangent) follows at

$$dV = -\lambda V dt \text{ or } \frac{dV}{V} = -\lambda dt \tag{2}$$

After the integration of eq. 2, the description for the sedimentation during any time is given. The integral for the time 0 with an initial volume  $V(0) = V_{max}$  to time  $t$  with the remaining volume  $V(t)$  has the form

$$\int_{V_{max}}^{V(t)} \frac{dV(t)}{V(t)} = -\lambda \int_0^t dt \tag{3}$$

with the solution

$$\ln V(t) - \ln V_{max} = -\lambda t \text{ or } \frac{V(t)}{V_{max}} = e^{-\lambda t} \tag{4}$$

The sedimentation coefficient  $\lambda$  will be written in the following form

$$\lambda = - \frac{\ln V(t) - \ln V_{max}}{t} \tag{5}$$

the derivative trend with respect to time is

$$V(t) = V_{\max} e^{-\lambda t} \quad (6)$$

Equation 6 is in relation to the basic equation for radioactive decay, so this could be used as a basic sedimentation equation in artificial depressions. The evaluation of sedimentation factor  $\lambda$  as the central input parameter is based on experimental investigations. In contrast with nuclear physics, no universal indications are available. The lack of qualified instrumentation for such measurements is only one reason for this limitation. Following the analogy for the sedimentation factor  $\lambda$ , the half-life period  $T_{1/2}$  could be used with the definition:

The half-life period  $T_{1/2}$  of an artificial depression is the time for a 50% reduction of the (dredged) volume due to re-sedimentation.

When describing the relation between the half-life period  $T_{1/2}$  and the sedimentation factor  $\lambda$  the remaining volume in the depression  $V(t_1)$  at the time  $t_1$  could be used

$$V(t_1) = V_{\max} e^{-\lambda t_1} \quad (7)$$

After expiration of the time  $T_{1/2}$ , that means the total time  $t_1 + T_{1/2}$  bisected by the artificial volume

$$\frac{1}{2} V(t_1) = V_{\max} e^{-\lambda(t_1 + T_{1/2})} \quad (8)$$

Using both equations above, it follows that

$$e^{-\lambda t_1} = 2 e^{-\lambda(t_1 + T_{1/2})} \quad (9)$$

and

$$-\lambda t_1 = \ln 2 - \lambda(t_1 + T_{1/2}) \quad (10)$$

or

$$T_{1/2} = \frac{\ln 2}{\lambda} = \frac{0,693}{\lambda} \quad (11)$$

The half-life period  $T_{1/2}$  is consequently a characteristic value which is independent from the previous sedimentation period. This is important when applying in practical applications. It is common to use the half-life period in a mathematically more simple form

$$e^{\frac{t \ln 2}{T_{1/2}}} = 2^{-\frac{t}{T_{1/2}}} \quad (12)$$

with the relation for  $\lambda$  the volume  $V(t)$  is indicated

$$V(t) = V_{\max} \cdot e^{-\frac{\ln 2}{T_{1/2}} t} \quad (13)$$

or

$$V(t) = V_{\max} \cdot 2^{-\frac{t}{T_{1/2}}} \quad (14)$$

Another important characteristic value for the behaviour of an artificial structure underneath a stable bottom is the average lifetime  $T_m$ .

By adjusting the assessed values, the average stability of the dredged volume defined as the area between the axis  $V(t)$ ,  $t$  and the function of sedimentation (eq. 5), it follows that

$$V(t) = V_{\max} e^{-\lambda t}$$

and from this

$$T_m = \frac{1}{V_{\max}} \int_0^{\infty} V_{\max} e^{-\lambda t} dt = \int_0^{\infty} e^{-\lambda t} dt = \left| -\frac{1}{\lambda} e^{-\lambda t} \right|_0^{\infty} = \frac{1}{\lambda} \quad (15)$$

With this, the average stability  $T_m$  for the structure result from the reciprocal value of the sedimentation factor  $\lambda$ . A more subordinated value in this context could be the remaining volume after expiration of the average lifetime:

$$V(T_m) = V_{\max} e^{-\lambda T_m} = V_{\max} e^{-1} = \frac{1}{e} V_{\max} \quad (16)$$

For practical applications, for example maintenance dredging, it is important to predict the time for determining re-sedimentation. Using the results above, this time could be calculated with the knowledge of the sedimentation factor  $\lambda$  respectively the half-life period  $T_{1/2}$ . If the required part of sedimentation is expressed with the factor  $p$  as percentage of the initial volume, it follows from eq. 6

$$V(t_p) = V_{\max} e^{-\lambda t_p}$$

with

$$V(t_p) = \frac{p}{100} V_{\max} \quad (17)$$

or

$$\frac{p}{100} V_{\max} = V_{\max} e^{-\lambda t_p} \tag{18}$$

and from this

$$\ln \frac{p}{100} = -\lambda t_p \tag{19}$$

the required time  $t_p$  as a function of  $\lambda$

$$t_p = -\ln \frac{p}{100} \frac{1}{\lambda} \tag{20}$$

or as a function of the half-live period  $T_{1/2}$

$$t_p = -\ln \frac{p}{100} \frac{T_{1/2}}{\ln 2} \tag{21}$$

Application

Using the information gained by repeated soundings which were a part of the observations made during re-sedimentation in the introduced test dredging, a first application of the theoretical considerations was made. The results are concentrated in table 2.

From equation 5, the respective sediment factor  $\lambda$  is calculated (column 4)

$$\lambda = -\frac{\ln V(t) - \ln V_{\max}}{t}$$

After the solution for  $\lambda$ , the half-life period is known as  $T_{1/2}$  from equation 11. Furthermore, the average lifetime  $T_m$  of the structure is one result. As one example in the last column shows, time  $t_p$  describes the span of time in which the artificial structure is refilled up to  $p = 10\%$  of the initial volume. The initial dredging volume  $V_{\max}$  was approx. 210,000 m<sup>3</sup> and the total observation time approx. one year (341 days).

Conclusion

Test dredging in connection with the design of an artificial approach and various observations provided the following main results:

- In general, re-sedimentation of the approx. 210,000 m<sup>3</sup> artificial underwater depression took on an exponential form over a one year period.
- Differences between sedimentation in a crater-shaped underwater structure and a channel as a negative line source exist but are highly influenced by the axis orientation in relation to the efficient current system.
- Based on the repeated measurements with echo sounding, the average sedimentation rate was calculated at 2.4 cm per day. To maintain a constant

depth as substantial as the one demanded for operating conditions, this value which in total equals approx. 9 m of sedimentation per year is important.

Table 2: Test dredging in the artificial approach - Niedersachsenbrücke -

V	ln V	t	$\lambda$	$T_{1/2}$	$T_m$	$t_p$ (p=10%)
[m <sup>3</sup> ]	-	[days]	[1/days]	[days]	[days]	[days]
212,650	12.267	0	-	-	-	-
201,900	12.216	3	0.017	41	59	136
194,530	12.178	12	0.0074	94	135	312
190,140	12.156	24	0.0046	151	217	502
171,780	12.054	54	0.0039	178	256	591
157,900	11.97	83	0.0036	193	278	641
126,200	11.746	116	0.0045	154	222	512
90,760	11.416	151	0.0058	120	172	399

80,390*	11.295	269	0.0036	193	278	641
35,410*	10.475	314	0.0053	131	189	435
Mean value			0.0061	140	201	465
Weighted Average			0.0046	152	220	508

\* Uncertainty in the echo sounding execution

- Due to the basic physical limitations of the echo sounding principle on such sloped bottoms, a precise determination of the underwater geometry is not possible (slope error, etc.). Normally, the slope given is too small.
- The average of the directly measured sedimentation rate over a two month period in the center area was determined at 4.1 cm/day by a linear gradient. Using this higher value, 15 m of sedimentation in one year must be calculated for dredging and disposal.
- During a strong gale of up to Bft No. 8, the sedimentation rate increased to 18 cm/day. After the event, there was a period without significant sedimentation which seemed remarkable.
- With respect to the area of the approach (~ 450,000 m<sup>2</sup>), the definition of the actual sedimentation rate will influence the choice of alternatives.
- In theory, the mathematical consequence is that continuous maintenance dredging in the horizon of the nautical depth will minimize the total quantity. Due to meteorological and hydrological as well as practical aspects, limitations must be considered.

- The need for repeated maintenance dredging in artificial coastal areas is determined by the number of stochastic meteorological events.
- When predicting sedimentation rates over a longer period, it is remarkable that single meteorological events do not necessarily increase the average value. This could be of importance for numerical simulation as well.
- After two years, no indication of the artificial depression could be determined by echo sounding.

## CHAPTER 227

### Risk assessment for coastal and tidal defence schemes

Meadowcroft IC<sup>1</sup>, von Lany PH<sup>2</sup>, Allsop, NWH<sup>3</sup> and Reeve DE<sup>2</sup>

#### ABSTRACT

This paper describes risk assessment techniques developed in a research project carried out for the UK National Rivers Authority (NRA) (Meadowcroft and Reeve, 1993). The main aim is to develop probabilistic design and analysis methods to assess the risks of failure for new and existing sea and tidal defence schemes. The flood risk takes account of the failure probability and the consequences of failure. There is a contrast between conservative design criteria that attempt to minimise failure rates, and risk-based design criteria that offer a more cost-effective solution despite a possible increase in failure frequency. The procedures are intended to be used in the design of new schemes, for assessment of existing defences and prioritisation of maintenance and refurbishment.

#### 1. INTRODUCTION

The paper outlines new procedures under development for the National Rivers Authority to assess risks of failure for new and existing sea and tidal defence schemes. The project includes assessment of areas at risk of flooding, but this paper concentrates mainly on risk assessment and probabilistic analysis of structures. The research is being used to formulate procedure for assessment of flood risk. The key elements of the procedures are:

- A tiered classification system;
- Modular procedures allowing more or less complex methods to be applied as appropriate;
- Risk defined as a combination of the probability and consequence of flooding;
- Screening tests using existing data such as that held in the National Sea Defence Survey (NSDS) to identify defences at greatest risk;
- Identification of principal failure modes and more detailed analysis of these using probabilistic methods;
- Advice on methods for flood area mapping and data collection as a means of

assessing the consequences of failure.

The paper firstly describes the overall structure of the procedures, and then examines in more detail the role of probabilistic methods in assessing flood risk.

**2. STRUCTURE CLASSIFICATION AND FAILURE MODES**

One of the first tasks of the research was to develop an appropriate classification system for structures. The classification system is hierarchical, based on three levels:

- Level 1: generic type eg narrow embankment with sloping face
- Level 2: general form of construction eg vertical wall with crest and back slope unprotected
- Level 3: detail of individual components eg revetment type

The advantage of this approach is that failure mechanisms at different levels of detail can be assigned to each level of the classification. The structure classification is used to guide preliminary assessment at the screening stage. The structure type affects its vulnerability to different failure mechanisms. Part of the structure classification system is

**Figure 1 Structure classification scheme. The structure type can be used as a guide to the most likely failure mechanisms, and to identify appropriate response functions.**

shown in Figure 1.

An example of the linkage between structure classification and response function is the selection of an appropriate method for calculating wave overtopping. Potential consequences of overtopping include flooding, danger to the public and damage to defence structures. Numerous methods are available depending on the geometry of the structure.

Four categories of structure each requiring different methods are detailed:

- i) For sloping seawalls, the actual overtopping,  $Q_{act}$ , may be calculated using an equation developed from the method by Owen (1980)

$$Q_{act} = A\theta \left( \frac{-B R_c J_r}{T_m \sqrt{gH_s}} \right) T_m g H_s \quad (m^3/s/mrun)$$

A and B can be obtained from standard tables

r is the effective roughness of the seawall slope, established from site visit or from table 3, Owen (1980)

$R_c$  is the freeboard (crest level minus water level)

- ii) For sloping seawalls with wave return walls, the method derived by Owen & Steele (1991) is appropriate. This extends from the method for sloping sea walls, with the freeboard being considered as the distance from SWL to the top of the wave wall, as opposed to the top of the seawall. It should be noted that this method was derived for recurved wave return walls and will therefore give a value which is less than the actual overtopping discharge for vertical wave return walls which experience a greater degree of overtopping.
- iii) Overtopping for vertical walls is calculated using standard graphs and the expression (Goda, 1971)

$$Q_{act} = Q \cdot (2gH_s^3)^{0.5}$$

- iv) For vertical seawalls with wave return walls, no defined method was found. It was concluded that the seawall and the wave wall should be considered as a single defence, taking the structure height as the height of the two defences combined. The method for standard vertical walls can then be applied.

Table 1 illustrates a simple look-up procedure to link seawall type, profile classification and calculation method. Profile references refer to the structure types identified in Figure 1.

A wide range of other failure mechanisms have been identified and appropriate response functions recommended (eg Allsop 1993).

Structure type	Profiles	Method
Sloping seawall	1.1, 1.2, 2.1, 2.2	(i)
Sloping seawall with wave return wall on crest	1.3, 1.5, 1.7, 2.3, 2.5	(ii)
Vertical seawall	3.1, 3.3, 3.5, 4.1, 4.3	(iii)
Vertical seawall with wave return wall	3.2, 3.4, 3.6, 4.2, 4.4 (assuming height of structure to be sum of seawall and wave return wall heights)	(iv)

**Table 1 Overtopping calculation method depending on structure classification**

A survey of flood defence failures has been undertaken as part of the project. This has shown that, while there have been a numerous reported flood events due to defence failures, information about failures of defences is normally very limited in scope, and is rarely sufficient for identifying the precise sequence of mechanisms leading to a failure. One may gain more useful information from studying rates of damage and deterioration, where the condition of the defence may indicate potential failure mechanisms.

#### Damage cause by burrowing animals

According to anecdotal and documented information from NRA staff, a particular area of concern is the damage caused by burrowing animals such as rabbits and badgers. The main problems are the serious structural damage caused, including voids and passages through embankments, the difficulty in carrying out effective repair, short of re-building the affected part of the embankment, and the likelihood of re-infestation. The number of rabbits, in particular, can be particularly difficult to control. In one severe case, over 1000 rabbits are reported to have been killed over a few months, but the embankment continues to be colonised. Conservation interests can have a great influence on the measures taken. There are, for example, controls on the disturbance of badger setts.

The project has found very little information on the effect of animal burrows on embankment safety and flood risk, either in terms of animal behaviour or from the point of view of hydraulic and geotechnical impacts. Research is at present underway to fill some of these gaps, but in the meantime, approximate methods such as assuming a reduced effective crest level can be used. Site investigation is also important, from recording the number of burrows, and their positions, to mapping the internal structure of voids caused by animals. Non-destructive investigation techniques may have potential to investigate the size, extent and location of burrows and other voids.

### 3. RISK ASSESSMENT METHODS

There are several different definitions of 'risk', but for our purposes, risk is defined as the combination of the probability or frequency of occurrence of a defined hazard, and the magnitude of the consequences. The method of combination is generally to multiply the probability and consequences. This gives a measure of the expected value of the consequence incurred in the time period being considered. Risk as defined is thus closely related to the assessment of benefits which is commonly carried out as part of the project appraisal process.

Even within the relatively narrow topic of flood risk, there are a number of aspects of risk likely to be of interest to user of the procedures:

- The danger to the public from flooding, expressed in terms of number of injuries or deaths, and associated frequency
- The probability of death or injury to individuals
- The frequency of flooding at different locations in the potential flood area taking account of all the possible causes of flooding and all possible failure mechanisms. This information can be shown as frequency contours.
- The depth and duration of flooding.
- The degree of risk inherent in each defence structure ie the expected annual consequences of failure of the structure
- 'What if' scenarios, ie flood outlines conditional upon some prescribed defence failure

A general procedure for risk assessment is illustrated in Figure 2, which illustrates the process of hazard identification, and assessing the probabilities and consequences of failure.

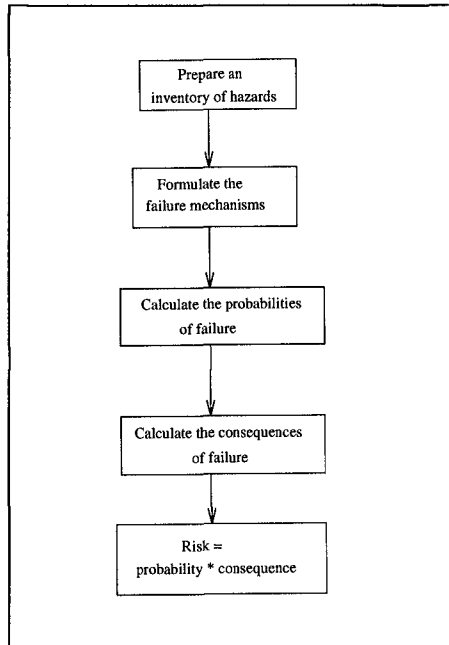

Although the concept of risk is straightforward, the implementation is complicated because a full risk assessment must consider *all* hazards which could result in damage or loss. Clearly some hazards will make an insignificant contribution compared to others, but in principal all hazards must be identified and studied as far as necessary to establish what degree of risk they pose. Similarly, even a relatively simple structure will have a number of potential failure mechanisms, and it will not usually be known with certainty which are the most likely to contribute most to the risk.

The procedure illustrated in Figure 2 should therefore be repeated for different hazards, and for different failure mechanisms. This would result in a large amount of work which would prevent the wide application of detailed risk assessment. This explains the need for simplified procedures to screen out 'low risk' structure and to identify those in need of the most detailed analysis.

The project has identified failure modes, defined as a number of individual mechanisms. Failure mechanisms are described using a nested system to reflect the level of detail of the classification system. At Level 1, the failure mechanisms are simply breaching and overtopping/overflow. At Level 2, we identify mechanisms affecting the main parts of the structure such as the seaward face, crest, and landward face. Level 3 considers failure of individual structure elements such as

breakage of revetment units.

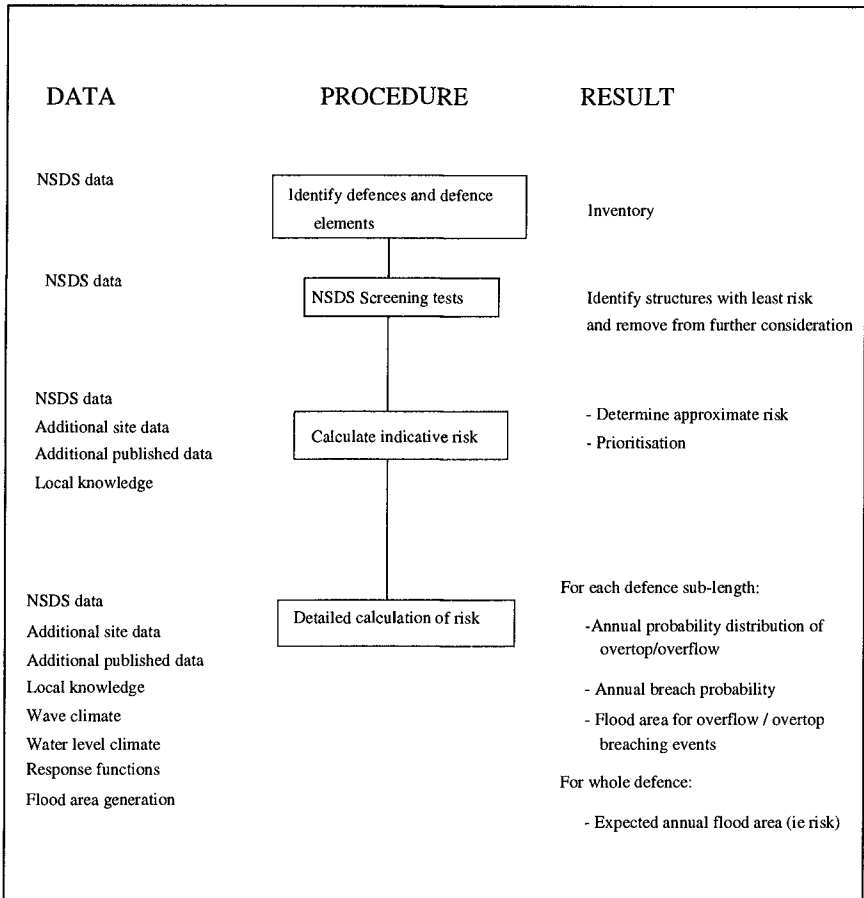

One of the early findings of this work was that, whilst conventional fault trees and event trees as used in the electronics and chemical industries may be suitable for systems of binary components that either fail or do not fail, they are not sufficient on their own for failure of sea walls and related structures. These exhibit complex failure modes with interactions between different damage mechanisms. For example, overtopping and geotechnical slope failure of the landward face of an embankment may not, individually, pose a high risk, but the damage due to the geotechnical failure will make erosion due to overtopping much more likely: the mechanisms interact. Furthermore, the quantity of water overtopping may be very important in determining the area flooded and hence the consequence: one cannot talk only of 'failure' and 'no failure' for this type of risk assessment, since a spectrum of outcomes can result.

**Figure 2 Overall procedure for risk assessment (from CUR/TAW, 1990)**

The project considers a number of practical techniques for dealing with a broader range of mechanisms needed for an assessment of a sea defence system. One particular method makes use of 'event chains' leading from a particular trigger event (ie storm), through failure mechanisms to set a of consequences. For each consequence, a probability of occurrence is calculated, conditional upon the initial event. It is necessary to incorporate connections between some event chains, to account for the physical dependence noted above.

An advantage of the method is that it provides a framework which can be applied at several levels of complexity, providing a modular approach at each level of detail appropriate to the degree of risk and data availability. This tiered approach is illustrated in Figure 3. The first steps make use of data already held by the NRA as part of the National Sea Defence Survey (NSDS). This has created a set of data about sea defences in England and Wales, including information such as the length and position of defences, and an assessment of their condition and effectiveness. The survey includes classification of the area of the potential flood area and the land use within that area. Thus the NSDS provides an important starting point for assessing risk. Automated screening tests have been developed using this data, and the indicative or relative risk is also based partly on NSDS data. More detailed assessment of risk requires additional site-specific data.

**Figure 3 Tiered assessment procedure showing level of data, analysis and results at each stage**

#### 4. PROBABILISTIC METHODS

Probabilistic methods are used to account for uncertainty in data values or in response functions. The main sources of uncertainty are:

- Identification of hazards
- Identification of failure processes / failure modes
- Development of damage leading to failure, time effects
- Data on load parameters, lack of data or errors in data
- Long term changes including climate changes
- Stochastic nature of loading, even if statistics are well known
- Structure geometry and material properties
- Responses: form of functions and empirical coefficients

- Thresholds for failure

Probabilistic methods can be applied to account for many of these uncertainties to give an estimate of the response which is consistent with our level of knowledge or ignorance. This estimate will generally be in the form of a probability distribution, although if a threshold for failure is defined, the result may be in the form of a failure probability. Of course, the exact *actual* or realised failure probability of a particular structure will only be known in the future, and it will have a value of either 0.0 or 1.0, but random variations in loads, and uncertainties in strengths and response functions prohibit us from predicting failure or otherwise exactly. We can only hope to estimate a probability of failure based on current knowledge.

Probabilistic methods enable uncertainties in strength and loading variables to be propagated through the risk assessment procedure. The final risk assessment therefore takes account of lack of precise knowledge of the structure properties, the environmental loading, and the response function. Probabilistic methods provide a basis for accounting for the effects of uncertainty in a structured and systematic manner. These can have significant cost and benefit implications. Probabilistic methods may be subjective, based on engineering opinion, or objective, based on Monte-Carlo sampling or analytical methods.

Development and application of probabilistic methods for structural design and analysis is described in more detail elsewhere (CIRI, 1977, Thoft-Christensen & Baker 1982). Application of a range of methods to coastal structures is described by Meadowcroft & Allsop (1994).

The simplest analytical methods (known as Level II, first order mean value methods) are in fact closely related to sensitivity tests: the key advantage is that they account for the variability in input parameters as well as the sensitivity of the response to the inputs, and probabilistic methods take account of the combined effects of variability of all relevant parameters.

Several examples are now given which illustrate the data required and results obtained from probabilistic methods.

#### Example 1: Level III (Monte Carlo sampling) prediction of damage to a rock armour structure

This simplified example demonstrates clearly the influence of variability in input parameters on the resulting prediction. The response function is the Van der Meer (1988) equation to predict the degree of damage,  $S$ , to rock armour under plunging waves as a function of structure and load parameters. In this case, the occurrence of the design storm is presumed, so the variability results from uncertainty in structure parameters such as rock armour size, and from errors in estimating the design wave height. There is also some uncertainty in the values of the empirical parameters  $a$  and  $b$  in the response equation: these can be treated like any other probabilistic input parameter.

Input parameter	Distribution	Standard deviation (coefficient)	Mean
Significant wave height $H_s$ (m)	Normal	10%	3.0 (depth limited to 0.55h)
Slope angle ( $^\circ$ )	None	-	0.5
Rock density ( $\text{kgm}^{-3}$ )	Normal	5%	2650
Nominal rock diameter $D_{n50}$ (m)	Normal	5%	1.3
Permeability parameter P	None	-	0.1
Wave steepness $s_m$	Normal	10%	0.05 (truncated at 0.07)
van der Meer parameter a	Normal	10%	6.2
van der Meer parameter b	Normal	10%	0.18

**Table 2** Input distributions for calculating probability distribution of damage

**Figure 4** Probability distribution for damage to rock armour structure

The resulting probability distribution (Figure 4) shows predicted damage for a structure designed for minor damage ( $S=2$ ). Reliability of the structure against other damage levels can be assessed. The probability of the damage exceeding 5, for example, is about 16%, and for  $S=8$ , corresponding to severe damage, about 3%.

Example 2 Level II assessment of damage due to overtopping

The amount of wave overtopping is a principal indicator of damage and failure of coastal structures. It is therefore important to be able to calculate the probability that a structure will fail to meet acceptable criteria for overtopping. These include the ultimate limit state (ULS) corresponding to damage which may lead to complete collapse and breach, and serviceability limit state (SLS) corresponding to failure to meet a service criteria such as danger to the public.

Level II methods are used to produce analytical approximations to the probability of failure. They are based on partial differentiation of the response function with respect to each of the probabilistic input variables.

The simulations shown below were carried out using a Level II probabilistic method, the Approximate Full Distribution Approach (AFDA). This is a relatively sophisticated technique that enables the use of input probability distributions which are non-normal, and uses iteration to converge on a more accurate solution than the mean value approach. Results in Table 3 show the impact of raising the crest of a structure on the annual probability of failure due to excessive wave overtopping. These results are illustrated in Figure 5, together with the annual probability of exceedance of a serviceability criteria.

Crest Level (mAD)	Annual probability of severe damage due to overtopping (ULS)
14.0	0.72
16.0	0.28
18.0	0.08
20.0	0.03

**Table 2** Example of results of probabilistic analysis of a seawall to establish annual probability of severe damage at an ultimate limit state, ULS.

A key advantage of the full distribution method is its ability to cope with non-normal distributions. In this example, the significant wave height and still water level were both specified using Weibull distributions. Use of distributions fitted to all data rather than to annual maxima or other selected data enables two or more time-varying load variables to be combined simply. It is not necessary to consider the reduced probability of an extreme value of one variable occurring at the same time as the extreme value of another. In this case waves and water levels are independent although techniques are available to incorporate correlation into Level II methods.

**Figure 5 Probabilistic analysis of overtopping: annual failure probability for serviceability and ultimate limit states**

### Example 3 Probabilistic assessment of slope stability

This example illustrates the use of the Level II method in conjunction with a numerical model of slope stability. The advantage of this approach over the Level III method is that it is not necessary to carry out many repeat simulations to build up the resulting probability distribution. This can be particularly onerous when predictions are made using a computationally-intensive numerical model.

The method relies on carrying out a small number of model runs to enable numerical, rather than analytical differentiation of the response with respect to each probabilistic input variable. In this way a fundamentally deterministic model is used to produce probabilistic results by appropriate selection of input data and suitable analysis of the results.

The model in this case was SLOPE, part of the Oasys suite of geotechnical programs. This was used to analyse a circular slip surface on the landward face of an earth embankment (Figure 6). The model gives the factor of safety  $F$ , which is essentially the restoring moment divided by the disturbing moment. Thus a value of  $F$  less than 1 indicates failure of the slope.

Figure 6 Circular slip failure mechanism for an earth embankment.

Input parameter	Distribution	Standard deviation (coefficient)	Mean
Cohesion $c'$ ( $\text{kNm}^{-2}$ )	Normal	29%	9.0
Angle of friction $\phi'$ ( $^\circ$ )	Normal	16%	31
Dry density $\gamma$ ( $\text{kNm}^{-3}$ )	Normal	2.5%	16
Phreatic surface $R_u$	Normal	8%	0.50

Table 4 Data used for Level II slope stability prediction

Probabilistic data is given in Table 4. All data was assumed to be normally distributed. The factor of safety calculated from the mean values was 1.6, but given the prescribed variability in soil properties, the probability that the factor of safety is less than 1.0 is 0.03, or 3%.

5. CONCLUSIONS

The risk assessment procedures outlined here encompass a broad range of activities, including identification of hazards and key failure modes, classification of structures, assessment of hydraulic loading conditions, probability of failure due to the principal failure modes and modelling consequences in terms of flooded areas.

In view of the number of defences to be assessed, we have adopted a tiered approach for classification and analysis: the early stages are characterised by approximate screening procedures, with more detailed assessment on selected defences thought to be at highest risk.

The results of this project will substantially improve the methods available to analyse the risks of failure for existing flood defence schemes, and to design new schemes to agreed risk levels. The procedures will provide a consistent, rigorous framework for comparative assessment of a wide range of flood defences in tidal and coastal

regions.

## 6. ACKNOWLEDGEMENTS

The research on which this paper is based has been supported by the UK National Rivers Authority (NRA) R&D Commission C - Flood Defence. Additional information has also been used from research at HR Wallingford supported by the Department of the Environment (DoE) under research contract PECD 7/6/248. The views expressed here are those of the authors and not necessarily those of the NRA or DoE.

## CHAPTER 228

### Water oxygenation in the vicinity of coastal structures due to wave breaking

C. I. Moutzouris<sup>1</sup> and E. I. Daniil<sup>2</sup>

#### Abstract

Experiments on oxygenation due to breaking waves on a uniformly sloping beach and on an S - type breakwater were performed. The water was chemically deoxygenated and dissolved oxygen (D.O.) concentration was followed over time in characteristic locations. Experimental data showed that the transfer velocity increased with increasing wave height for waves of the same frequency. Experiments with waves of the same wave height but increasing wave frequency showed also an increase in transfer velocity. The breakwater data give lower transfer velocities as compared to the sloping beach data for the same wave characteristics.

The one - dimensional transport equation was used for the determination of the transfer coefficients. Analysis of the data indicated that the transfer coefficients varied almost linearly with the vertical wave velocity at the water surface. A rather good linear correlation was obtained for the breaking wave data on the sloping beach, with much higher slope as compared to the case of non-breaking waves.

#### Introduction

Air/water gas transfer for water bodies is one of the main sources of dissolved oxygen (D.O.), an often used water quality index. It also acts as a sink of carbon dioxide and other greenhouse gases and has a significant role in global biogeochemical cycles of atmospheric compounds. Finally, air/water gas transfer is an important parameter in the design of hydraulic structures, as in the case of stepped chute spillways (Chanson, 1994), and can be used beneficially, as in the case of the SEPA (sidestream elevated pool aeration) project of the Metropolitan Water Reclamation District of Greater Chicago, that was awarded the 1994 Outstanding Civil Engineering Achievement Award (Civil Engineering, 1994).

Research on oxygenation dates back to 1925 (Streeter and Phelps, 1925, Streeter, 1926), when river pollution problems started to appear. Gradually,

interest spread to other water bodies (e.g. lakes and oceans) and other gases, such as carbon dioxide and methane (Brutsaert and Jirka, 1984, Wilhelms and Gulliver, 1991). Although air/water gas transfer is controlled by the interaction of the air/water boundary layer, the wave field is a parameter that has rarely been included in the predictive equations so far. However, its effect has often been noted qualitatively. Experiments on the effect of waves on gas transfer have been reported by Hosoi et al (1977), Hosoi and Murakami (1986), Jähne et al (1985,1987), Daniil and Gulliver (1991) and Wanninkhof and Bliven (1991). For lakes and oceans the transfer coefficient is usually correlated to the wind velocity. It should be noted though, that laboratory data and field data give different correlations and do not compare favorably (Liss, 1983, Daniil, 1988). It is generally recognized that the presence of waves increases the penetration of gases into the water. Gas concentrations in the water mass are found to be higher when waves are present, due to the action of a steering mechanism on the interface. Therefore, waves may be considered to have a positive effect on the oxygenation of water bodies. In the experiments of Hosoi et al (1977) D.O. was measured in one location of the flume only and neither the effect of horizontal diffusion nor the uniformity of D.O. concentration across the flume was investigated. Hosoi and Murakami (1986) measured the D.O. distribution across the flume. They concluded that oxygenation due to non-breaking waves was negligible and assumed that the whole flume is oxygenated through the breaking wave zone. This assumption yields much higher transfer coefficients than what would have been obtained if oxygenation through the remaining free surface had also been taken into account.

Wave breaking is a highly turbulent physical mechanism, that essentially creates a two phase flow, which facilitates the transfer of gases considerably. Therefore, it is believed that breaking waves have a further positive effect on the oxygenation of water masses. Until now the effect of wave breaking in water oxygenation has been described mostly qualitatively. Hosoi et al (1990) performed a number of experiments on reaeration due to wave breaking at coastal structures and proposed an equation indicating that the reaeration coefficient is correlated with the dissipated energy. They also note that in their experiments aeration increased with the height of incident waves and with the width of the breakwater. Moreover, impermeable sloping seawalls were more effective in promoting aeration than other structures.

A research program has started at the Laboratory of Harbour Works, Civil Engineering Department, National Technical University of Athens (NTUA) in order to investigate and quantify the effect of breaking waves on oxygenation. Oxygenation due to breaking waves is studied experimentally in a wave flume with a uniformly sloping beach (Daniil and Moutzouris, 1993, 1994a, b) and with an S-type breakwater. The influence of increasing wave frequency and wave height on the oxygen transfer coefficient is discussed.

### **Experimental Procedure**

Experiments on the transfer of oxygen under breaking waves were conducted in a wave flume of the Laboratory of Harbour Works, NTUA. The dimensions of the flume are 27.40 (length) x 0.60 (width) x 1.53m (height). A smooth sloping beach with a uniform slope of 1 (vertical) : 2.3 (horizontal) was

placed at the one extremity of the flume (Fig. 1). The water was chemically deoxygenated. Details for the experimental setup have been presented previously (Daniil and Moutzouris, 1993, 1994 a, b).

Fig. 1. Longitudinal view of the wave channel with the smooth sloping beach.

Additional experiments were performed with an S - type rubble mound breakwater with a slope of 1 (vertical) : 1.5 (horizontal) located 15.0 m from the wave maker (Fig. 2).

Fig. 2. Longitudinal view of the wave channel with the rubble mound breakwater.

Monochromatic waves were created by a wave generator of the piston type. The waves propagated along the flume and broke over the sloping beach or the breakwater. For the sloping beach experiments D.O. concentration in the water body was followed over time in three locations along the flume. Wave heights tested ranged from 5.6 to 15 cm and wave periods from 0.75 to 1.60 sec. For the breakwater experiments D.O. concentrations were measured in front and behind the structure. Wave heights tested ranged from 5.6 to 28.0 cm and wave periods from 0.75 to 1.60 sec. The water depth was 0.60 m for all experiments with the exception of experiment K6 that had a water depth of 0.83 m. Experimental conditions are shown in Table 1 for both sets of experiments.

#### Data Acquired

Fig. 3 shows D.O. - time histories as obtained from experiments B9, B6 and B7 with waves of the same frequency ( $T=1.45$ sec), but different wave height

( $H = 14.9, 12.0, 9.1$  cm) in the presence of the sloping beach. It is concluded that the transfer velocity increases as the wave height increases. Moreover, D.O. concentration becomes more uniformly distributed seawards of the breaker zone as the wave height increases, due to increase of horizontal dispersion. Similar comparison of D.O. - time histories for experiments with waves of almost the same height, but differing frequency shows that the transfer velocity increases, as the wave frequency increases.

**Fig. 3.** Comparison of D.O. - time histories for waves of the same frequency but different wave height breaking on a sloping beach (after Daniil and Moutzouris, 1993)

D.O.- time histories in the presence of (i) a sloping beach and (ii) a breakwater are presented in Fig. 4. Concentrations are found to be lower in front of the breakwater than along the sloping beach, due to a more moderate wave breaking in the former case. D.O. concentrations are found to be very low behind the structure and to increase in time due to transport of oxygen through the body of the breakwater. The saturation concentration,  $C_s$ , is also noted for the two cases ( $C_s = 8.4$  mg/l for the sloping beach and  $C_s = 9.86$  mg/l for the breakwater).

Fig. 4. D.O. - time histories for waves (incipient wave:  $H=7.1$  cm,  $T=0.75$  sec) breaking (i) on a sloping beach (open symbols) and (ii) on a breakwater (solid triangles refer to the concentration in front and solid circles to the concentration behind the breakwater).

#### Data Analysis

The one-dimensional transport equation was used for the analysis of the data. Data from locations where the composite effect of the horizontal transport was assumed to be negligible were used for determining the oxygen transfer coefficient. The transfer coefficient is determined from the following equation, using linear regression and the measured D.O. concentrations:

$$\ln (C_s - C) = -K_L (A/V) t + \ln (C_s - C_0) \quad (1)$$

where  $C$ ,  $C_0$  and  $C_s$  are the average, initial and saturation D.O. concentrations, respectively.  $K_L$  is the oxygen transfer coefficient,  $t$  is time,  $A$  is the projected free surface area on the horizontal plane and  $V$  is the aerated volume extending from the free surface to the bottom of the channel.

The coefficients  $K_L$  obtained from the above procedure, along with the wave parameters used in the correlations presented in the following sections, are listed in Table 2. The transfer coefficients were translated to 20° C according to the equation given by Daniil and Gulliver (1988):

$$(K_{L20}/K_L) = (Sc/Sc_{20})^{1/2} = (v/v_{20}) [293/(\theta+273)]^{1/2} (\rho/\rho_{20})^{1/2} \quad (2)$$

where  $Sc = v/D$  is the Schmidt number ( $Sc_{20} = 546$ ),  $v$  is the kinematic viscosity of water,  $D$  is the molecular diffusivity of oxygen in the water,  $\theta$  is the water temperature in degrees Celsius and  $\rho$  is the water density. The subscript 20 denotes the value of the corresponding parameter at 20° C. The water properties were determined by the relations given by Heggen (1983).  $H$ ,  $L$  and  $f$  are the wave height, length and frequency, respectively.

**Table 2.** Oxygen Transfer Coefficients and wave parameters used in the correlations for breaking waves on a sloping beach and on a rubble mound breakwater

Exp. No.	Satur. Conc. $C_s$ (mg/l)	Schmidt number $Sc$ (-)	$Hf \times 100$ (m/sec)	Transfer Coeff. $K_{L20} \times 10^5$ (m/sec)	Transfer Coeff. $K_L \times 10^5$ (m/sec)	Transfer Coeff. $K_L Sc^{1/2} \times 10^4$ (m/sec)
<b>Sloping beach data</b>						
A3	8.4	458	6.19	2.7	2.9	6.2
A2	8.3	446	5.24	5.0	5.5	11.6
B7	11.0	918	6.28	8.3	6.4	19.4
B6	11.2	967	8.28	15.0	11.3	35.1
B9	11.0	912	10.28	22.0	17.0	51.3
A4	8.7	506	7.47	5.1	5.3	11.9
A5	8.4	455	9.47	9.0	9.9	21.1
B8	12.0	1096	9.73	15.0	10.6	35.1
<b>Breakwater data</b>						
K2a	9.9	716	6.19	3.2	3.7	8.6
K3	8.3	450	8.28	6.9	6.3	14.6
K6	10.6	809	19.3	23.3	28.4	66.3
K2b	9.9	716	7.47	3.6	4.1	9.6
K1	9.9	701	9.47	6.3	7.1	16.7

The oxygen transfer coefficients  $K_L$ , as determined from the above analysis, are compared to the relation obtained for non-breaking waves by Daniil and Gulliver (1991). The two authors related the transfer coefficient to

the vertical wave velocity at the water surface and used a renewal model to express the average renewal rate as a function of a wave Reynolds number. They derived the following equation:

$$K_L Sc^{1/2} = 0.0159 H f \quad (3)$$

For breaking waves on a sloping beach from the present experiments the following equation was fitted to the data:

$$K_L Sc^{1/2} = 0.066 H f - 2.80 \times 10^{-3} \quad (\text{m/s}) \quad (4)$$

Equation (4) holds for  $H f > 0.056$  m/s, which was approximately the low limit of the present experiments, and expresses the general trend of the oxygen transfer coefficient for breaking waves. It is felt that a further expansion is needed to include a parameter describing the non-linearity of the breaking.

A comparison of the results obtained (see Fig. 5) shows that oxygenation in front of a breakwater is less significant than in the presence of a sloping beach, due to a less intense penetration mechanism. Breakwaters are causing wave reflection, which reduces the degree of wave breaking.

Equations (3) and (4) are compared to the experimental data in Fig. 5.

### Discussion

The experiments reported in the present paper demonstrate the importance of breaking waves in nearshore oxygenation. The oxygen transfer coefficient was described through a surface renewal model. The average surface renewal rate was correlated to the wave characteristics and the oxygen transfer coefficient was found to be proportional to the maximum vertical wave velocity at the water surface. The correlation for the breaking wave data on a sloping beach gave a much higher slope than that for non-breaking waves. Breakwater data give lower transfer coefficients compared to the sloping beach data, but higher than the non breaking waves for the same wave characteristics. The obtained relation for the sloping beach data needs to be extended in order to incorporate breaking wave parameters.

The experimental results presented here were obtained using tap water. They could be translated to seawater if the corresponding Schmidt number and the saturation concentration for seawater were introduced. Nevertheless, it is noted here that experiments by Downing and Truesdale (1955) on the effect of wind using seawater and distilled water had shown no significant difference.

Undoubtedly, the results are influenced by the scale of the experiments conducted. Scale effects are believed to be significant. For this reason, the research program of the Laboratory of Harbour Works, NTUA, was recently enlarged with further experiments executed in the large wind-wave facility of Delft Hydraulics, The Netherlands. The experiments were financed by the European Community Large Installations Program (LIP). A preliminary analysis of the experimental data collected clearly shows that oxygenation rates are considerably reduced, as a result of the larger dimensions (Tsoukala and Moutzouris, 1994, personal comm.).

Fig. 5. Variation of the transfer coefficients with the wave parameter  $H_f$ .

A first conclusion from the present experiments is that incorporating wave characteristics in water quality models can improve the design of nearshore sewage outfalls, taking advantage of the "self-cleaning" capacity of the water body. Coasts in which wave breaking is a dominant mechanism present considerable advantages from the point of view of oxygenation of the effluent by physical mechanisms. Disposing the effluent near the breaking wave zone can possibly be combined with reduced treatment, thus leading to a more economic design.

A second conclusion is that coastal structures, such as breakwaters, reduce the oxygenation rate of seawater, due to increased wave reflection. This could have some negative influence on the fauna, although the beneficial effect of rubble-mound structures to the number of fish population and the types of species developed in the area is by now well documented.

## CHAPTER 229

### Environmental Assessment of Hypothetical Large-Scale Reclamation in Osaka Bay, Japan

Keiji Nakatsuji<sup>1</sup>, Toshiaki Sueyoshi<sup>2</sup>, Kohji Muraoka<sup>1</sup>

#### ABSTRACT

In urban coastal areas in Japan, large-scale reclamation projects have recently increased, which have caused drastic changes in topographical features of the coastline. In Osaka Bay, the sea area of 5,200 ha have been reclaimed in the past 40 years and many development projects are under construction. As a natural consequence, the sea water has been polluted due to poor exchange of water with outer oceans and the load of nutritious substances discharged from rivers; hence, algal blooms occur independent of season and anoxia appears near the sea especially in summer. A 3-D baroclinic flow model is proposed to predict the tidally-interacting estuarine circulation and residual baroclinic currents in Osaka Bay and to evaluate the effects of hypothetical large-scale reclamation on the estuarine system.

#### INTRODUCTION

Osaka Bay is one of semi-enclosed urban coastal seas in Japan. High density populated and industrialized cities such as Osaka and Kobe are located at the head of Osaka Bay. The GNP (Gross National Product) of Osaka Prefecture approximately corresponds to that of Australia, in addition, the total amount of GNP of Osaka, Kobe and Kyoto does to that of Canada. Area of Osaka Bay is only 1400 km<sup>2</sup> and its mean depth is 28 m. In the past 40 years the coastal area of 5,200 ha have been reclaimed for satisfying the economical and industrial demand, and lots of development projects are under construction including a 511 ha for newly-built Kansai International Airport Island. As a result, the sea water has been polluted due to poor exchange of water with outer oceans and the load of nutritious substances from rivers; hence, algal blooms near the sea surface and anoxia near the sea bottom have

-----  
1 Dept. Civil Eng., Osaka University, Osaka 565, Japan.

2 Former student, Osaka University, Osaka 565, Japan

had adverse effects on fishery and recreation. Such a tendency, however, will have to continue because of the limited land and increasing volume of industrial and domestic waste products in the countries of their limited territory like Japan. Strategies for optimum environmental conservation must be examined in order to achieve integrated and multiple utilization of coastal seas in a sustainable manner.

Figure 1 shows a drastic change in topographical features of the coastline in Osaka Bay due to reclamation. The area of total reclaimed land is only 4 % against the total area of Osaka Bay at the present time. It, however, corresponds to 76 % as compared with the area of coastal waters shallower than 10 m depths. Such coastal area is of great importance for the special nursery of the fish and shellfish. Figure 2 shows the variation of shellfish catch with a cumulative area of reclaimed coastal area. It indicates that the reclamation causes strong damage to fishery.

Authors(1992) had already examined the impact assessment of large-scale reclamation on the tidal flow system and water quality transfer by the depth-integrated, two-dimensional finite element method. In the present study, since the density-induced current system is found to be of great importance, a three-dimensional baroclinic flow model is proposed to predict residual baroclinic currents and a tidal front observed in Osaka Bay and to evaluate the effects of hypothetical large-scale reclamation on the estuarine system.

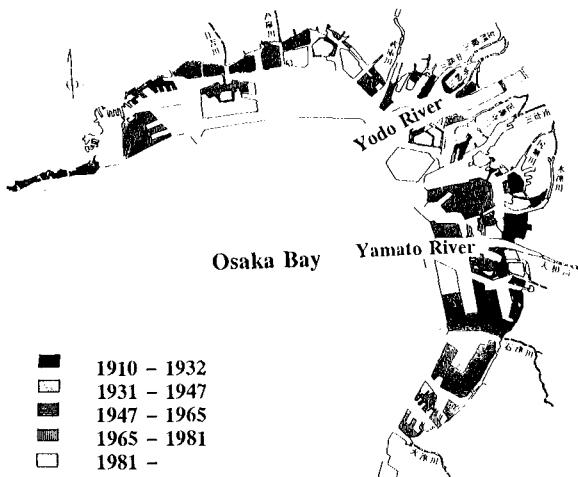

Figure 1. Change of shoreline due to reclamation projects in Osaka Bay.

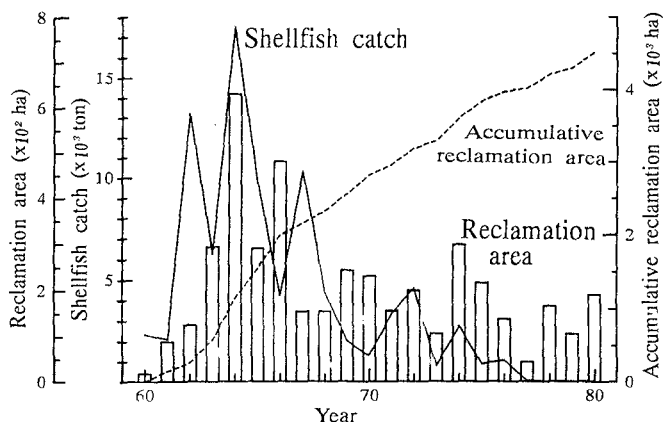

Figure 2. Variation of shellfish catch and cumulative area of reclamation.

### MODEL DESCRIPTION

The computation solves the primitive equations of the ocean, governing the conservation of volume, momentum in three dimensions and density-difference simplified by the Boussinesq assumption and hydrostatic equilibrium.

$$\frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} + \frac{\partial W}{\partial z} = 0 \quad (1)$$

$$\frac{DU}{Dt} - fV = -\frac{1}{\rho} \frac{\partial P}{\partial x} + \frac{\partial}{\partial x_i} (\epsilon_i \frac{\partial U}{\partial x_i}) \quad (2)$$

$$\frac{DV}{Dt} + fU = -\frac{1}{\rho} \frac{\partial P}{\partial y} + \frac{\partial}{\partial x_i} (\epsilon_i \frac{\partial V}{\partial x_i}) \quad (3)$$

$$0 = -g - \frac{1}{\rho} \frac{\partial P}{\partial z} \quad (4)$$

$$\frac{D\Delta\rho}{Dt} = \frac{\partial}{\partial x_i} (K_i \frac{\partial \Delta\rho}{\partial x_i}) \quad (5)$$

where  $(U, V, W)$  are velocities in the  $x, y$  and  $z$  directions,  $\zeta$  is the water elevation,  $P$  is the pressure,  $\Delta\rho (= \rho_s - \rho)$  is the density difference from the sea water density ( $\rho_s$ ),  $D/Dt$  is a nonlinear operation such that  $DA/Dt = \partial A/\partial t + \partial(UA)/\partial x + \partial(VA)/\partial y + \partial(WA)/\partial z$ ,  $\epsilon_i$  and  $K_i$  are the

eddy viscosity and diffusivity coefficients respectively in each direction, and  $f$  is the Coriolis parameter ( $0.8296 \times 10^{-4} \text{ s}^{-1}$ ). The pressure is obtained by integrating the vertical momentum equation (4) from the water surface ( $z = -\zeta$ ) to any depth. Therefore, the pressure gradient  $\partial P / \partial x_i$  can be expressed as a sum of the water surface gradient  $\partial \zeta / \partial x_i$  (barotropic mode) and the density gradient  $\partial \Delta \rho / \partial x_i$  (baroclinic mode).

A first-order closure scheme is used to account for the eddy viscosity and diffusivity coefficients. A small horizontal eddy viscosity or diffusivity ( $20 \text{ m}^2/\text{s}$ ) is used in all model runs. On the other hand, the vertical eddy viscosity coefficient are affected by the reduction of turbulence due to stable stratification. On the basis of the study of three-dimensional buoyant surface discharges by Murota et al. (1989), the Webb formula (1970) and Munk and Anderson's formula (1948) are adopted for  $\epsilon_z$  and  $K_z$ , with a neutral value of  $\epsilon_{z_0} = 0.005 \text{ m}^2/\text{s}$ . Both empirical formulae are functions of the gradient Richardson number,  $Ri \equiv g(\partial \rho / \partial z) / (\partial U / \partial z)^2$  as follows;

$$\epsilon_z / \epsilon_{z_0} = (1 + 5.2 Ri)^{-1} \quad (6)$$

$$K_z / \epsilon_z = (1 + 10/3 \cdot Ri)^{-3/2} / (1 + 10 \cdot Ri)^{-1/2} \quad (7)$$

In the computation of tidal flow, however, turbulence energy in straits becomes unrealistically large. Hence, the values of  $200 \text{ m}^2/\text{s}$  and  $0.05 \text{ m}^2/\text{s}$  are used near the straits for horizontal and vertical eddy coefficients, respectively.

Boundary conditions are the following. The model basin is initially filled with saline sea water of  $1022 \text{ kg/m}^3$ . Freshwater of zero salinity then flows near the surface from rivers located in the estuary head. The model ocean is everywhere bounded by solid vertical walls except the river mouth and the open seas.

Vertical walls are assumed impenetrative and slip, so that for solid boundary

$$\rho \epsilon_h \partial(U, V) / \partial x_h = \tau_h, \quad K_h \partial \Delta \rho / \partial x_h = 0, \quad V_n = 0 \quad \text{and} \quad \partial \Delta \rho / \partial x_n = 0 \quad (8)$$

where 'h' mean the normal and tangential components to the boundary and  $\tau_h$  means the shear stress along the boundary.

At the river mouth, the time-variation of river discharges is given according to the observed hydrographs and the water elevation is assumed to be zero, so that

$$Q = Q(t), \quad \Delta \rho = 0.0, \quad \partial \zeta / \partial x_n = 0 \quad \text{at river mouth} \quad (9)$$

The open sea boundaries are

$$\partial(U, V) / \partial x_n = \partial \Delta \rho / \partial x_n = \zeta = 0 \quad (10)$$

When a tidal flow is taken into account, the time variation of tidal elevation is added on the basis of harmonic analysis of observed tidal elevation,

$$\partial(U, V) / \partial x_n = \partial \Delta \rho / \partial x_n = 0 \quad \text{and} \quad \zeta = \zeta(t) \quad (11)$$

On the free surface ( $z = -\zeta$ ), fluxes of momentum and density are zero, so

$$\partial(U, V, \Delta \rho) / \partial z = 0 \quad \text{at} \quad z = -\zeta \quad (12)$$

On the ocean bottom ( $z = H$ ), the momentum flux is balanced by a bottom stress  $\tau_z$ , while the density flux and the vertical velocity are zero, so that

$$\rho \varepsilon_z \partial(U, V) / \partial z = \tau_z, \quad \partial \Delta \rho / \partial z = W = 0 \quad \text{at} \quad z = H \quad (13)$$

### OUTLINE OF 3-D BAROCLINIC FLOW COMPUTATION

The algorithm and computational scheme was written in the authors' published paper. (See Murota, et al.(1988))

The computational domain as shown in Fig. 3 covers Osaka Bay and surrounding coastal seas, Sea of Harima and Ki-i Channel, in order to evaluate the amount of flowing through Akashi and Kitan Straits as precisely as possible. The model's resolution is 1 km in the horizontal plane with seven vertical layers having thickness of 2, 4, 6, 8, 10, 15 and 15 m. The time increment is 30 seconds.

Figure 3. Topological features of Osaka Bay and computation domain

A semi-diurnal tide is represented by a sine-wave curve with a 12 hours cycle at two open boundaries. The amplitude and phase of tide are 36-39 cm and  $330^\circ$  at the boundary in Sea of Harima, and 46 cm and  $174^\circ$  at the boundary in Ki-i Channel according to the field surveys of the Ministry of Transportation. For the density-driven current, the average discharge and the density of the Yodo River was set to  $205 \text{ m}^3/\text{s}$  and  $0.997 \text{ kg}/\text{m}^3$  respectively. Another buoyancy flux is the thermal flux at the sea surface of  $29.7 \text{ cal}/\text{s}/\text{m}^2$  in summer, which was also taken into account.

### TIDAL FLOW PATTERN AND TIDAL FRONT IN OSAKA BAY

The computation results to be discussed here are that on the 36th tidal cycle, in which the change in the flow and density distributions over time is almost equivalent to those of the previous tidal cycle. Figure 4 shows the velocity and the density fields of the surface layer (1 m deep from the surface) when the eastward or westward flow through Akashi Strait reaches its maximum. The contours of density field are marked at every 10% of the density difference between the river water and sea water where  $\sigma_t = 23$ . When the eastward flow at Akashi Strait is at its maximum, the flow into Osaka Bay spreads in a jet-like form toward the southeast. The flow makes its way in clockwise circular arcs along a 20 m-deep contour line toward the Kitan Strait, off the coast of Sennan. Meanwhile the discharge from the Yodo River spreads southwest,

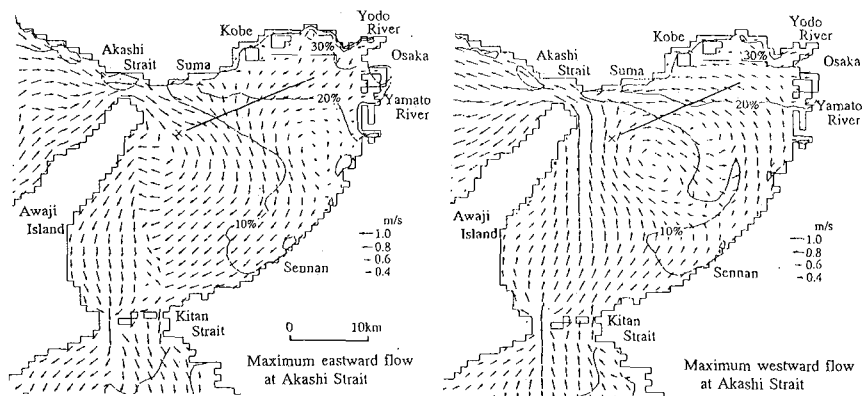

Figure 4. Surface flow vectors and density distribution at the maximum eastward and westward flow through the Akashi Strait.

running southward to cross the 20% density contour line at a right angle. The jet-like tidal flow from the Akashi Strait combines with this river discharge at the 20 m-deep point and continues southward.

When the westward flow is at its maximum, the water flow can roughly be divided into two: one running from the Kitan Strait northward along the east coast of Awaji Island, and the other that flows northward, off the coast of Sennan. Water from the Yodo River is carried by the tidal flow toward Kobe, a part of which flows into the Akashi Strait. The other part of the flow mixes with the circulation flow near Okino-se (indicated by X in Fig. 4). It is worth noting that the southeastward flow at Okino-se due to the eastward tidal flow persists even when the tidal flow direction changes. Between this southeastward flow and the flow in the inner bay, a discontinuous flow is observed. If the density distribution in Fig. 4 is represented in finer colour lines, the discontinuous boundary can be shown to be bands of different densities. That is a tidal front.

Figure 5 shows the density distribution at the cross-section of the tidal front, which is indicated by the solid line in Fig. 4. The horizontal 0 point corresponds to the 20 m-deep sea bed. The direction toward the inner bay (toward Osaka) is positive, and the direction toward the outer bay (toward Awaji Island) is negative. In the inner bay, approximately 5 m-thick stratification with  $\sigma_t = 22$  or lower is observed. The stratification is stable, rarely affected by the change in the tidal flow. The area where the sea bed is deeper than 20 m ( $x < 0$ ) is exposed to stronger tidal flows and, as a result, vertical mixing occurs. In this area  $\sigma_t$  is 22.5 or higher. Between these two areas, where  $\sigma_t$  is more than 20 and less than 22, density contours are almost perpendicular to the water surface.

Figure 5. Density distribution at the section across tidal front at the maximum eastward and westward flow through the Akashi Strait.

Figure 6. Surface density and its gradient distributions at the section across tidal front every three hours.

Figure 6 shows the horizontal distributions of surface density and its gradient every three hours. The gradient indicates the sharpness of the front. This figure shows that the tidal front on the cross section develops along the line connecting 20 m depth points. The density changes by  $\sigma_t = 2$  over 7 km on this plane. The density gradient is the greatest when the eastward tidal flow through Akashi Strait reverses westward. At this time the front is 2 km wide and  $\sigma_t$  rises from the head to the center of the bay by  $\sigma_t = 2$ . It is because the eastward flow through Akashi Strait spreads deep into the head of bay. Field data obtained by Yanagi and Takahashi (1988) indicated the density change of  $\sigma_t = 3$  over 5 km width of the tidal front. From these comparison, the computation results overestimate a little larger than observation ones.

### RESIDUAL BAROCLINIC CURRENT SYSTEM

Figure 7 shows the residual current distribution in the first (-1 m) and third layers (-9 m). The residual current is calculated by integrating the flow velocity over one tidal cycle, that is, 12 hours. The residual current in the surface layer consists mainly of the Okino-se Circulation and the east-coast residual current offshore of Sennan. The figure especially at the surface shows higher velocities than the tidally-induced circulation. The remnants of the density-driven current generated by the inflow of the Yodo River spread only slightly from the river mouth to Suma. This density-driven current is caught by the edge of the Okino-se circulation, and as a result, it enhances the Okino-se circulation and the east coast residual current in their surface layers. In the third layer, where the influence of density-driven

Figure 7. Residual baroclinic currents at the surface layer (-1 m) and the third layer (-9 m).

Figure 8. Observed residual current at 10 m depth corresponding to Okino-se Circulation and computed one at surface layer of 1 m depth.

current is less, there is a weak flow in the inner bay toward the Yodo River. Since the Okino-se circulation covers the surface to the bottom layers, they are assumed to be the remnants of the tidally-induced residual current. The strength of Okino-se circulation, therefore, changes depending on the tidal amplitude, but not on river discharges. According to the harmonic analysis of the time series of computed velocity fluctuation, it is found that the residual current component is possible to be larger than the tidal flow. (Nakatsuji et al.; 1994)

Figure 8 shows the comparison between residual current observed using four ADCP by Fujiwara et al.(1994) and computed one. Both results are substantial agreement with each other.

In order to understand the role of the residual current system on turbulent transport process, the numerical experiment was conducted that the four markers placed at the water surface near the Akashi Strait and inside Osaka Bay are traced by Lagrangian diffusion analysis based on Monte Carlo method. In this experiment, the spreading particles are assumed to move only at a surface layer.

If the particles are transformed by a tidal flow, they naturally return to their original points after one tidal cycle because the tidal flow behaves a periodic movement. As shown in Fig. 9, however, the computed tracers are far from their original positions and they remain in the center of Osaka Bay taking the shape of oval. After two tidal cycles, 24 hours, similar tendency can be observed. It suggests that the residual current system play a more important role on the transport process than the periodic tidal flow. Therefore, tracers are distributed with surrounding the Okino-se Circulation as a circle.

Figure 9. Computed trajectories of floating markers transported by the residual current system.

### IMPACT ASSESSMENT OF HYPOTHETICAL LARGE-SCALE RECLAMATION

For examining the effects of hypothetical large scale reclamation on the flow movement and water quality transport, two simple reclamation topographies are assumed. They are the reclamation of coastal waters shallow than 15 m and 18 m. The decreasing rates in area and volume correspond to 26 % and 11 % for the reclamation shallow than 15 m depth, and 36 % and 20 % for that shallow than 18 m depth. It is of importance that the impact assessment must be established from the view point of long-term and circumstance of whole coastal seas. According to the above-mentioned discussion, the 'Okino-se Circulation' and the 'tidal front' can be adopted as the physical indexes for assessment.

#### *Effects on Okino-se Circulation*

Figure 10 shows the distribution of residual baroclinic current at the surface layer supposing the hypothetical reclamation could be constructed. The outer boundary in the west side is adjacent to the line connecting 20 m depth points, where the velocity of residual current becomes smaller in the rate of 10 % as compared with that in the case of present topography. And, no particular difference between the cases of 15 m or 18 m reclamation. Since the Okino-se Circulation occurs at all depths in all cases, it is a tidally-induced residual current; hence, it is a matter of course that the effects of reclamation inside the head of bay has not strongly affected on the Okino-se Circulation developed near the Akashi Strait.

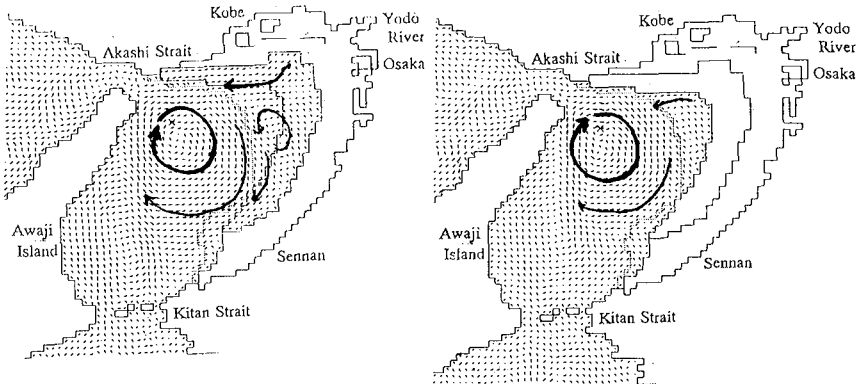

Figure 10. Residual baroclinic current at the surface layer in hypothetical reclamation of 15 m and 18 m depth.

Figure 11. Computed trajectories of floating markers after one tidal cycle in reclamation of 15 m and 18 m depth.

Figure 11 shows the computed trajectories of four markers after one tidal cycle. As compared with Fig. 9, there is a little difference in the computed trajectories between the present topography and the reclamation of coastal seas shallower than 15 m. However, in the case of reclamation of 18 m depth, continuous ring-shaped markers are distorted to be pushed into the head of bay.

#### *Effects on Tidal Front and Density Field*

Accompanied with the reclamation in shallow coastal seas, the volume of river water has direct effects on the stratification in the eastern bay or mixing process. For example, the computation indicates that the thickness of stratified and upper layer in the head of Osaka Bay becomes 8 m. Its thickness is twice as large as that observed in the present topography.

Figures 12 and 13 show the comparison of density and its horizontal gradient at the sea surface across the tidal front along the solid line shown in Fig. 4. The axis of abscissas is the same as Fig. 5. The '0' point corresponds to the sea bed of 20 m depth. The positive value in the abscissas axis means the direction of eastern bay. The maximum value of density gradient and its horizontal point indicate the strength and location of the tidal front, respectively. The maximum value and its location are almost the same between the present topography and the reclamation of 15 m depth. In addition, the density in the eastern sea ( $x > 0$ ) is mixed to gradually change in the range of  $\sigma_t = 19$  to 23 for the present topography and  $\sigma_t = 18$  to 22 for the reclamation of 15 m depth.

Figure 12. Distribution of surface density at the section across the tidal front against two reclamation cases.

Figure 13. Change of location and intensity of tidal front depending on the gradient of density at the surface layer (-3 m).

On the other hand, in the case of reclamation of 18 m depth, the volume corresponding to about 20 % of whole Osaka Bay is lost; so that mixing between river water and sea water becomes decreased and remained in the head of bay. As a result, there is  $\sigma_t = 18$  in the eastern sea, while  $\sigma_t = 22.5$  in the western sea. A tidal front, therefore, develops in the narrow band of only 2.5 km. The maximum density gradient, namely the strength of tidal front, is twice as large as other cases. The location moves about 5 km in the western direction.

## CONCLUSION

Through numerical experiments using a three-dimensional baroclinic flow model, the physical processes governing the flow movement and long-term mass transport processes in Osaka Bay, one of typical semi-enclosed coastal seas, are discussed. On the basis of discussion and the comparison of computation results with field observations, the 'Okino-se Circulation' and 'tidal front' are selected as the standards for examination of the impact assessment of hypothetical large scale reclamation in Osaka Bay. The computation results become clear from the physical viewpoint that the reclamation of coastal seas shallow than 15 m depth has not so strong effects on the flow movement and mass transfer processes, but that the reclamation of 18 m depth considerably affects them.

## ACKNOWLEDGEMENT

Authors are indebted to Dr Tateki Fujiwara, Associate Professor of Department of Fishery, Kyoto University for providing useful discussion on residual current system in Osaka Bay.

## CHAPTER 230

### FLOOD AND EROSION CONTROL IN THE CONTEXT OF SEA-LEVEL RISE

E. Bart Peerbolte<sup>1)</sup> and Herman G. Wind<sup>2)</sup>

#### ABSTRACT

Low-lying countries such as the Netherlands are very vulnerable to climatic changes, which are likely to cause an increase in sea-level rise. The most obvious threat is permanent inundation of unprotected low areas. However, such a 'final' situation will be preceded by a period of increasing episodic flooding and coastal erosion. Sea-level rise causes *safety* against flooding and erosion to reduce which should be accounted for in long-term coastal zone management plans. The question is to what extent such increases are tolerable and what can we do about it. This problem concerns the levels of safety which are desired, also in coastal areas which are already protected from flooding: is there a surplus of safety so that no intervention is required, or does the coastal defence system need to be adapted? The relevance of this question lies not perse in the threat of sea-level rise: the same question may be raised in the case of developing coastal areas, where economic values at stake increase: such developments cause a relative weakening of the flood defence system: the desired safety standards increase so that the existing defence system may not meet any longer the changed demand for flood protection and is to be adapted.

The above problem description was the background of a number of studies in the Netherlands to assess the impacts of a possible climatic change and to evaluate potential counter measures. A model has been developed for quick analysis of combinations of scenarios for climate change and potential counter measures. This paper describes the limitations of Cost Benefit Analysis as a tool for the appraisal of flood alleviation in view of the inaccuracies in investment costs and material flood damages.

## INTRODUCTION

The decision problem many coastal managers are facing concerns coastal protection. Intuitively, or explicitly by spelling out all possible advantages and disadvantages of possible protection options, the coastal manager puts the decision problem in a cost-benefit framework. In general, such a framework is not necessarily confined to monetary values only, also values in other units may play a role. Often a multi-criteria evaluation method is applied to evaluate all effects of the various options being compared.

However, the manager will tend to limit the amount of different units of expression in his decision framework, mostly he will try to monetize the effects in terms of benefits and costs, simply because he needs (monetary) budgets to implement any preferred policy. Therefore, the most appealing framework for the coastal manager is Cost-Benefit Analysis. Intangible effects and other, often external, effects which cannot be expressed in terms of money, are accounted for then as PM issues and are subject to, for example, environmental impact procedures. In this paper we point that there are practical problems when applying Cost-Benefit Analysis for the appraisal of flood protection and coastal defence systems, also in the case that only concrete monetized material benefits and costs are considered. These problems are due to the uncertainties in the various components, i.e. the various types of flood damages and cost estimates related to flood protection and erosion control.

## FRAMEWORK OF ANALYSIS

When applying the method of Cost-Benefit Analysis (CBA), there are some issues which need to be addressed, viz.

- *valuation*: how to value the different measures and effects in monetary terms;
- *time*: how to account for future costs and benefits;
- *scale*: how to determine the scale the effects are to be looked at (accounting stance).

Suppose we know how to handle these issues, the decision to invest in coastal protection, as far as monetary effects is concerned, is not difficult if the costs  $C$  of a scheme and the benefits  $B$  differ significantly, i.e. if  $C \ll B$  or  $C \gg B$ . If  $B \approx C$  a closer inspection of the uncertainties in the cost and benefits is required.

When appraising a coastal defence system it is generally tried to maximize the net benefits  $Z$  over the analysis period:

$$Z = W - C_I - C_F \quad (1)$$

where  $W$  represents the income in the endangered area,  $C_I$  the investment cost and  $C_F$  the flood (or erosion) damages.

In most cases the costs and benefits are uncertain and unequally distributed over time. Figure 1 shows an example of two investments in flood defence between which the flood damage and benefits are constant, as determined by constant hydraulic forcing. Economic development or natural phenomena like sea-level rise may cause the cost and benefit streams to change over time.

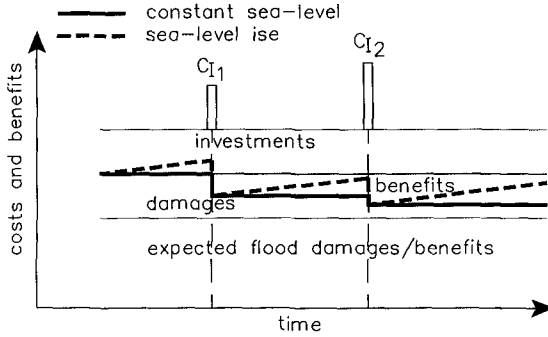

Figure 1 Costs and Benefits of flood protection

We suppose there is a number of  $K$  intervals, starting in the first year and with an investment  $C_{I_k}$  on the start of each interval  $k$ . Further each interval  $k$  ends on time  $p_k$ . The expected present value of the total investment cost  $C_{I_{tot}}$  is written as

$$E\{C_{I_{tot}}\} = \sum_{k=1}^K E\{C_{I_k} \cdot \alpha^{p_{k-1}+1}\}$$

where  $\alpha = \exp(-i)$  with  $i$  as the discounting factor.

In each investment interval flood and erosion damage may occur, and benefits due to flood protection. These damages and benefits are determined by the pattern of storm surges impacting on the structures, the structures themselves, and the topography and objects in the protected area. We need to capitalise these cost and benefit streams as follows in order to get the expected total damage to be put in the Cost-Benefit Analysis:

$$E\{C_{F_{tot}}\} = \sum_{k=1}^K \sum_{j=p_{k-1}+1}^{p_k} E\{C_{F_{k,j}}\} \alpha^j \tag{2}$$

and

$$E\{B_{tot}\} = \sum_{k=1}^K \sum_{j=p_{k-1}+1}^{p_k} E\{B_{k,j}\} \alpha^j \tag{3}$$

In principle, the expected benefits and costs can be compared now:

$$E\{B_{tot}\} < ? > E\{C_{I_{tot}}\} + E\{C_{F_{tot}}\}$$

Looking more in detail in the cost of flooding, we can schematize the cost of flood damage by

$$C_F = V \cdot F_p \cdot (1 + F_s) \quad (4)$$

where  $V$  represents the value of one or more flooded objects, and  $F_p$  and  $F_s$  damage factors, pertaining to primary and secondary (multiplier effects) flood damage.

The occurrence of flood damage is uncertain, depending on storm surge attacks, and the value of objects is often uncertain and can be estimated only from available statistical data on land-use and economics. Furthermore, the value of objects will change over time, due to development of activities in the flood-protected coastal zone. We suppose a growth factor of  $(1+g)$ . In order to project the time streams of costs and benefits in a reference year, we discount the benefits and costs, with a discounting factor  $i$ . Further the damage factors  $F_p$  and  $F_s$  are also uncertain variables. The expected value of the total flood discounted damage, in time interval  $k$  [ $p_{k-1}+1, p_k$ ] is written as:

$$E\{C_{F_{tot,k}}\} = E\left\{\sum_{j=p_{k-1}+1}^{p_k} V_j \cdot \alpha^j \cdot F_{p_j} (1 + F_{s_j})\right\} \quad (5)$$

where  $V_j$ ,  $F_{p_j}$  and  $F_{s_j}$  are uncertain variables. Further  $\alpha = e^{(-i+g)}$ .

By definition, and taking continuous functions for the uncertain variables,

$$E\{C_{F_{tot,k}}\} = \sum_{j=p_{k-1}+1}^{p_k} \int \int \int v_j \cdot \alpha^j \cdot f_{p_j}(1 + f_{s_j}) \cdot \prod(v_j, f_{p_j}, f_{s_j}) dv_j df_{p_j} df_{s_j} \quad (6)$$

Supposing  $V_j$ ,  $F_{p_j}$  and  $F_{s_j}$  are independent, we find

$$E\{C_{F_{tot,k}}\} = \sum_{j=p_{k-1}+1}^{p_k} \int \int \int v_j \cdot \alpha^j \cdot f_{p_j}(1 + f_{s_j}) \cdot \prod(v_j) \prod(f_{p_j}) \prod(f_{s_j}) dv_j df_{p_j} df_{s_j} \quad (7)$$

which leads to

$$\begin{aligned}
 E\{C_{F_{tot}k}\} &= \sum_{j=p_{k-1}+1}^{P_k} E\{V_j\} \alpha^j E\{F_{P_j}\} E\{1+F_{S_j}\} \\
 &= \frac{\alpha}{(1-\alpha)} (\alpha^{P_{k-1}} - \alpha^{P_k}) E\{V_j\} E\{F_{P_j}\} E\{1+F_{S_j}\}
 \end{aligned}
 \tag{8}$$

Similarly, the expected value of the total benefits incurred by the construction of a coastal protection system is written as

$$\begin{aligned}
 E\{B_{tot k}\} &= E\left\{ \sum_{j=p_{k-1}+1}^{P_k} B_j \alpha^j \right\} \\
 &= \sum_{j=p_{k-1}+1}^{P_k} E\{B_j\} \alpha^j \\
 &= \frac{\alpha}{(1-\alpha)} (\alpha^{P_{k-1}} - \alpha^{P_k}) E\{B_j\}
 \end{aligned}
 \tag{9}$$

The investments  $C_I$  are composed by the initial cost  $C_{IM}$  resulting from mobilisation and demobilisation, and the variable cost  $C'_{IV}$  depending on the "amount" of construction works, which is derived from the amount  $Q$  and the unit cost  $C_{IV}$ :

$$C_I = C_{IM} + Q \cdot C_{IV}
 \tag{10}$$

The expected value of the capitalized total construction cost is written as

$$E\{C_{I_{tot}}\} = \sum_{k=1}^K E\{C_{IM_k} + Q_k \cdot C_{IV_k}\} \alpha^{P_{k-1}+1}
 \tag{11}$$

Equations (9), (10) and (11) provide the framework for the evaluation of the difference between the benefits and costs resulting from coastal protection measures. The distributions of the various variables should be known to assess the reliability of the indicators, such as benefit-cost ratio, resulting from the CBA.

## UNCERTAINTIES

### Flood and erosion damages

The most violent case of coastal flooding in the Netherlands was the well-known February Storm Surge Flood in 1953. The impacts have been analysed in detail in governmental reports, consultancy reports and publications resulting in an idea about the uncertainty in flood damages. Further, in the case of riverine floodings, the Flood Hazard Research Institute in UK has collected a lot of material on flood damages [Penning-Rowse & Chatterton, 1977]. Also in France systematic research

damages [Penning-Rowsell & Chatterton, 1977]. Also in France systematic research is being carried out in the field of flood appraisal, focusing on the effect of flood warning systems [Torterotot, 1993]. In the Netherlands recently a major project has been carried out to assess the consequences of the December 1993 floods of the Meuse River, and to analyse the best options for structural and non-structural measures [Delft Hydraulics, 1994].

From analysis of the published data on flood damages due to the 1953 storm surge flood [CBS, 1953; TNO, 1982; TNO, 1989] it becomes apparent that there is quite some uncertainty about the size of flood losses [Peerbolte, 1993], this is confirmed by studies for other countries [Penning-Rowsell & Chatterton, 1977; Torterotot, 1993; Klaus & Schmidtke, 1990]. We conclude that the alleged accuracy in the assessment of direct material flood losses, in comparison with the assessment of losses to immaterial values is often overemphasized; even in the former category accuracy is not expected to be less than 40%. We will illustrate this figure by looking at the various damages resulting from the 1953 flood in the Netherlands.

The 1953 storm surge flood in the South-West of the Netherlands killed 1835 people and caused substantial damages, between 5 and 8 billion Dutch guilders on the current price level. The number of damaged houses and farms amounted to about 55,000, spreaded in a flooded area of more than 200,000 ha. Figure 2 shows the flooded areas. In the following some damage categories are described.

The cost of rehabilitation of agricultural land amounted to about DFL 6000 per ha (present prices) and was fairly constant across the flooded areas which is very substantial, in some cases 30 to 50% of the land price. The most important component is the repair and cleaning of ditches, drainage provisions, etcetera. However, it depends very much on the scale of the inundation and the violence of the flood. More recent minor floods in the Netherlands did not result in such high levels of damage to agricultural land.

Other damages to agricultural objects concern greenhouses in horticulture, plants and orchards, cattle, inventories, products and stocks of raw materials. Comparing observed, often estimated damages, with the values of the concerned objects, we observe a large variability in damage factors which supports the hypothesis that no fixed, overall valid values exist (Figure 3). It is seen from the graph that damage to greenhouses and inventories (agricultural equipment, vehicles, tractors) varies between 10 and 20%, to plants and orchards between 20 and 40%, and to stocks of products and raw materials, between 40 and 80%, a very large variability. Finally, the damage resulting from drowned cattle amounts to about 20% of the stock present in the affected area.

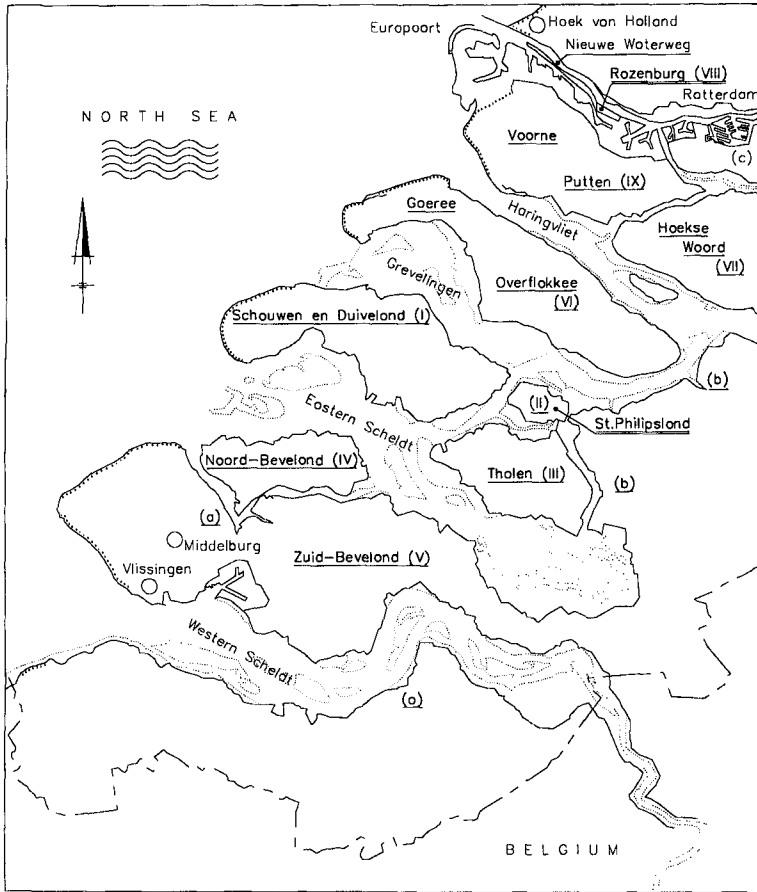

Figure 2 Areas flooded in 1953

Another picture is shown in the damages to the sector of industry, trade and banking, which is situated in the more populated areas. The core flooding areas which have been hit the most show damage factors for buildings and inventories of between 30 and 40%, and even up to 70% for stocks. The damage factors in the other core flooding areas and the surrounding areas are relatively constant with values between 10 and 20% for buildings and inventories, and between 20 and 40% for stocks (Figure 3).

The damage factor to motor vehicles amounts to about 10 or 20% of the replacement values, with the exception of some core flooding areas where the damage factors reach values of up to 40%.

Figure 3 Damage factors in flooded areas

Damage to residential houses and farms, and the private belongings of the inhabitants, such as furniture, represents an important damage category. In addition, damage to public buildings such as schools will generally contribute substantially to the flood damage. The graph in Figure 3 shows that in the core flooding area the damage factor for houses and farms varies between 20 and 40%. Damages to furniture are more or less limited to 10%. Beyond the core area, in areas a, b and c, a damage factor of about 20% results.

The number of objects affected by the flooding is large, as mentioned earlier, so we may expect a fairly reliable result of the above survey. The crucial factor in the damage assessment has been the social survey; the structure and accuracy of this survey have eventually determined the accuracy of the resulting damage factors. Because of the large number of observations it is expected that the influence of subjectivity is averaged out and that there exists really a variability in resulting damage factors of the order as concluded above. The resulting figures give insight into this variability. Such variations can be explained by different factors such as i) inundation depth, ii) flow velocities, varying especially near a breach in the dike, iii) the time available to take preparatory measures and to evacuate, iv) the water quality and v) the weather conditions [TNO, 1982].

### THE INFLUENCE OF FLOODING DEPTH

Earlier analysis of the influence of the flood depth on the damage factor resulted in the graph shown on Figure 4. In the TNO report by Duiser [TNO, 1982] it is stressed that the scatter in data is wide, although the dependency of the damage factor on flood depth is obvious. From analysis of different damage categories it appears that furniture, buildings in industry, trade and banking and inventory in agriculture have, again roughly, the same damage factors as houses and farm buildings. Stocks and inventories in industry and trade tend to a somewhat higher damage factor. In Figure 4 the damage factor is plotted as a function of the different damage categories.

A later literature survey [TNO, 1989] has not resulted in new data on coastal flooding; all found studies considered concern riverine flooding. As regards flood damages to houses this study also confirms that a high variability in data exists.

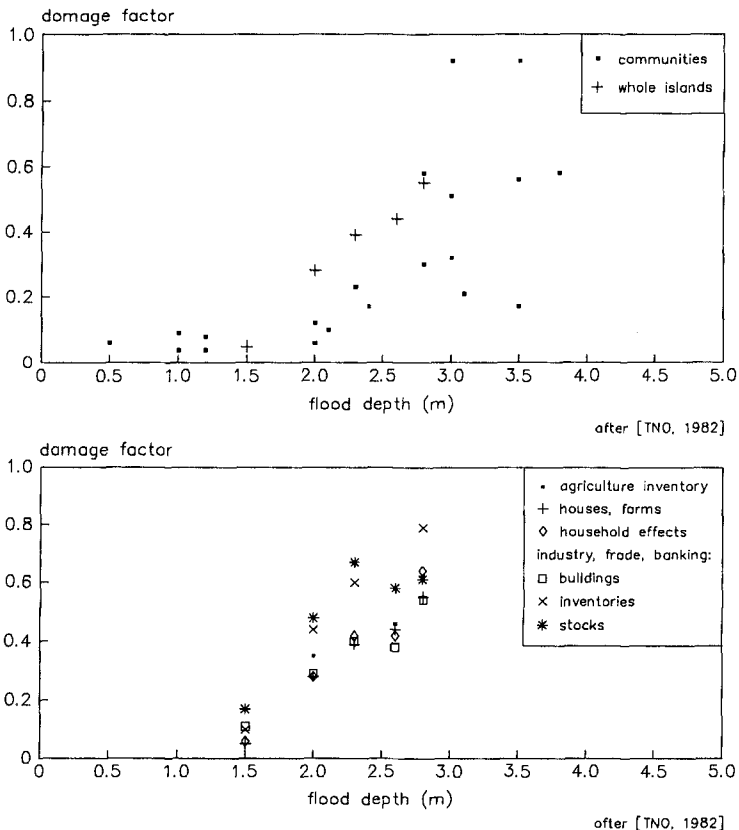

Figure 4 Damage-depth relationship

**CONCLUSIONS ON FLOOD DAMAGES**

Although major efforts have been undertaken to assess as precisely as possible the damages in real flood cases, a large variability in reported damage remains, partly due to a real variability in damages, for example caused by variations in flooding depth, duration and quality of buildings, but also partly due to differences in assessments. Whereas the 1953 damage data have been drawn from social surveys, focused on houses and household contents, the 1987-update of FHRC points to significant differences between perceived damages and real economic losses. Whilst the dependency on flooding depth may be obvious, as for example the work by TNO shows, a major scatter in data still exists, apparently because a lot of other parameters play a role in flood damages. For example, major influence on the variability

of damage factors is attributed to the effectivity of hazard warning systems and flood preparedness compared with physical parameters like flooding depth, flow velocities and flood duration.

Uncertainty in extreme water levels obviously adds to the uncertainty of flood damages. If the probability of exceedance of a certain design water level lies between  $3 \cdot 10^{-5}$  and  $2 \cdot 10^{-4}$ , the resulting expected damages may vary by 100% if the damage factors are uncertain and range between 20 and 40%, as has been shown above. So the strength of the flood protection system cannot be unambiguously defined in a CBA framework, and we should have insight in the distributions of the relevant uncertain parameters.

## SAFETY AND INVESTMENTS

Investments in dike-raising depend on a number of factors, which can be divided in two classes. First the required dimensions and strength of the dike are important factors. Secondly, the location of the dike determines the cost to a large extent. Dike sections in habitated areas are normally more complicated and hence costly to construct compared to dike sections in rural areas.

In the case of the Netherlands dike-raising is required when safety standards are no longer met. These standards are expressed in terms of water level exceedance probabilities as follows:

$$UF = 10^{-\frac{FB}{D}} \quad (12)$$

where  $UF$  represents the unsafety factor, determined by the decimating height  $D$  and the freeboard of the dike  $FB$ , being the difference between the actual crest level and the required level according to the safety standard. From analysis of the situation in the Netherlands it is concluded that the relative inaccuracy in  $UF$  may vary between 25 and 100% for dikes in coastal and deltaic areas, and even more than 100% in riverine areas Peerbolte, 1993].

Dike-raising  $p$  which is carried out as a response to a rise in sea-level of  $S_1$ , a rise in storm surge set-up of  $S_2$  and increases  $S_3$  in river discharges is related to these climate factors as follows [Peerbolte et al, 1991]:

$$p = \alpha S_1 + \beta S_2 + \gamma S_3 + 0.6\mu (S_1 + S_2 - \epsilon S_1) \quad (13)$$

The parameters  $\alpha$ ,  $\beta$  and  $\gamma$  reflect the propagation of sea-level changes and changes in river peak flow levels in the study area. Basically such parameters can be determined rather accurately. Wave run-up is accounted for by the parameter  $\mu$ , and depends on the design wave and structural properties. Also this parameter is relative

accurate. The morphological response of the sea-bed is represented by  $\epsilon$ . If  $\epsilon$  is equal to 0 (i.e. the sea-bed does not raise due to sea-level rise), its accuracy is not important, compared to the other parameters because it does not contribute to the required dike-raising. If sufficient sediment is supplied and if there is no human interference, it is generally expected that the sea-bed follows sea-level rise. In that case  $\epsilon$  is equal to 1 and only increase in storm surges may cause additional wave impacts leading to higher required dike-raising. In such cases the accuracy of  $\epsilon$  is important: 20 to 40% of the accuracy in required dike-raising is due to the accuracy of  $\epsilon$ . The fact that  $\epsilon$  is an important parameter in coastal areas is illustrated by the reduction in required dike-raising: if  $\epsilon$  is equal to 1, the required dike-raising is 25% less than in the case of  $\epsilon = 0$ , i.e. no sea-bed response to sea-level rise.

Finally we make a remark on the cost of dike-raising. From analysis by the Dutch Public Works Department it is concluded that the estimates of the cost of dike-raising vary between 10 and 40%. Figure 5 shows the total cost of dike-raising of all primary dikes (3400 km) in the Netherlands.

Figure 5 Cost vs. dike-raising of 3440 km primary flood dikes

## THE NETHERLANDS

The studies carried out so far have produced the computational models to evaluate the costs and benefits of flood protection and erosion control in a deterministic way. These models relates investments to flood protection measures on the one hand, and the expected flood damages to the protection level on the other hand, and provide the information to optimize the investments in dike-raising (Figure 6). Full description of the various underlying models can be found in [Peerbolte, 1993].

Figure 6 Principle of the shift in the optimal level of protection

Two aspects can be considered when evaluating these models: a) the cost of flood protection and coastal defence related to the protected tangible and intangible values, and b) the point of time at which the current dike-raising strategy, based on a rise of sea-level of 0.2m per century, should be reconsidered in order to maintain the present safety standards. As far as the cost of flood protection related to protected values is considered, in the Netherlands the benefits from flood protection obviously by far outweigh the necessary investments to maintain the established safety levels (see Figure 7). The optimal investment level (Figure 6) would be obtained if the dikes are raised with at least 1 metre [Peerbolte, 1993].

Figure 7 Estimated benefits and costs for different sea-level rise scenarios

As far as point b) is concerned, the conclusion is that it seems to be justified to reconsider this dike-raising strategy after 30 to 40 years, and to intensify dike-raising if the data point to a higher rate of sea-level rise. If, within this period of time a more serious scenario is seen to be inevitable, there is still time to switch to a dike-raising strategy matching these new predictions. This follows from computations of the unsafety factor and dike-raising cost, and the sensitivity thereof, for a number of sea-level rise scenarios. However, it should be kept in mind that the constraint on the system consisted of prescribed safety levels in terms of water level exceedance frequencies. These standard safety levels have been based on economic analysis by Van Dantzig [Delta Committee, 1962].

The above conclusions are based on modelling the different natural subsystems in the Netherlands, i.e. the coastal system, the estuarine systems in the North (Wadden Sea) and the South (Delta area), the lower and upper river systems, and the flood protected land itself, the analysis concentrated on the cost of dike-raising given a set of climate scenarios. The main conclusion regarding dike-raising is that there is no reason now to anticipate more severe scenarios than the present value of 0.2 m sea-level rise. With this scenario an average additional cost of roughly MFL 60 per year may be expected after about 60 years from now.

Vrijling has presented the formulation of a probabilistic optimization model on the basis of the problem definition by Van Dantzig whereby risk is defined as the product of uncertain flood levels and deterministic economic damages [Vrijling, 1993]. The above main conclusion regarding dike-raising is confirmed by the results of this probabilistic approach by Vrijlink.

## DISCUSSION

One of the arguments against CBA is that this method cannot account for intangible values like human life and distress. The present study shows that also uncertainties in the "concrete" material damages form an important drawback for a practical application of CBA in flood defence appraisal. The assessment of these damages involves a great deal of uncertainty. It is therefore recommended to estimate the distributions of the various uncertain economic parameters as well, such as the parameters related to construction cost and protected values, in order to be able to apply a more comprehensive probabilistic model than a model with only water levels as stochastic variable. It may even be considered to apply only the values protected as guiding parameter, without including a damage factor, and to choose (political choice) a fraction of the established values for investment in flood alleviation schemes.

## CHAPTER 231

### OFFSHORE BREAKWATERS VERSUS BEACH NOURISHMENTS A COMPARISON

M. Pluijm<sup>1</sup>, J.C. van der Lem<sup>2</sup>, A.W. Kraak<sup>3</sup>, J.H.W. de Ruig<sup>4</sup>

#### ABSTRACT

In the last decades two methods of coastal protection have become increasingly popular for the protection of sandy shores: beach nourishments and offshore breakwaters. In The Netherlands the first of both is well known and applied regularly. The second method has not been applied yet. With the increasing cost for beach nourishment and the apparent succes of offshore breakwater systems abroad, a study has been executed to the technical and economic feasibility of offshore breakwater systems in The Netherlands compared to the present strategy of beach nourishments. This paper highlights the results of this feasibility study.

#### INTRODUCTION

Protection of eroding sandy beaches can be done in many ways, each with its individual advantages and disadvantages. One of the things learned from the past is that dynamic coastal systems preferably should be kept dynamic. Including rigid structures in such environments often generate more problems than they solve. A demonstration of the new approach is the increase in application of beach nourishments as a shore erosion control measure.

---

<sup>1</sup> Head of Marine Department, Frederic R. Harris B.V., Badhuisweg 11, P.O. Box 87875, 2508 DG, The Hague, The Netherlands

<sup>2</sup> Senior Coastal Engineer, Frederic R. Harris B.V., Badhuisweg 11, P.O. Box 87875, 2508 DG, The Hague, The Netherlands

<sup>4</sup> Project Engineer, Rijkswaterstaat, National Institute for Coastal and Marine Management, P.O. Box 20907, 2500 EX The Hague, The Netherlands

A disadvantage of this method is the certainty that, at sites with structural erosion, the nourishment will be eroded in due course and will have to be repeated. Apart from expensive, to outsiders this gives the impression that money is thrown into the water. In order to reduce the number of maintenance nourishments (increase the timespan between two nourishments) one could therefore decide to protect the beaches with structures of some kind.

One of the successful methods, in certain cases, to achieve such protection is the application of offshore breakwaters. By interfering in the near shore sediment transport processes, offshore breakwaters influence the development of the coastline. It has been shown in numerous projects that offshore breakwaters have beneficial effects on beaches and can be used in combination with nourishments or even when nourishments are not applied.

For the Dutch coast where offshore breakwaters are not (yet) applied, but with a number of sites where beach nourishments are repetitively executed, it has been investigated whether application of offshore breakwaters will result in technically and economically feasible alternatives to singular beach nourishments.

## THE DUTCH COAST

Although The Netherlands is well known to many people for its dikes and the Deltaworks, most people do not know that the majority of the Dutch coastline does not consist of dikes. Of the approximately 350 km of coastline (Figure 1), 254 km (72%) consists of dunes, 38 km (11%) of beach flats, 34 km (10%) of seadikes and 27 km (7%) of seawalls, boulevards and the like. This makes it clear that the major part of the Dutch coastal protection effort is put into the protection and maintenance of dunes and beaches.

Fortunately the shape of and the conditions along the Dutch coast are such that only at a limited number of sites structural erosion takes place. With the increase in pumping capacity of dredgers since the 1950's and the success of the strategy, beach nourishments have been applied in increasing numbers (Figure 1, Roelse 1990). The total volume of sand applied in nourishments has increased significantly over the years. Starting with some 1.5 million m<sup>3</sup>/year in the 1950's the volume increased to

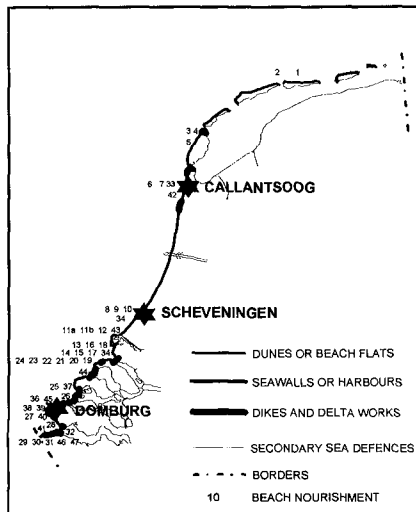

Figure 1 The Dutch coast

about 3 million m<sup>3</sup>/year in the 1970's and 1980's. Currently this figure has increased even further to about 5-7 million m<sup>3</sup>/year. The total budget currently made available by the Dutch government for beach nourishments is Dfl. 60 million per year (Hillen 1993).

In view of this budget it is not surprising that questions have been raised whether the applied beach nourishment strategy has not become too expensive and whether cheaper methods (or reduction methods) would not result in a reduction of total maintenance cost.

## SHORE PROTECTION METHODS

With the majority of the Dutch coast consisting of sand, it is not surprising that beach erosion problems are not new to the Dutch coastalmanagement organizations. In fact, at most of the locations along the Dutch coast where structural beach erosion takes place, shore protection measures have already been taken. In most cases these consist of groynes and at some places also dunefoot protection is applied. Some of these groyne systems have been set-up more than a century ago (the construction of the oldest systems has been initiated more than 200 years ago) and because of this, a lot of applied experience has been gained. Experience has shown that the effects of groyne systems along the Dutch coast are small (Verhagen 1990). Only at sites where tidal gullies run near the coast or for sites where a strong predominant oblique wave direction is present, groyne systems have some effect. For sites with a large variation in wave direction and hence a small nett littoral drift, the groyne systems hardly show a beneficial effect.

In view of this, new groyne systems were not proposed to reduce erosion of executed beach nourishments. Instead, because of experience gained abroad, offshore breakwaters were proposed as a seemingly attractive alternative for coastal protection of the Dutch coast. Questions to be answered in order to decide whether offshore breakwaters would be technically and economically feasible are:

Technically:            does an offshore breakwater system help to reduce repetitive nourishments and how much is the reduction?

Economically:        Will the cost for shore protection (including construction and maintenance of the offshore breakwater, remaining beach nourishment cost etc.) be less than the current practice of beach nourishments only?

The answer to these questions depends on many things and not the least on site conditions. With the numerous locations in The Netherlands where nourishments have been and are executed, it was decided not to relate the research to one site, but to three sites, each of which with its own specific site conditions.

## SITE SELECTION

After evaluation of potential sites, the three sites selected for further analyses were:

**CALLANTSOOG:** The beach and dunes near Callantssoog (Figure 1) are subject to structural erosion in the order of 1 to 2 m per year. The beach and dunes are relatively narrow and safety against flooding is the main argument for execution of regular beach nourishments (1976/ '77, '79/80, '86 and '91). The shore is protected with groynes, but is not intersected by breakwaters, rivers or others.

**SCHEVENINGEN:** The regularly (1969, '75, '85, '91) nourished beach at Scheveningen (Figure 1) is backed by a vertical seawall and is located just north of Scheveningen harbour. The shore is protected by groynes (constructed before construction of the harbour) and the coastline is intercepted by two short breakwaters (Figure 2). The vertical seawall prevents the construction of a mass sand storage in the form of dunes and consequently beach acts as the only sand buffer. Quick erosion of this beach during extreme events, the lee side effect of the harbour moles and the lack of natural regeneration are the major arguments why regularly beach nourishments have to be executed.

**DOMBURG:** The coastline at Domburg (Figure 1) is subject to structural erosion in the order of 4 m per year. Typical of the site is the presence of a vast system of sand banks in the nearshore area, albeit that a tidal channel runs between this sandbank system and the coast. A system of pile rows is aimed at keeping the tidal current away from the shore. For northwesterly storms the coastline is very sensitive to erosion. Any loss of sand in the tidal gully is a permanent loss. As a result the coast near Domburg has been nourished in 1986, '89, '90 and '92.

## OFFSHORE BREAKWATERS IN DUTCH COASTAL WATERS

What distinguishes the site conditions in Dutch waters from many of the other locations in the world where offshore breakwaters are applied, are two main items. First the tidal motion. The tidal range for the three sites varies between approx. 3.90 m (Domburg) and 1.50 m (Callantssoog). Consequently under normal tidal conditions the influence of an offshore breakwater is influenced by the water level and tidal current. The second is the influence of storms. Because of the funnel shape of the North Sea, northwesterly storms can generate considerable increases in water level (storm surge). With the majority of the land area behind the dunes well below mean sea level (MSL), the design storm surge level (in combination with waves) for which the sea defences should maintain safety is in the order of +5.50 m above MSL (1 in 10,000 years risk of flooding).

In order to keep the offshore breakwater system economically feasible it is clear that the breakwaters should be kept small. Hence under extreme conditions as indicated

above, the breakwaters will be submerged and their influence consequently reduced. On the other hand, for low water level conditions it is likely that the offshore breakwater system will emerge above still water level. These conditions impose special requirements in the design of the offshore breakwater system. Combinations of different water levels and wave height and consequently different loading conditions (submerged, emerged yet overtopping) must be taken into account in the design of the breakwaters.

Although for the cross sectional design of an offshore breakwater system numerous alternatives can be thought off, the combination of conditions indicated above imposes the requirement that a proper breakwater system must be designed for a wide range of different conditions (water levels, waves, currents). In addition, it is required that the costs for breakwater construction and maintenance are kept small. This led to the conclusion that a rubble mound breakwater type was to be preferred. Design rules would be available for all different loading combinations, construction and maintenance cost assessment would be easy and general experience with this type of breakwater is good.

Figure 2 Offshore breakwaters at Scheveningen

## PLAN VIEW AND CROSS SECTION OF OFFSHORE BREAKWATERS

Although a lot has been published on the application of offshore breakwaters (Dally and Pope 1986, Rosati 1990) and the physics by which offshore breakwaters function becomes more and more understood, accurate and straight forward design methodologies are not available.

The initial lay-out design of the offshore breakwater systems therefore has been based on rules from practice (Rosati 1990) relating dimensions as breakwater length, gap width, distance offshore etc. (figure 2). In this initial design stage it has been adopted as design requirement that tombolo formation (such large accretion of the beach that the accreted sand reaches the lee slope of the offshore breakwater - figure 2) should not develop. This requirement is invoked by the expectation that tombolo formation will result in blocking of longshore sediment transport and consequently causing large lee side erosion.

The combined effect of water level and wave height imposes special requirements on the cross sectional design of the rubble mound breakwaters. Especially the height of the crest relative to still water level and the width of the crest influence the overtopping (and thus the wave attack on beach and dune) as well as the wave loads on the breakwater itself.

Cross sectional design, offshore distance, breakwater length and gap width finally will determine the total volume of the breakwater construction materials. To keep the cost of the breakwater systems small, it was chosen to locate the breakwaters as near to the coast as possible (minimum depth) but far enough to prevent tombolo formation. For the Scheveningen site this resulted in the breakwater scheme of Figure 2. For the Domburg and Callantsoog site the proposed breakwater schemes were more or less similar.

The cross sectional design was chosen to be trapezoidal with side slopes of 1 in 1.5. This will result in a minimum rubble mound breakwater which will remain stable with a reasonable rock size as armouring. The height of the breakwater is dominant for the overtopping and the weight of the armour to be used. The higher the breakwater, the less the transmission and overtopping but the heavier the armour unit to be applied and visa versa. Eventually for Scheveningen it was decided to put the crest level of the offshore breakwater system at approximately +1.25 m MSL, just above mean high water of spring tides. Under these conditions the impact of the breakwaters on wave transmission is maximised, but this will reduce with increasing water levels. At extreme high water levels the breakwaters will be submerged and be subject to reduced wave forces despite the higher waves associated with the storm surges and deeper water. Finally under normal daily wind and wave conditions the breakwater system will be visible, not unimportant for the increasing pleasure craft navigation along the Dutch coast.

## **QUALITATIVE DESCRIPTION OF THE IMPACT OF OFFSHORE BREAKWATERS ON THE DUTCH COAST**

Before trying to estimate the magnitude of the effects of offshore breakwaters on the Dutch coast, it is first of all important to identify the processes involved. By understanding the processes involved, mathematical approximation of these processes

may be used to indicate the magnitude of the impact of offshore breakwaters. As implicitly indicated in the previous, a differentiation should be made between normal conditions (without storm surges) and extreme events (including storm surges). The influence of offshore breakwaters under these two conditions will be quite different.

**Figure 3** Offshore breakwaters: physical processes under normal conditions

### Normal Conditions

Under normal conditions the morphological processes at the coast under influence of waves and tidal currents result in predominant longshore sediment transport. The application of offshore breakwaters is under these conditions aimed at reducing the longshore sediment transport behind the breakwaters, by shielding the coast from predominant wave attack. Assuming that this can be accomplished, the result will be a reduced erosion behind the breakwaters or even sedimentation (Figure 3).

The offshore breakwater system will have a limited length and consequently will end somewhere. In the Dutch case, with a net longshore sediment transport in northerly direction, a reduction in sediment transport behind the offshore breakwaters is likely to result in erosion on the northside of a breakwater system (lee side erosion). This lee side erosion is an important phenomena which counter effects the positive effect of beach accretion behind offshore breakwaters. In the overall (economic) evaluation this lee side erosion and consequent additional beach nourishments should be taken into account.

Although longshore sediment transport will be dominant under normal conditions, the cross shore transport will also be influenced by offshore breakwaters. An important aspect in this cross shore transport under normal and fair weather conditions is the

transport of sediment towards the coast. Being primarily a bedload transport offshore breakwaters will block the onshore transport and prevent the natural rehabilitation of eroded beaches.

**Figure 4** Offshore breakwaters: physical processes under extreme conditions

#### Extreme Conditions

Under extreme conditions, the breakwaters may be submerged and wave conditions will be severe (Figure 4). Without offshore breakwaters under such conditions erosion of beaches and dunes can be expected. However, even though the offshore breakwaters are submerged, the crest level is still so high that the breakwaters will influence the wave conditions. Reduced wave conditions will result in reduced erosion of beach and dunes. Depending on the distance of the offshore breakwaters relative to the coastline, the resulting cross sectional storm profile of dune and beach may reach as far as the breakwaters. The breakwaters then could perform a containment function.

As indicated previously, a disadvantage of offshore breakwaters is that they not only prevent natural rehabilitation of the beach (and the dunes) from the seaward side of the breakwaters towards the coast, but also due to the reduced wave conditions behind the breakwaters from the landward side.

#### QUANTITATIVE DESCRIPTION OF THE IMPACT OF OFFSHORE BREAKWATERS ON THE DUTCH COAST

A quantitative assessment of the influence of all these processes on the coastline clearly will be difficult let alone inaccurate. This difficulty finds its origin in the complexity of the hydraulics and the coastal morphology processes. The current and

wave field between the breakwaters will have a strong two-dimensional effect. Generated bed shear stresses, radiation stresses etc. also will vary significantly in a horizontal plane. Gradients will not only occur parallel to the coast, but also perpendicular to the coast. Currently available coastline models are often one line models in which the complex water/sediment/structure interaction has to be included in a simple way. Usually only the sheltering of wave action is included in the model (Delft Hydraulics 1992, Hanson 1989). Changes of tidal current conditions are usually not included. In view of this it was concluded that the available one-line models are still limited in predicting shoreline changes with sufficient detail and reliability to support the design of offshore breakwater systems. Especially in feasibility studies where eventually costs will have to be implemented, a proper assessment of remaining nourishments volumes may be the key element of the outcome of the study.

A quantitative assessment of the influence of offshore breakwaters under extreme conditions may be made, assuming that under extreme conditions primarily cross sectional profile changes occur. With the breakwaters under water, the wave height still will be reduced and a reduction in cross sectional erosion may be expected. The effects of offshore breakwater on erosion profile development has been studied using two cross sectional erosion models (RWS-DWW 1992). The results of this study indicated that by applying offshore breakwaters, under extreme conditions a reduction in cross sectional erosion is achieved up to a maximum of 30%.

In view of the previous it appears to be impossible to conclude whether offshore breakwaters in The Netherlands would be economically feasible, not knowing the beneficial and negative effects of these breakwaters on the protected and adjacent coastline. One way to overcome this is to make the economic evaluation based on an assumed beneficial effect.

## **CROSS SECTIONAL DESIGN OF OFFSHORE BREAKWATERS**

As indicated previously, the offshore breakwaters have been designed as rubble mound breakwaters. The influence of water level and wave conditions have been taken into account in the design of the breakwaters, as well as the effect of wave breaking on the wave height and the wave height distribution.

A requirement in the breakwater design is the flexibility of the breakwaters. Further the breakwaters should not be sensitive to damage (maintenance) nor for excessive damage (collapse). To fulfil these requirements, the breakwaters have been designed out of one grade of (main) armour, without filter layers and core. Only a filterlayer/bottom protection is provided (Figure 5). The advantage of such design is that even with large damage, filterlayers and core can not be eroded since these are not applied. The porosity of the structure is high, which allows the application of relatively small main armour units. Major damage most likely will manifest itself in

the form of lowering of the crest. This will reduce the effect of the breakwaters on the wave conditions and thus on the coast. However, because of the single grade of main armour it would be relatively easy to increase the height again. Similarly because of the single grade main armour, extension or shortening the offshore breakwaters would be relatively simple.

**Figure 5** Scheveningen: typical offshore breakwater cross section

In the design of the breakwaters, the combination of design conditions required the breakwaters to be designed as overtopping breakwater and as submerged (reef) breakwaters. Applying appropriate design rules (CUR/CIRIA 1991) the cross sectional design for the Scheveningen site is presented in Figure 5. Similar designs were developed for the Domburg and Callantsoog site. Based on this type of cross section a cost estimate for the construction of the breakwater system was established.

## ECONOMIC EVALUATION

In the economic evaluation of the feasibility of offshore breakwaters in The Netherlands three main items have to be taken into account:

1. What are the present costs for coastline maintenance, i.e. without offshore breakwaters?
2. What are the future costs for coastline maintenance, i.e. with offshore breakwaters?
3. What are the costs for the construction of the breakwaters?

The evaluation will be illustrated for the Scheveningen location. For the other locations a similar approach has been followed.

#### Present costs for coastline maintenance.

The size of maintenance beach nourishments as executed in the past years approximates 70,000 m<sup>3</sup>/yr. Adopting a unit rate of Dfl 10.00 per m<sup>3</sup>, the yearly cost for beach nourishments for the situation without offshore breakwaters would be Dfl 700,000. With the length of the nourished beach being in the order of 2000 m, the yearly costs amount Dfl. 350.00 per linear meter of coast. These costs refer to the nourishments only. (The total yearly maintenance costs of the coastline are much higher, taking into account the costs for maintenance of the groynes, the seawall, the dunes etc. For these costs a total of Dfl 150.00 per linear meter should be added.)

#### Future cost for coastline maintenance.

The future cost for coastline maintenance depends on the effectiveness of the offshore breakwaters to reduce the costs for beach nourishments. Most optimistically would be a situation that the offshore breakwaters just counter effect the erosion (no remaining nourishments). Most pessimistically would be a situation that still additional nourishments would be required, varying from 0% (no additional nourishments) to more then 100% (more than currently required). The latter situation would develop, if behind the breakwaters sedimentation would take place and in the lee side of the breakwater system the nett sediment transport is generated again. With the nourishment cost at Dfl 350.00 per linear meter of coast per year, the future cost for nourishment may range between Dfl 0.00 and more than Dfl 350.00 depending the effectiveness of the offshore breakwater system.

#### Cost for breakwater construction

The capital costs for the breakwater cross section presented in Figure 5 is estimated at Dfl 15,000.00 per linear meter of breakwater. The cost per linear meter of coast is a function of the breakwater length and the gap width between the breakwaters. For the Scheveningen site a gap width - breakwater length ratio of 250/240 (system I) and 60/120 (system II) has been used. In the first case the capital costs are approx. Dfl 7,350.00 per linear meter of coast and in the second case approx. Dfl. 10,000.00 per linear meter of coast.

#### Comparison

The final comparison is based on a nett present value calculation for the shore protection with and without offshore breakwaters. In this calculation, the effect of the offshore breakwater on the coast is expressed in percentage of remaining nourishment (0% = no more nourishments, 100% = unchanged nourishment volume). The interest rate has been taken at 5% and the calculation period at 30

years. At the end of the calculation period, the breakwater rest value is assessed at 40% of the initial construction cost. Maintenance for the breakwater is 2% per year. The results for Scheveningen are presented in Figure 6. This figure indicates that both offshore breakwaters schemes proposed for Scheveningen are more expensive than beach nourishments only, given the adopted unit rates for breakwater construction material, sand etc.

**Figure 6** Scheveningen: NPV comparison for two systems

**Figure 7** Scheveningen: break even NPV

Using the same nett present value approach, Figure 7 indicates what the cost for offshore breakwaters per linear meter of coast may be, assuming the magnitude of the remaining beach nourishments, to reach a break even point with beach nourishments only. The figure indicates that if the effect of the offshore breakwater scheme is small (large remaining nourishments) the breakwater construction cost should be small. If the effect is large (small remaining nourishments) the breakwater construction costs may be higher.

Given these break even construction cost and the construction cost per linear meter of breakwater (based on Figure 5), the gap width/breakwater length ratio can be determined to reach the break even point for an assumed effect of the offshore breakwaters on the nourishment (Figure 8). This figure indicates that a reduction of the maintenance nourishment to 50% of the present nourishments should be achieved with a gap width/breakwater length ratio of approximately 4. With the large gaps thus resulting between the breakwaters it is assessed that this can not be achieved.

**Figure 8** Scheveningen: break even gap width/breakwater length ratio

**Figure 9** Scheveningen: break even relative cross sectional costs

Alternatively, knowing the break even costs for the offshore breakwater scheme, the average unit rate for the breakwater construction material has been determined. Using the cross sectional profile of Figure 5 and a gap width/breakwater length of 1 the average rates are indicated in Figure 9. It should be noted that the average cost for the breakwater according Figure 5 is approximately Dfl 187.00 per m<sup>3</sup>. The results indicate that if the effect of the offshore breakwater is large, the breakwaters can be constructed of a more expensive material (rock). When the assumed effect of the breakwaters is small, the breakwaters should be constructed of a cheap material (sand). However in the last situation, the offshore breakwaters are not breakwaters any more but offshore sandbanks. Under these situation the morphological processes will be quite different compared to statically stable offshore breakwaters.

**EVALUATION**

Often Coastal Zone Management organizations resent the application of repetitive beach nourishment as shore protection methodology. This aversion initially is generated by the idea that over the years, regular beach nourishments will cost a large amount of money. For this reason one tends to take protective measures to reduces the losses or even completely stop the erosion of the coast.

The qualitative evaluation of offshore breakwater schemes executed in this study indicates that for ongoing sandy coasts the erosion at the down drift side of the offshore breakwater scheme forms an important aspect and an argument to expect

that even after construction of offshore breakwaters, maintenance nourishments will still be required to counter measure this.

In cases where offshore breakwaters are applied and large storm set-up occur, erosion of beach and dunes still can be expected, although the magnitude of the erosion will be reduced. Hence in cases where single storms may have a large impact, offshore breakwaters will have a mitigating influence on the effect of each single event.

The quantitative assessment of the effect of offshore breakwater schemes on the coastline, especially for a hydro-morphological system including currents and waves, still appears to be complex. One-line coastline models available to the Consultant insufficiently represented this complex hydro-morphological system to supply reliable results to support the outcome of this study.

In that respect initial results of 2-dimensional modelling of offshore breakwater schemes show promising results. It is expected that in the future this will allow for more physically correct modelling and be the basis for a reliable assessment of the quantitative effect of breakwaters on the coast.

Because of the latter limitation, the economical feasibility study of the application of offshore breakwater in Dutch coastal waters has been based on an assumed beneficial effect. Rubble mound offshore breakwater do not show to be economically feasible with the unit rates for sand and breakwater construction materials as applicable in The Netherlands. Offshore breakwaters may become economically attractive when the construction cost is reduced. This may be achieved by alternative breakwater designs, but this has not been executed in this study.

Finally, one could argue whether other arguments can be raised to construct offshore breakwaters despite the higher cost. Assuming some beneficial effect of the offshore breakwater scheme, the average interval between consecutive maintenance nourishments will increase, giving to the public the impression that "less money is thrown into the water". Secondly, taking into account that the beneficial effect of an offshore breakwater scheme is partly counter affected by erosion at the down drift side of the breakwater scheme, offshore breakwater may be used to "shift" the problem. This can be applied to shift the nourishment activity to less frequently used beaches.

#### **Abstract**

DELFT HYDRAULICS' morphological model system is applied to the case of Keta Lagoon, Ghana; the results are compared with a physical model test carried out by DELFT HYDRAULICS in 1982.

#### **1. Introduction**

Predictions of morphological evolution in a coastal area are of importance in many engineering applications. Such predictions have often been made by carrying out physical model tests, which are usually very expensive and time-consuming, and which may suffer from scale effects. Nowadays, mathematical models offer a relatively cheap and efficient way for morphological predictions. However, validation of such models requires much attention.

The objective of this study is to test the coastal area model developed at DELFT HYDRAULICS against the measurements from physical model tests and to produce results for comparison with other models.

The study is part of the "G8 Coastal Morphodynamics" research programme, which is funded partly by the Commission of the European Communities in the framework of the Marine Science and Technology Programme (MAST), under contract no. MAS2-CT92-0027. For more background information see De Vriend et al. 1992). Details of the present study are described in Walstra (1994).

#### **2. Morphological model system**

The morphological model system to be tested here is a subset of DELFT HYDRAULICS' system DELFT3D, which has recently been developed in order to allow a flexible integration of the models for currents, waves, sediment transport, bottom

changes, water quality and ecology. The morphological system contains the first four models and a control model. This control model allows the user to prescribe any combination of processes and arranges the time-progress of each model and possible iterations between models. The models relevant to morphological simulations are outlined below:

#### *Waves*

Stationary multi-directional (short-crested) wave model HISWA (Holthuijsen et al., 1989).

#### *Hydrodynamics*

2D or 3D flow model TRISULA based on the shallow water equations, including effects of tides, wind, density currents, waves, spiral motion and turbulence models up to  $k-\epsilon$ ; for morphodynamic computations, a quasi-3D option to account for wave-driven cross-shore currents is available.

#### *Sediment transport*

New model TRANSP, including a sub-model TRSTOT, bed-load and suspended load transport according to several formulae, and TRSSUS, a quasi-three-dimensional advection-diffusion solver for suspended sediment, including temporal and spatial lag effects.

#### *Bottom change*

New model BOTTOM, which contains several explicit schemes of Lax-Wendroff type for updating the bathymetry based on the sediment transport field. Options for fixed or automatic time-stepping, fixed layers, various boundary conditions.

The first combination used in this study is similar to that used in the earlier MaST intercomparisons, viz. 2DH currents, multi-directional wave propagation and Bijker transport model.

The flow diagram for the combination of models applied in this study is given in Figure 1. Starting from an initial bathymetry, a number of wave computations covering a tidal cycle are carried out, followed by a run of the flow model which includes tidal and wave forcing. The wave and current computations can be iterated to account for full wave-current interaction. Sediment transport computations are carried out for a number of steps within the tide. The transports are averaged over the tidal cycle and the bathymetry is updated based on the residual transport pattern. A very important branch in this scheme is denoted B. Here, the discharge pattern is kept constant and (small) bottom changes are assumed to affect the current velocity only locally: at a constant discharge rate, the current velocity increases if the depth decreases. This is a reasonable assumption as long as the bottom changes are small and leads to an enormous reduction in computational cost. Typically, 20-40 so-called continuity correction steps can be taken in between full hydrodynamic runs (branch A).

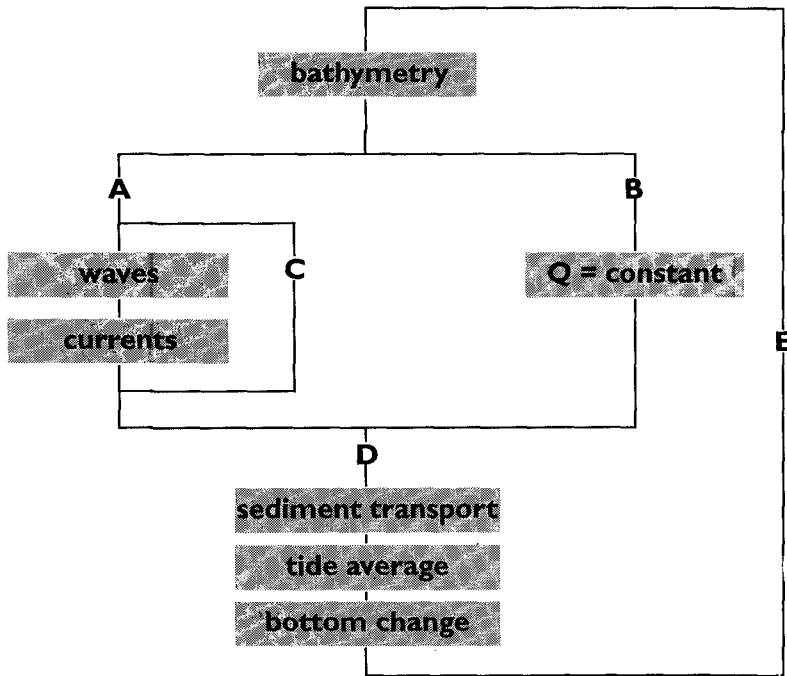

Figure 1. Flow diagram of morphological model system.

### 3. Test case

The town of Keta is situated in the south-east of Ghana, near the delta of the Volta River, and was built on a narrow sand ridge between the Gulf of Guinea and the Keta Lagoon. In past years Keta Town has suffered much from erosion, which attacked the heart of the town and destroyed a great number of houses.

Beside the great threat from the sea the main problem for the inhabitants of Keta is the lack of land at a sufficiently high level to enable them to construct their houses safe from the lagoon floods. The Keta Lagoon, with an area of 300 square kilometres, collects the run-off from a large catchment area. From the lagoon the excess water may find its way to the sea through a long winding channel towards the mouth of the Volta River. Most of it however evaporates during the dry season. In very wet years, the lagoon water level becomes so high that houses and crops on the lagoon side of the sand ridge are inundated. In the years 1963 and 1968 the situation was considered dangerous and a small cut was made in the

sand ridge. In both cases the excess water was discharged successfully into the sea, forming however, a tidal inlet of considerable capacity by scouring due to high lagoon levels (see Fig. 2). Consequently, traffic to and from Keta was interrupted.

Figure 2. Situation at Keta (with 1968/1969 breach)

#### 4. Physical model study

A physical (movable-bed) model study was carried out at DELFT HYDRAULICS in 1982 (Delft Hydraulics Laboratory, 1982). The aim of this physical model study was to investigate the possible stabilization of the lagoon outfall and to determine the most favourable layout of the outfall structure. The model has been calibrated by reproducing the conditions which occurred in 1963 and 1969.

In the model, a dyke was built separating the lagoon from the sea. At the sea-side, a uniform beach profile was applied. The bottom of the lagoon was horizontal. The sea and the lagoon were connected by a straight channel.

At the sea boundary, irregular waves were generated by means of a paddle-type wave generator at an angle of  $15^\circ$  to the coastline. In addition to the waves, two phases of steady current were generated with a water circulating system, representing an ebb and a flood respectively.

In the tests, measurements were made of the initial and final bed topography. A summary of the parameters used in the physical model is given below.

Physical model description	
Model scales	horizontal 36 vertical 28
Model size	30 m by 30 m
Bathymetry	beach profile: 1:15, depth 0 m to 0.125 m 1:45, depth .125 m to .28 m inlet channel: depth 0.19 m, width 2.4 m, 1:4 slopes lagoon: flat, depth 0.07 m
Waves	irregular wave height $H_s=0.07$ m, $T_p=1.5$ s, $15^\circ$ to coastline
Currents	ebb/flood, cycle time 2 hr 30 min. additional littoral drift (magnitude unknown)
Sediment	$D_{50}=0.21$ mm, $D_{35}=0.19$ mm
Test duration	75 hr
Measurements	bottom topography with intervals 1 m by 0.25 m no wave measurements no current measurements
Programs	Two sets of tests with different tidal discharges through the channel. Test case used here T0-3

### 5. Set-up of the numerical model

Since it is difficult to exactly reconstruct the physical model in the numerical model, a different approach was chosen: given the same prototype data that were used to schematise the physical model, a new schematisation was made for the numerical model. Prototype scale was used for the numerical model. It covers an area of 1500 m longshore by 1100 m cross-shore. A rectangular grid was used, initially with a uniform grid size of 15 m by 15 m and approximately 6500 active points. The first computations showed that the resolution at the channel entrance was rather poor with this grid, and consequently a variable grid size was applied, with cell widths ranging from 30 m in the lagoon and deep water to 5 m near the entrance. The bathymetry was obtained by scaling the physical model back to

prototype scale. Prototype scale significant wave height is 1.96 m, peak period is 8 s.

A tidal movement was assumed at the sea boundary, which is perpendicular to the coastline with a tidal range of 0.98 m. The tidal movement was described with the water level variation at the sea boundary. For simplicity, a sinusoidal variation was assumed with a period of 12 hr 30 min. The tidal data are primarily based on the field observations (mean tide). In the physical model, the tidal movement was schematized into an ebb and a flood phase each lasting for 1 hr. Inside the lagoon, the water level variations are very small (0.03 to 0.06 m) according to the field observations. Thus at the lagoon boundary (western, northern and eastern sides), the water level is assumed to be constant. i.e. at Mean Sea Level. Both lateral boundaries are prescribed as current boundaries. The current is the computed longshore current on a uniform beach, with a varying water level. All boundary conditions

The bed material chosen for the model has a uniform size distribution at all locations in the model. The characteristics of the material are:  $D_{50} = 0.54$  mm (with fall velocity of 0.0785 m/s),  $D_{35} = 0.30$  mm. A uniform roughness height of 0.1 m is assumed; the enhancement of bottom friction by waves is modelled using the Bijker approach.

Other characteristics are:  $g=9.81$  m/s<sup>2</sup>, density of sea water 1030 kg/m<sup>3</sup>, turbulent viscosity 2 m<sup>2</sup>/s and no Coriolis force.

## 6. Results

Figure 2 shows the initial bathymetry. The beach has a bed slope of 2% and connects the sea side area with an area of uniform water depth of 8 meter. The channel has a width of approximately 130 meters, the length of the channel is 250 meter and its depth is 5.4 meters below MSL. The sand ridge has a maximum height of 3.60 m above MSL.

Per hydrodynamic run, three wave computations were carried out to represent the tidal variation (LW, MSL and HW). after which the current model was run for 1.5 tidal cycle. Here, the wave forces were obtained by linear interpolation. Comparison with results for more wave runs per tide showed no significant differences.

Figure 3. Initial bathymetry in numerical model.

Figure 4. Wave height patterns near the entrance, High Water and Low Water.

In Figure 4, the initial Hrms wave height patterns for high water (HW) and low water (LW) are shown. The main effect of the water level variation is a horizontal shifting of the pattern. The effect of the current on the wave height pattern was investigated in trial runs and found to be significant. However, in order to reduce the complexity of the morphodynamic problem, this aspect was not taken into account further.

Figure 5. Current pattern at LW.

From trial runs without tidal variation it was clear that the wave-induced set-up forces a nett discharge into the lagoon. Though this may happen initially, in reality the lagoon will fill up until an equilibrium is reached. Through iteration the correct water level increase in the lagoon was found to be 0.091 m; with this mean level inside, the nett discharge through the channel was very close to zero. The boundary conditions in the lagoon were adjusted accordingly.

In Figures 5, 6 and 7 the current pattern is shown at LW, MSL and HW respectively. In all three cases the wave-driven longshore current is evident. During LW there is a strong ebb current which is forced sideways by the longshore current. The MSL phase shows mainly the longshore current and local effects of the channel. During flood, the longshore current accelerates towards the channel on the upstream side, whereas it is suppressed on the downstream side.

Figure 6. Current pattern at MSL.

Figure 7. Current pattern at HW.

The above results were obtained for the original coarse grid and showed a rather poor resolution at the entrance of the channel. For further computations, a much finer grid was applied, as is shown in Figure 8 for the velocity at MSL.

Figure 8. Current pattern at MSL, locally refined grid.

Sediment transport computations were carried out at 15 min. intervals; the sediment transports were averaged over a tidal cycle.

Morphodynamic computations were made using the tide-averaged transport patterns, since the morphological time scale of interest was much larger than the tidal period. However, for numerical reasons, a morphological time step in the order of 0.5-1.0 hour was used in the run presented here. The time step was computed automatically based on a Courant number criterion. Twenty steps using continuity correction were taken before each full hydrodynamic update. Results indicate that the number of intermediate steps may be increased further, since no shocks are evident in the time-evolution of the bottom.

Figure 9. Tide-averaged sediment transport on updated bathymetry after 5 tides. Detail near entrance.

Figure 10. Computed bathymetry after 5 tides.

Figure 11. Development of longshore profile at  $Y = 420$  m

In Figure 10, the computed bathymetry after 5 tides is shown. Clearly, the channel moves sideways due to the longshore current. The upstream part of the channel is accreting, whereas the downstream part erodes. This is further illustrated by Figure 11, which shows the evolution of the longshore profile at  $Y = 420$  m.

In Figure 12, the computed bed level changes are shown. For comparison, the bed level changes obtained in the physical model test are shown in Figure 13. In view of many uncertainties related to the actual conditions in the physical model and in view of scale effects, a quantitative comparison is not possible. However, a qualitative assessment can be made.

The accretion on the upstream (left-hand) part of the channel is reproduced in the numerical model. Also, the erosion on the downstream (right-hand) side and the deposition due to the ebb current are represented in the model.

The morphological development in the physical model has progressed much further than that in the numerical model. The time span modelled in the physical model is meant to represent approx. half a year, whereas the numerical model has not progressed beyond some days. The reasons for this will be discussed in the next Section.

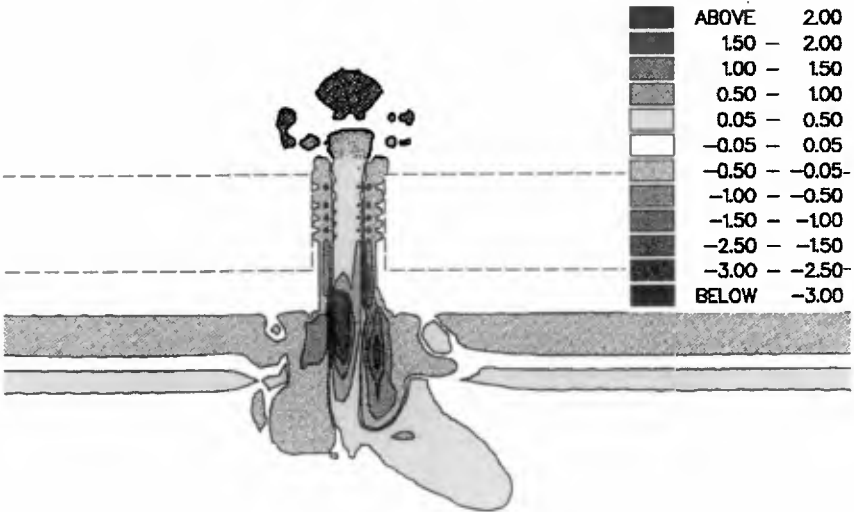

Figure 12. Computed bed level changes after 5 tides.

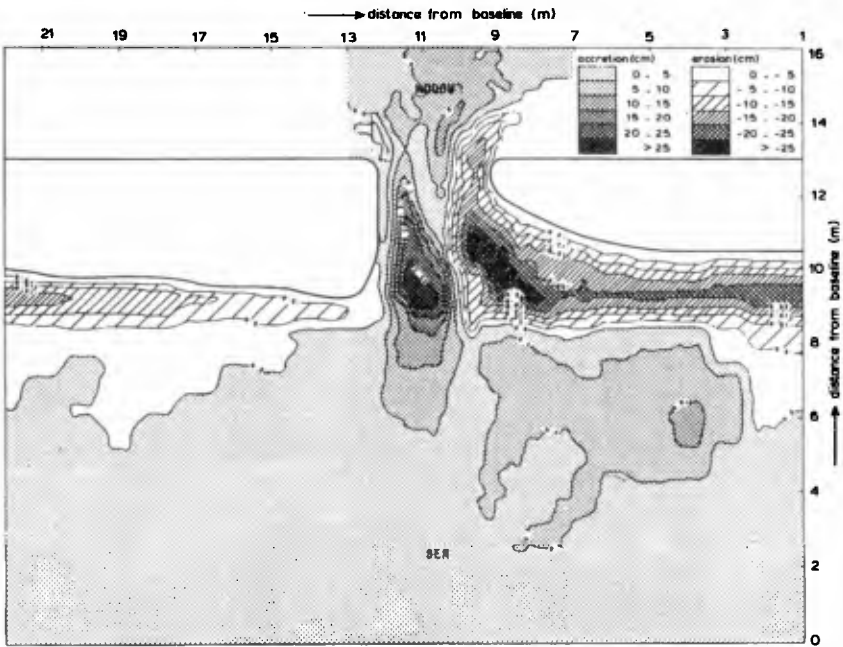

Figure 13. Bed level changes measured in physical model.

## 7. Discussion

The results presented so far are encouraging in the sense that important aspects of a complex morphodynamic system can be represented in a computer model. Problems of informatics and numerical stability have been dealt with to the point where we can again focus on the physical aspects.

An important phenomenon which has to be represented is the erosion of the dry beach. The model has to be able to deal with this in order to be able to describe the actual migration of the inlet. To achieve this, an "avalanching" mechanism must be included in some way. Here a problem to be solved is the fact that the very steep slopes that occur in reality cannot be modelled even in a very fine grid such as was applied here. A more general "slope term" may be the solution. Experiments using such a slope term have not yet yielded the desired effect in this case.

Another important aspect is wave-current interaction. Up till now, we have only applied the wave effect on the current in these computations; the current refraction effect is important in this case and will be further investigated.

The effect of waves on the current profile (undertow) and on the bed load transport (wave asymmetry effects) is significant, since a considerable part of the erosion in the physical model is due to cross-shore transport. A quasi-3D approach has been implemented and is currently under investigation.

Once a workable mechanism for eroding the dry beach has been established, the problems of running the model over longer time-scales will be reduced, and making predictions on a time-scale of interest to engineers will be quite feasible.

## CHAPTER 233

### Cost-benefit analysis of Shore Protection Investments

Luis Felipe Vila Ruiz<sup>(1)</sup>  
Fernando Bernaldo de Quirós<sup>(2)</sup>

#### Subject 2: Coastal processes: Shore protection

##### 0.- Abstract

The paper describes the methodology established in Spain to assess shore protection investments. The method consists of two phases: a pre-assessment based on physical and economic indicators and an assessment in which the financial, economic and social appraisals are estimated using cost-benefit analysis techniques.

The paper also contains the preparatory works to create a data-base necessary to establish a demand-modelling.

##### 1.- Introduction

The Spanish coastline is 7,883 km long, and stretches along 10 of the country's 17 Autonomous Communities. 4,990 km correspond to the Peninsula and 2,893 km to the Balearic and Canary archipelagos and to Ceuta and Melilla.

The 478 coastal towns have a permanent population of 14 million inhabitants, approximately 35% of the population of Spain, in a 36,252 km<sup>2</sup> area, 7.2% of the total area. This means that in the coastal towns, population density is 5 times greater than the national average.

---

<sup>(1)</sup> Asesor del Director General de Costas. Ministerio de Obras Públicas, Transportes y Medio Ambiente. P<sup>o</sup> Castellana, 67 - 28046 Madrid (España)

<sup>(2)</sup> Presidente de TEMA GRUPO CONSULTOR,S.A. Avda. de América, n<sup>o</sup> 37, 1<sup>a</sup> planta - 28002 Madrid (España).

It is estimated that international tourism will bring 60,000,000 visitors and about 40,000,000 tourists to Spain in 1994. The majority of this tourism (over 80%) is conventional sun and beach tourism. If national tourism is added to this conventional international tourism, the conclusion is, that in the peak period, population density in the coastal areas is 1,000 inhabit/km<sup>2</sup>, about 12.5 times the national average.

Tourist production in Spain comprises between 8% and 9% of the GNP.

Various reasons, among them town-planning pressure from fixed population settlements and the need to provide the coastal area with sufficient tourist capacity, have meant that between 1960 and 1980 the Spanish coast has rapidly deteriorated.

This deterioration and greater awareness of the population to environmental issues has created a desire to change the existing situation, by establishing a shore protection policy and regeneration of the already deteriorated shore, so that current and future generations will benefit, (sustainable development) and so that the quality of the environment is improved.

This desire for a change has been reflected in various actions.

- More and more shore investments, which have gone up from 225 million pesetas in 1979 to 19,766 million pesetas in 1993. (FIGURE 1)
- The enactment of a new Coast Law in 1988, which in the explanatory preamble stated: "Apart from a clash of interests on many occasions for land and sea public property, the overriding idea of this law is twofold: To guarantee its public character and conserve its natural characteristics by reconciling development demands with protection requirements."
- Preparation of an analysis, planning and appraisal method on shore investments from 1987.
- Writing of a 1993-1997 Coast plan.

The basic aim of the present document, is to describe the studies which the National Coast Office has conducted in recent years to rationalise planning and shore investment appraisal, so that, as mentioned earlier, sustainable development is maintained and shore protection and cost-effectiveness of investments is ensured.

**Millions of pesetas**

Figure 1. Investment evolution at the coast

## 2.- Description of the Cost-Benefit Analysis Method of Shore Protection and Utilisation

There were various reasons for establishing a method for appraising shore investments, in line with other public sector investments.

- A sharp rise in shore investments from 1983.
- Achievement of a rational and uniform method for comparing and selecting shore investments, since the financing of these investments compete with others also within the realms of the Budget.
- Correct sizing of the investments to be undertaken and determination of their order of priority, according to the benefit expected.
- Promotion of natural resources development in the shore environment, deteriorated in some areas, as a major factor in the economic development of the adjoining areas.

- Protection of the coastal environment and its regeneration in deteriorated areas.

This method has been developed in various studies, some theoretical, and others practical, with the compilation of basic information. The main studies are summarised below.

### 2.1.- The Manual on investment appraisal

In 1987, the first study was prepared "**Study on the appraisal of the social and economic effect of investments**". This study, theoretical in nature, began with a bibliographical search and it showed that there were hardly any records on this type of work. **Using the scant references found and the basic principles of optimal resource allocation, the fundamental guidelines were drawn up for a shore appraisal investment methodology.**

In 1989, and taking as the starting point the results from the previous study, a "**Manual on shore investment appraisal**" was written.

In this Manual three types of appraisals were established:

- **Financial appraisal:** It quantifies the effects of shore investments on public sector revenue and expenditure, as promoting the area of public land and sea property.

The most relevant items of cost and revenue are considered to be:

- On the cost side, are land cost, investment cost and variations in conservation and operating costs between situations "with and without" investment.
- On the revenue side, are the variations which occur with the collection of taxes for economic activity between the two aforementioned situations, as well as the variation in revenue from the Administration's operating of public services.

In order to calculate revenue and expenditure variations, it is necessary to **estimate the number of users** of coastal facilities, **using mathematical models to forecast demand**, and **average expenditure per user** on the various facilities.

In the financial appraisal, costs and revenue are assessed at market prices. Comparison of revenue and cost flows, for the time interval under analysis, means that traditional cost-effective investment appraisal indicators can be established, using the updating technique: **updated net benefit, cost-benefit ratio,**

internal rate of return, etc.

- **Economic appraisal:** Generally, in this appraisal the viewpoint adopted is that of the community. Therefore, the main effects under consideration are:

- As benefits, **variation of user and business surpluses between the situations "with and without"**. The main components of user surplus are the variations in the level of satisfaction as a result of the variation in quality and capacity of the beach (or the coast, in general) installations and facilities, variation in security and possible improvement in accessibility.

The business surplus is calculated for all the agents concerned and, in particular, for building Companies in the investment execution phase, and for service-lending Companies and owners of property or premises revalued by the investment, in the operating phase.

Cost components are basically the same as the financial appraisal components, although it has to be borne in mind that in the economic appraisal resource prices must be assessed in terms of opportunity cost, **or in terms of the highest value than at the moment of analysis which could result from alternative use** of these resources. This requires the corresponding adjustments of market prices and, in particular, removal of taxes which are only transfers between economic agents.

As for the financial appraisal, the habitual cost-effective indicators can be obtained in the economic appraisal.

- **Social appraisal:** This appraisal aims to measure what each investment project contributes to the general social aims. The most important of these aims are the following:

- Generation of employment, both in the investment execution phase and the operating phase.

- Redistribution of income. This effect can be considered as giving a greater weight to the benefits perceived or the costs borne by the lowest income groups, establishing weighting coefficients for different income levels.

- Protection and environmental improvement. The following can be considered:

- .. quantifying possible harmful effects of investment by the cost of the measures essential for avoiding them,

- .. estimating the cost of other alternative and essential actions for achieving the same beneficial effects on the environment which, in this instance, stem from the shore investments under analysis, or
- .. giving a monetary reference value to the property to be protected or improved (for example, monetary value attributable to a hectare of dunes or marshes).

## 2.2.- Database of beach supply and demand

The systematic application of an investment appraisal process on shore protection and utilisation requires, as has already been stated, other information such us:

- calculation of the demand for coastal installations and facilities and
- estimation of user unit expenditure.

This information is absolutely essential for investment in beaches.

For this reason, when the Method and Manual on shore investment appraisal had been prepared, a **Plan for recording data and surveys was established, with the intention of achieving a time series which** would facilitate the aforementioned estimates for different situations.

This campaign for recording data has been developed during 1990, 1992, 1993 and 1994 and a computing device has been designed for the inclusion and processing of annual data in order to have a sufficiently reliable chronological sequence.

The information collected every year is basically threefold:

- **Number of beach users.** Counts are done on a sample of beaches on working days, Saturdays and holidays, chosen randomly during the summer months (normally July, August and September).
- **Characteristics and user behaviour patterns.** Surveys are conducted, during the summer months, to a sample of users, who are asked for details on: nationality, length of stay, type of accommodation, length of time and means of transport from the summer abode to the beach, frequency of beach use, rating of beach quality, income group, amount spent on the main items (accommodation, beach services, transport, etc).
- **Data on beach supply.** These data refer to:

- Natural characteristics of the beach and its surroundings: beach plan, length, width, area, slope, sand type, quality of the water, rainfall, average temperature, wind system, sunshine hours, etc.
- Beach installations: Showers, changing rooms, WCs, sunbeds, parasols, promenade, car parks, etc.
- Town facilities: Town plan, hotel and other accommodation capacity, restaurants, bars, scenic view and surroundings, entertainment and recreation facilities, etc.

### 2.3.- Modelling of user demand

The models which have been used to explain the current demand for beach use and, mainly, to estimate future users for various beach characteristics and facilities include three types of variables:

- **Variables representing beach characteristics.**
- **Variables measuring potential users.**
- **Friction variables**, linked to the cost and the time it takes to get from the summer abode to the beach.

a) As regards the variables **representing beach characteristics**, on the one hand, ratings have been included on the beaches from the surveys to users and on the other hand, general beach characteristics have been included. The latter could possibly affect rating: length, width, promenade length, sand quality, number of showers, WCs, parasols, changing rooms, etc.

To avoid constantly having to conduct surveys to users on beach rating, for every possible investment study, and since it is impossible to conduct surveys on hypothetical future situations of the beach in question, preparation of a mathematical model beforehand has been considered instrumental for rating the beach. The dependent variable has been taken as the rating given by users to the beaches under study and independent variables as the general beach characteristics mentioned above.

After various trials and errors, the adjusted model corresponded to the formula:

$$R = e^{1,4973} \times Wid^{0,016928} \times Prom^{0,010299} \times Nat^{0,3083} \times WC^{0,008848}$$

where:

R = beach rating

Wid = average width of the beach, in metres

Prom = quotient of the length of the promenade by the length of the beach

Nat = sand nature and quality (1, 2 or 3)

WC = no. of WCs per km of beach, with a correlation coefficient  $r = 0.82$

b) Consideration of **variables representing potential users** has meant it has been advisable to conduct two model demand groups:

- for permanent resident demand, the representative variable has been taken as the population of adjoining towns,
- for tourist demand, the variable of hotel and other accommodation beds on offer multiplied by the occupation rate has been considered.

c) **Inclusion of variables representing the cost of accessibility to the beach, as a dissuasive factor** forces the models to be adjusted in line with the resident population, or the variable of hotel and other accommodation beds multiplied by the occupation rate, according to distance intervals, giving each interval an average value.

Bearing in mind these considerations, the adjusted models correspond to the formulae:

- For resident users:

$$U = 0,9385 \times P^{0,7531} \times R^{1,19506} \times D^{-0,51139}$$

- For habitual non-resident tourists:

$$U = 1,5018 \times P_t^{0,25030} \times R^{3,82106} \times D^{-0,47245}$$

In these formulae,

U = no. of users on an average day of the season considered.

P = resident population, in the distance interval of D average value.

D = average value of each distance interval considered, in metres.

R = beach rating, according to the model mentioned in section a).

P<sub>t</sub> = hotel and other accommodation places multiplied by the occupation rate.

The correlation coefficients are low in both cases,  $r = 0.64$  for residents and  $r = 0.58$  for tourists. Better results can be obtained by breaking down the models into: months, beach type, working days, Saturdays or holidays, etc. However, not enough data on the chronological sequence available meant these breakdowns could not be done in 1992 when these models were adjusted. Currently, we have the 1993 data and, shortly, we shall be having the 1994 data, then it will be possible to readjust and break down the models.

In addition to this readjustment, the models need to be made more sophisticated, so that it is possible to determine where new users have come from for the additional demand in response to improved beach characteristics and services. User type distinction is as follows:

- "Generated" users, that is to say, who previously did not use any other beach.
- "Captivated" users from another overcrowded national beach.
- "Captivated" users from a non-overcrowded national beach.
- "Captivated" users from other foreign beaches.

In fact, this distinction is vital, for financial, economic and social appraisals. It can be done, either by breaking down the models further into generated or captivated user type, or by developing a global model for analysing user deviation among the group of competing beaches. This is a line of research to pursue, coupled with extension of the supply and demand Database chronological sequence.

#### 2.4.- The determination of planning indicators

Application of the appraisal method established in this Manual, on the one hand, is aimed mainly at beach investments and, on the other hand, requires a technical project of the actions to be conducted and a relatively laborious appraisal process, especially while there is no database for a sufficient number of years.

**All this implies costs and analysis time which would be unjustified if, in the end, the investment were not considered to be financially, economically or socially profitable.** This risk will tend to be even greater where the most obvious cost effectiveness investments have already been made.

Therefore, a study is currently being developed for designing a set of indicators with the following aims:

- to have a rapid appraisal tool in keeping with the Manual, although less polished,

- to compare "grosso modo" alternative actions,
- to establish acceptable investment ceilings for various types of actions,
- to establish criteria and prepare indicators for measuring variation in user "satisfaction", as a result of various actions on the coast,
- to include measures of the effects on protection and improvement of the environment,
- to establish indicators not only for beach actions but for the rest of the shore.

With this in mind, a preliminary list of types of actions has been prepared for: beach regeneration, building of promenades, building of paths for coastal areas difficult to get to, protection of wall enclosures, protection and regeneration of dunes, building of seawalks, protection of cliffs, installation of recreation areas, preparation of areas for shallow or underwater fishing, water sports facilities, etc.

**For each of these actions, the basic and ancillary aims pursued will be established and depending on these aims, the indicators for measuring their level of achievement will be prepared.**

Since the study is still in the execution phase, it is not possible, for the time being, to advance any results. However, the intention is to establish a double entry matrix for action and aim typology, and the indicators to be calculated are defined in each intersected box in order to measure physical or monetary contribution of each type of action to each specific aim. **Considerable effort is being given to defining the aims precisely so that it is possible to quantify the level of achievement.**

For monetary indicators, average unit values will be established for each type of action and effect which can be assessed in monetary terms.

**It is thought that the preliminary appraisal process should be completed by applying a multicriteria appraisal method in order to achieve an operating synthesis.**

#### 2.5.- Theoretical scheme of the shore action planning process

Bearing in mind the studies conducted, experience obtained and the works in progress, a theoretical scheme of the shore action investment planning process could be the one represented in the following chart. **(FIGURE 2)**

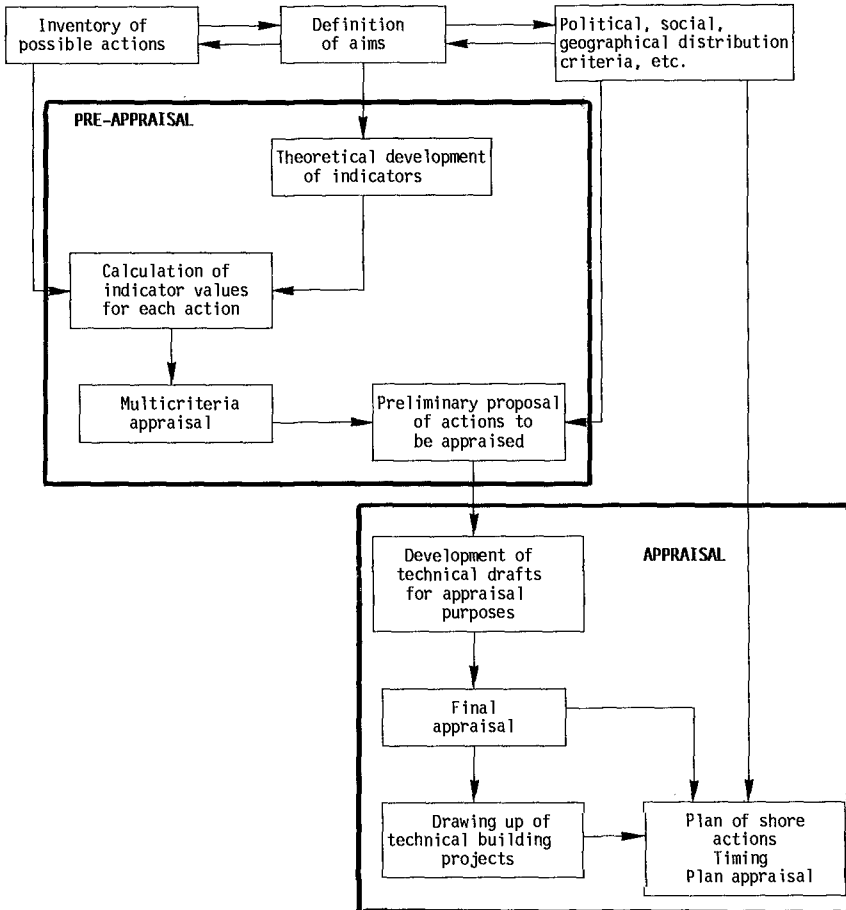

Figure 2

This chart illustrates that, beginning with political criteria and aims and knowledge of the shore, a relatively extensive inventory of possible shore actions can be established.

A pre-appraisal process is applied to this inventory, based on the establishment of indicators, and definitions of actions from a previous study. As a result of this pre-appraisal, a set of actions, probably viable from a technical and economical point of view, are selected and these are thoroughly analysed and appraised and the other remaining actions are discarded.

In the final appraisal phase, those actions selected in the first instance are defined more precisely by preparing the corresponding preliminary project and, the appraisal is made using the information in this preliminary project and the appraisal method in the Manual on shore investments is followed. The corresponding building projects are drawn up for the actions selected in the second phase and the execution of these projects are scheduled depending on their order of priority.

### 3.- Some actions implemented and Cost-Effective values obtained

Below are some examples of actions which have been implemented or are in progress, and the basic features of these actions and the cost-effective values obtained.

#### - Regeneration of the Pedralejo beach (Málaga)

Located in a modest district in the east of Málaga, with houses close to the sea. The beach has been regenerated with two free-standing breakwaters, two breakwaters in a Y shape and a breakwater with a flap to the west, and sand has been brought in. The already existing small fishing houses have been considerably revalued.

**Investment:** 489 million pesetas (M pt), at market prices

**Financial appraisal:** Updated net profit UNP = 71 M pt.

**Cost-Benefit Ratio** C/B = 1.15    **Internal Rate of Return** IRR = 7.37%

**Economic appraisal:** UNP = 1,322 Mpt    C/B = 3.7    IRR = 42.7%

**Social appraisal:** UNP = 1,496 Mpt    C/B = 4.06    IRR = 50.30%

#### - Regeneration of the Maresme: Premiá del Mar-Mongat (Barcelona)

The beach has virtually disappeared with the building of the Port of Arenys del Mar. Regeneration of the beach, about 7 km long, has consisted of building a breakwater and bringing in about two million m<sup>3</sup> of sand.

**Investment:** 972 million pesetas (M pt), at market prices

**Financial appraisal:** Updated net profit UNP = 238 M pt.

**Cost-Benefit Ratio** C/B = 1.25    **Internal rate of return** IRR = 8.63%

**Economic appraisal:** UNP = 2,314 Mpt    C/B = 3.38    IRR = 29.01%

**Social appraisal:** UNP = 2,678 Mpt    C/B = 3.75    IRR = 33.45%

- **Regeneration of Magalluf beach (Balears)**

Located at the western end of the bay of Palma de Mallorca, with an impressive hotel infrastructure, which causes massive overcrowding on this narrow stretch of beach.

136,000 m<sup>3</sup> of sand were brought in to a cove between two projections and naturally protected from the force of the waves by an existing island.

**Investment:** 176 million pesetas (Mpt), at market prices

**Financial appraisal:** Updated net profit UNP = 3656 Mpt.

**Cost-Benefit Ratio** C/B = 21.78 Internal Rate of Return IRR = 122.02%

**Economic appraisal:** UNP = 8,442 Mpt C/B = 48.97 IRR = 248.1%

**Social appraisal:** UNP = 7,991 Mpt C/B = 46.41 IRR = 241.7%

- **Regeneration of La Laja beach (Las Palmas de Gran Canaria)**

The aim of this regeneration is to provide Las Palmas with a beach for decongestion of Las Canteras beach. This has consisted of building two dikes, tipping 400,000 m<sup>3</sup> of sand, remodelling a promenade for cars and building a complex with cafeteria and public conveniences.

**Investment:** 835 million pesetas (Mpt), at market prices

**Financial appraisal:** Updated net profit UNP = -848 Mpt.

**Cost-Benefit Ratio** C/B = -0.02 Internal rate of return IRR = -11.04%

**Economic appraisal:** UNP = -272 Mpt C/B = 0.67 IRR = 1.53%

**Social appraisal:** UNP = 37.2 Mpt C/B = 1,04 IRR = 6.59%

- **Regeneration of the Gross beach in San Sebastián (Guipúzcoa)**

The aim is to provide the Gross district in San Sebastián with a stable beach, even at high tide, in order to reduce overcrowding on La Concha and Ondarreta beaches. Actions have consisted of prolonging the channelling of the River Urumea, the tipping 1,100,000 m<sup>3</sup> of sand and building a promenade and beach services. The regenerated length is about 900 m.

**Investment:** 2,773 million pesetas (Mpt), at market prices

**Financial appraisal:** Updated net profit UNP = 684 Mpt.

**Cost-Benefit Ratio** C/B = 1.25 Internal rate of return IRR = 9.03%

**Economic appraisal:** UNP = 4,833Mpt C/B = 2.74 IRR = 27.45%

**Social appraisal:** UNP = 4,833Mpt C/B = 2.74 IRR = 27.45%

- **Regeneration of the stretch of the shore Peñíscola-Benicarló**

This has consisted of extending the current 1,800 m of beach next to the town of Peñíscola towards the north, as far as Benicarló. It is about 6 km long and about 70 m wide. Planned actions are: reinforcement of the coastline, building a promenade, detour of the road towards the interior and tipping of sand.

**Investment:** 3,391 million pesetas (Mpt), at market prices

**Financial appraisal:** Updated net profit UNP = 4,572

**Cost-Benefit Ratio** C/B = 2.35 Internal Rate of Return IRR = 17.46%

**Economic appraisal:** UNP = 13,399 C/B = 4.95 IRR = 37.85%

**Social appraisal:** UNP = 16,160 C/B = 5.77 IRR = 43.59%

## CHAPTER 234

### Parametrization for conceptual morphodynamic models of Wadden Sea areas

Ernst Schroeder<sup>1</sup>, Roland Goldenbogen<sup>1</sup> and Hans Kunz<sup>2</sup>

#### Abstract

Climate changes could lead to remarkable changes of boundary conditions with respect to the interactions between hydrodynamics and morphology. This would impact especially coastal areas with movable beds like the Wadden Sea of the Southern North Sea. Therefore applicable tools for a prediction of morphodynamical development due to changing conditions are demanded. The German-Dutch research project "*Morphological development of the Wadden Sea region with special emphasis of the impact of an increasing relative sea level rise - WADE*" deals with the described problem by developing suitable conceptual morphodynamic models. An essential part of these models is parametrization. Empirical investigations were carried out for different tidal basins of the German Wadden Sea leading to parameters which describe and quantify the interactions between hydrological impacts and morphological responses. The gained results had been applied to a case study based on an empirical model.

#### Introduction

The German Wadden Sea consists of barrier islands, tidal basins and salt marshes which is important with respect to several ecological and economical aspects. Viewing the ecology, it is a consistent system of highly specialized flora and fauna. Beyond the actual geographical extension it is a remarkable resting- and

---

<sup>2</sup>Director, Dr.-Ing.

Coastal Research Station (CRS) of the Lower Saxonian Central State Board for Ecology, An der Mühle 5, D-26548 Norderney/Germany

breeding-ground for migrating birds. Economically it represents a main component of the coastal defence system by which the islands and the low lying parts of the marshland are protected. The Wadden Sea is also used for fishery and recreational means.

The goal of the investigations is to answer the critical question how tidal basins (tidal flat areas) will be influenced by changing hydrological and morphological boundary conditions and whether they will be able to keep pace with an accelerated relative sea level rise.

Therefore, a converted version of the model by Van Dongeren & de Vriend (1994) has been applied to predict the longterm behaviour of tidal basins. This empirical conceptual morphodynamical model needs parametrizations of the hydrographical and the morphological boundary conditions and their physical interactions. The paper deals with these parametrizations (tidal basins in total and as hierarchically systems of subareas) by empirical functions which are based on statistical analyses.

### Investigation area

The investigations have been carried out for two study areas along the German coast of the North Sea: The "East Frisian Wadden Sea" and the "Bay of Dithmarschen".

The East Frisian Wadden Sea extends about 80 km from the west (Osterems) to the east (Harle) see Fig. 1.

Fig. 1 East Frisian Wadden Sea with islands, tidal inlets, basins and subsystem-areas (1990)

It covers an area of about 800 km<sup>2</sup> between the mainland and its barrier islands. The East Frisian Wadden Sea contains 6 tidal inlets with the connected tidal basins. Each basin (intertidal catchment area) is divided into several "hierarchical subsystems", limited by the area boundaries.

The Bay of Dithmarschen is located in front of "Schleswig-Holstein". It is an open single tidal basin (Fig. 2). In 1972 and 1978 parts of the bay had been reclaimed: by the enclosure in 1972 about 11.5 km<sup>2</sup> in the southern part and in 1978 about 21.5 km<sup>2</sup> in the northern part. Before 1972 the area covers about 200 km<sup>2</sup>; it has been divided into "subsystems" - see Fig. 2.

Fig. 2 Bay of Dithmarschen with hierarchical subsystems (1969)

Both investigation areas are characterized by semidiurnal tides propagating east- respectively northwards along the coast. According to Hayes (1975) the areas can be classified as tide-dominated and high-mesotidal (the medium tidal range for the East Frisian-area is about 2.50 m; that for the Dithmarschen-bay is about 3.30 m). The significant mean wave heights (offshore) induced by the predominant wind out of the western sector are in the range of 1.0 m. Fresh water run off or discharges by sluices are negligible.

#### Data sets

The basis-data for the investigations of the East Frisian Wadden Sea are the three topography surveys from 1960, 1975 and 1990. The calculations for the Bay of Dithmarschen are based on 9 surveys carried out between 1942 and 1990. The density of data is very high and detailed.

The investigations have been executed by using a Geographic Information System (GIS, ArcInfo by ESRI<sup>TM</sup>) (Liebig, 1993). The topographical data of the study areas

were implemented by digitizing maps. All parameters have been calculated with this database as geometrical quantities.

### Parametrization

Within the scope of these investigations the parametrizations for the tidal basins and the subsystems were restricted to areas, volumes and a *characteristic height* describing the geometrical structure inside a tidal basin. In a further step it is desirable to include a parameter which describe the impact of the wave climate.

The extension of the areas for parametrization have been fixed by the intersecting lines between the actual topography and horizontal reference levels. The reference levels have been defined as horizontal planes. Exemplary calculations showed, that the error between horizontal and inclined planes are less than 1%. The reference levels are the mean high water (MHW), mean low water (MLW) and the German ordnance-datum (NN) which approximately corresponds with the MSL for the German Bight. The mean values have been calculated over the last five years before the survey. Missing data have been completed by using correlations between adjacent gauges.

With respect to the hierarchy of the subsystem structure the investigated functions were also checked for small areas. In general the scattering increases with decreasing size of the area. When subsystems are located close to the coastline, than the characteristics (tide- or wave-dominated) can be affected by tides or waves. The characteristics of subsystems may be influenced by anthropogenic changes of the boundaries, especially by land reclamation means - see Bay of Dithmarschen.

The spatial dimension (6 & 1 tidal inlets) allows complementary investigations to verify different relationships.

The "basic parameters" (O'Brien, 1931) are:

$A_b$	basin area
$A_c$	cross sectional area
$V_T$	mean tidal prism.

Additional geometric parameters describing the morphological structure of the Wadden Sea areas are (Renger, 1976):

$A_i$	intertidal area (MLW - MHW)
-------	-----------------------------

and (Dieckmann, 1985; Wieland et al., 1987):

- $l_i$  characteristic level of the intertidal area  
 $V_i$  intertidal sediment volume.

The last three parameters have been proven as valid to balance the morphological dynamics or the changing sediment volumes inside a tidal basin.

The validity of the functions for areas smaller than  $A_{b \text{ MHW}} = 10 \text{ km}^2$  is questionable as a result of local influences. Moreover the nonlinear functions needs a threshold value to estimate physical suggestive results. Also in this context the threshold value should be greater than  $A_{b \text{ MHW}} = 10^7 \text{ m}^2$  and  $V_T = 10^7 \text{ m}^3$  respectively.

General aspects and relations based on the parameter basin area  $A_b$

Amongst the basin area  $A_b$ , the mean tidal prism  $V_T$  is the main parameter which influences the shape and structure of the tidal inlet or the morphology respectively. Figure 3 displays the comparison between those data sets for tidal basins along the North Sea coast and the US-coast.

Results of investigations based on historic data which go back to the seventeens century are published by Niemeyer (1993).

Fig. 3 Basin area  $A_b$  versus tidal prism  $V_T$  - Comparison of data for the North Sea- and the US-Coast

Consistent data based on GIS-proceeding have been elaborated for a period of about 30 years for the East Frisian Wadden Sea and 50 years for the Bay of Dithmarschen. Figure 4a shows the data for the East Frisian

Wadden Sea with linear regression functions. It shows a tendency of increasing tidal prisms with time. This is possibly a result of changing tide levels (Fig. 6).

The quality of the results gained by statistical investigations are clearly explained by the data set of 1975: The scatter plot of  $A_b$  versus  $V_T$  in logarithmic scale displays a good fitting of the linear function (Fig. 5). The comparison of observed versus predicted values showed a satisfactory accordance not only for the tidal basins, but also for the small subareas.

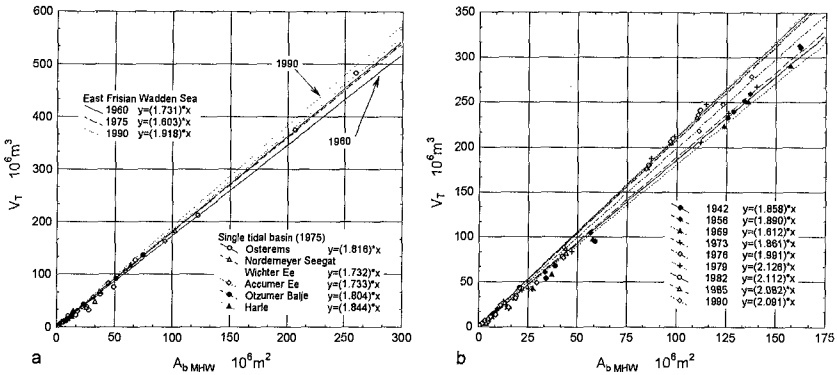

Fig. 4 Basin area  $A_b$  versus tidal prism  $V_T$  - East Frisian Wadden Sea (a) and Bay of Dithmarschen (b)

Fig. 5 Basin area  $A_b$  versus mean tidal prism  $V_T$  - East Frisian Wadden Sea (logarithmic scale)

The comparability of tidal basins of the East Frisian Wadden Sea has been investigated. The result is a concentrated bunch of functions that have no orderly sequence in regard to the location along the coast (Fig. 4a).

However, the fitted regression functions of the coefficients show a slight increase along the coast from west to east (Fig. 6).

Similar results are yielded by the investigations for the Bay of Dithmarschen (Fig. 4b). The coefficients are slightly higher than those of the East Frisian Wadden Sea. The mean value comes to 1.855 for the period between 1942 and 1969. On account of the reclamation in 1972, it would be expected that the function of 1973 would shift. But the decreasing MHW (0.05 m) and MLW (0.03 m) compensates this effect. The counterrotating effect occurred in 1976 as a result of the increasing tidal level and tidal prism.

Fig. 6 Coefficient "a" of  $V_T = a \cdot A_b$  MHW, MHW, MLW and MTR for locations of the East Frisian Wadden Sea

The data of the second reclamation in 1978 display a consistent outcome. The mean value comes to 2.095 for the period between 1982 and 1990. A weak tendency of a decreasing tidal prism and basin area is noticeable. The difference between the coefficients of 1973 ( $a = 1.862$ ) and 1990 ( $a = 2.091$ ) corresponds with an increasing tidal prism of about 12 %. The comparison between the East Frisian Wadden Sea and the Bay of Dithmarschen yield a greater tidal prism (3 to 9 %) relatively to the basin area for the Bay of Dithmarschen.

The second parameter which is used in modelling is the intertidal area  $A_i$ . The intertidal area is defined as the vertical projection of the topography within the limits defined by the MHW and MLW (Renger, 1976). The investigation of the relationships  $A_b$  versus  $A_i$  led to nonlinear functions. In contrast to the previous findings, the data do not show a continuous shifting (Fig. 7a). Because of the slight differences of the results for the distinguished time-periods, it is reasonable to calculate a mean function for the whole period; the result is:

$$A_{i \text{ MLW}} = 13.172 A_{b \text{ MHW}}^{0.837}.$$

Fig. 7 Basin area  $A_b$  MHW versus intertidal area  $A_i$  MLW - East Frisian Wadden Sea (a), Bay of Dithmarschen (b)

The data of the Bay of Dithmarschen display a similar image (the data are divided into two groups). There is no significant deviation due to the first reclamation in 1972. As a result of the second reclamation in 1978 there is a distinct shifting visible. The data from 1979 to 1990 tend to a backwards directed development due to a decreasing basin area  $A_b$  and an increasing intertidal area  $A_i$ . This led to the expectation that the mean function of the period 1942 to 1969 describes an equilibrium state (Fig. 7b):

$$A_i \text{ MLW} = 3.372 A_b \text{ MHW}^{0.923}.$$

Furthermore the relation of the intertidal area versus the basin area indicates a greater share of the intertidal area for the Bay of Dithmarschen than for the East Frisian Wadden Sea. The amount of this difference depends on the size of the basin area; for  $A_b = 100 \text{ km}^2$  the difference of  $A_i$  is 25 %.

The intertidal volume  $V_i$ , describing the sediment volume, is defined as the volume between MHW and MLW according to Wieland et al. (1987). This is the range which is mainly influenced by the tidal prism. The investigation shows two groups of data. One includes the data of the years 1960 and 1975. The regression functions are nearly coincident. The other one is the function of 1990, which is substantially different (Fig. 8a). The intertidal volume  $V_i$  decreased significantly compared to 1960 and 1975 as a result of a raise of MHW and MLW in

combination with changes of the topography (erosion). The function which describes the equilibrium state can be calculated with the data of 1960 and 1975. This leads to:

$$V_i \text{ MLW} = 32.99 A_b \text{ MHW}^{0.790} .$$

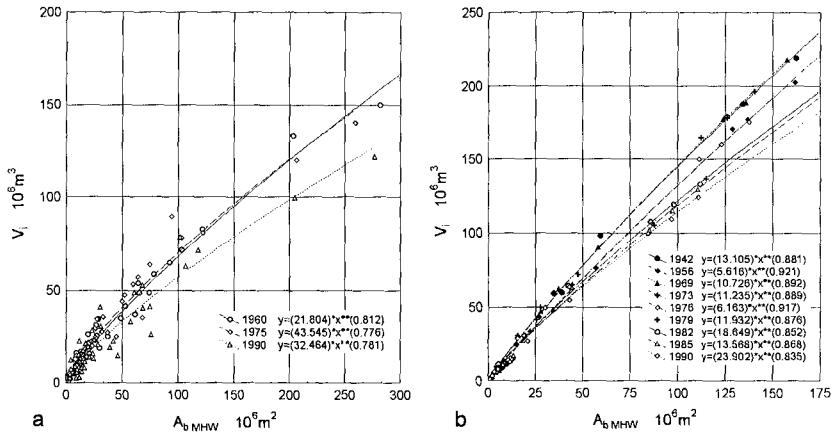

Fig. 8 Basin area  $A_b$  MHW versus intertidal volume  $V_i$  - East Frisian Wadden Sea (a), Bay of Dithmarschen (b)

The evaluation for the Bay of Dithmarschen shows three different relationships (Fig. 8b). The relations shown in the upper part enclose the years 1942, 1969 and 1973. The survey of 1973 had been carried out one year after the first enclosure. The middle part shows the functions of 1956 and 1976. The contradictory developments of both groups are mainly affected by changing water levels and are not the consequences of erosion or sedimentary effects. In the bottom-group of relationships, the scattering is very small; the tendency of decreasing intertidal volume results also in the growth of the MLW. The general tendency of decreasing tidal volumes relative to the basin areas results in the enclosure of the high lying supratidal areas in front of the coast. Based on 1942 and 1969 the equilibrium function is:

$$V_i \text{ MLW} = 11.96 A_b \text{ MHW}^{0.886} .$$

For investigations based on the relationship between basin area  $A_b$  versus cross sectional area  $A_c$  it is important, that the lowest scattering was found by using  $A_c$  related to the reference level NN (area between NN and the contour line).  $A_c$  was determined at the location with the strongest constriction of the streamlines. The

analysis led to linear functions (Fig. 9a). Based on all three data sets together, the mean function of the East Frisian Wadden Sea has been found as:

$$A_{c\ NN} = 0.000165 A_{b\ MHW}$$

The data of the Bay of Dithmarschen display the distinguished "influenced" and "noninfluenced areas" as a result of the enclosure works (Fig. 9b). The equilibrium function was calculated with the data of the last survey before enclosure (1969):

$$A_{c\ NN} = 0.000123 A_{b\ MHW}$$

Fig. 9 Basin area  $A_{b\ MHW}$  versus cross sectional area  $A_{c\ NN}$  - East Frisian Wadden Sea (a), Bay of Dithmarschen (b)

In order to describe the development of the height of intertidal areas or the volumes respectively, the characteristic level  $l_i$  (Dieckmann, 1985) has been investigated. Herewith it is possible to verify the progress of erosion or sedimentation for stages of dynamic equilibrium. The parameter  $l_i$  is defined as the level where the intertidal area  $A_i$  is half exposed and half submerged. This led to a characteristic level between MHW and MLW. The scatter plot of  $l_i$  versus  $A_{b\ MHW}$  shows an asymptotic behaviour with increasing  $A_{b\ MHW}$  (Fig. 10 and 11). The graphs contain the empirical function which represent the lower and upper limit of  $l_i$ . Deviations of  $l_i$  indicate a nonequilibrium stage of the subsystem or the impact of local influences by the different boundary conditions that lead to variations between the subsystem and its total tidal basin.

Fig. 10 Basin area  $A_b$  MTHW versus intertidal level  $l_i$  of the East Frisian Wadden Sea

Fig. 11 Basin area  $A_b$  MTHW versus intertidal level  $l_i$  of the Bay of Dithmarschen

Relations based on the parameter mean tidal prism  $V_T$

The mean tidal prism  $V_T$  has been defined as the volume between MHW and MLW. The analysis of the relationship between  $V_T$  and  $A_i$  led to the same behaviour as explained before (Fig. 12a and b). Remarkable is the overlapping bunches of functions for both investigation areas. This is possibly a result of the parameter  $V_T$  which implicitly includes the tidal range as one of the main boundary condition for the classification of tidal inlets (Hayes, 1975). The derivation of an equilibrium relationship are based on the years 1960 and 1975 for the East Frisian Wadden Sea and on 1942 and 1969 for the Bay of Dithmarschen. The relations are:

$$A_{i \text{ MLW}} = 15.50 V_T^{0.805} \quad (\text{East Frisian Wadden Sea})$$

$$A_{i \text{ MLW}} = 9.199 V_T^{0.841} \quad (\text{Bay of Dithmarschen}).$$

Fig. 12 Mean tidal prism  $V_T$  versus intertidal area  $A_{i, MLW}$  - East Frisian Wadden Sea (a), Bay of Dithmarschen (b)

Furthermore the relation tidal prism  $V_T$  versus intertidal volume  $V_i$  indicates the same grouping of influenced and noninfluenced surveys (Fig. 13a and b). The equilibrium functions are:

$$V_{i, MLW} = 36.83 V_T^{0.761} \quad (\text{East Frisian Wadden Sea})$$

$$V_{i, MLW} = 28.97 V_T^{0.812} \quad (\text{Bay of Dithmarschen}).$$

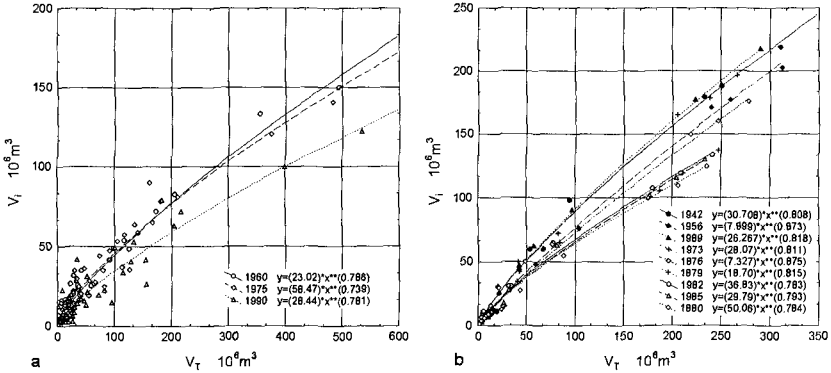

Fig. 13 Mean tidal prism  $V_T$  versus intertidal area  $V_{i, MLW}$  - East Frisian Wadden Sea (a), Bay of Dithmarschen (b)

It appears that the overall aspect about the amount of the intertidal volume relative to the size of basin area and tidal prism is greater for the Bay of Dithmarschen than for the tidal basin of the East Frisian Wadden Sea. The small differences during 1979 up to 1990

seems to tend to a new relationship as a result of changing geometrical boundary conditions.

### Example of application

The described functions (parameters) were applied in a conceptual morphodynamic model for large scale morphological changes of hierarchically structured channel-basin-systems in tide-dominated coastal areas. This model is based on Van Dongeren & de Vriend (1994). The model reproduces erosion and sedimentation due to changes of tidal parameters by moving sand volumes within a hierarchically system composed of channels and connected subareas (Goldenbogen, 1994). It has been applied for the Bay of Dithmarschen by using some of the above presented parametrizations (Schroeder, 1994):

$$A_i \text{ MLW} = 3.372 A_b \text{ MHW}^{0.923}$$

$$A_c \text{ NN} = 0.000123 A_b \text{ MHW}$$

$$l_i = 0.05 + 0.5 / ( 1 + ( 3 * 10^{-8} A_b \text{ MHW} )^2 ).$$

The simulation cover a period of 20 years. Figure 14 shows the results at the location southern of Büsum (see Fig. 2). Two superimposed effects have been calculated: a rise of the relative sea level (0.005 m/a) and the enclosures in 1972 and 1978.

Fig. 14 Comparison of model results and field data

On account of the small amount of the assumed relative sea level rise this influence does not become noticeable. The enclosures is reproduced by the model in a realistic manner. With the exception of the cross

sectional area  $A_c$ , which has been simulated by a continued process, all the other parameters show a discontinually pattern as impact of the enclosure (immediately reduction of predominant highly situated areas in front of the coastline). A new equilibrium stage requires an increase of the intertidal area  $A_i$  over time, as it, for example, has been after the first enclosure of the Bay of Dithmarschen in 1972.

The model does not consider influences of changing wave climate or the geometric shape of the basin. This require further adaptations of the equilibrium functions.

### Conclusions

The results of investigations for two different tide-dominated Wadden Sea areas of the Southern North Sea (open bay and bays sheltered by barrier islands) demonstrate, that a reliable parametrization of the interactions between hydrological impacts and morphologically responses is possible. This result is proven as well for tidal basins as for distinguished subareas of different size and location. However, the validity of functions for tidal areas smaller than  $A_b$  MHW = 10 km<sup>2</sup> is questionable. The proven empirical functions had been applied to a conceptional morphodynamic model. The results showed that empirical morphodynamical modelling is a suitable tool to reproduce transitional morphological stages leading from a former to a new equilibrium fixed by changed boundary conditions. The method can lead to a profound forecasting of the development of Wadden Sea areas in medium time scales, needed for decisions on engineering and ecological purposes.

## MUD TRANSPORT AND MUDDY BOTTOM DEFORMATION BY WAVES

Daoxian SHEN\* Masahiko ISOBE† and Akira WATANABE†

### ABSTRACT

The present study focuses on numerical simulation of wave height decay and muddy bottom deformation under wave action. Experiments have been performed to determine the vertical distribution of the water content ratio of mud. Using the experimental results, a simulation model has been set up to estimate change in the water content ratio in the mud bed. Also, a simple one-dimensional numerical model has been developed to predict the muddy bottom deformation under waves as well as the wave height decay. Wave flume experiments have been carried out and the changes in the bottom topography and wave height have been compared with the calculations.

KEYWORDS: Change in water content ratio, Wave height decay, Mud transport, Muddy bottom deformation.

## 1 Introduction

Along muddy coasts fine grained, cohesive sediment is consistently present in the nearshore waters and around the shoreline. These muddy bed sediments may have a significant effect on the hydrodynamic processes. Prediction of mud transport and resultant bathymetric change due to waves are essential in order to take effective countermeasures against erosion and siltation and to plan rational new works in coastal regions. Although many studies on mud transport under waves and on wave dissipation due to mud motion have been conducted (Gade, 1958; Dalrymple and Liu, 1978; Mei and Liu, 1987; Shibayama, 1993), only few attempts have been reported so far on the prediction of topography change on soft mud beaches.

The establishment of topographical change models for muddy beaches seems to be difficult for three reasons. First, the transport of fine-grained cohesive sediment is quite different from that of coarse-grained sediment. The cohesiveness

†Professor, Department of Civil Engineering, University of Tokyo, Hongo 7-3-1, Bunkyo-ku, Tokyo, 113 Japan

of soft mud makes its motion under the action of waves and currents more complicated than that of non-cohesive sediment. Second, the vertical structure of the concentration depends on both wave conditions and mud properties. Third, it is difficult to formulate a relationship for the local transport rate under the waves. It may be stated that our knowledge of mud transport processes has not yet reached a level where we can deal with these problems effectively.

On the other hand, the interaction between propagating ocean waves and a stable seabed or consolidated soil has received an extensive attention in the field of offshore and foundation engineering (Yamamoto, 1978; Zen and Yamazaki, 1991). However, their interest is either in the wave-induced liquefaction in a porous seabed or on the problem of unfavorable pore pressure, which could make the seabed or an offshore structure unstable.

The present study focuses on the numerical simulation of wave height decay and muddy bottom deformation under wave action. First, the vertical distribution of the water content ratio of mud was investigated experimentally, and numerical simulations on the change in the water content ratio in the mud layer were made. Then, a simple one-dimensional numerical model was developed to predict the muddy bottom deformation under waves as well as the wave height decay. Wave flume experiments were carried out and the measured changes in the bottom topography and wave height were compared with the calculations.

## 2 Vertical distribution of water content ratio in mud layer

### 2.1 Experiments

The water content ratio of soft mud strongly affects its rheological properties and the vertical distribution of the water content ratio is significant for estimating mud motion. In order to clarify the effects of wave action on the change in the water content ratio in mud layers, two groups of experiments have been performed using commercial kaolinite; one for static water loading and the other for regular wave loading.

In the first group of experiments, a plastic square tank with a side length of 45cm and a plastic circular bucket with a radius of 38cm were used. The depths of the newly mixed mud in the tank and the bucket were set to about 14.4cm and 12.1cm, respectively, above which water was poured to 30cm and 26cm depth in order to allow comparison with the other group of experiments.

During the experiments the vertical distribution of the water content ratio of the soft mud was measured for about 220 hours and the results from one test is shown in Fig. 1. Meanwhile, the settlement of the mud layers in the containers were also observed, and the results were displayed in Fig. 3.

Figure 1 indicates that the change in the water content ratio by mud consolidation is large near the fixed bed and small in the surface layer.

The other group of experiments on the effects of wave action were performed

Figure 1: Change in water content ratio in still water

Figure 2: Change in water content ratio under waves (WE93A.15)

Table 1: Experimental conditions on change in water content ratio

Run	Mud depth (cm)	Period (s)	Water content (%)	Wave height (cm)
WE92E	16.4*(8,8.4)	1.02	(182, 120)	5.52
WE93A	16.0	1.02	175	5.20
WE93C	12.0	1.02	175	6.00

\* two-layered bottom with a 8.0cm newly mixed upper layer and a 8.4cm consolidating lower layer

Figure 3: Settlement of mud layer in still water

in a large wave flume shown in Fig. 8, and the experimental conditions are summarized in Table 1. The water content ratio was measured at a few sections in the flume together with the distribution of the wave height and one typical example of the change in water content ratio is plotted in Fig. 2. This figure shows that the water content ratio in the surface layer increases with time due to the mud loosening whereas it decreases near the bottom because of the mud densification.

From the two groups of the experimental results, it can be seen that the change in the water content ratio of soft mud is caused by both wave action and self-weight. However, the roles of these two mechanisms are quite different. Gravity and static water only consolidate soft mud to consolidate whereas wave force can cause both "liquefaction" in the surface layer and densification in the lower layer of mud. Moreover, the densification produced by waves is much faster than that by static water and gravity. In addition, the position of the demarcation point of liquefaction and consolidation at a fixed section changes with the state of the mud consolidation.

The change in the water content ratio depends on both wave and mud layer properties. The influence of wave height on the change in the water content ratio has also been investigated experimentally, and the results are shown in

(a) Distribution of wave height measured in the x-direction(WE93C)

(b) Distr. of water content ratio measured in the x-direction(WE93C)

Figure 4: Influence of wave height on the change in water content ratio

Fig. 4. Figure 4b plots the distribution of the water content ratio measured in the on-offshore direction, and Fig. 4a depicts the corresponding wave height at the beginning of the experiment. The figure implies that a larger wave height produces a larger change in water content ratio.

**2.2 Simulation of the change in water content ratio**

The above experimental results suggest that wave action affects soft mud both through densification in the lower layer and liquefaction in the surface layer. Enlightened by the experimental investigation we first consider the two processes of mud consolidation and liquefaction separately, and then combine their effects on the change in the water content ratio linearly. We assume that mud densification which results in the decrease of the water content ratio is induced only by

the mud self-weight and the positive dynamic pressure or compressive stress, and reversely, that mud liquefaction which leads to the increase of the water content ratio is produced only by the negative dynamic pressure or tensile stress. Thus, the process of liquefaction is treated as the complete reversal of consolidation.

To describe the densification of the mud layer, the one-dimensional consolidation equation in soil dynamics is applied, and for general case written by,

$$\frac{\partial e}{\partial t} - \frac{\partial e}{\partial z} \left[ g(e) \frac{\partial e}{\partial z} \right] - f(e) \frac{\partial e}{\partial z} = 0 \quad (1)$$

where the parameters  $g(e)$  and  $f(e)$  depend upon the wave properties as well as the mud characteristics. As a first step, those parameters are estimated using the following formulas which are based on limited experimental results, trial computations, and dimensional analysis,

$$g_c = \frac{k_c(e)}{\rho(1+e)} \frac{dp_m}{de} \left\{ 1 + \alpha_c \left( \frac{H_w}{L} \right)^{m_1} \left( \frac{H_w}{\sqrt{hd}} \right)^{m_2} \frac{k_c(e) - k_l(e)}{k_c(e) + k_l(e)} \right\} \quad (2)$$

$$f_c = \frac{\rho_m - \rho}{\rho} \frac{d}{de} \left\{ \frac{k_c(e)}{1+e} \left[ 1 + \frac{k_c(e) - k_l(e)}{k_c(e) + k_l(e)} \right] \right\} \quad (3)$$

In the above equations  $e$  denotes the void ratio,  $k_c$  and  $k_l$  indicate the permeability in the conditions of compressibility and dilatation of mud,  $\rho_m$  and  $\rho$  are the densities of the mud and the sea water,  $p_m$  is the amplitude of the pore pressure,  $d$  the mud depth,  $H_w$  the wave height,  $L$  the wavelength, and  $h$  the water depth. The variables  $\alpha_c$ ,  $m_1$ , and  $m_2$  are constants.

Following Been and Sills (1981), the governing equation can be solved with the appropriate boundary and initial conditions.

Next, we consider the loosening of mud under waves which is tentatively called "liquefaction" in the present study. Because the process of liquefaction is regarded as the reversal of consolidation, all of the assumptions and equations mentioned above can be applied to calculate liquefaction. The parameters  $g(e)$  and  $f(e)$  are expressed as follows,

$$g_l = \frac{k_l(e)}{\rho(1+e)} \frac{dp_m}{de} \left[ \alpha_l \left( \frac{H_w}{L} \right)^{m_3} \left( \frac{H_w}{\sqrt{hd}} \right)^{m_4} \frac{k_c(e) - k_l(e)}{k_c(e) + k_l(e)} \right] \quad (4)$$

$$f_l = \frac{\rho_m - \rho}{\rho} \frac{d}{de} \left[ \frac{k_c(e)}{1+e} \cdot \frac{k_c(e) - k_l(e)}{k_c(e) + k_l(e)} \right] \quad (5)$$

where  $\alpha_l$ ,  $m_3$  and  $m_4$  are constants.

Finally, the vertical distribution of the water content ratio under waves and gravity can be estimated by combining linearly the effect of consolidation and liquefaction. The depth of the liquefied mud layer is also determined through this combination.

As an example, Fig. 5 compares the calculated and measured vertical distribution of the water content ratio of mud under waves, and the values of the main

Table 2: Computational parameter values for the experiment

$k_c(e)/[\rho_f(1+e)]$	$k_l(e)/[\rho_f(1+e)]$	$g_c$	$g_l$	$dp_m/de$
$4.0 \times 10^{-11}$	$3.0 \times 10^{-11}$	$7.2 \times 10^{-9}$	$1.9 \times 10^{-9}$	18.0

Figure 5: Comparison of the calculated and measured distribution of the water content ratio(WE93A.10)

parameters used in the computation are listed in Table 2. These values were determined by numerical experimentation. As can be seen from the figure, the calculated and measured shape of the vertical distribution agree well, but the magnitudes in the surface layer and near the fixed bed differ. This difference may partially be due to the neglect the nonlinear terms in the consolidation equations, and partially because of other model simplifications.

In summary, the simple model is applicable for predicting the vertical distribution of the water content ratio in the mud layer under wave action, keeping in mind the range of values employed in the experiment.

### 3 Muddy bottom deformation due to waves

#### 3.1 Development of a topographical change model

Following the general structure of numerical models of sandy topography evolution, a one-dimensional numerical model of muddy bottom deformation is developed with a model structure as shown in Fig. 6. This model consists of three submodels for calculating 1) the vertical distribution of the water content ratio in the mud layer, 2) the wave deformation and mud motion, and 3) the mud transport rate and bathymetric change.

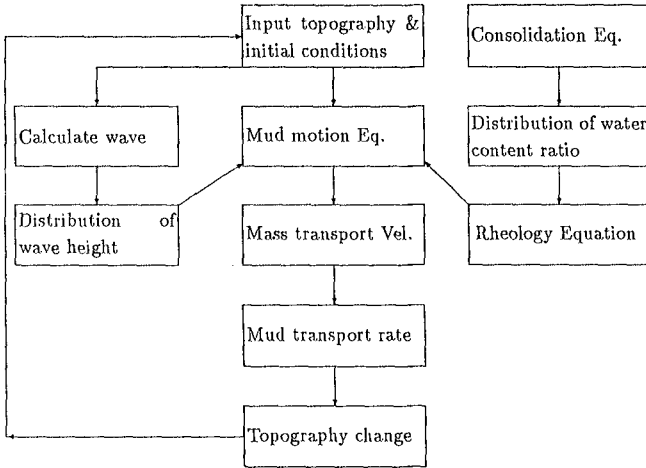

Figure 6: Structure of the numerical model of bottom change

First, let us discuss the calculation of the wave field. The mild-slope equation with the energy dissipation term is adopted to calculate the wave field,

$$\nabla \cdot (cc_g \nabla \phi) + (\sigma^2 \frac{c_g}{c} + i\sigma f_D)\phi = 0 \tag{6}$$

where  $\phi(x, y)$  is the velocity potential on the mean free surface assumed to be

$$\Phi(x, y, z, t) = \phi(x, y) \frac{\cosh k(z+h)}{\cosh kh} e^{-i\sigma t} \tag{7}$$

and  $c$  and  $c_g$  denote the wave velocity and the group velocity, respectively,  $\sigma$  is the angular frequency, and  $k$  the wave number. The energy dissipation coefficient  $f_D$  varies both with the spatial coordinate and time and is defined as

$$f_D = \frac{\epsilon_D}{E} \tag{8}$$

where  $E$  is the wave energy intensity, and  $\epsilon_D$  denotes the rate of energy dissipation per unit area estimated from the mud motion as,

$$\epsilon_D = \int_0^d \overline{\tau \frac{\partial u}{\partial z}} dz \tag{9}$$

where  $\tau$  is the shear stress in the mud layer and  $u$  the local velocity. The symbol  $\overline{\quad}$  denotes the average over one wave period and  $d$  the fluidized mud depth.

For the two-dimensional case with a constant water depth the equation (6) becomes

$$\frac{d^2 \phi}{dx^2} + \bar{k}^2 \phi = 0 \tag{10}$$

Figure 7: Definition sketch and coordinate system (Dissipation Area  $0 < x < x_l$ )

where

$$\bar{k}^2 = k^2 \left( 1 + \frac{icf_D}{c_g\sigma} \right) \tag{11}$$

One case of wave propagation over a muddy bed in a wave flume is discussed here. As shown in Fig. 7, the wave field is divided into three regions. The damping region occupies (D)  $0 < x < x_l$  and the flow domain extends to infinity ( $x \rightarrow \pm\infty$ ). Wave breaking is assumed not to appear in the regions studied. In regions (I) and (R), there are no energy dissipation,  $f_D = 0$ , and the solutions to Eq. (10) is

$$\phi_I = -\frac{igH_w}{2\sigma} (e^{ikx} + K_R e^{-ikx}) \quad x < 0 \tag{12}$$

$$\phi_R = -\frac{igH_w}{2\sigma} K_T e^{ikx} \quad x > x_l \tag{13}$$

where  $|K_R|$  and  $|K_T|$  represent the reflection and transmission coefficients, respectively. The damping region (D) is furthermore divided into  $n$  subregions because the dissipation coefficient varies with both the spatial coordinate and time, and the velocity potential in the  $j$ -th subregion is

$$\phi_{D_j} = -\frac{igH_w}{2\sigma} (B_j e^{i\bar{k}_j x_j} + F_j e^{-i\bar{k}_j x_j}) \quad x_{j-1} < x < x_j \tag{14}$$

where  $B_j$  and  $F_j$  are unknown constants to be determined and  $j = 1, 2, \dots, n$ .

By using the continuity conditions for  $\phi$  and its normal derivative, the unknown variables can be determined numerically from the following system of equations,

$$\phi_{D_j} = \phi_{D_{j+1}} \quad \text{at} \quad x = x_j \tag{15}$$

$$\frac{d\phi_{D_j}}{dx} = \frac{d\phi_{D_{j+1}}}{dx} \quad \text{at} \quad x = x_j \tag{16}$$

where  $j = 0, 1, 2, \dots, n$

For the simplest case  $n = 1$ , Liu *et al.* (1986) obtained an analytical solution for the equations given by

$$F = \frac{2 \left( \frac{\bar{k}}{k} - 1 \right)}{\left( \frac{\bar{k}}{k} + 1 \right)^2 \exp(-2i\bar{k}x_l) - \left( \frac{\bar{k}}{k} - 1 \right)^2} \quad (17)$$

$$B = \frac{2 - F \left( 1 - \frac{\bar{k}}{k} \right)}{1 + \frac{\bar{k}}{k}} \quad (18)$$

$$K_R = \frac{2 \left( 1 + \frac{F\bar{k}}{k} \right) - \left( 1 + \frac{\bar{k}}{k} \right)}{1 + \frac{\bar{k}}{k}} \quad (19)$$

$$K_T = \frac{2 - F \left( 1 - \frac{\bar{k}}{k} \right)}{1 + \frac{\bar{k}}{k}} \exp\{i(\bar{k} - k)x_l\} + F \exp\{-i(\bar{k} + k)x_l\} \quad (20)$$

Next, we turn to the simulation of the mud motion. The interaction between the waves and a muddy bottom is very complicated mainly because of the complex characteristics of mud, especially its rheological properties. We have derived an empirical rheological equation based on another set of experiments (Shen *et al.*, 1993a), and it reads

$$\tau = G\epsilon - \tau_G \tanh(\alpha_G \epsilon) + \mu\gamma + \tau_0 \tanh(\alpha_\mu \gamma) \quad (21)$$

where  $\tau$  is the shear stress,  $\epsilon$  the shear strain,  $\gamma$  the shear rate, and  $G$ ,  $\tau_G$ ,  $\alpha_G$ ,  $\mu$ ,  $\tau_0$  and  $\alpha_\mu$  are constants, of which  $G$  and  $\mu$  represent the elasticity and viscosity, respectively. Most of the constant parameters can be determined by rheological experiments and expressed as functions of the water content ratio.

It has been recognized that the interaction between the waves and the muddy bed will result in bottom deformation which produces a mild slope at the mud surface. The local mild slope strongly affects the mud motion in turn. Including the effect of the mild surface slope, the one-dimensional linearized equation of mud motion is modified as

$$\rho_m \frac{\partial u}{\partial t} = -\frac{\partial p}{\partial x} + \frac{\partial \tau}{\partial z} - (\rho_s - \rho)g \sin\theta \quad (22)$$

where  $\rho_m$ ,  $\rho_s$  and  $\rho$  denote the densities of the mud at any elevation, the mud at the surface layer and the water, respectively,  $\theta$  represents the surface slope angle of the mud layer,  $u$  is the velocity of mud particles,  $p$  the dynamic pressure which is calculated from the solution of the mild-slope equation, and  $\tau$  the shear stress evaluated by the proposed rheological relationship (21).

Numerical calculations have been carried out to solve the empirical rheological equation of soft mud, the mild-slope equation with the wave energy dissipation term, and the modified equation of mud motion.

Figure 8: Experimental set-up

After obtaining the wave height change and the local velocity of the mud particles, the mass transport velocity can readily be estimated from the following formula used by Huynh *et al.* (1991)

$$U_L = U_E + \overline{\frac{\partial u}{\partial x} \int u dt} + \overline{\frac{\partial u}{\partial z} \int w dt} = U_E + U_S \quad (23)$$

where  $U_E$  represents the Eulerian average velocity and  $U_S$  the Stokes drift. For the one-dimensional case, they are evaluated by

$$U_S = \overline{\left( -\frac{1}{c} \frac{\partial u}{\partial t} - u \frac{f_D}{2c_g} \right) \int u dt} \quad (24)$$

$$\mu' \frac{\partial^2 U_E}{\partial z^2} = -\frac{f_D}{c_g} \rho_m u^2. \quad (25)$$

where  $\mu'$  denotes the equivalent viscosity of mud.

Furthermore, the change in the local bottom elevation is computed by solving the conservation equation for sediment modified by Watanabe *et al.* (1984),

$$\frac{\partial z_b}{\partial t} = -\frac{\partial}{\partial x} (q_x - \epsilon_m |q_x| \frac{\partial z_b}{\partial x}) \quad (26)$$

where  $z_b$  denotes the change in the local elevation of the mud surface,  $\epsilon_m$  is a positive constant which is determined empirically, and  $q_x$  is the sediment transport rate per unit width estimated by

$$q_x(x) = \int_0^d U_L dz \quad (27)$$

Figure 9: Change in the local elevation of the mud layer

### 3.2 Experiments and comparisons with calculations

Laboratory experiments were performed in a wave flume 21m long and 0.8m wide (Fig. 8) to verify the developed one-dimensional numerical model. The completely mixed commercial kaolinite (water content ratio: 174%) was placed in the middle of the flume. The depths of the mud and water layer were set to 12cm and 30cm, respectively. During the experiment for a few hours, measurements were made on the distribution of the wave height along the direction of wave propagation, the water content ratio of the mud layer, the concentration of the suspended mud, and the change in the local bottom elevations.

The measurements of the change in the local bottom elevation were not easily performed because (i) the suspension of the mud layer makes the water layer translucent or opaque and (ii) the mud layer is too soft to resist loading. Therefore, some instruments which works very well in sand are invalid for mud. Based on trial and error, a set of height gauge reequipped and a set of elevation meter newly made were used simultaneously to measure the change in the local elevation of the mud bottom and to correct the measured values.

As an example, Fig. 9 shows the experimental results in terms of the measured elevation change. From these results, some understanding of and conclusions on the topography change can be obtained as summarized in the following:

a) The eroded volume is a little larger than the deposited volume for a short time interval, and the difference increases with the loading time due to both the mud suspension and the settlement of the mud layer.

b) The peak of the deposited area moves slowly with the loading time in the direction of wave propagation. An erosion trough was always produced in the offshore direction. In addition, the mud surface slopes have a tendency to become smaller and smaller with the loading time.

c) The wave has a larger damping ratio for the newly mixed soft mud, and the

Table 3: Computational conditions and main parameter values

Run	Mud depth (cm)	Period (s)	Water content (%)	Wave height (cm)
WE93B	12.0	1.02	175.4	4.95
$\rho_m$ (kg/m <sup>3</sup> )	$\rho_s$ (kg/m <sup>3</sup> )	$\tau_0$ (N/m <sup>2</sup> )	$\mu$ (Ns/m <sup>2</sup> )	G (N/m <sup>2</sup> )
1300	1270	7.0	4.8	55

damping ratio will decrease with the loading time due to mud consolidation. It seems reasonable to conclude that only a fluidized mud layer plays a role in the wave dissipation. If the mud is completely consolidated, it may not absorb wave energy. In fact, this conclusion has also been arrived at through other experiments not discussed here.

Next, we attempt to apply the one-dimensional model for a simple case of mud motion in the flume. Some additional simplifications and assumptions are added here on the basis of the experimental results. Because the change in the water content ratio of the mud layer is very small for a relatively short time interval, as a first step, we neglect this change. Moreover, we suppose that mud consolidation for a relatively short time interval has so little effect on the rheology relationships that the influence can be ignored. The settlement of the mud layer and the transport of suspended mud are also omitted. In addition, the vertical two-dimensional mud motion near the starting point of the flume ( $x = 0$ ) is simplified as one-dimensional by a so-called equivalent transforming of the local velocity of mud particles (Shen, 1993b).

Figure 10 compares the calculated and measured bottom change in the flume. The computational conditions and the main parameter values are listed in Table 3. It is seen that the calculated results of the bottom change have a similar tendency to the measured. However, at the right-hand side of the flume (downstream), the experimental results show that the mud motion stops at a certain position whereas the calculations can not simulate this phenomenon.

This discrepancy can be explained as follows. In the present one-dimensional model, an empirical rheology equation is utilized that implies mud will move under waves no matter how small the wave height is. In fact, the cohesive mud has a yield value that must be exceeded before the mud has a possibility to start moving. In addition, the simplifications and assumptions introduced in the present model have an effect on the prediction accuracy.

Figure 11 shows a comparison of the measured and calculated wave height distribution at the initial stage of an experiment, indicating a good agreement between them.

Figure 10: Comparison of measured and calculated bottom topography change in the flume

## 4 Conclusions

The present study focuses on investigating the vertical distributions of the water content ratio in a mud layer and numerical simulation of muddy bottom deformation and wave height decay.

The results of the first two groups of experiments have revealed that the change of the water content ratio is caused by both the wave action and the gravity of mud. However, the effects of wave action and gravity are quite different. The gravity only causes soft mud to consolidate, whereas the wave action can induce both the loosening in the surface layer and the consolidation in the lower layer of the mud. Numerical estimation of the change of the water content ratio in the muddy bed by the proposed simulation model has shown a similar tendency in the in the calculations as for the measurements.

A simple one-dimensional numerical model has been developed to predict the muddy bottom deformation under waves as well as the wave height decay. In conclusion, the one-dimensional model has been verified by the flume experiments to be applicable to predict the experimental phenomena, although its applicability is dependent on the accuracy of the rheological equation of mud.

## CHAPTER 236

### WAVE-INDUCED SEDIMENT RESUSPENSION AND MIXING IN SHALLOW WATERS

Y. Peter Sheng<sup>1</sup>, M. ASCE, Xinjian Chen<sup>2</sup>, and Eduardo A. Yassuda<sup>2</sup>

#### ABSTRACT

A field and modeling study on the resuspension and vertical mixing of sediments in Tampa Bay, a large shallow estuary, and Lake Okeechobee, a large shallow lake in Florida, U.S.A. has been studied. The study was aimed to obtain a quantitative understanding of the fundamental processes controlling resuspension and vertical mixing of sediments in the water column and to develop models for simulating resuspension and mixing of sediments in shallow waters. For the field study, field data (including wind, wave, currents, suspended sediments and water quality parameters) were collected from Tampa Bay and Lake Okeechobee during several episodic events. These data were then used for the development of a one-dimensional water column model of hydrodynamics, sediment dynamics and water quality dynamics. Results of the study indicate that during episodic events, bottom stresses induced by the wind waves are very effective in causing significant resuspension of sediments and nutrients from the bottom of shallow estuaries and lakes. Vertical turbulent mixing due to wind-driven and tidal currents, however, are more effective in distributing suspended sediments through the water column.

#### INTRODUCTION

A field and modeling study on the resuspension and vertical mixing of sediments has been conducted in a large shallow estuary (Tampa Bay in Figure 1) and a large shallow lake (Lake Okeechobee in Figure 2) in Florida. The primary objectives of the study are: (i) to quantify the fundamental processes controlling resuspension and vertical mixing of sediments in the water column, (ii) to compare the

---

<sup>1</sup> Professor, <sup>2</sup> Graduate Student, Coastal & Oceanographic Eng. Dept., University of Florida, Gainesville, Florida 32611-6590, U.S.A.

processes controlling resuspension and vertical mixing of sediments in the shallow estuary to those in the shallow lake, (iii) to develop models for simulating resuspension and mixing of sediments in shallow waters, and (iv) to quantify the effects of sediment resuspension and vertical mixing on contaminant transport in shallow waters.

To accomplish the objectives of the study, field experiments and numerical simulations were conducted. Because of scaling problems in laboratory simulation of field processes, only limited laboratory experiments were conducted.

### FIELD EXPERIMENTS

Field studies were conducted in Tampa Bay (Sheng et al., 1993a) and Lake Okeechobee (Sheng et al., 1993b) during episodic events in 1992 and 1993. For example, a no-name storm passed the Tampa Bay area in February 1992. A front passed Lake Okeechobee in January 1993. A "Storm of the Century" passed Tampa Bay in March 1993. To obtain data during the storms, instrument platforms (Figure 3) were deployed in the water bodies prior to the storms. For example, platforms were deployed at Site A and Site B (Figure 1) in Tampa Bay during 1993, while platform was deployed at Site A in Tampa Bay during 1992. Platform was deployed in Lake Okeechobee at Site L002 during 1993.

On each platform, instruments were mounted to measure wind (anemometer), wave (underwater pressure gauge), current (2-3 Marsh McBirney EM current meters), water level (vented pressure gauge), salinity and temperature (2-3 SeaBird CTD sensors), and suspended sediment concentration (2-3 OBS sensors). In addition, various instruments were mounted to measure such water quality data including dissolved oxygen concentration, pH, and concentration of various nitrogen and phosphorus species. With the exception of instruments for measuring nutrient concentrations, most instruments can be connected to a data logger to collect continuous data with 2-Hz sampling frequency over several (e.g., 5-7) days using battery power. 15-minute averaged data are also recorded. However, since the storms usually last less than 1-2 days, it is extremely difficult for the instruments to "capture" the storms. The instrument platforms usually have to be deployed in the water body 1-2 weeks prior to the arrival of a forecasted storm, activated 1-2 days before the storm, and retrieved a few days after the storm. The collection of nutrient data is particularly difficult since it requires immediate filtering of water samples at the data site.

The field data were used to provide information on the dominant forcing mechanisms for sediment resuspension/erosion and vertical mixing. In particular, statistical analysis was performed to determine the dominant frequencies and correlations of various physical parameters. In addition to the data analyses, numerical models were used to assist the interpretation of field data and to quantify

the various processes.

### NUMERICAL MODELING

Three-dimensional numerical models of sediment transport have been developed by Sheng (1986) and Sheng et al. (1991). In this study, since the focus is on the fundamental processes in the vertical water and sediment columns, a vertical one-dimensional numerical model was used. Basically, the vertical 1-D model developed by Sheng and Villaret (1989) and Sheng et al. (1989) was significantly modified to simulate the current, turbulence, and sediment dynamics in the water column. Basically, the one-dimensional model includes a hydrodynamic component and a sediment component. The hydrodynamic component of the 1-D model computes the horizontal velocities forced by wind, wave, and pressure gradients (associated with tidal circulation and baroclinic circulation). In order to simulate the vertical turbulent mixing throughout the water column, we developed a procedure which determines the horizontal pressure gradients (associated with tidal, wind-driven and density-driven circulations) in the water column by assimilating the measured 15-minute averaged currents into 1-D model simulation which uses a relatively large time step (e.g., 15 minutes). These slowly varying pressure gradients are then combined with the fast-varying wave-induced pressure gradients to drive the water column in the 1-D model simulation which uses a very small time step (about 1/100 of the wind wave period). These model simulations produce accurate vertical turbulent mixing and bottom shear stress under combined current-wave motion without resorting to ad-hoc wave-averaging procedure.

The sediment component of the 1-D model includes the following processes: vertical turbulent mixing, gravitational settling, resuspension/erosion, deposition and a fluid mud layer at the bottom. One important feature of the present 1-D model is that simultaneous deposition and resuspension/erosion are allowed, while the critical stress for deposition is generally several times larger than the critical stress for erosion. The resuspension/erosion rate of sediments is modeled as a linear function of the excess bottom shear stress (Sheng et al., 1989), while the deposition rate is computed by combining the deposition velocity formula of Sheng (1986) with the deposition probability of Krone (1993).

The 1-D models were used to simulate the measured suspended sediment data and to determine the resuspension/erosion rate during the storm events. The 1-D models were also used to test various hypotheses concerning dominant processes for sediment resuspension/erosion and mixing. A sensitivity study was also conducted to examine the effects of various model parameters on model results. Resuspension/erosion rates determined by the 1-D models were used in a three-dimensional model of sediment transport to simulate the long-term sediment transport in the estuary and the lake.

## RESULTS

Using the field data measured at 2 Hz sampling frequency, analysis was performed to determine the dominant forcing for sediment resuspension. For both the estuary and the lake, wind wave was found to be the dominant mechanism for sediment resuspension. In both the tidal estuary and the lake, currents played little role in causing sediment resuspension, but are primarily responsible for the vertical mixing of sediments.

For example, Figure 4 shows the wind speed and direction in Tampa Bay during a storm event (Julian day 30 to 40) in 1992. Figure 5 shows the measured horizontal North-South velocities and suspended sediment concentration at two vertical levels at Station A in Tampa Bay during Julian day 35.6 to 36.6, 1992. Because of the strong wind from the south on Julian day 36, significant wave-induced bottom stress caused resuspension of sediments. As shown in Figure 5, suspended sediment concentration increased from 10 mg/l to more than 40 mg/l in less than 2 hours. The simulated horizontal velocities and suspended sediment concentration at Station A as shown in Figure 6 compare very well with the measured data.

The sediments in the vicinity of Station A in Tampa Bay are composed primarily of silt with a small amount of clay. The resuspension of sediments led to release of ammonium adsorbed on the sediments into the water column. The one-dimensional model was used to simulate the currents, suspended sediment concentration, and ammonium concentration in the water column during the episodic event. Model results also suggest that fully turbulent boundary layer only exists during part of a tidal cycle. Thus, the presence of viscous sublayer should be incorporated into the model for accurate estimation of bottom stress and vertical mixing.

Three-dimensional flow fields in Tampa Bay have been simulated using a three-dimensional curvilinear-grid hydrodynamics model CH3D (Sheng 1989), which is capable of resolving the complex shoreline and navigation channel in Tampa Bay. As shown in Figure 7, the vertically-averaged currents in Tampa Bay during a typical flood tide are generally less than 50 cm/sec. During storm conditions, however, currents could be stronger and contribute to resuspension of sediments.

The resuspension event in Lake Okeechobee showed different behavior since the bottom sediments are consisted primarily of cohesive mud particles and flocs. Wind wave is also the driving force for resuspension of sediments. However, suspended sediment concentration can reach 100-2000 mg/l, depending on the location in water column. Near the bottom, there exists a very thin "lutocline" where sharp suspended sediment concentration gradient is found. The thickness of the lutocline varies significantly with time, as a result of variations in hydrodynamic forcing. As an example, results of a three-day simulation and field data at the Center-Lake Station C are shown in Figure 8. Erosion/resuspension and deposition

of fine sediments were described by relationships similar to those used in the Tampa Bay model. Flocculation apparently had a more significant effect on the gravitational settling of sediments in Lake Okeechobee than in Tampa Bay. Resuspension of sediments led to the subsequent release of phosphorus into the water column (Sheng 1993).

## DISCUSSIONS

The study demonstrated the significance of wind wave in causing resuspension of sediments and contaminants in shallow estuaries and lakes. The effect of wave groups on sediment resuspension was found to be insignificant. Wind-driven currents and tidal currents are generally insufficient to cause sediment resuspension, but are more effective in causing vertical mixing of suspended sediments. The process-based one-dimensional models were able to successfully simulate the mean flow, turbulent mixing, and suspended sediment dynamics in Tampa Bay and Lake Okeechobee. Model simulations showed that flocculation and lutocline dynamics are important processes in Lake Okeechobee but not in Tampa Bay.

## ACKNOWLEDGEMENT

The study was supported by the Florida Sea Grant and the South Florida Water Management District. Mr. Sidney Schofield and others of the Coastal & Oceanographic Engineering Department, and staff of the South Florida Water Management District contributed to the field experiments. Pittsburgh Supercomputing Center and Florida State Supercomputing Center provided some computer time.

## CHAPTER 237

### A NUMERICAL MODEL FOR BEACH DEFORMATION AROUND RIVER MOUTH DUE TO WAVES AND CURRENTS

by

Tomoya Shibayama\* and Akiko Yamada\*\*

#### Abstract

A numerical model is proposed for beach deformation under wave and current in river mouth area. The model includes three major driving forces for sediment transport which are wave, wave-induced current and river discharge. Interaction of wave and current is also included. Laboratory experiments are performed to be compared with numerical results. Wave field, current field and beach deformation are compared between laboratory and numerical results and good agreements are obtained.

#### 1. Introduction

In asian coastal region, we have many problems for the maintenance of waterway which connects big river port with open ocean. The examples are Chao Phraya river in Thailand or Mekong river in Vietnam. In the present paper, sedimentation and beach processes will be considered in river mouth area in order to minimize maintenance costs for these large rivers. A new numerical model is proposed for the simulation of beach processes in this area under waves, wave induced current and river discharges. Laboratory experiments are also performed to understand the physical mechanism of sediment transport and the results are used to examine the numerical model.

## 2. Numerical Model

A numerical model is developed to predict bottom topography changes around river mouth. The model is composed of three sub-models which are wave model, current model and beach deformation model. The wave field is calculated by using mild slope equation with including wave-current interaction effect (Ohnaka and Watanabe, 1990). The breaking point is determined by the comparison of wave phase velocity and water particle velocity. Near-bottom velocity variations and the distribution of radiation stress are evaluated by using the calculated wave field. The current field associated with sand movement is calculated including wave induced current calculated from distribution of radiation stress, and river discharge. The river current is introduced into the model as boundary conditions which are given as water level and depth-averaged current velocity at river area. Since we included wave-current interaction, it is necessary to calculate by iteration process in order to get converged solutions for wave calculation and current calculation.

Bed load transport rate is calculated from bottom shear stress caused by wave orbital motion, wave induced nearshore current and river current. The bottom friction factor is calculated from wave-current friction factor of Tanaka and Shuto (1980). Sand transport formula of Watanabe et al., (1986) is used to calculate bed load. Suspended sand discharge from the river and suspended sand due to wave breaking are also included in the model. The suspended sand flux from river is calculated from the following formula which is derived from Brown type formula.

$$q = A \frac{q_b}{1 - \lambda} \dots \dots \dots (1)$$

where

$$\frac{q_b}{u_* d} = 10 \left( \frac{u_*^2}{sgd} \right)^2 \dots \dots \dots (2)$$

and  $u_*$  : bottom shear velocity,  $\lambda$  : porosity,  $s$  : sand specific gravity in water and  $d$  : sand diameter. The value  $A$  is a empirical constant and set to be  $5 \times 10^{-4}$  for the present calculations.

The suspended sand is produced in river mouth and wave breaking area. The suspended sand concentration in wave breaking are given according to the result of Nielsen (1986). The suspended sand is transported by river current and wave-induced current and deposit to the bottom with sediment fall velocity (Numano et al., 1989).

Table 1: Laboratory Conditions

Case	Wave Period (s)	Deep Water Wave Height (cm)	Flow Velocity in River Mouth (cm/s)	River Discharge (cm <sup>3</sup> /s)
1	1.34	3.41	20.0	222
2	1.39	6.09	20.0	222
3	1.38	2.75	18.5	421

Figure 1: Laboratory Set-up

The calculated results of wave field, current field and bottom topography changes will be compared with laboratory results in order to examine the accuracy of numerical model.

### **3. Laboratory Experiment**

Laboratory experiments are performed in a wave basin designed to facilitate the understanding of the mechanism of sand movement as well as the behavior of wave and current field around river mouth. Well-sorted sand (median diameter 0.15 mm) are laid in the wave basin to make an 2.5 times 2.3 meter test bed with the initial slope of 1/20. A river mouth with water discharge was installed at upper end of the test bed. Figure 1 shows the laboratory set up. The distribution of wave height and the variation of near-bottom velocities in the test section are measured in details by using capacitant wave gages or an ultra-sonic velocity meter respectively for three conditions of monochromatic waves and river discharges.

The laboratory conditions are listed in Table 1. These conditions corresponds to the following situations: (1)effect of river discharge and effect of wave to sand transport are almost equivalent (case 1), (2)wave effect is greater than river discharge effect (case 2) and (3)river discharge effect is greater than wave effect (case 3). The changes of bottom topography during each experimental run are measured. In these three cases, bar or terrace are formed in front of river mouth and this may cause interruption of waterway.

### **4. Comparison of numerical results and laboratory results**

Figure 2 shows distributions of nearshore current for case 3. In the figure, calculated and measured velocities are shown. Here, the calculated values are depth-averaged values and the measured values are in the vicinity of bottom. The measured values may include the effect of undertow. As a result of interaction process, the calculated current field becomes asymmetric in terms of river mouth and this agrees with laboratory phenomena.

Figure 3 shows the comparison of wave field. The top figures show the two dimensional distributions of calculated wave fields by the numerical model. The bottom figures show the corresponding two-dimensional distributions of measured wave fields in the laboratory experiment. The middle figures show comparison of calculated and measured values in on-offshore distribution in front of river mouth. There are under-estimations of wave height in wave breaking area and over-estimations in the surf zone. This means the physical process

Figure 2: Measured and calculated current field (Case 3)

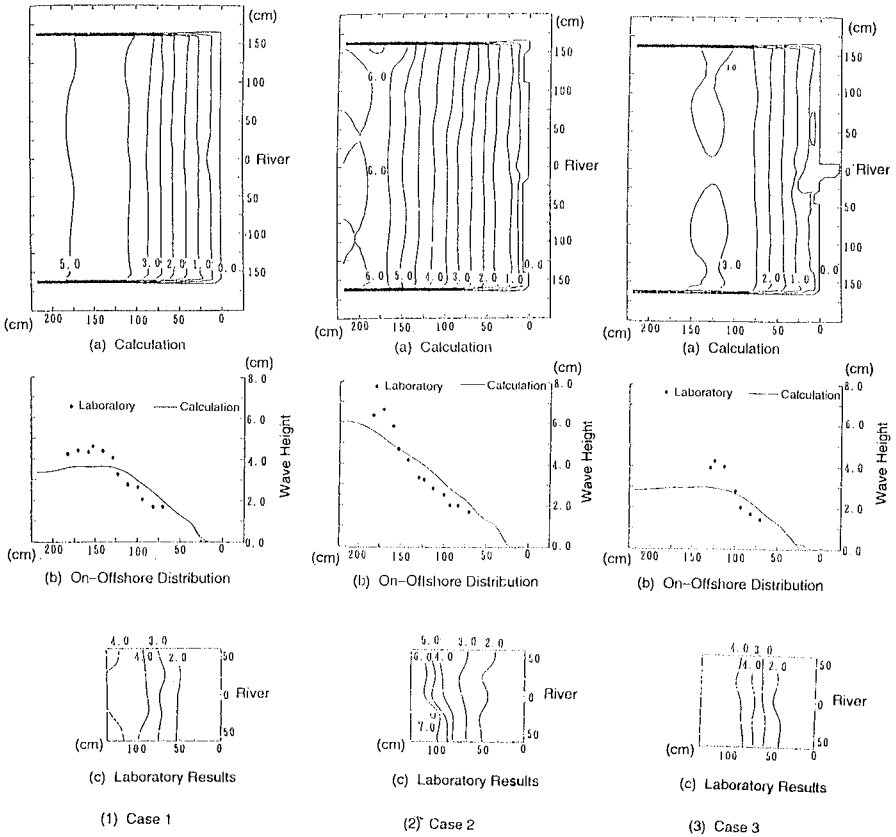

Figure 3: Comparisons of wave field  
(a)calculated wave field,  
(b)comparison of on-offshore distribution and  
(c)measured wave field in laboratory

Figure 5: Cross-sectional change of beach topography in front of river mouth

of interaction between wave and current in wave breaking area is not fully included in the numerical model.

Figure 4 is the comparison between calculated beach topography in the numerical model and measured topography in the laboratory experiment. The measured area in the wave basin is limited because of limited area of movable sand bed area. In case 3, terrace formation in front of river mouth is well estimated by the numerical model. In cases 1 and 2, bar formation in offshore area is clearly observed in laboratory but is not so clear in numerical model.

Figure 5 shows cross-sectional change of beach topography in front of river mouth. In case 3, we can observe the formation and offshore directed movement of terrace. In the calculation, the terrace gradually developed in front of river mouth.

From these figures, we can judge that the present numerical model, which includes wave-current interaction, bed load and suspended load due to wave breaking and river discharge, is useful to predict laboratory results of beach changes in the vicinity of river mouth areas.

## 5. Conclusion

A numerical model is developed for prediction of beach profile change in river mouth area. The model is compared with laboratory results. From the comparison, we can conclude that the model is not satisfactory but promising for the future development. The possible modifications are (1)more precise evaluation of wave field, (2)including the effect of vertical distribution of current field and (3)more precise evaluation of diffusion and dispersion process of suspended sand.

## CHAPTER 238

### Development of a Numerical Simulation Method for Predicting the Settling Behavior and Deposition Configuration of Soil Dumped into Waters

Kazuki Oda<sup>1</sup> and Takaaki Shigematsu<sup>1</sup>

#### **Abstract**

A numerical simulation method, which combines the Marker And Cell method and the Discrete Element Method, for analyzing the settling behavior and deposition configuration of the particles dumped into waters is described. Some calculated results are compared with the experimental ones, and what the settling behavior of the particles and the deposition configuration on the water bottom depend on is discussed.

#### **1. Introduction**

In recent years in Japan, large-scale man-made islands such as offshore ports and airports in coastal areas have been increasing in number. They are constructed in general by reclamation with a large volume of soil dumped from a split-hull barge. Hence, from the view point of both the construction management and environmental conservation, it has become very important to predict accurately the settling behavior and deposition configuration of soil. While there are a few studies ( Oda, 1989 ; Matsumi, 1992) which treated these problems, their studies can not predict them accurately because in which the interaction of an ambient fluid motion and a particle motion is not taken into consideration in theoretical analyses.

In the present study, a new numerical simulation method for predicting more accurately the settling behavior and deposition configuration of soil particles

---

<sup>1</sup>Dept. of Civil Engrg. Osaka City Univ. 3-3-138, Sugimoto, Sumiyoshi-ku, Osaka, 558

dumped into waters is developed, and what the settling behavior and deposition configuration depend on is discussed.

## 2. Simulation Method

The developed numerical simulation method consists of two phases; one is for analyzing the motion of each particle and the other is for analyzing the ambient fluid motion. In this paper the two dimensional calculation procedure will be presented( Oda, 1991 ).

### 2.1 Calculation of Particle Behavior

The motion of each particle is calculated by using the Discrete Element Method (the DEM) (Cundall, 1974) which is considered to be useful in analyzing the dynamic behavior of granular assembly.

The momentum and rotational momentum equations of particle  $i$  are written

$$(m_i + m'_i)\dot{u}_{pi} = \sum_j [F_x]_{ij} + f_x \quad (1)$$

$$(m_i + m'_i)\dot{w}_{pi} = \sum_j [F_z]_{ij} + f_z \quad (2)$$

$$(I_i + I'_i)\dot{\omega}_{pi} = \sum_j [M]_{ij} \quad (3)$$

where  $m_i$  and  $m'_i$  are the mass and added mass of particle  $i$  respectively,  $I_i$  and  $I'_i$  are the inertia and added inertia moment,  $u_{pi}$ ,  $w_{pi}$  are the horizontal and vertical velocity component of the particle,  $\omega_{pi}$  is the rotational angular velocity of the particle,  $[F_x]_{ij}$  and  $[F_z]_{ij}$  are the horizontal and vertical component of the force exerted between the particles  $i$  and  $j$  by their contact,  $[M]_{ij}$  is the rotational moment resulted from the contact with the particles  $i$  and  $j$ ,  $f_x$  and  $f_z$  are the fluid forces, "." represents the derivative by time, and  $\sum_j$  represents the sum with respect to every particle which contacts with particle  $i$ .

The forces  $[F_x]_{ij}$ ,  $[F_z]_{ij}$  and moment  $[M]_{ij}$  are calculated by

$$[F_x]_{ij} = -[f_n]_{ij} \sin \alpha_{ij} + [f_s]_{ij} \cos \alpha_{ij} \quad (4)$$

$$[F_z]_{ij} = -[f_n]_{ij} \cos \alpha_{ij} - [f_s]_{ij} \sin \alpha_{ij} + V_i \rho_p g \quad (5)$$

$$[M]_{ij} = -\frac{d_i}{2} [f_s]_{ij} \quad (6)$$

where  $\rho_p$  is the particle density,  $V_i$  is the particle volume,  $g$  is the acceleration due to the gravity,  $d_i$  is the diameter of particles  $i$ ,  $\alpha_{ij}$  is the angle between  $x$  axis and the segment of line which connects the center of particles  $i$  and  $j$ .  $[f_n]$  and  $[f_s]$  are the normal and tangential forces caused from their contact between the particles  $i$  and  $j$ , which are represented

$$[f_n]_{ij} = K_n \delta_n + \eta_n \delta_n / \Delta t_{DEM} \tag{7}$$

$$[f_s]_{ij} = K_s \delta_s + \eta_s \delta_s / \Delta t_{DEM} \tag{8}$$

where  $K$  is the spring constant,  $\eta$  is the damping coefficient,  $\delta$  is the relative displacement between the particles  $i$  and  $j$  during the time interval  $\Delta t_{DEM}$ , and the subscripts  $n$  and  $s$  represent the normal and tangential direction.

With the assumption that taking only the drag forces as fluid forces into consideration, the fluid forces acting on the particle  $i$  are written

$$f_x = -\frac{1}{2} C_D A_i \rho_f (u_p - u_f) \sqrt{(u_p - u_f)^2 + (w_p - w_f)^2} \tag{9}$$

$$f_z = -\frac{1}{2} C_D A_i \rho_f (w_p - w_f) \sqrt{(u_p - u_f)^2 + (w_p - w_f)^2} - \rho_f g V_i \tag{10}$$

$$C_D = \frac{24}{Re} + C_{D0}, \quad C_{D0} = 2.0 \tag{11}$$

$$Re = \frac{d_i \sqrt{(u_p - u_f)^2 + (w_p - w_f)^2}}{\nu} \tag{12}$$

where  $\rho_f$  is the fluid density,  $A_i$  is the cross sectional area,  $\nu$  is the coefficient of kinematic viscosity.

The interaction between particles and fluids is taken into account by calculating the drag force by using the relative particle velocity to the fluid given by Eq.(11).

The each particle acceleration at given time is calculated by solving Eqs.(1)~(3) explicitly, subsequently the velocity and location of each particle are determined.

### 2.2 Calculation of fluid motion

No calculation method will be presently available to analyze the ambient fluid motion caused by settling of a particle cloud. Edge and Dysart(1972) developed a model with the assumption that dumped material may behave as a dense liquid moving in waters. In the present method, an ambient fluid motion driven by a particle motion is analyzed by means of the MAC method under the assumption that the differences of the density of liquid-solid fluid which contains the particles may cause the motion of fluid.

The equation of continuity and momentum are respectively

$$\frac{\partial u_f}{\partial x} + \frac{\partial w_f}{\partial z} = 0 \tag{13}$$

$$\frac{\partial u_f}{\partial t} + u_f \frac{\partial u_f}{\partial x} + w_f \frac{\partial u_f}{\partial z} = -\frac{1}{\rho_f} \frac{\partial p}{\partial x} + \varepsilon_x \frac{\partial^2 u_f}{\partial x^2} + \varepsilon_z \frac{\partial^2 u_f}{\partial z^2} \tag{14}$$

$$\frac{\partial w_f}{\partial t} + u_f \frac{\partial w_f}{\partial x} + w_f \frac{\partial w_f}{\partial z} = -\frac{1}{\rho_f} \frac{\partial p}{\partial z} + \frac{\rho}{\rho_f} g + \varepsilon_x \frac{\partial^2 w_f}{\partial x^2} + \varepsilon_z \frac{\partial^2 w_f}{\partial z^2} \quad (15)$$

where  $\rho$  is the density of liquid–solid fluid which is evaluated as the mean density of liquid and particles, of which locations are determined by the DEM at some given time, in each numerical cell and  $\varepsilon$  is the coefficient of kinematic eddy viscosity which is calculated as follows

$$\varepsilon = 4 + 0.26v_0 + 32 \times 10^{-3}v_0^2 \quad (16)$$

where  $v_0$  is the fluid velocity component. This equation comes from the experimental observation by the ocean and meteorological agency in Nagasaki.

### 3. Calculation Condition

Some vertically two dimensional numerical simulations are performed in order to obtain the settling and dispersion behavior of particles dumped into waters from the water surface. The bottom of a container for dumping of particles is fixed on the water surface. After particles are arranged with short distances between other particles in the container, only the motion of each particle is calculated by using only the DEM until every particle stops to become stable in the condition of keeping the container bottom closed. Then the container bottom is opened, the motion of the particles and fluid are calculated.

According to making reference Kiyama (1983)  $10^{-6}$  sec is used for  $\Delta t_{DEM}$ . The value of the constants in the mathematical models are summarized in Table.1.

The calculation domain is taken between -50cm and +50cm in the horizontal direction for the MAC method and the cell size is taken constant:  $\Delta x = 2.5$ cm. The movements of particles and ambient flows are analyzed for the different water depths from 10cm to 100cm . The number of interior cells in the vertical direction is constant 40. The time step used in calculation is  $\Delta t_{MAC} = 10^{-5}$  sec.

## 4. Calculated Results

### 4.1 Comparison with the experimental results

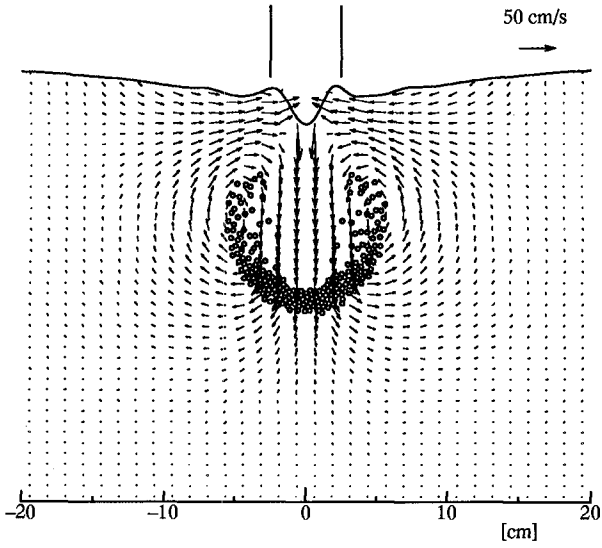

Fig.1 shows the calculated results of the settling and dispersion behavior of the particles with  $d=0.3$  cm diameter, of which the volume is  $20 \text{ cm}^3/\text{cm}$ , and the

Table 1. Values of the Constants in the Mathematical Model

Spring Constant	$K_n/\rho_p g = 4.23 \times 10^4 \text{ (cm)}$ $K_s/\rho_p g = 1.05 \times 10^4 \text{ (cm)}$
Dumping Coefficient	$\eta_n/\rho_p g = 2.47 \text{ (cm} \cdot \text{s)}$ $\eta_s/\rho_p g = 1.24 \text{ (cm} \cdot \text{s)}$
Friction Coefficient	$\tan \mu = 30^\circ$

(b)  $t = 0.4$  sec

Fig. 1. Calculated results

Fig. 1. Calculated results

Fig. 2. Settling velocity of a particle cluster

Fig. 3. Dispersion width of a particle cluster

movements of the ambient fluid flow at the specific time after dumping under the condition of water depth  $h=30$  cm and instantaneous opening of the container bottom of which width  $b_0$  is 5cm. From Fig.1, it may be seen that the particles are settling as a cluster rather than individually. These calculated results show a similar tendency to the experimental ones by Murota et al.(1988).

Fig.2 shows the comparison of the calculated results with the experimental ones on the settling velocity of the particle cluster. The settling velocity  $W_p$  is normalized by  $W_0 = \sqrt{(\rho_p/\rho_f - 1)gd}$ . Similarly the comparison of the calculated results with the experimental ones on the dispersion width  $B$  of the cluster in settling is shown in Fig.3. From Figs.2 and 3, it would be said that the present method can predict reasonably well the settling and dispersion behavior of particles.

#### 4.2 Deposition configurations and water depth

The distributions of the relative number of particles passing through per unit width of the horizontal plane at  $z/h = 0.2, 0.4, 0.6, 0.8$  and  $1.0$  in the case of  $h=10, 30, 50$  and  $100$  cm are shown in Fig.4. It should be noted that the distribution of relative number at  $z/h=1.0$  displays the deposition configuration of particles at rest on the water bottom. It is found in Fig.4(b) that for  $h=30\text{cm}$  the distribution has two peaks at  $z/h=0.4$  and the distance between two peaks becomes wider as the particles settling deeper. The deposition configuration on the bottom seems to be a mountain with two peaks. It can be seen in Fig.4 (c) that with settling of

particles two peaks are separated farther, those heights become smaller and the final deposition configuration becomes flatter. For  $h=100\text{cm}$ , the distribution seems to be almost uniform at  $z/h=0.6$  and subsequently the width and the height of the distribution become much wider and lower. These tendencies coincide with Mutoh's experimental results (1974).

Based on the experimental observation, he presumed that an increase in the horizontal fluid velocity near the bottom with the water depth induced an increase in the horizontal velocity of the particles near the bottom. But from the present calculated results it would be considered that the deposition configuration of the particles significantly depends on the dispersion behavior of the particles in the process of settling.

### 4.3 Settling behavior of particles and opening angular velocity of the container

Fig.5 shows the calculated results of the variation of space positions of particles and fluid velocity field at the moment of the contact of their lowest part with the water bottom with the opening angular velocity of the container bottom for  $h=30\text{cm}$ . From the calculated result for  $\omega = 30 \text{ deg./s}$ , each particle seems to be settling individually with characteristic of a single particle. But the particles for  $\omega=60 \text{ deg./s}$  would be settling as a cluster as shown in Fig.5(b). The cluster of the particles for  $\omega=90 \text{ deg./s}$  becomes larger than one for  $\omega=60\text{deg./s}$ .

The same calculations for  $h=10$  and  $50 \text{ cm}$  were performed. Based on those results for  $h=10\text{cm}$ , we could not see any longer the cluster of particles in settling even in the case of  $\omega=90 \text{ deg./s}$ . But for  $h=50\text{cm}$  the clusters could be seen in every case of  $\omega=30, 60, 90 \text{ deg./s}$  and became larger with an increase of the opening angular velocity of the container bottom. It is found, therefore, that the settling behavior of particles gets to depend more and more on the opening angular velocity of the container with in increase of the water depth.

### 4.4 Deposition configuration and opening angular velocity of the container

The deposition configurations under the condition of the particle volume  $V_0=20 \text{ cm}^3/\text{cm}$ , particle diameter  $d=0.3 \text{ cm}$ , the container width  $b_0=5\text{cm}$ ,  $\omega=30, 60, 90 \text{ deg./s}$ , and  $h= 10, 30, 50 \text{ cm}$  are calculated. From the calculated results as shown in Fig.6, it is found that the opening angular velocity of the container bottom does not effect on the deposition configurations in the case of  $h=10$  and  $30 \text{ cm}$ , but that for  $h=50\text{cm}$  the deposition width and height become wider and lower with an increase of the opening angular velocity. When the particles are dumped into waters with some opening angular velocity of the container bottom,

Fig. 4. Distribution of Relative Number of Particles Passing through the Horizontal Plane

Fig. 4. Distribution of Relative Number of Particles Passing through the Horizontal Plane

(a)  $\omega=30$  deg./s

(b)  $\omega=60$  deg./s

Fig. 5. Calculated results

Fig. 5. Calculated results

the particles settle as a cluster on condition that the water depth and opening angular velocity are larger and the particle cluster grows larger with an increase of the water depth as described in section 4.3. Hence, it would be thought that the growth of the cluster of particles in settling effects on the deposition configuration.

#### 4.5 Effect of the container width and the volume of dumped particles on dispersion width

The calculated results concerning the effect of the container width on a dispersion configuration when the volume of dumped particles is constant  $V_0 = 20 \text{ cm}^3/\text{cm}$  and the water depth is  $h = 30 \text{ cm}$ , are shown in Fig.7. The dispersion widths of particles in settling for  $b_0 = 2.5$  and  $5.0 \text{ cm}$  are almost the same and the deposition widths in both cases are also almost the same. But the dispersion and deposition widths for  $b_0 = 10 \text{ cm}$  are different from those for other cases.

Fig.8 shows the calculated results concerning the effect of the dumped volume  $V_0$  on the dispersion width under the condition that the container width is

(a)  $h = 10$  cm

(b)  $h = 30$  cm

(c)  $h = 50$  cm

Fig. 6. Variation of the deposition configuration with the opening angular velocity of container bottom

Fig. 7. Variation of dispersion width with container width

Fig. 8. Variation of dispersion width with the volume of particles

constant  $b_0=5.0\text{cm}$  and the water depth is  $h=30\text{ cm}$ . The dispersion width in settling and the deposition width on the water bottom become wider with an increase of the volume of dumped particles. Moreover what is evident comparing Fig.7 with Fig.8 is that the deposition width depends on the volume of dumped particles much more than the container width under the present calculation condition.

## 5. Conclusions

A calculation method for analyzing simultaneously the settling and dispersion behavior of particles and ambient fluid motion simultaneously was developed. It was founded that the calculated results of those behavior by the present method were reasonably good agreement with the experimental ones. Moreover the deposition configurations were calculated under the condition of the various water depths, container width, volume of dumped particles, and opening angular velocity of the container. The obtained results are summarized as follows :

- (1) The dispersion width of the settling particles and deposition width on the water bottom become wider with an increase of the volume of dumped particles.
- (2) The deposition width depends on the volume of dumped particles rather than the container width.

- (3) The deposition configuration depends on the water depth and it is influenced by the dispersion behavior of settling particles.
- (4) The increase of the opening angular velocity makes the deposition width wider in deeper water but it has few effect on the deposition configuration in shallower water.

## CHAPTER 239

### Plane Design of "SPAC"; Countermeasure against Seabed Scour due to Submerged Discharge and Large Waves

Takao Shimizu<sup>1</sup>, Masaaki Ikeno<sup>1</sup>, Hisayoshi Ujiie<sup>2</sup> and  
Kazuaki Yamauchi<sup>3</sup>

#### Abstract

Discussion is carried out on stability of submerged outlet structures of thermal power plants sited on sandy ocean beaches. The authors conceived the new scouring protection "SPAC" constructed by riprapping of the seabed just in front of the outlet. In this study, the authors investigated the plane design of the SPAC by means of 1/25 scale physical model. First of all, properties of seabed scour due to submerged discharge and monochromatic or multi-directional waves were examined. Secondly, the spreading process of the SPAC was investigated, and the necessary width of the SPAC was evaluated based on width of discharged current, and on the drift of discharged current effected by longshore current due to oblique incidence of waves. Finally, the physical model was verified by comparison with field data.

#### Introduction

In front of an outlet of a power plant sited on a sandy open beach, seabed scour due to submerged discharge and large waves causes instability of coastal structures

<sup>3</sup>Research Engineer, Tohoku Electric Co., Ltd., Japan Society of Civil Engineers, 7-2-1 Nakayama, Aobaku, Sendai City, Japan 981

such as discharge outlets.

Shimizu et al.(1991) proposed a new countermeasure called "SPAC"(Spreading Armor Coat). The SPAC is constructed by replacing seabed sand in front of an outlet with riprap rocks. During the seabed scouring due to current and waves, riprap rocks spread on the slope of the scoured hole forming an armor coat as shown in Poto 1. The SPAC thus protects the base of the outlet structure.

The process of cross sectional design of the SPAC shown in Fig.1 is as follows,(Shimizu et al.,1993).

Photograph 1. SPAC; Spreading Armor Coat

Figure 1. Cross Section of SPAC

1) Riprap diameter  $d$  is determined by the following equation, (Hasegawa, 1993) that gives riprap weight  $W$  that is stable against waves.

$$W = \gamma_r U_b^6 g^{-3} F_{rc}^{-6} (s_r - 1)^{-3} \quad (1)$$

where  $\gamma_r$  and  $s_r$  are respectively weight per unit volume and specific gravity of riprap rocks,  $U_b$  is bottom velocity,  $g$  is gravity acceleration. The value of the experimental constant  $F_{rc}$  is equal to 1.42.

2) Scour depth  $S$  is evaluated by the numerical simulation model, (Ushijima et al., 1992), not by a physical model experiment including scale effect.

3) Length  $R$  of the spreading region of SPAC is given by the following equations assuming that SPAC spreads as a single layer armor coat.

$$\text{if } S \leq 0.5 \delta \lambda^{-1} D^2 d^{-1} + D,$$

$$R = (\lambda^2 d^2 + 2 \delta \lambda S d)^{0.5} - \lambda d \quad (2)$$

$$\text{if } S > 0.5 \delta \lambda^{-1} D^2 d^{-1} + D,$$

$$R = 0.5 \delta D + \lambda d D^{-1} (S - D) \quad (3)$$

where  $D$  is the thickness of the SPAC,  $\delta = \cot \alpha + \cot \beta$ ,  $\lambda = \text{cosec} \alpha$ ,  $\alpha$  is the angle of repose of the scoured slope,  $\beta$  is the dredged slope angle. The value of  $\alpha$  was equal to 20 degree according to the experimental results.

4) Snecks should be inserted under the front edge of the SPAC in order to prevent sands from being sucked out through the void of riprap rocks after spreading. For the size of sneck, 1/3 of riprap diameter is recommended. For the amount of snecks, 15% of the riprap rocks of the spreading region is recommended.

In 1992, a SPAC works was carried out at Noshiro Power Station (Tohoku Electric Power Co.) facing the Japan Sea. In this study, the plane design of the SPAC is investigated to rationalize this countermeasure, by means of a 1/25 scale physical model simulating the sea condition in front of Noshiro Power Station.

#### SCHEME OF PLANE DESIGN

The process of plane design of the SPAC shown in Fig.2 is as follows.

1) Width  $B_f$  of scour is evaluated from the width of

Figure 2. Definition Sketch for Plane Design Parameters of SPAC

the discharged current at the front edge of the SPAC.

2) Width  $B_s$  of the spreading region of the SPAC is evaluated from  $B_f$ .

3) Drift  $B_d$  of discharged current is evaluated from the velocity of longshore current due to oblique wave incidence.

4) The required width  $B$  of the SPAC is evaluated from  $B_s$  and  $B_d$ .

#### PHYSICAL MODEL EXPERIMENTS

In the multi-directional wave basin shown in Fig.3, we made seabed model with a 0.3m water depth, a sea-wall model covered with model armor units, a submerged outlet model consisting of three assembled pipes, and a discharge channel model.

Experimental cases and conditions are shown in Table 1. In the cases A1, A2 and A3, we compared the process of seabed scour due to submerged discharge alone, discharged flow plus multi-directional waves, and discharged flow plus the highest one-tenth monochromatic waves. In the cases B1 and B2, we colored and numbered some of the riprap rocks in both cases, short SPAC ( $R+r$  is small) and long SPAC ( $R+r$  is large), and tracked the spreading process of the rocks. The riprap diameter was 3cm. In the cases C1 and C2, we investigated the drift of the discharged flow effected by the longshore current due to oblique wave incidence. Finally, in the cases D1 and D2, an attempt was made to verify this experimental result by field data.

Figure 3. Arrangement of Physical Model Experiment

Table 1. Experimental Cases and Conditions

Case	Seabed	Discharge	Waves
A1	flat sand bed grain size is 0.2mm	3 pipes $\phi = 10.7\text{cm}$ velocity is 1m/s	no wave
A2	ditto	ditto	multi-directional waves $H_{1/3} = 16.5\text{cm}$ $H_{1/10} = 21\text{cm}$ $T_{1/3} = 2.4\text{s}$
A3	ditto	ditto	monochromatic waves $H = 21\text{cm}$ $T = 2.4\text{s}$
B1	flat sand bed protected by SPAC $R+r = 60\text{cm}$	ditto	ditto
B2	ditto except $R+r = 150\text{cm}$	ditto	ditto
C1	1/50 slope solid bed	ditto	oblique incident monochromatic waves $H = 22.1\text{cm}$ $T = 2\text{s}$ offshore wave angle is $30^\circ$
C2	ditto	ditto	ditto except $H = 28.4\text{cm}$
D1	model of Noshiro P.S.	ditto except single pipe	multi-directional waves $H_{1/3} = 16\text{cm}$ $T_{1/3} = 2\text{s}$
D2	ditto	ditto	ditto except no wave in first 80hr.

PROPERTY OF SCOUR DUE TO CURRENT AND WAVES

Fig.4 shows the seabed scour due to submerged discharge and waves in the cases A1, A2 and A3. The scoured hole due to discharge alone is longer along the line of discharged flow, and the maximum scour depth appears farther from the outlet than in other cases. The scoured hole due to discharged flow plus multi-directional waves is shallower, but the maximum depth appears nearer to the outlet. The scoured hole due to discharged flow plus monochromatic waves is the deepest and this condition is the most severe with regard to the stability of the outlet structure. We therefore adopted the last condition to the design of the SPAC.

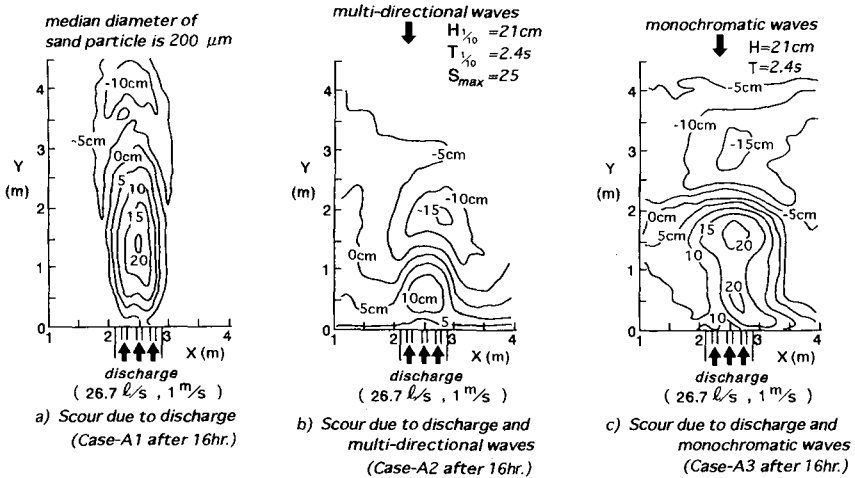

Figure 4. Seabed Scour due to Submerged Discharge and Waves

SPREADING WIDTH OF "SPAC"

Fig.5 shows the seabed scour in front of the SPAC in the cases B1 and B2. The foot of the outlet structure was successfully protected in both cases.

Fig.6 shows the spread profile of the SPAC in the cases B1 and B2. The spread profiles are well predicted by the previously mentioned equations (2) and (3), except that the predicted lengths of the spreading region of the SPAC are slightly longer than the experimental results.

Fig.7 shows the velocity distribution and half-value width of velocity of discharged current flowing against waves propagation in the early stage of Case A3. If the width of discharged current is represented by half-value width, it also represents almost 1/8-value width of sand transport rate distribution, because the sand transport rate is approximately proportional to the cube of the flow velocity. So, it was decided that half-value width  $B_f$  adequately represents the scour width.

Fig 8 shows the relationship between half-value width of discharged current velocity and offshore distance from the outlet in the case A3. The half-value width of discharged current is almost linearly proportional to the distance from the outlet.

Fig.9 shows the spread pattern of the SPAC for cases B1 and B2. The open circle at the end of the pin shaped mark shows the final position of spreading rock, and the other end shows the initial position of the rock. The closed circle shows unspread rock. The riprap rocks spreaded toward the center of the scoured hole, that is, the toe of the spreading SPAC. The spreading area of riprap rocks is perfectly covered by a spreading slope of half-value width  $B_f$  at the center part and a pair of fan shaped transient slopes at both ends. Width  $B_s$  of the spreading region of SPAC is the distance between both intersections of the fans and the initial front end of the SPAC.

Figure 9. Spread Pattern of SPAC

DRIFT OF DISCHARGED CURRENT

Fig.10 shows cross-shore distribution of longshore current velocity due to obliquely incident waves for cases C1 and C2, without discharge from the outlet.  $U$  on the vertical axis shows longshore current velocity normalized by analytical velocity  $U_{b0}$  at the breaking point, neglecting horizontal eddy viscosity. Closed triangles indicate longshore current velocity in front of reclaimed land in the experiment.  $Y'$  on the horizontal axis shows offshore distance from virtual shoreline under the condition of no reclaimed land. Smooth curves show velocity distribution of longshore current along a uniform slope beach after Kraus and Sasaki(1979). Longshore current velocity just in front of the seawall of the reclaimed land is nearly equal to or less than the velocity of longshore current along the beach.

$U$  is longshore current velocity normalized by analytical velocity  $U_{b0}$  at breaking point neglecting horizontal diffusion.

a) Longshore current due to small waves (Case-C1)

b) Longshore current due to large waves (Case-C2)

Figure 10. Longshore Current due to Oblique Incident Waves in front of Reclaimed Land

Fig.11 shows the drift of discharged current effected by longshore current for case C2. Vectors are flow velocity in the experiment. The curve from the outlet to the right is the trajectory of discharged current calculated by the following equation, (Katano et al.,1976).

$$(B_d / B_p) = 0.26 (u / V_0)^3 (Y / B_p)^4 \quad (4)$$

where  $B_d$  is the drift of discharged current,  $B_p$  is the width of the outlet,  $u$  is the longshore current velocity,  $V_0$  is the discharged velocity, and  $Y$  is the offshore distance from the outlet. The drift of discharged flow was well traced by the above equation.

Figure 11. Drift of Discharged Flow Effected by Longshore Current

VERIFICATION by FIELD DATA

Fig.12 shows the field data of waves and warmed water discharge observed at Noshiro Power Station from July 1992 to May 1993. In this period, the unit No.1 of the power plant was under trial running. We adopted a 4m height and 10s period significant wave, and 27.8m<sup>3</sup>/s discharge as the experimental condition for comparison with the field data.

Fig.13 shows the comparison between field scour and simulated scour on 1/25 scale model in the cases D1 and D2. Maximum scour depth 125cm in the field was well simulated as 5cm scour depth in each case of the 1/25 scale models. Scour width in the field was also well simulated in the case D1. The on-offshore length of the scoured hole in the model was smaller than for the field scour. A model scour occurs nearer the outlet structure than for the field scour.

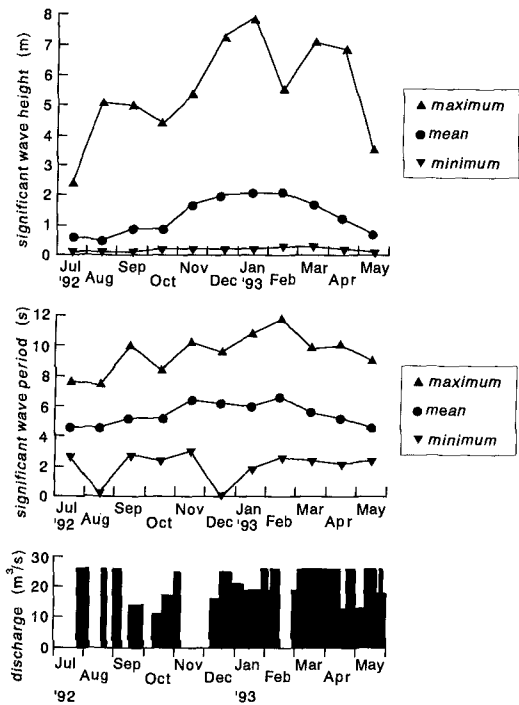

Figure 12. Field Data of Waves and Thermal Discharge Observed at Noshiro Power Station

a) Observed scour at Noshiro Power Station (after one winter)

b) Simulated scour due to discharge and multi-directional waves (Case-D1 after 8hr.)

c) Simulated scour due to discharge (Case-D2 after 80hr.)

d) Simulated scour due to discharge and additional multi-directional waves (Case-D2 after extra 8hr.)

Figure 13. Comparison between Field Scour and Simulated Scours in 1/25 Scale Physical Model

CONCLUSIONS

(1) The SPAC design is sufficiently safe for the condition of discharged flow and highest one-tenth monochromatic waves.

(2) The width of the SPAC can be determined by both the spreading width of riprap rocks and the drift of discharged flow effected by a longshore current.

(3) The spreading width of the riprap rocks can be determined by assuming a scouring width as the half-value width of the discharged current velocity distribution, and by turning the 20 degree slope around toes at both ridges.

(4) The drift of the discharged flow effected by a longshore current is determined by using a formula based on a longshore current distribution caused by oblique incident waves, and by using a trajectory formula of jet injected into the current orthogonally.

(5) It was verified by the field data that the design method of the SPAC based on the physical model was within the safety margins required for the stability of the outlet structure.

## CHAPTER 240

### MODELLING AND ANALYSIS TECHNIQUES TO AID MINING OPERATIONS ON THE NAMIBIAN COASTLINE

G G SMITH<sup>1</sup>, G P MOCKE<sup>1</sup> and D H SWART<sup>2</sup>

#### ABSTRACT

The extraction of diamondiferous ore deposits along the coastal strip of southern Namibia has called for novel mining techniques. Quantitative analysis of coastal processes incorporating the prediction of short and long term shoreline response has proved particularly useful in optimizing such techniques. Further attention has been given to assessing the impact of mining operations on the nearshore ecosystem through comprehensive monitoring and modelling analyses.

#### 1 INTRODUCTION

Diamond mining operations in the southern coastal region of Namibia involve temporary coastal protection and beach reclamation schemes as well as the projected discharge of mine overburden material into the nearshore zone. In the extreme south of Namibia, near the town of Oranjemund (Figure 1), NAMDEB construct sand seawalls to protect mining operations. These seawalls have been successfully used to reclaim precious mining terrain in a highly dynamic wave climate (Moller and Swart, 1988). The continuation of these reclamation efforts over an area where reduced quantities of seawall replenishment material is available has however called for optimization. In this regard the construction of massive groynes for enhancing shoreline progradation has been investigated.

A proposed initiative incorporates the use of a dredger so as to mine the overburden of a coastal region. As a result of the dredging, some 26 million m<sup>3</sup> of sediment will be discharged onto the neighbouring beach. The accretion resulting from this nourishment will effectively reclaim land and provide a protective beach which reduces water seepage during final mining operations. Coastline modelling has

<sup>2</sup> Director, Ematek, CSIR, P O Box 320, Stellenbosch, 7600, South Africa

proved extremely useful in the planning and assessment of this mining initiative.

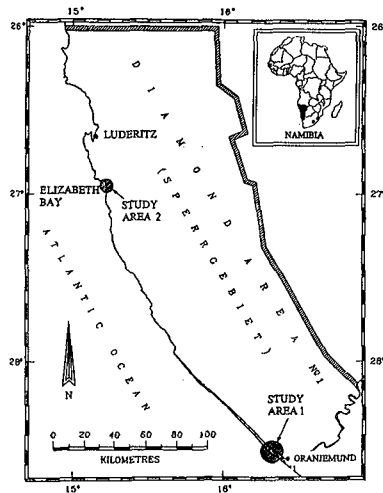

Figure 1: Location map indicating the diamond mining region within Namibia

Further north at Elizabeth Bay (Figure 1), NAMDEB mining operations involve the separation of undersized sediments from the diamondiferous ore. This fraction, comprising some 75% of the total excavated quantity of 20 million  $m^3$ , is discharged onto the beach in the adjacent sheltered bay. Due to the proximity of lobster and other biological communities, the necessity for assessing the environmental impact of such operations beyond the confines of the bay was identified. A comprehensive ongoing monitoring program, incorporating environmental measurements and predictive coastline and circulation modelling, was initiated for this purpose before commencement of mining operations.

## 2. ORANJEMUND

### 2.1 Environmental Conditions

The dynamic wave climate at Oranjemund, as derived from local Waverider buoy recordings has an average significant wave height of 2,2 m (average wave period is 12 seconds). Storms occur frequently, with significant wave heights over 4 m occurring about 25 times (average duration ~ 11,8 hours) per year. The predominant wave direction ranges between  $180^\circ$  and  $200^\circ$ .

The coastline is relatively straight, and lacking features such as headlands, is unprotected from wave attack. Vertical profile excursions of up to 4 m reflect the dynamic environment, where a sand grain size of approximately  $D_{50} = 500 \mu m$  occurs on the steep beach face.

Longshore sediment transport calculations as determined via a wave refraction study indicate a northward transport rate of 1,4 Mm<sup>3</sup>/yr. This rate was further verified via one-line modelling simulations (CSIR, 1979; CSIR, 1994a).

## 2.2 Seawall Mining Operations

Several attempts have previously been made to protect the coastal mining operation from wave action and to increase the mining area by mining closer to the waterline. One such attempt involved the placing of cobbles on the seaward face of a sand seawall, however the cobbles were removed and strewn across the beach. Various geofabric options such as covering the sand seawall with tarpaulins and protecting the seawall toe with cloth bags were also unsuccessful. In addition, short groynes were made from metal frames and filled in with boulders. However these structures did not penetrate sufficiently into the surf zone to interrupt the longshore sediment transport to cause accretion. Sheet piles were also used for a time, which allowed the mining of bedrock some 25 m closer to the sea. It was intended to re-use the piles as mining operations proceeded along the coast. However the percentage of sheetpiles which could be re-used was lower than predicted and the method was therefore found to be uneconomical. A further attempt involved the use of interlocking concrete blocks. These were interlocked laterally, but could slide downwards as sand was scoured from beneath them. This system was destroyed during the larger storms, however and took 8 to 10 days to re-establish. Since this system was also uneconomical, it was stopped. The most recent such initiative involved the use of flexible mattress, which failed principally due to toe scour.

The most successful of the protective structures has simply been a massive sand seawall (Figure 2), which has been practical to construct from the sand overburden material, and which is stripped almost to bedrock at a depth of some 20 m in places. Constant sand nourishment to the eroding seaward face of the seawall, which is 300 m to 800 m in length, ensures its structural integrity. At one stage of the mining operation, advantage was taken of the abundant sand overburden by advancing the seawall up to 300 m seaward. This ambitious scheme involved the placing of massive quantities of sediment on the seawall.

An interesting aspect of the study is that although a total of 12.7 million m<sup>3</sup> is used for the construction and maintenance of seawalls during the 5 year period, records show that at most 8 million m<sup>3</sup> of this amount was obtained from the mine. Thus a deficit of some 4.7 million m<sup>3</sup> exists. It is assumed that much of this material was rehandled, i.e. the material fed onto the wall is eroded and subsequently deposited to the north, where it is re-excavated and again fed to the wall.

Figure 2: Seawalls protecting the adjacent mining operations

Constant erosion from the seawall of average length 600 m occurred as it advanced northwards. Thus the quicker mining operations advanced, the less the total amount of material needed for the seawall. This is borne out by the optimization curve shown in Figure 3 which is constructed from data obtained during the mining operation. A regression analysis yields the equation of the curve:

$$V = 1450000R^{-0.963}$$

where:  $V$  = Volume of material used per metre length of the wall (in  $m^3$ ).  
 $R$  = Rate of northwards advance of the wall (in  $m/year$ ).

As can be seen from the curve, a rate of advance of less than about 500  $m/year$  is detrimental since it requires in considerable maintenance. High advance rates are, however, constrained by available resources and the necessity to maintain long seawall sections.

Figure 3: The relationship between rate of wall advance and sediment volume placed on the wall.

Further support for mining operations has been provided through an early warning system for wave attack. With the dominant incident southerly wave conditions at the site a remote link to waveriders to the south provides up to 12 hours of advance warning of extreme events.

### 2.3 Groyne "sand trap"

A unique initiative to capitalize on the high longshore transport rate, which is enhanced by the above-mentioned nourishment, is to construct groynes and thereby facilitate land reclamation updrift. A site favourable for both mining reasons and for groyne construction (i.e. foundations on a rocky outcrop) was selected, and one-dimensional coastline model simulations formed the basis of a detailed feasibility study.

Figure 4 shows the calibration of the one-line UNIBEST model for a 2 year period, over a 10 km coastline extent width. The relevant sediment sources are input to the model. This includes the beach nourishment as supplied to seawalls in the region, which varies between 60 000 m<sup>3</sup> and 270 000 m<sup>3</sup> at various locations along the coast. In addition, the point discharge of sediment from a processing plant is included (as indicated in the figure). This amounts to about 1.7 million m<sup>3</sup> of material; however this is somewhat finer material than that discharged to the seawalls.

As seen in Figure 4, the measured shoreline after 2 years is reasonably well predicted, taking into consideration that the measured beach cusps are not simulated by the model. In particular, the coastline accretion near the discharge point as well as a prominent coastline inflection point are well simulated.

Figure 4: Coastline calibration prior to groyne accretion predictions

On this basis the coastline evolution due to groyne lengths of 150 m, 200 m and 300 m was assessed. For each case, two scenarios were considered. The first assumed a large sand seawall which is built so that it extends 40 m beyond the coastline. This calls for considerable input of sediment to maintain wall integrity

with estimates from a modelling exercise indicating this to be from 540 000 m<sup>3</sup>/year to 740 000 m<sup>3</sup>/year. The second scenario assumed a protective sand wall (termed a "beachwall") constructed about 40 m above mean sea level. The anticipated maintenance quantity for this wall involves between 105 000 m<sup>3</sup>/year and 144 000 m<sup>3</sup>/year.

Table 1 illustrates the accreted areas obtained for each of these scenarios. Between 10% and 20% extra area is gained through the inclusion of seawalls. This is due to the land reclamation facilitated by the seawalls *per se*, as well as the extra sediment input which accretes at the groyne. The benefit of a longer groyne is obvious. As may be observed the accretion from a 300 m groyne is more than double that of the 150 m structure for the beachwall case.

**Table 1: Accreted areas**

Groyne length	Beachwall (m <sup>2</sup> )	Seawall (m <sup>2</sup> )
150 m	151 400	181 800
200 m	222 400	248 700
300 m	363 100	297 400

A conceptual structural design of the groyne was carried out in parallel with this study. There was a number of unique constraints associated with the design; namely security limitations restricting the hire of plant, unsuitable armour rock material in the region and a groyne lifespan limited to about 6 years. Concrete armour and Caisson-type structures were found to be the most suitable under the above constraints.

#### 2.4 Dredge Discharge

A proposed initiative is the removal of some 26 million m<sup>3</sup> of sand overburden via dredging. This material extends to a depth of -26 m MSL globally and has a sand composition which is roughly similar to the beach sediment. It is intended to discharge this volume of material, after screening for diamond extraction, onto the beach, where the coast has already accreted by some 300 m due to sediment from discharge at an adjacent processing plant. Considering the prevailing dynamic wave climate and sediment composition, high offshore losses of sediment from the discharge can be expected.

Primary objectives of the study are to assess shoreline changes for input to seepage rate calculations as well as to co-ordinate the discharge in order to maximise accretion of the coastline during the final stages of mining. The reason for this is to minimise seepage from the sea into the deep mining area which is totally dewatered at this final stage. In addition the mining region must be protected from wave attack

which could lead to flooding of the working area.

The calibration of the one-dimensional coastline model is illustrated in Figure 5, in which historical coastlines were obtained from a topographical map, aerial photographs and a recent beach survey. The simulation is run from the initial shoreline of 1971. As can be seen, each of the measured shorelines is reasonably well predicted by the model. Of particular interest is the period between 1979 and 1986, during which a decrease in the discharge rate led to the retreat of the coastline.

Figure 5: Calibration of the coastline model - dredge region

Further verification of the model was conducted by modelling a 20 km stretch of coast (Figure 6). In this simulation all of the major sediment inputs to the system were included as they occurred over the 23.4 year period. As seen, the model is fairly well validated against the measured coastline. The exception is in region of +5000 m, where unusually large accretion occurred.

Figure 6: Calibration of the coastline model - extended region

With the validity of the model verified, various scenarios were explored. Figure 7 illustrates the accretion resulting from an optimised strategy from 4 discharge points. As seen, the accretion fillet at the completion of the discharge is centered opposite the final region of dredging. With the intention being to mine the region subsequently; the predictions of 0.5 and 1.0 year later show that the accreted coastline is still centered around the appropriate region in spite of considerable erosion.

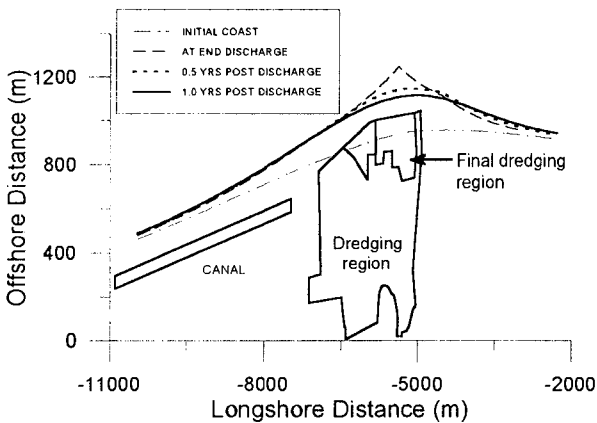

Figure 7: Coastline evolution in response to the optimised discharge strategy

**3. ELIZABETH BAY**

As schematized in Figure 8 some 75% of the mined ore deposit is discharged onto the beach within Elizabeth Bay. Although expected impacts on the sandy beach system within the bay have been deemed to be inconsequential, concerns have been

expressed regarding potential impacts on lobsters and other biological communities beyond the confines of the bay. The primary sediment input into the bay is at the eastern boundary, with a prominent sink the indicated aeolian dune corridor. The bay is relatively protected from incident waves, which are from a dominant southerly direction.

Figure 8: Schematisation of the sediment transport processes at Elizabeth Bay

### 3.1 Monitoring Programme

In anticipation of the commencement of mining operations at Elizabeth Bay in July 1991 a comprehensive monitoring programme was initiated the previous year. Data emanating from regular monitoring is supplemented by recordings made during the course of an earlier impact assessment (CSIR, 1988) as well as two field measurement campaigns (CSIR, 1992).

The principal components of the monitoring programme comprise aerial photography (including control sites), plant discharge (rates and granulometry), nearshore bathymetry, beach surveys, nearshore and beach observations (pro forma), wind recordings (two weather stations) and a bio-sampling transect.

### 3.2 Data Analysis

#### 3.2.1 Morphological response

Beach and nearshore bathymetric surveys recorded prior to mining operations constitute an effective baseline for assessing the impacts of discharge operations. The minimal changes apparent in these pre-mining surveys attest to a state of morphodynamic equilibrium within the bay.

For approximately the first 18 months of discharge operations an average monthly volume of the order 130 000 m<sup>3</sup> of sediment was discharged to the beach. This discharge, which was somewhat higher than originally anticipated, was concentrated at the outlet DP1 shown in Figure 9. Following a reduction in processing volumes, monthly rates have reduced to approximately 50% of the above figure since early 1993. Discharge was further extended to the more easterly outlets shown in Figure 9.

As further illustrated in the figure, shoreline response to the initial concentrated discharge is characterised by a local protrusion. A reduced and more distributed discharge thereafter, however, results in more even alongshore progradation.

Figure 9: Coastline evolution at Elizabeth Bay and principal discharge stations

The measured cross-shore profile response at a location near the area of maximum discharge is depicted in Figure 10. Within the context of an original impact assessment (CSIR, 1988) the SEAGAR2 cross-shore profile model was employed for determining equilibrium profile response due to the discharge. The significantly steeper measured profile reflects only limited alongshore and cross-shore redistribution of beach material.

With an average  $D_{50}$  grain size in the range 0,25 mm - 0,4 mm the discharge fraction is somewhat coarser than the native material ( $D_{50} \sim 0,15$  mm). In the medium term an equilibrium profile somewhat steeper than the native state will therefore result. As anticipated in the original impact assessment, this will have an initial negative impact on the intertidal biotic community.

Figure 10: Cross-shore profiles measured at Elizabeth Bay

The difference chart comparing the pre-mining February 1990 bathymetric survey to that of March 1994 illustrates how morphological changes have been confined to the nearshore area. Although the most significant variability occurs at the western end of the bay near the discharge point, some seawards movement of material is evident near the eastern extent of the survey area. As will be discussed in 3.2.2 this area is coincident with a flow convergence zone and associated rip-current.

Figure 11: Bathymetric difference chart (February 1990 - March 1994)

**3.2.2 Sediment budget**

Schematized in Figure 8 are the primary constituent components of the sediment budget at the study site. A theoretical analysis incorporating wave refraction modelling predicted an influx into the bay of the order 0,25 Mm<sup>3</sup>/yr. This longshore transport rate may be seen to be substantially less than further south at Oranjemund,

which is a far more exposed section of coast. It further reflects the influence of aeolian sediment pathways feeding the Namib desert, of which the study site constitutes a prominent component. Field and theoretical barchan dune movement studies have estimated an annual transport in the range  $0,15 \text{ Mm}^3$  to  $0,3 \text{ Mm}^3$ . With a negligible flux of sediment around the prominent Elizabeth Point at the western boundary, it is likely that the influx into the bay and the aeolian sink are in approximate natural balance.

A summation of volume charges computed from beach survey measurements accounts for roughly 70% of the total  $3,1 \text{ Mm}^3$  discharged to January 1994. The 30% discrepancy with the discharge quantity is primarily attributable to the restriction of volume calculations to the limiting depth of surveys, which is of the order of 1 m below MSL. Other factors are bulking errors and increased aeolian losses due to an enlarged deflation zone following beach progradation. A further factor, discussed below, is the offshore transport of suspended fines. With up to 8% of the discharge material having a diameter less than 0,1 mm it likely an appreciable proportion of the pumped discharge is lost in this manner. A reliable summation of these variable contributions appears to account for the discrepancy.

#### *Turbid plumes*

An ubiquitous feature of the study coastline is the apparition of turbid plumes. Aerial photographic and on site monitoring has highlighted an increase in extent and frequency of such plumes since the commencement of mining operations. Such plumes are, however, primarily manifested within the confines of the bay. During the course of two field exercises (CSIR, 1992) under contrasting wind and wave conditions plume related parameters such as temperatures, salinities, currents and suspended matter characteristics were measured. In Figure 12 is schematized recordings of particle inorganic matter (PIM) concentrations over the study domain. Although elevated near the discharge area concentrations are considered to be within the range of naturally occurring turbidity ( $\sim 5 \text{ mg/l}$ ).

Figure 12: Particle inorganic matter distribution on 18 May 1992

### 3.3 Predictive Modelling

#### 3.3.1 Plume dynamics

The two dimensional hydrodynamic TIDEFLOW model was used to simulate tidal and wind driven circulation in the study area. Such a model, which was calibrated against drogue measurements, was considered to be appropriate due to the vertically well mixed state of the bay as recorded during the dominant strong wind conditions. The computed hydrodynamic flow field was coupled with the PLUME dispersion model for the prediction of turbid plume response within the bay. Measured concentrations were used for validation of this model. In Figure 13(a) is shown the simulated plume response under the dominant southerly wind conditions. Although relatively high concentrations are evident in the vicinity of the discharge area, values beyond the bay confines are minimal. Somewhat higher values in the vicinity of the point are evident for the infrequent NE wind conditions (Figure 13(b)), however, values remain within the range of naturally occurring turbidity. Scenario modelling showed increased movement of turbid water beyond bay confines in the event of a prograded coastline, however, this was remedied by moving the discharge points further east.

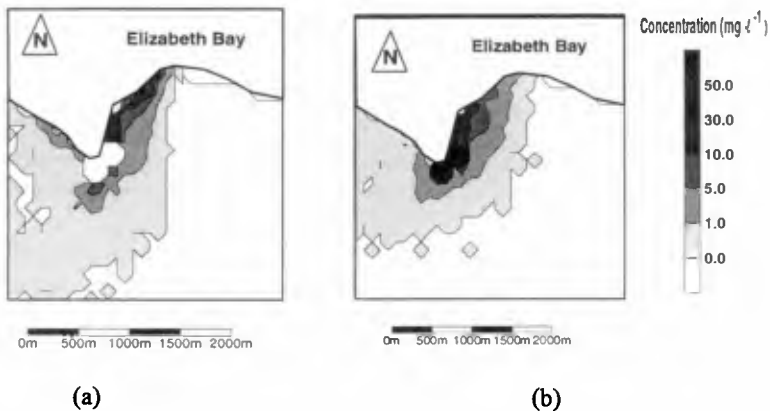

Figure 13: Modelled plume response after 48 hours for (a) a southerly and (b) north-easterly wind of 10 m/s

#### 3.3 Shoreline Response

Shoreline response to projected discharge was modelled, with reference made to the sediment budget discussed in Section 3.2.2 for definition of appropriate boundary conditions. The dominant contributions in this regard are an equivalent sediment influx and sink of the order 0,25 Mm<sup>3</sup>/yr at the eastern boundary and aeolian corridor respectively. Reference was made to the measured and equilibrium profile characteristics for the definition of short and longterm effective depths for the model.

As illustrated in Figure 14, the model is reasonably well validated against measured shoreline changes to date. Projecting the model to variable discharge scenarios, Figure 15 shows the engerated promontory developed by a concentrated discharge. A preliminary analysis of 2-D wave driven currents demonstrate the susceptibility to rip-current generation of such a prominent coastline feature. As is also shown in Figure 15, a distributed discharge strategy results in a more even progradation due to enhanced alongshore spreading of material.

Such an evolution will mitigate against prominent rip-current features, which may enhance seawards movement of different sediment size fractions.

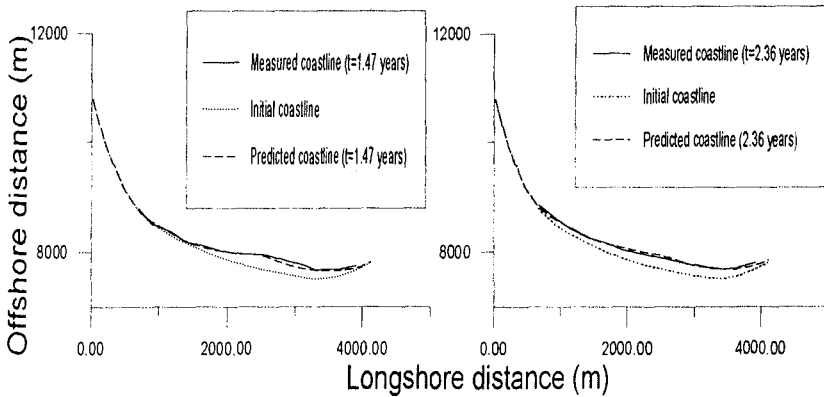

Figure 14: Calibration of the shoreline model at Elizabeth Bay

Figure 15: Discharge scenario simulations at Elizabeth Bay

## CONCLUSIONS

The comprehensive monitoring and analysis of environmental data has provided a critical underpinning element to coastal mining operations in Namibia. Assessments of the morphological response to variable mining strategies, which have led to the optimization of mining techniques, have been greatly facilitated by predictive modelling methods. Such methods, validated against available monitoring data, have further proved vital in assessing the potential impacts of such operations on adjacent eco-systems. In this regard, a controlled discharge strategy is not expected to pose a threat to biological communities beyond the confines of the bay.

## CHAPTER 241

### Engineering Approach to Coastal Flow Slides

Theo P. Stoutjesdijk<sup>1</sup>, Maarten B. de Groot<sup>1</sup>,  
Jaap Lindenberg<sup>2</sup>

#### Abstract

Flow slides can play an important role in the stability of coastal foreshores and structures, in harbour design, in dredging activities and placing of hydraulic fill structures. In the south western part of the Netherlands the phenomenon is of major concern for the protection against flooding by means of dikes. More than 1100 slides have been registered since the year 1800. In the paper the practical experience and the knowledge obtained from experiments and fundamental research is briefly summarized. An engineering approach to coastal flow slides that combines the Dutch experience with flow slides with results of fundamental research of the past 10 years, is described.

#### Introduction

It is now 45 years ago that Koppejan et al [1948] first published on the subject of coastal flow slides in the Netherlands. The major concern at that time was that parts of the sandy foreshore in the Dutch province of Zeeland, sometimes including parts of the dike or the entire dike body, suddenly liquefied and disappeared into deeper water. Figure 1 is an example of such an event along the shore of the Eastern Scheldt basin. These events were called flow slides, as the loosely packed sand, apparently without reason, lost its

-----  
<sup>1</sup>Delft Geotechnics, P.O.Box 69, 2600 AB Delft, The Netherlands

<sup>2</sup>Ministry of Transport and Public Works, Department of Road and Hydraulic Engineering, P.O.Box 5044, 2600 GA Delft, The Netherlands

stability and moved like a highly concentrated sand-water mixture. The major slides involved a tremendous quantity of sand, leaving behind very gentle final slopes.

Figure 1 Example of an actual flow slide along the shore of the Eastern Scheldt basin (Leendert Abrahampolder)

Flow slides can play an important role in the stability of coastal foreshores and structures, in harbour design, in dredging activities and placing of hydraulic fill structures. This paper deals with practical aspects of the phenomenon of flow slides. In many situations the chance that a flow slide will occur is negligible, but at the same time there is a need for practical tools to judge this risk. An engineering approach to coastal flow slides is presented that combines the Dutch experience with flow slides with results of fundamental research of the past 10 years.

## Description of flow slides

A flow slide can be described as an instability that occurs in a fairly gentle underwater slope consisting of loose sand, causing liquefied sand to flow out into an even more gentle slope. A flow slide may occur after a change in slope geometry, for example steepening and/or deepening of the channel as a result of scour. A rather small, but quick change in load may trigger the sudden liquefaction of a vast amount of sand, which subsequently flows down the slope (Kramer 1988). In many cases the triggering mechanism is not known. It is thought flow slides can be triggered by almost any small change in soil stresses, caused by for instance seepage due to tidal water level variation, vibrations, ship waves, and so on. Consequently, if the conditions in the subsoil required for liquefaction are present, it is of no great importance what exactly initiates a flow slide.

Flow slides also occur in other parts of the world, for instance along the banks of the Mississippi river (Torrey, 1994), along the slopes of artificial sand islands in the Beaufort Sea (Sladen et alii 1985). The risk of flow slides is also present during dredging works in loose sand, unless special preventive measures are taken.

If a loosely packed sand is loaded by applying a small shear stress the sand will tend to reduce in volume. If the pores between the grains are water saturated either water will have to flow out of the pores, or the water will have to be elastically compressed to effect this change in volume. If no water can flow out (undrained conditions) an excess pore pressure will be the result.

Excess pore pressure reduces the effective pressure, and with that, the shear strength of the soil. If the sand is present in an underwater slope this can result in slope failure. This slope failure may take the form of a small slip failure but if conditions are unfavourable enough this may develop into a full size flow slide. In our opinion, liquefaction often first starts near the toe of the slope. A sudden loss of stability at the toe leads to a retrogressive failure of the entire slope.

### **Dutch experience**

Flow slides are encountered in many parts of the world. The Dutch experience is largely limited to the estuaries in the South Western part of the Netherlands, and in some cases in harbours or sand gain pits elsewhere. Since 1800 records of flow slides and slip failures along the shores of the Province of Zeeland have been kept (Wilderom, 1979). Between 1881 and 1946 229 flow slides were registered, resulting in a total area lost of 660 acres and a displaced volume of 25 million m<sup>3</sup> (Koppejan et al, 1948). The material displaced during one single slide can amount up to 5 million m<sup>3</sup> and a recession of the shore line up to 400 m. On several occasions stretches of dike of several hundreds metres width were lost. Of a total of 1129 slides that have been registered between 1800 and 1979 a number of 200 were sufficiently documented to make further analysis possible. This has led to practical criteria for the occurrence of flow slides under Dutch circumstances. Among these conditions is the assumption that flow slides are mostly found in young holocene marine sediments. Local experience shows that older holocene deposits and pleistocene deposits are less susceptible to flow slides. This empirical rule may be subject to local conditions. In Zeeland the pleistocene deposits are often densely packed. The older holocene deposits can be deposited more slowly than the younger holocene deposits, resulting in a denser package of the material. In case of the older deposits also bonding effects may play a role. There may also be an influence of difference in stress history between the deposits. These factors can be different for other locations however.

One of the most important geometrical factors is the initial slope along the channel. Figure 2 shows the average slope inclination before the occurrence of more than 100 field flow slides (squares) as a function of total slope height or channel depth. Much scatter is found and a useful tendency can not be deduced from this graph. A reasonable explanation is that the scatter is primarily caused by differences in local circumstances among which different sand properties and different in-situ densities. Apart from that, the average slope angle is probably not the best measure for evaluating the flow slide susceptibility. It stands to reason that the inclination of the steepest part of the slope may be a better measure.

In Figure 3 therefore, instead of the average slope, the inclination of the steepest part of the slope is shown, again as a function of slope height for the more than 100 locations where flow slides occurred in the past. The idea is that

Figure 2 Actual flow slides compared to model results: Average slope angle before the slide as a function of slope height

Figure 3 Actual flow slides compared to model results: Slope angle of steepest part of the slope as a function of slope height

steepening due to scour will be most dangerous in the steepest part of the slope. The height of the steepest part varies between a few metres to about 30 m. Although a somewhat better result is found, the scatter remains rather dominant. Practical criteria for the initial slope inclination at which flow slides may take place, derived from the geometrical information gathered in Fig. 2 and 3, will be very uncertain if applied to a specific location and a large safety margin should be included. On the other hand the available data of flow slides in the field makes it possible to get a rough impression of the flow slide probability. Therefore the total number of slides within the period of the last 100 years combined with the total stretch of dikes and foreshore principally vulnerable for flow slides and the geometric data of the flow slide records are analysed thoroughly. Moreover the average chance that not only the foreshore is affected, but also dike failure takes place, in relation to the locally present foreshore length can be assessed too by using the available information concerning final slopes after occurrence of the slides. Although very useful in Dutch engineering practice, again this statistic result has to be treated very carefully if applied to a specific site where local geotechnical information is absent.

### **Measures against flow slides**

In past centuries no measures against the effects of flow slides along the foreshore were taken. The occurrence of dike falls was simply taken for granted. Secondary dikes were built behind the sea dike to keep the area of inundation limited. Since 1880, due to increased application of stone protection, in more and more stretches the recession of the shore line has been stopped. The number of flow slides and slip failures has reduced accordingly. The effectivity of shore protection in regard to the prevention of flow slides is not due to a reduction of flow slide susceptibility of the sand. Instead, fixing the foreshore makes steeper slopes impossible. The observations that flow slide occurrence was stopped after slope fixation confirmed the theory that in addition to sand properties and actual slope steepness, also change in geometry (e.g. steepening of the slope) is an important conditional factor for the occurrence of flow slides.

Another method, consisting of the application of groynes to arrive at a system of 'fixed points', was less successful. Although the objective of keeping the tidal channel away from the dike could be realized by this system, local scour caused slides near the tip of the groynes, causing the system to fail.

The risk of flow slides can be reduced by densification. Experiments using different densification techniques have been carried out in the Netherlands. The success of different techniques depends on material properties such as the amount of fines. Also, densification has to be possible up to a certain depth to be effective. In the Netherlands, one example of large scale densification is known. The subsoil of the Storm Surge Barrier in the Eastern Scheldt was densified, using a specially developed densification ship, the

Nautilus. With large vibratory needles, densification up to a depth of 30 metres could be realised. In most cases however, densification is not economically feasible.

## Experiments

Flow slides are seldomly witnessed, and then of course only surface events can be seen. Witness reports of flow slides indicate that the process can take several hours, during which at the surface sandmasses of one metre thick by several metres width slide down into the water. The retrogression speed is several metres per hour. There are also indications that under water the flow of sand and water is much quicker, in the order of metres per second. A fine opportunity to study flow slides were large scale tests on hydraulic fill in 1988 (Bezuijen and Mastbergen, 1988). During the test series sand bodies were constructed with varying deposition rates in a test flume of 2,5 m height. Especially the tests with fine sand ( $D_{50}$  of 135  $\mu\text{m}$ ) showed that flow slides were of major influence on the final slope angle. Tests with a coarser sand ( $D_{50}$  of 225  $\mu\text{m}$ ) showed considerably less flow slide susceptibility, resulting in steeper slope angles. Another remarkable result of these tests was the fact that slope height was very important. The sand body could develop to a height of 1 to 1,5 m before a flow slide took place, after which the same cycle started again. Pore pressure measurements showed that liquefaction occurred very sudden: pore pressures rose from zero to values indicating almost complete liquefaction within 0,1 seconds. After that the actual slide and the dissipation of pore pressures could last approximately one minute. The sand body of course was of limited dimensions, which can implicate that with increasing dimensions also the time scale in which events take place will be larger.

Other interesting large scale experiments were carried out between 1973 and 1976 (Kroezen et al, 1982). During these tests a loosely packed and water saturated sand body of 2.5 m high, 3 m wide and 25 m long was forced to liquefy at the fairly steep slope at one end of the mass consisting of fine sand. After that a retrogressive failure mechanism could be witnessed that displaced with a horizontal speed of 0.5 to 1.5 m per second through the sand body. In some tests the retrogressive failure almost reached the other end of the facility at 25 m distance of the location where the mechanism was initiated. Very gentle final slopes were found (up to 1 to 25). During the passage of the failure front excess pore pressures almost equal to the initial effective stress in the sand were measured, indicating that full liquefaction had taken place.

## Research

In 1981 fundamental research was started. By that time liquefaction could be understood in terms of critical density, as defined by the results of drained and undrained triaxial tests on soil samples (Lindenberg and Koning,

1981). Since then progress has been made in two aspects. First, it has been attempted successfully to describe the constitutive behaviour of loosely packed sands, based on the results of drained triaxial tests. On the one hand there is contraction, caused by shear stress, which results in excess pore pressure if no drainage can take place. Excess pore pressure in its turn leads to decompression. These two volumetric aspects can be measured separately in drained triaxial tests. If the behaviour of the soil is undrained, such as is the case in liquefaction problems, the tendency to contract and the tendency to increase in volume due to excess pore pressure have to compensate each other. Models that take these aspects in regard have proven to be successful in describing the response and failure of loosely packed sand in triaxial tests.

In underwater slopes in nature, shear stress is related to the foreshore geometry. Slope height and slope angle have influence on in-situ stresses. A research programme was started in 1985 to study the influence of slope geometry. A mathematical model has been developed in which the effects of sand properties and geometry characteristics were combined. The in-situ stresses for a given geometry are given by analytical formulae, obtained by generalizing the results of Finite Element computations.

These in-situ stresses are introduced in the liquefaction model together with the basic relevant constitutive behaviour of the sand as a function of sand density.

The model itself verifies for 500 points in the sand mass the so called instability criterion during an incremental slope steepening under undrained conditions (Stoutjesdijk, 1993):

$$d\gamma = 1/\lambda \cdot d\tau_{xy}$$

- $\lambda$  = stability factor
- $d\gamma$  = incremental change in shear strain
- $d\tau_{xy}$  = incremental change in shear stress

$\lambda$  is in fact the eigenvalue of a matrix system comprising the entire system of stress strain relations for the sand for given sand density.

Instability occurs if  $\lambda < 0$ . It means that an increase in shear strain can only be attended by a decrease in shear stress. Because slope steepening is generally accompanied by shear stress increase, the condition  $\lambda < 0$  in fact indicates that large shear deformation will take place. The instability condition has been assumed identical to liquefaction.

Because the stress state as well as the sand behaviour varies from point to point, and with slope angle and slope height, instability will start in one point in the sand mass for a certain slope angle. The corresponding slope is the critical slope inclination for the considered foreshore. As the slope steepening in the calculation proceeds, the unstable zone will grow. An extensive series of calculations has shown that the most critical zone in most cases is located next to or just below the toe of the slope. In Figure 4 the result of a calculation is shown. The figure shows several contourlines. Inside each area, defined by a

contourline, instability has occurred during the calculation for a certain slope angle. The most inner contourline gives the critical slope inclination, in this case 1 : 4.5 ( $\tan\alpha = 0.222$ ). The critical zone, as can be seen in Figure 4, is situated near the toe of the slope at some depth beneath the toe.

In the liquefaction model only two slope shapes can be introduced and the sand properties refer to one sand density for the entire mass. For practical purposes the properties of the most susceptible layer will be introduced in the model. This sandlayer only has to be considered critical when the calculated unstable zone has reached the layer boundary. The corresponding slope inclination is the critical inclination for that most sensitive layer. In case a second layer could be susceptible too, the calculation has to be repeated with the sand properties for that layer. In this way the stability of a foreshore can be assessed.

Figure 4 Example of a calculation result with the model. Note the situation of the critical zone inside the inner contourline.

### Verification

The research results have lead to a model for the prediction of flow slides. In the model slope height, slope angle and (material behaviour as a function of) relative density are the most important factors. The model has been verified on a number of flow slides, that have taken place in the past. Also the trend following from some 150 actual flow slides as shown in Fig. 2 and Fig. 3

can be compared with the results of model calculations. Average values for the input parameters have been used. Calculations were made for several slope heights and several relative densities. Relative density is defined here as  $Dr = (n_{max} - n)/(n_{max} - n_{min})$ , in which  $n$ ,  $n_{max}$  and  $n_{min}$  are the in-situ density, the maximum density and the minimum density. Fig. 2 and 3 show that most actual slides can be represented by relative densities between 0 and 0.6. Another important trend is the influence of the slope height or channel depth. The calculation results in Fig. 2 and 3 indicate that a flow slide may occur at a much more gentle slope in case of deeper channels. This effect is the logical consequence of the basic stress strain relations for sand, found from triaxial tests in the laboratory and introduced in the model.

## Practical approach

To make a prediction of the flow slide susceptibility for any particular situation with the flow slide model it is necessary to perform in-situ borings, in-situ density measurements, triaxial tests, calculations and analysis. For many practical applications this may either take too much time or may be too expensive. A set of calculations has been performed, based on Dutch sands and applicable to comparable situations only (similar material, tidal range 3 to 5 m). Unfavourable assumptions have been used to be on the safe side. The result is shown in Fig. 2 as the line marked "Dr=0, design values". In many cases information on local circumstances may lead to a less conservative result.

It is possible to derive an impression concerning the type of material and the in-situ density from cone penetration tests (CPT's). Probably, because of the relatively static character of this test, the CPT yields a better impression of in-situ density than more dynamic tests such as the widely used Standard Penetration Test (SPT's). A second advantage of the CPT is that a continuous image of the subsoil is obtained.

If the investigation is further pursued, then an extensive programme of field tests, laboratory tests and calculations has to be performed. Because of the size and the cost of these activities, it has to be considered whether or not the chance that the investigation will lead to limitation of preventive measures is present. The investigation consists of electrical density measurements, borings, sieve curve analysis, determination of maximum and minimum densities, triaxial testing and calculations with the flow slide model. This entire programme is necessary because the flow slide susceptibility of one particular situation can only be determined if detailed information on in-situ density and behaviour of the material of the site is available.

Uncertainties are introduced with each step of the procedure. These uncertainties can be quantified by assuming that each relevant parameter has a stochastic character, which can be described with the expectancy value, a standard deviation and a statistical distribution. Uncertainties concerning the calculation models can be implemented too. As described before, the liquefaction calculation model yields the eigenvalue  $\lambda$ . This  $\lambda$  can be conceived

as a function of the stochastic variables so that  $\lambda$  may be used as the reliability function in a probabilistic analysis. The probability analysis yields two results:

- the probability of the occurrence of a flow slide
- the contribution to the uncertainty of each of the parameters to the total failure probability.

The latter result enables the designer to decide whether additional investigations may help to increase the reliability of the assessment of potential flow slides. In this way, the design cycle of modelling and determining input parameters can be optimized.

## CHAPTER 242

### EROSION OF LAYERED SAND-MUD BEDS IN UNIFORM FLOW

Hilde Torfs<sup>1</sup>

#### Abstract

In a laboratory flume the formation and erosion of stratified sand-mud beds in uniform flow was studied. The experiments showed that depending on the initial conditions of suspended sediment concentration and mixture composition, consecutive inputs of a mud/sand suspension will lead to the formation of a layered sediment bed. Peaks in the measured density profiles show the different layers and indicate a possible segregation of the sand due to differential settling. During the erosion of the stratified bed, the sediments are eroded layer by layer. This results in a sequence of suspended load (fines) and bed load (sand) transport phases.

#### Introduction

The sediments in estuaries and coastal areas are generally a mixture of sand and mud. Due to tidal action the sediments are periodically suspended and afterwards, during slack water, deposited. This sequence of erosion and deposition results in many cases in a layered bed structure, because the sand fraction settles faster. In the Scheldt Estuary layers of a few millimetres up to two centimetres thick are found (Bastin 1974). Also for the Humber Estuary and the Severn Estuary sediment laminations are reported (Williamson 1991). Understanding the erosion of such sediment bottoms is important for the control of navigation channels, dredging activities and pollution as well as for the modelling of sediment transport in estuaries and coastal seas.

To study the fundamental aspects of the erosion of layered sand-mud beds, laboratory experiments in uniform flow were carried out. During these tests the whole erosion process was followed starting from the formation of the bed out of a suspension and looking at the layer thickness and the density profiles, over the incipient motion phase until the different modes of erosion of the stratified, mixed bed.

### Experimental Procedure

The laboratory set up consists of a 9 m long flume with a rectangular cross section of 40 cm wide. The total length of the flume is divided into 4 different regions: a 4 m upstream inflow region with fixed bed, a 3 m long glass wall measuring section with the sediment bed, a sediment trap and a 1.5 m downstream outflow region with fixed bottom. A settling tank (1 m high) can be mounted on top of the flume, above the measuring section.

The tank is filled with salt water ( $3 \text{ kg/m}^3$ ). To simulate a tidal cycle, at regular time intervals - twice a day - a slurry of mud mixed with sand is pumped into the settling tank. The slurry density results in suspended sediment concentrations in the settling tank of a few grams per litre, too low for hindered settling to occur but about the order of magnitude of the near bed sediment concentration after a heavy erosion event. This filling procedure is repeated until, after deposition of all the layers, a bed thickness of  $\pm 8 \text{ cm}$  is reached. For each layer the same amount of mass (same initial density and volume) is added. Exactly the same is done in a 0.1 m diameter perspex settling column of the same height. In the column the layer thickness can be read and density profiles can be measured using a gamma-densimeter. In this way both measurements are done without destruction of the sediment bed in the flume. Details on the experimental procedures can be found in Torfs (1994).

After the formation of the bed, the erosion experiment can start. The discharge in the flume is stepwise increased until the start of the erosion process is observed. The water levels upstream and downstream of the measuring section (sediment bed), the discharge and the cumulative weight of the bed load in the sediment trap are recorded continuously. At 15 minute time intervals samples of the suspended load are taken upstream and downstream of the sediment bed. With these data erosion rates and bed shear stresses can be calculated (Torfs 1994).

The sediments used in the experiments are mixtures of natural mud, dredged from the Scheldt river near Antwerp, and a uniform fine sand. In some preliminary tests, however, kaolinite and a montmorillonite pottery clay were used as cohesive fraction. Two types of natural Scheldt mud are used. Mud2 is a subtidal mud, with a sand content of about 15 %. Mud3 comes from an intertidal flat, the sand content was much higher, about 38 %. Mud3 was heavily contaminated with oil. Table 1 gives an overview of the mixtures used in the experiments.

**Table 1:** Used mud/sand mixtures.

Name of the mixture	Sand content	Initial density (kg/m <sup>3</sup> )	Number of layers	Mud type
J1	24.6	1006	4	Mud2
J2	18.1	1005	3	Mud2
J3	20.7	1005	3	Mud2
J4	26.6	1005	3	Mud2
J5	28.7	1005	3	Mud2
J6	40.8	1006	5	Mud3
J7	46.2	1006	5	Mud3
J8	53.1	1006	5	Mud3

### Measured Density Profiles

The different layers in the bed can be visually observed and measured in the transparent settling column. The stratification is also present in the density profiles measured using the gamma-densimeter. Fig. 1 is a typical example of a density profile for experiment J5. The profile shows density peaks indicating the layer interfaces. Part of the sand seems to be accumulated at the bottom of each layer and some of that sand probably intruded in the previous layer. In any case the peaks show that in the small time in between two inputs, the previous layer (with low densities at the top) already developed enough structural strength to carry the next denser layer. The presence of a high density sand layer depends on different factors (Toorman et al 1993 and Williamson et al 1992): the percentage of sand in the mixture (a slurry can only contain a certain amount of sand within its matrix), the density of the mixture (for higher initial densities hindered settling occurs preventing the sand of falling through the mud), the type of cohesive sediment and the supply rate. Another example of a measured density profile is presented in Fig. 2 for experiment J6, using Mud3. Also in this case the layered bed structure is clear.

Looking at the shape of the measured density profiles, there is a clear difference between the experiments with Mud2 (Fig. 1) and the experiments with Mud3 (Fig. 2). In both sets of density profiles some sort of segregation is visible. The density profiles from Mud2 mixtures however show a pronounced high density peak at the bottom of each layer and then a fairly uniform zone of constant density (around 1.06 kg/dm<sup>3</sup>). At the top of each layer some sort of low density peak can be seen as well. A similar feature

has been reported by Edge et al (1989). For Mud3 the density is decreasing throughout the whole layer. This could indicate that in this case sand is also withheld within the mud matrix and that there is a smooth evolution of sand content over the layer thickness. Mud3 already contained a high sand content, it could be that this sand is held within the mud and that only the additional sand falls through. Mud2 has a low natural sand content and here more (all?) sand falls through. Williamson et al (1992) showed that segregation increased with increasing sand content. They found for their experiments a sand content of about 47 % as maximum limit of sand held within the matrix. Above the limit segregation occurs. In the experiments of Huysentruyt (1994) on Mud2 the segregation limit was less than 10 % sand added (i.e. about 25 % total sand content). This agrees well with these tests: the sand content in the Mud2 mixtures was around 25 % and always segregation occurred.

**Fig. 1:** Density profile for experiment J5.

A comparison of all the density profiles shows higher peak densities in the case of Mud3 mixtures. For those mixtures the density in a layer varies between 1.08 and 1.14 kg/dm<sup>3</sup>. For Mud2 (with a lower sand content) the density in a layer goes from 1.05 to 1.12 kg/dm<sup>3</sup>. Williamson et al (1992) stated that an increase in the sand content leads not only to a higher segregation but also to a greater and faster consolidation and thus to higher densities. The higher permeability of the sand layer enhances the drainage of the pore water.

**Fig. 2:** Density profile for experiment J6.

Also the layer thickness is influenced by the sand content of the sediment mixture. Fig. 3 gives the average layer thickness for each experiment, including the preliminary tests, as a function of sand content. A general decreasing trend over all experiments is visible. But also the type of sediments can be partly responsible for that. If only the data for Mud2 are considered, a decrease of layer thickness with increasing sand content is noticed but the decrease seems to be much less pronounced. An extensive set of consolidation experiments with amongst others Mud2 by Huysentruyt (1994) showed that the settling behaviour is only affected by the addition of sand up to a certain maximum percentage of sand added. In the case of Mud2 an addition of 10 % and more sand does not change the settling behaviour any more. Segregation takes place and the thickness and density peak of the bottom layer remain the same. An addition of 10 % sand means a total sand content of about 25 %, the results of Fig. 3 again confirm this limit.

Fig. 3: Mean layer thickness as a function of sand content.

### Results of the Erosion Experiments

Fig. 4 gives an overview of an erosion experiment. The discharge in the flume is slowly increased, step by step. During the first step a thin film (only fine material) is lifted of the bed surface and goes into suspension. On the surface longitudinal fine lines appear. Increasing the discharge (step 2, Fig. 4), the erosion of the first layer (mainly mud) starts. The suspension concentration increases suddenly (suspended load downstream minus suspended load upstream = eroded material). At the beginning of this step, no bed load erosion occurs (slope of cumulated bed load in Fig. 4 is zero). After a while, the mud erosion decreases. Two different factors can cause this decrease. Due to the increasing bed density with depth, also the erosion resistance of the surface material increases during the erosion. Depending on the magnitude of the applied bed shear stress as compared to the erosion resistance, the erosion can eventually stop. Another possibility is that a sand layer is reached. That is the explanation in this case. The sediments in this layer are transported mainly as bed load. Hence, the slope of the curve of the measured bed load increases, whereas the difference between suspended load concentrations measured upstream and downstream decreases. Also the formation of sand ripples on the bed can be observed. These bed forms move towards the downstream end of the flume. Increasing the discharge (step 3, Fig. 4) increases the bed load transport of the sand until all the bed forms reach the downstream reservoir. Meanwhile at the upstream end of the sediment bed, the next mud layer becomes available and goes into suspension. The bed load decreases... For all experiments on layered sediment beds a similar sequence of suspended load and bed load transport is encountered, indicating a layer by layer erosion of the bed.

**Fig. 4:** Overview of an erosion experiment.  
(us = upstream, ds = downstream)

Although the bed densities are very low, between 1.06 and 1.15 kg/dm<sup>3</sup>, the experiments learned that the sediment bed has a significant erosion resistance. It is not clear if this is partly caused by the presence of sand in the matrix. Using an empirical formula (Eq. 1) presented by Delo in 1988,

$$\tau_{cr} = 0.0012\rho_d^{1.2} \quad (1)$$

with  $\tau_{cr}$  the critical shear stress for erosion in Pa and  $\rho_d$  representing the dry density in g/l, the calculated critical shear stresses for the surface layer lie between 0.1 and 0.2 Pa.

An important aim of this study was to look at the influence of the sand content on the erosional behaviour. For the determination of the erosion resistance, in general a higher sand content in the mixture means a faster consolidation and hence, higher bed densities that will lead to an increased erosion resistance. Of course also the type of sediment is important. During the erosion process, the presence of an important amount of sand in the sediment bed causes bed load transport. Depending on the amount of sand

in the mixture and the importance of the segregation, the bed load transport can be very significant and therefore, cannot be neglected in transport modelling.

### Conclusions

Sediment layering is known in many environments ranging from the tidal reaches of rivers to the deep sea. Energy variations are the main cause for the development of layers. During a period of high energy (flood) sediment is transported either as bed load or suspended load. As the energy level decreases first the coarse and then the finer sediments settle. Laboratory experiments have shown the formation of a layered bed as a function of mud type and sand content. The presence of sand enhances the consolidation, decreases the layer thickness and increases the bed densities.

Erosion of these layered sediment beds leads to a sequence of suspended load and bed load transport phases. The sand content normally increases erosion resistance of the deposited sediment bed by enhancing the consolidation and by increasing the bed density. The presence of a significant amount of sand in the sediment bed increases the importance of the bed load transport in the total erosion and sediment transport process.

## CHAPTER 243

### Standing wave induced soil response in a porous seabed

Ching-Piao Tsai\* and Tsong-Lin Lee\*\*

#### ABSTRACT

This paper presents the experimental results of the pore water pressures within the soil under the action of standing waves. Both the spatial and time variation of pore pressures are generally well agreement between the theory and the experiment. The experiments also show some nonlinear phenomenon of the pore pressures within the soil.

#### INTRODUCTION

When incident waves arrive to a breakwater they will be reflected, then normally or obliquely standing waves are formed in front of the structure. The forces of standing waves play a very important role for designing the coastal structures. There were a lot of theories concerning this subject. It was known from the previous reports (Smith and Gordon, 1983; Silvester and Hsu, 1989) that some breakwaters have failed possibly due to soil instability and trench scouring, rather than structural causes. The investigations of the soil response in front of such a structure under the action of waves are thus become important.

As gravity waves exert cyclic pressures on a sedimentary seabed, they penetrate into the porous medium and induce pore pressure within the soil column. The soil will lose its strength in bearing any load if the induced pore pressures

\* Associate Professor, Department of Civil Engineering, National Chung-Hsing University, Taichung 402, Taiwan, R.O.C.

\*\* Senior Graduate Student, Department of Civil Engineering, National Chung-Hsing University, Taichung 402, Taiwan, R.O.C.

become excessive in the soil skeleton. A number of theories have been developed for the wave-induced pore pressure in the porous medium, such as Yamamoto et al. (1978), Madsen (1978), Mei and Foda (1981) and Okusa (1985). There were many previous works investigated the wave-induced pore pressures in the laboratory as well as prototype conditions. However, only the case of the progressive wave was considered.

For the cases in front of a breakwater, Hsu et al. (1993) has developed a general three-dimensional solution of the soil response induced by the short-crested wave system. Tsai (1995) extended to the case of partially reflected waves and evaluated the potential liquefaction under the action of such a wave system. Their solutions can be reduced to the case of two-dimensional standing wave that the incident-wave is normally to a vertical wall. Mase et al. (1994) proposed a numerical model for calculating the soil response under the action of standing waves. This paper shows the experimental results of the standing wave induced pore pressure in the sand bed in front of a breakwater.

## EXPERIMENTS

The measurements of pore pressures within the sand bed due to the action of standing waves were conducted in a wave flume. The experimental set-up is shown in Fig. 1. The dimension of the wave flume is 2 m in width, by 2 m in height and by 100 m in length. Sand soil of medium firmness was filled 50 cm in depth and 2 m in length in front of the wall.

Fig. 1 Sketch of the experimental set-up.

The physical properties of the sand are measured: the specific gravity of soil  $G_s$  is 2.64, the mean grain size  $D_{50} = 0.187$  mm, the uniformity coefficient  $D_{60}/D_{10} = 1.8$ , the specific gravity is 2.64, permeability is  $1.2 \times 10^{-4}$  cm/sec, the water content  $w$  is 0.23, the porosity  $n = 0.38$  and the void ratio  $e$  is 0.62. Then the degree of saturation of the soil is 98% which is calculated from the formula  $S_r = wG_s/e$ .

The water depth  $d$  above the mudline is 45 cm. The wave periods  $T$  generated in the experiment are varied from 1.0 to 3.0 seconds. The wave heights of incident waves are ranged from 4 cm to 16 cm, from which the sand drifting is not obviously observed.

Under the position of anti-nodal point of the standing wave, the time variation of pore pressures at various distances from the mudline were measured by five pore-water pressure transducers. Also five transducers were placed horizontally below the mudline to measure the spatial variations of pore pressures.

## RESULTS AND DISCUSSION

The solution of pore pressures of the standing wave can be reduced from the three-dimensional solutions given by Tsai (1995), from which the solution of the two-dimensional standing wave are given by

$$P = \frac{p_o}{1 - 2\mu} \{ (1 - 2\mu - \lambda) C_1 e^{kz} + (1 - \mu) \frac{(\delta^2 - k^2)}{k} C_2 e^{\delta z} \} \cos kx e^{-i\omega t} \quad (1)$$

in which  $P$  is the wave-induced pore pressure in excess of the hydrostatic condition,  $k$  is the wave number,  $\omega$  is the wave frequency,  $t$  is the time; the  $x$ -direction is measured normal to the wall, and the  $z$ -axis is positive upward from the mudline. The parameter  $\mu$  is the Poisson's ratio of soil. The parameters  $\delta$  and  $\lambda$  are coupled with soil properties and wave conditions, they are given by

$$\delta^2 = k^2 \left[ \frac{K_x}{K_z} \right] - \frac{i\omega\gamma_w}{K_z} \left[ n\beta + \frac{1 - 2\mu}{2G(1 - \mu)} \right] \quad (2)$$

$$\lambda = (1 - 2\mu) \left\{ k^2 \left( 1 - \frac{K_x}{K_z} \right) + \frac{i\omega\gamma_w n\beta}{K_z} \right\} \left\{ k^2 \left( 1 - \frac{K_x}{K_z} \right) + \frac{i\omega\gamma_w}{K_z} \left[ n\beta + \frac{1 - 2\mu}{2G} \right] \right\}^{-1} \quad (3)$$

respectively, in which  $K_x$  and  $K_z$  are the coefficients of soil permeability in the  $x$ - and  $z$ -directions,  $\gamma_w$  is the unit weight of the pore water,  $n$  is the soil porosity and  $G$

is the shear modulus. While  $\beta$  is the compressibility of the pore fluid which can be related to the apparent bulk modulus of the pore water  $K'$  and the degree of saturation  $S_r$  (Verruijt, 1969), such that

$$\beta = \frac{1}{K'} = \frac{1}{K} + \frac{1 - S_r}{P_{w0}} \quad (4)$$

where  $K$  is the true bulk modulus of elasticity of water and  $P_{w0}$  is the absolute pore-water pressure. Coefficients  $C_1$  and  $C_2$  in the equation (1) can be determined from

$$C_1 = \frac{\delta - \delta\mu + k\mu}{\delta - \delta\mu + k\mu + k\lambda} \quad (5)$$

$$C_2 = \frac{k\lambda}{(\delta - k)(\delta - \delta\mu + k\mu + k\lambda)} \quad (6)$$

The above solutions are based on the assumptions that (i) The porous bed is homogenous, unsaturated, hydraulically anisotropic and of infinite thickness, and (ii) The soil skeleton and the pore fluid are compressible.

For comparisons of theory and experiment, some values of parameters are needed besides the physical properties of the sand stated above. These are the stiffness of soil,  $G\beta$ , in which  $G$  is the shear modulus of soil and  $\beta$  is the compressibility of the pore water, and the Poisson's ratio of soil,  $\mu$ . The value of  $\beta$  can be determined from the relationship of the apparent bulk modulus of the pore water and the degree of saturation  $S_r$  (see Yamamoto et al., 1978), from which it is given by  $\beta = 3.7 \times 10^{-6} \text{ N/m}^2$  for this study. From the best fit made by the series experimental data, it is adopted reasonably by  $G\beta = 5$  and  $\mu = 0.3$  for the soil of medium firmness. The permeability of soil in the experiment is considered as hydraulically isotropic, i.e.  $K_x = K_z = 1.2 \times 10^{-4} \text{ cm/sec}$ .

Unlike those of progressive waves, the pore pressures under the action of standing waves are spatial and time variations which are shown in Fig. 2 for both theoretical and experimental results measured below the mudline  $z = -10 \text{ cm}$ . The maximum pore pressure occurs at the position under the anti-nodal point of the standing wave ( $kx = 0$ ), while the almost zero value is at the nodal point ( $kx = \pi/2$ ). The pore pressures, under the position of the anti-nodal point, at various depths from the mudline are depicted in Fig. 3. It is found that the pore pressure decreases and a time-phase delay appears as the depth increases. It is noted that there is no

Fig. 2 Spatial and time variations of pore pressures below the mudline  $z = -10$  cm.

Fig. 3 Time variations of pore pressures at various depths, at  $kx = 0$ .

phase lag in the saturated soil theoretically, because the coefficient of  $C_2$  in equation (1) is zero.

The depth profiles of pore pressures ratio  $P/P_0$  are given in Fig. 4, in which  $P$  is the measured amplitude and  $P_0$  is the amplitude of bottom pressure of the incident wave estimated by linear wave theory. It is seen from the theoretical curves that the fully saturated condition ( $G\beta = 0$ ) gives the larger values than those of partially saturated soil. The measured amplitudes at the mudline are smaller than the theoretical values, as the larger wave height actions. In contrary, the measured values near bottom are slightly larger than those of theory. The former may be caused by the energy damping from water column through the porous bed, while the latter is due to the effect of finite thickness of soil in experiments as opposed to infinite thickness of the theory. Nevertheless, the experiments are good in agreement with the theory over all.

Fig. 4 The depth profiles of pore pressures ratio  $P/P_0$ , at  $kx = 0$ .

Fig. 5 Double humps of time variations of pore pressures, at  $kx = 0$ .

Fig. 6 Effect of the wave steepness on the pore pressures ratio  $P/P_0$ , at  $kx = 0$ .

It was known that the double humps appear in the time-history of pressures of nonlinear standing waves. This nonlinear phenomenon also influences the pore pressures within the soil column, which is shown in Fig. 5. Due to the effect of phase lag, the double humps become asymmetric as depth increases. However, it is obviously seen that the nonlinear effect can not be observed in the linear theory.

The pressure ratio  $P/P_0$  at the mudline and within the soil skeleton is independent on wave steepness theoretically. Nevertheless, it can be seen in Fig. 6 that the pressure ratio slightly decreases as the wave steepness increases, although the plotted points are scatter over a range.

## CONCLUSIONS

1. Standing waves are not only important for their forces on a maritime structure, but they have been received attention for their conducive scouring in front of a breakwater.
2. This study presented the experimental results of pore pressures under the action of standing waves.
3. In general, the spatial and time variations of pore pressures induced by the standing waves are well agreement between the experiment and theory.
4. It was found that some nonlinear characteristics of pore pressures exists for the larger wave cases.

## CHAPTER 244

### EROSION CONTROL BY CONSIDERING LARGE SCALE COASTAL BEHAVIOR

Yoshito Tsuchiya<sup>1</sup>, M. ASCE, Takao Yamashita<sup>2</sup> and Tatsuhisa Izumi<sup>3</sup>

#### Abstract

Due to the construction of Naoetsu harbor, severe beach erosion has taken place on the Joetsu-Ogata coast facing the Japan Sea. To establish a principal methodology for beach stabilization, large scale coastal behavior first is investigated by constructing a long-term shoreline change model in which the representative monsoon wave is introduced. Comparison of hindcast and actual long-term shoreline change shows that the proposed model can predict long-term shoreline change. Shoreline change after the construction of Naoetsu harbor also was predicted under the condition that natural sandy beaches had been retained. Results show that shoreline retreat is severe near the harbor and extends to the central part of the coast. To determine the most suitable location for headlands to be used for stabilizing the coast, long-term shoreline changes were calculated under the condition that a headland is given at several locations. We conclude that in principle when the boundary condition for shoreline change by headland is given near the Shinbori River, a sandy beach tends to have stable large scale coastal behavior during long-term shoreline change. We propose a principal methodology for beach stabilization, part of which is being used in current construction.

#### INTRODUCTION

When planning erosion control works for sandy beaches, investigation of their coastal behavior from the long-term and large-scale view points is extremely important. Local and temporal measures alter sandy beaches, sometimes destroying them. This is what coastal engineers have learned from their experiences during the past several decades in Japan. Many attempts have been made to control beach erosion throughout the world, but in the long term none have succeeded in stabilizing sandy beaches that are being eroded. Almost all the common countermeasures are of little use for stabilization as they cause beach profiles

gradually to become steep. This study treats beach erosion control on the Joetsu-Ogata coast, facing the Japan Sea, to show a principal methodology for sandy beach stabilization in which the large scale behavior of a sandy beach under continuous development is considered (Tsuchiya, Yamashita, Izumi and Tottori, 1993).

In 1967, the Disaster Prevention Research Institute, Kyoto University established a wave observatory on this coast for the investigation of the beach erosion mechanism and its control. A T-shaped observation pier that extends 260m offshore was constructed. The coast (shown in Figure 1) is a slightly concave sandy beach about 25 km long and is bounded by the Gotsu and Yoneyamazaki headlands respectively on its west and east ends. It has been an erosive beach since the construction of Naoetsu Harbor on the right side of the mouth of the Seki River in 1961. The history of the construction of coastal structures is shown briefly in the figure, and shoreline changes measured on aerial photographs also are shown. Severe beach erosion began

Figure 1. Location of the Joetsu-Ogata coast and the history of the construction of coastal structures in relation to shoreline change.

near the east end of the harbor due to the lack of longshore sediment transport and has propagated eastward in relation to the extension of the breakwaters in the harbor. The countermeasures taken have been sea dikes with armor blocks, offshore breakwaters and, recently, mild-slope revetments. Beach erosion has continued to take place, resulting in steep beach profiles, and little can be expected of these countermeasures in terms of beach stabilization.

The erosive process along this coast is investigated in terms of large scale coastal behavior. A long-term shoreline change prediction model is established by introducing the representative monsoon wave and qualifying the alongshore distribution of the longshore sediment transport rate. The hindcast result is compared with actual shoreline change from 1910 to 1961, before beach erosion took place. Calculations of wave and nearshore current fields are used to estimate the alongshore distribution of longshore sediment transport in relation to the extending breakwaters. The rates of longshore sediment transport are compared with those estimated from bottom topography changes. Numerical predictions of long-term shoreline change show the most suitable locations for the headlands to be constructed for beach

stabilization of large scale coastal behavior. Based on these findings, as well as on the theoretical background of the formation of stable sandy beaches, we propose a principal methodology for beach stabilization in relation to change in longshore sediment transport rates.

## HINDCAST OF SHORELINE CHANGE BEFORE CONSTRUCTION OF NAOETSU HARBOR

### Bottom topography for the computational domain

The oldest shoreline recorded by the Geographical Survey of Japan is shown in a topographical map issued in 1910. The biggest coastal structure in the area, at present, Naoetsu Harbor, was constructed in 1961. The coast, at least before 1961, probably behaved naturally, having had no artificial impact on it. Hindcasting the shoreline changes for the period 1910 to 1961 (before harbor construction), should provide important information about such natural external forces that act on long-term beach change as storm wave conditions and the magnitude of sediment input from rivers. The bottom topography for the computational domain was reproduced by connecting two maps, a marine chart and a topographical map issued in 1910, on the assumption that beach topography shallower than a 20m water depth can be replaced by the equilibrium beach profile proposed by Dean (1981);

$$h = Ay^{2/3} \quad (1)$$

where  $h$  is the water depth,  $y$  the distance taken offshore from the shoreline, and  $A$  the model constant which may be related to the beach sediment diameter. The bottom topography for the computational domain was obtained. The model constant varies alongshore. Nearly the same tendency for the alongshore distributions and maximum exists for both the model constant and sediment diameter near the observation pier.

### The long-term shoreline change prediction model

**(1) Shoreline change prediction model** A one-line shoreline change prediction model can be used. An outline of the model we used (Yamashita, Tsuchiya, Matsuyama & Suzuki, 1990) is explained. The equation of continuity for shoreline change is given by

$$\frac{\partial y_0}{\partial t} + \frac{1}{(1-\lambda)} \frac{\partial Q_x}{\partial x} = \frac{Q_R(t)}{h_c B} \delta(x-x_0) \quad (2)$$

where  $y_0$  is the shoreline change from the datum line,  $t$  the time,  $x$  the alongshore distance from the origin,  $h_c$  the critical depth for beach change,  $\lambda$  the porosity of beach sediment,  $Q_x$  the total rate of longshore sediment transport,  $B$  the width of the river mouth, and  $Q_R(t)$  the sediment input from the river as the beach sediment source. Practically, the CERC formula for the total rate of longshore sediment transport can be used;

$$Q_x = \frac{a\rho g^2}{64\pi} H_0^2 T K_R^2 \sin 2\alpha_{BS} \quad (\text{m}^3/\text{yr}) \quad (3)$$

where  $H_0$  is the deep water wave height,  $T$  the wave period,  $\alpha_{BS}$  the breaker angle to the shoreline,  $K_R$  the refraction coefficient,  $\rho$  the density of water,  $g$  the gravitational acceleration, and  $a = 1.26 \times 10^7$  an empirical constant that may be changeable in relation to sediment properties but is assumed to be constant in this

shoreline change prediction. Introduction of the geometrical relation in shoreline change and combing (3) and (2) yields

$$\left. \begin{aligned} \frac{\partial Q_x}{\partial t} &= \frac{\partial Q_x / \partial \alpha_{BS}}{(1 - \lambda) \{1 + (\partial y_0 / \partial x)^2\}} h_k \frac{\partial^2 Q_x}{\partial x^2} + A_R \\ A_R &= \frac{\partial}{\partial x} \left[ \frac{Q_R(t)}{h_k B} \delta(x - x_0) \right] \end{aligned} \right\} \quad (4)$$

where  $\alpha_{BD}$  is the breaker angle to the initial shoreline. This diffusion type equation can be solved under the given initial shoreline and boundary conditions by an implicit method to obtain the total rate of longshore sediment transport  $Q_x$ . By its use shoreline change can be obtained by solving (2). In practice, when boundary conditions are given at both ends where no longshore sediment transport exists, forward and backward differentials must be applied alternatively to solve this equation numerically.

**(2) The representative waves and their transformation** In long-term shoreline change prediction two methods have been used to estimate the most effective wave or the representative wave in shoreline change: a time series of waves to be obtained by long-term wave data, and a certain representative wave for shoreline change. In the second method, in practice the single representative wave is estimated by use of the annual total rate of wave power proportional to the longshore sediment transport rate which can be evaluated by long-term wave data. As the representative wave condition has been evaluated from the annual total rate of wave power under deep water wave conditions, relatively small waves have been estimated. It is questionable whether such waves actually cause shoreline change. In this paper, therefore, in relation to the monsoon wave sequences in the Japan Sea, we assume the representative waves shown in Table 1 where the 1st, 2nd and 3rd waves

Table 1. Representative waves proposed in relation to monsoon wave sequences and their properties.

Representative Waves	Wave Direction	Wave Period in sec	Wave Height in m
1st	NW5°W	6	2
2nd	NW	7	3
3rd	NW 10°N	8	2

respectively correspond to the monsoon wave sequences, generating and developing wind wave stages, and decaying swell stage.

At Naoetsu Harbor, wave observation has been carried out over a long period. From the collected data the annual averaged duration of waves higher than 2 m in terms of significant wave height was evaluated as 264 hr/yr. We assume that monsoon waves with a duration of 24 hr strike the coast 11 times a year. A representative monsoon wave is defined as a sequence of three successive representative waves each having a duration of 8 hr.

Using three representative waves, we could calculate their transformation. In the wave refraction diagrams shown in Figure 2(b) small black points indicate the breaking points. The breaker angles are so small that accurate calculation is needed to evaluate them. Figure 3 shows the alongshore distributions of breaker height and

and angle for the three representative waves, the dotted lines indicating smoothed breaker heights. Breaker height varies remarkably alongshore around the Gotsu headland, Naoetsu Harbor (the Seki River), and the Kakizaki River, in particular for the second representative wave. This is because of wave refraction by the localbottom topography. Note, however, that no remarkable alongshore variations

Figure 2. Wave ray diagrams and incident angle of the representative wave.

(c) The third representative wave.

Figure 3. Alongshore distributions of breaker height and angle for three representative waves.

take place, but there is a distinct change in breaker angle that is positive in the east direction west of the center of the coast but negative east of the center. This tendency is a direct reflection of longshore sediment transport along the coast, resulting in the formation of a coast bounded by the Gotsu and Yoneyamazaki headlands in relation to the sediment sources from the Seki and Kakizaki Rivers.

**(3) The boundary conditions** As stated earlier, the two main sediment sources are the Seki and Kakizaki rivers. The rates of sediment input from these rivers have been estimated, but it is not known what rate contributes to the sediment source. When sediment sources are given as point sources, a sharp river delta may develop which may not contribute to long-term shoreline change because the sediment input from the rivers is due to flooding in summer, whereas in the other seasons, sediment deposited near the rivers' mouths is transported by waves both as longshore and offshore sediment transport. In long-term shoreline prediction, the period of flooding that results in sediment input from the rivers actually is very short compared with shoreline evolution. Therefore we here have estimated the incident wave angle by changing the incident wave angle in deep water along the coast so that long-term shoreline changes could be calculated under the third representative wave condition, in which the wave height and wave period are 0.7 m and 8 sec, until we could successfully hindcast the actual shoreline on the Joetsu-Ogata coast. The final estimate of the incident wave angle is shown in Figure 2(a), the upper part showing the estimated incident wave angle and the lower part its wave ray diagram. As shown in Figure 1, an island (Sado Island) lies several tens of kilometers offshore. Waves are formed due to wave dispersion and diffraction by this island.

This may result in the change in the incident wave angle as discussed above. In the long-term shoreline change prediction, the boundary conditions are

1) At the Gotsu headland on a rocky shore, no longshore sediment transport is assumed to occur. Actually, a small sea cliff has supplied a small amount of sediment to the coast, but currently no sediment input is assumed.

2) At the Yoneyamazaki headland on a rocky shore bounded by small sandy beaches an offshore bottom topography composed of fine sand is assumed where there is longshore sediment transport.

3) As previously stated, the Seki and Kakizaki Rivers discharge at the coast, providing the sediment sources. Their annual sediment rates respectively are assumed to be 10,000 to 100,000 m<sup>3</sup>/yr and 5,000 m<sup>3</sup>/yr.

Based on these boundary conditions for shoreline change, long-term shoreline

change is hindcast in two steps:

- 1) First step: No sediment sources from the rivers are assumed. No longshore sediment transport is assumed at the Gotsu headland, but is assumed around the Yoneyamazaki headland.
- 2) Second step: The sediment sources from the rivers are added to the first step to evaluate the effect of the rivers on shoreline change.

### Hindcast long-term shoreline change and the representative monsoon wave

The shoreline changes hindcast are compared with those measured in 1910 and 1961 when there was a natural sandy beach along the coast before construction of Naoetsu Harbor. On the basis of the results of this comparison we propose the representative monsoon wave for the long-term shoreline change prediction model.

(1) **In the case of the first step** Using three representative waves, we hindcast long-term shoreline changes for 51 years. Figures 4, 5 and 6 show the respective shoreline changes hindcast by the first, second and third representative waves, the changes being shown for intervals of 10 years. In these figures, the upper part shows the alongshore distribution of the longshore sediment transport rate, the direction of

Figure 4. Hindcast shoreline changes in the period 1910 to 1961 for the first representative wave.

which is taken as positive in the easterly direction. The three respective lower parts indicate shoreline changes in the first and second steps, the sediment sources being given. In the cases of the first and second representative waves, the shoreline retreats near the Gotsu headland, whereas accretion takes place along the central part of the coast and little change occurs near the Yoneyamazaki headland. In contrast, in the case of the third representative wave, shoreline accretion takes place near the Gotsu headland and the central part of the shoreline due to westerly longshore sediment transport. Figure 7 shows the alongshore distributions of the longshore sediment

Figure 5. Hindcast shoreline changes in the period 1910 to 1961 for the second representative wave.

Figure 6. Hindcast shoreline changes in the period between 1910 to 1961 for the third representative wave.

transport rates for the initial shoreline condition and the three representative waves,

in which the dotted curve indicates the annual averaged rate of longshore sediment transport. This varies alongshore in relation to variations in breaker height (Figure 3), but shows the same tendency for alongshore distribution as the breaker angle shown in Figure 3. The first and second representative waves show the same tendency, but the third differs.

**(2) In the case of the second step** In Figures 4, 5 and 6, the shoreline changes predicted for the second step are shown. In these predictions, the sediment sources

are 1) 10,000 m<sup>3</sup>/yr and 5,000 m<sup>3</sup>/yr; 2) 100,000 m<sup>3</sup>/yr and 5,000 m<sup>3</sup>/yr. The sediment sources influence shoreline accretion in the central part of the coast and tend to decrease shoreline retreat near the Gotsu headland. For shoreline change, the alongshore changes in longshore sediment transport rate are given in Figure 7. This shows that the alongshore distributions change slightly near the river mouths, but here was remarkably little influence on shoreline changes by the sediment sources for period of about half a century.

Figure 7. Alongshore distributions of longshore sediment transport rates for the three representative waves and the annual averaged one when the sediment sources are 100,000 m<sup>3</sup>/yr and 5,000 m<sup>3</sup>/yr.

**(3) The representative monsoon wave and predicted long-term shoreline change**

As to the sequence of wind waves and swells generated by a monsoon, we have assumed that the representative monsoon wave is composed of first, second, and third representative waves each with a duration of 8 hours and that these repeat 11 times a year. Using the representative monsoon wave, we hindcast the change in the initial 1910 shoreline for 51 years, and compared it with the actual recorded shoreline change. In Figure 8 (a) the upper most part shows the alongshore distributions of the longshore sediment transport rates produced by the representative waves, and the lower three parts respectively indicate the comparison under the given conditions that 1) no sediment sources are given, 2) 10,000 m<sup>3</sup>/yr and 5,000 m<sup>3</sup>/yr are given from the rivers, and 3) 100,000 m<sup>3</sup>/yr and 5,000 m<sup>3</sup>/yr are given. Figure 8 (b) shows the detailed expression of shoreline changes produced by the sediment sources. The alongshore distribution of longshore sediment transport by the representative monsoon wave is shown by the dotted curve in Figure 7. The annual averaged total rate of longshore sediment transport reaches a maximum near Naetsu Harbor and amounts to about 50,000 m<sup>3</sup>/yr; nearly equal to the value estimated from the bottom topography change. In the alongshore distribution, it is positive and decreases gradually in the easterly direction on the central part of the coast, but changes to the westerly direction along the east part. This tendency demonstrates that the central part of the coast is depositional in long-term beach evolution and that easterly and westerly longshore sediment transport exists in relation to the breaker angle of the incident waves. The offshore bottom topography measured in the central part also is depositional.

From this comparison, we conclude that the long-term shoreline change calculated shows some shoreline retreat near the Gotsu headland and shoreline accretion along the central part of the coast, but it is in good agreement with the actual long-term shoreline change over 51 years. We therefore conclude that our proposed long-term

(a) Long-term shoreline changes hindcast for 51 years.

(b) Detailed expression of shoreline change under the given sediment sources.

Figure 8. Comparison of long-term shoreline changes hindcast by the representative monsoon wave with actual shoreline change from 1910 to 1961.

shoreline prediction model, in which the representative monsoon wave is introduced, is applicable for future long-term shoreline change prediction as large scale coastal behavior.

### PREDICTION OF SHORELINE CHANGE AFTER CONSTRUCTION OF NAOETSU HARBOR

#### Changes in the sedimentation system and longshore sediment transport rates

(1) Calculation of the wave and nearshore current fields As stated previously, Naoetsu Harbor was developed in 1961 with extending western breakwaters. Its

construction has changed the sedimentation system, resulting in severe beach erosion the area of which has expanded easterly in relation to the extension of the breakwaters. To establish a principal methodology for beach stabilization, we predicted changes in wave and nearshore current fields numerically in order to evaluate changes in the longshore sediment transport and shoreline along the coast. In considering large scale coastal behavior, long-term shoreline change along the

Figure 9. Changes in alongshore distributions of breaker height and angle in relation to the extension of western breakwaters in Naoetsu Harbor.

coast is predicted on the assumption that sandy beaches have remained when shoreline retreat has taken place. Various numerical simulation models of waves and nearshore currents have been proposed in terms of the so-called mild-slope equation and nearshore current equations. In relation to the extension of the western breakwaters, we calculated changes in the wave and nearshore current fields due to the construction of these breakwaters using a numerical model (Yamashita, Tsuchiya, Matsuyama & Suzuki, 1990).

**(2) Changes in the wave and nearshore current fields** Figure 9 shows changes in the alongshore distribution of breaker height and angle after the construction of Naoetsu harbor, S. 40, S. 45, S. 51 and S. 63 respectively indicating 1965, 1970, 1976 and 1988. The wave and nearshore fields have changed in the area where breakwater influence is marked. In the nearshore current field, some circulation has formed within the area, resulting in the westerly movement of longshore sediment (For more detail consideration, see Tsuchiya, Yamashita, Izumi and Tottori, 1993).

**(3) Alongshore distributions of longshore sediment transport rates** Using the wave characteristics for 1988, we calculated the alongshore distribution of longshore

sediment transport rates by (3), as shown in Figure 10 where the solid curves marked 1st, 2nd and 3rd were reduced by the first, second and third representative waves, and the dotted curve indicates the annual averaged total rate of longshore sediment transport. The total rate of transport is reduced near the harbor due to the effect of the break-

Figure 10. Alongshore distributions of longshore sediment transport rates for three representative waves and the annual averaged one after the construction of Naoetsu Harbor.

waters. A comparison of this figure with Figures 7 and 10 shows that longshore sediment transport has been reduced in the area near the harbor and that its direction is positive along the part of the coast west of the central area, but negative in the eastern part. Note that the location in which the direction of the annual averaged longshore sediment transport changes from easterly to westerly has become more easterly. We therefore conclude that construction of the large harbor has changed the sedimentation system and affected large coastal behavior.

**The mechanism of beach erosion and long-term shoreline change prediction**

As previously shown, the alongshore distribution of the longshore sediment transport rate has changed after the western breakwaters were built. It is of prime importance for the principal methodology of beach stabilization to show how this influences long-term shoreline change as large scale coastal behavior. In the numerical prediction of long-term shoreline change, we assume that natural sandy beaches have remained even after shoreline retreat has taken place.

Using the long-term shoreline change prediction model and the representative monsoon wave, we predicted numerically the shoreline change from 1961 for one hundred years, under the boundary conditions that at Naoetsu Harbor no longshore sediment is given and that longshore sediment transport exists at the Yoneyamazaki headland. Figure 11 shows the predicted shoreline change along the coast, the dotted curve indicating the initial shoreline, and the solid curves shoreline change at

Figure 11. Long-term shoreline change predicted for 100 years after the construction (1961) of Naoetsu Harbor.

intervals of 20 years. The prediction includes the influence of building the west breakwater shown in Figure 9. Due to the direct effect of the breakwater, severe shoreline retreat takes place down the coast from the harbor. A cusped foreland is formed inside the harbor due to changes in the wave and nearshore current fields. In contrast, in the central part near the Kakizaki River shoreline accretion takes place. This long-term shoreline change should be considered as one type of large scale coastal behavior for a coast bounded by two headlands. It should be mentioned that the depositional area is wider than the eroded area due to the westerly longshore sediment transport passing the Yoneyamazaki headland. If the total amount of longshore sediment transport from the headland is assumed to be reduced, the accretional area may become narrower. Note, however, that this tendency for shoreline accretion corresponds to the present bottom topography change. Actually, the various countermeasures have been taken along this coast have resulted in the retardation of shoreline retreat, but produced a steep beach profile.

### THE METHODOLOGY FOR BEACH STABILIZATION

#### Long-term shoreline change with boundary conditions

On the basis that long-term shoreline change is large scale coastal behavior, a principal methodology for beach stabilization must be established because a large coastal construction, Naetsu Harbor, has created a man-made boundary condition that is so effective for shoreline change that we must look for a methodology for stabilizing the whole coast.

Figure 12. One-hundred years of shoreline evolution with change in the location of the boundary condition.

Therefore, we predict long-term shoreline change for another condition that counters the man-made boundary condition of the breakwater. The new boundary condition is given at a location where longshore sediment transport is completely stopped, but no wave diffraction is introduced. As previously, we predicted the shoreline changes shown in Figure 12 where the upper and lower figures are the cases for the boundary conditions located 2 to 12km and 14 to 24km from the Gotsu headland. In this figure, the solid curves show the shoreline change for one hundred years at intervals of 20 years. Shoreline change is subject to the location of the boundary condition, but the nodal point for shoreline change clearly exists near the Shinbori drainage river and remains at the same location with change in the position of the boundary condition. This is a most important factor in shoreline change as large scale coastal behavior for stabilization of the coast against the man-made boundary condition.

### A principal methodology for beach stabilization

Generally, beach erosion takes place locally due to various causes of erosion, but it is more pervasive down coast. When countermeasures were taken to prevent further erosion at that location, more severe erosion took place down coast. To stabilize the coast against erosion, we must therefore first consider what will happen along the entire coastal area due to erosion as large coastal behavior. Second, we must investigate whether the coast can be stabilized by some boundary conditions for beach change. Once a possible boundary condition for stabilizing the coast in the large coastal behavior, based on the theoretical background of the formation of stable sandy beaches (Tsuchiya, Chin and Wada, 1993, and Tsuchiya, 1994) is found, a principal methodology for beach stabilization can be established.

Figure 13. The methodology for beach stabilization proposed for the Joetsu-Ogata coast where two west headlands are under construction.

As stated, there is the possibility of stabilizing the coast against beach erosion by constructing a boundary condition for shoreline change at the nodal point for shoreline change. However, how this boundary condition is to be constructed must be considered. We can not construct a mathematical headland that has no wave diffraction and deflection. It must be a headland that reflects natural headlands or small islands that produce as little wave diffraction and deflection as possible. Therefore, when a headland is constructed, another boundary condition is needed to compensate for its direct influence in order to stabilize the down coast for making stable sandy beaches form. Based on the boundary condition found from viewing long-term shoreline change as large scale coastal behavior, we propose the methodology for beach stabilization shown in Figure 13, in which the upper part shows the alongshore distribution of the longshore sediment transport rate estimated by numerical calculation (solid curve) and from the bottom topography change (dotted curve). The lower part shows the proposed series of headlands used as boundary conditions for shoreline change. It should be noted that the direction of the longshore sediment transport rate has changed from easterly to westerly due to

changes in the wave and nearshore current fields (Tsuchiya, Yamashita, Izumi and Murakami, 1994). These two west headlands shown in the figure are now under construction.

## CONCLUSION

In establishing a methodology for beach stabilization, two principal roles must be taken into account: 1) Beach erosion must be considered over the entire coastal area as large scale coastal behavior and possible measures for stabilizing the coast from erosion found. 2) Based on the theoretical background of the formation of stable sandy beaches, a principal methodology for beach stabilization must be established. Beach erosion on the Joetsu-Ogata coast and its stabilization have been investigated in terms of these roles. The main conclusions are

(1) By introducing the representative monsoon wave, a prediction model for long-term shoreline change could be proposed using the so-called one-line model. This model was applied to hindcast long-term shoreline change on the Joetsu-Ogata coast, which is bounded by two headlands, for the 51 years before the construction of Naoetsu Harbor. The results agree well with the actual shoreline changes that are part of the large scale coastal behavior.

(2) On the assumptions that a natural sandy beach has remained during shoreline evolution and that the direct influence of building a harbor breakwater is introduced, we predicted long-term shoreline change for 100 years after the construction of the harbor. Severe shoreline retreat takes place along the west part of the coast, but shoreline accretion occurs along the east part. This tendency is very similar to the current bottom topography change.

(3) We have also predicted long-term shoreline changes with a given boundary condition for shoreline change. We found the most suitable location for the boundary condition to be the nodal point for shoreline change. Based on the large scale shoreline change and the theoretical background of the formation of stable sandy beaches, a principal methodology for beach stabilization has been proposed that uses a series of headlands.

## CHAPTER 245

### SHORELINE EROSION DUE TO OFFSHORE TIN MINING

By Suphat Vongvisessomjai<sup>1</sup>, Member, ASCE

#### ABSTRACT

Phuket is a well-known island resort on the west coast of the peninsula of Thailand and it is rich in tin deposits. Tourist and tin mining are conflicting especially in Bang Tao Bay. Before offshore tin mining in the bay, the bathymetry is quite simple/natural and the bay is almost in equilibrium with offshore sand movement by storm waves and onshore sand movement by swell. After tin mining in 1987, people in Villages 4 and 5 sent a petition to district and city officers from May to June 1988 to the effect that offshore tin mining in the bay had caused beach erosion and road damage, and that the dredger owner should be responsible for the cost of repairs. The sounding map makes in this study reveals that deep holes are created by dredgers, those nearshore are found to interrupt the cyclic changes and sand movement on the beach that results in a permanent loss of sand into the dredged holes and causes shoreline erosion; the maximum erosion in the middle of the bay is 40 meters in the 3 years from 1987 to 1990. A field test during May to June 1991 confirms that the high rate of shoreline erosion is consistent with that found in large wave tank experiments. Offshore tin or sand mining should not be made in shallow water where sand is mobile. If offshore mining were allowed nearshore, conditions should be imposed so that the bathymetry in the vicinity of the offshore mining should not change significantly.

#### INTRODUCTION

Phuket is a well-known island resort on the west coast of the peninsula of Thailand as shown in Fig.1. In general, tin mining is not presently allowed in most of the beach resorts of the island except in Bang Tao Bay where two concessions were granted for offshore tin mining in the belief that the dredged materials, after the sorting out for tin by the dredgers, would be replaced in the dredged holes, which would not change the bathymetry much.

---

<sup>1</sup> Professor, School of Civil Engineering, Asian Institute of Technology, P.O. Box 2754, Bangkok 10501, Thailand.

The study area in the vicinity of the Dusit Laguna beach of the Bang Tao Bay on the west coast of Phuket island is shown in Fig. 1. The bay is attacked by waves during the southwest monsoon from May to September. Predominant waves attacking the bay are mainly from the west and they cause onshore-offshore transport with not so much alongshore transport. During the northeast monsoon, the wind blows from land to sea over the bay; therefore, there is negligible wave action in the bay. In addition to these monsoons, the bay is occasionally attacked by cyclonic waves prevailing in the Andaman Sea. The bathymetry of Bang Tao Bay before offshore tin mining is quite natural as shown in Fig. 1c.

From May to June 1988, at the beginning of southwest monsoon, severe waves caused erosion of the shoreline and road damage in the Bang Tao Bay. People in Villages 4 and 5 sent a petition to district and city officers to the effect that offshore tin mining in the bay was the cause of beach erosion and road damage and that the dredger owner should be responsible for the cost of repairs. On October 15, 1988 the Minister of Industry visited the site and asked the Mineral Resources Department to order the dredger to dredge beyond 500 meters from the shoreline. The Mineral Resources Department (1990) studied the cause of erosion of the Bang Tao Bay with the assistance of the Committee for Co-ordination of Joint Prospecting for Mineral Resources in Asian Offshore Areas (CCOP) and concluded that (i) severe waves caused erosion of all beaches on the west coast of Phuket in 1988 and (ii) the instability of the BangTao shoreline due to previous tin mining on land might be the cause of erosion. Due to the limited time of the study, no reason for erosion caused by offshore tin mining could be found, however the search would be studied further.

The causes of the shoreline erosion can be initially listed as follows:

1. Storm waves with high wave steepness generated by cyclones or southwest monsoon move sand on the beach offshore.
2. Alongshore currents generated by inclined breaking waves move sands alongshore and deposit it somewhere.
3. Offshore tin mining close to the beach creates holes which draw beach sand.

The objectives of this study are as follows:

1. To make field surveys to collect relevant data and to monitor dredger activity.
2. To find out the causes of beach erosion.
3. To recommend remedial measures to conserve the beach resorts from erosion.

Steps to solve the problem are as follows: a review of the literature is made first on the effects of the offshore dredged holes on shoreline erosion. The most important part of this study is the field survey which is then described, while field data and their interpretation are finally presented.

## REVIEW OF LITERATURE

There are limited reports on the effects of offshore dredged holes on shoreline erosion; the followings are some examples.

**Motyka and Willis (1974)** presented the preliminary results of a study of the beach erosion by wave refraction over offshore dredged holes. A mathematical model was used of an idealized sand beach, typical of those on the English Channel and the North Sea coasts of Great Britain. Depth and side slopes of dredged area and original water depth before dredging were varied. Beach erosion increased with increasing hole depth and with depth. At present, dredging was not allowed shoreward of the 18 m depth contour on sediment supply considerations. Their results suggested that for the North Sea and the English Channel coasts, the effects of wave refraction also point to an 18 m minimum depth. This is approximately half the wavelength of the most common wave period, and a fifth of the length of the extreme wave period; hence it might be possible to extrapolate these results to other areas on a wavelength basis. Beach erosion due to holes in water depths greater than half the length of "normal" waves, or a fifth of the length of extreme waves, was negligible. They concluded that results were conservative, that the study was predicting larger amounts of erosion than would occur in nature. This was due to the fact that erosion was caused by differences in sediment transport along the beach, and the assumption in the refraction calculation that wave energy could not propagate along the wave front tended to exaggerate these difference.

**Price, Motyka and Jaffrey (1978)** dealt with the licensing procedure of dredging and assessed how dredging might affect the coastline. They provided some guidelines on the monitoring of shoreline erosion due to dredging:

(1) Beach drawdown - This usually occurs during storms due to the action of high steep waves. Beach material is eroded from the upper foreshore and moved seawards. However, during periods of calmer weather the material is returned to the beach by long low swell. If the dredged area is too near the coastline then this dynamic equilibrium can be upset, in that material may be transported from the upper portion of the beach into the dredged hole and erosion of the foreshore may result. The active zone of offshore-onshore movements extends to a certain depth of water and a certain distance from the shore. Thus, with respect to beach drawdown, there are two criteria - a minimum depth of water and a minimum offshore distance.

(2) Interception of sediment - If the beach is being fed from offshore by current and wave action then dredging may trap a proportion of this material and interrupt the supply to the shore. It is very important, therefore, that dredging should be excluded from any deposits which are moving actively. The threshold of movement of sediments. The dredged trenches above a certain depth within the active zone of littoral movement may interrupt the beach littoral system in that they serve as a trap to littoral sediment that would travel either onshore or alongshore.

(3) Dredging area included offshore banks - Offshore banks help to protect the coastline from wave attack either by dissipating wave energy as a result of bed friction, by partial breaking of the waves, by refraction or by any combination of these three. A permanent lowering of the crest of the bank due to dredging can result in changes of the wave refraction pattern and hence changes in the net angle of wave attack at the shoreline. Thus, under certain circumstances, dredging from offshore banks can alter the rate of littoral drift and hence affect the stability of the shoreline.

(4) The effect of changes in wave refraction - As waves approach the shore, they travel with a group velocity that is dependent upon their period and upon the depth of water. If the water depth increases locally, e.g., over a dredged hole, the velocity and wavelength change. The local increase in wave celerity due to the increase water depth causes changes in the angle of wave approach to the beach. Such changes result in a variation in the rate of littoral drift along the shoreline and can cause either accretion or erosion.

**Kojima, Ijima and Nakamuta (1986)** carried out comprehensive coastal engineering studies over four years in order to evaluate the impact of offshore dredging on shorelines as well as the adjacent seabed along the Genkai Sea, Japan. The results (data presented) indicated a possible relationship between sand mining and the shoreline changes. Although the available data were not sufficient to establish a direct cause-and-effect relationship between offshore mining and beach instability, the correlation was sufficient to serve as a warning of a potentially serious problem. Moreover, dredged holes above the water depth of about 30 meters were found to be refilled with sand which would be mainly transported from the onshore side, thereby interrupting the beach littoral system by trapping sand which might travel in the on-offshore or alongshore direction and causing a steeper beach slope in the long run. It was advisable, therefore, that the indiscriminate removal of sand from seabed be avoided at such water depth of 35 meters. Thus, offshore mining that would minimize interruption of beach littoral system should be operated below a depth of 35 meters in the study area.

**Uda, Agemori and Chujo (1986)** investigated the conditions of the dredging of the offshore bed on the Kochi Coast, facing Tosa Bay, Japan. Aerial

photographs and the sounding data of the coast were analyzed to obtain the beach changes accompanied by the formation of the dredged hole. The flood of the Niyodo river brought large amount of sediment to the coast; the sediment outflow from the river fell into the dredged hole by eastward littoral drift. The hole was refilled slowly from the west side by the littoral drift directing eastward. An abrupt change of the topography due to the onshore-offshore sand transport did not happen as the dredged hole was filled by river sediment carried by the flood and littoral current.

**Larson, Kraus and Sunamura (1988)** developed a numerical model for simulating beach profile change in the surf zone produced by wave-induced cross-shore sand transport. Model development was founded on two data sets from large wave tank experiments performed by the U.S. Army Corps of Engineers in the years 1956-1957 and 1962 while the second data set was from experiments performed at the Central Research Institute of Electric Power Industry in Japan.

Storm waves with high wave steepness erode the beach producing offshore bars while swells with low wave steepness accrete the beach bringing back bar material onto the beach; the cyclic changes of beach are shown in Fig.2. When storm waves attack a beach for a sufficiently long time, its beach profile would approach an equilibrium. In other words, when sand moves offshore the offshore bar simultaneously increases in volume to approach an equilibrium size as shown in Fig. 3. Their chronological changes of beach profiles for 2 cases are shown in Fig.4. At the beginning of an attack by storm waves, the beaches change rather quickly but they change rather slowly when they approach the equilibrium. Correlation analysis involving wave and beach profile parameters showed that equilibrium bar volume was most closely related to wave height  $H_o$  and sand fall velocity  $w$  (or grain size). A large wave height implied a larger bar volume, and a higher fall velocity (or larger grain size) produced a small bar volume. A regression relationship was derived relating the non-dimensional equilibrium bar volume  $V_{eq}/L_o^2$  to the quantities  $H_o/(wT)$  and  $H_o/L_o$  according to

$$\frac{V_{eq}}{L_o^2} = 0.028 \left( \frac{H_o}{wT} \right)^{1.32} \left( \frac{H_o}{L_o} \right)^{1.05} \quad (1)$$

where deepwater wavelength  $L_o = gT^2/(2\pi)$  and  $T$  = wave period.

Note that the active zone of sand movement is confined mainly in the surfzone where waves are broken due to their instability in shallow water when the water depth is about equal to the wave height. Therefore, the higher wave would create a wider surfzone and would result in much more active sand transport.

**Dette and Uiczka (1987)** investigated dune recession and beach erosion at prototype scale in the big wave flume in Hannover, Germany. Results on time

-dependent erosion volume and recession of dune were presented for “**dune without foreshore**” and “**dune with foreshore**” in Figs.5 and 6. The simulated wave had a significant height of 1.5 m and peak period of 6 sec at 5 m depth of water, while the sand used had a median diameter of 0.33 mm. In the presence of the foreshore, compared to the profile development due to regular waves, the recession of the dune’s edge was only about one-third of that recession measured for dune without the foreshore. The bar location was about 10 m further seaward. Hence, the breaking occurred further away from the dune’s face and a wider surf zone provided additional dissipation of wave energy.

## FIELD SURVEY AND RESULTS

### Program of Field Survey

Field data on wave climate, alongshore current, wind and resulting beach erosion were collected to obtain pertinent information on morphological changes and offshore dredging effects on the shoreline. The characteristics and behavior of the beach were monitored by field measurements of beach shape and profile, soundings and bed material sampling. Locations of dredgers operating in the bay were measured daily by reading the angles of the dredger at two observation locations onshore.

Three soundings have been made for an area of 2.5 km alongshore by 1.5 km offshore, the first at the end of October 1990 before the arrival of dredgers; the second at the end of April 1991 by the end of dredging; and lastly at the end of October 1991 after the attacks of southwest monsoon waves. The first and the last soundings were accompanied by beach profile measurement and beach material samplings.

Waves and winds were measured at two locations about 300 m offshore, together with alongshore current at one hour intervals during the daytime.

### Topographical Change

From the above three soundings maps surveyed in October 1990, and April and October 1991, the following topographical changes could be seen.

(1) Shoreline erosion - Comparing contour lines of soundings in 1990 with those in 1987 for the shorelines, it was found that severe erosion occurred between DL3 and DL5. Average erosion rate from 1987-1990 was about 7 meters per year with the maximum of about 13 meters per year in the vicinity of Inlet 2.

(2) Creation of deep holes nearshore - It can be seen from Fig.7 of the sounding of the Bang Tao Bay in October 1990, that many deep holes were created by dredgers operating nearshore from 1987 to 1990 as compared with the natural bathymetry before offshore tin mining, shown in Fig.1c. These nearshore deep holes interrupted the cyclic changes of the beach in terms of erosion by storm waves and subsequent accretion by swells (Fig.2) and, therefore, resulted in a permanent loss of sands from the erosion of beach into the

dredged holes. It can be seen from the beach profiles at DL1, DL2, DL3 and DL4, plotted in Figs.8 (a), (b), (c) and (d) respectively, that deep holes existed at an offshore distance of about 300 meters, while the beach profiles at DL5 and DL6 in Figs.8(e) and (f) respectively are more natural, namely without deep holes nearshore. The onshore sides of these nearshore deep holes in the active zone of sediment movement by wave action; the mobile sediment will fall down the steep slopes of the deep holes especially the deep hole A4 at DL4. Comparing these beach profiles with those in Fig.6, it can be seen that profile DL4 is similar to that of dune without foreshore while profiles DL5 and DL6 are similar to that dune with foreshore. Therefore, nearshore deep holes changed the natural beach of dune with foreshore to dune without foreshore which experienced a much higher rate of erosion.

(3) Field test of shoreline erosion - In order to obtain an order of magnitude estimate of shoreline erosion, a test was made by dumping about 6,000 m<sup>3</sup> of sand on the beach for alongshore distance of 300 m. The beach-fill was agitated by the southwest storm waves on June 2-4, 1991 and approximately half of the filled sand was eroded while the remaining half was eroded during June 5-13, 1991. Practically, no erosion occurred on May 15 to June 1, 1991. According to the wave data collected during May 18 - June 13, 1991, wave heights were the largest on June 2 - 4 and 9 - 13 with a range of 1.0 - 2.5 m while the wave period was about 6.4 sec. During the period of June 5 - 8, wave heights were around 0.8 - 1.4 m with a wave period of 8.1 sec. The wave condition was calmer from May 18 - June 1 with wave height of 0.4 - 0.9 m and period of 8.2 sec. Slope of beach at the upper section is steeper compared to that of the offshore side in the mid tidal zone. When waves attacked upper section of the beach at high tide the erosion rate was higher. The average erosion volume per meter of beach was 20m<sup>3</sup>/m.

### Field Conditions

Winds and waves change from year to year. However, their trends or orders of magnitude are common. The most probable of commonly recorded waves measured in this study during the southwest monsoon by Vongvisessomjai and Huq in 1991, as compared with those measured earlier in 1980 shown in brackets (Gayman, 1983) are as follows:

Month	Wave Height (m)		Period (sec)	
	1991	(1980)	1991	(1980)
May	0.3-0.5	(0.0-0.5)	7.0	(4.5)
June	0.5-1.5	(0.5-1.0)	7.0	(6.5)
July	0.5-1.5	(0.5-1.0)	7.0	(6.5)
August	0.5-1.5	(0.5-1.0)	7.0	(6.5)

The above wave characteristics could serve as commonly recorded waves on the west coast of Phuket during the southwest monsoon.

The southwest monsoon waves are mainly from the southwest or west or northwest. As they propagate into shallow water and break near the shoreline, their crestlines are almost parallel or make some small angles with respect to the shoreline. Therefore, they generate no alongshore current or alongshore current towards the north/south direction. The magnitudes of alongshore current measured in this study are about 0.15 - 0.20 m/sec. with a north or south direction in May, a predominantly north direction in June and a predominantly south direction in July and August 1991.

The erosion volume  $V_{eq}$  of the equilibrium profile (Eq.1) depends on deepwater wave height and fall velocity (or grain size). A larger wave height implies a larger erosion volume, and a higher fall velocity (or larger grain size) produces a smaller erosion volume. Using typical median diameters of 0.5 and 0.2 mm, wave period of 6.5 sec and wave heights of 0.5 - 2.0 m, the computed erosion volumes  $V_{eq}$  are listed below:

$d_{50}$ (mm) (1)	$H_o$ (m) (2)	T(sec) (3)	$L_o$ (m) (4)	w(m/s) (5)	$H_o/L_o$ (6)	$H_o/(wT)$ (7)	$V_{eq}$ (m <sup>3</sup> /m) (8)
0.5	0.5	6.5	66	0.074	0.008	1.01	1
	1.0				0.015	2.08	4
	1.5				0.023	3.12	10
	2.0				0.030	4.16	20
0.2	0.5	6.5	66	0.027	0.008	2.85	3
	1.0				0.015	5.70	15
	1.5				0.023	8.55	39
	2.0				0.030	11.40	77

The erosion volumes of fine sand ( $d_{50}=0.2$  mm) are about four times those of coarse sand ( $d_{50} = 0.5$  mm). These computed erosion volumes agree well with those tested in the field of shoreline erosion of 20m<sup>3</sup>/m.

### RECOMMENDATION

1. Offshore tin mining or sand mining should not be made on the west coast of Phuket in shallower water than 15 meters based on wave conditions and sand characteristics at the site compared with those of England and Japan of 18 and 35 meters respectively.

2. If offshore tin mining were allowed nearshore in shallower water than 15 meters, conditions should be imposed so that the bathymetry in the vicinity of offshore mining should not change significantly.

3. Beach nourishment should be made around Inlet 2 in order to restore the beach of Dusit Laguna; structural control of shoreline erosion would not be effective here due to the presence of nearshore deep holes.

## CHAPTER 246

### Behaviors of Fluid Mud under Oscillatory Flow

Hiroyuki Yamanishi<sup>1</sup> and Tetsuya Kusuda<sup>2</sup>

#### *Abstract*

Characteristics of settling velocity of fine particles and movements and the mechanism of maintenance of the fluid mud layer under oscillatory flow are investigated to control the transport flux of suspended solids in estuaries and the coastal zone. Settling velocity of fine particles under oscillatory flow is reduced as a function of only the local concentration. Motion of fluid mud depends on shear stress acting on the interface between the overlying water layer and the fluid mud layer and the horizontal pressure gradient. Especially, the horizontal pressure gradient causes a phase lag between the overlying water layer and the fluid mud movements. Velocity profiles calculated by a linearized model agree well with the measured velocity profiles in spite of assuming the kinematic viscosity in the fluid mud layer to be homogeneous. The apparent viscosity in the fluid mud layer is approximately 200 times as large as that of pure water.

#### **1.Introduction**

The water layer on mud bed under waves and currents is generally divided into two parts; one is the overlying water layer which is comparatively dilute in concentration and the other is the fluid mud layer which is high in concentration. Moving fluid mud under waves and currents maintains a loose state without consolidation on the bottom. Concentrations of the fluid mud layer are 1 order to 2 orders of magnitude higher than those of the overlying water layer. The flux of suspended solids transported in the fluid mud layer is larger than that in the overlying water layer, though the transport rate of suspension in the fluid mud layer is smaller than that by advection in the overlying layer.

A series of field measurements on shoaling of Kumamoto Port, located in the west side of Kyushu Island, were carried out to confirm effects of submerged mounds against siltation (Tsuruya *et al.*, 1990). Three trenches were set inside the navigation pass of Kumamoto Port under construction. One was surrounded by a

<sup>2</sup>Professor, Dept. of Civil Eng., Kyushu University.

type of submerged mound, but the others were not. Although there was little difference of deposition amounts between them under normal conditions, heavy depositions were observed in the no submerged mound trenches under some severe conditions. From these temporal variations of the depositional amounts inside these three trenches during about a year, the submerged mounds were found effective against siltation. These facts also indicate that fluid mud moves along the sea bed under waves. Results of the field measurements made by Odd and Owen(1972) and Smith and Kirby(1989) also suggest the existence of a high concentration layer near the bottom. Therefore, studies on behaviors of fluid mud under currents and waves are of importance for siltation. Furthermore, so far, as is known, little work has been done on the mechanism of maintenance of fluid mud layers under waves and currents.

The purposes of this study are to explain the formation process of the fluid mud layers, the vertical transport process between suspended solids and fluid mud, the mechanism of maintenance of the fluid mud layers, settling velocity of particles, viscosity in fluid mud, the role of pressure gradient within fluid mud layers, and modeling of the fluid mud movement under oscillatory flow. These results will give useful suggestion on what maintains the fluid mud layer under oscillatory flow and the control of shoaling.

## 2.Theoretical Analysis

A fluid mud layer, according to Ross and Mehta(1989) and our experimental results, consists of both mobile and stationary fluid mud layers. Fluid mud moves as not solid but viscous fluid because the fluid mud layer is high in concentration. Around the upper interface between the overlying water and the fluid mud, a zone of high concentration gradient exists, which is referred to as "lutocline." Based on these facts, in order to accurately formulate the equations of motion of the layer, a multi-layered fluid model was used(Yamanishi and Kusuda, 1991). The model, however, could not show any phase lag of movement between both layers. In this study, in order to explain the causes of the phase lag, a simple linearized and horizontally uniform model was applied. As a model, a simplified vertical structure is adopted as illustrated in Fig.1, where the x axis is taken at the interface. Since the motions of the fluid mud are subjected to both shear stress acted on the interface and the horizontal pressure gradient,  $\partial p/\partial x$ , in the fluid mud, the motions of the fluid mud are modeled by superposing two motions induced by these two forces. The

Fig.1 Definition sketch for fluid mud model

following assumptions are made owing to model the motions of fluid mud under oscillatory flow:

- (a) Each layer moves only to the horizontal direction;
- (b) Velocity  $U$  in the overlying water is a function of time  $t$  only;
- (c) The advective terms in the equations of motion are negligible small;
- (d) The pressure amplitude is uniform in the vertical direction; and
- (e) The kinematic viscosity in each layer is homogeneous.

Under the above assumptions, the linearized equations of motions of the fluid mud and overlying water become as follows:

**Overlying water layer(  $z \geq 0$  ):**

$$\left\{ \begin{array}{l} \frac{\partial U}{\partial t} = -\frac{1}{\rho_1} \frac{\partial p}{\partial x} \dots (1) \\ \frac{\partial u_1}{\partial t} = -\frac{1}{\rho_1} \frac{\partial p}{\partial x} + \nu_1 \frac{\partial^2 u_1}{\partial z^2} \dots (2) \end{array} \right.$$

**Fluid mud layer(  $-d \leq z < 0$  ):**

$$\frac{\partial u_2}{\partial t} = -\frac{1}{\rho_2} \frac{\partial p}{\partial x} + \nu_2 \frac{\partial^2 u_2}{\partial z^2} \dots (3)$$

where,  $u_j$ ,  $p_j$ ,  $\nu_j$  and  $\rho_j$  are the horizontal velocity, the pressure, the kinematic viscosity and the layer-averaged density, respectively. The subscript  $j$  indicates each layer, so that  $j=1$  for the overlying water layer and  $j=2$  for the fluid mud layer.

In order to analytically solve Eqs.(1)~(3), some solutions described by using the complex representation are supposed as the following equations:

$$U = -i \widehat{U} e^{i\omega t} \dots (4)$$

$$\tilde{u} = -i \widehat{\tilde{u}} e^{i\omega t} \dots (5)$$

$$u_2 = -i \widehat{u_2} e^{i\omega t} \dots (6)$$

$$\widehat{U} = a\omega \dots (7)$$

$$\partial p / \partial x = -\widehat{p}_x e^{i\omega t} \dots (8)$$

$$\widehat{p}^* = \rho_1 a \omega^2 \dots (9)$$

where,  $\widetilde{u} = u_1 - U$ ,  $a$  is the amplitude,  $\omega$  is the frequency ( $\omega = 2\pi/T$ ,  $T$ ; period),  $t$  is the time,  $\widehat{\phantom{x}}$  indicates the amplitude, and  $i$  is the imaginary unit ( $i^2 = -1$ ).

The boundary conditions necessary to solve them are as follows:

$$u_1 = U(t), \text{ for } z \rightarrow \infty \dots (10)$$

$$u_1 = u_2, \text{ at } z = 0 \dots (11)$$

$$-\rho_1 \nu_1 \frac{\partial u_1}{\partial z} = -\rho_2 \nu_2 \frac{\partial u_2}{\partial z}, \text{ at } z = 0 \dots (12)$$

$$u_2 = 0, \text{ at } z = -d \dots (13)$$

The velocity  $U(t)$  in the overlying water is regarded as a function of time  $t$  only. These boundary conditions satisfy the continuity of the velocities and stresses across  $z=0$  and the non-slip condition at  $z=-d$ .

The analytical solutions of  $u_1$  and  $u_2$  which satisfy the above boundary conditions are as follows:

$$\left\{ \begin{array}{l} u_1 = -i \left\{ (1 - e^{-\lambda_1 z}) \widehat{U} + e^{-\lambda_1 z} \widehat{u}_i \right\} e^{i\omega t} \dots (14) \end{array} \right.$$

$$\left\{ \begin{array}{l} u_2 = -i \left[ \left\{ 1 + \frac{\sinh \lambda_2 z}{\sinh \lambda_2 d} - \frac{\sinh \lambda_2 (z+d)}{\sinh \lambda_2 d} \right\} \cdot \frac{\widehat{p}}{\rho_2 \omega} + \frac{\sinh \lambda_2 (z+d)}{\sinh \lambda_2 d} \widehat{u}_i \right] e^{i\omega t} \dots (15) \end{array} \right.$$

where,

$$\widehat{u}_i = \frac{\rho_1 \nu_1 \lambda_1 \widehat{U} + \rho_2 \nu_2 \lambda_2 \frac{1 - \cosh \lambda_2 d}{\sinh \lambda_2 d} \cdot \frac{\widehat{p}}{\rho_2 \omega}}{\rho_1 \nu_1 \lambda_1 - \rho_2 \nu_2 \lambda_2 \frac{\cosh \lambda_2 d}{\sinh \lambda_2 d}} \dots (16)$$

$$\lambda_1 = (1 + i) \sqrt{\frac{\omega}{2 \nu_1}} \dots (17)$$

$$\lambda_2 = (1 + i)\sqrt{\frac{\omega}{2\nu_2}} \dots (18)$$

From results of the simulations, validity of the model is examined with respect to behaviors of fluid mud and the phase lag.

### 3.Experiments

**Figure 2** shows a U-shape oscillating water tunnel used in this study. This water tunnel does not allow the horizontal transport of fluid mud even for a long time experiment. Mud used was obtained at the Ariake Bay where the maximum tidal range is 5m. This fluid mud was directly sampled from the surface of stationary mud at an ebb tide. The mud consists of clay(55.6%), silt(41.7%) and sand(2.7%) as an average. Its mean diameter and density were  $4.0\mu\text{m}$  and  $2540\text{kg/m}^3$ , respectively.

**Fig.2** U-shape oscillating water tunnel

After pouring a mud-seawater mixture with a certain concentration into the tunnel, experiments were immediately started. During the experiments, suspension in the tunnel was sampled through pipes at several points toward the vertical direction at a prescribed time interval, and concentrations of suspended solids were measured with membrane filter. The motion of fluid mud was monitored by a video camera with a closed-up lens and motor-driven camera with extension rings. Pressure in the fluid mud layer was also measured to understand pressure effects.

### 4.Results and Discussion

#### **(1)Settling velocity of particles**

**Figure 3** indicates some temporal changes of the interface in height. In addition, its change under a quiescent state is plotted on it. These plots indicate that the fluid mud exits as suspension on the bottom. The settling velocity of the interface decreases gradually because of the decrease in the apparent velocity of particles. This settling of particles is determined by the local concentration  $C$  only. In this case, the equation governing the vertical mass concentration is:

$$\frac{\partial C}{\partial t} - \frac{\partial F_a}{\partial z} = 0 \dots (19)$$

$$F_a = w_s C - F_e = w_{as} C \dots (20)$$

Here,  $C$  is the local concentration,  $F_a$  is the apparent settling flux,  $w_s$  is the settling velocity,  $F_e$  is the vertical solids flux and  $w_{as}$  is the apparent settling velocity. The z-axis is taken to be upward from the bottom. The apparent settling velocity can be calculated by using the following equation on the basis of the concentration profiles under a quiescent state and oscillatory flow:

$$\overline{w_{as} C} |_{z=h} = - \frac{\partial}{\partial t} \int_0^h C dz \dots (21)$$

in which,  $\overline{w_{as}}$  and  $\overline{C}$  are the average apparent settling velocity and the average

Fig.3 Temporal changes of the interface in height

concentration at a certain height ,  $h$ .

If  $F_e$  in Eq. (20) is equal to zero, the settling velocity  $w_s$  under a quiescent state is obtained. Figure 4 depicts the settling velocity  $w_s$  and the settling flux  $w_s C$  under a quiescent state. If the settling velocity  $w_s$  is assumed to be a function of only the

Fig.4 Settling velocity under a quiescent water

local concentration as the formers (ex., Smith and Kirby 1989), the following best fit relation between the settling velocity and the concentration under a quiescent state is derived from Fig.4.

$$\left. \begin{aligned}
 w_s &= 0.4 C^{4/3} \text{ (mm/s)} & C \leq 1 \text{ (kg/m}^3\text{)} \\
 &= 0.4 & 1 < C \leq 2 \\
 &= 0.42 (1 - 0.005 C)^5 & C > 2
 \end{aligned} \right\} \dots (22)$$

Similarly, Fig.5 shows the apparent settling velocity  $w_{as}$  and the flux  $w_{as}C$  calculated by Eq.(21). In order to compare the apparent settling velocity  $w_{as}$  under oscillatory flow with the settling velocity  $w_s$  under a quiescent state. Eq.(22) is also drawn in the same figure. The apparent settling velocity  $w_{as}$  is evidently smaller than  $w_s$  and the observed values scatter. This results from that the settling velocity is subject to shear rate and floc size in addition to local concentration of suspended solids. Furthermore, it is possible to describe the changes in height of fluid mud layers by using the method of Kynch(1952). Toorman and Berlamont(1992) adopted this method in order to unify a hindered settling model and a soil mechanics model by estimating apparent settling velocity under a quiescent state. However, these results can not directly explain the mechanism which maintains a fluid mud layer under

Fig.5 Settling velocity under oscillatory flow

oscillatory flow. Consequently, the maintenance mechanism of fluid mud layers is considered due to the balance between settling flux by gravity and upward flux produced by mixing. If each term could be estimated on the basis of the results, the maintenance mechanism of the fluid mud layer would become clear, and the temporal changes in height of fluid mud layer by using the mass conservation equation could be solved at the same time. This problem seems to be worthwhile for further research work.

**(2) Kinematic viscosity in fluid mud**

Some results simulated by the linearized model are shown in Figs.6 and 7. Figure 7 is velocity profiles measured and calculated at different times. The calculated conditions are taken as the period  $T=3\text{sec}$ , the horizontal amplitude  $=5\text{cm}$ , the apparent kinematic viscosity  $\nu_2=2 \times 10^{-4}\text{m}^2/\text{s}$  and the fluid mud layer thickness  $d=2.1\text{cm}$  in order to compare with the experimental data. It is also important to consider the wall effect. Here, the results have been corrected by assuming an oscillating Poiseuille flow.

Assuming the kinematic viscosity in the fluid mud layer to be uniform as a Newtonian fluid, these results agree well with the measured values. The viscosity in the fluid mud layer used for the calculation notices about 200 times as large as that of pure water. There is an Einstein equation applicable to a dilute suspension but not for dense suspension. Furthermore, the present theoretical analyses for the viscosity of

Fig.6 Analytical solutions

Fig.7 Calculated velocity profiles compared with measurements in the fluid mud

suspension are insufficient for engineering purposes, yet. In general, the viscosity (or kinematic viscosity) is a function of void fraction and shear rate. Here, based on the constitutive equation (Eq.(23)) obtained experimentally by Kusuda *et al.* (1994), the apparent viscosity in the fluid mud was evaluated.

$$\mu_a = \mu_w (6.1 D^{0.66} + 1) \times \left\{ 3.8 \times 10^3 \left( \frac{\rho_2 - \rho_w}{\rho_2 - \rho_w} \right)^{1.7} + 1 \right\} \text{ (Pa} \cdot \text{s)} \dots (23)$$

Fig.8 Apparent kinematic viscosity profiles in the fluid mud

in which,  $\mu_a$  is the apparent viscosity,  $\mu_w$  is the viscosity of water,  $D$  is the shear rate,  $\rho_s$  is the particle density and  $\rho_w$  is the water density. After the flow field was calculated by Eqs.(1) and (2) and the following equation (Eq.(24)), the apparent viscosity was estimated.

$$\rho_2 \frac{\partial u_2}{\partial t} = - \frac{\partial p}{\partial x} + \frac{\partial}{\partial z} \left( \mu_a \frac{\partial u_2}{\partial z} \right) \dots (24)$$

Calculation was repeated until the apparent viscosity calculated by Eq.(23) converges.

Figure 8 expresses a result of the apparent kinematic viscosity obtained by Eq.(23). The apparent viscosity is also about 10 to 100 times as large as that of pure water. Because a power exponent function of shear rate is involved in Eq.(23), the apparent kinematic viscosity at a small shear rate in Fig.8 becomes extremely large. In order to obtain the apparent viscosity with high precision, the fluid mud should be regarded as an elastic or a visco-elastic fluid at small shear rates or considered the change in apparent density under oscillating shear stress.

**(3)Phase lag between overlying water and fluid mud**

Figures 6 and 7 also indicate the phase lag between the overlying water layer and the fluid mud layer velocities. This implies that the motion of fluid mud is different from that of viscous fluid under shear flow. So that, the motions of fluid mud

(  $T=3\text{sec}$ ,  $a=5\text{cm}$ ,  $v_2 = 2.0 \times 10^{-4} \text{ m}^2/\text{s}$ ,  $d=2.1 \text{ cm}$  )

Fig.9 Observed and calculated phase lag profiles

layer are governed by both horizontal pressure gradient and shear stress acted on the interface between the overlying water and the fluid mud layers. Especially, the horizontal pressure gradient causes a phase lag between them. Therefore, when velocity in the fluid mud decreases under a positive pressure gradient, it becomes slower to lose the kinematic energy by high viscosity in the fluid mud. As a result, the fluid mud may move opposite against the overlying water. This phase lag may be derived from Eq.(6). Therefore, as  $\hat{u}_2$  is a complex velocity amplitude, it is transformed by the following equation;

$$\begin{aligned}
 u_2 &= -i\hat{u}_2 e^{i\omega t} \\
 &= -i(\hat{u}_R + i\hat{u}_I) e^{i\omega t} \\
 &= -i\sqrt{\hat{u}_R^2 + \hat{u}_I^2} e^{i(\omega t + \psi)} \dots (25)
 \end{aligned}$$

$$\psi = \tan^{-1}\left(\frac{\hat{u}_I}{\hat{u}_R}\right) \dots (26)$$

where,  $\hat{u}_R$  and  $\hat{u}_I$  indicate the real part and the imaginary part of  $\hat{u}_2$ , respectively.

Figure 9 compares the experimental results with the calculated ones. There is slight difference between the measured and the calculated values, but the analytical solutions approximately explain the experimental results. This simple model proposed here describes well the phase lag at the fluid layer movements. In these ex-

periments, the phase lag ranged from  $\pi/12$  to  $\pi/4$ .

## 5. Conclusions

The summary of the results is as follows:

- (1) Settling velocity was shown as a function of only the concentration of suspended solids;
- (2) The maintenance mechanism of fluid mud layers is due to the balance between the settling flux by the gravity and the upward flux produced by mixing in the fluid mud layer;
- (3) The viscosity in the fluid mud layer is approximately 100 times as large as that of pure water.
- (4) The motion of the upper layer in the fluid mud depends on shear stress acted on the interface between the upper water layer and fluid mud layer. The motion of the lower layer in the fluid mud layer is mainly governed by horizontal pressure gradient. This causes a phase lag between the upper layer and the fluid mud movements.
- (5) The fluid mud layer moves in advance, compared to the overlying water layer and in this experiments the maximum phase lag was  $\pi/4$ .

## CHAPTER 247

### FORMATION OF HABITATS FOR BIVALVES BY PORT AND HARBOR STRUCTURES

K.Yano<sup>1</sup>, S.Akeda<sup>2</sup>, Y.Miyamoto<sup>3</sup> and S.Kuwabara<sup>4</sup>

#### ABSTRACT

Impacts of the construction of large-scale port and harbor at open sandy beach on inhabitation of the Japanese surf clam (*Spisula sachalinensis*) have been studied. It has been found that the populations of the Japanese surf clam has been increasing with the extension of the breakwater since the start of the construction of Ishikari Bay New Port in 1972. A series of numerical simulation was carried out to estimate the changes over time in the currents distribution around Ishikari Bay New Port associated with the construction of the breakwater for each construction phase. The change in dominant areas of the Japanese surf clam in the harbor over the years is explained by patterns of nearshore currents around the port. The construction of Ishikari Bay New Port resulted in the formation of a new fishing ground of the Japanese surf clam and an increase in the populations of the clams.

**INTRODUCTION**

In recent years, demand has been increasing for port and harbor construction to co-exist with nature and preserve the environment. It is becoming more important to examine the effect of the construction of port and harbor facilities on the accumulation and propagation of fish, shellfish and reef resources.

Figure 1 shows the relationship between the length of the breakwater extended and catches of Japanese surf clams (*Spisula sachalinensis*) around the Tomakomai Port located on southwest Hokkaido's Pacific coast. The Japanese surf clam catch in Tomakomai city began increasing gradually in 1985 and has increased sharply since 1987. The catch of this clam in Tomakomai in 1990 was 15% of the total catch in Hokkaido. This increase in the amount of the yearly total in Tomakomai is considered to be an effect of the Tomakomai east and west port facilities. Especially, the construction of the East Port District is assumed to have been playing a particularly important role.

Figure 1: Catches of Japanese surf clams and the breakwater extension at Tomakomai Port (East Port District)

These effects of the port and harbor structures on inhabitation of fishery resources has received much attention from fishermen. The Hokkaido Development Bureau has been conducting studies on the functions of fishery harmony provided by port facilities such as breakwaters. Based on the results of these studies, the present paper describes resource-culturing effects on the Japanese surf clam by the port and harbor construction of Ishikari Bay New Port, whose construction began in 1972.

#### THE ECOLOGY AND FISHERY OF JAPANESE SURF CLAM

Sasaki (1992) reported the ecological characteristics of Japanese surf clam. The Japanese surf clam (Figure 2) is a large bivalve inhabiting in sandy, shallow zones along the wide coastal range of Tohoku and Hokkaido. It has been an important fisheries resource. In general, Japanese surf clams spawn in June and July in Ishikari. When the larvae have grown to about 0.2 to 0.3 mm in shell length, they shift to a benthic life after having drifted in the water for about one month. There is a considerable decrease after the clams shift to a benthic life, particularly marked soon after this shift. Less than 1% of those who start a benthic life reach the age of two years. The major factors for the decrease of juvenile and mature clams are being washed ashore by action of large waves (Figure 3) and natural mortality.

For the clams to mature and grow to a size that contributes to the reproduction of the resource, it takes about 4 years in southern Hokkaido and 5 years in Ishikari Bay and eastern Hokkaido. Most of the individuals with a shell length of more than 7.5 cm are mature. Hokkaido bans catching clams smaller than 7.5 cm.

#### CONSTRUCTION IN ISHIKARI BAY NEW PORT AND CHANGES IN CATCHES OF THE SURF CLAMS

Ishikari Bay New Port is located about in the center of the sandy shore and 7 km southwest of the mouth of Ishikari River in Hokkaido (Fig.4). The bottom slope is very gradual, and the average gradient from the shoreline to the depth of 50 m is about 1/500. The progress of the construction of the port between 1972 and 1992 is shown in the Figure. The entire current of Ishikari Bay moves north in summer and weakens in winter. At present, most of the north, island and east breakwaters, the eastern and central areas and the central channel are complete. The construction of the western area is under way.

Figure 2: Japanese surf clam (mature size)

Figure 3: Bivalves washed ashore

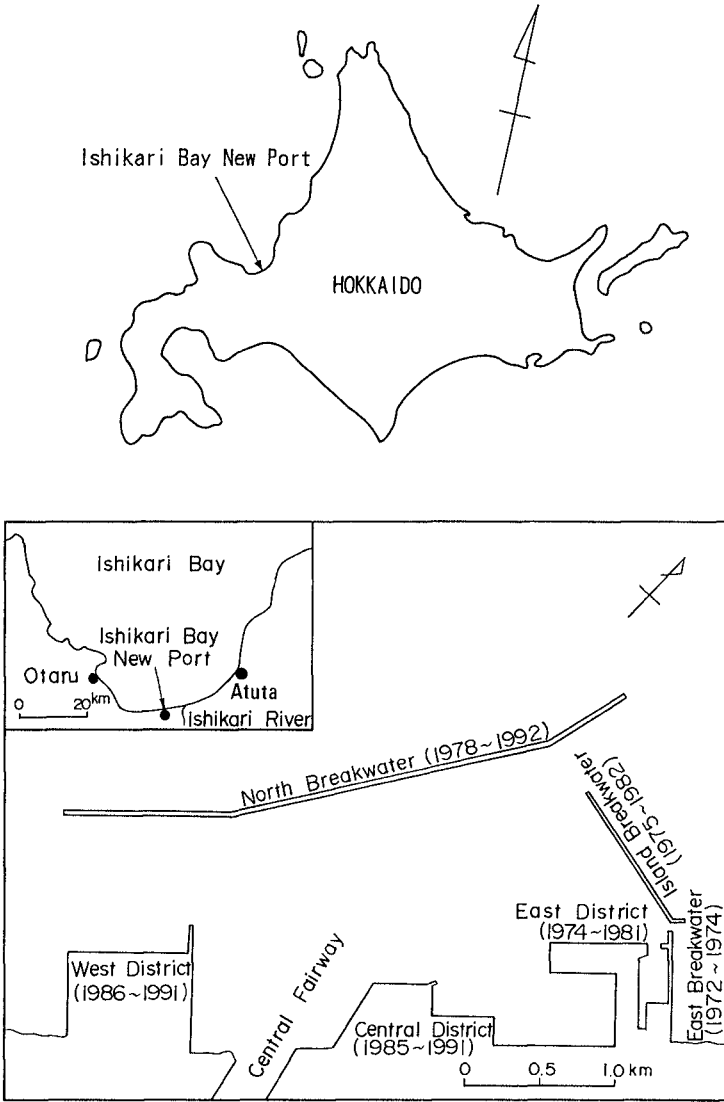

Figure 4: Location map and progress of the construction of Ishikari Bay New Port

To understand the influence of the extension of the breakwater in Ishikari Bay New Port on catches of Japanese surf clams, the relationship between the length of the breakwater extended and catches of Japanese surf clams in the town of Ishikari is shown in Fig. 5. As the figure shows, a sharp increase in the catch of the clams coincided with construction of the breakwaters. Considering the fact that 4- to 5-year-old clams are caught, the remarkable increase in that period seems to be related to the east breakwater built in 1972 to 1974. The catch has not been increasing since 1980 because they restricted the catch in order to preserve the resources. Furthermore, a drastic catch decrease in 1982 and 1983 can be attributed to extreme storm waves that occurred in December 1981, with the maximum wave height at 9.8 meters with a wave period of 10.1 seconds. A strict regulation on clam fishing was enforced after 1983 led to an increase in the catches in 1987. This increase trend continues today.

Figure 5: Catches of Japanese surf clams and breakwater extension at Ishikari Bay New Port (data of catches from Hokkaido Government)

COMPARISON OF THE POPULATIONS OF THE CLAM IN AREAS SURROUNDING ISHIKARI BAY NEW PORT

Figure 6 shows the changes over time in the density of mature Japanese surf clams (the number of mature clams per  $100 \text{ m}^2$ ) in the Ishikari, Otaru and Atsuta areas, which was estimated from surveys on populations. As evident from the figure, the Otaru area had the highest density of mature clams for the decade after 1975, while the clam density in the Ishikari area was about half that of in Otaru. The major factor in this difference was probably that the median grain size of the sediment in Otaru was about  $0.2 \text{ mm}$ , which is suitable for the Japanese surf clam, while the diameter increased northward from Ishikari to Atsuta and these areas were not suitable habitats for the Japanese surf clam.

After 1985, changes in oceanographic conditions resulting from the construction of Ishikari Bay New Port, the accumulation of drifting larvae, the promotion of the settlement of immature clams and the fishing regulation were thought to have had a combined effect toward increasing the density of mature clams in the Ishikari Bay western area, including the Otaru area. The density of mature clams in the Ishikari area increased to almost the same level as in the Otaru area. On the other hand, the construction of Ishikari Bay New Port did not so contribute to the Atsuta area, an area influenced by the Ishikari River, and there was little change over time in the density.

Figure 6: Change of regional population size of Japanese surf clam (data from Hokkaido Government)

CHANGES IN HABITATS OF THE JAPANESE SURF CLAMS

In order to clarify the effect of breakwaters on the formation of habitats for the surf clams, we calculated the nearshore current around Ishikari Bay New Port for 1979, 1984, 1989, and 1992, and examined the relationship between the pattern of nearshore current and the distribution of mature Japanese surf clams associated with the construction of port and harbor facilities. The nearshore current model using an energy balance equation was used to calculate the currents. The direction of waves, wave height and wave period used in the calculation are NW, 1.6 m and 6.0 seconds, respectively. Figure 7 diagrams changes in the dominant areas of Japanese surf clams around Ishikari Bay New Port, based on the existing references obtainable from fishermen's associations and on inquiries to fishermen. The nearshore currents calculated at different stages of the construction of the breakwaters are also indicated in the figure.

When one compares the phase of construction of the port and harbor facilities with changes in the distribution of Japanese surf clams, it seems that as construction in the eastern area (the east and island breakwaters) was completed and construction started on the north breakwater and moved to the central area, the central channel and to the western area, the distribution of the mature clams tended to shift from the eastern sea area to the west. It is clear from Figure 7 that the stagnant and eddy-current areas were created by the construction of port and harbor facilities, and mature Japanese surf clams were distributed in the areas.

In addition, in the beginning, the mature clams were distributed in the harbor where the water became calm due to the breakwater construction. However, as the water became even calmer, the diameter of sediment grains became finer, and became muddy, thus becoming unsuitable as a habitat for the Japanese surf clam. It was no longer a major distribution area of the mature Japanese surf clam after 1985 when Ishikari Bay New Port went into operation. Based on these facts, it is presumed that the distribution of mature Japanese surf clams changes along with the changes in stagnant and eddy-current areas caused by the construction of breakwaters; the distribution is concentrated in areas which are relatively calm in the beginning, and shifts along with the changes in the sediment and feeding environment.

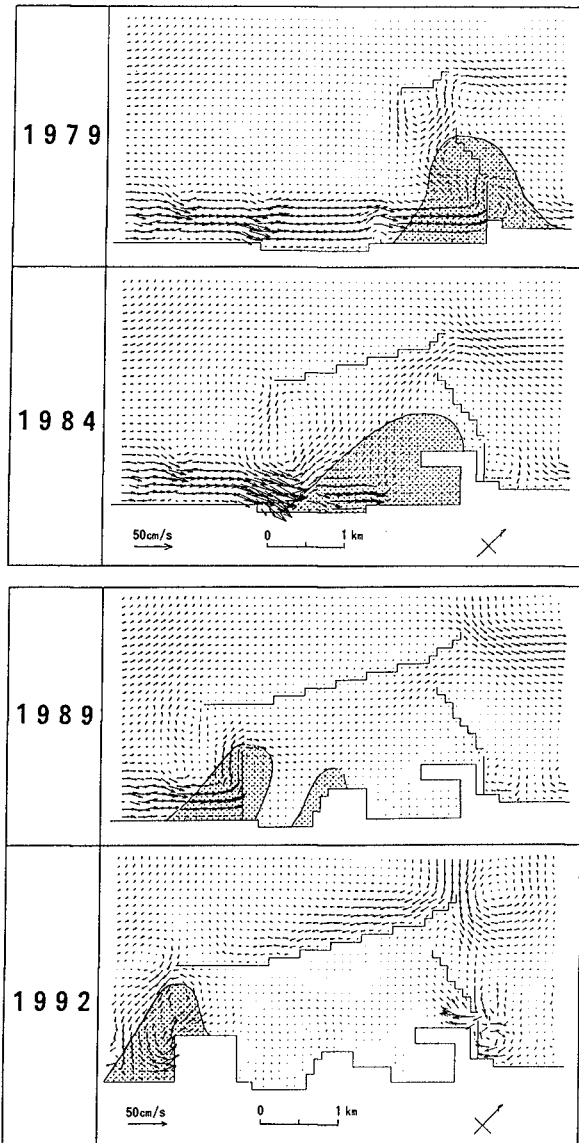

Figure 7: Change in calculated velocity field of nearshore current and dominant areas of highly dense distributions of mature Japanese surf clams

DOMINANT AREAS OF HIGHLY DENSE DISTRIBUTIONS OF JUVENILE SHELL

Figure 8 shows the distribution of juvenile Japanese surf clams in and around Ishikari Bay New Port in 1992 (Ohsaki et al., 1993). As indicated before, the eddy-current areas correspond to those of the areas of highly dense distribution of the juvenile shells. This was probably because the eddy-current areas formed by the near shore currents accumulated the planktonic larvae of the Japanese surf clams, or because they prevented the dispersal of the larvae to elsewhere. This, in turn, resulted in an increase in the number of juvenile shells settling on the sea bottom. Figure 9 shows change in the distribution of juvenile shells. The drastic decrease in March 1985 can be attributed to extreme storm waves that occurred in January 1985, with significant wave height at 4.9 meters with wave period at 9.9 seconds. In spite of these dispersion, the dominant areas of clams were unchanged.

Hydraulic experiments have confirmed that Japanese surf clams with shell lengths of 10-50 mm began to drift or to move as a result of overturning at a current velocity of 29-50 cm/s, and that about 10% died after having been vibrated in the sand for 24 hours (Watanabe, 1982, 1983). These are the reasons Japanese surf clams, which inhabit the wave breaking zone where the velocity of the nearshore current becomes greater, tend to be reduced due to being washed ashore. On the other hand, the eddy-current area formed around the breakwater can act as a relatively calm area in relation to waves coming from a certain direction. Therefore the eddy-current area is assumed to contribute to the survival of the Japanese surf clam when storm wave attack the coast.

SUMMARY

In this report, it is investigated the impact of the construction of the large-scale port and harbor at the open sandy beach on the Japanese surf clam. The principal results are as follows:

(1) Planktonic larvae of Japanese surf clams accumulated in the stagnant and eddy-current areas created by the breakwaters; this promoted the settlement of juvenile shells.

(2) Mature Japanese surf clams were found distributed around the stagnant and eddy-current areas, which were areas of relative calmness, and which were formed in association with the extension of the breakwaters.

(3) The construction of Ishikari Bay New Port resulted

in the formation of a new fishing ground of the Japanese surf clam and an increase in the populations of the clams.

## CHAPTER 248

### USE OF THREE-DIMENSIONAL HYDRODYNAMICS MODEL FOR TIDAL INLETS STUDIES

E.A. Yassuda<sup>1</sup> and Y.P. Sheng<sup>2</sup>, M.ASCE

#### ABSTRACT

This study utilizes a multi-dimensional hydrodynamics model originally developed by Sheng (1989) and later modified by Sheng *et.al* (1992) to first quantify the flow field in Little Sarasota Bay in Florida, USA with a closed (present condition) and an opened (proposed condition) Midnight Pass, and then to produce a closure curve of the Midnight Pass. This study demonstrates that robust multi-dimensional hydrodynamics models can be used to provide more quantitative analysis of tidal inlet stability.

#### INTRODUCTION

Tidal inlets connect various bays and lagoons to coastal oceans. As such, tidal inlets can have significant effects on circulation and transport in the bays/lagoons as well as longshore sediment transport in the coastal oceans. For example, tidal inlets can affect the location of nodal zones and flushing of materials into and out of the bays/lagoons (e.g. Sheng *et.al.*, 1992). Tidal inlets can also affect longshore sediment transport by causing erosion on the downstream side of the inlet while causing deposition on the upstream side of the inlet (Dean and Dalrymple, 1994).

Tidal inlets, however are not very stable and often require dredging to keep them open. Since the closing and opening of tidal inlets can significantly affect the circulation and transport within bays/lagoons, it is essential to be able to predict the stability of tidal inlets. Escoffier (1940) performed a simple analysis to study the stability of a tidal inlet. van de Kreeke (1985) analyzed the stability of multiple inlet

---

<sup>1</sup> Graduate Student, <sup>2</sup> Professor, Coastal & Oceanographic Eng. Dept.,  
University of Florida, Gainesville, Florida 32611, USA.

system. Basically, for a single inlet system, one needs to calculate a "closure curve" that relates the cross-sectional area of an inlet with the maximum current in the inlet for given tidal conditions, inlet length and inlet shape. The next step is to compute an equilibrium velocity or bottom stress at which the sediment transport capacity of the inlet currents is just sufficient to remove the sediment deposited in the inlet. Van de Kreeke (1992) pointed out that to determine the exact closure curve for a real inlet, it requires a full-fledged multi-dimensional model for the hydrodynamics of the inlet and the bay.

This study is an extension of a project funded by the Sarasota Bay National Estuary Program. The primary objective of the project was to quantify the circulation and transport in the Sarasota Bay system, located in the southwest coast of Florida, USA (Figure 1). The Sarasota Bay project consists of a field study and a modeling study. For the field study, the University of Florida collected continuous data of surface elevation, current, salinity, water temperature, turbidity, and wind at five stations during two months in 1991, and two months in 1992. For the modeling study, the three-dimensional circulation model CH3D, originally developed by Sheng (1989), was applied, improved, calibrated and verified.

The estuarine system shown in Figure 1 is actually formed by two interconnected sub-systems: the Tampa Bay system, which is a classical coastal plain estuary, with a manmade navigation channel, and the Sarasota Bay system, which is a multiple-inlet shallow coastal lagoon. In the southern part, the Little Sarasota Bay has an average depth of less than 2 meters and a manmade IntraCoastal Waterway (ICW) which bisects the length of the bay. In Little Sarasota Bay, a tidal inlet, Midnight Pass, has been closed since 1983, and much has been discussed about the feasibility and potential environmental implications of its proposed opening.

Based on the field data collected in 1990 and 1991, the CH3D model has been applied and verified for the Sarasota Bay and Tampa Bay system. There is generally a good agreement between model results and field data, with the errors on the order of 5-10% for surface elevation and 10-20% for currents (Sheng and Peene, 1992; Sheng *et al.*, 1992; Sheng *et al.*, 1994a). The effect of the Midnight Pass on the circulation and tidal flushing inside the Little Sarasota Bay was studied by Sheng *et al.* (1992).

This study utilizes the CH3D model to first quantify the flow field in Little Sarasota Bay with a closed (present condition) and an opened (proposed condition) Midnight Pass, and then to produce a closure curve of the Midnight Pass in its proposed opened conditions.

## METHODOLOGY

To study the stability of a tidal inlet, one can use the simple analysis of

Escoffier (1940), O'Brien and Dean (1972) or, in the case of multiple inlets, the analysis of van de Kreeke (1985). All these methods are based on the Keulegan repletion coefficient, which is strictly applicable to the case of uniform water level over the entire bay, an inlet flow depending exclusively on the head difference between the bay and the ocean, and a friction term represented by the Manning's coefficient (Figure 2). According to Escoffier (1940), the following limitations should be considered in applying this analysis:

- "The available values for Manning's  $n$  are based on observations made in uniform prismatic channels and their reliability in nonuniform channels such as those usually found in inlets is uncertain;
- Little is known about the loss of head that takes place due to the contraction and expansion of the currents passing through the inlet; and
- The formula is for steady state flow and ignores the temporal acceleration."

In addition, the simple analysis ignores the nonlinear effects associated with complex geometries inside the bay.

To improve estimates of the simple analysis, an approach which does not contain any of the above assumptions should be used. For this study, the CH3D model was used to quantify the detailed flow pattern in the vicinity of the Midnight Pass. To determine the closure curve of the Midnight Pass, the bottom shear stress within the opened Midnight Pass was simulated using both the 3-D version and the 2-D vertically integrated version of CH3D.

CH3D is a three-dimensional hydrodynamic model which can use non-orthogonal boundary-fitted grid as well as orthogonal or Cartesian grids. This feature allows the model to better represent the small scale processes in bays/lagoons with complex geometries. The vertical turbulent eddy coefficients are computed from a simplified second-order closure model, and the horizontal turbulent eddy coefficients are assumed to be constant, which vary with grid size and horizontal current.

In order to make the stability analysis more quantitative, it is necessary to characterize the capacity of an inlet to transport sediments in terms of the bottom shear stress. In the three-dimensional model CH3D (Sheng, 1989), the bottom shear stress is obtained from the near bottom velocity within a logarithmic boundary layer, according to:

$$(\tau_x, \tau_y) = \left[ \frac{\kappa}{\log(z_1/z_0)} \right]^2 \cdot \sqrt{u^2 + v^2} \Big|_{z_1} \cdot (u, v) \Big|_{z_1} \quad (1)$$

where,  $(\tau_x, \tau_y)$  are components of bottom shear stress,  $\kappa$  is the von Karman constant,  $z_1$  is the reference height,  $z_0$  is the bottom roughness height, and  $(u, v)$  are the horizontal velocity components at  $z_1$  within the bottom boundary layer. The only empirical coefficient,  $z_0$  appears in the logarithmic denominator, thus making it less sensitive.

In the 2-D vertically-integrated model, the bottom shear stress is obtained from the vertically-averaged velocity components  $(U, V)$ , according to:

$$(\tau_x, \tau_y) = \frac{g}{H C_c^2} \sqrt{U^2 + V^2} (U, V) \quad (2)$$

where  $g$  is gravitational acceleration,  $H$  is total water depth, and  $C_c$  is the Chezy coefficient.

In the simple analysis, the repletion coefficient relates the inlet cross-sectional area to tidal forcing and bottom friction, according to (Keulegan, 1967):

$$K = \frac{T}{2\pi a_0} \frac{A_c}{A_B} \frac{\sqrt{2ga_0}}{\sqrt{K_{en} + K_{ex} + \frac{fl}{4R}}} \quad (3)$$

where  $T$  is the tidal period,  $a_0$  is the tidal amplitude,  $A_c$  is the inlet cross-sectional area,  $A_B$  is the bay surface area,  $K_{en}$  is the friction loss at the entrance,  $K_{ex}$  is the friction loss at the exit,  $f$  is the Darcy-Weisbach friction coefficient,  $l$  is the inlet length, and  $R$  is the hydraulic radius of the inlet.

## RESULTS FOR AN IDEALIZED INLET-BAY SYSTEM

Before performing the analysis of inlet stability in Midnight Pass, the 2-D results of CH3D were compared with the simple method for the case where the simplified assumptions were valid. A Cartesian grid with 40 by 30 cells was used, with a uniform grid spacing of 250 m. The tidal forcing along the boundary was represented by a sinusoidal wave with an amplitude of 46 cm and a period of 12 hours. The depth in the offshore region and inside the bay was assumed to be a constant 2 m. The inlet cross-sectional area was varied by keeping the width constant and varying the depth from 50 cm to 2 m.

Figure 3 shows the ebb flow in the idealized bay in a five day simulation for

the case of an inlet with 1.5 m depth. Repeating this simulation for different inlet configurations, it was possible to construct two closure curves for the hypothetical inlet, one for each inlet width, and then to compare these results versus the curves obtained from the simple analysis (Figure 4). The closure curves present the maximum ebb velocity (in cm/s) as a function of the inlet cross-sectional area (in  $m^2$ ), for a given tidal forcing and Manning's coefficient. These curves clearly demonstrate the concept of critical cross-sectional area at which the velocity attains its maximum. The dots represent the 2-D model results and the solid lines represent the results of simple analysis. In the second plot, a different closure curve was obtained due to a different width of the inlet, which affects the hydraulic radius. Different values of hydraulic radius corresponding to rectangular, trapezoidal and parabolic cross-sections were used, but the simple analysis does not seem to be sensitive to different shapes in cross-section.

Results of the 2-D model and the simple analysis shows some discrepancies, particularly in terms of the critical cross-sectional area. The discrepancies can be attributed to the high sensitivity of the simple analysis to the Manning's coefficient. In this case, even the 2-D model requires significant calibration. Although the 3-D version of CH3D also contains some model coefficients, these coefficients are less empirical, and the bottom friction formulation shown by Equation (1) is much more robust than the Chezy-Manning formulation shown by Equation (2).

#### APPLICATION TO MIDNIGHT PASS, FLORIDA

The CH3D model was sufficiently calibrated and validated with data from Tampa Bay and Sarasota Bay (Sheng and Peene, 1992, Sheng *et al.*, 1992). For this study, the 2-D and 3-D versions of CH3D were used to compute the detailed flow within the Midnight Pass under various hydrodynamic forcing conditions, and various configurations of the Midnight Pass. The closure curve obtained from the 3-D model runs and the simple analysis is shown in Figure 5, wherein the dots represent the CH3D results while the solid lines were obtained from the simple analysis using different Manning's coefficients. The simple analysis is highly sensitive to the Manning's coefficient, thus producing a wide range of values of maximum velocity.

CH3D was used to simulate three scenarios: the first scenario (solid circle) represents the bay prior to the dredging of the IntraCoastal Waterway (ICW); the second one (square) represents the bay with the ICW and a shallow inlet (1.5 m deep); the third one (triangle) represents the bay with the ICW and a deeper inlet (3 m deep); and the fourth one (circle) represents the bay with the ICW and a much wider inlet. Results shown in Figure 5 indicate that the ICW made the Midnight Pass less stable. Figures 6,7 and 8 show the residual flow fields obtained from the 30 day simulations corresponding to each of the three scenarios.

Figure 9 shows the stability curve expressed in terms of the bottom shear

stress, the cross-sectional area of the Pass, and the equilibrium bottom shear stress of Bruun (1978). This shows that the inlet is only marginally stable even for the case without the ICW.

## DISCUSSION

Due to its importance to human activities, tidal inlets have been a subject of coastal engineering studies for many years. Studies have showed that physical processes in tidal inlets are quite complex and much scientific study is needed to improve the empirical engineering analysis. This study demonstrates that multidimensional numerical hydrodynamics model can be used as a comprehensive tool to provide more accurate analysis and guidance to further understanding of the physical processes involved.

Our modeling study showed that the IntraCoastal Waterway (ICW) probably made the Midnight Pass more unstable, although the Pass was only marginally stable for a long time prior to its closure. This is consistent with the earlier suggestions by Davis *et al.* (1987) and Dean (1992), which did not provide a quantitative analysis.

To determine if the Pass should be opened, a more comprehensive and quantitative study is needed. The CH3D model can be used to simulate the circulation and inlet stability under a variety of hydrodynamic conditions and inlet configurations. Additional parameters such as water quality dynamics and sediment can be considered by using a coupled hydrodynamics-sediment-water quality model being developed (e.g., Sheng *et al.* 1994b).

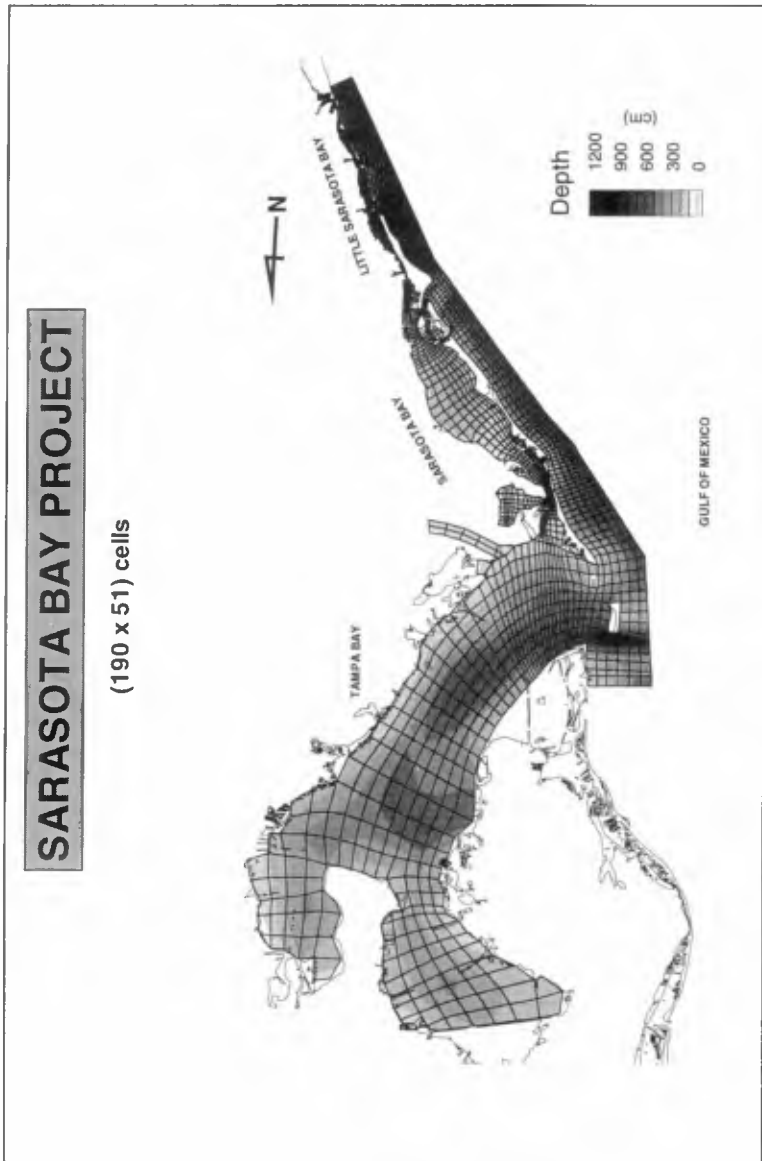

## ACKNOWLEDGEMENT

The authors wish to express their gratitude for support of the Sarasota Bay National Estuary Program and valuable discussions with R.G. Dean, D. Tomasko, and J. van de Kreeke.

## CHAPTER 249

### Study of Upwelling Phenomena of Anoxic Water 'A-oshio'

Jong Seong Yoon<sup>1</sup>, Keiji Nakatsuji<sup>2</sup>, Kouji Muraoka<sup>2</sup>

#### ABSTRACT

The field data analyses and both two dimensional hydraulic and numerical experiments were performed to understand the physical features of the 'A-oshio' appearance in Tokyo Bay. Lots of field observations show that the 'A-oshio' phenomenon may be intimately related with the upwelling of the anoxic water in the bottom layer under the wind blowing towards off-shore for more than a couple of days. Therefore, the two-dimensional hydraulic and numerical experiments are performed for clarifying the wind-induced upwelling and mixing processes in a two-layered stratified flow system with a downstream open boundary, which is exposed to wind stresses at the water surface. In these experiments, the upwelling phenomena are found to occur only in the range of  $Ri_x \times (2h_1/L) \leq 12.0$ . The numerical experiments are quantitatively confirmed to show a good agreement with the results of field observation and hydraulic experiments.

#### INTRODUCTION

Recently, unique phenomena have been frequently observed in the head of Tokyo Bay in Japan during late summer to autumn. The color of surface water changes to milky-blue or milky-green when the northeast wind blows during a couple of days. Fisheries have been damaged by lots of perish of fishes and shellfishes. Such phenomena are called 'A-oshio' regarding to the color of water. 'A-o' means blue and 'shio' does a tide in Japanese.

According to lots of field observations, an 'A-oshio' phenomenon is considered to be accompanied by the upwelling of anoxic bottom water. When an off-shore wind blows, the surface water is transported towards off-shore induced

1 CTI Engineering Co., Ltd, Osaka City, Osaka 540, Japan  
2 Dept. Civil Engng., Osaka University, Osaka 565, Japan

by wind-driven surface stress ; hence, the bottom water moves upwards along a sea bed to make compensation for the transported surface water. The color of 'A-oshio' water is considered to be changed by the oxidation of sulfide included in the upwelled bottom water which becomes anoxic during summer under no vertical mixing due to the strong stratification and the biological activities. The 'A-oshio' phenomenon, therefore, is fundamentally different from 'Akashio' (a red tide in Japanese), which is biologically induced by the excess propagation of plankton. The 'A-oshio' phenomena, therefore, can be treated as the upwelling of anoxic bottom water from the physical view point and the oxidation from the chemical one.

Even though many field observations have carried out, the detailed mechanism of 'A-oshio' appearance has been left unsolved. The reason is that only several points-measurements are not sufficient to obtain the understanding of overall physical features. The present paper, therefore, is to examine the physical mechanism regarding to 'A-oshio' appearance.

First of all, the field data obtained in Tokyo Bay are analyzed to understand the physical characteristics during the 'A-oshio' appearance. Secondly, two-dimensional hydraulic and numerical experiments are carried out to clarify the interface movement and the upwelling phenomena in a two-layered stratified flow system exposed to wind stresses at the surface. A downstream condition is set to be opened in the similar sense as semi-enclosed coastal seas or small bays. There is few experiments with such a condition, although many experiments in an enclosed flume have been done for simulating the mixing processes occurred in the lakes or reservoir. The mixing process is unsteady and rapidly changed; hence the measurements in hydraulic experiments are too difficult. Therefore, the two dimensional numerical experiment with  $\kappa$ - $\epsilon$  turbulence model and non-hydrostatic assumption is also performed to support the physical understanding of 'A-oshio' in the quantitative sense.

## FIELD OBSERVATION ABOUT 'A-OSHIO' IN TOKYO BAY

### Previous Study About 'A-oshio' Phenomenon

Tokyo Bay is one of the highly eutrophicated bays in Japan. The topographical feature of Tokyo Bay is shown in Fig. 1. It has an area of  $1200 \text{ km}^2$ , and the average depth is about 17 m. The ratio of area less than 10 m depth against a total area is about 30%. The numbers of No.1 to No.13 as shown in Tokyo Bay indicate the location of observation stations conducted by The Environment Agency.

The bay is surrounded by metropolitan cities including Tokyo and many industrial factories where more than 24

million peoples live. A large amount of nutrients and organic matter have been drained into the bay. It is known that the eutrophic status of the bay is hypertrophic condition, and algal blooms have been occurred through a year. It makes the color of surface water change to reddish-brown, that is a red tide ('Akashio' in Japanese). The 'Akashio' recently tends to occur independent of season and worldwide coastal seas, especially in the urban coastal seas.

A shaded area shown in Fig.1 indicates the coastal waters where the 'A-oshio' has often appeared. In summer, an amount of discharged river water and the heat transfer through the sea surface make the stratification strength, which results in damping the vertical transfer of momentum and eutrophicated matters. The bottom water, hence, becomes anoxic due to the precipitation and the decomposition of organic matters produced by algal blooms and the hydrogen sulfide occurs in the bottom layer (Kakino (1986)).

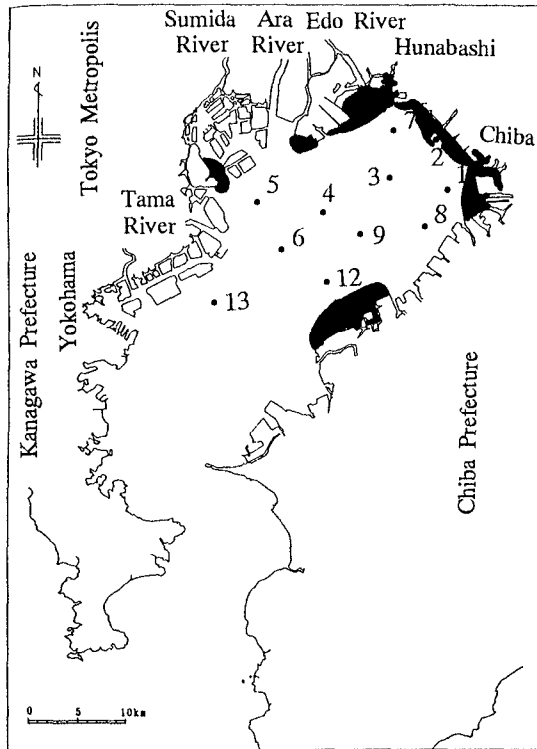

Figure 1. Topological feature of Tokyo Bay and observation stations. A shaded area indicates the coastal waters where 'A-oshio' has often appeared.

Figure 2 shows a photograph of the 'A-oshio' appearance observed on 8th September, 1988 in Hunabashi Port, which is located at the head of Tokyo Bay as shown in Fig. 1.

Table 1 shows the time variation of 'A-oshio' appearance, the perish of shellfishes and the production of a short-necked clam reported by Kakino(1986). For example, late in September 1985, 30,000 ton of short-necked clam perished which brought the economical damages about 3.6 billion yen for fisheries.

Tominaga et al. (1988) reported the presence of colloidal particles of sulfur in the boundary layer between surface oxygen-sufficient water and anoxic bottom water at the head of Tokyo Bay.

Figure 2. 'A-oshio' appeared in Funabashi Port located in the head of Tokyo Bay. This photograph was taken from air on 8th September, 1988.

### Oceanographical and Meteorological Features of 'A-oshio'

The Environment Agency has conducted field measurements for 7 years from 1988 in order to clarify the mechanism of 'Aoshio' from the multi-view points such as physical, chemical, biological and ecological aspects. During the field observations from 22th July to 11th August, 1992, 'A-oshio' appeared during 3rd August to 6th August.

Figure 3 shows the time variation of wind velocity and direction observed by the Chiba Meteorological Observatory. It is of great interest that before the 'A-oshio' appearance the southwest (on-shore) wind stronger than 5

Table 1. Field data of 'A-oshio', perish of shellfishes and the year production of clam (Kakino; 1986)

Year	Month, Day	Appearance of Aoshio etc.	Influence to the Shellfish	Production of Clam (ton)
1975	late in September	Aoshio (middle or large scale)	partly perish of clam	22,099
1976				7,238
1977	8.10~8.16	Aoshio(large scale)	perish of clam	12,843
1978	7.8~7.10	Aoshio(middle scale)	mass perish of clam	8,620
1979	6.13 7.16~7.17 8.14 9.30	Aoshio(small scale) Aoshio(middle scale) Aoshio(middle scale) Aoshio(middle scale)	negligible negligible negligible negligible	2,610
1980	8.2~8.5 8.26 9.9 9.19 9.25	Aoshio(large scale) Aoshio(small scale) Aoshio(small scale) Aoshio(small scale) Aoshio(small scale)	negligible negligible negligible a few perish of clam negligible	6,979
1981	late in July	anoxic water	perish of clam	5,907
1982	7.27~7.29 bearly in August	Aoshio(large scale) turbid water	a few perish of clam perish of clam	3,843
1983	6.8 6.18	Aoshio(small scale) Aoshio(small scale)	negligible negligible	2,972
1984				7,349

Figure 3. Time variation of wind velocity and direction at the Chiba Meteorological Observatory

m/s kept blowing from 30th July to 1st August, and in succession the northeast (off-shore) wind blew. The northeast or east northeast wind stronger than 5 m/s kept blowing from 1st August. The former event may play a role to make the stratification strengthen. Other observations show that there is heavy rainfall before the 'A-oshio' appearance. The authors point out that such events of south-west wind blowing or lots of rainfall are of fundamental importance in considering the mechanism of 'A-oshio' appearance. Namely, strong stratification is a necessary condition for 'A-oshio' appearance.

Figures 4 and 5 show the distributions of water temperature, salinity and dissolved oxygen (DO) along the vertical section from the stations No.7 to No.13, the location of which is shown in Fig.1. The measurements were conducted on 22th July and 4th August. The thermal stratification remarkably develops depending on heat flux through water surface in summer. The contours of temperature and salinity show a layered structure of 24 °C to 18 °C and of 26 ‰ to 34 ‰, respectively. The difference in water temperature between the upper and the lower layers is about 6 °C on 22th July. The contour lines of DO also show horizontal in the upper layer and the anoxic water less than 5 mg/l exists deeper than 5 m depth on 22th July. The contours of 0 and 1 mg/l DO, however, indicate no stratification but a curious tendency. It may be induced by the error in measurement at station No.6. It is found from these distributions except the profile of DO that the strong stratification develops on 22th July.

On the other hand, on 4th August, the contours of 22 °C temperature, 31.5 ‰ salinity and 4 mg/l DO are upwelled to attain to water surface near No. 7 station. It is worth noting that the counter lines of 2 and 3 mg/l DO tend to deepen gradually in the off-shore direction. Such a tendency is physically reasonable. If a wind blows off-shore in the long term, the water surface tends to lean upward in the same direction as wind-blowing, namely in the offshore direction in this case. And, the stratified interface leans downward in the offshore direction according to the balance of pressure. The 0 and 1 mg/l DO contour lines is upwelled to -6 m depth at the station No. 7. As compared with Figs. 4 and 5, it is clarified that the upwelling of the hypolimnetic anoxic water was caused by the northeast wind blowing continuously for four days from 1st August.

Joh (1989) pointed out that the formation of the anoxic water mass correlates well with the temperature difference between the surface and the bottom layers based on field data obtained in Osaka Bay. The same tendency was confirmed in Tokyo Bay by The Environment Agency (1991). It indicates that the stratification affects not only the upwelling phenomena but also the generation of anoxic water.

Based on the above-discussed field observations, a conceptual sketch of 'A-oshio' appearance can be drawn as Fig. 6.

Figure 6. Conceptual sketch of 'A-oshio' appearance

## TWO DIMENSIONAL HYDRAULIC AND NUMERICAL EXPERIMENTS

Both hydraulic and numerical experiments are carried out in the present study. It is because only the hydraulic experiments are too difficult to quantitatively understand the unsteady phenomena such as the flow movement and strong mixing processes at the stratified interface.

### Setup of Hydraulic Experiments

The experimental facility is shown in Fig. 7. It is composed of a main test flume (an acrylic flume of 600 cm length, 15 cm width and 30 cm depth), a wind tunnel (6 shuttlecock of 100 cm and the maximum rotation of 1500 rpm) and a large tank (300 cm length, 200 cm width and 25 cm depth) connecting with the downstream end of the test flume. The experiments were conducted in a stratified flow system with two layers of fresh water and salt water. The degree of stratification depends on the density of salt water. The initial thickness of the upper layer was always kept to be 10 cm. Mean velocities in the upper layer were measured using a LDV (Laser Doppler Velocimetry) and the analyses of tracer trajectories. Two 35 mm cameras and a video camera were used to observe the movement of the stratified interface and its mixing process. The density profiles were measured using a salinometer.

Figure 7. Experimental facility of two-layer stratified flow system with wind tunnel

### Setup of Numerical Experiments

A two-dimensional numerical experiment was also performed under the same physical conditions as hydraulic experiments. The governing equations were composed of the continuity equation, the longitudinal and vertical momentum equations and the diffusion equation of density. The non-hydrostatic model of SIMPLE method (Patankar, 1980) was used. The  $k-\epsilon$  model was used to represent turbulent transfer of momentum and scalar quantities. The standard values were used for the unknown constant values including the  $k-\epsilon$  equation. The resolution was 7.5 cm and 1 cm in the longitudinal and vertical directions, respectively. The hydraulic conditions are as follows; the friction velocity due to the wind stress at the water surface  $u_* = 6.5$  cm/s, the upper layer depth  $h_1 = 10$  cm, and the range of  $Ri_* = 23-1090$  and  $Ri_* \times (2h_1/L) = 0.76 \sim 36.3$  depending on the density difference, in which  $L$  is the length of flume, in other words, the distance of the wind blowing.

### EXPERIMENTAL RESULTS AND DISCUSSION

Spigel and Imberger (1980) proposed that the mixed-layer dynamics in lakes or reservoirs could be classified into four regimes in terms of Wedderburn number defined as  $We = Ri_* \times (2h_1/L)$ . It means the product of the Richardson number and the aspect ratio of the two-layered stratified flow system. Furthermore, Thompson and Imberger (1980) indicated on the basis of numerical experiments that the stratified interface could be upwelled to attain the water surface in the case of the Wedderburn numbers 'We' less than 3 or 4. Since the present experiment with an open downstream condition is a little different from the

experiment of Imberger et al.,  $Ri_* \times (2h_1/L)$  is used as the dimensionless parameter.

The time variation of observed density interface is shown in Fig. 8 in the case of  $Ri_* \times (2h_1/L) = 36.3$  and 12.0. The observation points are the upstream, the center and the downstream of hydraulic flume. In these figures, the axis of ordinates indicates the water depth, while the axis of abscissas does the passing time after the wind blowing starts. That is, the water depth  $h_1 = -10$  cm indicates the initial position of the interface. The middle layer is defined as the water mass mixed with fresh water and salt water, which usually lies upon the density interface. In the case of  $Ri_* \times (2h_1/L) = 36.3$ , the stratification due to density difference is so completely superior to the wind shear during the experiments that the vertical mixing and the variation of the density interface hardly occur during the wind blowing. On the other hand, in the case of  $Ri_* \times (2h_1/L) = 12.0$ , it is observed that the mixed layer at the upstream end upwells after about 70 seconds, and the density interface does after 110 seconds.

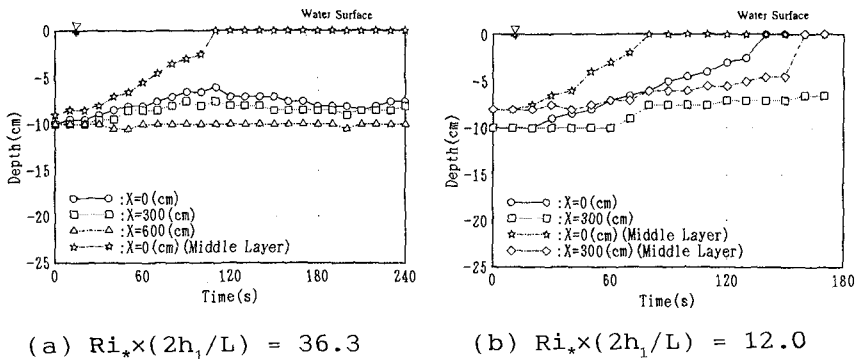

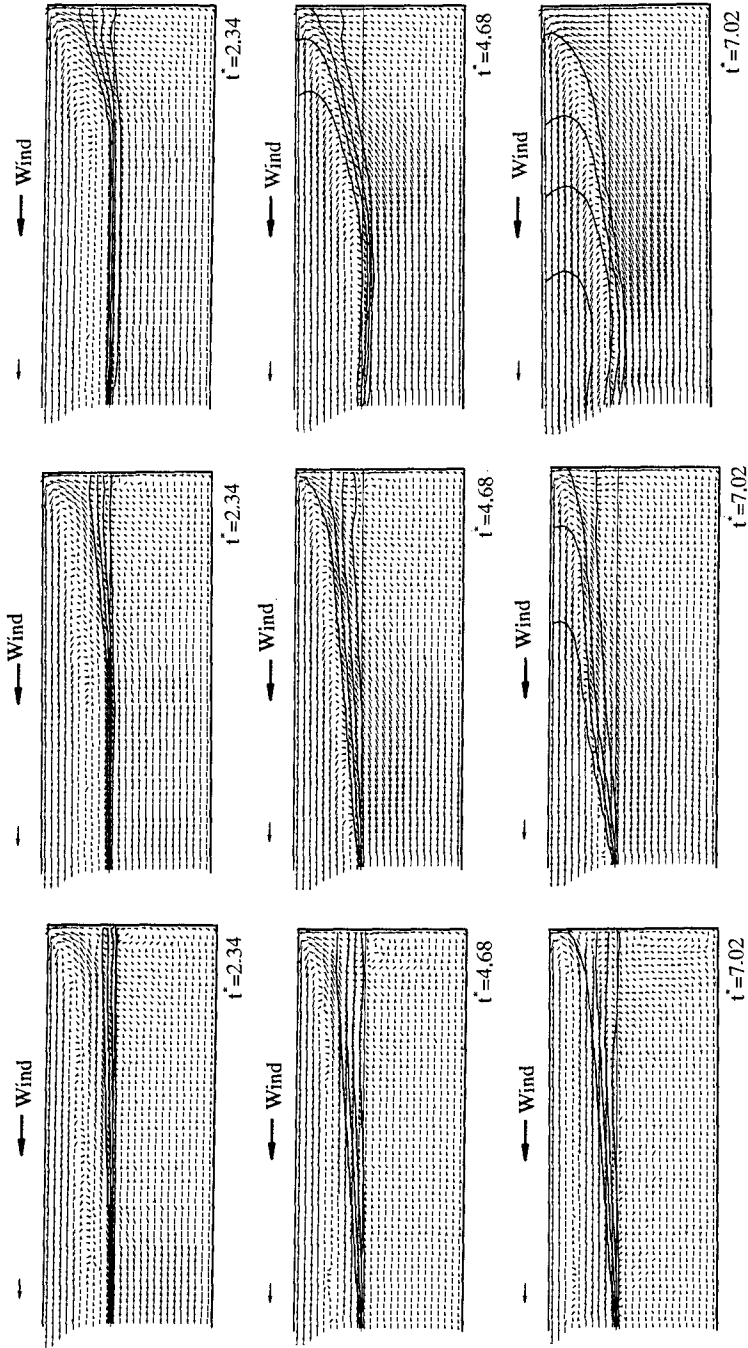

Figure 8. Time variation of density interface during wind blowing

Figure 9 shows the time variation of velocity and density difference fields obtained by numerical experiments in the flume with the open downstream condition. The values of  $Ri_* \times (2h_1/L)$  are 36.3, 12.0 and 3.1. And the value of  $t^*$  shown in the figures is the dimensionless passing time after the wind blowing, which is defined as  $t^* = tu_* / h_1$ . The density difference between fresh water and salt water are plotted every 20% from 10% by the contour lines.

It was confirmed by authors' experiments (1994) with a closed downstream condition that the results of numerical experiments are in a good agreement with those of hydraulic experiments. In the case of an open downstream bound-

(a)  $Ri_* \times (2h_1/L) = 36.3$

(b)  $Ri_* \times (2h_1/L) = 12.0$

(c)  $Ri_* \times (2h_1/L) = 3.1$

Figure 9. Effects of stratification on the distributions of velocity and density difference fields in a two-layered stratified flume with an open downstream condition

any condition, vertical circulation in the upper layer of the flume is not observed. The density interface upwells at the upstream side and the mixing occurs in the same manner as the closed flume experiments in cases of larger Wedderburn number. (See; Yoon et al.(1993)) On the basis of both hydraulic and numerical experiments, it is found that the upwelling of density interface at the upstream end occurs in the range of  $Ri_* \times (2h_1/L)$  less than 12.0. The deepening of density interface is observed only for the case of weakly stratification,  $Ri_* \times (2h_1/L) = 3.1$ . In the present computation, the vertical position of stratified interface is postulated to be fixed as  $h_1 = -10$  cm and the gradients of all hydraulic variables are constant at the downstream condition. Therefore, when the entrained volume into the upper layer is not balanced with the compensated one, which is inflowed in the lower layer from the connected large tank, the stratified interface is possible to deepen with time. It is not sure whether the deepening phenomena is caused by the postulated downstream condition or not, but it may be one of the reason of the deepening.

Figure 10 shows the comparison of computed vertical profiles of mean velocity with observed ones in the case of  $Ri_* \times (2h_1/L) = 36.3$  and 12.0. The computed mean velocity gives a good agreement with measured ones at the middle section of the flume. It may be suggested from this figure that the upper layer flows in the same direction as the wind blowing, while the lower layer flows in the reverse direction in order to compensate the entrained volume of the lower layer to the upper layer.

(a)  $Ri_* \times (2h_1/L) = 36.3$

(b)  $Ri_* \times (2h_1/L) = 12.0$

Figure 10. Comparison of computed vertical velocity profiles with observed ones

APPLICATION TO NUMERICAL EXPERIMENTS TO TOKYO BAY

It is easy on the basis of above discussion to evaluate whether the 'A-oshio' appears or not in the head of Tokyo Bay by the calculation of  $Ri_* \times (2h_1/L)$  based on field data obtained. Table 2 shows the observed hydraulic values during 'A-oshio' appearance in Tokyo Bay.  $\Delta\rho$  means the difference in density between the upper and the lower layers,  $h_1$ ; thickness of the upper layer,  $W_{10}$ ; wind velocity at 10m upper from water surface,  $L$ ; longitudinal length of Tokyo Bay and  $T_m$ ; the calculated time for upwelling of density interface to water surface.

According to Table 2, it is confirmed that the 'A-oshio' phenomena, namely the upwelling of anoxic water in the lower layer, would occur in the range of  $Ri_* \times (2h_1/L)$  less than 10.0 in the limits of obtained field data. The values are within the computation criterion value of  $Ri_* \times (2h_1/L) = 12.0$ . As shown in Table 2, the condition of 'A-oshio' appearance is that the wind of mean velocity over 4 m/s blows continuously for more than two or three days. It shows a good agreement with the previously observed results during 'Aoshio' appearance, too.

Table 2. The values of  $Ri_* \times (2h_1/L)$  during 'A-oshio' appearance in Tokyo Bay

Observed Date	$\Delta\rho$ ( $\text{kg/m}^3$ )	$h_1$ (m)	$W_{10}$ (m/s)	$Ri_*$	$\frac{2h_1 Ri_*}{L}$	$T_m$ (hr)
16-17, July, 1979	4.0	10.0	3.3	25,000	10.0	49.3
20-21, Aug, 1985	10.0	7.5	4.2	28,940	8.7	31.3
5-6, June, 1986	4.0	7.5	3.0	22,680	6.8	38.4

Where,  $\Delta\rho$ : difference of density between upper layer and lower one,  $h_1$ : depth of upper layer,  $Ri_*$ : Richardson number,  $L$ : longitudinal length of Tokyo Bay,  $T_m$ : time for upwelling of density interface to water surface

CONCLUSIONS

The data analyses of many field observations and the two dimensional hydraulic and numerical experiments were conducted in order to make clear the hydraulic conditions of 'A-oshio' appearance in Tokyo Bay. The following conclusions can be obtained.

- (1) 'A-oshio' phenomena can be treated as the upwelling phenomena of the anoxic water in the bottom layer under the wind blowing towards offshore for more than a couple of days based on lots of field observations.
- (2) In the two dimensional hydraulic and numerical experiments, the upwelling phenomena are found to occur only in the range of  $Ri_* \times (2h_1/L) < 12.0$ .
- (3) The results of numerical experiments are also confirmed to agree well with those of hydraulic experiments.

## CHAPTER 250

# Sea Level Rise and Coast Evolution in Poland

Ryszard B. ZEIDLER<sup>1</sup>

### Abstract

*Trends established for ten Polish tide gauge stations show the annual mean sea level (AMSL) growth rate from 0.8 to 2.9 mm per year in recent 35 years, and a linear trend computed for the years 1901–1990 yields some  $1.2\text{--}1.6 \pm 0.2$  mm/yr. Annual SL maxima (ASLM) trends are about one-half of the ASLM trends. Positive 6-hr SL increments  $\Delta h$  from storm events show a growing trend associated with 'storminess'.*

*In the 'retreat' option for Polish coast, the impact zones between contour lines 0–0.3 m, 0.3–1 m, and 1–2.5 m cover respectively 845, 883 and 476 km<sup>2</sup>, thus 2204 km<sup>2</sup> in total, in addition to 30 km<sup>2</sup> of beaches and dunes likely to dissappear for ASLR2. Described by Zeidler (1992) are various 'full protection' techniques adopted.*

*The Baltic atmospheric circulation is found to change as to direction but not as to wind speed. Subsequent (Fig. 9) insignificant changes in the net sediment transport, in the order of 15% per century are noted. Hence the coast evolution due to climatic changes in wind circulation patterns seems less important than the anticipated sea level rise induced changes.*

### 1 INTRODUCTION

The Baltic Sea forms Poland's borders along 500 km. It is a shallow, almost land-locked sea. Its salinity is low, barely 7-8 ppt in the Polish coastal zone.

The Polish coast consists of two basic types — sandy dunes (including barrier beaches) and cliffs. The former stretch along most of the coast while cliffs occupy slightly above 80 km. Coastal barriers between the sea and lakes are well developed in the central and eastern parts of the coast. The Hel Peninsula is a unique spit system separating the Gulf of Gdańsk from open sea. Because of its intensive erosion and multifarious importance, it has become a subject of concern to both Polish and international authorities.

The present climate of both Poland and its coast is believed to undergo perceptible change due to global warming. However, as for many other areas, the possible changes in precipitation, evaporation, transpiration, and their uncountable outcomes over the Baltic Sea and its drainage area, are all not amenable to

---

<sup>1</sup>Professor, Polish Academy of Sciences' Institute of Hydro-Engineering *IBW PAN* 7 Koscierska, 80-953 Gdansk, Poland

ready prediction. Global circulation models (GCM) are not yet powerful enough to yield a reliable prediction of climate change in regions such as Poland's coastal zone. Yet one can focus attention on the most likely and conspicuous outcome of such change, the sea level rise.

At the same time, some research programmes under way in Poland and the Baltic area (cf. Miętus 1993, 1994) are centered around changes in regional atmospheric circulation, thus adding to identification of hazardous meteorological and hydrologic processes in the Polish Baltic coast zone and coupling of atmospheric circulation and sea level. The two aspects of climate change, i.e. sea level rise and wind patterns are dealt with in this paper, in linkage with coast evolution.

The warming of climate in southern Poland is seen in Figure 1 while changes perceptible in seawater are noted in Figure 2.

## 2 ACCELERATED SEA LEVEL RISE (ASLR)

### 2.1 *Annual Mean and Maximum Sea Level in Poland*

Recent examination of trends and statistical distributions in sea level datasets, revised and updated for the Polish coast, has partly confirmed some earlier conclusions drawn for mean sea level and exposed new findings for extremum sea levels. The trends have been established for ten Polish tide gauge stations, which show the mean sea level growth rate from 0.8 (Kołobrzeg) to 2.9 (Gdańsk) mm per year in last 35 years, with acceleration in recent years (Zeidler et al. 1994). A linear trend for the years 1901–1990 has not been rejected statistically at the 0.05 significance level, and has been found to be smaller than the above figures for 35 years (i.e. some  $1.2\text{--}1.6 \pm 0.2$  mm per year).

### 2.2 *Storminess and Wave Climate*

Annual sea level maxima (ASLM) add to the present knowledge of the Polish Baltic hydrology. Inherent trends and periodicities have been examined (cf. Zeidler et al. 1994). The ASLM trends have been found to approach 0.53 mm/yr at Swinoujście, 0.7 mm/yr at Kołobrzeg and 1.73 mm/yr in Gdańsk, thus about one-half of the mean-sea level trend. Hamming windowing displayed significant periodicities about 8, 5–6 and 3 years. Bartlett testing confirmed the data independence for Gdańsk but not for the other stations. Seasonal occurrence of the maxima is obvious — 74% of all ASLM occurred between November and February, these months encompassing all ASLM with 10% exceedance and 91% of 25% exceedance (remaining 9% in October and March).

Another interesting research objective attacked now consists in description of the correlation matrices for joint sea level and wave height events under storm conditions observed and hindcast along the Polish Baltic. This programme is hoped to be fruitful both scientifically and practically (design of coastal and maritime structures basing on more than just one storm parameter such as sea level).

For the identification of both 'regular' and extreme storm-induced sea level changes as well as definition of hazardous sea states it is worthwhile to examine short-term increments of SL and count them in some statistically representative classes in order to see if those numbers change in longer time scales, which would point to the presence of what could be labelled a 'storminess change'. This has been done under the programme indicated in the acknowledgements, and

Figure 1. Air temperature in Cracow (20-year moving average)

Figure 2. Water temperature and salinity variation in the Baltic Sea as exposed by Piechura in 1993.

Figure 3. 11-yr moving-average mean SL at the most reliable Polish tide gauge stations (cf. Zeidler et al. 1994).

Figure 4. ASLM exceedance curves fitting the Gumbel distribution for three Polish tide gauge stations; (A) Świnoujście; (B) Kołobrzeg; (C) Gdańsk; cf. Zeidler et al. (1994).

Figure 5. Trends in annual occurrence numbers for 6-hr sea level increments  $\Delta h$  for three Polish stations.

the basic findings are illustrated in Figure 5. For the three stations analyzed, the positive 6-hr SL increments were found from time series extending over some forty-odd years. As they had to be statistically meaningful, the increments  $\Delta h$  were arranged in three classes (slightly different for every station), and the central class data are presented in Figure 5. It is seen that the occurrence numbers of  $\Delta h$  show a growing trend.

The above conclusion agrees with similar findings for the occurrences of annual crossings of some sea levels regarded as 'warning' and 'emergency' levels (roughly 60 and 80 cm above MSL in Poland, respectively). Those occurrence numbers, too, have been observed to grow over decades. To further investigate this issue, statistical series have been found under our programme for both  $\Delta h$  and sea level alone. Similar behaviour and agreement of the two families with Pearson type III exceedance functions, above some thresholds of 70 cm for SL and 25 cm for  $\Delta h$ , is notable. This proves that sea levels above 70 cm (or 570 as a standard format of reference in Poland) can indeed be identified with a short-term rise in SL (recall that  $\Delta h$  classes in our analysis have been only positive). Then the statistical distributions of high sea levels are representative of hazardous situations associated mostly with growth of the sea level, not incidental fall.

### 3 POLAND'S VULNERABILITY TO ASLR

#### 3.1 General

Of the three response strategies suggested by IPCC we selected only two, i.e. 'retreat' and 'full protection' ('adaptation' was largely neglected).

The Polish 'Study Area' has been defined as the area within which the physical effects of the accelerated sea level rise (ASLR) over the next century could be felt. The inland boundary of the study area was chosen as the +2.5 m contour.

Out of the total length of the Polish coastline, the 'open sea' coast is almost exactly 500 km (of which 72 km on both sides of the Hel Peninsula), while the banks of the Szczecin Bay measure about 240 km, and those of the Vistula Bay about 100 km.

Because of their distinct features, distinguished have been four major Areas: the Odra Estuary (Area 1), western dunes and barrier beaches (Area 2), central-east dunes and barrier beaches with the Hel Peninsula (Area 3), and the Vistula Delta (Area 4). Area 1 includes the agglomeration of Szczecin (and Świnoujście), while Area 4 encompasses the three-city complex of Gdańsk, Gdynia and Sopot, together with Elbląg.

The division into three impact zones permitted a convenient distinction through the study area cross-section within which flooding probabilities could be assessed: (I) between 0.0 m and +0.3 m MSL contours; (II) between +0.3 m and +1.0 m MSL; (III) between +1.0 m and +2.5 m MSL.

The data collected from maps, reports, computations, studies and other sources (e.g. land-use, socio-economic etc) were entered pertaining to each of the impact zones separately in working tables. Flooded areas (i.e. areas 'lost') could then be readily deduced as zone I at ASLR1 (30 cm/100 yrs) and zones I+II at ASLR2 (1 cm/yr), while the area at risk was defined as II+III at ASLR1 and III at ASLR2.

For the purposes of assessment, the following habitats have been distinguished: coastal waters, beaches and dunes, forests, lagoons and barrier lakes,

rivers and estuaries, and swamps/bogs. Coastal forests display the highest biodiversity among all coastal habitats.

### 3.2 *The Extent of Vulnerability for the 'No Measures' Option*

The extent of inundation and population hazards in our study area are visible in Tables 1 and 2.

The impact zones between contour lines 0–0.3 m, 0.3–1 m, and 1–2.5 m cover respectively 845, 883 and 476 km<sup>2</sup>, thus 2204 km<sup>2</sup> in total, in addition to 30 km<sup>2</sup> of beaches and dunes likely to disappear as a result of ASLR2 (and some 10 km<sup>2</sup> due to ASLR1).

The principal ASLR impact in the Odra estuary will consist in inundation extending at ASLR2 up to River Rurzyca (KM 695). Polder dykes have crests about 1.5–2 m above MWL. At higher stages most polder dykes will be overtopped. The inundated polders will include those of Miedzyodrże (between East and West Odra), around the Szczecin Bay, Swina and Dziwna. Equally endangered by flooding are urban areas of Szczecin (primarily Dąbie district), Świnoujście, Trzebież and other towns. Indirect effects encompass damage to sewerage and other infrastructure. Parts of the Ports of Szczecin, Świnoujście and Police are also vulnerable. The impact zones I and II within Area 1 measure in total 163.8 and 496.6 km<sup>2</sup>, respectively.

All Polish coastal polders, arranged in eight complexes of 243 polders measuring 183,557 hectares will be at stake.

In Areas 2 and 3, narrow coastal barriers between the sea and low-lying lakes (much as lagoons or embayments in other area) could erode, making inland areas widely accessible to sea water. The higher levels attained by storm surges in ASLR scenarios will destroy foredunes and erode barrier islands and spits. The lowered barriers will then be susceptible to storm washover. The lakes will grow more saline.

Stowiński National Park and Łeba dune field, a memorable natural landscape, special enough to be included on UNESCO's list of the world's Biosphere Reserves, are endangered as well. The Hel Peninsula, a quite unique spit formation separating the Gulf of Gdańsk is most vulnerable, and will become a smaller island if no measures are applied.

Gdańsk, Szczecin, Świnoujście and Gdynia ports are all flooded and at risk, though to different degree. For instance, the industry of Gdańsk (ports included) occupies 430 and 330 hectares in impact zones I+II and III, respectively. In addition, Gdańsk is now a lively industrial, scientific and cultural centre of northern Poland. The endangered urban areas of Gdańsk cover 450 and 680 ha in the same zones. Full prevention measures should be taken to avoid any loss of this valuable and historical piece of our study area.

One should point out the importance of ports and several shipyards in Gdańsk, Gdynia and Szczecin, the industrial hinterland, such as oil refinery linked to oil terminal in Gdańsk in Area 4 and the Lower Odra power plant and the large chemical plant and port at Police in Area 1, the architecture, historical, and cultural values of old cities, primarily Gdańsk in Area 4, and numerous roads and railways, in addition to other infrastructure.

The Vistula Delta covers an area of 2,320 km<sup>2</sup> with major cities of Gdańsk, Elbląg and Malbork. Its polder area occupies 180,000 hectares (2% of the land area of Poland). Most of its depressions and low land will be damaged. The dikes already built will be too low for the new hydrological conditions, especially ASLR2. They have been designed to stay under water not longer than a couple

Total		142,690	92,150	234,840

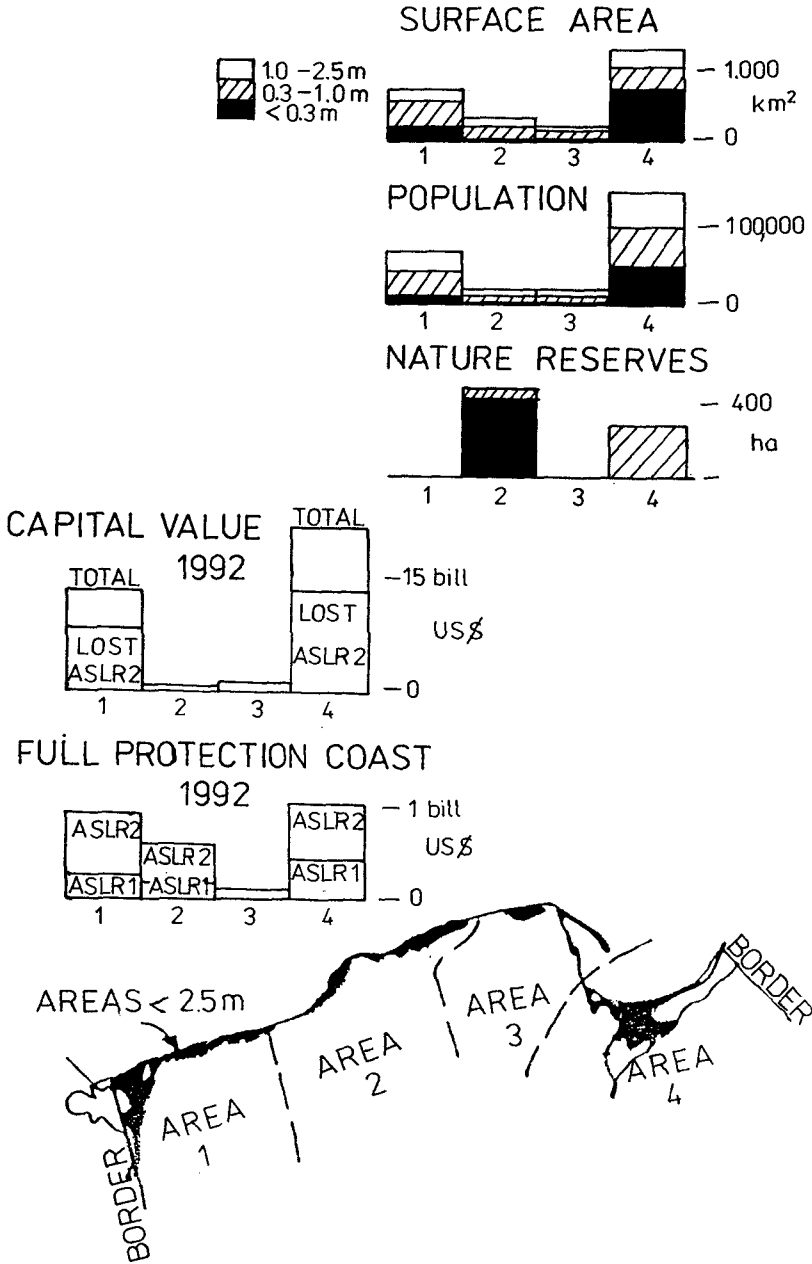

Figure 6. Poland's study areas, lost values in retreat and costs of both retreat and 'full protection

of days. In summary, the area losses under ASLR1 and ASLR2 are very heavy — 672 km<sup>2</sup> (80% of all Area 1–4) and 948 km<sup>2</sup> (55%) respectively. The length of roads flooded is 400 km and 564 km in the two cases, in addition to 35 and 126 km of railways, 300 and 415 km of primary power lines, and 26 bridges.

Enhanced shoreline erosion and shore retreat has been analysed by the use of field data, Bruun computations and numerical models. All results point to a figure exceeding 150 m of shoreline and dune retreat in the course of 100 years of ASLR2 scenario. The counterpart for ASLR1 can be estimated at 50 m per 100 years.

Hence the impact zones between contour lines 0–0.3 m, 0.3–1 m, and 1–2.5 m cover respectively 845, 883 and 476 km<sup>2</sup>, thus 2204 km<sup>2</sup> in total, in addition to 30 km<sup>2</sup> of beaches and dunes likely to disappear as a result of ASLR2 (and some 10 km<sup>2</sup> due to ASLR1).

### 5.3 Outline of the Full Protection Option

Described by Zeidler (1992) are various protection techniques adopted. From that variety of possible coastal defence measures we have chosen dykes, sea-walls, offshore breakwaters, artificial beach nourishment and land elevation, in addition to local land abandonment. Many structures are new, and some existing structures are proposed for reconstruction and adaptation to new ASLR conditions.

*Inter alia*, full protection of the Odra estuary means preservation of the polders on peripheries of the estuary. (107 and 280 km of new dykes must be constructed in Area 4 under ASLR1 and ASLR2, respectively; the lengths of adapted dykes are 243 and 324 km). In Areas 2 & 3, new polders require new facilities such as pump stations, drainage and other infrastructure. In our concept of Hel Peninsula protection we rely mostly on artificial nourishment. In Area 4, it seems imperative to keep the present agricultural use of the Vistula Delta (much as the lower Odra Valley), especially in the polder areas.

Hence full protection of Zulawy polders at ASLR2 requires a bulk adaptation of the existing dykes and the construction of some new dykes and storm and flood prevention facilities. At ASLR2, one should construct 52 km of new dykes and adapt 647 km of those presently in use. Under ASLR1, the respective numbers are 13 and 600 km.

The adaptation should encompass river dykes on Zulawy, frontline dykes on the Vistula Bay, lower dykes around Lake Drużno, and river dykes along Rivers Szkarpa and Nogat, and Kanal Jagiellonski, which make up the navigation route between Gdańsk and Elbląg. The Vistula dykes should be adapted on some 35 km from the mouth upstream. Other rivers will require new dykes, in addition to the adapted ones.

The storm barrier at the entrance of River Tuga should be virtually redesigned in view of ASLR2, and other river gates must be considered to keep storm surges away from the delta.

Additional protection should also be secured on polders around the Vistula Bay (at Krynica Morska, Przebrno, Kadyny, Tolkmicko and Pasłęka).

An outline of the damage and cost incurred over the four Study Areas of Poland's coast in the case of the two response strategies is given in Figure 6 for the sake of better illustration of the notions and quantities in the description above.

It is worthwhile to note that the cost of protection, although high in absolute terms and demanding as to huge investments, is roughly tenfold lower than the value of the property lost, not to mention the fringe losses.

## 4 POLISH COAST EVOLUTION

### 4.1 *Historical Lessons*

The vulnerability assessment for Poland was basically aimed at quantification of the losses and protection measures due to flooding and inundation, as beach erosion contributed marginally to the overall damage. Lessons of such flooding were learned in the past, as illustrated in Figure 7 for the Vistula Delta ('Żuławy'). The mouth and branches of the Vistula River were migrating in the past, with obvious bearing on the overall shore evolution. Long-term evolution of 'open sea' was also recorded. Depicted in Figure 8 is an example of cliff retreat encountered in Poland over roughly 700 years. The factors controlling long-term changes are currently analyzed and modelling approaches are now endeavoured at IBW PAN.

Routine topographic and bathymetric data have been collected at the *IBW PAN* Coastal Research Facility situated on the Polish coast of the Baltic Sea some 80 km from Gdańsk. Along with parameters of wind, waves, currents and other hydrologic factors, topographic features have been measured since 1983 on a 2.7-km beach and nearshore zone extending some 800 m from shoreline. The beach profiles have been arranged every 100 m. The first systematic and mutually compatible records of beach and shore topography date back to 1964, and echosoundings plus tachimetry are continued every four weeks.

In addition to Lubiatowo, a few other sites have also been made available to *IBW PAN* staff, such as Bulgarian Black Sea or Senegalese coast off St. Louis, not to mention the cartographic material for Poland's coastal units such as Hel Peninsula. Hence we have insight into a considerable bulk of a reliable field database stretching over a reasonably long span of time. This data set encompasses mostly sandy beaches, and partly cohesive beds. It has been used for various research purposes. At present we focus attention on its use to model the large-scale coastal behaviour (Pruszek & Zeidler 1993).

### 4.2 *Gross Forecast of Coast Evolution*

It has been mentioned that the present attempt of the forecast of coast evolution due to climate change is largely confined to two factors: sea level rise and atmospheric circulation. So far they are treated separately: ASLR in VA and wind change via the chain of effects schematized in Figure 9. Both factors will hopefully be combined in a joint algorithm taking into account a variety of interactions.

At present we adhere to the recent findings that the atmospheric circulation over the Baltic Sea changes as to direction but not as to wind speed (Miętus 1994). The prevailing wind direction tends to follow more and more closely the major axis of the sea. Hence it is assumed that the south-westerly winds blowing along the Polish coast for most time now become more westerly, at the cost of the southerly ones. In the analysis it is taken for granted that among the major eight directional sectors the southern ones are reduced at a rate of 2.5% per 50 years while their northern counterparts gain the same, and the same is repeated in the west-east direction, at the cost of the easterly winds.

The procedure illustrated in Figure 9 reflects the natural and common logics: from wind to sediment transport. From statistical yearly distributions of wind speed and direction for the intervening Baltic fetches one computes waves by a spectral method, uses a Battjes-Jansen procedure for irregular wave trans-

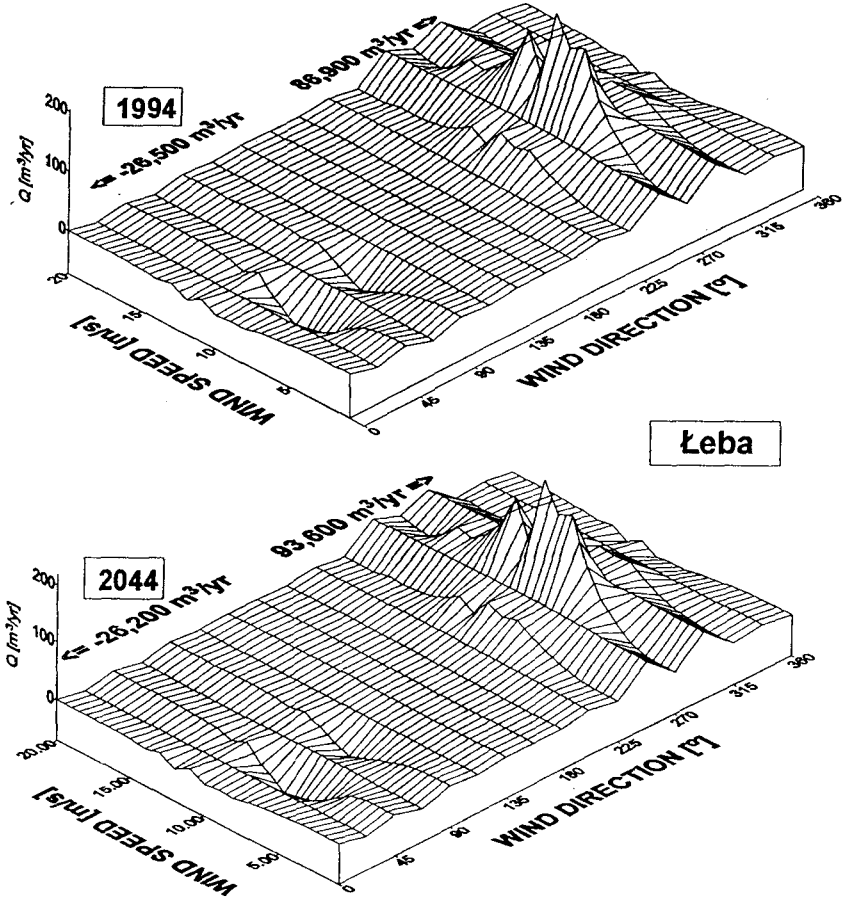

Figure 9. Two-dimensional (wind speed-direction) distributions of sediment transport rates across the entire shore profile at Leba (east-central Polish coast) in the years 1994 and 2044.

formation in the shoaling zone, employs the IBW PAN method for prediction of wave-induced currents, and computes the sediment transport rates basing on the modified Bijker method.

## 5 CLOSURE

The transition from sediment transport rate to shore evolution is being implemented by simple tools basing on one-line theory, apparently sufficient for this type of gross estimates. At present it is somehow striking to note fairly insignificant changes in the net sediment transport, in the order of 15% per century. It may then be concluded on a very tentative basis that the coast evolution due to climatic changes in wind circulation patterns are less important than the anticipated sea level rise induced changes.

### FORMATION OF DYNAMICALLY STABLE SANDY BEACHES ON THE AMANOHASHIDATE COAST BY SAND BYPASSING

Ikuro Chin<sup>1</sup>, Minoru Yamada<sup>2</sup> and Yoshito Tsuchiya<sup>3</sup>, M.ASCE

#### Abstract

Due to the construction of fishery harbors up coast, severe beach erosion has taken place on the Amanohashidate Coast of Japan, a typical sand spit, resulting in such a reduction of the sand spit that countermeasures have had to be taken. The sand bypass method recently has been used to stabilize the sandy beaches on this spit. Annual change in the configuration of a sandy beach formed between groins first is considered in relation to erosion countermeasures and the sand volume bypassed. We found that the sandy beaches along the Amanohashidate Coast are being formed with little fluctuation at what approaches the stable condition. On the basis of the theoretical background of the formation of stable sandy beaches (Tsuchiya et al.,1993; Tsuchiya,1994), a satisfactory comparison of the actual and theoretical shoreline configurations was made.

Next, alongshore change in the longshore sediment transport rate was investigated in relation to the sand volume nourished and bypassed. We found that when the sandy beaches formed between groins have nearly reached the stable condition, the relation between the longshore sediment transport rate and wave energy power results in an estimated necessary sand volume to be bypassed of  $5,000\text{m}^3/\text{yr}$ . We conclude that in the case of the Amanohashidate Coast, the use of sand bypassing could well form a series of dynamically stable sandy beaches between groins, the sand volume required for bypassing being only  $5,000\text{m}^3/\text{yr}$ .

INTRODUCTION

Results of the most recent survey of the actual state of coastal erosion in Japan show that beach erosion on shorelines forming part of a sand spit has taken place due to the construction of coastal structures that interrupt longshore sediment transport (Uda,1992). Beach erosion also is reported to be actively advancing in many countries of the world (Tsuchiya, 1982). Silvester(1993) has published a geomorphological review that shows that the formation and deformation of sand spits play an important part in the formation and development of barrier beaches. He defines the mode of spit construction and the erosive conditions, and suggests an approach to the control of beach erosion on a sand spit coast.

As seen in Figure 1, the Amanohashidate Coast is a typical sand spit that extends in the direction of the predominant longshore sediment transport in Miyazu Bay.

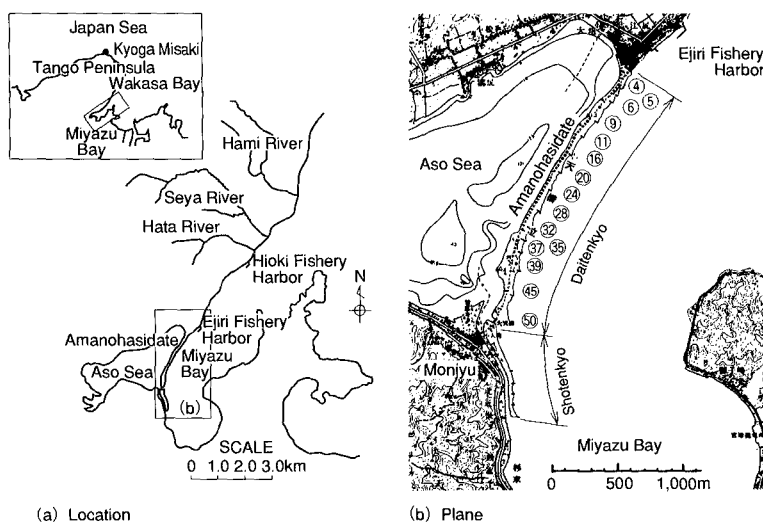

Figure 1. Location and plane figure of the Amanohashidate Coast.

Therefore, if longshore sediment transport is interrupted at an updrift point, beach erosion is inevitable and will take place immediately on the downdrift side of the coast in terms of the continuity of sediment transport. In fact, soon after the construction of breakwaters in both the Ejiri and Hioki fishery harbors upcoast, the natural sandy beaches of Amanohashidate began to be eroded, and groins were erected to protect the shoreline. Recently, beach nourishment and sand bypassing have been applied for the first time in Japan (Yajima,1982; Kuroda,1985). As a result, beautiful sandy beaches have been reformed, as shown in Figure 2. These sandy beaches appear gradually to be approaching dynamic stability. Bypassing the amount of sediment necessary to maintain dynamically stable sandy beaches

therefore may aid in protecting this shoreline, a significant reason for the application of this method.

We here describe the annual change in the shoreline position of sandy beaches formed between groins in relation to changes in the volume of sediment used for beach nourishment and for sand bypassing. The processes by which sandy beaches between groins reach stability are investigated in relation to the theoretical background of the formation of stable sandy beaches reported by Tsuchiya, Chin and Wada(1993) and Tsuchiya(1994) in order to determine the minimum amount of sand to be bypassed.

Figure 2. Formation of a series of sandy beaches between groins on the Amanohashidate Coast.

## APPLICATION OF THE SAND BYPASS METHOD

Three types of countermeasures against beach erosion have been taken on this coast: groins, beach nourishment, and sand bypassing. At present, these three measures used in combination prevent beach erosion, and have re-established sandy beaches. Small and large groins first were constructed about 1955 and functioned for about 25 years; but, they did not prove very effective because the sandy beaches continued to erode, and the sand spit has gradually been reduced. From 1979 to 1985 beach nourishment was carried out and resulted in a shoreline advance of about 20m, sand being deposited on the upstream coast of the large groins and transported sand being accreted along the front edge of the groins. Thus, over the Daitenkyo area of the spit (Figure 1), continuity of sand transport has nearly been accomplished (Kyoto Prefecture, 1987). Since 1985, a so-called "conveyer belt" of sand transport (Bascom, 1970), has been formed, which has increased the feasibility of using sand bypassing. After tests, sand bypassing has been done on a large scale. As of 1992, the total volume of sand nourished and bypassed for a 9-year period was about 120,000m<sup>3</sup>.

## REFRACTION CHARACTERISTICS OF WAVES INCIDENT TO SANDY BEACHES

Past wave data recorded for Miyazu Bay, shows there is a relation between the waves in Miyazu Bay and those in the open sea (Kyoga-Misaki). Of the open sea wave characteristics, the wave periods are of very wide range (significant wave

period  $T_{1/3}=5\text{--}12$  sec), and swells are frequent in the monsoon (Kyoto Prefecture, 1987). These waves pass in through the wave window in Miyazu Bay. In terms of this wave window, however, the relation between waves in the open sea and those in the bay has not yet been determined; therefore, the representative waves coming onto the Amanohashidate Coast can not be specified. In terms of wave refraction and the wave window, we first determine the conditions of the waves incident to the coast that control beach change, then using the specified representative waves, we calculate the wave refraction to obtain the breaker characteristics.

### Observation of incident breaking wave rays by aerial photography

As shown in Figure 1(a), the wave window for the Amanohashidate Coast is very narrow; therefore, limited waves come in to the beach. To predict the breaker characteristics along the beach, detailed calculation of wave transformation is necessary, therefore an aerial observation of the incident waves was conducted (Figure 3). The wave rays calculated by the wave ray method and the wave crest lines observed are approximately orthogonal at the breaking points. This indicates that the calculated wave rays are of sufficient accuracy. The observed wave period is nearly equal to 8.0sec, and wave period at Kyoga Misaki, when the photographs were taken, also was 8.0sec. Waves with the direction of  $N48^\circ E$  off Wakasa Bay were incident at that time, and they were directly incident because the angle of direction is within the range of the wave window of Miyazu Bay.

Figure 3. Wave crest lines taken from aerial photographs.

### Calculation of wave transformation

As to the wave conditions in the deep sea off Wakasa Bay, the incident waves are subjected to angles of direction from N to  $N48^\circ E$ . For the refraction calculations, taking into account the wave window of Miyazu Bay as well as the plane topography, the wave periods used are: a) 10–12 sec, the periods of relatively long waves coming with the swell into the bay for N to  $N35^\circ E$  with the passage of the winter monsoon and b) 6–8 sec, the periods of the wind waves for  $N35^\circ E$  to  $N48^\circ E$ . Results calculated using the detailed bottom topography of the coast, including Miyazu Bay, show that waves from  $N45^\circ E$  to  $N48^\circ E$ , which are within the range of the wave window of Miyazu Bay, come directly in; that the most effective are the waves from  $N45^\circ E$  to  $N48^\circ E$  with a wave period of 8sec and those from  $N40^\circ E$  to  $N45^\circ E$  with the same wave period; and that they are incident to the beach at nearly the same angle. The estimated breaker angles of the incident waves correlate

well with the breaker heights along the beach for a representative wave height of 1.0m offshore of the Amanohashidate Coast.

**ANNUAL CHANGE IN THE SANDY BEACH CONFIGURATION**

Because sediment movement results in beach change, it is important to understand sediment characteristics, in particular the grain size distribution on the beach. Figure 4 shows the median grain size,  $d_{50}$ , of the shoreline sediments, indicating that on the whole the beaches along this coast consist of fine sediments. The alongshore distribution of grain size can be regarded as almost uniform on the coast in the case of the representative season (winter); but, the grain size ranges from  $d_{50}=0.1\sim 0.2\text{mm}$  for the very fine sand of Daitenkryo beach to  $d_{50}=0.2\sim 0.5\text{mm}$  for the somewhat coarse sand of Shotenkryo beach.

Furthermore, as concerns the sediments in the mouth of the rivers flowing into the area upcoast, which are regarded as the source of littoral sediments, their grain sizes, are somewhat coarser than those on the Amanohashidate Coast. Hence, the source sediment can be said to have been transported downstream by the longshore current, producing a fine grain size that is almost the same as that of the sediments brought to the Amanohashidate Coast by longshore sediment transport.

Groins serve as natural headlands that function to control changes in the sandy beach configuration between groins, thereby approaching the condition of beach stability. Using the definition of stable sandy beaches shown in Figure 5 (Tsuchiya,1991), the annual change in sandy beach configuration is obtained in relation to the

annual changes in the sand volume nourished and bypassed. Moreover, the morphological characteristics of stable beaches are obtained. Figures 6 and 7 respectively show the annual changes in shoreline positions and in the sand volume deposited between representative groins.

Figure 4. Alongshore distribution of grain size  $d_{50}$  along the shoreline and at river mouths.

Figure 5. Two kinds of beach form.

Shoreline changes are expressed by the changes in the maximum indentation ratio of the bay ( $y_{max}/L$ ) together with the position. After 1986, little change took place (Figure 6) and the tendency is to approach equilibrium at each headland. In Figure 7, in which the sand volume deposited between groins is plotted as a deviation from the beach formation of 1980~1981, almost the same tendency is shown, although there is some fluctuation. Until 1986, when beach nourishment was actively carried out, the outcome shows large fluctuation. In this case, bottom soundings were made at 10~20m intervals along the shoreline, the level staff method being used for all sections with a water depth shallower than 4.0m.

To show the relationship between the sand volume nourished and deposited in greater detail, the ratio of these values is plotted annually in Figure 8. A ratio of less than 1.0 means that the sand volume deposited is less than that directly nourished, whereas for a ratio of more than 1.0 it is greater. In both cases, with some variation, since 1986 the ratios have been almost constant. The uppermost headland group, Nos.4 and 5 (represented by the star), corresponds to the former case in which almost all the sand nourished is transported as longshore downdrift. That is, under the stationary condition, beaches already have sufficient sand volume, what is called "a feeling of fullness". If an excess volume of sand is supplied to such a beach, the

Figure 6. Annual change in the maximum indentation rate and the position.

Figure 7. Annual change in the sand volume deposited at groins.

Figure 8. Annual change in the ratio of the sand volume deposited to that nourished.

longshore sand transport rate on the downdrift side of the beach may increase. In the latter case of a ratio of more than 1.0, sand transport coming from the updrift side is trapped between the groins, and the beach is nourished naturally under the function of the headland and the action of natural forces even when a lesser volume of sand is nourished directly. This is distinctly seen on headlands Nos.15 and 20.

Figure 9 shows the relation between  $y_{max}/L$  and the sand volume deposited to that nourished for the sandy beaches between the headlands. Changes in all three elements are shown for the headlands selected (only the sand volumes nourished are shown for the other headlands), the numbers indicating the years when the beach sand was nourished. This figure shows changes in  $y_{max}/L$  and the sand volume deposited on the downdrift side of the beach, due to sand fill on the updrift beach: a) the sand volume nourished on the updrift side intricately related to the increase in the sand volume deposited on the downdrift side, and b) the larger the sand volume deposited on a beach, the lower the indentation rate; i.e., the shoreline position advances.

Changes in indentation,  $b/L$ , averaged spatially are shown in Figure 10. The ratio of  $b/L$  decreases as the sand volume deposited increases and generally the shoreline position advances, whereas the ratio tends to be constant once the volume of sediment exceeds a certain limit. Figure 11 shows the annual changes in the shoreline angle,  $\beta$ , on

Figure 9. Annual change in the maximum indentation rate and sand volume deposited.

Figure 10. Relation between the mean indentation rate and the sand volume deposited.

Figure 11. Annual change in the shoreline angle ( $\beta$ ) of the sandy beaches.

the beach immediately on the updrift side of the headland, which depend on the shoreline position and sand volume deposited. Because angle  $\beta$  has remained almost constant since 1986, the beaches have tended to approach the steady state condition with only slight fluctuations.

The most interesting finding here is that there has been no orderly formation of stable sandy beaches from the updrift side. The position of the beaches on the sand spit and the function of the sedimentation between groins, as well as the effects of artificial sand nourishment, may produce a time lag spatially in the formation of stable sandy beaches.

Finally, the maximum indentations  $y_{max}/L$  are compared to the results for morphological characteristics of dynamically stable beaches given in Figure 12. The data representing the relation between  $y_{max}/L$  and shoreline angle  $\beta$  are in good agreement with the lines found by Tsuchiya (1987), further evidence that the sandy beaches between the groins on the Amanohashidate Coast have, to a high degree, already are in dynamically stable conditions.

Figure 12. Relation between the maximum indentation rate on and shoreline angle ( $\beta$ ) of sandy beaches.

**SHORELINE CONFIGURATION AND THE FORMATION OF DYNAMICALLY STABLE SANDY BEACHES**

On the basis of the results found for annual changes in the plane form of the actual shoreline, the beach process of approaching the dynamically stable condition was considered in terms of the theoretical background of stable sandy beaches (Tsuchiya, Chin and Wada,1992; and Tsuchiya,1994). Figure 13 gives a comparison of the actual and theoretical shoreline configurations (theoretical ones, dotted curve) to show whether the sandy beaches have achieved or are approaching stability. The parameters used for the theoretical calculations were estimated from the representative wave breaker characteristics obtained by calculating the wave transformation and from the actual nearshore configuration characteristics obtained in survey of October 1991. These are shown in Table 1. As

indicated by the actual shorelines in Figure 13, the annual sand nourishment and sand bypassing done since 1980, sedimentation between the groins has increased annually, resulting in shoreline advance. In December 1984, the shorelines adjacent to the just updrift sides of the groins reached the tips of the groins. Since then, the shorelines generally have shown an annual advance and have tended to be in the steady state, even though locally there has been some fluctuation.

As to the process of approaching and forming nearly stable beaches, a) the observed shoreline forms are asymptotically approaching the theoretical forms and b) on the whole the two are equivalent, although some differences in local configurations exist because the diffraction effect of the waves due to the presence of the groins was not introduced to the theory. On the basis of all these findings, we conclude that the sandy beaches that presently exist on the Amanohashidate Coast have been steadily approaching the dynamically stable condition.

Figure 13. Comparisons between observed shoreline forms of sandy beaches between groins and theoretical ones.

## ESTIMATION OF LONGSHORE SEDIMENT TRANSPORT RATE

The longshore sediment transport rate,  $Q_x$ , is calculated using the continuity equation for beach change, on the basis of the detailed survey results for beach deformation. Up to 1986 the effect of sand nourishment on the time and spatial fluctuations of  $Q_x$  is large. Results after 1986, which show less fluctuation, were adopted.

Figure 14 shows the alongshore changes in the longshore sediment transport rate under the beach process of approaching a stable sandy beach. The annual sand volume bypassed averages about 5,700m<sup>3</sup>, with little annual fluctuation. There are three types of the alongshore change of  $Q_x$ :  $\partial Q_x/\partial x > 0$ ,  $\partial Q_x/\partial x < 0$ , and a combination of both. The following correspondence exists for these changes, where  $x$  is the coordinate taken to be positive on the downdrift side: first, for periods ② and ③ shown in the figure, there is alongshore change from  $\partial Q_x/\partial x < 0$  to  $\partial Q_x/\partial x > 0$ . In period ② the rate  $Q_x$  decreases toward the downdrift side on the sandy beaches, indicative that on the whole drift sand is deposited on the beaches. On the downdrift groin of No.50, the rate is only 1,000m<sup>3</sup>/yr. In period ③, the rate  $Q_x$  increases on all the beaches, and is 12,000m<sup>3</sup>/yr on No.50. This is because the sand volume deposited during period ② and that bypassed at the beginning of period ③ are both transported as longshore drift sand. In period ④, the regions  $\partial Q_x/\partial x < 0$ ,  $\partial Q_x/\partial x > 0$ , and  $\partial Q_x/\partial x = 0$  appear on the beaches. Note that the fluctuations of  $Q_x$  in alongshore change are greatly reduced as compared to those in periods ② and ③ and, on the average, the rate  $Q_x$  being equilibrated with the sand volume bypassed at any point on the beaches. This indicates that for almost stable beaches even if an unequilibrium occurs in the longshore sediment transport rate, the beaches probably function by themselves, thereby reducing the differences in the rate. That is, a series of groins are considered to serve as headlands that directly control drift sand accretion and erosion in turn and that function organically in the general stabilization of the sandy beaches.

As the alongshore gradient of the longshore sediment transport rate should be related to the magnitude of the topographical beach changes, the alongshore changes in beach sand volume are shown in Figure 15. Although the magnitude of fluctuation differs according to the groin, in general a longshore sediment transport rate with a range of approximately 10<sup>3</sup>-10<sup>4</sup>m<sup>3</sup>/yr responds to fluctuation in the sand volume between groins with an annual

Figure 14. Alongshore change in the longshore sand transport rate.

Figure 15. Alongshore change in the beach sand fluctuation rate.

maximum of  $\pm 1,000\text{m}^3$ . Even though such fluctuations are observed, the annual averaged longshore sediment transport rate (indicated by the broken line in Figure 13) is about  $5,300\text{m}^3/\text{yr}$ , and as uniformly plotted alongshore agrees very well with the sand volume bypassed. From this, we assume that at present the sediment transport system in the Daitenkyo area functions very satisfactorily for the formation of dynamically stable beaches.

To establish both only beach stabilization and the applicability of the sand bypass method using groins, it is necessary to determine the longshore sediment transport rate and to recognize the alongshore change in the course of beach erosion under the continuity of sediment transport. The beach process before 1976 should provide useful information. Figure 16 shows the alongshore change of the annually averaged longshore sediment transport rate, as derived by the procedure described previously that is based on change in the beach sand volume surveyed. The drift sand treated here could not, however, necessarily be specified longshore sediment transport because the entire sand volume carried away from the eroding beaches is taken into account; therefore, offshore sediment transport may be included to some extent in the data given in the figure. We estimate that the sediment transport rate has been as much as  $20,000\text{m}^3/\text{yr}$  on the average, even after small groins were constructed; but, once small and large groins were placed in combination, the rate was reduced to approximately  $10,000\text{m}^3/\text{yr}$ . The value of the spatial gradient of the longshore sediment transport rate is positive everywhere, and it is almost constant, whereas its magnitude tends to be reduced, which corresponds to the progress made in the countermeasures taken against beach erosion. This means that in general sandy beaches in the area of concern, continued to erode and be weakened. These facts led to the very important finding that generally sand bypassing decreases the longshore sediment transport rate to about  $5,000\text{m}^3/\text{yr}$  (as stated above) and that sandy beaches become well stabilized through the alongshore balance of the sediment transport rate.

Taking into account that longshore sediment transport depends substantially on the breaker angle  $\alpha_b$ , the facts discussed above suggest the following: the breaker angle formed before the use of sand bypassing was comparatively large because the beaches had been severely eroded and had a poor-looking, saw-tooth like profile; whereas, after sand bypassing the shorelines have advanced, drift sand has accumulated, and the beaches have become dissipative so that sandy beaches have formed well, decreasing the angle  $\alpha_b$ ; i.e., sandy beaches between groins have

Figure 16. Alongshore change in the longshore sediment transport rate before sand nourishment and bypassing.

oriented their shorelines as parallel to the breaking wave crest as possible, reducing sediment transport. Therefore, in regard to future beach maintenance by means of sand bypassing the following must be considered: Approximately  $5,000\text{m}^3/\text{yr}$  of bypassed sand is considered sufficient to maintain the dynamically stable sandy beaches that presently exist. With regard to appropriate sand volume control, increases and fluctuations in sand drift and beach sand caused by an excess volume of bypassed sand should be avoided. Minimization of the sand volume to be bypassed and fluctuations in the sediment transport rate must also be further considered. To what extent these amounts can be minimized remains to be determined.

## CONCLUSIONS

The main conclusions of our study are

- (1) Sandy beaches that have formed between groins on the Amanohashidate Coast because of the use of sand bypassing have already come very close to being dynamically stable beaches.
- (2) This has been confirmed because in terms of the theoretical background of the formation of stable sandy beaches, the actual shoreline forms surveyed have converged into a steady state with decreasing fluctuations, and the shoreline formation process in general has been asymptotically approaching the theoretical results.
- (3) These phenomena and the relation between the longshore sediment transport rate during the formation of stable sandy beaches and the corresponding magnitude of the sand volume fluctuation, provided appropriate maintenance is not neglected, show that the necessary sand volume to be bypassed is only  $5,000\text{m}^3/\text{yr}$ .
- (4) One criterion of the sand bypassing method therefore, the sand volume bypassed, can be precisely controlled through the formation of dynamically stable sandy beaches.

## ACKNOWLEDGMENTS

We are grateful to Professor Yuichi Iwagaki, Meijyo University, for his valuable suggestions about this research. We also are grateful to the Ministry of Transport for its cooperation in the implementation of this research and for permission to using part of the findings from its surveys of erosion control and shore protection on the Amanohashidate Coast.

## CHAPTER 252

# **The Reconstruction of Folly Beach**

by

Billy L. Edge<sup>1</sup>, Millard Dowd<sup>2</sup>, Robert G. Dean<sup>3</sup> and Patrick Johnson<sup>4</sup>

### **ABSTRACT**

*Folly Beach is an island, nearly 10 km long, south of the entrance to Charleston Harbor. A large beach nourishment plan was planned and conducted to counter the large erosion rates the Island has suffered for several decades. Because of the limitation on operations dictated by the turtle nesting season in the local area, it was required that all construction be completed in one season and extending from November 1 until May 15, 1993. During the construction of the Project, which included 1,908,000 m<sup>3</sup> of material, two very significant winter storms caused some loss of material to the offshore and some damage to the pipeline system. The majority of the material moved by the storm has either migrated back onto the beach or stabilized in a lower part of the subaqueous profile. The success of the first phase of construction of this 50 year project is in many ways attributed to the excellent working relationship between the City of Folly Beach, the Charleston District of the Corps of Engineers and the contractor. The long term success of the project will depend upon the frequency and severity of the storms which attack the project.*

### **BEACH NOURISHMENT AS AN EROSION CONTROL MEASURE**

There have been many designs and attempts to halt erosion along the coast of the United States as well as other nations. In many instances the attempts have been ill conceived and did not perform as expected. One of the most successful approaches to dealing with eroding areas is to provide solutions which are in harmony with nature. The

best solution known today for many of the severely eroding beaches is the addition of sand into the natural littoral system. Although this has been accomplished in rare circumstances by hauling sand from inland borrow pits, the most common methods employ dredging from riverine sources, inlets or from offshore sources. Normally these projects require not only initial reconstruction but periodic renourishment at five to eight year intervals.

According to the Corps of Engineers (1994), the total cost for beach nourishment over the 44 year period of record in 1993 dollars has been \$1,150,000,000 or \$26,100,000 per year. The federal share of beach nourishment costs has been approximately 60 per cent. This report estimates that over the next 54 years, another \$505,000,000, in 1993 dollars, will be spent on future renourishment of these projects. Moreover if all of the other 26 shore protection and beach restoration projects which are awaiting authorization, construction or funding are approved then the total annual construction costs in 1993 dollars would be approximately \$34,000,000. Currently, the United States spends considerably less on beach protection and nourishment than does Germany, Japan, The Netherlands or Spain. The amount invested by the United States in relation to the economic value of the beaches, rated in terms of the income from travel and tourism, is significantly less than that of the countries listed above.

The most well known and successful beach nourishment project in the United States is the Dade County Beach Project near Miami, Florida, where seven million cubic meters of sand were placed. There have been many other projects with nearly equal success save for the stability offered by the magnitude of the nourishment project. A recently completed project at Folly Beach, South Carolina is a good example of a long term erosional beach where the reconstruction of the beach by dredging in the back river has helped stabilize the beach, bolstered the local economy and helped the local environment.

### ***FOLLY BEACH***

Folly Beach is a barrier island near Charleston, South Carolina. The nearly 10 km long island has experienced large rates of erosion of approximately 1.4 m per year for over 100 years. The Island, as shown in Figure 1, is south of the entrance to Charleston Harbor with its deepened channel and jetties extending nearly 6 km seaward.

The Corps of Engineers (1987) estimated that as a result of the completion of the jetties a net southerly alongshore drift of approximately 122,00 to 152,000 m<sup>3</sup>/year has been permanently blocked. They showed that in response to the channel stabilization begun in 1878, the offshore shoals have lost 199,000,000 m<sup>3</sup> of sand resulting in an increase of the wave energy of 100%. A further evaluation of the relationship of the erosion on Folly Island to the navigation project is given in Edge and Dean (1991). The barrier island provides significant public access with two county parks, 50 public accesses with dune walk overs, a fishing pier and both onstreet and public parking lots. The construction of the beach nourishment project was based on cost sharing of 85% Federal and 15% local participation. The local sponsor is the City of Folly Beach. As local sponsor, the City of Folly Beach was involved in the plan formulation, project

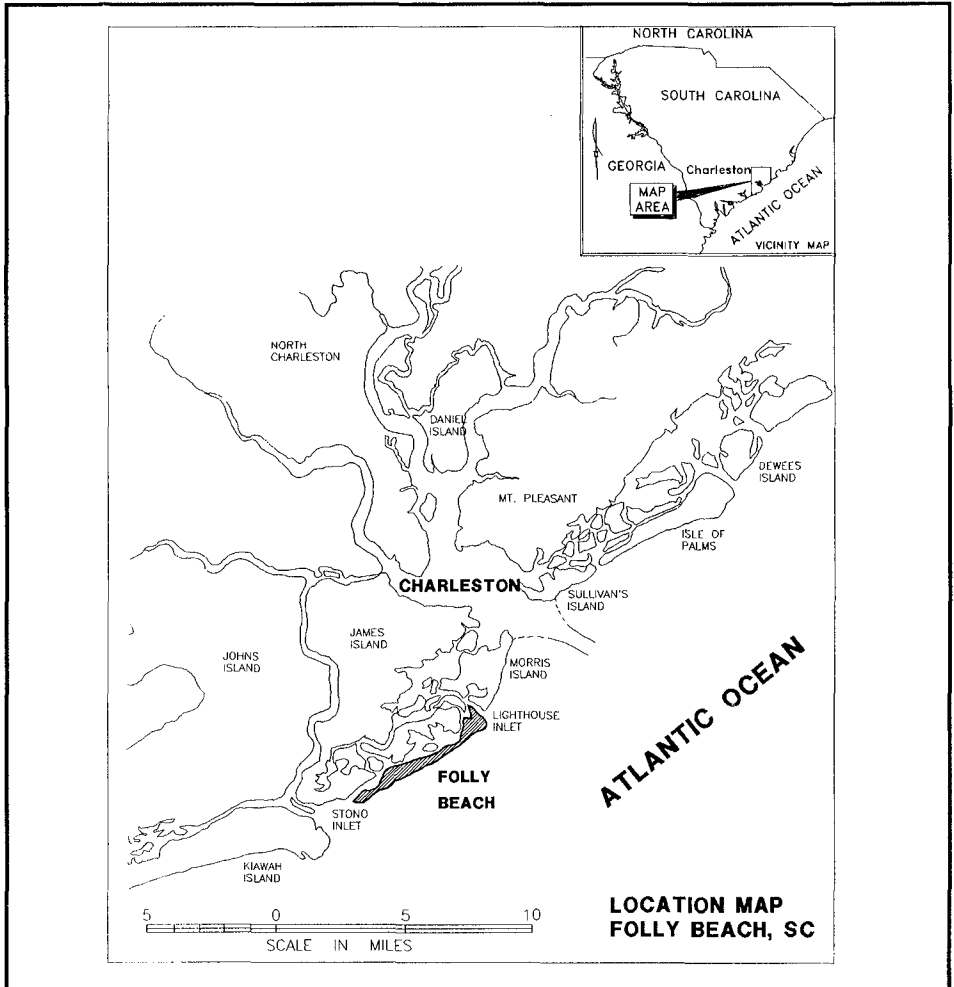

Figure 1. Location map of Folly Beach, South Carolina and the nearby jetties for Charleston Harbor

review and approvals and the City provided all lands, easements and rights of ways for the project. The City is responsible for maintenance of the project and providing the local share for all future renourishment requirements.

### *THE NOURISHMENT PLAN*

The United States Congress authorized a beach erosion project at Folly Beach in 1979. The project was restudied pursuant to Section 501 of the 1986 Water Resources Development Act. In 1988 a Section 111 report was completed which found that 57

percent of the erosion was directly attributable to the Federal navigation project at Charleston harbor. An economic re-evaluation was completed in 1988 and again in 1989 after Hurricane Hugo; the final project was then developed.

The final project design provided for the initial reconstruction of approximately 8.6 km of shoreline and periodic renourishment for a period of 50 years. The plan called for the initial placement of 1,908,000 m<sup>3</sup> of material which would be obtained from the Folly River landward of the Island at the southern end. The design placement quantities ranged from 175 m<sup>3</sup>/m to 250 m<sup>3</sup>/m (70 yd<sup>3</sup>/ft to 100 yd<sup>3</sup>/ft .) The construction section included a storm berm at 2.7 m above MSL with a width of 4.6 m sloping down on a 1:10 grade to a berm at elevation 2.1 m which extended seaward from 18 to 40 m. The native beach sand had a mean grain size from 0.12 to 0.21 mm with a composite of 0.17 mm. Early measurements of the borrow site showed a composite mean grain size, of 0.15 mm.

Final engineering plans were based upon the results of SBEACH and GENESIS simulations performed by the Coastal Engineering Research Center (U.S. Army Corps of Engineers, 1991). Two important results of the model studies indicated that (a) in the area of most severe erosion nine existing groins should be rebuilt to slow the unusually high erosion rate and (b) the project would require renourishment approximately every 5 to 8 years.

### ***CONSTRUCTION***

Because of the requirements that all construction be completed in one season between November 1 and May 15, the number of potential contractors who could meet these special requirements was limited. The limitation on operations was dictated by the turtle nesting season in the local area. Moreover, because of environmental concerns and the location of the borrow area, the contractor would have to pump up to a distance of approximately 12.5 km. There were only three contractors which bid on the project. In the Fall of 1993, a separate contract was let for grassing the dune at a cost of approximately \$260,000. Engineering, land acquisition, environmental studies and other miscellaneous costs were estimated at \$3,227,650. The 50-year cost of the project is estimated to be \$115,000,000. During the initial construction, several winter storms occurred but two were significant and caused production to cease. Both storms caused major relocation of up to 6 km of pipeline and claims for loss of material and time. The second storm on March 12 - 14, 1993, was called the "Storm of the Century." That storm created hurricane force winds along much of the Atlantic seaboard.

### **THE SOLICITATION**

As previously noted, the most limiting factor facing the potential contractor was the requirement that the total beach fill placement and groin construction be completed by May 15, 1993. This date represented the beginning of the nesting and hatching season of the Loggerhead Turtle. This requirement forced construction to be performed in the winter months thereby ensuring the most extreme weather conditions under which to

do the dredging and other construction. The third factor was the entire issue of dredge pipeline; the length of line required to effect placement of the fill; the limited space available for maneuvering with and storage of more than 9.1 km of shorepipe; and requirements for transporting the shorepipe to the site by truck due to bathymetric conditions surrounding the shoreline of the island and the lack of commercial dockage available.

The bid opening was held on November 9, 1992, one month after the solicitation. A comparison of the bid amounts submitted by each contractor for the major features of the contract is shown in Table 1.

**Table 1. Folly Beach Contract Bids**

Item	Bidder 1		T. L. James & Co.		Bidder 3	
	Unit price	Total \$US	Unit price	Total \$US	Unit Price	Total \$US
Mob & demob for dredging		1,038,500		1,500,000		800,000
Mob & demob for beach fill placement, groin demolition & new groin construction		100,000		13,050		16,000
Beach fill (m <sup>3</sup> )	4.47	8,550,000	2.52	4,825,000	3.33	6,375,000

### THE CONSTRUCTION PLAN

Concerns were expressed relating to the issue of quantity, delivery, storage, and placement of the various types of pipeline necessary to transport the material from the borrow area to the beach. The lack of any moorage deep enough to serve a fully loaded pipe barge and the spatial constraints that existed on the island adjacent to the beach

would force the Contractor to haul the 650 pieces of 15 m shorepipe to several small pipe laydown areas strategically placed along the beach. Unloading equipment capable of handling these pipes in such constrained conditions had not been included in the estimate, creating an unforeseen cost. Also the designated pipeline route from the borrow site to the beach required that over 600 m of shore pipeline be located in extremely shallow water through an existing marsh to a shore connection.

The hydraulic cutterhead dredge, *Tom James*, was used for the project. At the center of the pumping system of the *Tom James* is a 16 cylinder Enterprise diesel delivering up to 6000 shaft hp to a centrifugal pump. The pump has a 91 cm suction and a 76 cm discharge and could house impellers ranging from 210 to 240 cm. Based on hydraulic models of the dredge and booster system it was empirically determined and endorsed by historical performance that a 213 cm impeller could be used. The dredge had been dredging at depths of up to 15 m on the Mobile River and was equipped with a 30 m ladder. Based on the vertical limit of dredging allowed within the borrow area at Folly Beach, the decision was made to replace this ladder with the 20m ladder available in Houma, LA. Both ladders supported the 1800 hp ladder pump used to improve the pumping capacity of the main pump. The dredge was returned to the Houma Yard and the short ladder was installed in Mobile. On Dec. 18, 1992, refitted for the Folly Beach, the dredge and attendant plant, along with 700 m of floating pipeline began towing, via the Gulf Intracoastal Waterway, to Folly Beach.

The dredge arrived on site on December 30, 1992, and began preparations to begin dredging. The Plan of Operation submitted to the Corps indicated that dredging would begin at Station 0+00 proceeding in a northerly direction. The dredge was to make two 60 m cuts from Station 0+00 to Station 52+00, three 60 m cuts from Station 52+00 to Station 78+00, and four 60 m cuts from Station 78+00 to the limit of borrow at Station 115+00. (Note that stationing is in the original units of feet as specified in the contract plans.) As also dictated by the contract, the borrow site was to be excavated to a maximum depth of 5.5 m MLW in the first two designated reaches and 6.1 m MLW in the last reach.

A 3050 m submerged line was installed from the borrow area to the south end of the island where it connected with 9750 m of shorepipe. A shore connection was made at Station 91+00S. Starting at this location and pumping northerly conserved 500 m between Station 91+00S and the south limit of work at 107+00S to be used to prevent a shutdown in the event of damage to the pipeline on the beach or the installation of the booster. The flow from the 76 cm ID discharge pipes was trained by a 330 m levee located along the approximate break point of the berm. The trained flow of the effluent slurry served to maximize the retention of material, thereby increasing the efficiency of the dredging process while simultaneously minimizing the loss of the material placed in the surf zone. Stationing of the project and the location of the borrow area are shown in Figure 2.

Equipment for the beach fill operations was hauled by truck to the project. In accordance with the proposed plan of operations three bulldozers, two Caterpillar D6H LGP and a Cat D6D LGP were used to manage and dress the fill. Two Caterpillar 518S

Corps chose to control the quantity of required fill at any given point along the beach. Although design templates for various portions of the project were included in the project plans, these templates were not the conventional static geometry. The templates were instead, dynamic, holding constant the total number of cubic meters of fill for each linear meter of advance; adjustments in the width of the berm were made to compensate for changes in the required quantity. This approach, while rendering a more finite and predictable final fill quantity, substantially complicated both the placement of the fill and the computation of the pre- and post dredging volumes.

Specifications required that both pre and post dredging surveys be taken in the form of cross sections at a frequency of 30 m intervals, normal to the project baseline, with no more than 7.5 m between individual measurements. These cross sections were taken within five days prior to the time of placement of the fill and as soon as practical after the placement of the fill. The cross sections were taken by conventional leveling techniques beginning 15m landward of the project baseline and extending seaward until the -1.0 m NGVD<sup>5</sup> contour was reached.

Seaward from the -1.0 m contour to a point 460 m distant from the project baseline, cross sections were taken with echo sounding instrument. This task was complicated substantially as a result of the vertical oscillations of the survey vessel between the crests and troughs of the waves. Under these conditions conventional hydrographic survey procedures for correcting data for the effects of tide and draft would yield grossly unreliable and nonrepeatable measurements. The Contractor used a "surf boat" for data collection. The surf boat system consisted of a 6m, broad beam skiff equipped with a Del Norte DMU 547 Microwave Positioning System for horizontal positioning, an Odum Echotrac 3100 semi-portable fathometer using a dual frequency 24/208 Khz transducer for vertical measurement, and a 486DX laptop computer installed with data collection software developed by the Contractor.

The unique feature in the surf boat system was the method by which compensation for heave was made. A Spectra-physics Laserplane<sup>TM</sup> plane laser was placed above a point of known elevation, NGVD datum, and an height of instrument taken from the point to the infrared light beam. As a data collection event occurred, a differential measurement between the bottom of the receiver mast and the point at which the receiver mast was intersected by the beam was recorded. This differential measurement combined with the known distance from the bottom of the mast to the face of the transducer and the depth measurement, defined the vertical component of the measurement as an elevation relating to project datum.

### **DEMOLITION AND CONSTRUCTION OF GROINS**

Prior to construction, the remains of nine timber groins existed just north of the Holiday Inn site from project Station 1+50N to 49+60N. The nine groins were from 100-150 m in length with a total of 100 m required to be moved. The removal of these groins and any other remains of old structures immediately adjacent was necessary for

---

<sup>5</sup> NGVD represents approximately mean sea level.

driving new sheetpiles to replace the wooden groins. The removal of these structures required the handling of old creosote pilings.

The new groin design consisted of steel sheet pilings driven into the ground at  $\pm 0.3$  cm vertical tolerance. The soils adjacent to the sheet piling were to be stabilized using a layer of geotextile covered by a layer of blanket stone and subsequent layer of armor stone. Much of the existing armor stone surrounding the existing timber groins was recovered and reused. The stones were laid so that they would interlock creating a surface less susceptible to movement by wave action. Lastly, a steel reinforced concrete cap was installed on top of the steel sheet pilings.

A vibratory hammer was used to drive the sheet pilings. The pile driving was vertically controlled by the use of a teflon-coated dual template allowing 6 m sections of piling to be driven at one time. When pile driving on an individual groin structure was completed, forming and pouring of the concrete cap was done. Finally the placement of the geotextile and stone work was performed using a 690LDC and a 890JD John Deere trackhoe and two John Deere 544 front end loaders. In addition to the problem of limited workspace and times available for working, the tidal and wave action created erosion problems adjacent to the groins far in excess of what the contractor expected for this type of construction.

#### **DREDGING AND PLACEMENT OF BEACH FILL**

In addition to the hydraulic dredge, *Tom James*, provision was made in the estimate to allow for the use of the *Atlas Booster* should the required line lengths on the north end of the project hinder production to such a level so as to jeopardize completion before the May 15 deadline. A comprehensive selection of peripheral equipment comprising the attendant plant was also delivered. Two 900 hp tenders and a smaller 600 hp tug were used to move and position the dredge within the borrow area, handle pipelines, and shift swing anchors as advance in the cut dictated. Also accompanying the dredge were two "skadgit" stiff leg derricks, a 10,000 lb. crane, and numerous barges employed in fuel and water storage, raw materials supply, welding, and pipe barges.

The dredge was placed in the southwest portion of the borrow area and was hooked onto the shortest length of pipeline for the project. A wye valve was placed at the end of the shore connection. This wye valve allowed the fill to proceed either north or south as needed. On January 12, 1993, the dredge began pumping material from the borrow site and placing it on the beach at Station 91+15S and advancing in a northerly direction. The dredge was positioned at Station 57+00 in the borrow area and began pumping through 2865 m of pipeline with a velocity of 3.4 m/s. Dredge positioning was performed by the Del Norte DMU 547 Microwave positioning system.

The dredge was equipped with a six blade serrated cutter ideal for the sandy conditions encountered in the borrow area. Although borings taken prior to dredging indicated that sufficient material of acceptable quality was available within the borrow area, as the dredge moved north several areas yielded high shell content. These shell deposits had a negative effect on production. Adjustments were made in dredge position as these areas were encountered.

Near the end of February, the contractor realized that using the *Tom James* alone to complete the project would jeopardize the timely completion of the contract. The decision was made to use the 3600 hp *Atlas Booster*. Arrangements were made and the booster was towed to the site. As pipe line length approached 7600 m, production continued to drop off at a progressively greater rate. On April 19, 1992, the booster was installed at a point 1220 m down line of the dredge. Though not immediate, the result was impressive. The production rate is shown in Figure 3. The upper line represents gross output at the borrow site and the lower line represents the net output on the beach. The booster pump was placed on line when the line reached about 7,300 m (24,000 ft). Small mechanical repairs and adjustments to the new hydraulic system improved the production from 1140 m<sup>3</sup>/hr. to 2430 m<sup>3</sup>/hr. This system was maintained until the terminus of the project, Station 175+00N, was reached on April 17, 1992. Once pumping was completed to the northern limits of the project, the pipeline was pulled back to refill the area between the newly constructed groins. Also remaining to be pumped was the 500m south of the initial starting point at Station 91+00S. On April 29, 1993, the dredging was completed and demobilization from the site was begun.

Dredge production on the project was estimated at 1,300 m<sup>3</sup>/hr yielding 26,000 m<sup>3</sup> for each day of operation. The dredge operated a total of 72 days without a booster and twenty-nine days with the booster pump in operation. In the final analysis, the dredge pumped on the project 101 days for the original contract amount plus an additional 126,160 m<sup>3</sup>. This represents a daily production of 20,300 m<sup>3</sup>. Approximately 2.7M m<sup>3</sup> of borrow material was removed to place 2.0M m<sup>3</sup> of material on the beach. This represents an overfill ratio of 1.4.

The distribution of non effective time during production is given in Figure 4. It is obvious that a large amount of non-productive time was created by adding or moving beach pipelines and pipelines to the dredge. Weather was not a significant factor as was originally considered and did not cause appreciable down time.

As the end of the project approached preparations were made to commence tilling in areas where the fill had a compaction of greater than 500 psi. The compaction measurements were taken with a cone penetrometer between the seaward side of the storm berm at elevation 2.7 m NGVD and the high tide line. A total of five tests were taken at 61 m intervals for each 305m acceptance reach within five days of the placement of the fill. Areas not meeting the criteria defined above were required to be tilled to a depth of 0.9 m. On April 22, 1992, tilling of areas determined to be deficient commenced using a D8D equipped with a clearing rake. The tines on the rake were marked with paint at .9m to guide the operator. On May 8, 1993 tilling was completed.

### **STORMS DURING CONSTRUCTION**

After eighteen days of continuous production, a major winter storm occurred on 5-7 February 1993. The storm surge reached 1.5 m NGVD with waves of 1.5 to 2.4 m (Ebersole, Nielans and Dowd, 1995). The storm caused severe damage on property in the community and did considerable damage to the fill being placed on the beach. The fill operations were approaching the seawall fronting the Holiday Inn in the vicinity of

Figure 3. Production rate of *Tom James* versus length of pipeline.

Station 12+00S when the storm commenced. Contract specifications required that only 114 m<sup>3</sup>/m be placed against the concrete seawall in front of the Holiday Inn in an area of severe erosion. The resultant narrow berm width provided insufficient space to operate the equipment necessary to accomplish the fill operation. These contradicting requirements, one contractual and one practical, required that placement of a quantity of material far in excess of the design fill in order to create a berm with adequate width to facilitate the continued operation of the tractors.

As the storm built to full intensity, the waves began to severely erode the newly placed fill. By the next day conditions had worsened. The dredge continued to pump; however, the purpose was no longer to fill to required line and grade but to maintain the integrity of the pipeline. As the storm intensity increased these efforts were proven to be ineffective. In the afternoon of February 6 the shorepipe, now resting on bare rock, was broken apart by the pounding surf. Damage to the beach between Stations 11+50S and 6+50S was extensive. Pieces of 15 m shorepipe, dislocated and tossed in the surf, were strewn about on the beach. The portions of the pipeline not broken apart, once straight, now meandered up the beach. Shore crews recovered the loose pieces of pipeline and, at the direction of the Corps of Engineers removed the pipeline back to Station 11+50 and began refilling the area.

A second major storm occurred on March 3 and 4 with a maximum storm surge of 1.4 m NGVD and waves of 1.5 to 2.1 m. This storm created additional losses with most located at the seawall in front of the Holiday Inn. The third and strongest storm occurred on March 12-14 with wind gusts up to 35 m/s (Ebersole, Neilans and Dowd, 1995). This storm, called the "Storm of the Century," caused a storm surge of 1.4 m

Figure 5. Distribution of non-effective time for *Tom James* during construction

above NGVD with large waves. The contractor continued pumping throughout the storm to keep the pipeline full of water. There was much erosion of the placed material because of this storm.

The last storm resulted in the loss of 25,000 m<sup>3</sup> of material as well as the destruction and/or replacement of 200 m of pipeline. In addition to these losses the contractor also requested fair compensation for the additional 156,000 m<sup>3</sup> of fill required to create an adequate berm for sustaining the fill process.

### ***MONITORING***

As noted previously, surveys were conducted within one week prior to placement and immediately after the profile was constructed. Thus the total sand placed and remaining in the section out to -9 m NGVD was captured. Following the first and third winter storms, surveys were completed which showed the loss of some material and the redistribution of other material. After project completion, semiannual surveys have been conducted across the profile at 31 stations to closure depth. These surveys are part of the statewide monitoring program.

Figure 5 shows a comparison of the volume of sand which was placed on the beach with the design quantities specified in the construction plans. Note that the plans only allowed 114 m<sup>3</sup>/m (45 yd<sup>3</sup>/ft) at the seawall fronting the Holiday Inn in the center of the City. The Holiday Inn property had an existing seawall jutting seaward of the adjacent properties and the design was selected to only provide as much sand as necessary to carry the dredge pipe on the ocean side of the wall. Moreover, the project design

considered that the primary objective was shoreline protection and the seawall at the Holiday Inn did not require any additional protection by the new beach. The Holiday Inn is located approximately between stations 15+00S and 5+00N. Center Street in the City of Folly Beach was used for the 0+00 in the construction stationing. The quality of the material obtained from the borrow area was compared with the native beach material and it was determined that the borrow material when placed on the beach had a  $d_{50}$  equal to or greater than the native beach material at the time it was sampled.

### BEACH RESPONSE

The most obvious change in the beach profile since construction has been by the waves in the two large winter storms between the end of construction and January 1994. These storms caused the movement of sand from the dry sand beach to the offshore area. Surveys show that the sand did not disappear; where the contractor placed 225 m<sup>3</sup>/m of sand initially, 225 m<sup>3</sup>/m of sand remained in the section although some of it did move to between 1 and 4 m below mean sea level. This adjustment of the beach fill generally occurs more slowly over a period of 12 to 18 months with the resulting dry sand beach being about 45% as wide as the newly placed sand after the adjustment period. It is expected however, and the early data indicated this to be true, that the profile will

Figure 5. Comparison of the design (dark line) and the actual placement quantities.

continue to recover until by the end of the 1994 summer season it should have nearly 45% of the predicted initial equilibrium profile. As the beach fill ages there will be long-shore movement of the material as well. In fact the surveys and observations of 1994 indicate a movement of the material in the area of the "washout" to the northeast and somewhat to the southwest. As of July 1994, 95% of the placed material was accounted for within the limits of project construction according to Ebersole, Neilans and Dowd (1995).

Figure 7 is represents the movement of the mean high water line over the period of July 1993 until January 1994. Note that the stationing is taken from the most south-westerly end of the project. In the figure "HI" represents the location of the Holiday Inn. This figure shows the relationship of the shoreline position to the project baseline so the results of position are all relative to the baseline. It is interesting to note that there has been recession of the mean high-water line in general all along the beach and that two areas have particular features. The first area is the Holiday Inn area where after the first winter storm, the shoreline moved landward as far as the seawall where it cannot approach the baseline any closer. The second area of interest is at the "washout" where the sand moved both offshore and probably alongshore to the northeast between the first and second surveys.

Figure 8 shows the same information in the form of shoreline advance/erosion over the period of record. Although the general trend is toward erosion it must be remembered that these surveys only show the response of the summer post nourished beach to the winter storm season. As noted previously, the beach is adjusting and "hot spots" are appearing as the sediment moves alongshore and equilibrates by moving out into the equilibrium profile further from the baseline. Surveys are being taken quarterly to track the movement of the sediment. The quarterly surveys are being correlated with tide and wave records.

### ***PERFORMANCE PREDICTION***

The performance of a beach nourishment project is dependent upon the quality and quantity of sand placed, presence of stabilization structures, project length, the wave climate that tends to spread out the sand along the beach and the background erosion rate, which in this case, is primarily due to the interruption of the longshore sediment transport by the Charleston Entrance jetties and navigational channel. Project performance may be considered in terms of: (1) the equilibrium beach profile formed and the associated dry beach width, and (2) the spreading out of the sand in the longshore direction. Based on equilibrium beach profile concepts, the equilibrium additional dry beach width would be less than 10 m compared to 22 m if the native and borrow sand sizes had been equal. Considering a representative wave height of 0.9 m, based on the Wave Information Study (Hubertz, et al., 1993), the time required for the project to lose 50% of the material placed is approximately 4 years. Of course, the losses near the ends of the project at any one time will be much greater than the average. The monitoring results will be compared to the predicted profiles after the first annual surveys are completed.

Figure 7. Shoreline position relative to the project baseline showing response to winter storms.

Figure 8. Change in shoreline position between the periods of July-Oct '93 and Oct-Jan '94.

### ***SUMMARY***

The reconstruction of Folly Beach is an example of the success of a dredging - beach nourishment - project which was successfully completed within the environmental constraints of winter conditions, very short time windows, and large pumping requirements. The success of the project is in many ways attributed to the excellent working relationship between the City of Folly Beach, the Charleston District of the Corps of Engineers and the personnel of T. L. James & Company. The long term success of the project will depend upon the frequency and severity of the storms which attack the project.

## CHAPTER 253

### **The Complementary Interaction between Beach Nourishment and Harbour Management : Four Cases in Spain**

**Gregorio Gómez-Pina (\*) & Jose L.Ramírez(\*\*)**

#### **ABSTRACT**

This paper describes several results on beach nourishment and harbour management interaction, within the authors' area of responsibility. These positive results show the socio-economic benefits which can be achieved through effectively combining harbour and coastal requirements.

#### **1.- INTRODUCTION.**

Although harbour works have sometimes produced negative effects on the coast, there can be works which, by combining harbour and coastal requirements satisfactorily, could improve the scenario which exists in some coastal areas adjacent to the harbour. In particular, harbour dredged material, if adequate, should be used for beach nourishment and/or littoral drift restoration. Also, Coastal & Harbour Authorities should work in coordination from the initial stages of the projects where a combined design could satisfy the objectives of both parties.

#### **2.- OBJECTIVE.**

The main objective of this paper is to describe several positive results of beach nourishment and harbour management interaction, which have been achieved within the authors' technical area of responsibility, at the Spanish Coast Directorate (MOPTMA). These cases have been chosen to demonstrate the socio economic benefits which can be achieved through effectively combining harbour and coastal requirements.

---

(\*) Civil Engineer, MSc Ocean Engineering, Coastal Project Manager, Area I, General Directorate of Coasts; Address : Dirección General de Costas, Ministerio de Obras Públicas, Transportes y Medio Ambiente (MOPTMA), Paseo de la Castellana 67, 28071 Madrid, Spain.

(\*\*) Technical Civil Engineer, Projects & Works Division, Area I; Same Address.

Although at the time of writing the first abstract our intention was to describe four Spanish cases, we have added one more case which we found interesting within the scope of this paper. The main points of this paper are the following : I.- Effects of Harbour Works on the Coast. (Some examples of "uncoordinated works"). II.- Positive Results of Coordinated Works. III.-Conclusions and Recommendations.

### **3.- EFFECTS OF HARBOUR WORKS ON THE COAST.**

(Some examples of "uncoordinated works").

Before showing the positive results of coordinated works (which is the main object of this paper), we would like to show, as an example, some pictures related to what we could call "uncoordinated works" in Spain. The negative effects on the coast produced by the construction of harbour breakwaters are classic topics in Coastal Engineering and can be found all over the world.

Typical negative effects which the presence of harbours cause on the coasts could be the following: A) Littoral Drift Interruption B) Beach Change Induced by a Harbour and C) Effect of Wave Reflection on the Coast Induced by a Harbour Breakwater. Fig.1 depicts a view of Almerimar Marina, located in the Almerian coast. Note the interruption of the littoral drift and the improper design of the marina entrance.

Fig 1. A View of the Effect Caused by the Littoral Drift Interruption.  
(Almerimar Marina, Almerian Coast)

Fig.2 shows the destruction of the seafront due to the coastline erosion caused by the negative effect produced on coast by the construction of the aforementioned marina.

Fig.2.- Erosion Caused by Littoral Drift Interruption.

In Fig.3 the siltation at the entrance channel is clearly indicated "on site" by the length of the first author's kayak paddle.

Fig.3.- Siltation at the Marina Entrance Channel.

#### **4.- SOME POSITIVE RESULTS OF COORDINATED WORKS**

A summary of the cases of positive results of coordinated works is shown below:

##### **A.-DREDGING WORKS**

- 1.- HARBOUR ENTRANCE CHANNEL DREDGING AND URBAN BEACH NOURISHMENT (Cádiz Harbour and Urban Beaches)
- 2.- HARBOUR ENTRANCE CHANNEL DREDGING AND LITORAL DRIFT RESTORATION (Huelva Harbour-Playa de Castilla Beach)

##### **B.- COMBINED HARBOUR/BEACH DESIGN**

- 1.- A DESIGN WHICH COMBINES A SHELTERED INNER HARBOUR BASIN AND A NEW URBAN BEACH (Algeciras Harbour-La Línea Beach)
- 2.- A DESIGN WHICH COMBINES AN EXISTING INNER MARINA BREAKWATER AND A NEW URBAN BEACH (Gijón Marina-Levante Beach)
- 3.- CREATION OF BOTH BEACH AND HARBOUR (Luanco Beach and Harbour)

The first point deals with harbour dredging and how the dredged material was used : urban beach nourishment and littoral drift restoration.

In the second point Coastal & Harbour Authorities coordinated the combined design of harbour and coastal works.

## **5.- DREDGING WORKS**

### **5.1.- GENERAL**

Traditionally the dredging of a harbour channel was a matter which concerned only Harbour Engineers. The different phases of the dredging projects were mainly carried out focussing on harbour engineering requirements.

Years ago, the question of whether or not the sand in a harbour channel could be suitable for a possible beach nourishment or for a littoral drift restoration project was not a concern of the Port Authority.

In other words : the countless millions of cubic meters of sand regularly wasted in dredging operations might have been more suitably used in beach nourishment or littoral drift restoration projects if Maritime Civil Engineers at that time had been more aware of the importance of combining both harbour and beach considerations.

Speaking in general terms, harbours need more water depth for their extensions and the coastline will benefit with beach nourishment. To obtain a real benefit, dredged materials should accomplish the following requirements :

a.- Dredged Material Quality.

b.- No Negative Effect on the Coast.

c.- Proper Attention to Archeological Artifacts (if applicable).

Harbour and coastal engineers should "coordinate" their works from the initial stages of the project.

Multidisciplinary teams (marine biologists, geologists and archeologists, as well as environmental and landscape specialists) should participate during the different phases of the projects.

## **5.2.- HARBOUR ENTRANCE CHANNEL DREDGING AND URBAN BEACH NOURISHMENT: CADIZ HARBOUR AND URBAN BEACHES.**

The need to dredge the entrance channel in Cádiz Harbour, together with the loss of dry beach width, at the popular urban beach of La Victoria under normal daily high tide conditions, prompted the Spanish Directorate of Ports and Coasts to plan a joint project looking at both harbour and beach requirements.

Furthermore, two other very popular urban beaches, Santa María del Mar (adjacent to La Victoria Beach) and La Caleta, were nourished. It should be noted that this was the first time in Spain that a dredging project of such importance (more than 6 million m<sup>3</sup>) was planned fulfilling both harbour and coastal engineering needs.

Due to the great historical importance of Cádiz bay, archaeological works were also carried out by specialists during different phases of the project, recovering more than 5.000 artifacts, mainly coins.

The sand volumes needed for the nourishment of the aforementioned beaches were (1.730.000 m<sup>3</sup> in project). The total project budget was 3.900 Mill. Pts.

In order to identify suitable borrow areas for beach nourishment, specific survey, geophysical, vibrocoring and biological studies were undertaken by the Coastal Project Division of the Spanish Ministry of Public Works and Transportation (MOPTMA). Also, specialists carried out submarine prospects to investigate the existence of valuable archeological deposits.

Owing to the location of La Victoria beach and Cádiz Harbour, it was necessary to lay a 90 cm diameter pipeline from the La Cabezuela inner quay, where a barge was loading sand from the dredge, to the beginning of La Victoria beach. The sand by-passing works had to pass over the main motorway and a train line to reach the beach, using approximately 5 kilometers of pipeline.

Two modern trailing hopper dredgers ( ANTIGOON AND HAM 310) were used, the former performing 90% of the work. The average sand nourishment ratio was 45.000 m<sup>3</sup>/day. The fact that only 0.75% of the volume was refused for beach nourishment indicated the efficiency of the preliminary studies and dredging operations.

The selective channel dredging plan obtained from vibrocoring studies enabled the coastal project engineers to use different grain size diameters depending on wave exposure location :  $0.2 < D_{50} < 0.30$  mm, for most of the beach and  $0.30 < 50 < 0.30$  mm, for the relatively more exposed Northerly final part of the beach.

The initial colour of the sand (apparently very dark) changed very quickly into the same nice colour as the native sand, as soon as the dumped sand dried and oxidized, as was expected. Otherwise, the beach nourishment project would not have been a succes popularly speaking.

A three year field monitoring program is being carried out to obtain a better understanding of the La Victoria beach behaviour, with respect to the littoral processes and coastline kinetics. This will aid coastal managers to adopt effective coastal management strategies regarding beach stability.

The following picture depicts an aerial view of La Victoria Beach under daily high tide conditions. Notice the occupation of the former dune by high buildings and the seafront as well as waves impinging upon the vertical face of the sea-front.

Fig.4.- A detail of the La Victoria Beach under Daily Tide Conditions Prior to Beach Nourishment.

The following pictures show the general dredging plan for beach nourishment, as well as a detail of the beach width (Notice the blocks used to protect the seafront from waves under daily high tide conditions).

Fig 5.- General Dredging Plan for Beach Nourishment.

Fig 6.- La Victoria Beach after Beach Nourishment.

### **5.3.- HARBOUR ENTRANCE CHANNEL DREDGING AND LITORAL DRIFT RESTORATION ( Huelva Harbour-Playa de Castilla Beach).**

The Huelva Harbour Authorities have recently carried out a project to dredge the main harbour entrance channel. Approximately 5 million cubic meters of sand could be adequate for beach nourishment. Presently Coastal Authorities are studying the feasibility to build a submerged bar at -4 m. water depth to restore the littoral drift interrupted, among other causes, by the Huelva Harbour breakwater. These works will enhance a previous littoral drift restoration project carried out at the adjacent beach, Playa de Castilla (Refer.1, 2 & 3), where 1.5 million cubic meters of sand were supplied to form a protruding area, aimed at restoring the net littoral drift balance. The following picture depicts the erosion existing at the end of Playa de Castilla, in Matalascañas Beach. It should be noticed that this erosion is also caused by the former construction of a seafront and buildings on the dune.

Fig.7.- Erosion at the End of Playa de Castilla (Matalascañas Beach)

## **6.- COMBINED HARBOUR AND BEACH DESIGN**

### **6.1.- A DESIGN WHICH COMBINES A SHELTERED INNER HARBOUR BASIN AND A NEW URBAN BEACH.** **(Algeciras Harbour and La Línea Beach).**

The need to provide a sheltered inner basin in Algeciras Harbour was combined with the creation of an urban beach in great demand by the La Línea city's population. The following picture shows an aerial view of the works.

Fig.8.- A view of La Línea Beach Restoration.

### **6.2.-A DESIGN WHICH COMBINES A SHELTERED INNER HARBOUR MARINA AND A NEW URBAN BEACH (Gijón Marina-Levante Beach).**

An urban beach and seafront were designed taking advantage of one of the marina's existing breakwater (Fig.9). Navigational and sedimentation problems at the marina entrance channel were two important problems taken into consideration, as well as the overall integration of the beach design into the existing urban development. In this case the Gijón Harbour Authorities were responsible of the whole project and work. The technical staff of the Coastal Authorities cooperated during different stages of the project.

The geophysical studies carried out by coastal specialists were used by the Gijón Harbour technical staff to determine the potencial sand reserve areas, after undergoing vibrocoring and biological studies. These latter studies were very beneficial to Coastal Authorities to plan future beach nourishment projects along the Asturian coastline, and in particular for the next case of Luanco Beach.

The project consisted of the construction of two breakwaters and the dumping of 380,000 m<sup>3</sup> of sea bottom sand. It was necessary to dredge 17,000 m<sup>3</sup> of rock, as well as to demolish 32,000 m<sup>3</sup> of an existing seawall protruding into the sea. The project cost was 1,000.000.000 pts. The projected magnitudes obtained for the new beach are the following : HTWL beach : 60,000 m<sup>2</sup>; (3 m<sup>2</sup> /p); 20,000 people; M.T.W.L. beach : 100,00 m<sup>2</sup> ; (3 m<sup>2</sup> /p) 33,000 people. Breakwaters'length: 400 m; Seafront length: 800 m.

Fig.9.- A Composite Aerial View of Gijón Marina & Levante Beach

Next figure shows aerial views just after project completion.

Fig.10.- Aerial Views after Project Completion.

### **6.3.- CREATION OF BOTH BEACH AND HARBOUR** **(Luanco Beach and Harbour).**

This final case is the creation of both beach and harbour in Luanco (Asturias). The harbour has been designed by the Asturian Ports Division and presently there are local discussions about the feasibility of its construction. Since the construction of a lateral groin was considered necessary to create a new beach, the design of the beach was carried out taking into account the geometry of the future harbour. A relatively low-crested groin was designed in order to achieve the minimum visual impact. The section of this groin could be enlarged as a part of the outer harbour breakwater. Fig 11 is an aerial view of Luanco; note the scarce existing beach. The cost of the beach restoration has been 120 million pts. A sea front has also been designed to restore and integrate the maritime facade. Both projects are expected to be completed by the summer of 1995.

Fig.11.- An Aerial View of Luanco (Asturias).

Fig.12 schematizes the combined beach & harbour design.

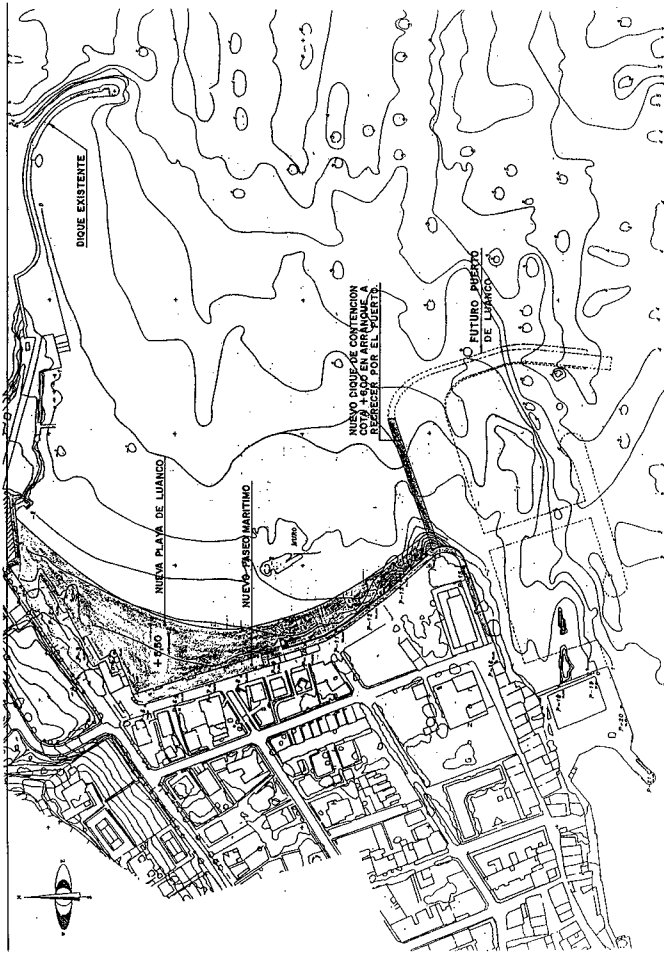

Fig.12.- Projected Luanco Beach .

## **7.- CONCLUSIONS AND RECOMENDATIONS**

A.- Although it is known that harbour works frequently have produced negative effects on the coast, there can also be works that combined harbour and coastal requirements satisfactorily. This could improve the scenario existing in some coastal areas adjacent to the harbour.

B.- The harbour and coastal technical staff should coordinate the works from the initial stages of the project, taking into account other multidisciplinary teams such as marine biologists, geologists and archeologists, as well as environmental and landscape specialists.

C.- The existence of strong legislation which protects the litoral, such as the actual Spanish Shore Act, that prohibits the use of sand for purposes other than beach nourishment, make it possible to succesfully accomplish the works described in this paper.

## **8.- ACKNOWLEDGEMENTS.**

We are grateful to the many people and multidisciplinary teams who have participated in all the projects described herein.

Without the interest and involvement of the Harbour and Coastal Authorities of Cádiz, Huelva, Algeciras and Gijón, these coordinated projects could not ever have been accomplished.

## CHAPTER 254

### Wave Impacts on the Eastern Scheldt Barrier Evaluation of 5 Years Field Measurements

Leo Klatter<sup>1</sup>, Hans Janssen<sup>2</sup>, Michiel Dijkman<sup>1</sup>

#### Abstract

During the past five years an extensive program of field measurements has been carried out to evaluate the effects of wave impacts on the Eastern Scheldt Barrier in the Netherlands, under operational conditions. High impact pressures were measured. The evaluation of the measurements shows that these high pressures affect only a small area simultaneously.

#### Introduction

The Eastern Scheldt Barrier is located in the southwest part of the Netherlands. The barrier has been built across three main channels in the mouth of the Eastern Scheldt, respectively one kilometer, one kilometer and two kilometers wide. The actual barrier consists of 62 basic sections that are 45 meters wide (see figure 1). The sand bed is covered by a filtermat. On this mat concrete piers are placed. The flow opening is formed by two concrete beams. A steel gate, driven by hydraulic cylinders, can close the opening. On top of the piers a motorway bridge is located. The piers and sill beams are packed in by a rubble sill structure. All structural elements, piers, beams and gates, were prefabricated at a dry construction site and have been placed in open sea with heavy floating equipment. The barrier has been completed in 1986. Until 1994 11 storm closures were performed.

Figure 1: Elements in the Eastern Scheldt Barrier

### Wave Impacts

Under storm conditions the barrier is subject to wave attack from the North Sea. During the more severe storm surges the gates of the barrier will be closed. These gates are subject to wave impacts during the closure operation of the barrier, when the girders of the gates, which are located at the North Sea side of the barrier, cross the water level. After the gates have been closed the front and top side of the upper beam are subjected to wave slamming. Wave impacts on the bottom of the beam occur, when the gates are open, under moderate storm conditions and with more severe conditions just before the gates start closing.

The design impact forces for the gates and the upper beam were determined from extensive scale model tests. For the design computations the wave impacts were schematized to a triangular pressure diagram, as shown in figure 2. The rise time and decline time have average values of respectively 0.05 s and 0.10 s. The peak pressure varies from 0.45 Bar to 0.65 Bar (1 Bar = 100 kN/m<sup>2</sup>) depending on the wave conditions and the location in the barrier.

Figure 2. Schematized Impact Pressure

### Monitoring Program on Wave Impacts

In an early stage of the design of the barrier it was decided to set up a monitoring program to evaluate the hydraulic aspects of the barrier. This program consisted of field measurements of hydraulic loads on the barrier and the response of the structure (Klatter, 1990). In this program the wave impacts on the barrier were included. For the monitoring program on wave impacts a selection was made on the most critical items of the design. Critical, because the construction was very sensitive to a certain aspect or because the design technique was uncertain. For the monitoring program wave impacts on the main girders and supports of the gate and against the bottom of the upper beam were selected as critical items for the design (see figure 3).

Wave impacts on the girders of the gates generated such large impact pressures that the design of the gate had to be adapted several times to reduce these pressures. These aspects were therefore included in the monitoring program. The girders were instrumented in two locations: one at the center part of a top girder, the other at the end of a bottom girder near the joint with the support.

For the upper beam wave impacts against the bottom of the beam were regarded to be critical, because the relatively light weight prestressed concrete beam could be lifted from its supports.

For the monitoring of the wave impacts, one gate and one upper beam were instrumented with accelerometers, pressure gauges, a water level gauge and force gauges. Details of the instrumentation are given in tables 1, 2 and 3, and in figures 4 and 5.

force gauge	2	$\pm 10 \text{ MN}$	100 Hz
water level gauge	1	1.6 m	10 Hz

Table 3. Instrumentation Upper Beam

The water levels are measured on both sides of the barrier and the wave spectra are measured by a directional wave buoy, located approximately 500 m seaward of the barrier. The measurements were concentrated in measurement campaigns during storm closures of the barrier.

### Results

The measurements of wave impacts on the top girders of the gate were performed during the closure operations of the gates, when the girders cross the water level. Under these conditions 10 successful measurement series were obtained. From these series the most severe impacts were selected for further analysis.

Date	Time	$H_s$	D4	D5	D6	D7	D8	D9
		m	Bar	Bar	Bar	Bar	Bar	Bar

Table 4. Maximum Impact Pressures Gate Girder

The measured maximum impact pressures are presented in table 4, for impacts with a maximum pressure over 0.50 Bar on one or more of the sensors.

The maximum impact pressure registered is 2.27 Bar with a significant wave height of 2.20 m. The time history of this impact is given in figure 6. In figure 7 the peak is given in more detail.

Figure 6. Registration Maximum Pressure

Figure 7. Pressure Peak (Detail)

The measurements of wave impacts on joints of the bottom girder and the support show relatively moderate impact pressures. The instrumentation is located close to the edge of the gate. The gate edge crosses the water level during the closure of the barrier at the first phase of a storm surge. At this time the water flows into the Eastern Scheldt. The closure causes a translation wave that accelerates the rise of the water level at the North Sea side. The result is that the instrumented section crosses the water level so rapidly that hardly any wave impacts occur. The maximum recorded impact pressure is 0.37 Bar.

The wave impacts measurements against the bottom of the upper beam start with an outside water level 1 meter below the bottom level of the beam and end with the start of the closure of the gates. Under these conditions 14 successful measurement series were obtained. From these series the most severe impacts were selected for further analysis. A problem for the analysis is that only 4 of the 10 pressure gauges functioned during all measurement campaigns. The maximum pressures recorded with these remaining gauges are presented in table 5, for the (7) most severe impacts registered.

Date	Time	H <sub>g</sub>	D35	D36	D37	D39

14-feb-89	13:22:51	1,00	0,52	0,28	0,34	0,14

Table 5. Maximum Impact Pressures Upper Beam

To illustrate the wave impact on the upper beam and the response of the beam the time series of two pressure gauges (D35 and D36) of the impact recorded at 14<sup>th</sup> February 1989 at 13:13:50 are presented in figure 8. This figure shows a sharply peaked impact which first hits the North Sea side of the beam bottom and moves to the Eastern Scheldt side in the wave direction.

Figure 8. Registration Impact pressures Upper Beam

The response of the beam is illustrated by the acceleration registered at V33, presented in figure 9 (see figure 5 for the instrumentation). The response starts at the first hit of the beam. After the impact the beam vibrates in its natural frequency of approximately 5 Hz.

Figure 9. Registration Acceleration Upper Beam

The response of the support force to the impact is presented in figure 10. Note that the short wave impact (with a amplitude of 675 kN) is small in comparison with stationary support force (of approximately 6000 kN).

Figure 10. Registration Support Force Upper Beam

### Discussion of the Results

In the field measurements high impact pressures were recorded ( $> 2$  Bar). The frequency of exceedance of the maximum impact pressure on the gate girders and the upper beam is estimated between 1% and 0.1%, based on the total number of waves recorded during the measurements. These maximum pressures are higher than the design values (0.45 - 0.65 Bar). The design values were determined for larger impact areas, however. The measured peak pressures are representative for only a small area related to the dimensions of the sensors (diameter approximately 1 cm). The maximum pressures measured in the field show a very large spatial variation. Because of this variation, the impact pressure, averaged over a larger area, will be relatively small; smaller than the design values.

An other item of discussion is the type of wave impact. From the model tests impacts were expected with a sharp pressure peak and little air content. The impacts registered in the field show even sharper peaks and there is hardly any sign of the high frequency oscillations, that indicate air intrusion (compare Hattori 1990). The observed oscillations, see for example figure 8, are

related to the vibration of the structural elements itself. The pressure peaks were analyzed in more detail. The rise time was in the order of 0.01 s and the decline time in the order of 0.02 s, see figure 7.

A quantitative comparison of the results of the field measurements with the scale model tests appeared to be quite difficult for different reasons. In the field measurements local pressures were measured, while in most of the model tests impact forces, averaged over a larger area, were measured directly. Because the spatial variation is much greater than expected, the average impact force in the field can not be computed accurately from the individual pressure registrations. This effect is intensified by the failure of a number of the pressure sensors. Another handicap for the comparison of the field results with the model results are the instationary boundary conditions in the field measurements.

### Conclusions

Wave impacts with high pressures were recorded during the field measurements. The wave impacts show sharp pressure peaks. The impact pressures show a large spatial variation. The impact pressure, averaged over a larger area, is relatively small.

The type of impact observed in the field is comparable with the type of impact, that was expected from the model tests. The spatial variation observed in the field measurements is much greater than expected from the model tests. The two-dimensional and stationar character of the model tests differs from the three-dimensional instationary field conditions.

Finally some general conclusions on field measurements of wave impacts can be given:

- This sort of monitoring programs are long term projects. It appeared to be very difficult to manage this type of projects in a constantly changing organisation with shifting priorities and budgets.
- The measurements are performed with relatively moderate boundary conditions. One has to keep this in mind with te selection of the phenomena to be measured.
- The measurements are not repeatable.

## CHAPTER 255

### Salinity and Water Levels in the Weser Estuary during the last hundred years - Anthropogenic influences on the Coastal Environment

H. Kunz<sup>1</sup>

#### Abstract

Today the Weser Estuary (Unterweser) is one of the most regulated rivers in Europe. It connects the harbour of Bremen with the Southern North Sea (German Bight) and is used by ocean-going ships. The first substantial deepening was done during the last decade of the 19th century. As the vessels became larger, the river has been deepened and widened for several times. The sequence of engineering works changed drastically the hydrological, morphological and ecological conditions within the Unterweser. The tidal water levels and the salinity had been measured since the beginning as part of an extended interdisciplinary monitoring program providing sound data over one century. These data are a valuable base to investigate the impact of the regulation works on the natural ecosystems of the coastal environment and on demands of the society, such as flood protection, irrigation, drainage. New questions arise from the vision, that impacts might be amplified by global climate changes.

#### Channelization of the Unterweser-estuary

The Unterweser-estuary is an important link for the merchandise town Bremen to the deep water of the North Sea (Fig. 1). The depth of the Unterweser decreased after the middle ages. To ensure the competitiveness of the Bremen-harbour, several attempts to deepen the river had been made since the 18th century. However, they were of limited success - KELLER (1901), ROHDE (1970). The first substantial step towards channalization was executed

-----  
<sup>1</sup>Coastal Research Station (CRS) of the Lower Saxonian Central State Board for Ecology, An der Mühle 5, 26548 Norderney/Germany, Director of CRS, Dr.-Ing.

between 1883 and 1895 after the plans of FRANZIUS (1888) by concentrating the tidal currents in a dredged channel (tidedependent draft of 5.0 m), which had been stabilized by embankments, groynes, training walls. In principal, similar techniques were applied during the following construction periods to reach drafts of 7.0 m (1913/16 and 1921/24); of 8.0 m (1925/29, with an extension to 1939); 8.7 m (1953/59) and of 10,5 m (1973/79), which is called 9.0 m -correction due to the sea-chart-zero as the new reference datum-level - WETZEL (1987).

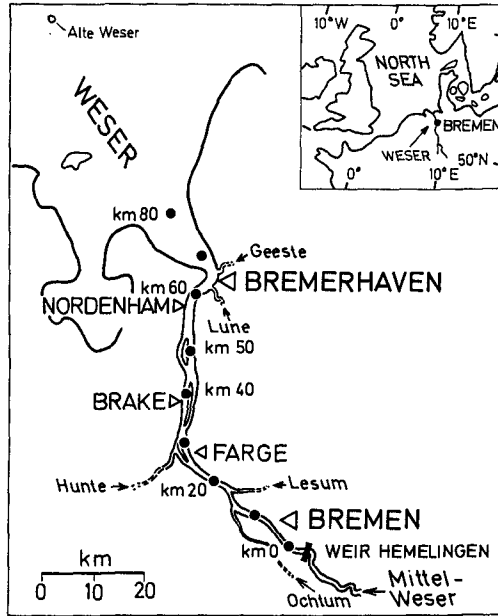

Fig. 1 Location map of the Weser Estuary (Unterweser)

After the first correction it was necessary to limit the tidal influenced part of the river by a weir in Bremen-Hemelingen, stopping erosion and groundwater intrusion (1906/11).

The time scale of the channelization is displayed on Fig. 2, righthand picture. The development of the channel-bottom depth relative to the German datum (NN, which is approximately equal to mean sea level) over time is shown on the picture below, lefthand.

The correction works changed the morphology drastically and influenced the hydrological and ecological conditions substantially. Fig. 3 gives an example on the development of the cross-section in the Bremen-area. The river surface, as well as the riparian area between Bremen und Bremerhaven, were reduced by the sequence of works to about one third and about 60 % of the eulittoral embankments of the navigable channel were covered by various packing material; most of the highly valuable backwaters and flats were lost (BUSCH et al. 1989).

Additionally dykes were displaced towards the river and storm surge barriers were installed in tributaries.

Fig. 3 Cross-sections (Unterweser-km 11, Bremen-Hasenbüren) before 1887 and as designed later

Hydrology

The water levels in the Unterweser are influenced by tides (propagating from the German Bight to the weir in Bremen) and freshwater run off (discharge measured at the gauge of Intschede, upstream the weir). General information on these input-data are displayed on Fig. 4: the tides (HW, LW) are semidiurnal (M2 + S2); the high values for the run off (HQ) occur mainly in spring, the low values (LQ) in late summer or autumn.

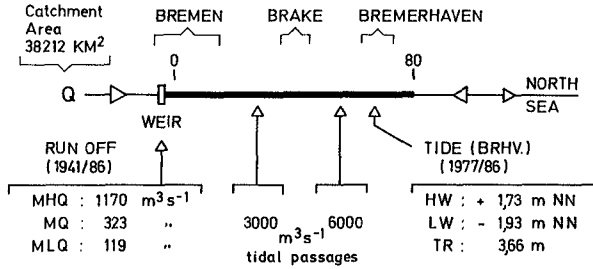

Fig. 4 Hydrological data for the Unterweser

The tidal curves on Fig. 5 provide information, how nowadays the tide propagates into the estuary. A comparison with Fig. 2, lefthand on top, shows how water levels and tidal range have changed with respect to the situation before the first regulation. The low water level (MLW) has been lowered in the upper part of the Unterweser, while the high water level (MHW) remained comparably unaffected. Thus the tidal range increased in Bremen from almost zero to about 4.0 meter. A more detailed picture is given by the graphs on Fig. 6.

The first construction periods, including the 8.0 m-correction, had the main impact on the changes of the water levels. The influence of the first correction had

Fig. 5 Tides in the Unterweser (Bremerhaven to Bremen) for averaged conditions. Data: Federal Water and Shipping Authority Aurich, Bremen, Bremerhaven

Fig. 6 Development of mean high water (MHW), mean low water (MLW), mean tidal range (MTR) over 100 years in the Unterweser at Bremen and Bremerhaven

been underestimated with an error of prediction up to almost 1.5 m. The impact of the 8.0 m-correction (water level-difference) reached up to about 0.75 m (WALTHER, 1954). An extended discussion concerning the impacts of the distinguished Unterweser-corrections on tides, water levels, tidal range is published by WALTHER (1954), STRÖHMER (1963) and is documented in unpublished reports (WSV 1957/85) of the Federal Water and Shipping Authority. The impact of the regulation works on extrem high water levels during storm floods is overlapped and hidden by the predominant anthropogenic influences caused by the coastal protection means, such as diking (in former days often combined with land reclamation) and storm surge barrages.

Monitoring programs

There had been many objections against the first large Unterweser-regulation proposed by FRANZIUS. An important group were the farmers who especially worried about higher water levels, more salinity and their correlated effects. Thus an extended monitoring program was established and executed over about one hundred years

with only one large gap caused by the second world war. Additionally, money was paid to compensate in advance parts the presumed disadvantages (PLATE, 1951). These were about the same actions as they are nowadays required in Germany for the environmental impact assessment and common to promote the implementation of projects: it was a progressive and really successful approach. A substantial part of the program focused on the water quality of the Unterweser-estuary, especially concerning the salinity. Fig. 7, left shows the location where samples were taken; information on the observation-periods are added. The measured data (once a week at high water) were supplemented by a large number of special investigations related to space (e.g. verticals, cross-sections, longitudinal profiles) and time (e.g. tide circles, periods with special hydrological conditions) - WSV (1957/85).

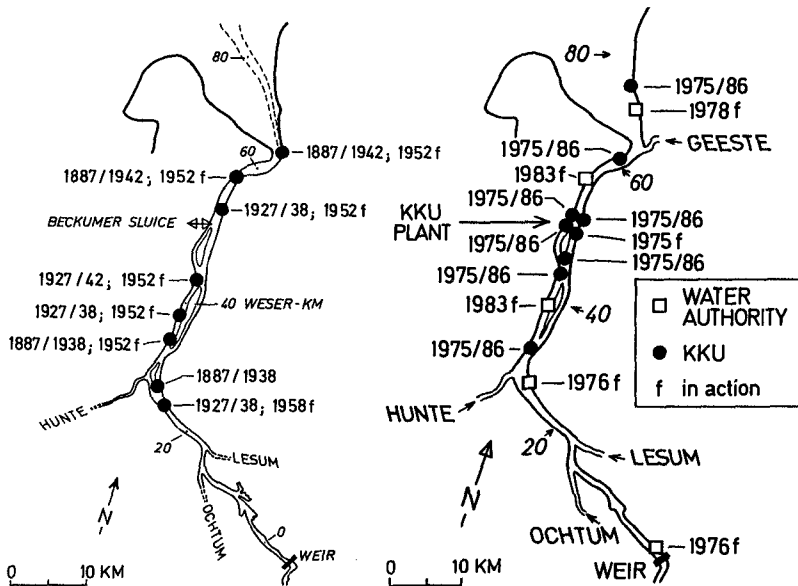

Fig. 7 Location of the Unterweser-Stations.  
Left: weekly sampling. Right: permanent recording

A system of permanent working stations had been installed since 1975. Fig. 7, right distinguishes stations which were established by Water Authorities and those, which were specifically established to control the KKU-nuclear power plant KUNZ (1979). These stations are interlinked with measurements, which are regularly done by fast running boats (KUNZ et al. 1984).

The Unterweser is classified as a well mixed estuary; it has been proven, that the data gained by the stations in one measuring point can approximate the average situation of the cross-section sufficiently well with respect to the aims of the long term and large scale monitoring programs - e.g. WSV (1957/85), BARG (1979). However, interpretations of the data are limited to the fixed targets.

Salinity

The salinity in the Unterweser-estuary is mainly caused by the intrusion of saltwater from the sea and is additionally affected by the salt which discharge factories into the upper parts of the Weser - e.g. Lüneburg et al. (1975), Arge Weser (1982). The distribution of salinity in the estuary is influenced by the tidal motion and the fresh water run off ( $Q_0$ ). This is shown in principal on Fig. 8. The graphs are simplifications for a defined phases of the tide ( $K_f$ ,  $K_e$ ).

Fig. 8 Distribution of salinity in the brackish area of an estuary. Left: impact of run off (discharge  $Q_0$ ). Right: influence of the tidal motion ( $K_f$ ,  $K_e$ )

The changing of salinity over time (tidal cycles) is shown on Fig. 9, left (salinity is proportional to the displayed conductivity  $L_f$ ) for different areas (location of the stations see Fig. 7, right) of the Unterweser. The tide-phase-time of the flow turnings (flood, ebb) are indicated as  $K_f$ ,  $K_e$ . The distribution of the conductivity (longitudinal profiles) for the phases  $K_f$  and  $K_e$  can be drawn from the  $L_f$ -values of the five stations. The result is shown on the righthand picture.

Longitudinal profiles for the phase  $K_f$  have been measured by sensors which were installed in fast running boats. Results provides Fig. 10, left: areas in which the measured curves fit in dependency of the significant

fresh water run off ( $Q_0/10$  after BARG, 1979). The profiles on the right picture have been derived from all measured profiles. The large impact of the run off value on the salinity is obvious. Comparable results have been published by BARG (1979) with salinity-data (NaCl) of the KGU-stations.

Fig. 9 Left: Conductivity ( $L_f$ ) over time for different measurement stations in the Unterweser. Right: Conversion of the  $L_f$ -data into longitudinal  $L_f$ -profiles for the tide phases Kf and Ke (KUNZ 1979)

Fig. 10 Longitudinal profiles for Total Salinity (ST) as function of ( $Q_0/10$ ). Left: envelopes for groups of measured profiles. Right: ST-functions ( $Q_0/10$  is parameter) calculated with measured profiles

Investigations concerning the influence of the Unterweser-regulation works on the salinity-distribution in the brackish area of the Unterweser have been based on the long term data of the sampling stations. Longitudinal profiles for the phase Kf were constructed with these data, as demonstrated in principal by Fig. 9, right; e.g. STRÖHMER (1963), PLATE (1951), GRABEMANN et al. (1983) and nonpublished reports WSV (1957/85). An example is given by Fig. 11, where salinity-data (NaCl) for the time-period 1890 to 1975, selected for the mean run off (MQ), had been converted into longitudinal profiles. The data for the period from 1890 to 1932 are combined in the picture to the left: no significant influence of the regulation works. The interpretation of the righthand picture (1931 to 1975) is more difficult. GRABEMANN et al. (1983) tried to separate the natural from the man induced fluctuations and came up with the result, that the influences of the natural long-term changes (trends of relative sea level rise, characteristics of the tides - e.g. JENSEN et al. (1993)) - dominate the other impacts. This corresponds to results achieved by HN-models.

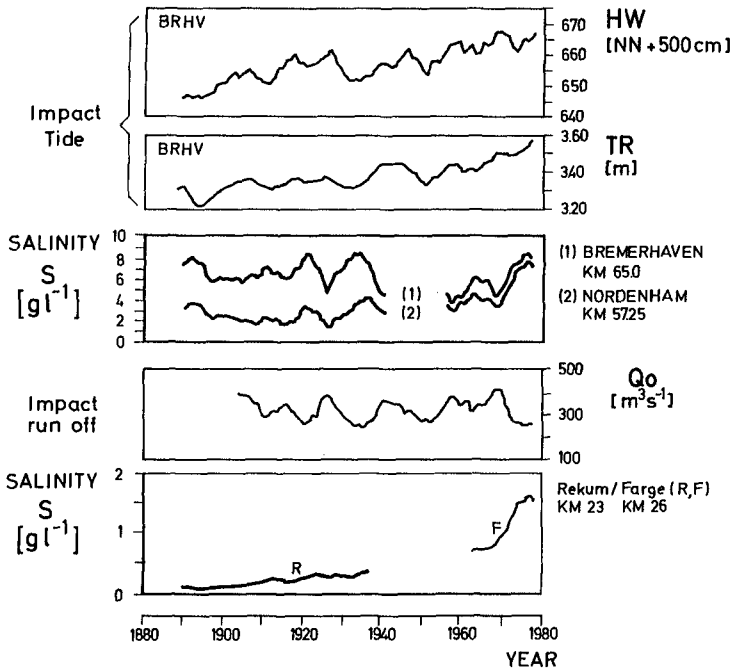

Fig. 11 Development of the NaCl-Distribution (profiles) in the Unterweser between Käseburg/km 36,5 and Bremerhaven/km 65.8 for mean Run Off (MQ), 1890 to 1975 - GRABEMANN et al.(1983), Shipping Authority Bremen/Aurich

The development of the salinity  $S$  ( $\text{NaCl}$ ) over time is shown by Fig. 12 to 14 for selected stations. The Fig. 12 combines  $\text{NaCl}$  values (Station Bremerhaven (Brhv.), Nordenham, Rekum/Farge) with information on the main impact parameters: tides (HW, TR) and run off (discharge  $Q_0$ ). The increase of salinity in the Bremen-area (Rekum/Farge) is caused by industrial salt-discharges into upstream parts of the river in combination with the  $Q_0$ -parameter - ARGE WESER (1982). The salinity-graphs for Bremerhaven and Nordenham show similar downs and ups related to  $Q_0$ ; there seems to be a trend towards increasing values and a steepening of the gradient since about 1970. This is most likely induced by changed hydrological conditions and not by the sequence of correction-works - e.g. BARG (1979), GRABEMANN et al. (1983), WETZEL (1987), WSA BRHV (1991).

DATA : STRÖHMER (1970), GRABEMANN et.al.(1983), WSV (1957/85)

Fig. 12 Development of the Salinity  $S$  in the Unterweser (Bremerhaven, Nordenham, Rekum/Farge) and of hydrological Data: High Water (HW) & Tidal Range (TR) at Bremerhaven (BRHV); Run Off ( $Q_0$ ) for Intschede, (all values as five yearly running means)

Fig. 13 displays for the station Nordenham (km 57,25) how the salinity has been controlled by the fresh water discharge ( $Q_0$ ). The diverting graphs before 1906 may be related to the first correction. However, that's not conclusive. From 1955 onwards different behavior is obvious, which presumably is caused by the increased tidal range, as mentioned before.

Fig. 13 Combination of Salinity S (NaCl) for Nordenham (km 57.25) with the Run Off ( $Q_0$ ) at Intschede-gauge after STRÖHMER (1970)

Fig. 14 Development of the Salinity S at the Beckum-slucice (km 51) for  $Q_0 = 150, 200, 300 \text{ m}^3/\text{s}$  since 1917. PLATE (1951), WSV (1957/85)

Since the content of salinity in the Unterweser-estuary is important for irrigation means (e.g. drinking water for cattle), the samples had also been taken in the Beckum-sluiice (intake for irrigation water) at km 51 - e.g. PLATE (1951), WALTHER (1954). The development of the NaCl over time with respect to distinguished run off-values ( $Q_0 = 150, 200, 300 \text{ m}^2/\text{s}$ ) is shown on Fig. 14. The salinity has increased and led to problems during periods of low run off ( $Q_0$ ), especially since the fifties as a result of the mentioned effects.

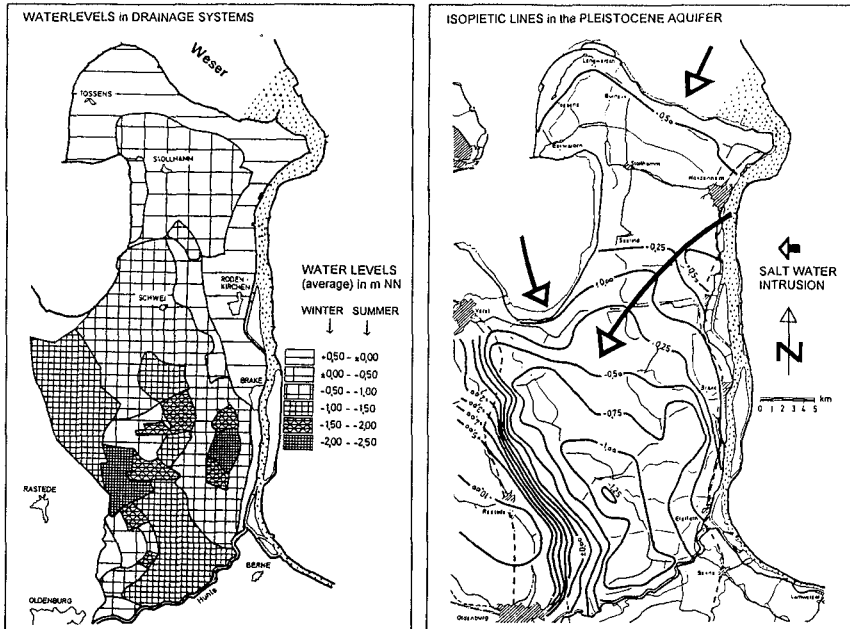

Fig. 15 Saltwater intrusion from the Unterweser into the aquifer of the lowlands. Left: Water level in the drainage system (ditches). Right: Isopiestic lines in the pleistocene aquifer and direction of the anthropogenic induced salt water intrusion - KUNZ (1993)

#### Effects on groundwater

The intrusion of saltwater out of the Unterweser into the groundwater (holocene and pleistocene) of the low lying areas is influenced by the regulation works. This question has become more important, as extensive

drainage systems were installed. Nowadays the water levels in the drainage ditches are far below the mean water level of the Unterweser (about NN), as to be recognized from Fig. 15, left. Consequently the isopiestic lines of the pleistocene groundwater has been changed and the intrusion of salinity out of the Unterweser can increase - Fig. 15, right. This impacts the holocene cover layers by vertical directed flows. The main driving force in the synergism of the addressed impacts is the drainage; the effects of the Unterweser-regulation works are comparatively small - KUNZ (1993).

### Conclusions and final remarks

For almost 100 years regular water samples were collected at several stations along the Unterweser-estuary on a scheme which remained unaltered. The combination with the tide gauge data provide an unique data set on salinity and water levels. This is a remarkable achievement of the Federal Water and Shipping Agencies and their scientific staff, who devoted time and effort into this admirable task. Today this valuable data set is of more than local interest. The traditional sampling scheme has been supplemented by extensive measurement programs and numerical modelling throughout the last decades. However, many controversially discussed questions concerning developments and impacts were only to be answered by referring to the long term data. This is an example which should encourage society to require appropriate long term monitoring programs being obligatory for every human activity that has substantial impact on the environment. The modern tools, such as modelling, information systems etc. should not lead to the believing, that we can do without providing sustainable field data-records on the anthropogenic changings of our environment to the next generations.

## CHAPTER 256

### REVIEW OF SOME 30 YEARS BEACH REPLENISHMENT EXPERIENCE AT DUNGENESS NUCLEAR POWER STATION, UK

By Dr Roger Maddrell<sup>1</sup>, Bill Osmond<sup>2</sup> and Bin Li<sup>1</sup>

#### INTRODUCTION

Dungeness was formed initially as a shingle bar across a bay that existed between Winchelsea and Hythe at the end of the last glaciation (see Figure 1). The bar was the early coast and caused the landward accumulation of estuarine deposits, which now form the marshes. Shingle continued to accumulation on the seaward side to form the Ness. The present alongshore drift, resulting from refraction and diffraction of the dominate southwest waves, moves shingle eastward, eroding the southern coast and causing accretion along the eastern side (see Figure 2). The past morphology of the Ness, first described by Lewis, 1932, can be seen clearly from the shingle ridges, which represent old coastlines.

In the late 1950's the then Central Electric Generating Board (CEGB) chose the Ness as a nuclear power station site. Studies at that time by Sir William Halcrow & Partners (Halcrow) established that the rate of erosion of the southern shore was of the order of 1.1m annually, but near the point of the Ness, where the Station was to be sited, could be up to 1.5m annually, with an annual rate of drift of about 125,000m<sup>3</sup>. Various schemes for protecting the Station frontages from erosion, and thus flooding, were examined (Halcrow, 1963) and one of recycling shingle from the accreting east face of the Ness

---

<sup>1</sup> Sir William Halcrow & Partners Ltd, Burderop Park, Swindon, Wiltshire SN4 0QD, UK

<sup>2</sup> Nuclear Electric plc, Dungeness 'B' Station, Dungeness, Kent, UK

was recommended. The proposed volume of gravel initially was 15,000m<sup>3</sup> annually, but rising to 20,000m<sup>3</sup> with the construction of the second station.

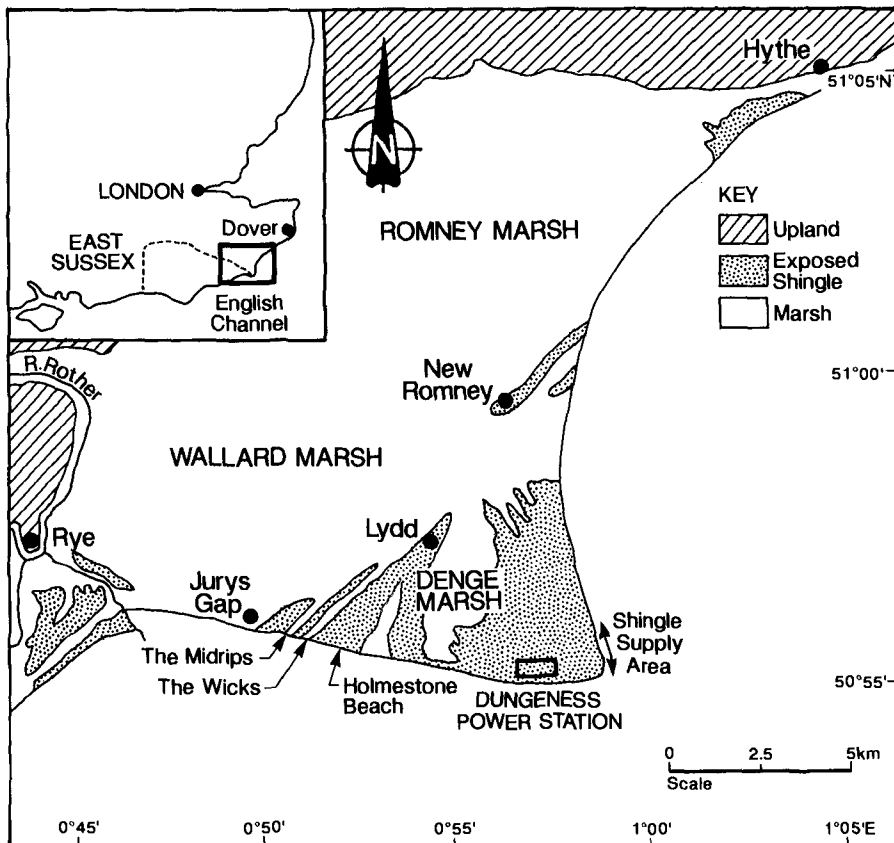

Figure 1 : Site Area

Beach feeding has been continuous since 1965, concentrating mainly at the western, updrift, end of the site. As the updrift coast eroded, the recharge area became more and more out of regime, requiring additional shingle to hold it. Recent studies recommended that a policy of coastal retreat or coastal set back should be implemented. This has resulted in a considerable saving to the amount of gravel required for beach feeding and a

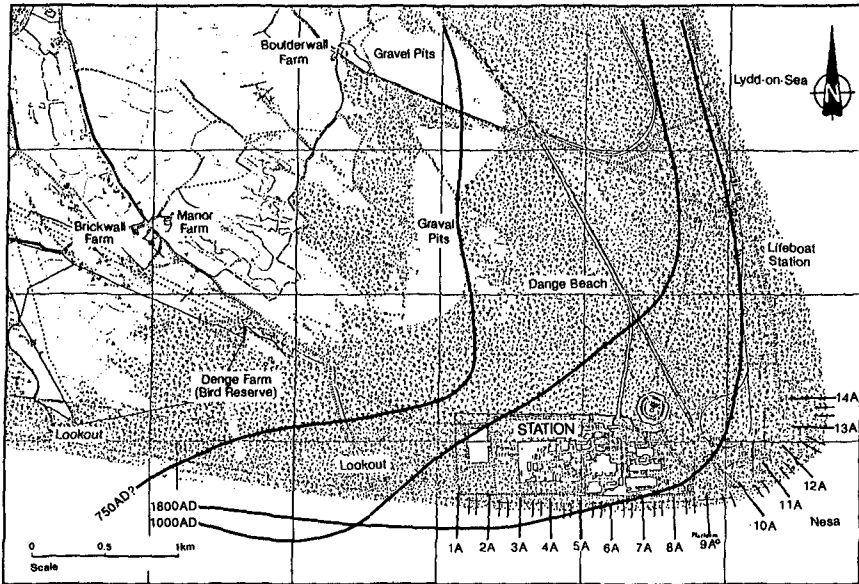

reduction in the impact of winning material from the supply area.

### **EVOLUTION OF DUNGENESS**

The post-glacial marsh and shingle deposits attain a thickness of some 30m and are derived from a combination of terrestrial and marine sources (Long, 1994). Between 4000 and 2000 BP sea-level was relatively stable at about -2.5m OD, but during the last 2000 years it rose by about 2.5m. There has also been considerable subsidence, which in the last 4000 years has been between 1-2mm per year (Shennan 1989; Long and Shennan, 1993). The net relative sea level rise is predicted to be about 0.4m by the year 2050 (Maddrell and Burren, 1990).

Shingle probably entered Romney Bay by 5300-6000 BP, although radiocarbon-dated shells collected from -34m OD beneath the Station are only 3000-2000 years old (Greensmith and Gutmanis, 1990), which suggests that the shingle in this area is considerably younger than 2000 years old. The shingle is driven in a west to east direction by the dominant SW waves and the chronological development of the Ness can be seen in the remaining ridge pattern (see Figure 2). However, the dating is tentative as the time of shingle deposition can only be established where the shingle is underlain by organic sediments, which can themselves be dated by radiocarbon or where shoreline positions can be estimated from historical and archaeological sources. Unfortunately, the former condition is rarely met, while the latter provides only an approximate chronology, which tends to be restricted to the last 1500 years. Lewis and Balchin's 750? shoreline (see Figure 2) was based on Ward's 1931 interpretation of two Saxon Charters, which indicate the approximate position of the coast at this time. The 1600 shoreline is based on M Pokers' 1617 map of Romney Marsh, which is one of the earliest relatively accurate maps, while the 1800 shoreline is obtained from the 1794 Ordnance Survey. The 1990 BP coast is from recent radiocarbon dating.

There are three areas of low-lying marsh deposits to the west of the Station eg The Midrips, which have been interpreted as evidence for 'several oscillations of level from the late Neolithic times to the Bronze Age' (Lewis and Balchin 1940). There are also raised ridge levels north of the Station, which are taken as evidence of more severe climatic conditions during the Middle Ages.

**Figure 2 : Historical Coastline at Dungeness and the survey lines at the Station**

The Ness is a continually evolving feature, as can be seen on Figure 2, with shingle erosion on its southern face and deposition on the east. The siting of the Station at the tip of the Ness close to the south coast, while morphologically controversial, was mainly because of the close proximity of deep water (-30m OD) adjacent to the Ness.

**BEACH FEEDING**

**General**

Southeast England is subsiding which, when combined with the rise in mean sea level, has meant a requirement for an increased level of coast protection for the southern

eroding face of the Ness in front of the Station. Inundation was seen during construction in 1960 and 1961 and more recently in local areas adjacent to the site in 1983, 1984, 1989, 1990 and 1992. The need for flood protection is reflected in the increase in recharge volume, which increased from some 15,000m<sup>3</sup> at the beginning to some 70,000 m<sup>3</sup> in 1992. Breastwork and two local groynes were constructed for emergency protection, but are now buried.

The volumes of beach feed material required has been established by surveying specific sections of the beach at the end of the winter, with the recommended shingle being placed on the beach over the following winter period. Initially this was done by ground surveys, but in recent years has been done by photogrammetry.

The idea of recycling shingle for use as beach protection was unique at the time and has been the subject of regular review. The most recent review indicated that not only was this the most effective method of protection (costing less than the interest payment of a more formal method of protection), but was also environmentally friendly.

The southern coast of Dungeness is being held at two points, the Station and at Jurys Gap, some 8km to the west (see Figure 1). An erosive bay has formed between these two stable points, decreasing the alongshore supply of shingle to the Station frontage over the years. Thus, the main point of beach feed, which lies at the western end of the station, was becoming more and more exposed as the up drift coast has receded and the natural supply of shingle dwindles. Consequently, in recent years the amount of beach feed required was in excess of 50,000m<sup>3</sup> annually.

The beach feeding scheme has operated for 28 years during which time Halcrow have produced annual reports describing the work done during the previous season and recommending the quantities and positions for shingle feeding during the forthcoming season. Until 1972 the amount lost during the year was replaced at locations which had suffered the greatest erosion and was distributed in roughly equal proportions at a series of points. After 1972 it was realised that a more efficient method of protecting the beach would be to place most of the recharge at the western end, allowing natural movement to distribute the shingle over the frontage.

The levels along each of the cross-sections are now established on the 42 sections, which are at 100m intervals, by photogrammetric methods. It is considered that the 1:5000 scale of photography normally used allows individual beach levels to be determined to an accuracy of within approximately  $\pm 0.20$  metres (assuming no errors in the control grid). There are 14 sections each with three sub-sections (see Figure 2), 9 in front of the station and 5 downdrift in the supply area. One of the major advantages of the beach feeding scheme has been its flexibility and the ability to respond quickly to potential problems and periods of intensive storms. Figure 3 shows the gross losses, the quantities of material deposited and the volume changes each year since beach feeding began in 1965. The total volume of shingle between profiles 1A and 9A has increased by some 102,394m<sup>3</sup> between 1965 and 1993/94, resulting from an average annual recharge of about 30,000m<sup>3</sup>, with an average annual gross loss of about 26,500m<sup>3</sup>. The records clearly demonstrate that the beach feeding successful stabilised the beach and that the build up of the profiles have been sufficient of balance the increased losses in extreme years. A typical profile of the build up of shingle over the years can be seen on Figure 4.

Figure 3: Volume changes from 1965 to 1994

The beach feeding programme has been effective in preventing flooding and damage to the Station. Prior to 1983 there appear to be no records of serious flooding, apart from during construction, but there has been flooding adjacent to the site on:

- 28th January - 1st February 1983
- February 1984
- November 1984
- Winter 1989-1990
- February/March 1990
- August 1992

This increase in the potential flood risk may be related to an increase in wave energy during the period (see Figure 5) and has led to a change in the "emergency" and "normal" profiles. These profiles for sections 1A to 9A were conceived nearly 30 years ago. The original concept was that the "normal" profile should be the minimum cross-section of beach to be maintained, where the "emergency" profile represented conditions which could lead to major overtopping of the beach and flooding, hence requiring "emergency" works. The levels were increased last year to take account of the impact of a tsunami wave, which has a 1 in 10,000 year return period.

### **Past Investigations**

In an effort to reduce the annual costs associated with the beach feeding programme, and any adverse environmental impacts, Halcrow have for many years attempted to relate beach loss to local meteorological conditions. It was originally hoped that this would allow predictions of required recharge volumes to be made without the expense of conducting an annual aerial survey. While this would never totally replace the need for surveys, it would allow their frequency to be reduced to say once every two or three years.

The 1969/70 Halcrow report described an early attempt to relate the incident energy flux to the quantity of shingle moved, but this proved unsuccessful because only four years of records were available. The 1978/79 study the

correlated the observed shingle loss and wind gusts which exceeded 47 knots ie storm conditions. This proved to be reasonably successful, but in the early 1980's it was proved less so. One of the difficulties in trying to establish any correlation stems from the fact that the average annual gross loss, represents a fairly thin layer over the surface of the total shingle volume of approximately 1.25 million m<sup>3</sup> contained within the survey section limits ie the losses are only approximately 2% of the total. Furthermore, the computations do not allow for irregularities in the beach profiles between the measured cross-sections which are at 100m centres. The gross loss has to be determined by the difference of these total volumes, over successive years, so that small errors in the determination of the total volume have a significant effect on the calculation of the gross loss for any one year. It was concluded that no simple relationship exists between beach losses and non-directional wind intensity.

#### **Analysis of Beach Erosion**

It was originally predicted in 1963 that the natural supply of littoral material from the west of the station, which was about 120,000m<sup>3</sup> would slowly reduce with time, requiring a commensurate increase in beach feeding. This effect results from the gradual formation of a shallow bay between the stabilized sections of the coast at Jury's Gap and the Station. This was confirmed by beach plan shape modelling, which shows the yearly gross shingle loss along the Station is rising, on average, by some 880m<sup>3</sup>/year. The previous analysis of the seven year rolling means in 1984 showed the annual rate to be 540m<sup>3</sup>.

The cumulative average annual gross loss of beach material upto 1992 was 29,490m<sup>3</sup>. However, the average over the past five years has been 42,000m<sup>3</sup>. In the previous five years it was 30,000m<sup>3</sup> ie 1983 to 1987, 25,000m<sup>3</sup>/year from 1978 to 1983, and 24,000m<sup>3</sup>/year for 1973 to 1978.

#### **Wave Data**

Offshore wave data were derived using a parametric wave model based on wind measurements between 1971 and 1990. Such models are limited to hindcasting of locally generated waves within defined fetches. To determine the importance of swell, wave data were obtained from the British Meteorological Office's wave model for the years 1989 to 1992. The swell wave portion of the wave spectrum,

coming up the Channel from the Atlantic was found to be 25%.

Section 7A (see Figure 2)

**Figure 4: Beach Movement 1965-1992**

The available wind wave data were statistically analysed to produce seasonal, directional, yearly and average values of wave energy, with only the last four years including swell waves. Values of alongshore energy were derived for each year and used to produce a trend analysis as shown in Figure 5. Despite the wide scatter of data there is clearly an increasing trend in longshore wave energy. The gradient of the graph is approximately 16 KN/year.

The increase in wave energy may in part account for the increased rate of annual shingle loss also shown in Figure 5. For example, equating the long term average gross beach erosion to the long term average alongshore drift gives a figure of approximately 500m<sup>3</sup>/year increase in beach erosion, which can be directly attributed to an overall increase in wave energy. Subtracting this figure from the

880m<sup>3</sup>/year derived from the trend analysis of gross erosion gives a figure of 380m<sup>3</sup>/year, which may be attributed to the changes in alongshore drift at Station.

**Figure 5: Annual Shingle Losses and Wave Energy**

While the trend lines show a clear correlation between increasing beach loss and wave energy, the comparison of individual years shows large deviations and therefore little predictive capability based on annual results. Figure 5 shows alongshore wave energy plotted against beach loss for the years 1989-1990, 1990-1991, 1991-1992 and 1992-1993. While there is a good fit for some years, the energy available for 1989-1990 underpredicts the beach loss. However, the winter of 1989-90 was marked by a series of four gales, some with hurricane force winds, all of which coincided with spring tides which weakened the beaches. Had not the gales of 1989-90 occurred on spring tides, the measured gross loss of material at the Station would have been much less. Thus, a simple analysis of alongshore energy will tend to underpredict beach losses for those years affected by extreme water levels.

The past studies have shown that while there was a reasonable relationship between wave energy and the littoral transport, it was not a simple one. Predictions can vary depending on the coincidence of high wave energy

and surges during the period and the predicted and actual volume, could vary by as much as a factor of 2.

#### **ALONGSHORE TRANSPORT**

The present alongshore shingle transport rate of about 90,000m<sup>3</sup> was established using an existing beach plan shape model. Studies were also carried out using electronic pebbles to monitor shingle movement during the storms and the transport rates of different sizes of shingle. These 'smart' pebbles show, rather surprisingly, that the larger shingle travelled at a faster rate possibly because of the greater area of exposure of the larger shingle in a mixed grading. Studies of the grain size of material on the beach also showed significant changes both in relation to storm and the size of the feed material.

#### **BEACH PLAN SHAPE MODELLING**

There is sufficient gravel accreting on the eastern coast of the Ness which can be used to improve and strengthen the beach at the Station. However, it was realised that taking increasing amounts of gravel could adversely affect the downdrift coastline, especially as it is the source area for beach feeding elsewhere. Consequently, there was a review of the beach feeding, which included, in particular, a sediment transport model in order to predict the drift rates and future changes in coastal morphology.

Three schemes were adopted for examination during the model study, namely:

- Scheme 1 - supply beach feed at Section 1A (see Figure 2) to maintain the existing beach line. This corresponds to the present beach feeding policy.
- Scheme 2 - supply beach feed at Section 4A (see Figure 2) to maintain the existing beach line east of it. Beach sections to the west of Section 4A are allowed to evolve naturally.
- Scheme 3 - Construct a long strong point at Section 9A (see Figure 2),

at the downdrift end of the site and use accumulated material to maintain the beach east of Section 1A as in Scheme 1.

The model was run to simulate fifty years operation of each of the above schemes. The feed quantities envisaged for each scheme are shown on Table 1.

Year	Scheme 1 Feed at Section 1	Scheme 2 Feed at Section 4	Yearly Saving in m <sup>3</sup>
1	40,000	13,172	26,828
5	41,000	18,494	22,506
10	41,119	23,816	17,303
20	42,548	28,902	13,646
50	46,627	35,970	10,657

**Table 1 Predicted Feed Quantities (m<sup>3</sup>/year)**

As can be seen, Scheme 2 shows considerable savings over Scheme 1.

#### **ECONOMICS OF BEACH FEEDING AND ALTERNATIVES**

The economics of beach feeding at the Station were last examined in detail in 1983 in connection with studies for a proposed new station. As discussed earlier, in the last five years beach recharge quantities have increased significantly, and it was considered necessary to reassess the economics of the present operations compared with alternative forms of coastal protection.

From the earlier beach recharge quantities and trends, it was concluded that the base estimate for quantities should be 40,000m<sup>3</sup>/year ie the situation before managed coastal retreat or set back, using upper and lower bound figures of 125m<sup>3</sup>/year and 500m<sup>3</sup>/year for the rate of increase of beach recharge.

The above figures were used to calculate the Net Present Value (NPV) of the following cost of beach recharge discounted over a period of 50 years:

Initial Recharge	Rate of Increase	NPV in £
40,000m <sup>3</sup> /yr	125m <sup>3</sup> /yr	3,033,471
40,000m <sup>3</sup> /yr	500m <sup>3</sup> /yr	3,469,502

The alternative forms of coastal protection considered in the 1983 review of coastal protection included:

- beach feeding
- several forms of groyne and breastwork
- artificial headlands and an initial beach fillings
- an armoured revetment

The comparison of various options was based on Net Present Values for 35 year and 105 year life spans. These are summarised in Table 2.

SCHEME		Net Present Value £ X 10 <sup>6</sup>	
		35 Year Life	105 Year Life
1	Beach Feeding	2.1	2.7
2	Timber Groynes and Breastwork	4.8	5.7
3	Mass Concrete Groynes and Timber Breastwork	5.7	6.5
4	Armabrade Steel Sheet Piled Groynes and Timber Breastwork	8.2	9.4
5	Two Strongpoints and Initial Feeding	4.3 plus cost of lee scour	4.3 plus cost of lee scour
6	Revetment of Armour Units	15.3	15.3

**Table 2 Net Present Values of Coastal Protection Schemes at Dungeness, 1983 Prices.**

These costs clearly demonstrate that the existing practice of beach feeding is the most economic form of coastal protection. The present policy of managed retreat or set back enhances the benefits.

## CONCLUSIONS

### Review of Beach Feeding

- The beach feeding campaign has been effective in preventing flooding and damage to the Station.
- It is the most cost effective method of protection.

### Beach Movement and Meteorological Conditions

- An analysis of wave data derived from wind hindcasting showed a recent increase in wave energy and a clear correlation between increasing wave energy and increasing beach loss. However, the comparison with values for individual years did not show a good correlation with measured beach losses and wave energy. The inclusion of swell waves provides a more reliable predictive method for calculating beach losses in all but the most extreme years.
- In the past five years beach feed quantities have increased dramatically. Recent studies have concluded that there has been an increase in the number of severe storms affecting Wales and Southern England, although this does not form part of a clear statistical trend. Moreover, these recent storms would not have appeared to be so unusual had not the 1970's and early 1980's been so mild.

### Economics of Beach Feeding and Alternative

- A net present value of beach feeding for the 1992-1993 season over a lifespan of fifty years was established using an updated base estimate of the annual beach feed quantity and the future annual increases.

- Beach feeding, ignoring the benefits of coastal retreat, is still significantly cheaper than the other forms of coastal protection.

#### Coastal Retreat

- The concept of coastal retreat has lived upto its expeditions, significantly reducing the quantities of shingle required, thus reducing costs and any adverse environmental and geomorphological impacts that might stem from shingle extraction from the supply area.

## CHAPTER 257

### PROJECT, WORKS AND MONITORING AT BARCELONA OLYMPIC BEACHES

Carlos Peña (\*) & Manuel F. Covarsl(\*)

#### 1.- INTRODUCTION.

Barcelona is the second city in Spain(2.3 million inhabitants) after Madrid (4 million) and is also the city that held the last Olympic Games in July 1992.

It is the third segment of a physiographic unit beginning at Tordera River Delta and ending at the port of Barcelona.(A description of the whole physiographic unit can be found in ref. 1 by Carlos Peña 1992).

But in the last decades it became one of the ugliest and most degraded part of the coast of Spain. Everybody considered most of the sea-front side as the rubbish dump where everybody could get rid of everything.

In addition to this, there was some groins constructed to assure the discharge of Barcelona sewage draining system.(Nowadays there are still from time to time, rain water discharges there).

#### 2.- THE SCHEME.

The first important decision to be taken when the recovery of this part of the city was decided was to choose between the simple sand nourishment or the stabilization of the coast line with rigid structures.

The previously existing groins have conditioned the solution to recover the beaches of Barcelona sea-front. If these groins were not there as an unavoidable condition the solution probably was a simple and periodic sand nourishment since in the vicinity of Barcelona many millions cubic meters of coarse sand are available at less than 30 m. depth water.

---

(\*) Civil Engineers, General Directorate of Coasts;

Address : Dirección General de Costas, Ministerio de Obras Públicas, Transportes y Medio Ambiente (MOPTMA), Paseo de la Castellana 67, 28071 Madrid, Spain.

But since it was necessary to keep and improve the discharge capacity of the draining system of Barcelona, the solution finally adopted was to rigidize the coast and to build pocket beaches between every couple of groins.

A schematic plan of the whole project in front of the Olympic Village can be seen in fig.1 and a part of it in fig.2.

### **3.- THE WORKS**

The landscape has deeply changed; a marina has been constructed as part of the Olympic Games infrastructure, beaches can be found instead of previous rubbish tips, and the groins have been rebuilt in order to assure the stability of the beaches.

Fig. 13 shows an aerial view of the whole area in 1993 after the works have been completed.

As a whole, 1,485,476 m<sup>3</sup> of sand have been pumped to the beaches and most of the groins have a submerged part in order to stabilize the sand without horizon visual intrusion, supporting the submerged part of the sand profiles at the southern part of every pocket beach of this project.

As we can see later this part of the project only partially did work properly.

An important element is the submerged groin of fig.3a and fig.3b. It was designed with a double purpose: The first one is to act on the incident waves in order to make them refract in the same way as an emerged breakwater would do. The second one is to support the submerged profile of the Somorrostro Beach.

It was built with the crown at mean sea water level to in order to keep the horizon line free of visual intrusion as much as possible.

In order to precisely design this part of the project so that to keep the energy transmission coefficient below 0.1 and to test its stability, a lot of experiments were carried out at the Centro de Estudios y Experimentación de Puertos y Costas (CEPYC-CEDEX, ref.2). As a result, the groin has the crown 34 m. wide at mean sea water level.

The coast line was predicted using only very simple numerical models (logarithmic spiral of Carlos Garau - ref.3 - and the theory of pocket beaches of Silvester - ref.4 -), and available visual wave data records. We all were well aware that, since these visual wave data are not very accurate, some errors could be done in the project as a whole.

Works have been completed just before the Olympic Games (July-1992), and since then the whole project is being monitored.

### **4.- THE MONITORING**

The monitoring has been focussed and divided in three different parts:

### a) Topography

The cartography and drawing of the sea-land line has been done in June and February of 1993 and April and June of 1994.

Some of the results of this topographic work are shown in fig. 4 and 7 , where also the coast line of 1987 previous to the project and the so called theoretical line have been drawn. This last line has been obtained by means of Garau logarithmic spiral theory and proves to be good enough to predict future coast lines when complete, accurate and reliable wave climate are not available.

### b) Bathimetric surveys

Bathimetric surveys of the whole area have been carried out just after the works have been completed in June 1992 and September 1993.

The lower part of fig.10 shows the measured profiles obtained at the key plan of the same fig.10. The profile of July 87 previous to the works is also included.

It is clear that these three profiles should fit below 7 or 8 m. depth but it can be seen that they do not fit even below 10 or 12 m. depth. Therefore some error (systematic or not) must have been introduced. This kind of trouble is very common in making bathimetries all over the world and as a matter of fact, this kind of surveys are useless for scientific purposes. Further investigations, research and experimentation should be done in order to improve bathimetric technic. Anyway, if we correct all the profiles forcing them to fit below 10 m. depth, (upper part of fig. 10)we can draw the map of erosion and deposition areas, and we can find out a slight trend in the sand to move to the South, except in Nova Icaria Beach which is fully stabilized by the submerged groin (fig.8) and Somorrostro Beach which shows a trend to tilt towards the Port's mouth (fig. 5).

### c) Tracers

The very same sand of the beach colored with rhodamine, uvitex and auramine was used to trace the movements of the sand. Two hundred points were sampled twice in 1993 to find out the movements of six different tracers. The results of two of them are shown in figures 6 and 9 showing the same general trend found out in the bathymetric surveys but with another very important conclusion: The submerged breakwaters and groins are not impermeable to movements of sand grains although we are not able to quantify the amount of sand that traversed them.

## **5.- CONCLUSIONS**

1) The logarithmic spiral theory of Carlos Garau and Silvester is a very useful tool to predict the coast line changes.

2) Further research should be carried out to make available better bathimetric technic.

3) Tracers are a very useful tool to find out the general trends of sand movements.

4) As far as Barcelona beaches is concerned we can conclude that the project as a whole is working well but a few small corrections should be introduced because:

a)The equilibrium shape of the pocket beaches seem to be slightly tilting to the south.

b)The submerged breakwaters and groins are not completely impermeable to sand movements.

c)The Somorrostro Beach is slightly tilting to the Port's mouth.

## CHAPTER 258

### SANTA CRISTINA BEACH NOURISHMENT WORKS AND MONITORING PROGRAM

E. TOBA, G. GOMEZ-PINA and J. ALVAREZ 1

#### ABSTRACT

The purpose of this paper is to analyze the suitability of the solution adopted to restore Santa Cristina beach in La Coruña (Spain). The solution, which did not include any structures such as groins, consisted of adding 450.000 M3. of sand dredged from the sea bottom.

Also, a monitoring program was carried out for two years in order to implement appropriate coastal management strategies.

#### 1.- INTRODUCTION

##### 1.1 Morphological Description and Historic Evolution.

Santa Cristina beach lies at the southern end of the La Coruña estuary ("Ría"), approximately 6 Kilometers from the estuary's entrance, forming a classic spit configuration which includes in its interior the Burgo Estuary as well.

The beach has a semi-circular shape and is approximately 1.000 meters in length.

Santa Cristina and Bastiaqueiro Grande beach, which is located to the East of Santa Cristina beach and separated from it by Fiaiteira Point, comprise the bottom of the La Coruña Estuary.

-----

MINISTRY OF PUBLIC WORKS, TRANSPORTS AND ENVIRONMENT, SPAIN.

Manuel Murguía, 6

LA CORUÑA-15011-SPAIN

From East to West, the beach is bounded landward by:

- a pier abutting against a vertical wall 80 meters long
- a vertical wall, approximately 150 meters long, built upon rocks (where "Casa Sara" was formerly located)
- rubble-mound protection, 700 meters in length,  $\cot\alpha=1.5$  and above the Highest Tidal Level (HTL)
- beach and dune, 300 meters in length.
- El Burgo Estuary rivermouth, bordered on its Western end by a cliff and Oza Point, known as the "El Pasaje" zone.

Urban development of the spit, in addition to the effect of the coastal defense works and sand mining in the past, caused the near destruction of almost one Kilometer of dry beach.

Santa Cristina Beach before urban development of the spit (see figure 1 and 2)

FIG.2 SANTA CRISTINA BEACH. 1.950 (PHOTO: BLANCO)

### 1.2 Previous Analysis

Two preliminary studies were performed to evaluate the feasibility of the nourishment project: one by the CEPYC, and the second by Professor Losada, University of Cantabria.

The studies treated the variations of the tidal prisms or river flow of the El Burgo Estuary, incident waves variations, changes to the terms of the global balance of sediments equations, and the deterioration of the land areas adjoining the beach.

The following conclusions were reached:

- During the period studied, the beach would have lost approximately one million cubic meters (600.000 M<sup>3</sup> between the highest high tide and lowest low tide, and 400.000 M<sup>3</sup> between the lowest low tide and the bathymetric 5, which would not have undergone any significant changes in its position.

- The loss would occur in the Eastern zone of the beach.
- The tidal shoal was shifted approximately 100 meters to the West, but keeping its morphology.
- The principal cause of the changes was sand mining carried out during the last century.
- Construction of the Barrié de la Maza Dike has not caused important changes to the beach's contour.
- Construction of the Paseo Marítimo protective breakwater has caused the dismantling of 400 meters of dry beach, although the volume of sand affected by this disappearance is small, approximately 150.000 M3.

Figures 3, 4, 5 and 6, illustrates the shoreline evolution.

FIG. 4 LA CORUÑA ESTUARY - AERIAL PHOTO 1.945

FIG. 5 SANTA CRISTINA BEACH BEFORE NOURISHMENT WORKS.  
AERIAL PHOTO 1.990

After studying the effect of the newly constructed Oza Dock on Santa Cristina beach, it was concluded that it would be feasible to restore the spit to its original position, by means of adding approximately 450.000 M3 of sand dredged from the sea bottom. This figure is similar to the one reached by the CEPYC. (See fig. 7 and 8)

FIG. 6 SANTA CRISTINA BEACH BEFORE NOURISHMENT WORKS

## 2. HYDRODINAMIC CONDITIONS

- Wave regime

- Return Period (years)	Hs (m)
15	9,5
50	10,7
100	11,3
150	12,1

- Tidal range, 4M

- Wave diffraction effect (outer breakwater and the new inner quay of Oza)

- Effect of tide currents

- Annual maximum discharge (instantaneous) 15,9 M3/sg

- Annual average discharge 1,8 M3/sg

FIG. 7 SANTA CRISTINA BEACH BEFORE NOURISHMENT WORKS

FIG. 8 SANTA CRISTINA BEACH AFTER NOURISHMENT WORKS FORECAST.

### 3. SEDIMENTOLOGICAL CHARACTERISTICS

#### - NATIVE SAND

D50= 0,18 mm at -1.0 meter water depth

D50= 0,15 mm at -5.0 meter water depth

#### BORROWED SAND

450.000 m<sup>3</sup> of sand from the sea bottom was added which is D50 = 0,45 mm at -5.0 meter water depth. (FIG.9)

Furthermore, the rubble mound defending the sea front was modified to satisfy aesthetic and social considerations. The city's population can now enjoy sitting on the stepped sea front which has become a popular meeting point at night for the city's teenagers.

FIG. 9 SANTA CRISTINA BEACH AFTER NORISHMENT WORKS

4. MONITORING

4.1 Bathymetric Procedure Utilized

To eliminate possible errors in the oceanographic devices normally used, as well as the influence of the tides, it was decided to gather data as if treating a classic leveling situation on land, that is to say, obviating the sea.

Once the data information was known, it was analyzed by computer to obtain level curves, volumes, etc.

Presently, bathymetric and granulometric works are performed every three months to monitor its evolution for the purpose of identifying areas where accretion and erosion occur. (Fig. 10)

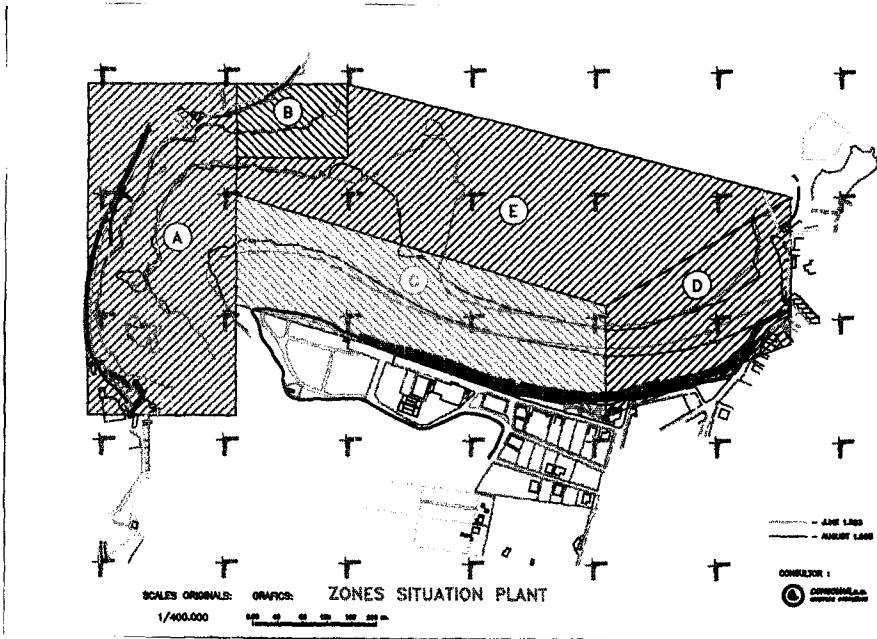

FIG. 10 ZONES SITUATION PLANT

#### 4.2 Elements Studied

The following elements have been studied:

- evolution of the beach's high and low tide lines
- beach transects and channel
- comparison between the areas of erosion and accretion
- volumetric changes of the eroded and accreted areas

#### 5. BEACH EVOLUTION/DEVELOPMENT

The beach has a 900 m.l. coastline which is exposed directly to waves. (See figure 11)  
 The eroded area (600 meters in length) is situated between the transversal outlines 1 and 4 in the East zone and reflects a typical spiral form due to the diffraction process. In this area, the beach is at  $30^\circ$  angle with respect to the alignment of the spit, as indicated in the outlines 5, 6 and 7, whose bathymetrics are noticeably parallel to the Paseo Marítimo and have experienced no changes during the entire process. Therefore, we can emphasize that this alignment corresponds to the beach's geomorphological equilibrium position.

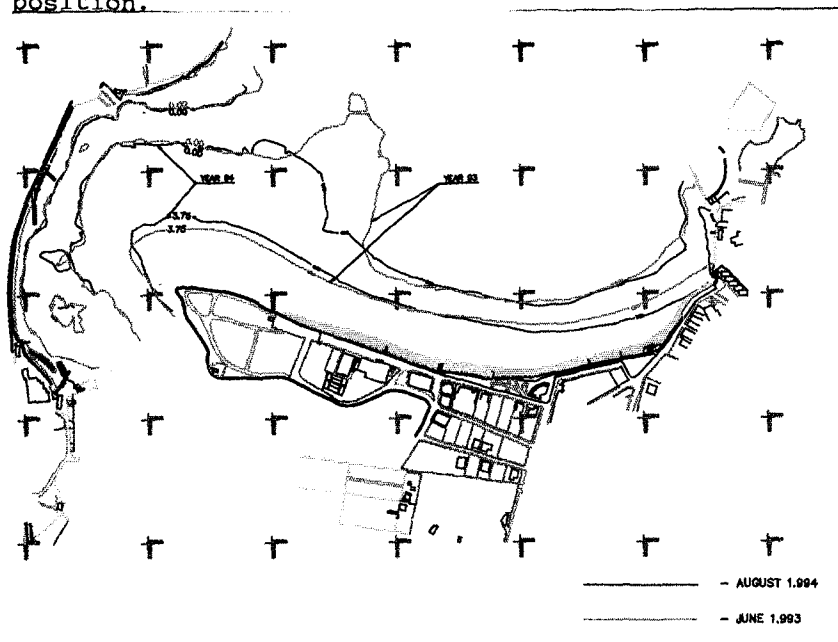

FIG. 11 BEACH EVOLUTION/DEVELOPMENT JUNE 1.993-AUGUST 1.994.

Figure 12 shows the isopachetes curves in the period june 1.993 - august 1.994

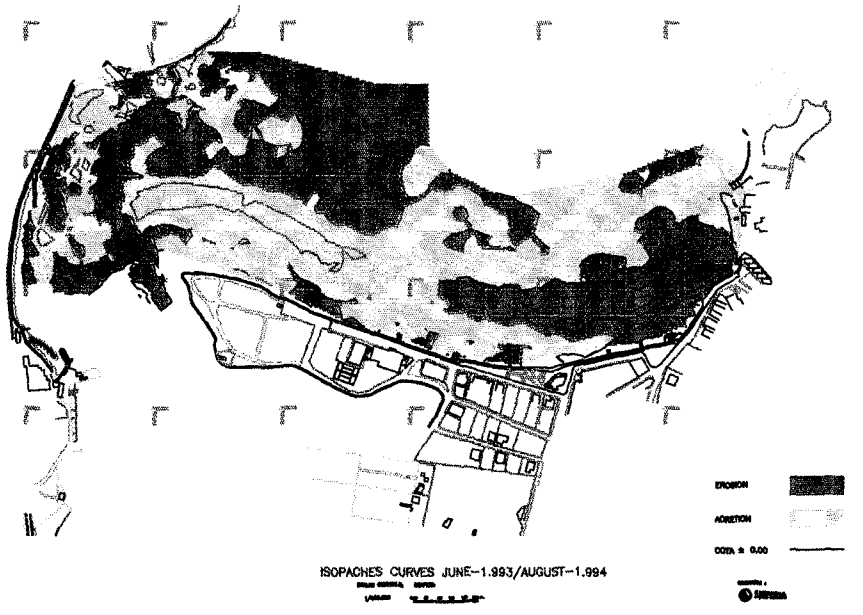

FIG. 12 ISOPACHES CURVES JUNE 1.993 - AUGUST 1.994

The sediment drift movements are showed in figures 13 and 14.

The sand eroded at the beach's Eastern zone is carried and deposited to the Western zone (spit) where significant growth is noted both in surface and elevation as a result of receiving 52.000 M3 continuously in two years (actual monitoring period).

The beach area submerged under the low tide has lost 17.000 M3 due to erosion in the last year. This sand has shifted to the spit's mouth (extreme West) and to the left bank of the river mouth.

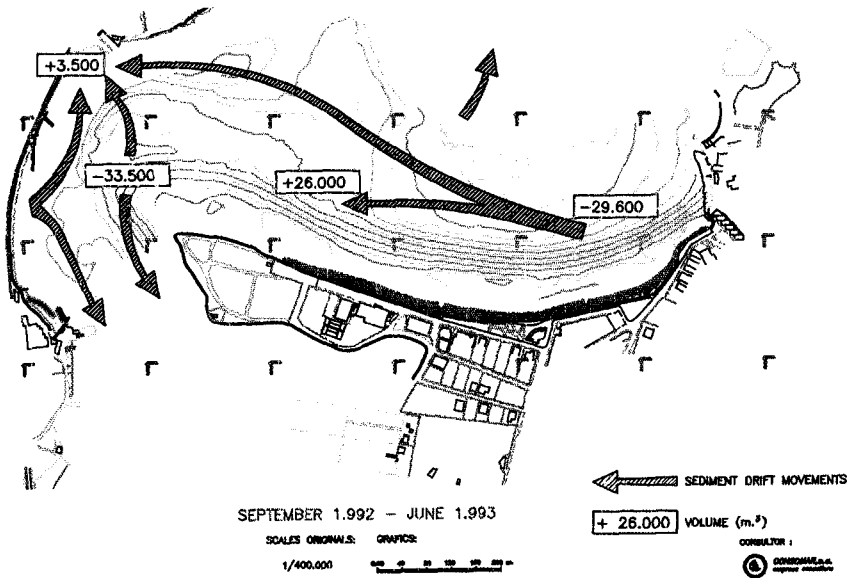

FIG. 13 SEDIMENT DRIFT MOVEMENTS SEPTEMBER 1.992 - JUNE 1.993

FIG 14 SEDIMENT DRIFT MOVEMENTS JUNE 1.993 - AUGUST 1.994

One of the causes of this phenomenon could be the diffractive effect produced by the new Oza breakwater, which was constructed after the beach's nourishment works had been completed, and whose effects (already predicted in the previously mentioned studies) were as follows:

1. Wave height will be reduced at every point on the beach: approximately 50% reduction in the Western half of the beach and 20% reduction in the Eastern half.

No significant change to the wave's transversal gradient will be noted, except in the beach's extreme Western sector.

2. The wave's angle of incidence will not change in the Eastern half of the beach and in the Western half, will be modified approximately 15°, reaching maximum values of 30° in the extreme Western sector of the beach.

Based on data gathered during the monitoring period, the following points can be made:

a) Coastline retreat (outline 2) "East zone" has been:

	Elevation +0,00	Elevation +3,75
Period Sept. 92 to June 93:	-28,00	-28,00
Period June 93 to Aug.94:	-10,00	-21,00
	-----	-----
TOTAL	-38,00	-49,00

b) Coastline advancement (outline 8) "West zone" has been:

	Elevation +0,00	Elevation +3,75
Period Sept. 92 to June 93:	-2,00	+36,00
Period June 93 to Aug.94:	+13,00	+18,00
	-----	-----
TOTAL	+11,00	+54,00

The results of the profiles evolution are showed in figures 15 and 16.

FIG. 15 PROFILE - 2

FIG. 16 PROFILE - 4

## 6. CONCLUSIONS

1<sup>a</sup> The evolution of the beach in the two annual periods studied are similar.

2<sup>a</sup> The east side is being wearing away continually. The semi-circular shape of the beach is identical to an spiral. Typical shape of beaches that are resting on by the balancing diffraction's surge.

3<sup>a</sup> The central area remains in balance and there-is no significant change.

4<sup>a</sup> The west side (arrow) wins an amount of sediments. Coming mainly from the east side. The arrow go forward parallel to itself and in the direction of the flow of the mouth of the Mero river, being more noticeable the advance in the high tide than in the low tide.

5<sup>a</sup> The element of control studied shows and equilibrate sedimentary balance between erosion and accretion.

## CHAPTER 259

### DESIGN AND CONSTRUCTION OF AN EXTENDED BERM BREAKWATER AT PORT OF HAINA, DOMINICAN REPUBLIC

Joaquin Fernandez<sup>4</sup>, Daniel Gomez<sup>5</sup>

#### ABSTRACT

This paper presents the design, model test, and construction to rehabilitate a deteriorated rubblemond breakwater at Port of Haina, south shore of Dominican Republic (Figure 1). The original structure, 350 meter east breakwater and 250 meter west breakwater of rock and concrete block construction, was badly damaged during the storms in 1979 as shown in Figures 2 and 3. After numerous temporary repairs and studies, a rehabilitation design plan was approved. Construction started in June 1993 and is expected to complete by the end of 1995.

## INTRODUCTION

The Port of Haina, a fully developed port complex with a wide spectrum of cargo handling capabilities, is located on the southern coast of the Dominican Republic at the mouth of the Haina River. The harbor is protected against incoming waves by two breakwaters (Figure 2). During the fall of 1979, the site was affected by two hurricanes, Frederick and David, which resulted in considerable damage to the breakwaters. 110 meters of the east breakwater and 65 meters of the west breakwater were essentially destroyed (Figure 3). Since that time, progressive deterioration of the structures warrants a full rehabilitation of the breakwaters. Frederic R. Harris, Inc. was appointed by the Ministry of Public Works of the Dominican Republic to supervise the design review and construction inspection of the breakwaters.

The original contract plan was prepared by TAMS in 1989. During the bid process, the Government of Dominican Republic invites contractors to propose alternative designs leading to lower construction cost and equal or better stability. The winning bid, presented by Conde and Van Oord ACZ (Reference 1), proposed an alternative design featuring extended berm and low, wide crest. This "Extended Berm Breakwater" is different from the conventional "Berm Breakwater" in design concept proposed by Baird et al (Reference 2).

Figure 2 Site Photo

This breakwater design underwent extensive three-dimensional hydraulic model test conducted by Delft Hydraulics and was certified by Danish Hydraulic Institute. The alternative berm breakwater was approved by the Government of Dominican Republic and is being constructed since June 1993.

The construction site is subject to an 8.2 meter significant design wave height with 14 second wave period. The toe of breakwater is located in up to 15 meter water depth. Due to the large design wave, the conventional design by TAMS called for an 80 ton concrete block armor unit. The alternative breakwater by Van Oord ACZ adopted an extended berm design with typical berm width of 20 meter and a wider crest width at 20 meter.

The concept of an extended berm is to pre-break the incident wave further out at the berm elevation. The armor stability is greatly enhanced due to wave breaking on a level surface instead on a slope. The runup height is also reduced by the extended berm. Due to the higher armor stability and lower runup, the alternative berm breakwater is able to adopt a smaller concrete armor unit (40 ton vs 80 ton) and a lower crest elevation (5.0 meter vs 8.2 meter) as shown in Figure 4.

Approximately 30% cost savings are accomplished due to reduced armor and stone sizes and quantities and cheaper handling and transportation costs. By reducing the size of concrete cube, reinforcement is no longer required which simplifies the casting process and increases the production rate.

#### DESIGN CONCEPT

The basic design concept is to respect the geometry and alignment of the existing destroyed breakwater as much as possible in order to reduce excavation and dredging in the old remains. Adopting such a design approach results in non-standard breakwater cross-sections for which no standard design rules have been developed yet. Similar concepts have proven to be economical in other breakwater rehabilitation projects such as Tripoli breakwaters, Libya; Arzew breakwater, Algeria; Ashdod, Israel and Sines, Portugal. In the first two projects a horizontal berm, similar as for Haina had been applied. For Ashdod a dynamic berm has been applied, for Sines a stepped sloping profile was used.

Prior to the development of an alternative design, the causes of damage, state of the damaged breakwaters

and the re-design prepared by TAMS have been studied carefully, as well as the constructibility of the designs. The following discuss background, design approach, and special features of the alternative berm breakwater.

Figure 3 Existing Condition

Figure 4 Typical Section

## Background

The existing breakwaters has been severely damaged by tropical hurricanes passing through the site. The condition of the breakwaters is described as severely damaged armor layers, displacement of concrete caps at the east head section, settlement and severe deterioration of concrete cap walls, and severe damage to the harbor side armor due to overtopping waves. Due to these instabilities the existing profiles, especially the east breakwater, show a flattened shape.

The head of the main breakwater (East Breakwater) situated at approximately -10 meter is located at the edge of a reef running down to approximately -40 meter on a slope of 1V:3H. This means that severe plunging almost deep water waves are directly hitting the breakwater head. The boundary and design conditions are summarized as follows:

Water Level Tides are small in the area and due to the large foreshore depth, the effect of wind setup can be neglected. The maximum still water level fluctuations to be considered are between + and -0.50 meter.

Currents Tidal currents are small in the region and are generally less than 1 meter/second.

Waves The maximum significant wave height offshore Port of Haina at a water depth of 40 meter is 8.7 meter, which is equivalent to a 250 year event. The corresponding wave period is about 16 second. The critical design wave direction is south-east.

Subsoil Conditions The subsoil conditions along the breakwater are characterized as cemented sand varying between dense and very dense.

## Design Criteria

The following design criteria have been adopted for the alternative design:

- During the maximum design wave condition ( $H_s=8.7m$ ) only small damage and displacements to the primary armor is accepted, after which the breakwater must remain able to fulfil its function.
- Hydraulic (dynamic) stable, damage criterium of the rock toe due to severe wave conditions is acceptable as long as it remains to fulfil its function of supporting the armor cubes.

- Displacement of armor units into the entrance channel is not allowed.
- For the underlayers and core material the filter requirements should be met such that no material can wash through the upper- and armor layers.
- No breakage of armor units due to severe wave attack is acceptable, so that the use of special shaped armor units (Dolosse, Tetrapods) will not be considered.
- Wave overtopping during moderate storms (recurrence interval of less than 10 years) must be negligible.

### **Extended Berm Breakwater Design**

Since the critical wave direction is from the southeast, the east breakwater was redesigned with a complete new concept of extended berm principle which would reduce the crest height and armor size while at the same time achieving more protection on wave overtopping and wave transmission. The berm has been designed along the following principles based on experiences on the previous designs such as Tripoli and Arzew and previous model tests:

- The horizontal berm elevation will be constant along the length of breakwater except for the head, where it will be raised in such a way that the amount of excavation of the old breakwater can be reduced to a minimum.
- The width of the berm may vary along the breakwater depending on the local water depth in such a way that the requirements for stability and overtopping are met along the total length of the breakwater.
- The armoring of berm consists of concrete cubes with varying weight, depending on the local wave attack, in such a way that the requirements for stability are met.
- The existing crest base will be improved in such a way that the breakwater will be accessible for trucks and/or cars.

After having developed this basic concept of berm breakwater it has been tested and optimized to an acceptable level of confidence in the 3-dimensional model of Delft Hydraulics Laboratory which tests have been inspected and evaluated by the Danish Hydraulic Institute.

### Geometrical Design

In general the berm level is -0.5 meter MSL, however, at the head section the elevation of the berm has been raised to +3.2 meter MSL, in order to reduce the amount of the excavation of the breakwater remains to a minimum. The width of the crest (approximately 70 meter) is such that wave overtopping over the head will still be negligible. The berm width is 25 meter in the deep sections but at shallow sections the berm width has been reduced to 10 meter for economic reasons. The width of the head section is approximately 70 meter.

Depending on the local wave attack the main armoring varies from 20 tons to 40 tons concrete cubes. The 40 tons concrete cubes are used for the most severely attacked sections, in a double layer for the 1:1.5 side slope of the head and in the transition from head to trunk and in a single layer for the toe of the head and the outer part of the crest of the transition. The 20 tons concrete cubes are used for the less severely attacked sections, such as the crest and the rear of the head, the rear and inner part of the crest of the transition, and the front and rear of the outer trunk section.

The toe of the armor layers is constructed in an excavated trench to ensure stability of the cubes at the toe and to support and protect the cubes on the slope against sliding during wave action. The trenched depth at the toe vary from -5.0 meter at the head to -3.0 meter at the trunk.

### MODEL TESTS

A three dimensional model investigations was carried out at Delft Hydraulics in a wave basin on a linear scale of 1:47. Three test series each consisting of 5 runs of 4 hours prototype were performed applying irregular waves of the JONSWAP type. Due to the exposed position of the west breakwater head particular attention was focused on this part. Especially the breakwater toe was in some occasions directly attacked by the impact of breaking waves. On those locations the toe had to be excavated into the seabed in order to avoid failure of the toe and thus to avoid consequential damage to the armor layer on the 1V:1.5H slope which was supported by the toe. Due to these measures the overall stability remained satisfactory in all test runs up to the maximum significant wave height of 8.7 meter. The following describe more details of the model test.

### Model Scales

Tests have been performed, using a linear scale factor of  $n = 47$ . As gravity forces are predominant in case surface water waves are to be modeled, the Froude number  $v/\sqrt{gD}$  should be identical in model and nature. From this the scales follow for:

$$\begin{aligned} \text{velocity } n_v &= n \\ \text{time } n_t &= n \\ \text{mass } n_m &= n^3 \\ \text{mass density } n &= 1 \end{aligned}$$

For dynamic similarity in rubble-mound stability models the scale factor of the Reynolds number  $vD/\nu$  should also be 1. From these two equations  $n_{\text{Froude}} = n_{\text{Reynolds}} = 1$  it follows that  $n = n^{1.5}$ . Since in all tests water was used and thus  $n = 1$ , perfect dynamic similarity can not be obtained. However by selecting a linear scale factor of sufficient size the effects of viscous forces are minimized.

### Test Program

A total of 3 tests has been performed. Each test consists of 5 runs of 4 hours each. In the first test the amount of excavation was reduced as much as possible by using a conventional toe of 3-6 ton rock on the original seabed level. This test was not satisfactory regarding design conditions. Especially the toe of the head section showed considerable damage, resulting in a great number of displaced cubes. Besides the armor layer of 3-6 ton rock on the rear of the trunk did not remain stable.

To improve the stability, the toe structure and the rear of trunk were changed in the second test. In the second test the toe structure consists of a single layer of 40 ton cubes having a width of 4 blocks, while the top of the toe structure was at the original seabed level. The slope of the rear of the trunk was changed from 1:1.5 to 1:2. The armor layer of the 3-6 ton rock was replaced by 20 ton cubes. The second test was satisfactory.

For the third test the width of the 40 ton toe was reduced to 3 blocks, which also increased the distance from the toe to the steep foreshore. The third test was satisfactory except for the 40 ton blocks were displaced into the entrance channel, for which the second test the toe was stable. Therefore it can be stated that using the positive results of test 2 and test 3 will result in

a satisfactory design. The layout and cross sections of this recommended design are shown in Figures 6 and 7.

Figure 6 Layout of Recommended Design

Figure 7 Typical Section of Recommended Design

## CONSTRUCTION

Construction of the breakwater began in June, 1993 with an estimated 18 month construction period. Special features of the construction work include the following:

### **Large quantities of concrete blocks**

Approximately 2,000 units of 40 ton and 6,000 units of 20 ton concrete blocks are used. Due to the large quantity, an on-site mixing plant is set up to deliver mixed concrete with trucks to the casting yard. Due to the limit of space, concrete units are stacked 3 units high. Each casted unit is inspected visually for cracks, spalling and defects. The rejected units are used at non-critical area or substitute for rock armor. The armors are not reinforced. Photos 1 and 2 presents the production of concrete blocks.

### **Quarry Production**

A large quantity of rocks has to be produced and delivered on site to keep up with the pace of construction. The approximate quantities of rock include:

0 - 1 ton of core stone:	101,600 Cubic Meter
1 - 3 ton of underlayer:	65,200 Cubic Meter
3 - 6 ton armor:	10,100 Cubic Meter

The quarry is located approximately 10 kilometer from site. The local quarry are predominantly limestone with good quality and durability in sea water. The average density of stone is 170 pounds per cubic foot. All rocks delivered to site are inspected for integrity and size, rejected armor are broken and used for underlayer or core material. Photo 3 shows typical rock armor used for west breakwater.

### **Toe Excavation and Concrete Block Placement**

Since deep trench has to be excavated for toe, underwater camera and diver are used to ensure the proper construction of the toe. Concrete blocks are placed randomly with specified density. The blocks are casted with slots on both sides and lifted with a special grip developed by the contractor as shown in Photos 4 and 5.

### **Dredging and Excavation**

Approximately 74,000 cubic meters of material are dredged at the toe, channel, and existing breakwater. During

construction of west breakwater, an extra 13,000 cubic meter of soft silt layer at the head and partial trunk section has to be dredged with hydraulic pump to ensure a firm foundation.

### ONCLUSIONS

The alternative design of berm breakwater is able to employ a smaller concrete block and a less toe trenching requirement. The design was aided with a physical model test and has been proved to be effective at various construction sites. Although several design changes were made, the construction is proceeding well and is expected to complete in 1996.

## CHAPTER 260

### Rehabilitation of the West Breakwater - Port of Sines, Portugal

O.T. Magoon, J.R. Weggel, W.F. Baird, B.L. Edge, R.W. Whalin, D.D. Davidson, & E. Mansard

American Society of Civil Engineers, Waterways, Port Coastal & Ocean Division,  
Rubble Mound Structures Committee  
P.O. Box 279, Middletown, CA 95461, USA

#### Introduction

In 1978, construction of what is now termed the "West Breakwater" at the Port of Sines, Portugal, was nearing completion when it suffered severe damage from a large storm having significant wave heights estimated at nine meters. In February 1979, a subsequent storm with significant waves near the design height of eleven meters virtually destroyed the breakwater. The breakwater, armored with 40 ton dolosse, was approximately 1.7 km long and extended generally southward from the mainland to provide the primary wave protection for the Port of Sines as shown in Figure 1.

Sines is about 120 km south of Lisbon. Water depths of 50 meters exist close to shore at this site making it a viable site for a deep water port. The site is exposed to waves approaching generally from the west to northwest. The spring-tide range is about 3.6 meters. Cargo entering the port includes oil and coal (Dias & Toppler 1993). Petrochemicals and refined petroleum products are exported. Tankers off load their oil at berths 2 and 3 located immediately leeward of the west breakwater shown in Figure 2. With a water depth of 28 meters, berth 2 accommodates tankers up to 350,000 dwt. Berth 1 in the original design could have accommodated tankers up to 500,000 dwt, however, the severe storm damage to the breakwater and a reassessment of port development vis-a-vis changes in the world's tanker fleet resulted in abandoning berth 1. In addition to providing berths itself, the west breakwater shelters a number of other facilities within the harbor complex including the refined products loading berths, coal terminal, break bulk and the proposed container cargoes.

#### Emergency Repairs

In August 1979, following the damaging storms, emergency repairs were started on the west breakwater so that port operations could continue while final rehabilitation plans for the breakwater were developed. Emergency repairs to a 500 meter-long section of the west

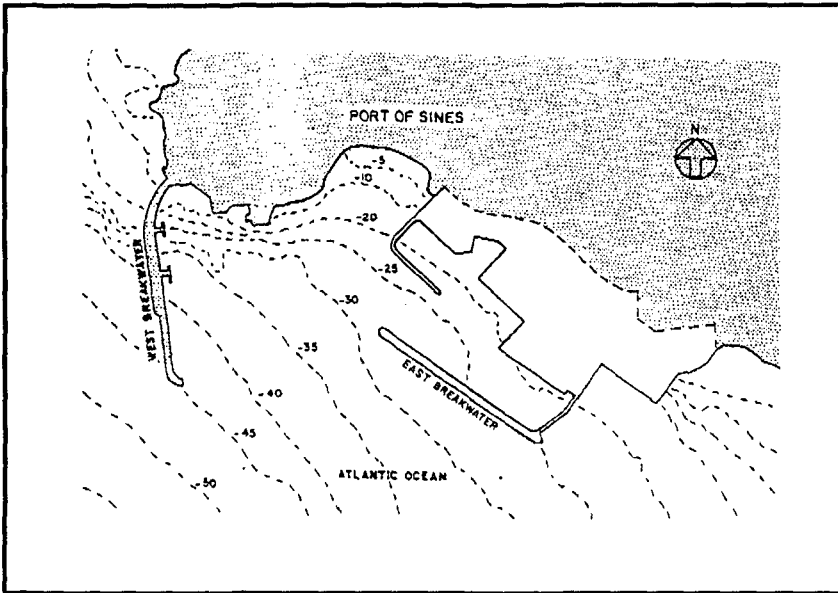

Figure 1. Final Port Master Plan 1985, Sines, Portugal (After Dias and Toppler, 1993)

breakwater were completed in May 1981. Repairs to the breakwater included the placement of 40 ton dolosse from the landward end of the breakwater out to berth 3 and the placement of 90 ton "Antifer" cubes between berth 3 and berth 2 on a slope flatter than that of the original breakwater.

Subsequent to construction, hydraulic model tests of the emergency repairs were made in 1981 at a 1:12 scale (the results of these tests are summarized by Mol, et al., 1983). Generally, the model tests showed that no modifications to the armor adopted for the emergency repairs were necessary. The gaps between the armor blocks and the parapet could be filled to reduce wave impact pressures. The tests also showed that the pipelines on the west breakwater needed protection from overtopping and that improvements to the breakwater from its landward root to berth 3 were necessary.

These results were preliminary to the design of the definitive breakwater rehabilitation, however, the emergency repairs undertaken between 1979 and 1981 imposed some constraints on the final rehabilitation. (Ligteringen, van der Meer and Rita, 1993)

### The Final Design

Additional studies were undertaken for the final breakwater rehabilitation including a reassessment of the wave climate at Sines based on hindcasts for the period 1956-1980 and for 20 major storms, numerical and physical model refraction analyses, additional hydraulic model stability tests -- including some with instrumented armor blocks to measure armor block

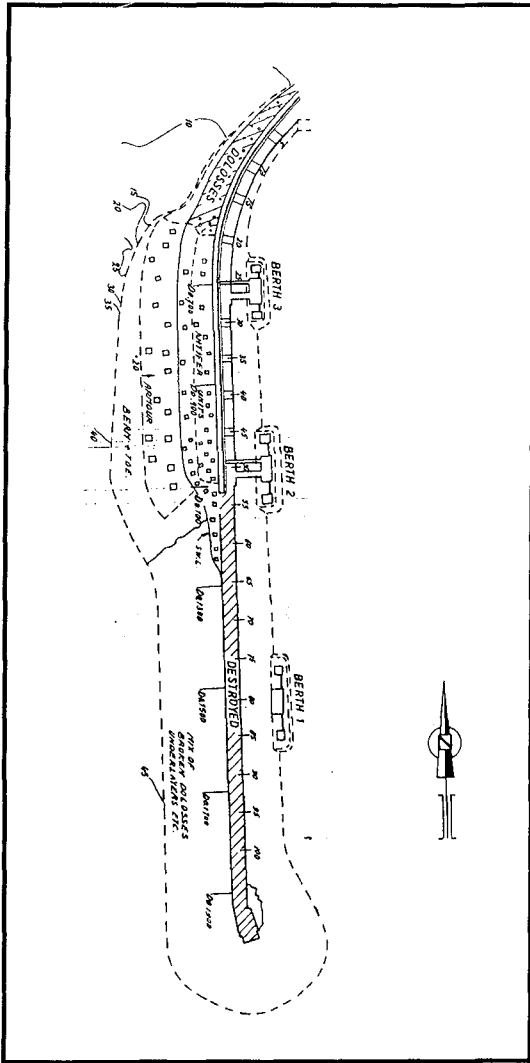

Figure 2. Sines West Breakwater Following Emergency Repairs, April 1981 (After Ligteringen, van der Meer and Rita, 1993)

hydraulic model tests.

The probability that minor damage (2%-3%) would occur at least once during the project's lifetime was 40% and the probability of major damage at least once was 15%. Therefore, based on previous tests of armor unit breakage, a velocity of 3 meters/sec was adopted as the impact velocity causing breakage to the breakwater. (Ligteringen, Ramos, van der Meer and Rita, 1993)

accelerations, prototype- scale Antifer cube impact tests to assess the conditions under which the cubes might break, geotechnical modeling and a study to establish the optimum length of the rebuilt breakwater and its effect on port operations.

The wave height distribution adopted for the design condition has a significant height with a return period of 100 years of  $H_s = 14$  meters. A 50 year return period of  $H_s = 13$  meters, and a 10 year return periods of  $H_s = 11$  meters. While refraction coefficients as high as 1.1 were found for some incident wave periods and directions, no increase in wave height due to refraction was assumed for the design. Design criteria adopted for the outer section of the breakwater trunk (between berths 2 and 3) allow 2% to 3% armor damage by the 100 year event ( $H_s = 14$  meters), based on a project lifetime of 50 years, and 10% damage by the 300 year event ( $H_s = 15.5$  meters). These levels of damage were those established in the earlier

The outer end of the breakwater, beyond berth 2, underwent continued deterioration following the 1978-1979 storms and the design of the new rebuilt breakwater head would have to include some of the remaining debris. See Figure 4. Some of the debris was removed by blasting and excavating, but most of the debris formed the new base of the breakwater head. An optimization study led to the decision to rebuild 500 meters of the outer portion of the west breakwater -- out to the location of the former berth 1, rather than just 300 meters as had originally been planned. This new, round head was armored with 105 ton Antifer cubes having the same dimensions as the 90 ton cubes. Concrete with a density of 3.1 ton/m<sup>3</sup> was used to produce the heavier cubes. The final design, which uses three layers of high density Antifer cubes over the entire breakwater head section, was not model tested.

### Monitoring Program

An extensive monitoring program is currently underway which measures waves, currents, tides, wind, etc., and their effect on the breakwater cross sections (Pita, et al., 1993). Periodic visual and photographic inspections are made from the top of the west breakwater and by boat. These inspections are made monthly between the months of October through April and in the mid-summer -- for a total of 8 inspections per year. In early spring, a yearly inspection is made by scuba divers to determine underwater conditions. Additional data includes: yearly hydrographic surveys, aerial photography/photogrammetry and topographic of the breakwater's cross section. Additionally, special surveys are conducted after storms with significant wave heights greater than 5 to 8 meters. A storm with a 5 meter wave height triggers a visual inspection of the breakwater, while a storm with 8 meter waves triggers a complete set of visual topographic, hydrographic, and photographic measurements.

This paper is the result of a Seminar on the reconstruction of the Sines West Breakwater in Portugal organized by the ASCE Rubble Mound Structures Committee and hosted by the Sines Port Authority, 17-18 September 1993. The complete text of the papers presented at the Seminar and referenced in this paper were published by the American Society of Civil Engineers in New York, NY. The Rubble Mound Structures Committee gratefully acknowledges the extraordinary efforts and the friendly spirit of cooperation of the Administracao do Porto de Sines in making this information available to the Civil Engineering Profession.

Rubble Mound Structures Committee Members who participated in the Sines West Breakwater Seminar and inspection were: Orville Magoon, J.R. Weggel, W.F. Baird, B.L. Edge, E. Mansard and R. W. Whalin.
