A series of model tests was carried out in a wave basin at LNH to quantify the effect of long-crested, oblique waves on rubble mound breakwaters. Four types of armouring units (quarry stone, Antifer cube, tetrapod and ACCROPODE®) were tested, under six angles of wave attack (0°, 15°, 30°, 45°, 60°, and 75°). Overtopping, toe berm and main armour stability were studied as functions of wave obliquity. A method is proposed to reduced the results obtained under oblique waves to those obtained under normal waves, allowing thus for the use of formulae derived under normal waves for the design of a breakwater under oblique wave attack.

#### **Introduction**

Scale model tests aimed to define guidance for the design of breakwaters are mainly conducted in wave flumes, because this is the easiest (and then the cheapest) way to vary the numerous structural parameters involved. Therefore, the effect of wave obliquity on the stability of such structures has been hardly investigated so far, and the estimation of the possible influence of that parameter is often based upon conjectures or derived from tests not directly related to breakwater stability (run-up measurements on smooth mild slopes mainly).

A few tests, or re-analysis of tests, have been found in the literature, which give some trends for the stability of rubble mound breakwaters under oblique waves.

Whillock (1977) made tests on a 1:2 slope armoured with dolosse under regular wave attack at a fixed period. Results of his tests showed a slight decrease in stability up to an angle of wave attack  $\beta$  of 60° and then, at  $\beta = 75^\circ$ , quite a large increase in stability.

This trend for dolosse was also mentioned by Gravesen and Sorensen (1977) who, reviewing tests data with random waves, stated a slight decrease in stability when increasing  $\beta$  (with a minimum at  $\beta = 45^\circ$ ), although they did not noticed such a large increase for angles higher than 60°. For quarry stone, the same authors found

---

<sup>1</sup> EDF - Laboratoire National d'Hydraulique, 6 Quai Watier, 78400 Chatou, France.

that stability was not much affected for  $\beta$  ranging from  $0^\circ$  to  $45^\circ$ , but was then increased a lot at higher angles.

Van de Keeke (1969) performed tests with regular waves (at a fixed period) on rocks for 3 different slope angles (1:1.5, 1:2 and 1:3) and for  $\beta = 0^\circ, 30^\circ, 45^\circ, 60^\circ$  and  $90^\circ$ . He found exactly the same trends as the above mentioned ones.

Gamot (1969) reported tests on a breakwater armoured with tetrapod and stated that the armour stability was increased with increasing angle of incidence, this effect being noticeable as soon as  $\beta > 40^\circ$ . He also mentioned that, once they are initiated, damage increase faster under oblique waves than under normal waves.

Finally, Markle (1989) conducted tests in which toe berm stability was investigated, some of these tests being performed at  $\beta = 45^\circ$ . What he concluded, despite very few tests were conducted, is that there was no great difference in stability associated with different angles of wave attack. Some general trend of higher stability under oblique wave could however be seen, although not well defined.

As only very few papers exist in the literature, a series of model tests was carried out at LNH to quantify the effect of long-crested, oblique waves on the stability of rubble mound breakwaters. Advantage was taken from these tests to study also the influence of oblique waves on overtopping and toe stability. Four types of armouring units - quarry stone, Antifer cube, tetrapod (two layers units) and ACCROPODE® (one layer unit)- were tested, under six angles of wave attack  $\beta - 0^\circ$  to  $75^\circ$ , each  $15^\circ$ . A comprehensive description of these tests is given in Galland (1993).

Fig. 1 Breakwater cross-section (measures in m).

**Model design and layout**

Although these tests do not refer to any field study, the cross-section of the breakwater was defined in such a way that it could represent an actual one. With reference to the maximum significant wave height to be tested ( $H_s = 0.135$  m), the depth of the toe berm below the water level ( $h_t = 0.12$  m) was chosen so that the toe was under strong influence of hydrodynamic forces and the crest elevation ( $h_c = 0.12$  m) so that overtopping was allowed at the same time as damage should start (under normal waves). Doing this way also ensures that the armour layer (which is the main element under study) has a realistic number of units rows, and then a behaviour similar to the one that could occur in the field.

The breakwater consisted in four trunks, each one being 3 m long and armoured with one of the studied units. The total length of the breakwater, including two roundheads, was about 16 m. The rear slope and the crown wall blocks were artificially stabilised, in order to prevent destruction of the breakwater by rear slope degradation and/or crown wall tilting.

### **Breakwater cross-section**

The cross-sections for concrete units were identical and a 1:4/3 slope was chosen (fig. 1). For quarry stones however, the slope was changed into 1:1.5, which is a more realistic value for that armouring unit.

The crown wall blocks, the core, the toe berm, the rear armour layer and the lower part of the front cover layer were identical for all armour units.

### **Characteristics of the units**

Characteristics of the armouring units and toe rocks are given in table 1. The weights and mass density are mean values over at least 30 dry units. In the following,  $\Delta$  is the relative mass density and  $D_n$  the nominal diameter of the unit considered.

Block	$\rho_r$ (kg/m <sup>3</sup> )	W (10 <sup>-3</sup> kg)	$\Delta D_n$ (10 <sup>-2</sup> m)
ACCROPODE®	2310	44.7	3.51
Antifer block	2400	48.6	3.82
Tetrapod	2540	61.6	4.48
Armour rock	2850	(W <sub>50</sub> ) 90.0	5.85
Toe rock	2500	(W <sub>50</sub> ) 38.0	3.75

*Table 1. Characteristics of units.*

Grading characteristics of the rocks used for that study are presented in table 2, together with their mass density.

Rock	W <sub>min</sub> (10 <sup>-3</sup> kg)	W <sub>max</sub> (10 <sup>-3</sup> kg)	W <sub>50</sub> (10 <sup>-3</sup> kg)	W <sub>85</sub> /W <sub>15</sub>	$\rho_r$ (kg/m <sup>3</sup> )
Armour layer (main)	55.0	145.0	90.0	2.05	2850
Underlayer	1.8	9.3	5.0	1.83	2650
Toe berm	27.0	55.0	38.0	1.34	2500
Rear slope	2.8	10.0	6.6	1.57	2660
Cover-layer (lower part)	5.0	17.0	10.0	1.93	2630

*Table 2. Characteristics of rocks.*

Placement of armouring units was realised according to the procedure relative to each unit : for concrete units, this means that the prescribed mesh was respected and, for quarry stones, that they were tipped on the slope. A cover layer armoured with a given armouring unit was always built by the same person, to ensure a good reproducibility in the way of placing the units.

### **Test conditions**

The programme included 6 series of tests, each one being defined by its angle of wave incidence (0°, 15°, 30°, 45°, 60° and 75°). The normal wave test was aimed to

be the reference when analysing the results. To limit the number of investigated stability parameters, the breakwater was placed on a flat bottom (water depth  $h = 0.45$  m) and, as one test consisted in 8 steps with increasing wave height, the peak wave period was tuned at each step so that the wave steepness remains a constant ( $s_{0p} \cong 4\%$ ). The steps duration was adapted so that the total number of waves in each one was 2000. It was large enough a number to ensure both a suitable statistical distribution of waves and a stabilised damage evolution at the end of each step. Targeted wave characteristics are presented in table 3.

Step	1	2	3	4	5	6	7	8
$H_s$ (m)	0.030	0.045	0.060	0.075	0.090	0.105	0.120	0.135
$T_p$ (s)	0.71	0.87	1.00	1.12	1.22	1.32	1.41	1.50
$L_{Op}$ (m)	0.78	1.18	1.56	1.96	2.32	2.72	3.10	3.51
Duration (')	22	26	30	34	37	40	42	45

Table 3. Targeted wave characteristics.

### Test facilities

The tests were performed in a wave basin (fig. 2) which overall dimensions are 33 m x 28 m x 1 m, the maximum water depth being 0.45 m. This basin is fitted out with a hydraulic flap-type wave maker, which paddle is 17 m long, 0.85 m high and can move round the basin, allowing this way for a 180° rotation. The four walls of the basin were equipped with wave absorbers in order to avoid re-reflection.

Fig. 2. Test set-up and location of surface elevation measurement for oblique wave attack (example,  $\beta = 15^\circ$ ).

## **Test procedures**

### **Generation and measurement of waves**

Random waves were generated according to a JONSWAP type spectrum, with  $\gamma = 3.3$ . The wave signals were calculated following the "Deterministic Spectral Amplitude" method, by adding 100 sinusoidal components. They covered the whole steps duration and were computed prior to the tests, which ensured a good reproducibility in the succession of waves during a given step for all tests.

Evaluation of the wave heights is of prime importance for such a study. Under normal waves, water surface elevation was measured with three gauges, which enables to separate incoming and reflected waves by mean of a spectral analysis. Incoming waves characteristics (peak period  $T_p$  and significant wave height  $H_s$ ) were determined this way.

Under oblique waves however, it was not possible to separate incoming and reflected waves. It has then been decided to measure only a "global wave height" (incoming+reflected) at a location in the wave basin that was not optically under direct influence of reflection (cf. fig. 2).

Surface elevations were also measured in front of each test section to ensure that the wave field was homogenous. Wave measurements and their analysis were performed over the whole duration of each step, i.e. over 2000 waves.

### **Damage evaluation**

Damage level to the armour layer  $D_a$  was determined by counting, at the end of each step, both blocks that were removed out of the cover-layer and blocks that were distinctly displaced. Armouring units were coloured and the armour layer consisted in a succession of horizontal coloured stripes, the width of which was two blocks (two median diameters for rock), so that displaced blocks were those displaced out of their coloured band, while still standing in the cover layer. All displaced or removed blocks were counted at the end of each step, so that *cumulated* damage was evaluated.

Cumulated damage to the toe berm  $D_t$  was determined in the same way, but by counting the number of removed blocks only (reshaping not considered).

Damage measurements were made on a 1 m wide section in the centre part of each trunk, called the test section in the following, in order to avoid side effects at the junction of two trunks when oblique waves are performed. Before counting, the water level was lowered to the toe mound. Damage levels are expressed as the percentage of displaced and removed units in the test section.

### **Overtopping measurement**

The number of overtopping waves was recorded on a paper-recorder, over the whole duration of each step, at the centre of each trunk by use of a wave gauge placed on top of the structure. Calibration enabled to discriminate between green water and broken spray. Overtopping was expressed as the percentage of overtopping waves  $N_{ov}$ .

## **Experimental results**

### **Wave field**

The main problem here is the impossibility to separate incoming and reflected waves for the tests under oblique waves, which makes questionable the comparison

between the results of these tests, and even more with those under normal waves. To clear up that point, all steps 7 were re-run with normal waves after all tests had been performed, ensuring very carefully that waves were measured in strictly identical conditions : same wave signal, same location of the wave gauges, same position for the wave guides as during the tests. The global wave height measured under oblique wave was then compared to the incident normal wave height. As their relative difference is expected to grow up with increasing wave height (the reflected wave becoming higher), the comparison between these two values for step 7 is a good evaluation of the accuracy of the global wave height as an estimate for the incident wave height under oblique waves. As this relative difference was lower than 6% for all tests, the global wave height as measured under oblique waves was thus considered as a reasonable approximation of the actual incident one.

### Armour stability

The curves shown hereafter present the percentage of moved armour blocks  $D_a$  as a function of the non-dimensional significant wave height  $H_s/\Delta D_n$ , and are limited to  $D_a < 20\%$ , which is their most significant part.

Table 4 below gives the relative variation in wave height with respect to normal wave when increasing obliquity, corresponding to several given damage levels (start of damage,  $D_a = 5\%$  and  $D_a = 10\%$ ).

$\beta$ (°)	15	30	45	60	75
Antifer Cube					
$D_a < 0.1\%$	+ 56 %	+ 52 %	+ 54 %	+ 130 %	+ 140 %
$D_a = 5\%$	+17 %	+ 31 %	+ 31 %	-	-
$D_a = 10\%$	+ 4 %	+ 13 %	+ 18 %	-	-
Tetrapod					
$D_a < 0.1\%$	+ 52 %	+ 50 %	+ 44 %	+ 48 %	+ 140 %
$D_a = 5\%$	+ 8 %	+ 4%	+ 5 %	+ 22 %	-
$D_a = 10\%$	- 3 %	- 4 %	+ 2 %	+ 16 %	-
Rock					
$D_a < 0.1\%$	- 17 %	+ 65 %	+ 35 %	+ 49 %	+ 98 %
$D_a = 5\%$	0 %	+ 10 %	+ 6 %	+ 6 %	-
$D_a = 10\%$	- 4 %	+ 6 %	+ 15 %	+ 18 %	-
ACCROPODE <sup>®</sup>					
$D_a < 0.1\%$	- 23 %	+ 23 %	+ 38 %	+ 21 %	-
$D_a = 1\%$	+ 12 %	+ 19 %	+ 26 %	-	-

Table 4. Relative variation of  $H_s/\Delta D_n$  with  $\beta$ , with respect to normal waves, for start of damage ( $D_a < 0.1\%$ ),  $D_a = 5\%$  and  $D_a = 10\%$ , or  $D_a = 1\%$ . (- indicate that the corresponding damage level was not reached).

Some trends can be seen in table 4 which indicate an increase in stability with increasing angle of wave incidence. Results are detailed below for each unit.

#### Antifer cube

Four trends can be observed from table 4 and fig. 3 :

- stability increases with increasing wave obliquity,
- start of damage is delayed under oblique waves : it corresponds to a wave height 50 % higher for  $\beta = 15^\circ$ ,  $30^\circ$  and  $45^\circ$  than under normal waves,

- damage, once initiated, increases faster under oblique waves than under normal waves : about two times faster for  $\beta = 15^\circ, 30^\circ$  and  $45^\circ$ ,
- For  $\beta > 45^\circ$ , the increase in stability is so high that nearly no damage occurs.

Tetrapod

Exactly the same trends (cf. table 4 and fig. 4) as for Antifer cube can be noted, although they are somewhat less pronounced and valid mainly for  $D_a < 10\%$

These results (increasing stability with increasing obliquity, faster damage increase under oblique waves) are consistent with those reported by Gamot (1969).

Fig. 3. Armour stability - Antifer cube

Fig. 4. Armour stability - Tetrapod

Fig. 5. Armour stability - Quarry stone

Fig. 6. Armour stability - ACCROPODE®

Quarry stone

From fig. 5 and table 4, start of damage seems to be slightly delayed under oblique waves, but quarry stone is seen to be not very sensitive to wave obliquity, at least at low damage levels ( $D < 5\%$ ). For higher damage levels and  $\beta \geq 30^\circ$ , some trend is noticeable that could indicate an increasing stability for increasing angle of incidence. However, stability strongly increases at  $\beta = 75^\circ$  only.

These points are in accordance with the results of previous works (Gravesen and Sorensen (1977), Van de Keeke (1969)), although the increase in stability was noticed as soon as  $\beta \geq 60^\circ$ .

### ACCROPODE®

Evolution of ACCROPODE® stability with increasing wave obliquity (fig. 6) is quite different from those observed till now. At  $\beta = 15^\circ$ , the armour layer behaves similarly as under normal wave attack, with a very sudden failure (characteristic of a one layer unit) which has led to retain a zero-damage criteria for the design of breakwaters armoured with this unit. At higher angles, its behaviour however significantly differs : after some damage, units rearrange so that the armour is stable again and no more damage occur. This could be explained by the high interlocking of this one layer unit.

### **Toe berm stability**

The curves shown below present the percentage of removed toe blocks  $D_t$  as a function of the non-dimensional significant wave height  $H_s/\Delta D_n$ .

A distinction can be made here between the results for Antifer cube and tetrapod on one hand, and quarry stone and ACCROPODE® on the other hand.

#### Toe berm at Antifer cube and Tetrapod armour layer

The same trends as for the corresponding armour unit can be made (fig. 7 and 8) :

- stability increases with increasing wave obliquity,
- start of damage is delayed under oblique waves : it corresponds to a wave height 45 % higher for  $\beta = 15^\circ, 30^\circ$  and  $45^\circ$  than under normal waves,
- damage, once initiated, increase faster under oblique waves than under normal waves : about 1.6 time faster for  $\beta = 15^\circ, 30^\circ$  and  $45^\circ$ ,
- For  $\beta = 75^\circ$ , the increase in stability is so high that nearly no damage occurs.

What could be add is that, provided that high damage levels to the toe are accepted, a  $15^\circ$  wave incidence could be more dangerous than normal wave.

Fig. 7. Toe stability - Antifer cube

Fig. 8. Toe stability - Tetrapod

#### Toe berm at quarry stone and ACCROPODE armour layer

The behaviour of toe berm at quarry stone and ACCROPODE® armour layer (fig. 9 and 10) is rather atypical. Initiation of damage is not so much delayed under oblique

waves, and the only marked trend is an increase in stability with increasing wave incidence for  $\beta \geq 30^\circ$ . However for ACCROPODE®, the same trend as for Antifer cube and tetrapod can be noticed, that is that damage could possibly be higher at  $15^\circ$  than under normal waves.

Fig. 9. Toe stability - Quarry stone

Fig. 10. Toe stability - ACCROPODE®

Out of the scope of this study but important to notice, is that very high damage levels to the toe berm were reached without endangering the stability of the armour layer.

**Overtopping**

The curves shown hereafter present the percentage of overtopping waves  $N_{ov}$  as a function of the significant wave height  $H_s$ .

For all the units studied here, the percentage of overtopping wave  $N_{ov}$  is seen to present the same features (fig. 11 to fig. 14):

- overtopping is equivalent under normal waves and a  $15^\circ$  incidence,
- overtopping then decreases with increasing wave obliquity,
- at  $\beta \geq 60^\circ$ , overtopping is reduced to nearly zero, except for quarry stone.

Fig. 11. Overtopping - Antifer cube

Fig. 12. Overtopping - Tetrapod

Fig. 13. Overtopping - Quarry stone

Fig. 14. Overtopping - ACCROPODE®

**Discussion**

The aim of this study was not to derive new formulae for the design of rubble mound breakwaters armour layer and toe berm or for the evaluation of overtopping rates, but to provide a better idea of the influence of wave obliquity and also to propose a way for taking into account that influence in existing formulae.

In this idea, and as the apparent slope of the breakwater turns from  $\text{tg}\alpha$  under normal waves into  $\text{tg}\alpha \cdot \cos\beta$  under a  $\beta$  angle of wave attack, it is of interest to study all the above mentioned phenomena as functions of  $H_s \cdot \cos\beta^x$  instead of functions of  $H_s$  only,  $H_s \cdot \cos\beta^x$  being then an *equivalent normal wave height*.

The remaining problem is of course to determine the coefficient  $x$  : results are not numerous enough to allow for the use, from a scientific point of view, of a numerical "best fit" method and the evaluation of  $x$  has then to be derived by visual adjustment, being thus subject to some interpretation.

All the curves for armour, toe berm stability, and overtopping have been re-plotted against  $H_s \cdot \cos\beta^x$ , with the best estimates for  $x$  (fig. 15 and fig. 16). A summary of the values obtained for  $x$  is given in table 5 below.

Such an approach is not fully satisfactory : first because, in some cases, the adjustment is not very good and second because it can not represent the change in the slope of some of the curves that occurs under oblique wave. Nevertheless it could be very useful for the preliminary design of breakwaters.

	Antifer cube	Tetrapod	Quarry stone	ACCROPODE®
Armour stability	0.6	0.3	0.25	1
Toe stability	0.6	0.4	0.6	0.4
Overtopping	1	0.6	1/3	0.75

Fig. 16. Re-plot of the results against the equivalent normal wave height

As a general remark, it should be noted that the results obtained within this study do not support the vague belief in a lower stability at small angles of wave incidence (say  $\beta = 10^\circ$ - $30^\circ$ ). Such a belief is mainly based on run-up measurements, which have been shown to be maximum at  $\beta = 10^\circ$ - $30^\circ$  on smooth, mild slopes (Tautenhain et al. (1982), CUR/CIRIA (1991)).

The numerical values derived within this study are to be taken with great care, as they result from a single test at each wave angle. Many authors (Jensen (1984), Burcharth et al. (1986), Galland and Manoha (1991) for instance) have indeed stated a large scatter in results of such tests, so that a well-defined characterisation of the influence of wave obliquity should be derived from series of identical tests.

But what is important here, is that the results are not drowned into the scatter but *do really define* the trends reported above ; only the actual values of the gains obtained under oblique waves are not known exactly.

## Conclusions

Under the conditions tested :

- flat bottom (no shoaling effect),
- JONSWAP spectrum,  $\gamma = 3.3$  (no influence of spectrum width or wave groupiness),
- constant wave steepness,  $s_{op} \cong 4\%$  (constant surf similarity parameter  $\xi_{op}$ ),
- 2000 waves per step (no influence of storm duration),
- one series of tests per angle of wave incidence (scatter not considered),

the following conclusions can be drawn :

### Armour stability

#### *Concrete units*

- armour stability increases with increasing angle of incidence,
- initiation of damage is delayed under oblique waves,
- once initiated, damage increases faster under oblique waves (Antifer cube, tetrapod).

#### *Quarry stone*

- armour stability is not much influenced by wave obliquity at damage levels lower than 5%,
- at higher damage levels and at incidence higher than  $15^\circ$ , armour stability slightly increases with increasing wave obliquity.

### Overtopping

#### *All units*

- overtopping is equivalent under normal waves and at a  $15^\circ$  angle of wave incidence,
- then, it continuously decreases with increasing incidence.

### Toe berm stability

#### *Concrete units*

- toe berm stability is equivalent, and can even be lower, at a  $15^\circ$  angle of wave attack and under normal waves,
- then it increases with wave obliquity.

#### *Quarry stone*

toe berm stability continuously increases with increasing obliquity.

### Equivalent normal wave height

Results obtained at an angle of wave attack  $\beta$  and a wave height  $H_s$  are equivalent to those obtained under a normal wave height  $H_s \cdot \cos\beta^x$ ,  $x$  being a coefficient which depends on the phenomenon and the unit under consideration. This way, it is possible to use formulae derived under normal wave attack to take into account wave obliquity, for preliminary design of breakwaters.

However it is important to keep in mind that these conclusions result from a single series of tests at each wave incidence, and therefore do not take into account the scatter often reported. Trends presented in this paper are assessed because of the continuity in the evolution of the phenomena they represent, but numerical values should be taken just as estimates. Further testing is still required in order to derive reliable laws taking into account the influence of wave obliquity on the stability of rubble mound breakwaters.

## CHAPTER 78

### WAVE LOADS ON SEADYKES WITH COMPOSITE SLOPES AND BERMS

by  
Joachim Grüne<sup>1</sup> and Hendrik Bergmann<sup>2</sup>

#### Abstract

This paper deals with investigations on loads from wave-induced shock pressures on seadykes with composite slopes and berms. The investigations have been done with large scale laboratory tests, using different wave climate characteristics ( regular waves, PM - spectra and field spectra ). Two different types of dyke cross-sections have been investigated: one with an upper slope 1:6 and a berm in front, and the other one with composite slopes 1:3 in the lower part and 1:6 in the upper part. The presented results were discussed with respect to the influences of wave climate, of absolute waveheights and of geometrical conditions.

#### Introduction

Due to the increasing of storm surges and the supposed long-term rising of water levels at the coastlines of the North Sea, wave loads on seadykes have become again more important for savety analysis of existing dykes. Air entrainment and wave climate characteristics under real sea state conditions play an important role both on shock pressure occurrence and on wave run-up process. Thus boundary effects and scale effects have to be minimized by using field data or large scale laboratory test data. The results presented in this paper were obtained from large scale laboratory tests in the "Large Wave Channel" ( GWK ) at Hannover, Germany, within an extensive research program on stability on sloping seadykes and revetments ( supervision Prof. Führböter + ), which had been supporting partly by the German Research Foundation ( DFG ) for more than 10 years. Previous results from this research program on wave loads on **uniform slopes** have been reported recently for example by Grüne ( 1992 ) for shock pressures and by Sparboom, Grüne, Haidekker & Grosche ( 1990 ) for wave run-ups.

<sup>1</sup> Dipl.-Ing., Senior researcher, Deputy Operation Manager of Joint Institution Large Wave Channel ( GWK ) of the University of Hannover and the Technical University of Braunschweig, Merkurstrasse 11, 30419 Hannover, Germany.

<sup>2</sup> Dipl.-Ing., Researcher, Hydrodynamic and Coastal Engineering Dept. of Leichtweiß Institute of the Technical University of Braunschweig.

First results from the recent investigations with **composite slopes and berms** on loads from shock pressure occurrence will be presented in this paper. First results on loads from the wave-run-ups measured synchronously within the same testseries are reported by Schüttrumpf, Bergmann & Dette ( 1994 ).

### Test equipment and data recording

The investigations have been conducted in the Large Wave Channel ( GWK ) at Hannover ( Grüne, Führböter, 1976 ), which is a joint institution both of the University of Hannover and the Technical University of Braunschweig.

Two different types of dyke cross-sections were installed, which are shown in figure 1. A uniform slope of 1:6, which had been used for previous investigations, in its lower part, firstly was replaced by a berm up to 3.3 m above bottom ( upper cross-section in Fig.1 ), then secondly replaced by lower slopes of 1:3 ( middle and lower cross-section in Fig.1 ). To get a wide range for the vertical distance  $D_c$  between stillwaterlevel *SWL* and slope junction, the replacing by lower slopes of the composite slope cross-sections has been done in two steps. In the first step the lower slope was built up to the same level as the berm ( 3.3 m above bottom ), in the second step up to 4.5 m above bottom.

Waves were measured with wire gauges in front of the wave generator and in front of the dyke cross-sections. The wave induced shock pressures were measured with pressure cells on the slope surfaces in vertical distances of roughly 10 cm. The areas on the dyke surface with installed pressure cells are indicated in figure 1. For the testseries with the berm and the composed slopes with a lower slope up to 3.3 m above bottom pressure cells only were installed on the upper slope 1:6. Furthermore wave run-up was recorded with a step run-up gauge.

The testseries for each of the three dyke cross-sections in figure 1 were conducted with two water levels ( 4.0 m and 5.0 m above bottom ). For each testseries with one of these both waterlevels three different types of wave characteristics were generated: Regular waves, PM - spectra ( narrow banded ) and field spectra ( wide banded ); roughly 15 single tests with each of these three wave climate types. The generated field spectra had been measured in front of similar dyke cross-sections at the german coast during high storm surges.

For data collecting two different modes have been used: With the first one all analog signals from pressures cells, waves gauges and wave-run-up gauges were continuously digitized with 100 Hz and then stored by the main processing computer. With the second mode only higher individual shock pressure events were stored additionally by a personal computer, using 200 ms long time intervals of the pressure signals as uncontinuous windows with a digitation rate of 1 kHz. The advantage of this sample method is the high digitation rate, but due to that the disadvantage is, that the sample is time-restricted, which leads to lossings of total

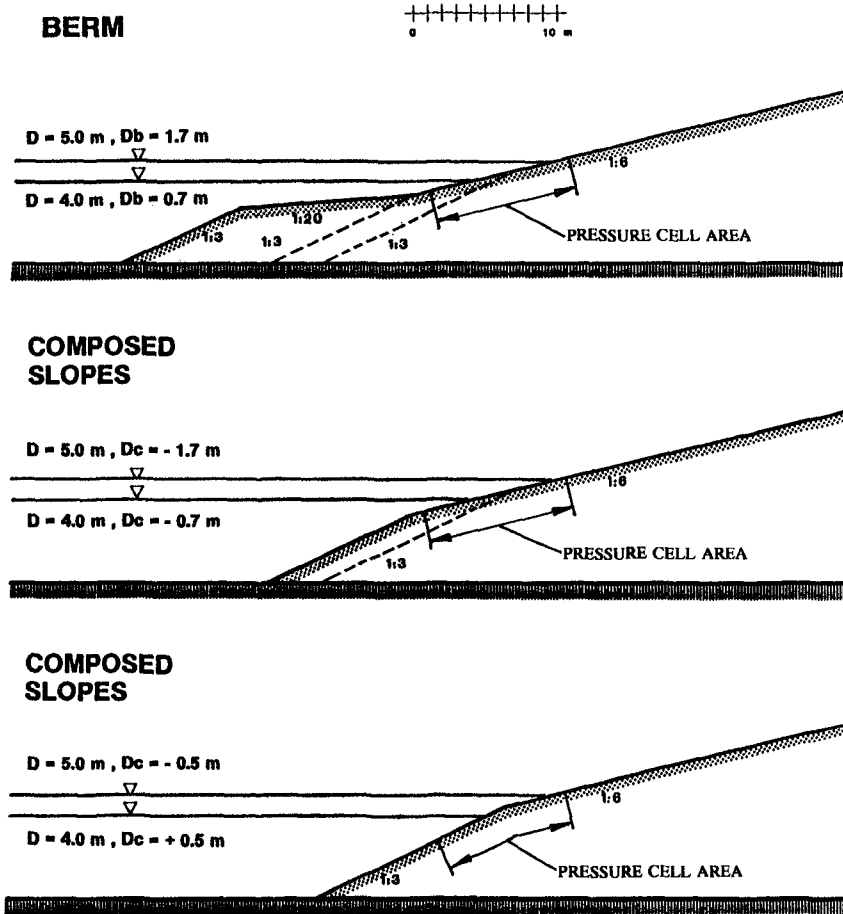

Fig. 1 Dyke cross-sections with berm and composed slopes, investigated in the LARGE WAVE CHANNEL (GWK)

events, especially if the threshold level is accomplished by high quasi-static pressures or by spikes from noises. Therefore a complete data analyzing of all testseries with all pressure cells was done from the 100 Hz digitized datafiles. It must be mentioned, that there were some reduced peak pressure values for higher shock pressure events compared with the 1 kHz-digitation-mode, depending on the peak pressure rising time. The reductions mostly were small, but some rare events were reduced up to approximately 30%. With respect to the stochastic behaviour the influence of partly reduced maximum peak pressure values on the general characteristics of shock pressure occurrence seems to be small.

### Analyzing of shock pressures, definitions

Shock pressures occurring on sloping dyke surfaces are damped more frequently compared to those on vertical walls. Furthermore, especially under real sea state conditions, partly they are mixed with pressure components from waves and wave run-ups. Thus it is often very difficult to distinguish the real shock pressures from the steep wavefronts or the wave run-up fronts, especially if one use normal speed records. In previous reports the author has described an detailed method of analyzing pressure-time histories from high-speed records, which allows a summerizing of the numberless different occurring shapes of pressure-time histories by anatomy parameters ( Grüne 1988a, 1988b, 1992 ).

Using this parameterizing mode, it was possible to evaluate a generalized model of shock pressure occurrence with respect to deterministic and stochastic characteristics. The deterministic parts of the model are represented by local distributions of the anatomy parameters on dyke surface. The local distributions may be divided into different local ranges, which each of it represents a certain state during the breaking process.

For the stochastic part of the generalized model stands the superposition with the stochastic fluctuations of the anatomy parameters. Most data of the different anatomy parameters spread like stars at the sky. But nevertheless there are some clear tendencies and some envelope conditions. There are many possibilities of relating the parameters one with another, reasonable trends were found in dependence on the peak pressure values  $P_{max}$ . In all cases the quality of correlation increase with increasing  $P_{max}$ . Thus the higher peak pressures may be seen as indicators both for general shock pressure occurrence and for details of anatomy parameters.

The following definitions and notations have to be given with respect to the presentation of the results in this paper:

- The maximum pressure value ( peak pressure ) of an individual shock pressure event usually is defined as  $P_{max}$  [  $10^4$  Pa , ( m waterhead ) ].
- The maximum value of all peak pressures  $P_{max}$ , recorded during one single test is defined as  $Max P_{max}$  and is either analyzed from the data of each pressure cell separately, when the results are presented as local distributions or analyzed from all pressure cells, when presented in dependence of the breakerindex  $\xi$ . All pressure data are related to waveheights  $H$  and are therefore dimensionless, using [ m waterhead ] for pressures and [ m ] for waveheights.
- The waves were generated with a closed loop system, to prevent rereflexion at the wave generator. Thus the generated waveheights have been used. A comparison with the waves, measured in front of the dyke shows sufficient agreements, especially for irregular waves. All waveheights  $H$  are defined as mean waveheights for regular waves and as significant waveheights  $H 1/3$  for irregular waves.

- The unit for the local distribution on the slope surface is defined as waveheight related vertical distance  $\Delta D/H$  between pressure cell and stillwaterlevel SWL as shown in figure 2. The vertical distance between the slope junction and SWL is defined as  $D_c$ , as shown in figure 3. The waterdepth on the slope as  $D$  and the waterdepth on the berm as  $D_b$ .
- The pressure data are either presented in dependence of the breakerindex

$$\xi = H * \tan \alpha / \sqrt{H/L_0}$$

with  $H = H_m$ ,  $T = T_m$  for regular waves and  $H = H/3$ ,  $T = T_p$  for irregular waves or as local distributions. An example for a local distribution of the waveheight related maximum peak pressures  $Max P_{max}/H$  is shown in figure 4. The lefthand plot shows for one single test the local distribution of  $Max P_{max}/H$  for each pressure cell. In the righthand plot such local distributions from all tests within a testseries with constant boundary conditions ( for this example:  $D = 5.0$  m,  $D_c = - 0.5$  m, PM - spectra,  $H = 1.10$  m ) have been summarized by an envelope curve.

Fig. 2 Definition of  $\Delta D$

Fig. 3 Definition of  $D_c$

Fig. 4 Example for a local distribution of pressure data  $Max P_{max}/H$

### Results for the dyke with a berm

Figure 5 shows the local distributions of the envelope curves for the testseries with regular waves. It is obvious, that for the testseries with a waterdepth of 5.0 m ( left hand plot ) there is a clear trend of higher waveheight related pressures  $Max P_{max}/H$  with decreasing absolute waveheight  $H$ , which may easily be explained by stronger breaking of higher waves on or in front of the berm due to restricted waterdepths  $Db$  on the berm. There is also a trend of shifting of the local maximum value area to smaller related waterdepths  $Delta D/H$  with increasing absolute waveheight  $H$ , which is also caused by the restricted waterdepth on the berm. A comparison with the corresponding results for the 4.0 m waterdepth in the left hand plot shows, that the trend to higher pressure values is only dominant for waveheights  $H \leq 0.5$  m. With the waterdepth  $Db$  of 0.7 m all higher waves must be broken at least partly.

Fig. 5 Local distributions of  $Max P_{max}/H$  for testseries with regular waves

The same trends were found for the results of the testseries with PM - spectra in figure 6, but the differences between the values  $Max P_{max}/H$  of the different waveheights  $H1/3$  are smaller. That is caused by the fact, that not all waves in the irregular wave train were broken compared to a regular wave train with same waveheight  $H$  as  $H1/3$  in the irregular wave train. The same trend also is obvious in figure 7, where the data  $Max P_{max}/H$  of all single tests with regular and irregular waves are plotted versus the breakerindex  $\xi$ .

The envelope curves of the local distribution for all tests with an absolute waveheight  $H$  ( $H1/3$ ) of 1.10 m are plotted for the different wave characteristics

in figure 8. The results indicate for all tests with regular waves smaller pressure values  $Max Pmax/H$  than for irregular waves. Similar results were found for other waveheights. The influence of wave characteristic also comes out in figure 9, where all test results are plotted versus the breakerindex  $\xi$ . Both the influence of wave characteristics and of restricted waterdepth can be seen distinctly.

Fig. 6 Local distribution of  $Max Pmax/H$  for testseries with PM - spectra

Fig. 7  $Max Pmax/H$  versus breakerindex  $\xi$  for of regular and irregular waves

Fig. 8 Local distribution of  $Max P_{max}/H$  for different wave characteristics

Fig. 9  $Max P_{max}/H$  versus breakerindex  $\xi$  for different wave characteristics

The mentioned trends lead to summarizing all test results as shown in figure 10, where the maximum peak pressures  $Max P_{max}/H$  are plotted versus the waveheight related waterdepth  $Db/H$  on the berm. Both for regular and for irregular waves the same tendency comes out clearly, but with a different mean or upper value gradient. The corresponding maximum value  $Max P_{max}/H$  for an uniform slope 1:6 is plotted in figure 10 as a dotted line. This value is a constant one due to much higher waterdepth and was estimated from previous field and large scale laboratory investigations.

Fig. 10  $Max P_{max}/H$  versus waveheight related waterdepth  $Db/H$  on the berm

It is obvious, that compared to the uniform slope value for the berm, there are as well lower as higher pressure values, depending on the waveheight related waterdepth  $Db/H$  on the berm. Both effects may be explained either by the wave breaking effect in front of the berm ( slope 1:3 ) for lower  $Db/H$  or by the wave shoaling effect on the 1:20 slope of the berm for higher  $Db/H$ . Further it can be expected, that the increasing effect due to shoaling is limited by higher related waterdepths and that the upper value curve goes finally back to the uniform slope 1:6 value. Finally it must be remarked, that decreasing pressure values on upper slope 1:6 due to wave breaking automatically cause higher pressure values on the berm slopes 1:20 and 1:3, which could be recognized during the tests visually and acoustically.

#### Results for the dyke with composed slopes

The trends with respect to absolute waveheight and to wave characteristics differ for the results of the testseries with composite slopes between the testseries in dependence on the level of slope junction and stillwaterlevel. In contrast to the

results for the berm the trend of higher peak pressures  $Max P_{max}/H$  in dependence on the absolute waveheights  $H$  for the testseries, which is most influenced by the upper slope 1:6 ( $D = 5.0$  m,  $D_c = -1.7$  m), is negligible for regular waves and only small for irregular waves, respectively, as shown in figure 11.

If one compare the influences of the different wave characteristics on the results in figure 12, there is the same trend to lower pressure values  $Max P_{max}/H$  for regular waves, which was found for the berm, but with a smaller magnitude.

The maximum values of all single tests of this testseries are plotted in dependence on the breakerindex  $\xi$  in figure 14a. There is a certain influence of the wave characteristics, but the influence of the absolute waveheights was found to be more or less negligible.

A different trend was found for the testseries, which is mostly influenced by the lower slope 1:3, as the junction of the slope is 0.5 m above SWL ( $D = 4.0$  m,  $D_c = +0.5$  m). The tendency on the influence of absolute waveheights in figure 13 changes to higher values  $Max P_{max}/H$  with higher absolute waveheights, less clear for regular waves, but very clear for the PM - spectra.

Fig. 11 Local distribution of  $Max P_{max}/H$  for testseries with regular waves.

For the different wave characteristics in figure 15 still a trend was found to higher pressure values with irregular wave trains, which also comes out clearly with the plot of all results versus the breakerindex  $\xi$  in figure 14d.

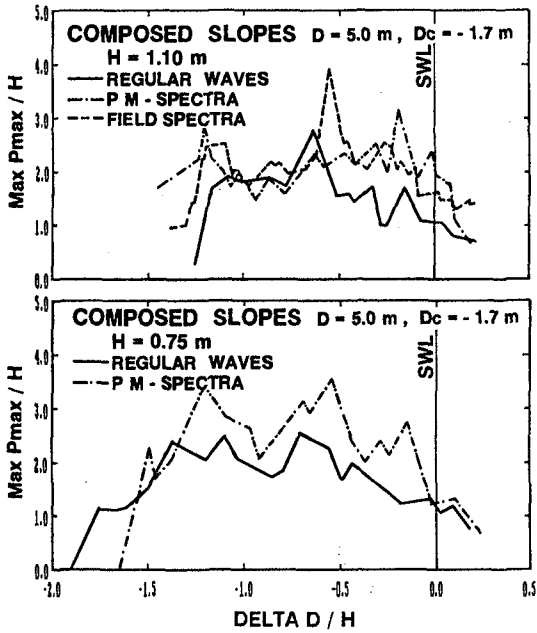

Fig. 12 Local distribution of  $Max P_{max}/H$  for different wave characteristics

Fig. 13 Local distribution of  $Max P_{max}/H$  for regular waves and PM - spectra

Fig. 14 a

Fig. 14 b

Fig. 14 c

Fig. 14 d

Fig. 14 *Max Pmax/H* versus breakerindex  $\xi$  for all testseries with composed slopes

Fig. 15 Local distribution of  $Max P_{max}/H$  for different wave characteristics

Similar results were found with the other both testseries ( $D = 4.0$  m,  $D_c = -0.7$  m;  $D = 5.0$  m,  $D_c = -0.5$  m): Firstly, no distinct trend for the dependence on absolute waveheight  $H$  for regular waves, but a small one for irregular waves. Secondly, the influence of the wave characteristics is evident as shown in figure 14b and 14c, where all test results are plotted versus the breakerindex  $\xi$ . Smaller pressure values  $Max P_{max}/H$  were found for regular waves, as well as in all other testseries.

To summarize the pressure results from all 4 testseries with composed slopes, the pressure values  $Max P_{max}/H$  of all single tests have been plotted versus the waveheight related vertical distance  $D_c/H$  between slope junction and stillwaterlevel  $SWL$  as shown in figure 16 for regular waves (upper part) and irregular waves (lower part). If the slope junction lies below  $SWL$ , the slope 1:6 seems to be dominant. If the slope junction lies above  $SWL$ , the lower slope 1:3 with higher pressure values is dominant. The transition range has a high gradient, if the slope junction is around till roughly half a waveheight below  $SWL$ . The eye-fitted upper value distributions are plotted as dotted lines in figure 16. A qualitative generalisation is given in figure 17. The asymmetry of the influences from both slopes with respect to the distance  $D_c/H$  between slope junction and  $SWL$  is distinct.

Also peak pressure values smaller than for any of both slopes occur at  $D_c/H$  roughly half a waveheight below  $SWL$  from the testseries with  $D = 4.0$  m,  $D_c = -0.7$  m. From the local distributions of the results it was found, that these results may be partly effected by the restricted pressure cell area below  $SWL$ , because for this testseries pressures only have been measured on the upper slope 1:6.

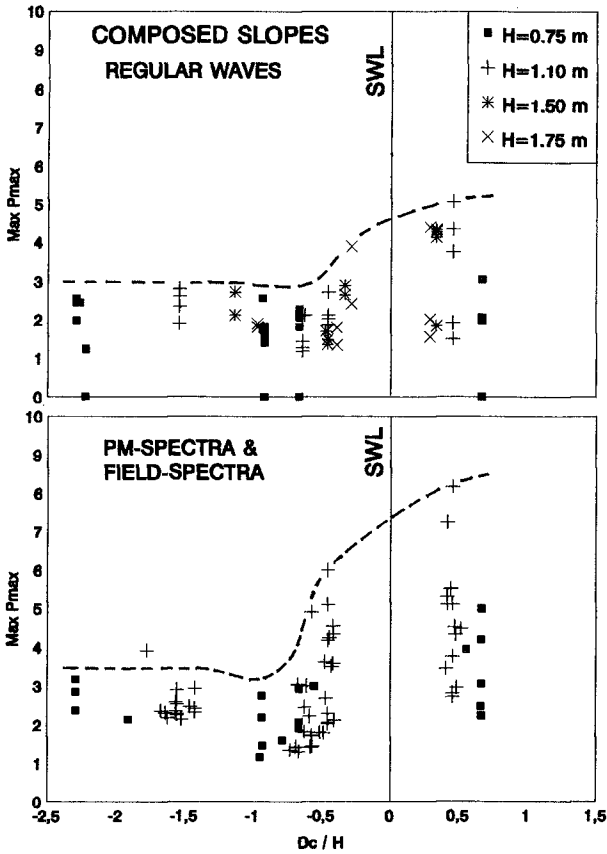

Fig. 16  $Max Pmax/H$  versus  $Dc/H$  for all tests with composed slopes

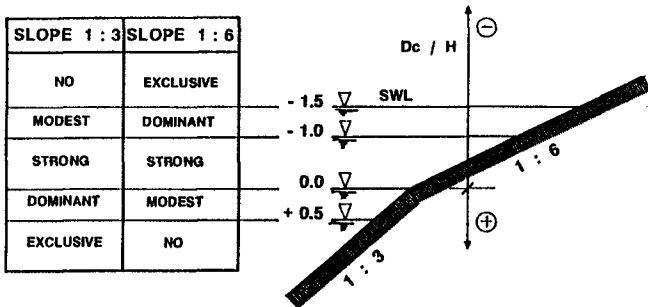

Fig. 17 Scheme of influence of slopes on shock pressure occurrence

### Conclusion

From the results the following statements on the maximum peak pressure occurrence may be concluded:

- There are trends in dependence of the absolute waveheight, but in different ways:
  - a.) Where wave trains are broken at least partly, before they reach the slope ( for instance at the berm ), the waveheight related maximum pressure values  $Max P_{max}/H$  increase with decreasing absolute waveheights  $H$ .
  - b.) Where waves trains are broken completely by the slope ( for instance at composed slopes ), the pressure values  $Max P_{max}/H$  may increase with increasing absolute waveheights  $H$ .
  
- There are strong influences of the wave characteristics:
 

Regular waves always lead to smaller related pressure values  $Max P_{max}/H$ , if regular waveheights  $H$  are compare with irregular waveheights  $H1/3$ . This confirmed previous results for the uniform slopes, that for comparison one should use mean waveheights both for regular and irregular waves. Nevertheless one should not use regular wave results for design of coastal protection works generally.
  
- Some special effects of geometrical conditions can be stated:
  - a.) For a slope with a berm in front, the peak pressures  $Max P_{max}/H$  may decrease due to breaking effect or increase due to shoaling effect depending on waterdepth on the berm.
  - b.) For composed slopes there is a transition range, which is asymmetric with respect to the distance  $D_c$  between slope junction level and stillwaterlevel  $SWL$ .

## CHAPTER 79

### COMPUTERISED METHODOLOGY TO MEASURE RUBBLE MOUND BREAKWATER DAMAGE

Bruno CHILO<sup>1</sup> , Franco GUIDUCCI<sup>1</sup>

#### Abstract

The damage of rubble mound breakwater is a basic interest in the field of design and realisation of coastal works. The individuation of formulations to associate this element with the geometrical characteristics of structures and wave climate conditions is carried out using physical model tests. It is therefore necessary to implement an objective damage valuation method able to point out armour units movements on the layer from the settlement phase to the collapse.

A methodology able to permit an exact measurement of the external layer armour units movements and its damage has been carried out by ESTRAMED S.p.A.; it consists on a computerised analysis of armour units movements in order to give an objective valuation of the damage.

Such methodology is based on photographic images analysis of the armour taken from a fixed point. The procedure permits to determine the position of each armour unit on the images relative to the subsequential damage stages and the movement of each armour unit.

#### Introduction

The experiences relevant to the Port of Sines Main Breakwater, the improvement of computers capabilities, the wider use and the development of the physical modelling and the studies carried out in the last years improved the analysis of the rubble mound breakwater damage. Relations between rubble mound breakwater stability and incident waves and section characteristics were deduced.

---

<sup>1</sup> ESTRAMED S.p.A. - Via Campobello n°6 - 00040 POMEZIA - ROMA - ITALY.

The breakwater stability is usually referred to the eroded volume or to the percentage of units moved more than a fixed threshold.(A.I.P.C.N. 1992, British Standard, 1991).

The measurements of these parameters are extremely important to carry out investigations on the rubble mound breakwater damages and to grow research in this field.

The use of objective methodology to describe the phenomenon from the first movement up to the collapse is essentially.

### Methodology purposes

At ESTRAMED S.p.A. a methodology that allows to measure the external layer armour units movements by a computerised procedure, was developed.

Aims of the methodology were the following:

- to get information on the small armour units movements;
- to obtain objective measurements of the layer damages;
- to analyse armour units movements in a time comparable with the stability test duration.

It is necessary to obtain information on the small armour units movements as the experience on the physical models to test the rubble mound breakwater stability indicates. Small armour units movements are very important because they allow the description of layer damages under the action of ordinary wave motions and to evaluate the entity of the first settlement of the breakwater and therefore, on experiments in which comparative or repetitive tests are required, to make a correct comparison of breakwaters behaviour under the action of extreme waves.

A precise knowledge of small and large movements of the units make possible to draw graphs of the damage on the basis of the incident waves characteristics. These graphs are useful tools for the designer in order to choose the best solution considering the entire structure behaviour, not only in severe damage conditions. Small armour units movements analysis is of interest for the comparison of different solutions even when no severe damage level is reachable, for example, during tests on structures where the wave attack is limited by bottom effects.

The use of a standard laboratory method to measure rubble mound breakwater damage guarantees the repetitiveness of test results and permits to compare results obtained from a large number of experiences carried out by different laboratories, increasing in this way the base of available experimental data for further formulations.

To obtain analysis results of armour units movements in a time comparable with the tests duration allows to make strategy choices on the next tests to be carried out. This permits the optimization of the tests programme and therefore, a large number of damages stages can be easily examined obtaining more information compared to the methodologies often used to measure rubble mound breakwater stability.

### Methodology description

The methodology consists of five subsequent activities:

- set up of rubble mound breakwater armour units;
- acquisition of breakwater images in the subsequent conditions of damage and their importation into the computer;
- images processing;
- check and eventual corrections of images processed;
- print out of the analysis results.

Armour units in nine different colours are employed to build the external layer of the armour so that two units of different colours are located between two units of the same colour and the individuation of the position of each armour unit on each images is facilitated.

The colour selection for armour units painting is very important in this methodology. Each colour must be detected as different from the others by the computer analysis. The achievement of this objective depends on armour units colouring, lighting sources, breakwater contour characteristics, photographic equipment and images filtration; a useful set of colours was selected by Estramed carrying out several tests.

Once placed the units, it is necessary to draw a white point on the sight view of each of them as shown in figure 1 where in the white window are highlighted the units with the same colour. The movement of this point on the sequential images will show the armour unit movement.

Figure 1 - Set up of rubble mound breakwater armour units

In order to permit the comparison of the different images, at the beginning of the experiments it is necessary to put three marks in the model so that the software can be able to compensate eventual shot point movements and to adopt one single coordinates system to locate each armour unit on each image.

The methodology permits to acquire rubble mound breakwater images in different damage stages and to import them into the computer. The camera station must be fixed and located in such a way that the shooting plane is parallel to the breakwater armour. Images have to be acquired without water in order to avoid reflection and refraction phenomena. The procedure uses a still video camera and a digitiser card with a resolution of 768x576 pixel to acquire and to import the images into a personal computer. Images must be taken at the end of the section construction and after each wave attack.

Once imported into the computer the images are analysed by a software that was set-up by Estramed. Such analysis individuates for each armour unit its colour and the coordinates of the white point located on it as pointed out in figure 2.

Figure 2 - Example of the analysis result

At the end of this phase, a further analysis is carried out on the files containing, for each image, the coordinates and the colours of the units in order to verify the number of armour units of each colour among all the images. If any inconsistencies arises (for example the number of armour units can be lower compared to the previous one in the case where one or more units rotate on themselves without originate unit barycentric movements, hiding the white evidence point) the operator, who disposes of an edit menu, points out and solves them.

Scope of the second analysis phase is to individuate the position of the same armour unit among all the different images. The procedure performs an analysis examining two files relevant to subsequent images: the file relevant to the less damaged condition is considered as reference for the computation of the units movements. The analysis is carried out taking into account separately armour units of the same colour. As first step, each armour unit of the first image is coupled with the nearest unit of the second image having the same colour in a range less than 0.5 times the characteristic length of the unit. Successively, the analysis is carried out on the not yet associated units increasing the range up to two and half times the characteristic length of the unit as shown in figure 3.

Figure 3 - Scheme of criteria to identify same unit in two successive images

The successive step on the not yet associated units is the coupling of the units present inside circular sectors (see figure 3) which centres are located on the units of the first image, which axis of symmetry is a vertical line and which angle is initially equal to  $10^\circ$  and is successively increased by step of  $10^\circ$  up to  $180^\circ$ . If two possible associations are individuated in the sector, the procedure chooses the one with the minimum angular value compared to the vertical.

Once the coupling of the units has been carried out, the results of the analysis are submitted to the operator for check and for eventual corrections.

The software shows a screen with four windows as shown in figure 4. An image is shown in the upper left window while the successive one appears in the upper right one. The lower right window shows the armour units movements and the lower left one displays an edit menu and the following information:

- number of units for each colour individuated in the two images;
- total number of units individuated in each image;

- number of reference marks individuated in each image.

If any inconsistencies arise the operator can correct the results using the edit menu in a proper way.

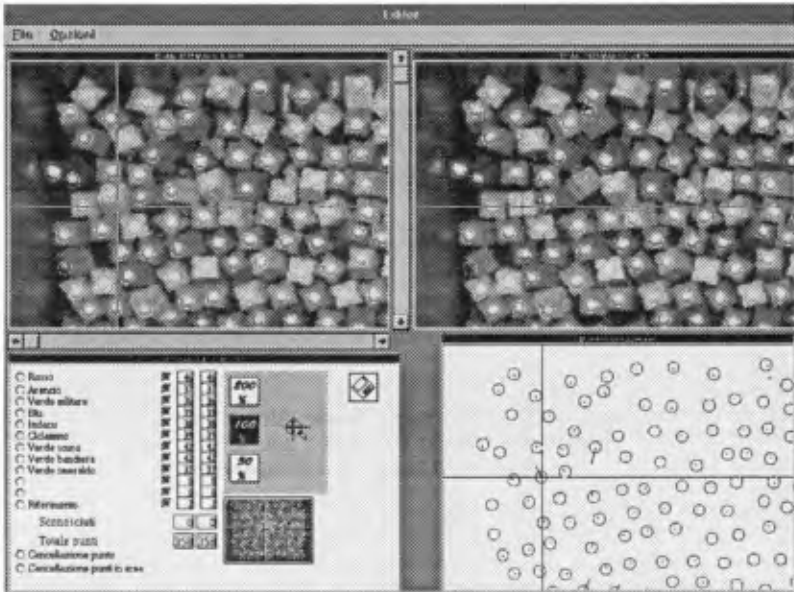

Figure 4 - An example of the results of the units movements analysis

A sequence of the results of the units movement analysis relevant to a test series with increasing waves is shown in figure 5.

The first image (upper left) of figure 5 was taken after the construction of the model and before the start of the tests. The second image (upper right) shows the units movements measured after a test with a very low significant wave height while the last image (lower right) shows the damage of the breakwater after a test characterised by a significant wave height higher than the design one.

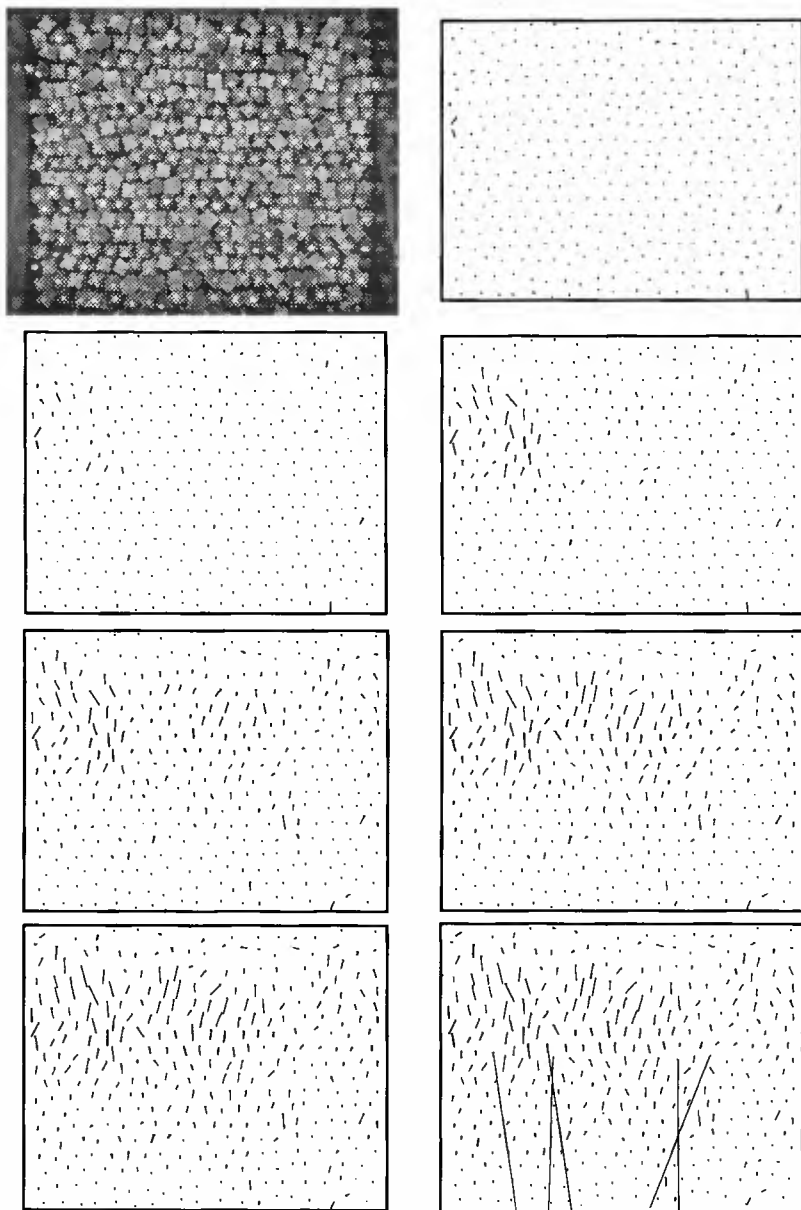

Figure 5 - A sequence of the results of the units movements analysis

The methodology allows to obtain a wide range of information about the units movements. Many information on the small movements of the units can be obtained, too.

A standard plot of the results of the analysis indicates for each test or wave height the percentage of armour units which movements were less than fixed values that are generally part of the characteristic unit length (B). In figure 6 a plot of the results relevant to the analysis of figure 5 is shown.

Figure 6 - Units movements versus significant wave height

The methodology has been tested comparing its results with those obtained using a traditional approach. The agreement was very good, at any rate, it must be noted that both methods find difficulties when an unexpected collapse of the whole breakwater happens (with more than 30% of armour units dislocated). This is not a real limit to the method application because, in such conditions the single armour unit movements doesn't give any essential indication on breakwater stability.

Fields of application of the methodology

The methodology has several fields of application in laboratory testing.

A first field is relevant to the two dimensional physical modelling. The methodology allows to carry out objective measurements which are essential for repetitive or comparative tests; to describe accurately the damage behaviour of the breakwater armour and to obtain results in a very short time. In the Estramed S.p.A. Laboratory the methodology has been employed in two dimensional tests to individuate also the movements of toe protection blocks and submerged crest blocks.

A second field is relevant to the three-dimensional physical modelling. Treating these models as plane images, the methodology cannot describe the armour units absolute movements but the parameters to asses a roundhead stability are various and not limited to the armour units movement. Therefore the computerised analysis gives a useful contribute that can be surpassed only using a very sophisticated three dimensional survey system.

Two-dimensional and three-dimensional applications of the methodology are currently used at Estramed S.p.A. Laboratory.

### Conclusion

The computerised methodology allows a reliable and objective measurement of rubble mound breakwaters damage.

The analysis of a stability test is obtained at the end of each run in a shorter time than the test duration.

The use of this methodology permits the standardisation of test modalities and damage levels measurements.

The application in reality of this methodology, with some modifications could bring a remarkable increasing to rubble mound breakwaters know-how.

## CHAPTER 80

# WAVE BREAKING OVER PERMEABLE SUBMERGED BREAKWATERS

Masataro Hattori<sup>1</sup> and Hiroyuki Sakai<sup>2</sup>

### Abstract

A laboratory experiment was carried out in a wave tank to examine significant features of wave breaking over permeable submerged breakwaters and to determine the breaker height and depth indices. Submerged trapezoidal-shaped breakwaters were placed on a 1/20 steel slope, and permeability of the breakwaters was varied.

The experiment showed that the breaker height and depth change with the breakwater permeability governing the strength of return flow over the breakwater. Breaker height index was developed in terms of the integrated parameter  $\xi_s$  proposed by Hara et al. (1992), which consists of the geometrical and structure properties of the breakwater as well as properties of incident waves. To determine the breaking position or depth, additional indices were also proposed. Validity of the computation scheme of the breaker height and position were confirmed by comparisons with the experiments.

### INTRODUCTION

As is commonly known, permeable and submerged, low-crested rubble-mound, breakwaters force to break incoming steep waves and dissipate effectively the wave energy. Therefore, many breakwaters of this type have been built or planned at various locations to stabilize an eroded beach and to reduce damages of coastal and harbor structures due to severe wave actions.

<sup>2</sup> Engineer, Urban Development Bureau, Yokohama City, Minato-cho 1-1, Naka-ku, Yokohama City 231, Kanagawa Prefecture.

To meet requirements of the design and construction of the structures, many theoretical and experimental studies are extensively making to deepen understanding of the physics of wave breaking due to the submerged breakwater. The wave breaking may be sufficient to provide the principal control over the wave motion and resulting phenomena around the submerged breakwater, especially behind the breakwater, such as wave transmission, wave set-up, and so on. It seems likely that lack of a sound understanding of wave breaking over the submerged breakwater acts as a bottleneck of the physical and numerical examinations on the hydraulic function of the submerged breakwater.

A series of laboratory experiments was conducted to examine breaking wave properties over permeable submerged breakwaters and to determine the empirical relationships or breaker indices developed from measurements.

The results from the study will be useful for modeling the nearshore wave field around the breakwater and for predicting the evolution of the protected beach profile.

## EXPERIMENTAL EQUIPMENT AND MEASUREMENTS

### Experimental

Figure 1 shows the general arrangement of equipment. Experiments were carried out in a 20-m-long, 0.30-m-wide, and 0.55-m-high glass-walled wave tank, containing a steel beach of 1 on 20 slope. Monochromatic waves were produced by a reflection-absorbed wave maker of flap-type, installed at one end of the tank.

Six model breakwaters of same geometry, as shown in Fig. 2 and composed of the gravel materials or armor concrete blocks, were placed on the slope.

Fig. 1 General arrangement of equipment (units: m).

Fig. 2 Dimension of model breakwaters (units: m).

placing condition of the breakwater were determined based on actual breakwaters in Japan. The breakwaters had an upslope and downslope ( $\tan\theta$ ) of 1:3, a 0.75m crest width ( $B$ ), and a 0.225m height ( $d_s$ ). The porosity ( $\epsilon$ ) were varied between 0.17 and 0.52 by changing the material size. In situ porosities were determined from the weight, volume and specific gravity of the materials used. Physical properties of the materials are listed in Table 1.

Table 1 Physical properties of materials used.

Porosity $\epsilon$	Material Used	Material Size (cm)
0	Concrete	---
0.17	Gravel	1.7
0.25	Gravel	2.8
0.38	Gravel	4.0
0.50	Armor Block	7.5
0.52	Gravel	5.0

### Measurements

As see in Fig. 1, water surface elevations were recorded at three wave gage arrays, which consist of either three or four capacitance-type gages. Wave array 1 was located at an uniform water depth section to resolve the incident and reflected wave heights using the method of Mizuguchi (1990). Wave array 2 was placed at the section of the seaward toe of structure slope to measure the incident wave height. Array 3 was set behind the breakwater to measure the transmitted wave height.

Wave data were collected for 2 minutes at 100 Hz, but only 10 successive waves were analyzed to obtain the wave height, mean surface elevation  $\bar{\eta}$  and its variance  $\eta_{rms}$ . Wave profiles on and around the breakwater were recorded by a high-speed video of 200 frames per second. The wave properties were read from the still pictures, with aids of 1.0 cm square grid system attached on the sidewall glass. Incident wave parameters are listed as follows;

- Incident Wave Height :  $H_1 = 2.0 \text{ cm} - 10.0 \text{ cm}$   
 Incident Wave Period :  $T = 0.8 \text{ s} - 1.5 \text{ s}$   
 Water Depth  
   on Horizontal Bottom :  $h_1 = 31.2 \text{ cm}$  and  $35.0 \text{ cm}$   
   above Breakwater Crest :  $R = 3.75 \text{ cm}$  and  $7.50 \text{ cm}$

## INCIPIENT BREAKING

A schematic of a wave profile at breaking on the structure seaward slope of breakwater is depicted in Fig. 3.  $H_B$  and  $h_B$  are the wave height and the water depth at breaking.

Fig. 3 Definition sketch of breaking wave and demarcation of breaker zone.

There are several ways of defining the break point. After careful inspection of the video pictures of breaking waves profile,

we defined the breaking point as the point where the wave height is maximum. This definition ensured us stable judgement of the breaking point from video pictures. Breaker types observed over the submerged breakwater were basically the same to these over a plane sloping beach, spilling, plunging, and collapsing.

Breaking range of waves passing across the breakwater is demarcated into the three following zones, as shown in Fig. 3;

- Zone I : on the offshore sloping beach in front of the breakwater,
- Zone II : on the structure seaward slope, and
- Zone III : on the breakwater crest.

Thus we will examine characteristics of the wave breaking for each zone.

High-speed videos of the wave profile over the breakwater revealed that return flow over the crest and offshore slope of the breakwater influences the wave height and position at incipient breaking. In particular, a strong return flow over a impermeable submerged breakwater produces a variety of collapsing breaker, which the wave crest remains unbroken and the lower part of the front face breaks just like a hydraulic jump due to rapid flows (Smith and Kraus, 1990; Katano et al., 1992). The effects of the return flow on the breaker characteristics are weakened rapidly with decrease of the return flow strength, in other words, with increase of the breakwater permeability.

## BREAKER HEIGHT INDEX ON OFFSHORE SLOPING BEACH, ZONE I.

Due to the permeability and low crest of the submerged breakwater, wave reflection from the breakwater is low, but slightly higher than the plane sloping beach (Katano et al., 1992). As the result, experiments confirmed that the incipient breaker height in Zone I is predicted reasonably well by Goda's breaker index (1978), as given by Eq. (1), with a slight change of the value of empirical constant  $A$  from 0.17 to 0.15.

$$\frac{H_B}{L_0} = A \left[ 1 - \exp\left(-1.5 \frac{\pi h_B}{L_0} (1 + 15 \tan^4 \beta)\right) \right] \quad (1)$$

,in which  $H_B$  and  $h_B$  are the wave height and water depth at breaking,  $L_0$  the wave length in deep water, and  $\tan \beta$  the offshore beach slope. It is, therefore, considered that a steep wave approaching the breakwater is transformed principally by the shoaling effect caused by the plane slope of offshore beach.

## BREAKER HEIGHT INDEX ON THE BREAKWATER, ZONES II AND III.

### Integrated Parameter for Breaker Height.

Previous studies have been made on the wave breaking forced by low crested mound-type breakwaters as well as by barred and reef beaches. However, those have still failed to determine an appropriate breaker index as a function of the breakwater properties and the incoming wave parameters.

Hara et al. (1992) conducted extensive numerical experiments on the transformation of a solitary wave passing across an impermeable submerged breakwater of trapezoidal type, located on horizontal sea bottom. Based on regression analyses of the numerical computations, they propose a parameter for the breaker height index,  $\xi_s''$ , given by Eq. (2). It refers to a modified surf similarity parameter.

$$\xi_s'' = \left[ \frac{B}{h_s} + \frac{(d_j/h_s)}{(3.5 \tan \theta)^{0.2}} \right] \frac{(d_j/h_s)}{(H_j/h_s)^{0.4}} \quad (2)$$

,where  $H$  is the wave height, and subscript S denotes the quantity at the offshore toe of breakwater. The parameter comprises the physical properties and placing condition of the breakwater as well as incident wave properties. From this context, the parameter  $\xi_s''$  is named the integrated parameter of breaker height.

Prior to employment of the integrated parameter, we will discuss briefly influences induced by differences in the experimental conditions of the present and Hara's studies, such as the character of incident wave, bottom profile, and permeability of the breakwater.

The experiments indicated that an incident periodic wave passing across the breakwater behaves almost like solitary wave. In addition, it was found that wave and current field in the vicinity of the breakwater display a very similar one produced in the numerical simulation, owing to the low wave reflection of the breakwater. As for the bottom slope, the wave shoaling on a plane slope was taken account by replacing the wave height in  $\xi_s''$  with that at offshore toe of the breakwater.

**Breaker Height Index as a Function of Integrated Parameter.**

Complete analyses of the wave data on incipient breaking waves yield an empirical relation for the breaker height in terms of the integrate parameter  $\xi_s''$ , as given by Eq. (3).

$$\frac{H_B}{L_0} = A_B \left(\epsilon, \frac{R}{h_s}\right) \left(\frac{2B}{5d_s}\right)^3 \left(\frac{h_s}{L_0}\right) \xi_s'' \tag{3}$$

,where  $R$  is the water depth above the crest, and  $A_B$  is the empirical function and is written as

$$A_B \left(\epsilon, \frac{R}{h_s}\right) = [1.0 - 0.12\left(\frac{R}{h_s}\right) - 0.6\epsilon] \exp \epsilon \tag{4}$$

, representing the permeability effect of total breakwater system. However, the value of  $A_B$  varies very slightly between 1.0 and 1.2 within limits of the experiments.

Figures 4 and 5 show plots of the breaking wave steepness,  $H_B/L_0$  versus the relative wave height at seaward toe of the breakwater,  $H_s/h_s$ , to illustrate the ability of Eq. (3). It is noticed that the breaker height index, Eq. (3), describes surprisingly well the measurements.

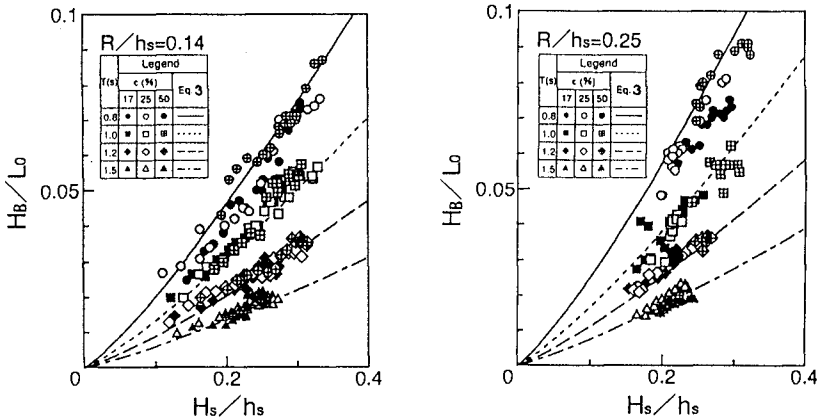

Fig. 4 Relation between  $H_B/L_0$  and  $H_s/h_s$ . Fig. 5 Relation between  $H_B/L_0$  and  $H_s/h_s$ .

Calibration of Eq. (3) is also made by using wave data of Izumiya et al. (1989). They carried out experiments of the wave transformation due to a two-layered submerged breakwater having rather complicated structure, as shown in Fig. 6. Porosity of the main breakwater body is 0.20. Figure 6 is an example of the

comparison of Eq. (3) with their measurements. Although there is some scatter to the measurements, Fig. 7 shows reasonable agreements between the measured and computed breaker heights for their whole data.

Fig. 6 Comparison of Eq. (3) with data of Izumiya et al. (1989).

Fig. 7 Agreement of Eq. (3) with the whole data of Izumiya et al. (1989).

The agreements in Figs. (4) through (7) substantiate the validity and applicability of the proposed breaker height index Eq. (3). In addition to this, the integrated parameter  $\xi_s$  is likely to be very promising to other problems, such as wave breaking on barred and reef beaches. Using data of wave breaking over a triangle-shaped bar of Smith and Kraus (1990), breaker steepness  $H_B/L_0$  is shown, in Fig. 8, as a function of the relative wave height at offshore toe of the bar. Equation (5), represented by lines in Fig. 8, agrees the data and follows their trend well.

$$\frac{H_B}{L_0} = 0.35 \left( \frac{h_s}{L_0} \right) \xi_s^{-3} \quad (5)$$

Fig. 8 Relation of  $H_B/L_0$  to  $H_s/h_s$ , illustrating the ability of  $\xi_s$ . Wave breaking over triangle-shaped bar. (Smith and Kraus, 1992)

**Breaking Position or Depth on the Breakwater**

Breaker depth  $h_B$  can not be calculated directly from the breaker height index, because Eq. (3) does not include explicitly the breaker depth. It is, therefore, required an additional index completely to determine the breaking condition on the breakwater. To do this, at first, we will examine the wave breaking on the breakwater crest, in Zone III, where the still water depth is very shallow and constant.

Following Goda (1964), the relative wave height  $H_B/R$  is plotted, in Fig. 9, as

a function of the relative wave crest height  $h_c/R$  to determine the breaking position on breakwater crest.  $h_c$  and  $R$  are the wave crest height and the still water depth above breakwater crest. Plus and cross marks represent measurements for nonbreaking wave, and various solid and open marks for breaking waves.  $\eta_c$  is the wave crest height from still water level. The lines of  $\eta_c = 0.5H$  and  $H$  refer to relations for small amplitude wave and solitary wave, respectively. Broken line in Fig. 9 represents the bounds that incident waves pass across the breakwater without breaking.

Fig. 9  $h_c/R$  as a function of  $H_B/R$  for the incipient breaking on breakwater crest.

As noticed from Fig. 9, the breaker crest height approaches that of a solitary wave, as increasing the breaker height,  $\eta_c \approx 0.75H_B$ . This indicates that the wave breaking on breakwater crest depends clearly on the trough depth of preceding wave and not on the still water depth above the crest,  $R$ . As a result, wave breaking on the crest is of a depth-limited wave, mainly controlled by the vertical asymmetry of incoming wave profile. Based on the results, the conditions under which waves break on the breakwater crest are examined by relationships between  $H_B/R$  and  $\epsilon$ . In Fig. 10, solid circle and triangle marks represent the lowest wave height when breaking occurs on the crest. And open

Fig. 10 Relation between  $H_B/L_0$  and  $\epsilon$  for determining the bounds of wave breaking on breaker crest.

marks represent the lowest wave height when breaking occurs on the crest. And open

ones show the breaker height at top of the structure slope. Two conditions of wave breaking on the breakwater crest can be determined as follows; (1) the lowest breaker height at the shoreward limit of wave breaking is given by,

$$\frac{H_B}{L_0} = \left(\frac{R}{L_0}\right)^{\frac{6}{7}} \exp(2.7\epsilon - 1.8) \quad (6)$$

Therefore, Eq. (6) refers to the condition that if breaker height computed from Eq. (3) is lower than that from Eq. (6), the wave passes across the breakwater without breaking. And (2) the breaker height at top of the seaward structure slope is

$$\frac{H_B}{L_0} = \left(\frac{R}{L_0}\right)^{\frac{6}{7}} \exp(1.2\epsilon - 0.8) \quad (7)$$

Visual analyses of the wave profile videos reveal that the breaker height changes exponentially with distance from top of the seaward breakwater crest, and that the shoreward limit of breaking position on the crest depends mostly on the breakwater porosity  $\epsilon$ . Equation (8) is derived from the results with respect to the shoreward distance,  $x_{NB}$ , from top of the structure slope to the bound beyond which wave breaking does not occur.

$$\frac{x_{NB}}{B} = 0.5 - 0.75\epsilon \quad (8)$$

Equation (8) indicates that the breaking position displaces toward the top of structural slope with increasing the breakwater porosity, this results in reduction of the return flow strength over the crest. The wave breaking on breakwater crest depends basically on the permeability rather than roughness of the crest surface.

By taking account of Eqs. (6) and (7), an empirical equation (9) for estimating the position of wave breaking on the crest is determined:

$$\frac{x}{B} = \frac{1}{2} \left[ \ln \left\{ \left(\frac{H_B}{L_0}\right) \left(\frac{R}{L_0}\right)^{-\frac{6}{7}} \right\} - 1.2\epsilon + 0.8 \right] \quad (9)$$

This relation refers to as the breaking position index.

### Breaking Position or Depth in Zone II

As pointed out by the previous experimental and numerical studies (Rojanakamthorn et al.,1990), we also found experimentally that wave breaking on the seaward structural slope of the breakwater can be described reasonably well by

a criterion, similar to Miche (1951) and Hamada (1951). Their criterion can be rewritten by using the dispersion relation of linear waves, as Eq. (10).

$$\frac{H_B}{L_0} = A'_m \tanh^2(k_B h_B) \tag{10}$$

, in which  $k_B$  and  $h_B$  are the wave number and water depth at breaking.  $A'_m$  is the coefficient determined from the continuity condition of breaker height at top of the seaward structure slope ( the boundary between Zones II and III). Using Eq. (7),  $A'_m$  is written as·

$$A'_m = \left[ \left( \frac{R}{L_0} \right)^6 \exp(1.2\varepsilon - 0.8) \right] / \tanh^2(k_R R) \tag{11}$$

, in which  $k_R$  is the wave number for the water depth above the crest. Figure 11 displays the range of the minimum and maximum values of  $A'_m$  as a function of the porosity  $\varepsilon$ , within the limits of the experiments. It is noticed from this figure that the value of  $A'_m$  in case of  $\varepsilon = 0$  is almost the same to Miche's coefficient of  $A'_m = 0.142$  for a plane sloping beach.

To confirm applicability of the breaker height index Eq. (10), Fig. 12 shows predicted and measured values of  $H_B/L_0$  as a function of  $k_B h_B$ . Equation (10) agrees with the measured breaker height on the seaward structure slope.

**Comparisons Between Measured and Calculated Breaker Height over the Breakwater**

In the two previous sections, the two additional breaker indices, Eqs. (9) and

Fig. 11 Relation between  $A'_m$  and  $\varepsilon$ .

Fig. 12  $H_B/L_0$  as a function of  $k_B h_B$ , illustrating the validity of Eq. (10).

(10), have been developed for the breaking zones II and III in order to determine the breaking position. Consequently, substitution of Eq. (3) into Eqs. (9) and (10) yields the distance of breaking position for Zone III and the breaking depth for Zone II, respectively.

Figures 13 and 14 are prepared to confirm this approach. Wave steepness  $H_B/L_0$  at incipient wave breaking over permeable submerged breakwater is shown as a function of the relative distance  $x/B$ , from top of the structure slope. It is noticed that synthetic trends generated by Eqs. (9) and (10) follow observed data trends very well. Discrepancies between predicted and observed values appear to result from variability inhering in the wave breaking.

Fig. 13 Variation of  $H_B/L_0$  as a function of  $x/B$ .

Fig. 14 Variation of  $H_B/L_0$  as a function of  $x/B$ .

## CONCLUDING REMARKS

A laboratory experiment was conducted to discuss and determine the conditions of incipient breaking over permeable submerged breakwaters. In this study, Breaking range of waves passing across the breakwater was divided into the three following zones; Zone I: on the offshore sloping beach, Zone II: on the seaward structure slope of the breakwater, and Zone III: on the breakwater crest. Height and position of the breaking wave were examined for each zone, and the breaker height and position indices were developed from measurements.

Main findings are summarized as follows;

- (1) Permeability of the submerged breakwater plays an important role in reduction of the strength of return flow over the breakwater. The return flow changes the breaker height and breaking position as well as the breaker type.
- (2) The integrated parameter  $\xi_s$  of Hara et al. (1992) expresses remarkably well synthetic trends of observed data of the wave breaking over the breakwater. The parameter is versatile; it can be applied to cases of wave breaking over barred and reef beaches.
- (3) Breaker height and depth for Zone I are calculated from Goda's breaker index, Eq. (1), by changing value of the empirical constant to  $A=0.15$ . Breaker height index, Eq. (3), for Zones II and III is determined as a function of  $\xi_s$ .
- (4) Additional indices, Eqs. (9) and (10), are developed to estimate the breaking position in Zone III and breaker depth in Zone II, respectively.

In conclusion, the computation scheme of the breaker height and depth (position) on and around permeable submerged breakwaters is shown as follows;

Zone I: On the offshore sloping beach,  
 $H_B$  and  $h_B$ , calculated from Eq. (1).

Zone II: On the seaward structure slope of the breakwater,

$$Eq.(1)|_{h_B=h_s} > \frac{H_B}{L_0}|_{Eq.(3)} \geq Eq.(7)$$

$H_B$  and  $h_B$ , calculated from Eqs. (3) and (10).

Zone III: On the breakwater crest,

$$Eq.(7) > \frac{H_B}{L_o} \Big|_{Eq.(3)} \geq Eq.(6)$$

$H_B$  and  $x_B$ , calculated from Eqs. (3) and (9).

If wave height calculated from Eq. (3) is smaller than that given by Eq. (6), the wave will pass across the submerged breakwater without breaking.

## ACKNOWLEDGEMENTS

We are grateful to Mr. K. Tachikawa, student of the Graduate School of Science and Engineering of Chuo University, for his help in the experiments and data analyses.

## CHAPTER 81

### WAVE FORCES ACTING ON A VORTEX EXCITED VIBRATING CYLINDER IN WAVES

Kenjiro Hayashi<sup>1</sup>, Futoshi Higaki<sup>2</sup>, Koji Fujima<sup>3</sup>

#### ABSTRACT

An experimental investigations into the wave forces acting on the vortex-excited vibrating vertical circular cylinder in regular waves have been performed with emphasis being placed on the amplification of the wave forces caused by the fluid-structure interaction. The cylinder is vibrating only in the transverse, cross-flow, direction by means of the restriction of the vibration of the in-line direction. The results indicate that the existence of amplification of the lift forces acting on the vortex-excited vibrating cylinder in comparison with the stationary cylinder is a function of the ratio of wave frequency  $f_w$  to the natural frequency of the cylinder in water  $f_{nw}$  and Keulegan-Carpenter number at still water level  $CKC$ . The in-line forces are also amplified in the range of  $CKC$  where large amplitude of oscillation in the transverse direction occurs.

#### INTRODUCTION

The wave forces acting on a small diameter offshore structure are usually resolved into two components. One, the inline force, acts in the direction of wave propagation and the other, the lift force or transverse force, acts in the transverse direction of it. The predominant frequency of lift force caused by vortex shedding is a multiple of that of the inline force. Therefore, the

structure's dynamic response to the lift forces "Vortex-excited vibration" must be considered more significantly.

A great number of studies for the vortex-excited vibration of a circular cylinder in steady flow have been made. An important phenomenon of this vibration is that of "lock-in" between the frequency of the vortex shedding and the frequency of the vibrating cylinder. Under "lock-in" condition, large resonant vibration occurs and the lift forces acting on this vibrating cylinder are amplified by the fluid-structure interaction, Blevins (1977).

A similar phenomenon may occur under certain conditions if a flexible cylinder is placed in planar oscillatory flow or in waves. However, this has not been sufficiently understood and relatively little work has been carried out into this interesting problem in harmonic flow and in waves.

The results for the amplification of the forces acting on a vortex-excited vibrating cylinder in harmonic flows have been reported by Sarpkaya and Rajabi (1979), Hayashi et al. (1990) and Sumer et al. (1994). Sarpkaya and Rajabi (1979) show that at perfect resonance, the lift forces acting on a vortex-excited vibrating cylinder in planar oscillating flow are amplified nearly two times compared to that of rigidly mounted cylinder. Hayashi et al. (1990) show that the lift and in-line forces acting on a vortex-excited cylinder vibrating only in cross flow direction being resonant with the second harmonic component of the lift are amplified in the ranges of Keulegan-Carpenter number  $4 < KC < 8$  and  $6 < KC < 16$  respectively. The maximum increase in the lift force is about 200% at around  $KC=6$  and that in the in-line force is about 100% at around  $KC=8$ . Sumer et al. (1994) have studied the influence of  $KC$ , reduced velocity  $V_r$ , amplitude of cylinder vibration and wall-proximity effect to the forces acting on a cylinder vibrating only in cross-flow direction. Their results show that the increase in the drag coefficient is about 50-200% for around  $KC=10$  and nearly negligible for the range  $60 < KC$  and the increase in lift force is up to 200%.

The results for the amplification of the forces acting on a vortex-excited vibrating vertical cylinder in waves have been reported by Isaacson and Maull (1981), Zedan and Rajabi (1981), Angrilli and Cossalter (1982). They show that the increases of lift forces acting on a vortex-excited vertical cylinder are 70-290% for  $f_w/f_{nw}=1/2$ ,  $CKC=10-12$  and  $kd=1-3.9$ , 60% for  $f_w/f_{nw}=1/3$ ,  $CKC=17.8$ , and  $kd=0.88$ , and 90% for  $f_w/f_{nw}=1/4$ ,  $CKC=35.9$ , and  $kd=0.62$ , where  $f_w$  and  $f_{nw}$  are the incident wave frequency and the natural frequency of cylinder in water,  $k$  is the wave number, and  $d$  is the mean water depth.

Hayashi (1984) shows that the lift forces acting on

a vortex-excited vibrating vertical cylinder in waves are amplified in the range of  $5 < CKC < 15$  for  $f_w/f_{nw}=1/2$  and  $kd=1.83$  and in the range of  $18 < CKC < 30$  for  $f_w/f_{nw}=1/3$  and  $kd=1.01$ . Maull and Kaye(1988) shows similarly that when  $f_w/f_{nw}$  is fixed at  $1/2$ , the lift forces are amplified in the range of  $5 < CKC < 12$  for  $kd=1.32$  and  $1.73$ .

The forces acting on a partial parts of a flexibly mounted vertical cylinder in waves have been measured by Bearman(1988) and Borthwick and Herbert(1988). Force coefficients of in-line and lift forces from the flexibly mounted cylinder are found to be larger than those for the same cylinder but with a rigid mounting.

In the present paper, experimental investigations into the wave forces acting on the vortex-excited vibrating vertical cylinder in regular waves have been described with emphasis being placed on the amplification of the forces acting on the cylinder caused by the fluid-structure interaction.

EXPERIMENTS

Laboratory experiments were carried out in a wave flume 40m long, 0.8m wide, and 1m deep. The general arrangement of the test cylinder is shown in Figure 1. In order to give a high degree of rigidity to the test cylinder, both ends of it are connected to the core cylinder. The flange weights are attached to the core cylinder above the test cylinder to adjust the equivalent mass  $m_e$  of the test cylinder.

The support plate is attached to the holder flag at the bottom end of the test cylinder. Both end in the inline direction of the support plate are pivoted on the floor of the flume to prevent vibration in the inline direction. The upper end of the core cylinder, above the water level, is mounted with springs only in the transverse direction. Each spring is connected to a strain-gauged steel canti-

Fig. 1 General Arrangement of Test Cylinder

lever by wire. Two strain gauges were fixed on each cantilever to measure its bending moment produced by the force acting on the end of it through the springs and wires. Strain gauges were connected into a wheatstone bridge circuit in the bridge conditioner to produce the output signal corresponding to the displacement of the top end of the core cylinder in the transverse direction.

In order to obtain the relationship between the output voltage signals from the bridge circuit and the top end displacements of the core cylinder, known loads are applied horizontally to the top end of the core cylinder by weights hung over a pulley.

Free vibration tests are performed in air and in still water. The damping factor, obtained from the logarithmic decrement, and the natural frequency of the test cylinder are measured by releasing its top end from an initial displacement and recording amplitude decay of the transient oscillation of the cylinder. The equivalent mass per unit length of the test cylinder in water,  $m_e$ , is calculated from the measurements of natural frequency and stiffness of test cylinder in still water, Hayashi(1984). Thus the value of  $m_e$  includes the mass of structure and the entrained fluid.

Two kinds of experiments, Tests-A and Tests-B, are carried out. The experimental conditions in Tests-A are shown in Table 1. Where  $k(=2\pi/L, L=\text{wave length})$  is the wave number,  $f_{na}$  and  $f_{nw}$  are the natural frequencies of the test cylinder in air and in water,  $h_{ta}$  and  $h_{tw}$  are damping factor of the cylinder in air and in water,  $\rho$  is the density of water, and  $\beta(=D^2 f_w / \nu, \nu = \text{kinematic viscosity of water})$  is the viscous-frequency parameter.

The still water depth  $d$  is 40cm. The test cylinder, of outside diameter  $D=1.9\text{cm}$  and  $73.7\text{cm}$  length, is at-

Table 1 Experimental Conditions in Tests-A

Case	D (cm)	d (cm)	$f_w$ (Hz)	$f_w/f_{nw}$	$kd$ ( $2\pi \cdot d/L$ )	CKC	$\beta$
V1	1.9	40	1.07	1/2	1.92	5.2-26.4	386
V2	1.9	40	0.7	1/3	1.03	5.6-38.0	253
V3	1.9	40	0.53	1/4	0.73	4.5-35.1	191
$f_{na}=2.17\text{Hz}, f_{nw}=2.12\text{Hz}$ $h_{ta}=0.002, h_{tw}=0.005$ Mass ratio : $m_e/(\rho_w D^2)=14.9$ Reduced damping : $K_s=2m_e(2\pi h_{ta}/(\rho_w D^2))=0.37$							
S1	1.9	40	1.07		1.92	5.5-25.5	386
S2	1.9	40	0.70		1.03	2.8-39.9	253
S3	1.9	40	0.53		0.73	2.1-36.4	191

tached to the support plate(25x10x0.2cm) with the core cylinder of 0.9cm diameter and 78.5cm length.

In Case V1-V3, the relationship between the vortex-excited vibration of the test cylinder and the Keulegan-Carpenter number at still water level  $CKC=U_{ms}.T/D$ , is measured. Where  $U_{ms}$  is the maximum horizontal water particle velocity at still water level and  $T$  is the wave period. In each of these Cases, the frequency ratio,  $f_w/f_{nw}$ , is fixed at around one value of the values of the resonance frequency ratios,  $f_w/f_{nw}=1/2, 1/3$ , and  $1/4$ .

In Case S1, S2, and S3, the base bending moment  $FL_m$ (=the moments about the bottom of the test cylinder) due to the lift forces acting on the test cylinder rigidly mounted with strings replacing the springs in the transverse direction are measured in the similar waves used in the Case V1, Case V2 and Case V3.

In Tests-B, in-line and transverse forces acting on a partial part of the test cylinder are measured by using a force sleeve supported by two components small load cell installed in the test cylinder as shown in Figure 2. The force sleeve of outside diameter  $D=3\text{cm}$  and 3cm length is positioned 15.9 cm below still water level with water depth  $d=80\text{cm}$ . The test cylinder of outside diameter  $D=3\text{cm}$  and 98.5cm length is attached to the support plate(20x5x0.6cm) with the core cylinder of 1cm diameter and 104.6cm length. The conditions are shown in Table 2. The measurements are made for both cases of vortex-excited cylinder being resonant with the second to sixth harmonic components of lift forces( $f_w/f_{nw}=1/2-1/6$ ) and rigidly mounted cylinder for comparison.

MODEL FOR VIBRATION

The definition sketch of the test cylinder, which illustrates the transverse response of the cylinder which is rod pivoted on the bottom of flume and supported by spring in the transverse direction, is shown in Figure 3. The dynamic response of the cylinder to the lift forces may be described by using the equation of motion as

$$M_{mt} \cdot \ddot{y}_h + C_{mt} \cdot \dot{y}_h + K_{mt} \cdot y_h = FL_m, \quad \text{--- (1)}$$

where  $\ddot{y}_h$ ,  $\dot{y}_h$  and  $y_h$  are the transverse displacement, velocity and acceleration of the cylinder at still water level,  $M_{mt}$ ,  $C_{mt}$  and  $K_{mt}$  are the effective mass, damping and stiffness of system.  $M_{mt}$  includes the mass of cylinder and added mass in water.  $C_{mt}$  includes the structural damping and fluid damping.  $K_{mt}$  includes the stiffness due to the spring force, and the buoyancy and distributed weight when the cylinder is in a deflected position from the vertical.  $FL_m$  is the bending moments around the pivot which is produced by the lift force acting on the cylinder.

$M_{mt} \cdot \ddot{y}_h$ ,  $C_{mt} \cdot \dot{y}_h$  and  $K_{mt} \cdot y_h$  show the moments

Fig. 3 Coordinate System

produced by the inertia forces, the damping forces and the stiffness of the structure respectively. Thus, Eq.(1) shows the equivalence of the moments taken about the pivot of the base, Hayashi(1984).  $FL_m$  may be expressed in a series form as

$$FL_m = FL_m(n) \cdot \sin[2\pi \cdot n \cdot f_w \cdot t + \phi(n)], \quad \text{---(2)}$$

where  $FL_m(n)$ ,  $n=1,2,3---$ , is the  $n$ th frequency component of  $FL_m$  and  $\phi(n)$  is the phase lag. The amplitude  $Y_h(n)$  of response vibration  $y_h$  to  $FL_m(n)$  may be given as the solution of Eq.(1) as

$$Y_h(n) = FL_m(n) / K_{mt} \cdot [ \{ 1 - (n \cdot f_w / f_{nw})^2 \}^2 + (2h_{tw} \cdot n \cdot f_w / f_{nw})^2 ]^{-1/2} \quad \text{---(3)}$$

, where  $h_{tw}$  is the total damping factor of the cylinder in water and may be expressed as the sum of the structural damping factor  $h_s$  and fluid damping factor  $h_f$ , Hayashi and Chaplin (1991).

RESULTS AND DISCUSSION FOR TESTS-A

Figure 4 shows the decay of free oscillations  $y_h$  of the test cylinder in air and in water, which is used in the experiments of Tests-A. Figure 5 shows the variation of the damping factor  $h_{tai}$  in air and  $h_{twi}$  in still water,  $d=40$ cm, with the non dimensional amplitude  $Y_{hi}/D$ . Where  $Y_{hi}$  is the amplitude of  $i$ -th oscillation of the cylinder  $y_h$  at still water level. The values of  $h_{tai}$  and  $h_{twi}$  for each amplitude of  $Y_{hi}/D$  are defined as

Fig. 4 Decay of Free Oscillation

Fig. 5 Variation of Damping Factor with  $Y_{hi}/D$

$$h_{tai} \text{ or } h_{twi} = 1/(2\pi) * \{\ln(Y_{hi-2}/Y_{hi+2})\}/4, \quad \text{---(4)}$$

where  $Y_{hi-2}$  and  $Y_{hi+2}$  are the amplitudes of the  $(i-2)$ th and  $(i+2)$ th periods respectively (see Figure 4).

The value of  $h_{tai}$ , which shows the structural damping factor, is nearly independent of the value of  $Y_{hi}/D$ . The constant value of  $h_{ta} = 0.002$  is written in Table 1. On the other hand, the value of  $h_{twi}$ , which is composed of structural damping and fluid damping, is independent of amplitude effect only for low values of  $Y_{hi}/D$  and it becomes amplitude dependent at higher value of  $Y_{hi}/D$  owing to the characteristics of the fluid damping. The constant value of  $h_{twi}$ ,  $Y_{hi}/D < 0.3$ , is nearly corresponding to the theoretical value of  $h_{twc} = 0.0045$  which is derived from the Stokes's theory, Stokes (1851), for the forces on a cylindrical pendulum bobs oscillating at low KC number, Hayashi and Chaplin (1991). The increase of  $h_{twi}$  in  $Y_{hi}/D > 0.3$  may be due to the appearance of vortex-sheddings. The variation of the  $h_{twi}$  with  $Y_{hi}/D$  is approximated by the regression equation as

$$h_{twi} = 0.005 + 0.01 * (Y_{hi}/D)^{2.15}. \quad \text{---(5)}$$

The variation of  $Y_{hm}(n)/D$  and  $Y_{hc}(n)/D$ ,  $n=2,3,4$  are shown in Figure 6 (a),(b),(c) where  $Y_{hm}(n)$  is the Fourier amplitude of measured displacement  $y_h$  and  $Y_{hc}(n)$  is a calculated value obtained by substituting the measured

moments  $FL_m(n)$  acting on the rigidly mounted cylinder into Eq.(3). Here  $FL_m(n)$ ,  $n=1-4$ , is the first four harmonics of  $FL_m$ , which are measured for the three values of  $kd=1.92$ , 1.03 and 0.73 in Case S1, S2 and S3. In calculation, Eq.(3) is coupled to Eq.(5) by means of  $Y_h(n)=Y_h=Y_{hi}$ .

The measured response  $Y_{hm}(n)$ ,  $n=1, 2, 3$ , is above the predicted response  $Y_{hc}(n)$  in the range of  $8 < CKC < 15$  for the case of  $f_w/f_{nw}=1/2$ , in the range of  $12 < CKC < 23$  for the case of  $f_w/f_{nw}=1/3$ , and  $25 < CKC$  for the case of  $f_w/f_{nw}=1/4$  respectively. These phenomena may be due to the amplification of the lift acting on the vortex-excited vibrating cylinder caused by the fluid-structure interaction. Similar phenomena are obtained by Maull and Kaye (1988) for the case of  $kd=1.73$  and 1.32.

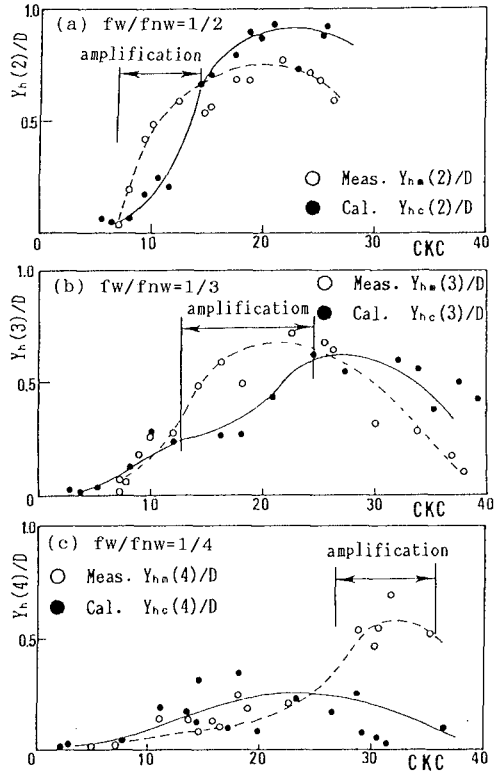

Fig. 6  $Y_{hm}(n)$  and  $Y_{hc}(n)$

RESULTS AND DISCUSSION FOR TESTS-B

The traces for free decay of oscillations  $y_h$  and of the forces  $dF_Y$  in air and in water are shown in Figure 7 (a) and (b), where  $dF_Y$  is the transverse, Y-direction, forces acting on the unit length of the force sleeve, which is measured by the load cell in the test cylinder used in Tests-B. The relationship between these  $dF_Y$  and  $y_h/D$  are shown in Figure 7 (c). From this figure,  $dF_Y$  in air and in water may be expressed as

$$dF_Y, (\text{in air}) = dF_{Y1a} = m_{sa} * d^2y_h/dt^2 = 2.37 * y_h/D, \quad \text{--- (6)}$$

$$dF_Y, (\text{in water}) = dF_{Y1w} = m_{sw} * d^2y_h/dt^2 = 5.17 * y_h/D, \quad \text{--- (7)}$$

where  $dF_{Y1a}$  and  $dF_{Y1w}$  are inertia forces acting on the unit length of force sleeve in air and in water, and  $m_{sa}$  and  $m_{sw}$  are reduced mass per unit length of the force sleeve in air and in water.

The variations of  $\eta$ ,  $y_h/D$ ,  $dF_Y$ ,  $dF_{Ya}$ ,  $dF_{Yw}$ ,  $dF_X$  with time for both cases of vortex-excited cylinder and rigidly mounted cylinder for comparison for the case of  $f_w/f_{nw}=1/2$ ,  $CKC=12$ ,  $kd=2.41$  are shown in Figure 8 (a),(b) and (c). Here  $\eta$  is the water surface elevation. The Keulegan-Carpenter number at the level of force sleeve, 16cm below the still water level is  $LKC=7.5$ .  $dF_X$  and  $dF_Y$  are in-line and lift force acting on the unit length of force

Fig. 7 Decay of Free oscillation

(A) Vibrating Cylinder

(B) Rigid Cylinder

Fig. 8  $\eta$ ,  $y_h/D$ ,  $dF_Y$ ,  $dF_{Ya}$ ,  $dF_{Yw}$ ,  $dF_X$  versus time

sleeve, which are measured by the two components small load cell.  $dF_{Ya}$  and  $dF_{Yw}$  are defined as

$$dF_{Ya} = dF_Y - dF_{YIa} = dF_Y - 2.37 \cdot y_h/D, \quad \text{---(8)}$$

$$dF_{Yw} = dF_Y - dF_{YIw} = dF_Y - 5.17 \cdot y_h/D. \quad \text{---(9)}$$

$dF_{Ya}$  shows the transverse fluid force acting on the unit length of the force sleeve.  $dF_{Ya}$  may be composed of the inertia force due to the added mass of water, the fluid damping force and the loading force per unit length of force sleeve. Thus  $dF_{Yw}$  shows the transverse force which is composed of the damping and the loading force per unit length of force sleeve in water. When the test cylinder is vibrating in resonance condition,  $f_w/f_{nw} = 1/2, 1/3, 1/4, 1/5, 1/6$ ,  $dF_{YIa}$  and  $dF_{YIw}$  may be estimated by using Eq.(6) and Eq.(7).

$dF_X$  shows the in-line fluid force acting on a unit length of force sleeve in water because the vibration of the in-line direction is restricted.

We can recognize that the forces  $dF_X$ ,  $dF_{Ya}$  and  $dF_{Yw}$  acting on the

- Isaacson and Mall [fw/fnw=1/2 Ks=3.54]
- ▼ Zedan and Rajabi [fw/fnw=1/2 Ks=0.83]
- Anglilli and Cossalter [fw/fnw=1/2 Ks=0.98]
- [fw/fnw=1/3 Ks=0.98]

Fig. 9 Amplification versus CKC for fw/fnw=1/2

vibrating cylinder are large compare to the forces  $dF_X$  and  $dF_Y$  acting on the rigidly mounted cylinder.

Fig. 9 (a)-(e) show the variation of the non-dimensional cylinder vibration ( $Y_h/D$ ), wave forces ( $dF_X$ ,  $dF_Y$ ), and amplification factor ( $M_X$ ,  $M_Y$ ) with CKC for the case of  $f_w/f_{nw}=1/2$ . Here  $Y_h(\max)$  and  $Y_h(\text{rms})$  are the maximum half-amplitude and the root mean square value of the cylinder displacement  $y_h$  at still water level.  $VF_X$ ,  $VF_{Ya}$  and  $VF_{Yw}$  are the root mean square values of in-line and transverse forces,  $dF_X$ ,  $dF_{Ya}$  and  $dF_{Yw}$ , acting on the force sleeve of vibrating cylinder.  $RF_X$ ,  $RF_{Ya}$  and  $RF_{Yw}$  are the root mean square values of those of the rigidly mounted cylinder. The amplification factors  $M_X$ ,  $M_{Ya}$  and  $M_{Yw}$  are defined as

$$M_X = VF_X / RF_X, \quad \text{---(10)}$$

$$M_{Ya} = VF_{Ya} / RF_Y, \quad \text{---(11)}$$

$$M_{Yw} = VF_{Yw} / RF_Y. \quad \text{---(12)}$$

Figure 9 (d) and (e) shows that  $M_X$  increases with increasing  $Y_h/D$  and  $M_{Ya}$  is little affected with increasing  $Y_h/D$ .  $M_{Ya}$  is large in the range of  $6 < \text{CKC} < 13$  where  $Y_h/D$  increases rapidly with increasing CKC. This range of CKC, where the amplification of lift force is large, is nearly consistent with the results obtained for  $f_w/f_{nw}=1/2$  in Tests-A, see Figure 6 (a). The amplification factor  $M_Y$  obtained by Isaacson and Maull(1981), Zedan and Rajabi(1981), and Anglilli and Cossalter(1982) for the case of  $f_w/f_{nw}=1/2$  are plotted in Figure 9 (e) only for reference. It should be noted that their results are obtained for the total lift forces acting on the vertical cylinder in waves.

The variations of the cylinder vibration  $Y_h/D$  and the amplification factors with CKC for  $f_w/f_{nw}=1/3$ ,  $1/4$ , and  $1/6$  are shown in Figure 10 (A),(B) and (C) respectively. We can also recognize that  $M_X$  increases with increasing  $Y_h/D$ , which is nearly consistent with the results obtained in the case of steady flow, Griffin et al.(1975) and Sumer et al. (1994), and  $M_{Ya}$  is a little affected with increasing  $Y_h/D$ .  $M_{Ya}$  is a function of  $f_w/f_{nw}$  and CKC. The amplification factor  $M_Y$  obtained for the total lift acting on the vertical cylinder by Anglilli and Cossalter (1982) for the case of  $f_w/f_{nw}=1/3$  is also plotted in Figure 11.

The value of  $M_{Yw}$  is bigger than 1 in the range of  $6 < \text{CKC} < 13$  for  $f_w/f_{nw}=1/2$ . On the other hand, it is less than 1 for  $f_w/f_{nw}=1/3$ ,  $1/4$  and  $1/6$ . We need more consideration to the characteristics of  $M_{Yw}$ .

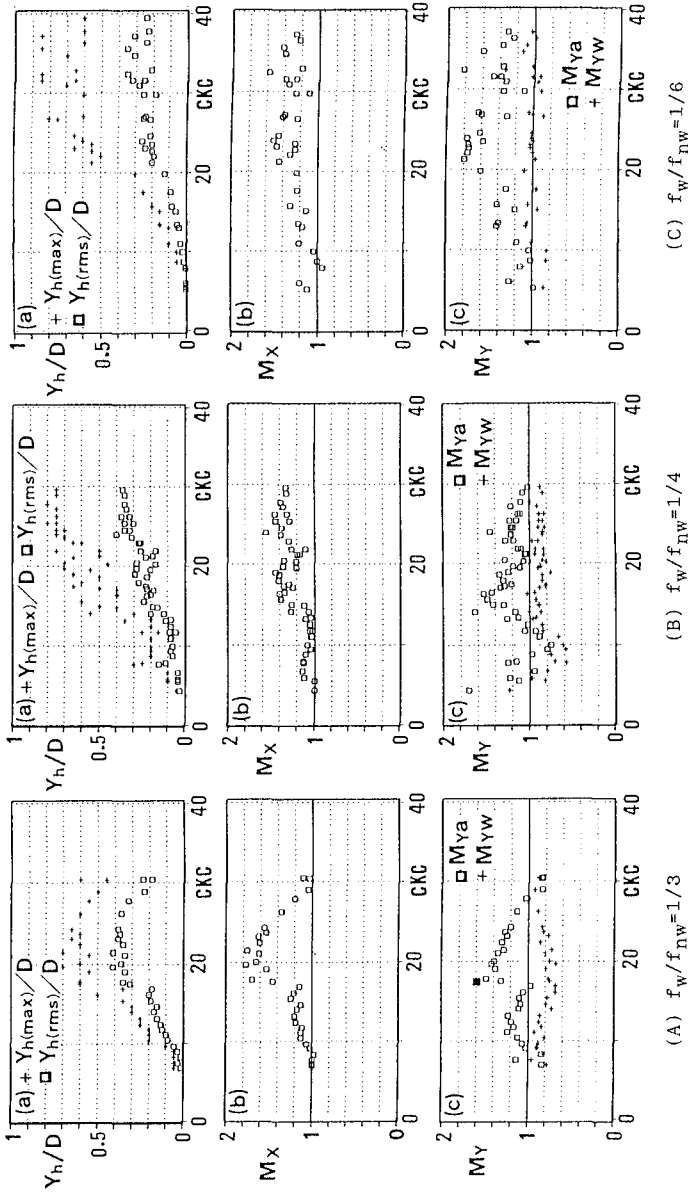

Fig. 10 Cylinder Vibration and Amplification Factor

## CONCLUSIONS

The main conclusions obtained in this study are summarized as follows:

- 1). The existence of the amplification of lift force acting on the vortex-excited vibrating cylinder in comparison with the rigidly mounted cylinder is a function of the ratio of wave frequency  $f_w$  to the natural frequency  $f_{nw}$  of the cylinder in water and Keulegan-Carpenter number at still water level. When  $f_w/f_{nw}$  is fixed at about 2, large amplitude of transverse, cross-flow, vibration  $Y_h/D$  of cylinder occurs in the wide range of CKC, but the amplification of lift occurs only in the range of  $6 < CKC < 13$ .
- 2). The in-line force acting on the partial part of the vortex-excited vibrating cylinder is amplified with increase of cross-flow vibration  $Y_h/D$ .

## CHAPTER 82

# Overtopping of sea walls under random waves

D M HERBERT<sup>1</sup>, N W H ALLSOP<sup>1</sup> and M W OWEN<sup>2</sup>

### Abstract

Over the last fifteen years a long running research programme has been undertaken at HR Wallingford to investigate the overtopping discharge performance of a wide range of sea walls. The research, which is funded by the Ministry of Agriculture, Fisheries and Food, is principally aimed at deriving methods to enable design engineers to determine the overtopping performance of a particular sea wall cross-section under a range of wave and water level conditions. The studies have generally used random wave physical model tests in order to collect data which can then be employed to derive empirical equations that describe the level of overtopping discharge.

### 1 Introduction

This paper describes recent research work at HR Wallingford, based on the results of physical model tests, aimed at quantifying the overtopping performance of recurved and vertical sea walls. The work is a continuation of a large research programme which has resulted in the derivation of empirical methods for assessing overtopping discharges on embankment sea walls.

### 2 Summary of previous work

Considerable stretches of the United Kingdom (UK) coastline are protected by a simple earth embankment, consisting of a sloping seaward face, a horizontal crest just a few metres wide and possibly a rear slope. These embankments are

---

<sup>1</sup> Coastal Group, HR Wallingford, Wallingford, OX10 8BA, UK

<sup>2</sup> Llanfair Caereinion, Welshpool, Powys, SY21 0DS, UK

particularly frequent in rural areas, where the seaward face is often protected either by grass or pitched stone. In the late 1970's the then Hydraulics Research Station carried out an extensive research programme to determine the overtopping discharge behaviour of embankment type sea walls, culminating in the production of design guidelines (Owen, 1984).

The design method established for embankment sea walls is based on a dimensionless discharge parameter,  $Q_*$ , and a dimensionless freeboard,  $R_*$ . These two parameters are defined below:-

$$Q_* = Q / (T_m g H_s) \quad (1)$$

$$R_* = R_c / (T_m \sqrt{gH_s}) \quad (2)$$

where  $Q$  is the mean discharge overtopping the crest of the sea wall,  
 $T_m$  is the mean wave period,  
 $H_s$  is the significant wave height,  
 $g$  is acceleration due to gravity  
and  $R_c$  is the sea wall freeboard (the height of the sea wall crest above still water level).

The dimensionless parameters are connected by the following exponential equation:-

$$Q_* = A \exp (-BR_*/r) \quad (3)$$

where  $r$  is a roughness coefficient  
and  $A$  and  $B$  are empirically derived coefficients dependent upon the structure slope.

Typical values of these empirical coefficients vary from  $A=0.00794$  and  $B=20.12$  for a 1:1 slope to  $A=0.025$  and  $B=65.2$  for a 1:5 slope. Recommended values of the roughness coefficient vary from  $r = 1.0$  for smooth impermeable slopes,  $r = 0.85-0.9$  for turf,  $r = 0.8$  for one layer of stone rubble on an impermeable base and  $r = 0.5-0.6$  for two or more layers of rubble.

Further work on bermed sea walls (Owen, 1984) showed that equations (1) - (3) could also be applied to these type of structures by modifying the empirical coefficients  $A$  and  $B$ . This work illustrated that, in general, the most effective berm for reducing overtopping is located at or close to still water level.

Wave basin tests using long crested waves (Owen, 1984) indicated that overtopping can increase for angles of approach up to  $30^\circ$  off normal with the

worst overtopping occurring at about 15° off normal. Under short crested seas (CIRIA, 1991) the overtopping discharge remains roughly constant for wave directions between 0° and 30° off normal before tailing off at larger angles.

Allsop and Bradbury (1988) completed model tests in which measurements were made of the overtopping discharge for vertically faced crown walls mounted on top of rock revetments or breakwaters. A change to the relationship given by Owen (1984) was suggested with the introduction of a new dimensionless freeboard parameter,  $F_*$ , defined as follows:-

$$F_* = R_c^2 / (H_s^2 g T_m) \quad (4)$$

The equation connecting the dimensionless discharge and freeboard was also modified:-

$$Q_* = A F_*^B \quad (5)$$

where A and B are coefficients dependent upon the geometry of the structure cross-section.

### 3 Recurved Walls

In many urban areas the traditional embankment type sea wall frequently incorporates a wave return wall at its crest. This wall can be located either at the top of the seaward slope, or else it can be sited a few metres back allowing the crest berm to be used as a promenade. A series of physical model tests were subsequently undertaken to measure the overtopping discharges of a range of recurved wave return walls for different sea wall slopes, water levels and wave conditions (Owen and Steele, 1991).

The model tests were carried out in a wave flume at a nominal geometric scale of 1:15. Smooth impermeable sea wall slopes of 1:2 and 1:4 were tested under a range of wave and water level conditions but always with a constant sea steepness (based on the mean deep water wave length) of  $s=0.045$ . Although wave return walls with a very wide range of profiles have been constructed at different locations around the UK coastline, only the basic profile originally suggested by Berkeley - Thorne and Roberts (1981) was used in this study. However, the distance between the top of the seaward slope and the foot of the wave recurve was varied throughout testing. Figure 1 illustrates the general configuration of the model tests.

Two options were investigated as a means of defining the effectiveness of wave return walls. The two alternative definitions were:

- the ratio of the measured overtopping discharge to the discharge which

would have occurred if the return wall had been removed, and the seaward slope had been extended up to the same elevation as the top of the return wall.

- the ratio of the measured overtopping discharge to the discharge which would have occurred if the return wall had been absent.

The second definition was the most appropriate as it appeared to be a much more direct indicator of the performance of the return wall. During the course of the analysis it became clear that one factor governing the effectiveness of the return wall was the height of the wall relative to its position above the still water line. Accordingly the dimensionless height of the wave return wall was defined as:-

$$W_* = W_h/R_c \quad (6)$$

where  $W_h$  is the height of the wave return wall from its base to its top and  $R_c$  is the freeboard between the top of the seaward slope (which is at an identical elevation to the base of the return wall) and the still water line.

Using the above definition of the effectiveness of the wave return wall, it is necessary to know the overtopping discharge which would have resulted during the tests if the wave return wall had been absent, for identical wave conditions, water levels and sea wall geometry. Measurements of these discharges were not made specifically for this study but used the results of the earlier research programme (Owen, 1984).

Figure 1 Definition of parameters, recurve wall

Figure 2 Recurve wall results, 1:2 slope, 0m crest width

For each test in the present study, the overtopping discharge to be expected without the wave return wall was calculated using equations (1) - (3). The measured discharge overtopping the wave return wall, expressed in dimensionless terms as  $Q_{*w}$ , could then be compared with the dimensionless discharge at the crest of the sea wall,  $Q_*$ , (ie the recurve has been removed) to give the discharge factor,  $D_f$ . Thus:-

$$Q_{*w} = Q_w / (T_m g H_s) \tag{7}$$

$$D_f \approx Q_{*w} / Q_* \tag{8}$$

where  $Q_w$  is the mean discharge overtopping the wave recurve.

In selecting a method of presenting the data, consideration was given to the way in which a designer could use the information. Figure 2 shows the form of presentation which was finally selected, in this case for a sea wall with a 1:2 slope and with the wave return wall placed directly at the top of the slope (ie the crest width,  $C_w = 0$ ). In this graph the abscissa is the dimensionless crest berm freeboard,  $R_*$ , as defined in equation (2), which can be calculated from the actual freeboard and the wave height and period. Each line on the graph represents a constant value of the dimensionless wave return wall height,  $W_*$ , which can be

determined from the wall height and the actual freeboard. Knowing the values of  $R_*$  and  $W_*$  allows a discharge factor  $D_f$ , to be established from Figure 2. Use of equation (3) to calculate the dimensionless discharge at the crest of the sea wall,  $Q_*$ , then enables  $Q_{*w}$  to be determined from equation (8). The mean discharge overtopping the wave recurve,  $Q_w$ , may be determined from equation (7).

The method outlined above allows the overtopping discharge of a sea wall with a recurve wall to be estimated provided that the crest width and sea wall slope are equal to one of those combinations tested. However, a single design graph would be preferable, together with some means of estimating the overtopping discharge for conditions not specifically tested. Given the scatter of results in Figure 2, and the fact that fewer than the ideal number of tests were completed for each structure cross-section, it was decided to investigate whether a standard slope could be fitted to all lines having the same dimensionless wall height.

All of the individual graphs were overlain and, using the 1:2 slope with a zero crest width as the baseline, the data sets displaced in the horizontal direction. With the appropriate displacements the individual  $W_*$  data sets tended to collapse on to a straight line. An iterative procedure was used to find the displacements which, using the method of least squares to find the line of best fit, gave the highest overall coefficient of correlation for all the data sets. This overall coefficient of correlation was taken as the average of all the coefficients of correlation of all the data sets for different dimensionless wall heights.

The result of the analysis described above was a single design graph which is illustrated in Figure 3. In this figure the abscissa is the dimensionless adjusted crest berm freeboard,  $X_*$ , which is defined as follows:-

$$X_* = R_* A_f \quad (9)$$

where  $A_f$  is an adjustment factor dependent on the structure cross-section.

Hence  $R_*$  may be calculated from equation (2), whilst typical adjustment factors are given in Table 1. Thus a discharge factor can be obtained from Figure 3 and the overtopping discharge calculated as before (see equations (1), (7), and (8)).

The results of the model tests showed that recurved wave return walls can have a very dramatic effect on the overtopping discharges of sea walls. For some test conditions the discharge was reduced by almost three orders of magnitude compared to the expected situation without the return wall. Although some reduction would be obtained by simply raising the basic sea wall by the same amount as the height of the return wall, calculations indicated that only one order of magnitude reduction in overtopping could be expected. This point is well illustrated in Figure 4. For either a 1:2 or a 1:4 sea wall, the figure shows a plot of the overtopping discharge against the total height of the sea wall, for a

Sea wall slope	Crest width, $C_w$	$W_B/R_c \geq 2/3$	$W_B/R_c \leq 1/2$
		Adjustment factor, $A_f$	Adjustment factor, $A_f$

1:2	4	1.07	1.34
1:2	8	1.10	1.38
1:4	0	1.27	1.27
1:4	4	1.22	1.53
1:4	8	1.33	1.67

Table 1 Adjustment factors

Figure 3 Design graph, recurve wall

Figure 4 Effect of raising the crest

particular wave condition and water level. Starting from a crest elevation of 1.0m with no wave return wall, the solid lines show the reduction in discharge which is obtained by adding a return wall of gradually increasing height. The broken line shows the reduction obtained by raising the crest height, without any wave return. For a given total height of sea wall, the incorporation of a wave return wall greatly reduces the overtopping discharge compared to simply raising the crest.

The analysis outlined above was also applied to the data obtained by Allsop and Bradbury (1988) who measured the discharges overtopping a rock armoured slope topped with a crown wall. In all cases these tests were carried out for a seaward slope of 1:2 and a crest width equivalent to two rock diameters. The crown wall had a significantly less efficient profile than that proposed by Berkeley-Thorn and Roberts (1981) as used in the other recurved wall tests.

The results, which are illustrated in Figure 5, showed considerably more scatter than for the smooth impermeable slopes. This was thought to be due to the different degrees of energy absorption on the slope and of drainage into the crest for different wave and water level conditions. Also shown in Figure 5 are the discharge factors for the equivalent smooth impermeable slope with a crest width of  $C_w = 4.0$  metres. The discharge factors for a return wall mounted on top of a rock slope are very much better (lower) than for a smooth slope despite the less effective recurve. The reduction in discharge factor must therefore be due to the effects of the rock slope.

Figure 5 Rock slope compared with 1:2 slope with recurve, 4m crest width

The probable explanation for the lower discharge factors on the rock slope is as follows. As the wave runs up the slope and on to the crest, its forward progress is arrested by the return wall, increasing the depth of water on the crest. For an impermeable slope the remainder of the wave run-up to some extent rides over this cushion of water and a fraction overtops the wave return wall. On a permeable slope water reaching the return wall is able to drain away through the armour layer thereby limiting the depth of water at the crest. Hence wave run-up finds it more difficult to overtop a wave return wall on permeable than an impermeable slope.

Recent work has concentrated on assessing the efficiency of recurve walls under

oblique wave attack. Physical model tests have been completed, at a scale of 1:25, using both short and long crested random waves with angles of wave attack ranging from 15° to 45° off normal. The preliminary analysis of the oblique data appears to indicate that discharge factors are larger, and hence the recurve is not as efficient, when compared to normal wave attack.

#### 4 Vertical walls

Vertical or near vertical sea walls are common in urban areas and are often sited behind shingle or sandy beaches. Work detailing the overtopping performance of vertical walls had previously been completed by Goda (1975). Goda investigated approach slopes of 1:10 and 1:30 and offshore sea steepness of  $s_{om} = 0.012, 0.017$  and 0.036. These conditions were considered to be unrepresentative of conditions around the UK coastline where the steepness of storm waves is greater and the bathymetry of approach is generally shallower.

Figure 6 Definition of parameters, vertical wall

A series of physical model tests was therefore undertaken with the aim of confirming and extending the work of Goda so that it was more applicable to UK coasts (Herbert, 1993). Consequently three approach bathymetries of 1:10, 1:30 and 1:100 were used in the model with offshore sea steepness ranging from 0.017 - 0.060. Other parameters that were varied included the offshore wave height, the water depth at the toe of the sea wall and the freeboard of the wall. These parameters, which are illustrated in Figure 6, were varied to ensure that the model tests were completed in the zone of interest identified by Goda.

Figure 7 Vertical wall discharges, 1:30 slope,  $s_{om} = 0.036$

The model data gave good agreement with the work of Goda. This is illustrated in Figure 7 where a dimensionless discharge,  $Q^\#$ , is plotted against a dimensionless water depth,  $h/H_{so}$ , where:-

$$Q^\# = Q / (2gH_{so}^3)^{1/2} \tag{10}$$

$H_{so}$  is the offshore significant wave height and  $h$  is the water depth at the toe of the structure.

Lines of constant values of the dimensionless freeboard,  $R_c/H_{so}$ , are illustrated on the graph where  $R_c$  is the height of the crest above still water level.

For a given dimensionless freeboard, maximum overtopping discharges occurred when  $1.4 < h/H_{s0} < 2.0$ . These conditions correspond to waves breaking immediately seaward of the structure toe. The breaking waves often pass directly over the crest of the seawall. For  $h/H_{s0} < 1.4$  waves break before they reach the vertical wall. A considerable amount of energy is dissipated during breaking and hence overtopping is reduced. If  $h/H_{s0} \ll 1.4$  the waves break farther offshore and overtopping is further reduced. Conversely, for  $h/H_{s0} > 2.0$ , waves are unbroken when they reach the structure and this also leads to a reduction in peak overtopping discharge. As waves travel into shallower water they steepen before breaking. When the water depth at the structure is large relative to  $H_{s0}$  little or no shoaling occurs and overtopping is commensurately lower. For unbroken waves, as the  $h/H_{s0}$  ratio increases the level of shoaling, and hence overtopping, is reduced. Eventually the effect of water depth at the structure and bed slope will become insignificant and overtopping will be a function of wave height and freeboard only. Therefore, for large values of  $h/H_{s0}$ , overtopping discharges will approach a constant value for a given dimensionless freeboard,  $R_c/H_{s0}$ .

## 5 Further work

A fieldwork deployment, designed to measure overtopping discharges at prototype sites, has been completed on the North Wales coast. This work is being analysed and compared with results from physical model tests. Furthermore measured discharges are being compared with present guidance on allowable overtopping with particular reference to vehicular and pedestrian safety.

Work is presently being undertaken to assess the performance of a wide range of sea wall cross-sections under oblique wave attack. The structure cross-sections, which are being physical model tested using both long and short crested waves, include simply sloping sea walls with and without recurved walls, bermed sea walls and vertical walls.

A design manual is being planned which will describe and detail the overtopping performance of sea walls and the standards to which they should be designed. It is anticipated that draft copies of this manual will be available in the latter part of 1995.

## 6 Acknowledgements

The authors would like to thank the Ministry of Agriculture, Fisheries and Food for their continued support for the work described in this paper. The work of Mr A A J Steele, who performed the majority of the experimental work, is also gratefully acknowledged.

## CHAPTER 83

### Stability of High-specific Gravity Armor Blocks

Masahiro Ito<sup>1</sup>, Yuichi Iwagaki<sup>1</sup>, Hiroshi Murakami<sup>2</sup>

#### Abstract

The stability coefficient of the well-known the Hudson formula,  $K_D$ , has been established by many laboratory tests for various types of armor blocks with a range of specific gravity 2.16~2.47 representative of normal concrete. Design manuals for coastal structures do not describe the adoption of high-specific gravity armor blocks for use in field construction. To examine the effect of specific gravity on stability of Tetrapods, then a laboratory test was conducted by using Tetrapod models of different weights which are composed of five values of specific gravities. Temporal changes of damage ratio arranged test conditions that satisfy the Hudson formula do not coincide among each other, depending on wave period and specific gravity. The effect of the specific gravity on their stability is discussed. As a result, it is found that the relationship between the stability and the specific gravity is considerably affected by the surf similarity parameter and Reynolds number.

#### Introduction

The stable weight of armor units which are used in the cover layer of groins, breakwaters and wave absorbing works is evaluated by the Hudson formula (1959). The Hudson's stability coefficient of armor blocks made from a normal concrete with specific gravity of about 2.30, such as Tetrapod and Dolos, have been determined on the basis of laboratory tests. These tests have been performed using a wide range of experimental conditions for wave height, wave period, and structure slope, using regular waves. As for the use of the armor blocks on beaches and coast lines, there are the following problems and needs:

---

<sup>1</sup> Professor, Department of Civil Engineering, Meijo University, Shiogamaguchi 1-501, Tempaku-ku, Nagoya 468, JAPAN.

<sup>3</sup> Nippon Tetrapod Co. Ltd.

armor blocks, that is to say, the maximum weight of Tetrapod as a armor block is 784 kN (80 tf) at the present time, but this weight becomes unstable for wave heights over 9 m for seaward slopes of 1 on 4/3 of typical breakwaters.

- (2) When large scale construction equipment such as floating cranes or derrick barges are difficult to move the place such a far detached-island, then small size and more stable armor blocks have to be used.
- (3) Construction site with limited storage space for armor blocks.
- (4) Armor blocks in a corner or head of breakwaters, groins or wave absorbing works receive the complex wave action due to the combined wave-flow induced due to waves. Then, thus parts a weak point in armor blocks and are easily broken.
- (5) To hold the natural beauty of beaches, coastlines, and harbors, smaller and stable armor blocks are required.

For these problems and needs, high-specific gravity armor blocks are considered more suitable. These armor blocks are smaller than the same weight units made from normal concrete. They are more stable against waves. Also it is possible to reduce structure size by using these armor blocks.

A manufacturing method for producing high specific gravity armor blocks is made possible by mixing a heavy stone, or crushed or grained iron ore such as pyrite into the concrete. The "heavy stone" concrete reaches specific gravity of about 2.7~2.8. In the iron ore concrete mixture, the specific gravity becomes greater than 3.0. Such high-specific gravity armor blocks have been already put to a practical use in Japan.

Previous investigation of the high-specific gravity armor blocks, Zwamborn (1978) discussed the effect of specific gravity as the ratio of armor unit volume to wave height based on the past laboratory data that had been performed using rubble-stones of different specific gravity by Kydland and Sodefjed, and dolosse of different specific gravity by Gravesen and Sørensen. Zwamborn reported that by rearranging some test data with dolosse of different specific gravities (2.4, 2.75 and 3.05), the dimensionless wave height,  $(V/H^3)\cot\theta$ , based on block volume,  $V$ , wave height,  $H$ , and slope angle of armor layer,  $\theta$ , is proportional to the specific gravity in water to  $-3.0$ ,  $-3.0$  and  $-4.0$  power for 1, 2, and 5 per cent damage, respectively. But in the Hudson formula, its exponent value is constant ( $-3$ rd power) and well accepted. The authors (1992a, 1992b, 1994) have been carrying out the laboratory study using Tetrapod models of various sizes and specific gravities in order to investigate the effect of specific gravity on the stability for waves. On the basis of the tests results, this paper discusses the effect of specific gravity, surf similarity parameter, and Reynolds number as a function of the block-size and wave characteristic. Recently, Takeda et al. (1993) discussed the relationship between stability and specific gravity, based on the laboratory tests using high-specific gravity armor blocks. He pointed out that the wave period considerably affects the stability-specific gravity relationship.

Thus, investigations on the stability of high-specific gravity armor blocks have been not insufficient up until the present time. Design manuals for coastal structures do not describe the adoption of high-specific gravity armor blocks for use in field construction. The effect of the specific gravity on armor unit stability, therefore, must be further investigated.

**Advantages of high-specific gravity armor blocks**

The effect of the specific gravity on the resistance against wave action is possible to be calculated using the Hudson formula. Assuming that the Hudson's stability coefficient  $K_D$  is a constant for Tetrapod (8.3), the slope angle of armored structure is a constant, the unit weight of normal concrete  $w_c$  is  $22.54 \text{ kN/m}^3$  ( $2.3 \text{ tf/m}^3$ ), and the unit weight of water  $w_w$  is  $9.8 \text{ kN/m}^3$  ( $1 \text{ tf/m}^3$ ), then, we can obtain the ratio of the design wave height for high-specific gravity armor block,  $H/H_c$  to the change of the relative specific gravity against the normal concrete,  $S_r (=w_r/w_w)$ , from the Hudson formula assuming that both blocks are the same size ( $l_B = \text{const.}$ ). Where  $w_r$ ,  $w_c$  and  $w_w$  are the unit weight of any specific gravity armor units, normal concrete, and water, respectively. The effect of  $S_r$  on  $H/H_c$ , the resistance against wave action is shown with a solid curve in Fig. 1. The results show the relative block weight  $W/W_c$  of high-specific gravity to normal concrete, which is also shown with a broken line curve in Fig. 1. Here  $H$  and  $H_c$  are the design wave height of any specific gravity and normal concrete, respectively. It can be seen from this figure that  $H$  in the armor blocks of specific gravity  $S_r = 3.0$  is possible to resist about 1.5 times wave height,  $H_c$ , for the normal concrete of the same size. However, this finding holds only when  $K_D$ -values are the constant though the specific gravity ranges.

**Laboratory test**

To examine the effect of specific gravity on stability of Tetrapod, models of different weight were used, composed of five different values of specific gravities (1.82, 2.30, 2.77, 3.40, 4.27). A total of 21 different Tetrapod models were used. The range of Tetrapod models used varied between a vertical height of  $l_B = 3.29 \sim 16.6 \text{ cm}$  and a weight of  $W = 0.27 \sim 22.85 \text{ N}$  ( $27.7 \sim 2329.6 \text{ gf}$ ). The sizes and weights of Tetrapod models used in the laboratory tests are listed in Table 1. Model weights on each row (A, B, C, D, and E) within this table are obtained for each specific gravity

by giving  $K_D=8.3$  (in  $0 < \text{Damage ratio} \leq 1\%$ ),  $\cot\theta=4/3$ ,  $w_w=9.8 \text{ kN/m}^3$  ( $1 \text{ tf/m}^3$ ), and given a constant Hudson formula design wave height. The design wave height of the models in each row of Table 1, becomes nearly equal, despite difference in specific gravity.

As shown in Fig. 2 the wave basin was divided into the seven flumes, each having a free water zone of 2.5 m in front of the wave paddle. Model breakwaters used in the stability test were constructed within every other flume. The control flumes had wave absorbing net-mats, which were set on a slope of 1 on 10 used to minimize the multiple wave reflection which takes place between wave paddle and breakwater model in normal flumes. In the laboratory test, regular waves were generated continuously on the Tetrapod model for a total of about 1,500 waves under no-overtopping conditions. The 1,500 waves are equivalent to prototype wave action of about 4 hours for a wave period of 10 sec. Wave flume B was constructed with a geometry to increase wave height. Each Tetrapod model was constructed randomly in two layers, on a slope of 1 on 4/3 as shown in Fig. 3. Laboratory test conditions are summarized in Table 2. The damage progression of Tetrapod models was observed continuously by a 8 mm Vidco-camera. The damage rate, defined as the ratio of the number of blocks that moved to the total number of armor blocks in the two layers, was measured with a display playing back the Video.

## Test results

A temporal damage change of Tetrapod models attributed to the difference of specific gravity based on test data, is shown in Fig. 4. The damage to the Tetrapod models of each different specific gravities should be similar to each other. These Tetrapod models (A-3, A-4, A-5) are listed the same row of Table 1. The design wave height of these armor units is nearly equal. However, these damage curves differ due to specific gravity. As to a reason for the difference,

Fig. 4. Temporal damage changes due to the difference of specific gravity

Miyazaki	5	14	50	4.0	11.8	7.1E+06	5.4	Typhoon 7119

considerations must be given to the fact that stability is affected by the specific gravity. Selecting identical wave heights from the test data in the same size Tetrapod model, a temporal damage change is shown for each wave period in Fig. 5. Damage curves, generally, must be similar to each other regardless of the difference in wave periods. Hudson's (1959) stability coefficient is independent of wave period. But from Fig. 5 it is recognized that stability becomes a function of the wave period.

From field data, we can investigate damage ratio, significant wave height, and block weight of Tetrapod. The technical report by Takeyama and Nakayama (1975) reported on damage of failure of coastal structures by large waves in Japan. These field data are listed in Table 3. The field data includes the effects of oblique incident waves, deflection waves, and scour in or around the toe of breakwater slope. The damage ratios shown in this table, then, are considerable large (range from 30% to 50%). Hudson's stability coefficient in this table is obtained by converting wave height to equivalent significant wave height. Regular waves were converted based on the equation,  $H = 1.5H_{1/3}$ . This equation follows the equations proposed by Fan et al. (1983) and Tanimoto (1985) as

$$H = 1.4H_{1/3} \quad (\text{Fan et al.}) \quad (1)$$

$$H = (1.5 \pm 0.37)H_{1/3} \quad (\text{Tanimoto et al.}) \quad (2)$$

The evaluated surf similarity parameter  $\xi$  and Reynolds number  $R_s$  are also listed in Table 3.

Fig. 6. The relationship between  $K_D$ -values and specific gravity in two types of damages

### Effect of specific gravity on stability

The rocking only (no-damage) and the 0~1 % damage are selected from the laboratory test data. Fig. 6 shows these data which show the relationship between Hudson's stability coefficient,  $K_D$ , and the specific gravity in water,  $S_r-1$ . In this figure, the  $K_D$ -values scatter wildly for the difference in the specific gravity in water. The effect of the specific gravity on stability (rocking only and 0~1% damage) can not be clearly established from this figure. In the Hudson formula, the stability coefficient  $K_D$  should be constant because it should considerably depend on the shape of armor units. Therefore, the stability coefficient must be independent of the change of specific gravity. But  $K_D$ -values scatter wildly for the different  $S_r-1$  values as shown in Fig. 6. Then the Hudson formula may not satisfy the test data.

### Theoretical discussion

As above discussed, the effect of the specific gravity on the stability disagrees with the Hudson formula. As this reason it is considered that many factors affect Hudson's stability coefficient, including effects due to wave steepness, relative depth, Reynolds number, drag coefficient, acceleration of wave motion etc. as described by Hudson (1959).

Reviewing the Hudson formula, the stability coefficient  $K_D$  is expressed by;

$$K_D = \frac{w_r H^3}{W(S_r - 1)^3 \cot \theta} \quad (3)$$

where,  $W$  is the weight of armor unit,  $w_r$  is the unit weight of armor unit,  $H$  is the design wave height,  $S_r (=w_r/w_w)$  is the specific gravity of armor unit,  $w_r$  is the unit weight of armor unit,  $w_w$  is the unit weight of water,  $\theta$  is the angle of structure slope measured from horizontal in degrees, and  $K_D$  is the stability coefficient varying primarily with the shape of the armor units, degree of interlocking, damage rate, etc.

The behaviors of armor units is affected by slope angle, wave breaking, wave runup, and rundown, and is sensitive to the surf similarity parameter  $\xi$ ,

$$\xi = \frac{\tan \theta}{\sqrt{H/L_o}} \quad (4)$$

where  $L_o$  is the wave length in deep water.

Hudson (1959), Dai and Camel (1969), and Sakakiyama and Kajima (1990) have pointed out that the stability of armor units is affected by the Reynolds number related the scale of laboratory tests. The Reynolds number is expressed

using the velocity of wave motion and a characteristics length of the armor block as

$$R_e = \frac{\sqrt{gH}(W/w_r)^{1/3}}{\nu} \tag{5}$$

where  $\nu$  is the kinematic viscosity,  $g$  is the acceleration due to gravity. Rewriting Eq. (3) using Eqs. (4) and (5), the stability coefficient  $K_D$  is expressed as follows:

$$K_D = \frac{R_e^2}{\xi^4(S_r - 1)^3} C_R \tag{6}$$

where

$$C_R = \frac{L_o^2 v^2}{g} \left(\frac{w_r}{W}\right)^3 \tan^5 \theta \tag{7}$$

From Eq. (6), it is shown that the stability coefficient  $K_D$  is proportional to the -3rd power of the specific gravity in water, the -4th power of the surf similarity parameter, and the 2nd power of the Reynolds number.

**Stability and Surf similarity parameter**

Fig. 7 shows the relationship between  $K_D$ -values and the surf similarity parameter for the test data and the field data listed Table 3. In this Figure, the  $K_D$ -

Fig. 11. Effect of Reynolds number on  $K_D$ -values

values agrees well with the solid curve expressing the relationship of  $K_D \propto \xi^{-4}$  in Eq. (6). The relationship between the  $K_D$ -values and the surf similarity parameter for each specific gravity are shown in Fig. 8(a)-(c), respectively. From these figures, the relationship between the  $K_D$ -values and the surf similarity parameter agrees well the solid line indicating the relationship of  $K_D \propto \xi^{-4}$ . Fig. 9 shows the relation

of  $\xi$  to  $K_D$  arranged together from Fig. 8(a) to Fig.8(e) using the specific gravity as a parameter. Fig. 10 shows the relationship between the stability coefficient and specific gravity in water. This figure was obtained by rearranging Fig. 9 taking the surf similarity parameter as a parameter. From Fig. 10, it can be seen that the stability coefficient decreases with increasing specific gravity in water dependent on  $K_D \propto (S_r - 1)^{-3}$ , as indicated in Eq. (6). From Fig. 10, stability is affected by the surf similarity parameter, and increases with decreasing the surf similarity parameter.

Sawaragi et al. (1983) pointed out that Iribarren's number reaches a minimum value around the surf similarity parameter of  $\xi \approx 3$  due to the occurrence of wave-armor unit resonance on the basis of the laboratory tests of rubble mound breakwaters. Losada (1990) discussed the effect of the surf similarity parameter on the stability function,  $\varphi = 1/(K_D \cot \theta)$ , by rearranging laboratory test data for various armor units. Then he pointed out that the stability function increases inversely proportional to decreasing surf similarity parameter. These findings are contrary to authors results as above discussed. The discrepancy between the authors and Losada may cause the reason that the range of the surf similarity parameter used and the size of armor unit model is not in agreement.

### Stability and Reynolds number

It can be considered from Eq. (6) that the stability coefficient  $K_D$  is affected by the Reynolds number. Then, the relationship between the Reynolds number and the  $K_D$ -values of the zero damage test data and the field data listed in Table 3, is plotted in Fig. 11. This figure is also plotted with the dark circle indicating Tetrapods only from the paper by Simada et al. (1986), who investigated the stability of Tetrapods, Dolosse, and Koken-blocks. These armor units are made from normal concrete ( $w_c/w_w = 2.30$ ). The armor blocks had a weight range of  $W = 0.16 - 484$  kN (16 gf - 49.39 kgf), and were tested in the medium and large wave tanks. It is shown from Fig. 11 that the  $K_D$ -values increase rapidly with increasing Reynolds number, up to  $R_e = 10^5$  which corresponds to small and medium test scales in the range of Reynolds number  $R_e = 8 \times 10^3 - 10^5$ . Over this value the  $K_D$ -values gradually reach a constant. The  $K_D$ -values fit well with the solid line indicating the relation of  $K_D \propto R_e^2$ . The  $K_D$ -values beyond  $R_e = 10^5$  deviates from the trend depicted by the solid line. Such changes in  $K_D$ -values may be caused by scale effects. This has been indicated by Dai and Camel (1969) and Shimada et al. (1986). A wider range of scales and numerous test data are needed to further the understanding of the affects of specific gravity and the surf similarity parameter as they related to  $K_D$ -values and the Reynolds number.

### Conclusions

The effect of the specific gravity on the hydraulic stability of Tetrapod is examined on the basis of numerous laboratory test data. These data were obtained using the total of 21 different models composed five values of specific gravity;

1.82, 2.30, 2.77, 3.40, and 4.27. The discussion includes test and field data reported by another researchers. Conclusions drawn from the results obtained in this study are as follows:

- (1) Hudson's formula does not include the effect of wave period. Then Hudson's stability coefficient must be independent of wave period. But this coefficient is considerably influenced by wave period.
- (2) Trends are not seen for the relationship between  $K_D$ -values and specific gravity. But by arranging the relationship as a function of the surf similarity parameter, it is found that the  $K_D$ -values decrease with increasing surf similarity parameter, where  $K_D \propto \xi^{-4}$ .
- (3) The relationship between the  $K_D$ -values and the specific gravity in water is shown by the relation,  $K_D \propto (S_r - 1)^{-3}$ , when the surf similarity parameter is taken into account. The  $K_D$ -values decrease with increasing specific gravity.
- (4)  $K_D$ -values from the test data correspond well to the 2nd power of the Reynolds number within a range of Reynolds number between  $R_e = 8 \times 10^3 - 10^5$ . In  $R_e \geq 10^5$ , the  $K_D$ -values gradually reach a constant as Reynolds number increases. Therefore the stability of high-specific gravity armor blocks, is affected significantly by scale effects.

It should be remarked that the conclusions of (1), (2), and (3) are results that are discussed on the basis of the data of small and medium test scale included the scale effects.

### Acknowledgement

The authors would like to thank Mr. George F. Turk, Research Hydraulic Engineer of U.S. Army Coastal Engineering Research Center for proofreading the draft paper. We also grateful to the undergraduate and graduate students of Department of Civil Engineering at Meijo University for their kind assistance in the laboratory test.

## CHAPTER 84

### Rock armoured beach control structures on steep beaches

Jones R.J.<sup>1</sup> & Allsop N.W.H.<sup>2</sup>

#### ABSTRACT

This paper presents the results of a research study to quantify the stability of rock armoured groynes on steep shingle beaches. The research was needed to identify why significant numbers of rock revetments and groynes have suffered greater damage than would be predicted by conventional design methods. The paper describes the design and execution of tests in a large wave basin, at notional scales of 1:10-20, on four types of typical beach control structures. The test structures were constructed on a model shingle beach of slope 1:7, and were subjected to random waves of steepnesses  $s_m=0.02$  or  $0.04$ .

The tests confirmed that armour damage may be substantially greater than predicted by existing methods, even on simple slopes under normal wave attack. The results of the damage analysis have been used to suggest modified coefficients to van der Meer's plunging wave formulae.

#### 1. INTRODUCTION

The use of shingle beaches in a coastal defences increasingly requires control structures to maintain and retain the beach. A variety of structures are in use (Fig 1), including rock groynes and/or breakwaters, and revetments. The main structure types in use, not necessarily in the UK, may be summarised:

- a) near-shore, detached, breakwaters;
- b) low-crest or reef breakwaters;
- c) submerged breakwaters or sills;
- d) rock groynes, bastion or inclined;
- e) rubble revetments.

Studies at Wallingford on the influence of the control structures on the beach response to wave action, reported by Coates (1994), suggest that rubble groynes are often the most cost-effective of these structures in controlling movements of shingle beaches, and significant research is underway to describe the effect of structure plan configuration and geometry on the plan re-shaping of the beach. As shingle beaches may become depleted without re-nourishment, or may be locally denuded by strong oblique wave attack, back-

<sup>2</sup> Professor (associate), Department of Civil Engineering, University of Sheffield; Manager Coastal Structures, HR Wallingford, Howbery Park, Wallingford, UK.

beach rubble revetments may also be required to form a stronger rear defence.

**Figure 1 Beach control structures**

The main parameter set by structural considerations on all armoured control structures is the median armour size. The armour slope angle chosen interacts with the armour size needed for a given stability level, but is also set by consideration of wave reflections and overtopping. Many other dimensions, and aspects of construction practice, relate closely to the unit armour size. If under-sized, rock armour will move excessively, leading to deterioration of the armour, and/or erosion of fill. Structural changes to the groyne will in turn lead to higher wave overtopping, and/or beach erosion. It is important therefore to ensure that any damage to the structure remains below acceptable limits. Various methods may be used to calculate the armour size, but are only fully valid for normal attack on simple cross-sections. Allsop et al (1995) present evidence where some structures have experienced more damage than expected by their designers, and/or deemed acceptable by their owners.

The problem of increased damage armour appears to have been most severe on steep shingle beaches, typically in the UK at slopes between 1:5 to 1:10, with the average near to 1:7. It is likely that such steep slopes have significant influences on the form and strength of wave breaking onto any structure constructed on the beach, thus modifying the waves from the form of deep or intermediate depth waves for which most design methods have been derived. Most of this paper therefore describes hydraulic model studies conducted to measure armour damage on beach control structures on steep beaches, and the analysis then conducted to devise appropriate design methods.

## 2 METHODS TO CALCULATE ARMOUR STABILITY

Design methods for rock armour focus on calculation of the median armour unit mass,  $M_{50}$ , or the nominal median diameter  $D_{n50}$  defined in terms of the median unit mass and rock density  $\rho_r$ :  $D_{n50} = (M_{50}/\rho_r)^{1/3}$ . The most common calculation methods are the Hudson

formula given in the Shore Protection Manual by CERC (1984); or equations by Van der Meer (1988). Hudson developed a simple expression for the minimum armour weight for regular waves which may be written in terms of the median armour unit mass,  $M_{50}$ , and wave height,  $H$ :

$$M_{50} = \rho_r H^3 / (K_D \cot \alpha \Delta^3) \quad (1)$$

where  $\rho_r$  is the density of rock armour ( $\text{Kg/m}^3$ );  $\rho_w$  is the density of (sea) water;  $\Delta$  is the buoyant density of rock,  $= (\rho_r/\rho_w)-1$ ;  $\alpha$  is the slope of angle of the structure face; and  $K_D$  is a stability coefficient to take account of the other variables. Values of  $K_D$  corresponded to the wave height giving least stability in tests with regular waves on permeable cross-sections subject to little overtopping. Slight re-shaping of armour was expected, and values of  $K_D$  correspond to "no damage" where 0-5% of the armour was displaced.

An alternative method was derived by Van de Meer (1988) who included model data by Thompson & Shuttler at Wallingford, extended this by further tests at Delft, and derived new formulae for armour damage which include the effects of random waves, range of core / underlayer permeabilities, and distinguish between plunging and surging wave conditions respectively.

$$H_s/\Delta D_{n50} = 6.2 P^{0.18} (S/\sqrt{N_z})^{0.2} \xi_m^{-0.5} \quad (2a)$$

$$H_s/\Delta D_{n50} = 1.0 P^{0.13} (S/\sqrt{N_z})^{0.2} \sqrt{\cot \alpha} \xi_m^P \quad (2b)$$

where the parameters not previously defined are:

- P notional permeability factor
- S design damage number  $= A_e/D_{n50}^2$ , and  $A_e$  is erosion area
- $N_z$  number of waves
- $\xi_m$  Iribarren number  $= \tan \alpha / s_m^{0.5}$
- $s_m$  wave steepness  $= 2\pi H_s/gT_m^2$ , and  $T_m$  is the mean period;

and the transition from plunging to surging is given by a critical value of  $\xi_m$ :

$$\xi_m = (6.2 P^{0.31} (\tan \alpha)^{0.5})^{1/(P+0.5)} \quad (2c)$$

Damage to armour on a range of core / underlayer configurations were analysed. Values of  $P$  given by Van de Meer vary from 0.1 for armour on underlayer over an impermeable slope, to 0.6 for a homogeneous mound of armour, with intermediate values of 0.4 and 0.5 also described. These formulae were derived for normal wave attack, and do not include corrections for roundheads or junctions.

### 3. DESIGN OF MODEL STUDIES

#### 3.1 Test structures and facility

The objective of the physical model tests was to quantify the stability of rock armour on four typical rock armoured structures on a 1:7 beach slope:

- a) a breakwater or groyne roundhead, Type 2, (Fig 2);
- b) an L-shaped groyne, formed from a) above;
- c) an inclined groyne, Type 1, (Fig 3); and
- d) a simple 1:2 rubble sea wall slope.

The 1:2 sea wall section was tested primarily as a control structure, damage to which could be compared directly with predictions by the existing design formulae.

Figure 2 Type 2 roundhead groyne

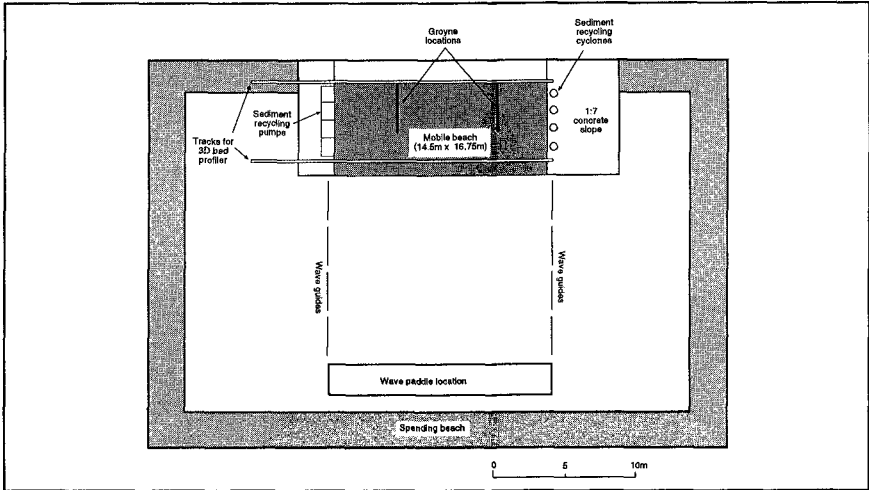

Figure 3 Type 1 groyne

Early in the research, a review of prototype structures suggested that the crest level should allow overtopping, and often fell between significant and 2% run up levels. The 2% run-up level was calculated using empirical prediction methods in CIRIA (1991). The principal test parameters may be summarised:

Water and bed levels	0.0m; -0.7m
Target wave height	$H_s = 0.13\text{m}$ , ( $H_s/\Delta D_{n50} = 1.7$ )
Mean sea steepnesses	$s_m = 0.02$ and $0.04$
Test duration	$N_z = 1000$ and $3000$ waves
Armour and core size	$D_{n50} = 0.045\text{m}$ ; $D_{n50} = 0.024\text{m}$
Side slope angles	$\text{Cot } \alpha = 2.0$
Toe and crest levels	$-0.36\text{m}$ , ( $-8D_{n50}$ ); $+0.22\text{m}$ , ( $+5D_{n50}$ )

**Figure 4 Roundhead Basin test facility**

The structures were constructed and tested in a large wave basin which measured 40m by 27m (Fig 4). The models were not to a particular scale, so analysis of measurements used dimensionless terms, but the structures may be viewed as modelled at ratios of between 1:10 and 1:20. Two structures were tested at one time. Type 1 and 2 groynes were tested in the first series. The Type 1 groyne was then replaced by the sea wall, and the Type 2 groyne was modified to the "L" shape (Fig 5).

**Figure 5 Plan of L-shaped groyne**

The 1:2 slope sea wall section was 1.0m wide (equivalent to  $22 D_{n50}$ ). The toe was set at the same level as the toe of the "L" shaped and roundhead groynes.

The low level groyne, Type 1, was 4.7m long ( $105 D_{n50}$ ), 0.94m ( $21 D_{n50}$ ) wide at the base, and reached a height of 0.2m ( $4.4 D_{n50}$ ) above the beach. The armour was laid to a thickness  $t_a=2D_{n50}$ , slopes of 1:2, and crest width of  $3D_{n50}$ .

The high level roundhead groyne, Type 2, was shorter and wider than the Type 1 groyne at 2.95m (66  $D_{n50}$ ) long and 1.38m (31  $D_{n50}$ ) wide at the widest part of the roundhead. The crest was 0.31m (6.9  $D_{n50}$ ) above the beach at the seaward end.

The "L" shaped groyne was formed by extending from the roundhead of the Type 2 groyne. The groyne was 2.96m (66  $D_{n50}$ ) long, with a side limb of 2.38m (53  $D_{n50}$ ). A straight section of 1.0m (22  $D_{n50}$ ) formed the "L" shape.

Three 5m random wave paddles produced normal wave attack for these tests. The 1:7 slope beach used by Coates (1994) measured 12.5m by 8m, and this area was covered by an automatic three-axis bed profiler. Profile measurements of the structures were recorded on a personal computer, allowing armour displacements to be quantified by comparing profile lines over selected areas of each model. The measured damage was compared with damage predicted by the Van der Meer method for simple sections.

**3.2 Test conditions**

These tests were designed to give useful data over a wide range of structural and environmental variables. The experiments were intended to give intermediate armour damage at wave heights less than the maximum possible in the basin, equivalent to  $H_s/\Delta D_{n50}=2.6$  for armour of  $D_{n50}=0.045m$ . The "target" wave height was equivalent to  $H_s/\Delta D_{n50}=1.7$ , and this wave height was used in the design of the model structures.

Around European coastlines, storm wave conditions are generally steep and narrow-banded, often described well by the JONSWAP spectra. Storm waves are relatively steep, but armour damage also depends upon sea steepness. These tests used two steepnesses,  $s_m=0.02$  and  $0.04$  to explore the possible effects of longer waves. Each test was planned to be run for  $N=1000$  and  $3000$  waves duration.

**Figure 6** Sea wall damage,  $s_m=0.04$ ,  $P=0.5$

**3.3 Test procedures**

The first part of each test used 100 waves, during which close observations were made of

the structures. If no movement was seen in these 100 waves, the test was stopped. If any damage (including rocking) was observed, then the test continued to 1000 waves when each profile line was re-surveyed. The test then continued for a further 2000 waves. After each test the structures were re-surveyed and photographed. If they had been damaged such that repair was necessary, the armour was re-built around the zones damaged. Testing was stopped when the structures needed re-building.

Profiling covered set lines over each of the groyne under test. The profiler incorporated a touch-sensitive foot of diameter equivalent to  $0.8D_{n50}$ , and took observations at  $0.5D_{n50}$  intervals along each profile line. The profile results were used to calculate the area of erosion on each profile line,  $A_g$ , and hence the damage parameter  $S$  defined in section 2.

4. TEST RESULTS

4.1 Simple slopes

The test results were initially very surprising, as virtually all of the profiles showed significantly more damage than predicted by conventional formulae (Fig 6). Some local increases in damage had been expected, but not the consistently greater damage found here. Analysis attention was focused first on the 1:2 sea wall slope, and equivalent section on the L-shaped groyne, but even these simple cases showed significantly greater damage than predicted by the Van der Meer equations. During the analysis period, additional data on the performance of armoured groyne on two bed slopes became available from tests at CEPYC in Madrid. Initial analysis of these had been presented by Baonza & Berenguer (1992), and their test data were further analyzed by Allsop & Franco (1992) as part of the EC MAST project G6-S. These data also indicated that the sea bed slope might be significant in increasing armour damage.

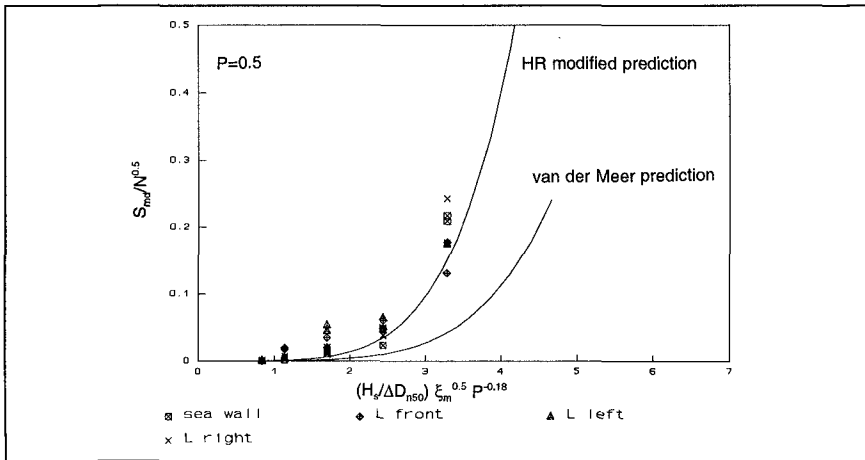

Figure 7 Sea wall and front face of "L" shaped groyne

Damage results for the sea wall section alone are summarised in Figure 6, using axes based on equation (2a) that allow results for each wave steepness and test duration to be presented together. The standard Van der Meer equation for plunging waves is shown, together with a version of the equation with a revised coefficient:

$$H_g/\Delta D_{n50} = 4.8 P^{0.18} (S/\sqrt{N_z})^{0.2} \xi_{cm}^{-0.5} \tag{3a}$$

The fit of the data to this modified equation is good over the area of main interest. Further support for the revised equation is given by the comparison of damage on the front face of the "L" shaped groyne with the sea wall, shown in Figure 7.

**Figure 8** Damage to curved parts of "L" shaped groyne

**Figure 9** Damage to curved parts of "L" shaped groyne

The first result from this analysis was therefore the conclusion that damage is significantly increased by steep (local) beach slopes, even for simple slopes subject to normal wave attack. A modification to the Van der Meer equation for plunging waves is given in equation (3a), and a similar increase for surging waves would be given by:

$$H_g/\Delta D_{n50} = 0.77 P^{-0.13} (S/\sqrt{N_z})^{0.2} \sqrt{\cot \alpha} \xi_{cm}^P \tag{3b}$$

**4.2 Roundhead and "L" shaped groynes**

Once the effect of the steep beach slope had been accounted for, the test results suggest that some sections of the more complex 3-dimensional structures experience greater damage than the simple slopes under normal wave attack, but that the spread of damage spatially is somewhat variable. This is shown in Figures 8 and 9 where damage on the opposing sides of the "L" shaped groyne are contrasted with the new equation (3a). For most positions, the modified prediction method in eqn (3a) gives a reasonable estimate of the damage, but for the zones shown in Figure 8, damage at larger wave heights is still greater than would be predicted by the new method. In itself, this is not surprising, as it is well known that breakwater roundheads require larger armour units, and/or shallower slopes for the same stability as trunk sections.

**4.3 Inclined, Type 1, groyne**

Damage to the inclined groyne, Type 1, varied along its length, with the location of greatest damage depending on wave height and period. The mean level of damage taken over the active length of the groyne, and derived by averaging the erosion areas from each profile, fits the general prediction given by eqn (3a), and is summarised in Figure 10.

**Figure 10 Summary of Type 1 groyne results**

Peak values of (local) damage along the length of the groyne however often reached twice the mean, often at the wave run-up and run-down limits along the groyne, and this is illustrated in Figures 11-13 which show local levels of damage plotted against position along the groyne from the landward end for increasing relative wave heights. For  $H_s/\Delta D_{n50}$  up to 1.72 (Figures 11-13), damage only exceeds  $S=5$  at 1000 waves over small regions. For  $H_s/\Delta D_{n50}=2.16$  (Fig 14) however, damage over most of the length of the structure has exceeded this criterion.

**8 CONCLUSIONS**

These tests have shown that the stability of armour on beach control structures depends critically on the local sea bed slope. Results from tests using a beach of 1:7 were used to

develop a modified coefficient for use in the Van der Meer equation. The changes to the coefficients are equivalent to increasing the mean armour mass by a factor of 2.2 to maintain armour stability.

Figure 11 Type 1 groyne,  $s_m=0.04$ ,  $H_s/\Delta D_{n50}=0.83$

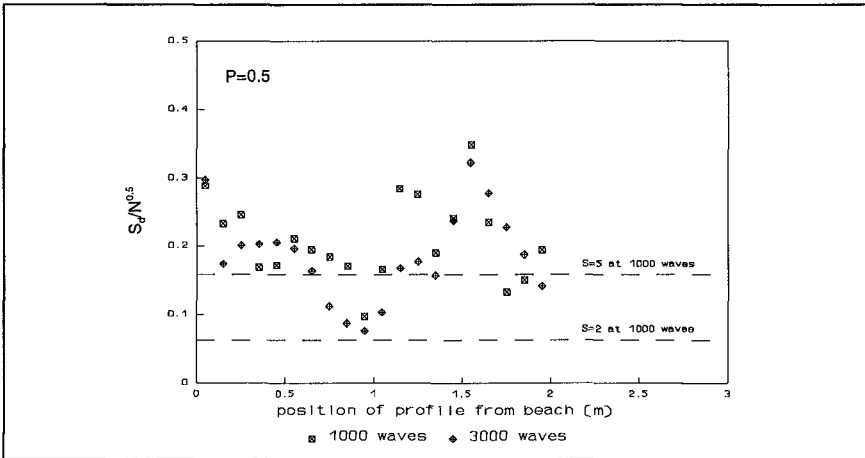

Figure 12 Type 1 groyne,  $s_m=0.04$ ,  $H_s/\Delta D_{n50}=1.12$

**Figure 13** Type 1 groyne,  $s_m=0.04$ ,  $H_s/\Delta D_{n50}=1.72$

**Figure 14** Type 1 groyne,  $s_m=0.04$ ,  $H_s/\Delta D_{n50}=2.16$

This study has identified some unusual effects, and some unexpected conclusions. The tests suggest that steep beach slopes may change the form of wave breaking such that the performance of structures in or behind steep (beach) slopes should be reviewed to identify whether a more general effect may lead to problems.

**ACKNOWLEDGEMENTS**

The laboratory studies covered in this paper were supported by the UK Ministry of Agriculture, Fisheries, and Food under Research Commissions on Flood Defence. Additional support was given by the European Union under MAST I project G6-S, and by HR Wallingford. The hydraulic model tests covered in section 5 were conducted by RJ

Jones assisted by MK Reeves and P Bona in the Coastal Group of HR Wallingford, and supervised by NWH Allsop. The authors are most grateful for the assistance of Andrew Bradbury of the Coast Protection Unit of New Forest District Council for valuable advice in the analysis of the laboratory tests, and for the additional data from Hurst Spit; to CEPYC and to C Franco of University of Rome for assistance in the MAST project G6-S topic 3R2.

Preparation of this paper was supported by the University of Sheffield and HR Wallingford.

## CHAPTER 85

### Effect on Roughness to Irregular Wave Run-up

Jea-Tzyy Juang\*

#### ABSTRACT

A study of the irregular wave runup and rundown phenomenon on rough impermeable slope is conducted in order to investigate the effects of various surface roughness to the wave runup-rundown activities based on various kind of dyke and incident wave conditions. The roughness of dyke surface was defined as  $f_r$  which is functions of shape of the slender rectangular obstacles and its displacement distance. Results shows that the correlation between the relative significant runup height ( $R_{us}/H_s$ ) and the incident wave steepness ( $H_s/L$ ) have the same tendency either in regular or in irregular waves. The relative runup height has its maximum value when the dyke slope ( $\cot\theta$ ) near 2. Next, the runup characteristics in regular wave was agree well with the Rayleigh distribution but it is a little bit smaller than that the Rayleigh's in irregular wave. Besides, the strong correlation between the wave runup and the surf similarity parameter  $\xi$  was found. The decrease of the relative run-up height with the increase of the surface roughness was got also. It may be useful to applied into the design work of the seawall.

#### INTRODUCTION

Wave run-up on coastal structures such as seawalls, dykes and so forth, is an important factor in the design of the height of the structures; therefore, many studies on the wave runup phenomenon and its characteristics have been carried out. However, the studies of the effect of roughness on the dyke to the run-up height are still scarce to find. Therefore, a study of the irregular wave run-up and run-down phenomenon on rough impermeable slope was conducted here in order to investigate the effect of various surface roughness to the wave runup-rundown activities based on the different kind of the dyke and the incident wave conditions.

ANALYTICAL CONSIDERATION

Based on the concept of control volume, the correlation among the incident wave energy, the reflected wave energy and the energy dissipation during the wave run-up and overtopping (as shown in Fig. 1) can be written as (Cross, 1972)

Fig.1 Definition sketch of runup and overtopping

$$E_i \cdot C_g - E_r \cdot C_g - \frac{E_o}{T} = \frac{PE - E_o}{T} \cdot K_1 \tag{1}$$

- where  $E_i$ : Incident wave energy density
- $E_r$ : Reflected wave energy density
- $C_g$ : Group velocity
- $E_o$ : Overtopping energy
- PE: Potential energy of the entire runup wedge above SWL
- $K_1$ : Rundown energy loss coefficient
- T : Wave period

By condition of no overtopping, the above equation can be simplified as

$$E_i \cdot C_g - E_r \cdot C_g = \frac{PE}{T} \cdot K_1 \tag{2}$$

The potential energy PE can be computed (Juang, 1992) by the following equation with all notations was shown in Fig. 2.

Fig.2 The shape of runup wedge

$$\begin{aligned}
 PE &= \rho g \left\{ \int_{X_1}^{X_2} \frac{Y^2}{2} dx - \frac{R^3}{6\alpha} \right\} \\
 &= \frac{1}{2} \rho g \left\{ \frac{M^2}{2n+1} (X_2^{2n+1} - X_1^{2n+1}) - \frac{2 \cdot MA}{n+1} (X_2^{n+1} - X_1^{n+1}) \right. \\
 &\quad \left. + A^2 (X_2 - X_1) - \frac{R^3}{3\alpha} \right\} \tag{3}
 \end{aligned}$$

in which Y is the water surface elevation above the still water level at maximum runup. Its corresponding equation is

$$Y = M \cdot X^n - A \tag{4}$$

where X is the distance from the trough shoreward; A is the amplitude at the trough and M, n the coefficients that was function of surf parameter  $\xi (= \tan\theta / \sqrt{H/L})$  as shown in Table 1.

By using the linear wave theory, the wave height in front of the inclining dyke becomes

Table 1 Values of M and n

cot $\theta$	0.5	1.0	2.0	3.0
M	$54.228 \xi^{-3.5}$	$5.993 \xi^{-3.68}$	$1.748 \xi^{-4.67}$	$0.437 \xi^{-3.19}$
n	$1.0075 \xi^{0.19}$	$0.608 \xi^{0.59}$	$0.858 \xi^{0.64}$	$0.873 \xi^{0.59}$

$$H = H_i + H_r = H_i(1 + K_r) \quad (5)$$

where  $H_i$ : incident wave height  
 $H_r$ : reflected wave height  
 $K_r$ : reflection coefficient

Due to the wave energy was proportional to the wave height, therefore we can have

$$E_r = K_r^2 \cdot E_i \quad (6)$$

Substitute eq.(6) into eq.(2), the equation becomes

$$E_i(1 - K_r^2) \cdot C_g \cdot T = PE \cdot K_1$$

$$\text{or } PE = \frac{1 - K_r^2}{K_1} \cdot E_i \cdot C_g \cdot T$$

#### DEFINITION OF ROUGHNESS COEFFICIENT

The roughness of the dike surface in this experiment study was made of small rectangle slender obstacles on the dyke as shown in Fig.3. The idea of that frame was come from the stream flow. Because the roughness coefficient at the bottom of the river was proportional to the diameter of the bed particles. Therefore, the roughness coefficient  $f_r$  in this study was defined by the following step.

- (1)  $f_r \propto D$ ; the higher the height of the slender obstacle, the rougher the roughness coefficient.
- (2)  $f_r \propto 1/W$ ; the wider the width of the slender obstacle, the smoother the roughness coefficient.
- (3)  $f_r \propto A_r = BD/D_m(B+W_m)$ ; the bigger the ratio of the effective cross section  $A_r$  to the maximum cross section, the rougher the roughness coefficient.

Fig.3 Definition diagram of the roughness coefficient

To view the whole situation that mentioned above, we can defined the roughness coefficient as follow

$$f_r = \frac{BD^2}{WD_m(B + W_m)}$$

Various roughness coefficient (include  $f_r=0$ ) with different ratio of D/B and W/B was shown in Table 2.

Table 2 Contrast table among D/B, W/B and  $f_r$

D/B	0	0.25	0.25	0.25	0.5	1.0	1.0	1.0
W/B	0	4.5	3.0	1.5	1.5	4.5	3.0	1.5
$f_r$	0	0.0025	0.0038	0.0076	0.0303	0.0404	0.0606	0.1212

#### EXPERIMENT STUDY

A series of tests was carried out in a 100m long, 1.5m wide and 2m height wave flume. A random wave generator of servo-controlled electro-hydraulic system that was made by Danish Hydraulic Institute in Denmark is installed at one end. Artificial dyke model of various rough surface (include smooth) with four different kind of dyke slopes ( $\cot \theta = 0.5, 1, 2, 3$ ) were installed at the other end where was 45m from the wave generator. The flume was divided into two sections. One equal 100 cm and the other 40 cm. The later (smaller) channel was used for measure the incident wave which will not to interfere by the reflected wave. All the experimental apparatus is shown in Fig.4.

Several wave gauge (ch.1 to 5) of capacitance type was used for measured the incident waves (Ch.1 to 4) and the run-up (Ch.5). The experiment was complete in conditions on fixed water depth (40cm) and incident wave period (1.2sec). The incident significant wave height are approximate to 3.5, 5.8, 6.8, 7.5, 8.0 and 8.8cm separately. The random waves used for tests were simulated to have Pierson-Moskowitz type spectra. Both of water surface variations of incident wave and run-up height were recorded simultaneously by an analog data recorder. The recorders were digitized by an A-D converter at a sampling interval of 0.025 sec. The measuring duration is about 100 sec.

Fig.4 Layout of the test flume

For data analysis, at the beginning, there have two ways to analyze the characteristics of incident and run-up waves. One is the statistics method to count out the significant wave. The other is the spectra analysis method to calculate the spectra energy then the significant wave height. Due to wave height and period are very important factors in wave structure interaction such as wave run-up. Therefore, the dimensionless distribution of relative wave height ( $H/H_m$ ) to wave period ( $T/T_m$ ) of the experimental waves was compared as shown in Fig.5. In the figure, it can be seen that the relative wave period ( $T/T_m$ ) increases with the increase of wave height in the smaller waves ( $H < 1.3H_m$ ), but wave periods are distributed around  $T/T_m=1.3$  in the wave field higher than arbitrary critical value ( $H > 1.3H_m$ ). Meanwhile, from the data shown in the figure, we have

$$\begin{aligned}
 H_{1/10} &= 1.97 H_m \\
 H_{1/3} &= 1.56 H_m \\
 T_{1/3} &= T_{1/10} = T_{max} = 1.3 T_m
 \end{aligned}$$

It is identified from the above results that the joint distribution of wave height and period has a good agreement with the analyzed results of field data by Goda (1985). In other words, it can be stated that the simulated irregular waves used in model tests represent random ocean waves fairly well.

Fig.5 Joint distribution of wave height and wave period

In order to investigate the distribution status of the run-up waves of the irregular wave. The computational method of statistical significant wave height was used for counting the significant runup height ( $R_{us}$ ) also. Part of the results ( $f_r=0$  &  $f_r=0.1212$ ) was shown in Fig.6 and Fig.7 respectively. From those figures, we can find the distribution of irregular wave runup heights ( $R_{us}$  to  $R_{um}$ ) provides a good approximation to the Rayleigh distribution on the smooth surface dyke. But it will be overestimated when the dyke slope milder than 1 to 2 in rough surface ( $f_r=0.1212$ ) test.

Secondly, all the experiment data which shows the relationship between the significant relative run-up and run-down height with the surf parameter was shown in Fig.8. In the figure, the envelope lines (1) and (2) indicate the extreme value of the relative run-up and run-down height respectively. Which was got from the experiment result by  $X_{ue}$  (1991) in condition of smooth dyke slope.

As to the effect of roughness to irregular wave runup, the relation diagram between the significant relative runup height and the surf similarity parameter in different kind of the surface roughness ( $f_r=0\sim 0.1212$ ) was shown in Fig.9. From those figures, we can find that the effect of roughness to the relative runup height was certainly. If we sum up those correlation curves toge-

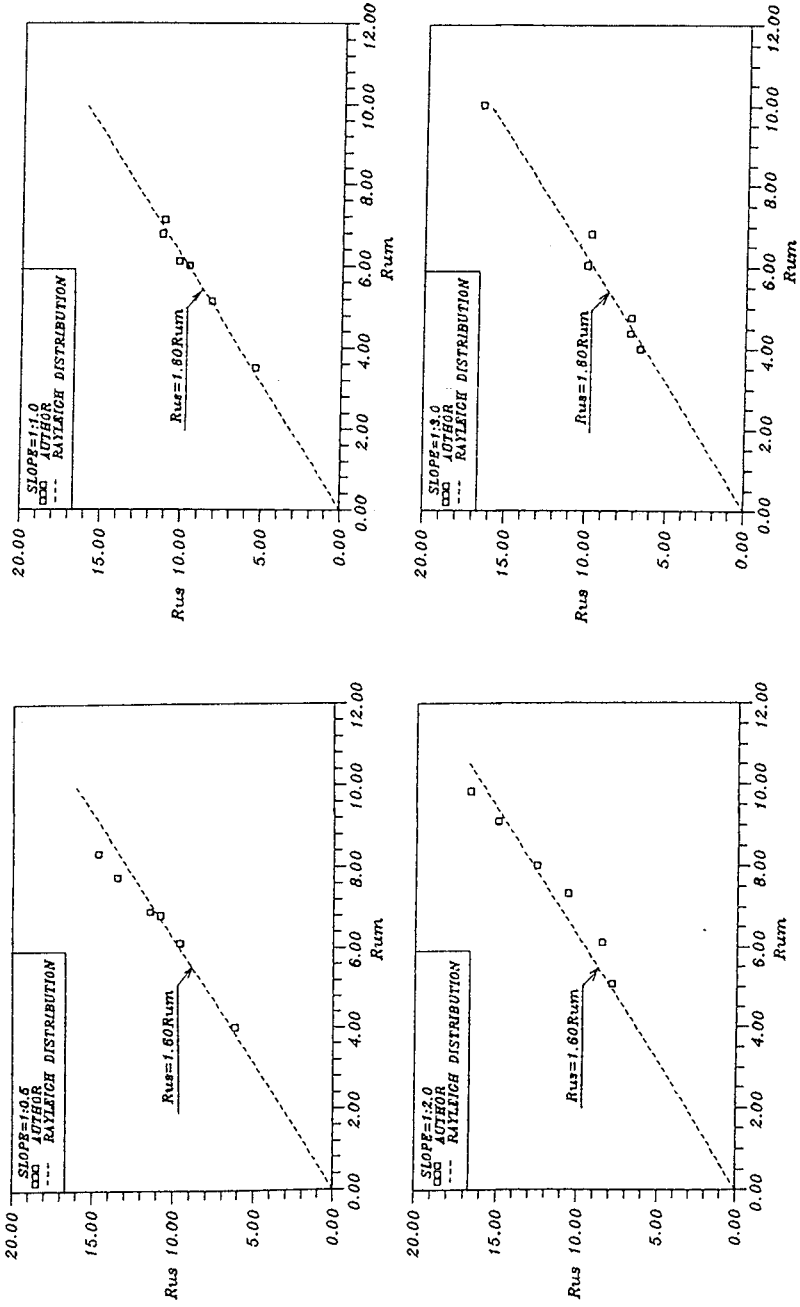

Fig. 6 Relationship between significant runup height and mean runup height in smooth dike

Fig. 7 Relationship between significant runup height and mean runup height in rough dike

Fig.8 Relationship between run-up-down height and surf parameter

ther, we can find the rougher the surface of the dyke slope, the lower the relative runup height decreased as shown in Fig.10. When the roughness coefficient approach to 0.1212, the corretation curve between the relative runup and the surf parameter was very similar with those results which was presented by Ryu in 1990 in rubble mound experiment.

At last, the normalized relationship between the relative run-up and rundown height and the surf parameter was shown in Fig.11 and 12 respectively. The meaning of normalized stand for the ratio of relative run-up(down) height in rough dyke compared with those in smooth dyke. From the figures, we can see that when the surf parameter becomes bigger, that means the dyke slope approach to vertical, the influence of roughness to wave run-up-down height will vanished.

### CONCLUSIONS

- 1.The distribution of the irregular wave runup heights provides a good approximation to the Rayleigh distribution on the smooth surface dyke. But it will be overestimated when the dyke slope milder than 1 to 2 in rough surface test.
- 2.The effect of roughness to the relative runup height was certainly and the rougher the surface of the dyke slope, the lower the relative runup height will decreased.
- 3.When the roughness coefficient approach to 0.1212, the relation

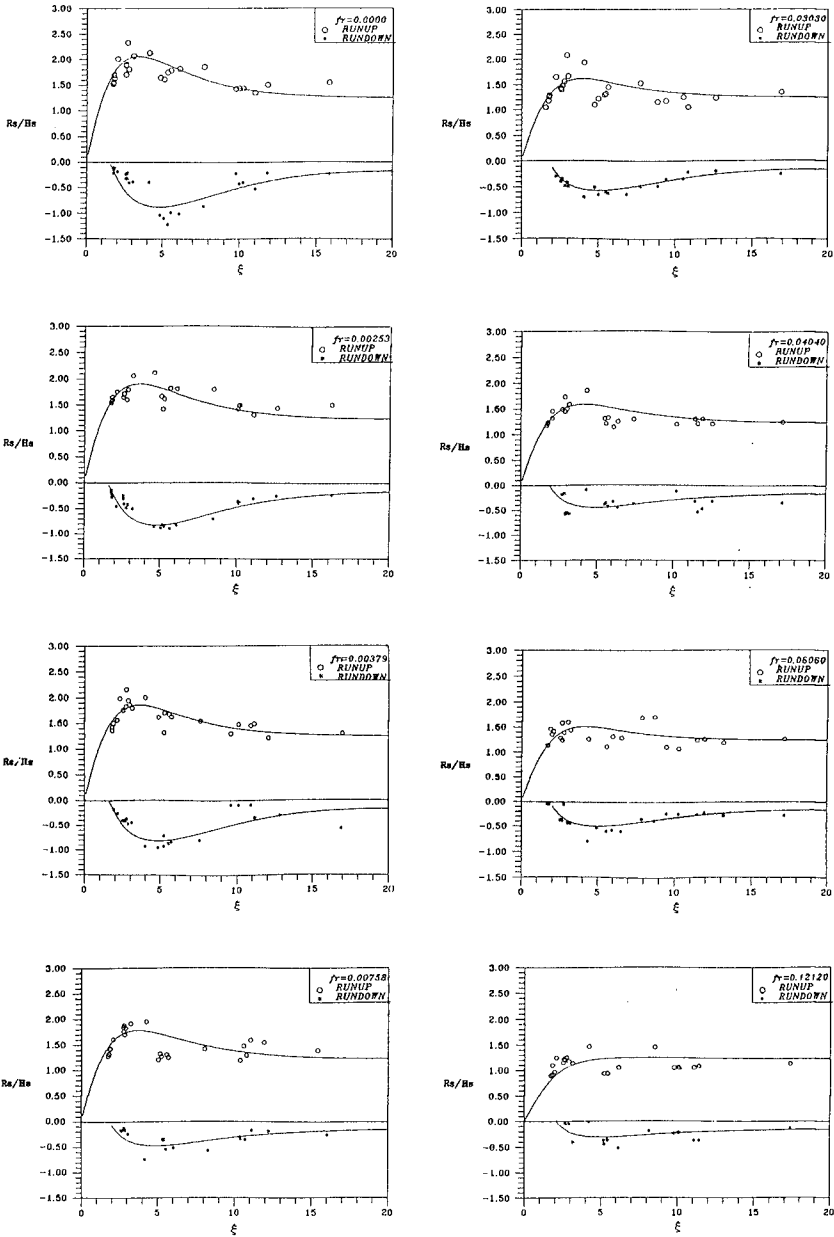

Fig.9 Relationship between significant relative runup height and the surf parameter

Fig.10 Comparison of relative runup in various rough surface

Fig.11 Normalized correlation of runup height to surf parameter

Fig.12 Normalized correlation of rundown height to surf parameter

curve between the relative runup height and the surf parameter was quite similar with those results in rubble mound experiment.

4. When the surf parameter becomes bigger, that's the dyke slope approach to vertical, the influence of roughness to wave run-up-down height will vanished.

#### ACKNOWLEDGEMENTS

This study was sponsored by the National Science Council of ROC under Grant NSC 81-0209-E124-01. The author would like to thank Mr. J. M. Chou, C. C. Chien and Miss E. J. Chien for their assistance in experiment and preparing the manuscript.

## CHAPTER 86

# Wave Overtopping of Breakwaters under Oblique Waves

Jørgen JUHL<sup>1</sup> and Peter SLOTH<sup>1</sup>

### Abstract

A series of hydraulic model tests has been carried out in a wave basin with the aim of studying the effect of oblique waves on the wave overtopping of traditional rubble mound breakwaters without superstructure. The model tests concentrated on measuring the mean overtopping discharge for wave attacks varying from 0° (perpendicular to the structure) up to 50°. Analyses of the overtopping results were made with respect to the significant wave height, wave steepness, crest free board, crest width and angle of wave attack. The paper describes the influence of these parameters on the mean overtopping discharge for a traditional rubble mound breakwaters with an armour layer slope of 1:2.0.

### Introduction

Wave overtopping of coastal structures is influenced by a large number of parameters related to breakwater geometry, construction materials, and hydrographic data. Some of the main parameters are listed below:

*Geometrical parameters:*

free board, crest configuration and width, slope of armour layer (irregular slope), and water depth

*Construction material parameters:*

porosity, stone shape and diameter (artificial blocks)

*Hydrographic parameters:*

wave height, wave period, angle of wave attack, wave steepness, spreading, wave sequences, wind conditions, and water level

---

<sup>1</sup> Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark

Wave overtopping is normally studied under perpendicular wave attack in wave flumes. Jensen and Juhl (1987) have shown overtopping data from model testing of rubble mound breakwaters and sea dikes. The paper mainly concentrates on mean overtopping discharges, but also includes a description of the horizontal distribution of the overtopping behind a breakwater, individual wave overtoppings and the influence of wind on wave overtopping, and a comparison to prototype measurements.

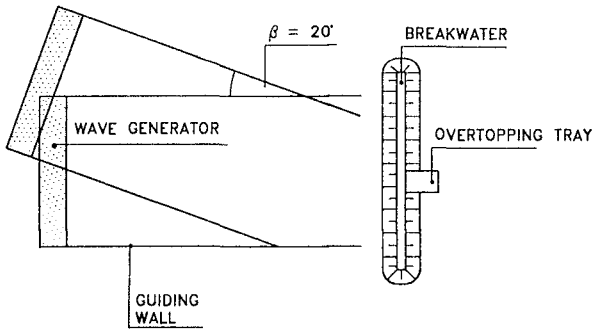

Franco et al (1994) have established a formula for the mean overtopping discharge for vertical breakwaters exposed to perpendicular wave attack. The influence of various geometrical types of breakwaters is taken into account using influence factors in connection with the general formula for a fully vertical breakwater. Further, a prediction formula for the probability distribution of individual overtopping volumes is presented. The effect of overtopping volumes on persons and cars behind a crown wall of a vertical breakwater was assessed by Franco (1993), and a set of critical overtopping discharges were proposed (safety criteria).

Only a little research has been made to study the influence of the angle of wave attack on the amount of overtopping water. De Wall and Van der Meer (1992) have carried out tests on the influence on wave run-up and overtopping on smooth slopes. The angle of wave attack,  $\beta$ , was varied from  $0^\circ$  up to  $80^\circ$ , and tests were performed with both long-crested and short-crested waves. For long-crested waves, a few tests showed larger run-up for angles between  $10^\circ$  and  $30^\circ$  than for perpendicular waves, but on average no increase was found. This also applies to the average measured overtopping discharges. For perpendicular wave attack, no difference in wave overtopping was measured between tests with long-crested and short-crested waves, whereas for oblique waves the influence of the angle of wave attack was less for short-crested waves. A reduction in the mean overtopping discharge of about 40 per cent was found for long-crested waves with an angle of  $50^\circ$  and of about 15 per cent for short-crested waves.

Galland (1994) has measured the number of waves overtopping rubble mound breakwaters exposed to oblique wave attack. The model tests were made with four different types of armour units, ie quarry stones, accropodes, antifer cubes and tetrapodes. In the case with quarry stones, the test results for long-crested waves showed a significant decrease in the percentage of waves overtopping the crest by increasing the angle of wave attack. For a dimensionless free board,  $R_c/H_s$ , higher than 2.0, no overtopping waves were measured, and for  $R_c/H_s = 1.0$  the percentage of overtopping waves was about ten per cent for perpendicular waves which was reduced to no overtopping waves for an angle of  $75^\circ$ .

## Model Set-up and Test Programme

Physical model tests have been carried out in a wave basin at the Danish Hydraulic Institute with the aim of measuring mean overtopping discharges defined as the volumes of wave overtopping per unit length of the breakwater per unit time. The basin was equipped with a movable wave generator in order to study the effect for different angles of wave attack, see Fig 1. The tests were carried out using long-crested irregular waves generated on basis of a Pierson-Moskowitz spectrum.

**Fig. 1** Model plan for the basin tests showing the set-up for perpendicular and 20° wave attack.

The modelled structure had a total length of about seven metres and was constructed as a traditional rubble mound breakwater with a core, filter layer and armour layer of quarry stones, see Fig. 2. The size of the armour stones was selected not to allow for significant damage during testing, ie a nominal diameter,  $D_{n,50}$ , of about 0.04 m. The model consisted of a horizontal seabed which together with the use of a fixed breakwater height of 0.45 m means that variations in the crest free board were obtained by changes in the water level.

The wave conditions in the model were measured by seven resistance type wave gauges located in front of the breakwater. For perpendicular wave attack, the incident wave conditions and the reflection coefficients have been calculated using a multi-gauge technique. The significant wave height was calculated as  $4 \times \sqrt{m_0}$ , where  $m_0$  is the zeroth moment of the spectral energy density function.

The overtopping water was collected in a 0.6 m wide tray located immediately behind the breakwater in a level corresponding to the crest elevation of the breakwater. This means that the recorded wave overtopping refer to water passing the rear edge of the breakwater crest. By measuring the total amount

of overtopping water after each test with a duration of 600 to 1800 seconds, the mean overtopping discharge,  $q$ , was calculated.

**Fig. 2** Typical cross-section of breakwater used in the overtopping tests.

The following ranges of parameters were tested in the model study (all measures are in model measures):

- Significant wave height,  $H_s$ : 0.05 to 0.11 m
- Peak wave period,  $T_p$ : 0.8 to 2.0 s
- Wave steepness,  $s_{0p}$ : 0,018, 0,025, 0,030 and 0,045
- Crest free board,  $R_c$ : 0.050, 0.075 and 0.100 m
- Width of crest,  $B$ : 0.16 ( $4 \cdot D_{n50}$ ), 0.21 and 0.26 m
- Slope angle,  $\cot \alpha$ : 2.0
- Angle of wave attack,  $\beta$ :  $0^\circ$  to  $50^\circ$  in steps of  $10^\circ$

The wave steepness is given by the ratio between the significant wave height and the deep water wave length calculated on basis of the peak wave period:

$$s_{0p} = H_s/L_{0p} = 2\pi/g \cdot H_s/T_p^2$$

A parameter often used in the research on coastal structures is the surf similarity parameter given as:

$$\xi_{0p} = \tan \alpha / \sqrt{s_{0p}}$$

The model tests were run in test series with fixed wave steepness, ie a fixed ratio between the significant wave height and the deep water wave length. Thus all tests were made with a surf similarity parameter larger than 2 (two), which means that the wave conditions can be characterised as non-breaking waves.

The dimensionless free board, defined as  $R_c/H_s$ , varied between 0.5 and 2.0, which means that the tests covered both low and high crested breakwaters.

## Test Results

This section includes analyses of the influence of the various tested parameters (wave height, wave steepness, crest free board, crest width and angle of wave attack) on the mean overtopping discharge. The influence of each of the parameters is described in the following.

Previous studies and the analysis of the test results showed that it is important to distinguish between situations with a large amount of water passing the breakwater crest, 'green water', and situations with a small amount of water passing the crest, 'spray'. Observations in the model showed that a rule of thumb to distinguish the two types of wave overtoppings is the dimensionless free board,  $R_c/H_s$ . It was found that for  $R_c/H_s$  larger than unity, the major part of the wave overtopping will occur as spray, whereas for  $R_c/H_s$  less than unity green water is dominant.

### Influence of Wave Height

Previous research on wave overtopping has shown that the wave overtopping increases almost exponentially with the wave height, which is confirmed by the present model tests. An example of the influence of the significant wave height on the overtopping volume is shown in Fig. 3 for an angle of wave attack of  $40^\circ$ . It should be noted that also the wave period changes due to the fixed wave steepnesses. It is observed that for perpendicular waves, the wave steepness has some influence on the overtopping. This influence became smaller for oblique waves, and for  $40^\circ$  no influence is found.

**Fig. 3** Plot of the overtopping volume as function of the significant wave height,  $H_s$ . Crest free board,  $R_c=0.05$  m. Crest width,  $B=0.16$  m. Angle of wave attack,  $\beta=40^\circ$ .

### Influence of Wave Steepness

The influence of the wave steepness is shown in Fig. 4 for two crest free boards, ie a low-crested and a high-crested breakwater. From the results, it is found necessary to distinguish between two different cases, ie  $H_s > R_c$  and  $H_s < R_c$ . There is a tendency for decreasing overtopping volumes by an increase in the wave steepness for the case of  $H_s > R_c$ , whereas there is a tendency for increasing overtopping volumes for the case of  $H_s < R_c$ . The test results show that the influence of the wave steepness is decreasing for oblique waves, and generally no influence is found for an angle of wave attack of  $30^\circ$  as shown in Fig. 7.

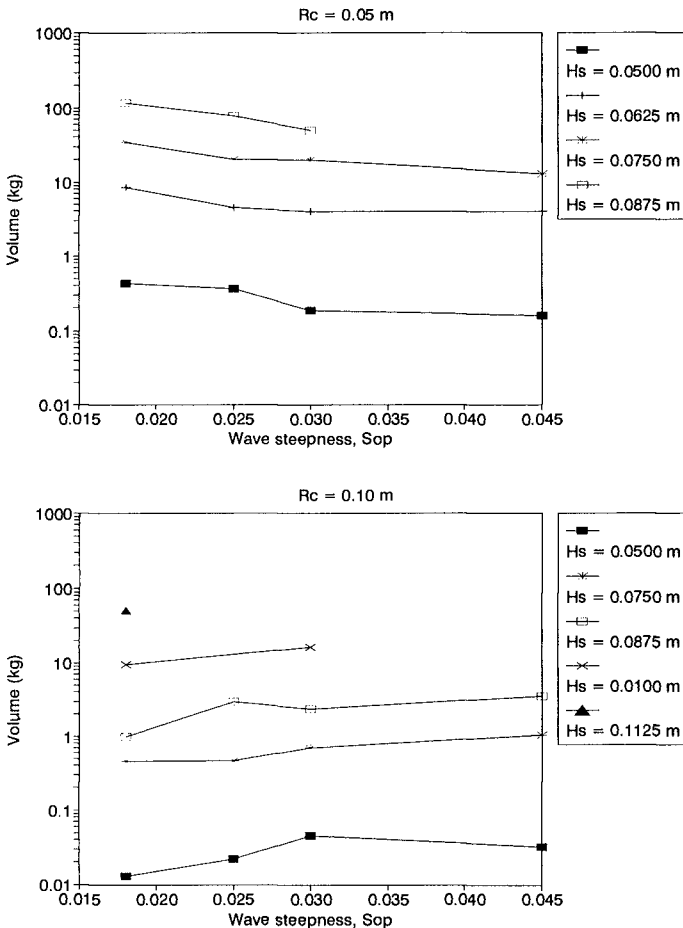

Fig. 4 Plots of the overtopping volume as function of the wave steepness,  $S_{op}$ . Crest width,  $B=0.16$  m. Angle of wave attack,  $\beta=0^\circ$ .

### Influence of Crest Free Board

Tests were made with three different crest free boards, which resulted in a dimensionless freeboard,  $R_c/H_s$ , ranging from 0.5 up to 2.0. The crest freeboard together with the significant wave height are the major parameters governing the amount of water overtopping a breakwater. Examples of the influence of the crest free board are shown in Fig. 5. Comparison of the result for perpendicular wave attack and for an angle of  $20^\circ$  shows that the influence of an increase of the crest free board is larger for the latter case, which is due to an increased distance from the intersection of the still water level with the main armour layer to the rear side of the crest (the location of the measuring tray).

**Fig. 5** Plots of the overtopping volume as function of the crest free board,  $R_c$ .  $H_s=0.075$  m. Crest width,  $B=0.16$  m.

### Influence of Crest Width

Three crest widths were studied for perpendicular wave attack. Generally, it was found that the overtopping volume is decreasing with increasing crest width. However, the influence is smaller than the influence of the significant wave height and the crest free board. An example of the test results is presented in Fig. 6.

**Fig. 6** Plots of the overtopping volume as function of the crest width,  $B$ . Crest free board,  $R_c=0.10$  m. Angle of wave attack,  $\beta=0^\circ$ .

### Influence of Angle of Wave Attack

Test were carried out with angles of wave attack varying from  $0^\circ$  (perpendicular waves) up to  $50^\circ$  in steps of  $10^\circ$ . Typical examples of the influence of the angle are shown in Fig. 7, which includes the dependency of the wave steepness (it should be noted that the overtopping volumes are plotted in a linear scale). A pronounced characteristic in some of the cases is a maximum in the amount of wave overtopping for an angle of  $10^\circ$ .

In order to study in more details the influence of the angle of wave attack, dimensionless plots of the test data are shown in Fig. 8. These plots present the ratio between the overtopping volume for oblique waves and for perpendicular waves as function of the angle of wave attack for each of the three tested crest free boards. This ratio corresponds to a reduction factor taking into account wave obliquity. The plots show some scatter, but general trends can be recognised.

In the case with the smallest tested free board ( $R_c=0.05$  m), the average of the tests shows a maximum in the mean overtopping discharge for an angle of  $10^\circ$ . A pronounced decrease in the overtopping is found increasing the angle of wave attack to  $20^\circ$  and  $30^\circ$ . For an angle of about  $50^\circ$ , the amount of overtopping water is on average reduced by 90 per cent compared to perpendicular wave attack, ie a reduction factor of 0.1. This reduction in the wave overtopping for an angle of wave attack of  $50^\circ$  is significantly higher than the reduction of about 40 per cent found for smooth slopes in De Wall and Van der Meer (1992).

**Fig. 7** Plots of the overtopping volume as function of the angle of wave attack,  $\beta$ . The plots include the influence of the wave steepness,  $s_{op}$ . Crest width,  $B=0.16 \text{ m}$ .

For the cases with higher free boards, only a few tests show a maximum in the overtopping for an angle of  $10^\circ$ , and on average a decrease is found. Comparing the three plots, it is found that the influence of the angle is getting more pronounced for the cases with the higher free boards. For the highest tested free board ( $R_c=0.10 \text{ m}$ ), a reduction factor of about 0.2 is found for an angle of  $20^\circ$ .

**Fig. 8** Plots of the ratio between the overtopping discharge for oblique waves,  $q_\beta$ , and for perpendicular waves,  $q_0$ , as function of the angle of wave attack.

The overtopping volumes in De Wall and Van der Meer (1992) refer to the amount of water passing the crest of a slope, which is a relevant measure in the case of an impermeable slope. In the case of a permeable rubble mound breakwater, the amount of overtopping water will be dependant on the location of the measurement, ie the volume will be different when measuring at the front side edge or rear side edge of the crest due to the porous crest of the breakwater. The difference in the reference location of the overtopping measurements will have an effect on the influence of the angle of wave attack, as the distance from the front edge to the rear edge of the breakwater will increase with the angle of wave attack. Further, in the case of a rubble mound breakwater, the permeable layers will result in a faster decrease of the overtopping volume than for an impermeable slope.

## Dimensionless Presentations

Through the years, overtopping results have been presented in numerous ways, including dimensionless plots. The most used dimensionless parameters are the dimensionless overtopping discharge,  $Q=q/\sqrt{gH_s^3}$ , and the dimensionless free board,  $R=R_c/H_s$ .

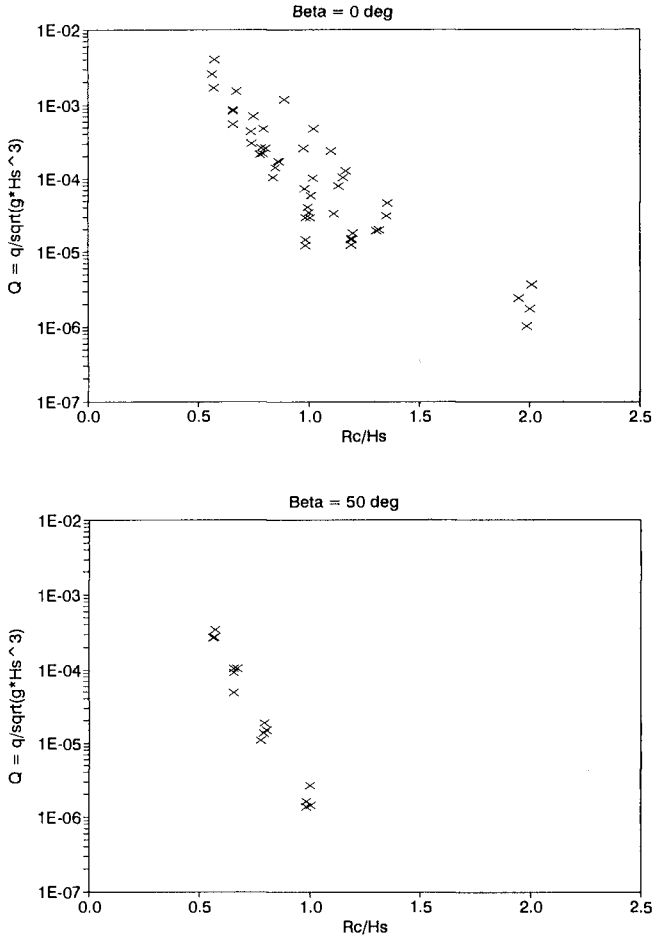

Examples of dimensionless plots of the test results obtained for perpendicular waves and for waves with an angle of  $50^\circ$  are shown in **Fig. 9**. The plots show that the test data for dimensionless free boards less than about 1.5 can be fitted to a straight line, ie  $Q$  can be described by an exponential function of  $R_c/H_s$ .

The model tests carried out with different crest widths showed that this parameter has an influence on the overtopping, and it is found that a combination of the crest free board and width can be used for describing the combined influence of these two parameters. For a fixed wave steepness, the dimensionless mean overtopping discharge can be fitted to an exponential function using  $(2R_c+0.35B)/H_s$  as parameter.

The test results show that the influence of the wave steepness is small compared to the influence of the other tested parameters, and that it is decreasing for oblique waves. A dimensionless plot excluding the influence of the wave steepness is presented in **Fig. 10** for all the tests made with perpendicular waves. The overtopping data are found to fit reasonable to the dimensionless parameter,  $(2R_c+0.35B)/H_s$ , ranging between about 1.5 and 4.0.

Dividing the dimensionless overtopping discharge with average reduction factors for wave obliquity (see the plots presented in **Fig. 8**), all the overtopping data are presented in a dimensionless plot in **Fig. 11**. The figure presents the dimensionless overtopping discharge divided by the influence factor as function of the established dimensionless parameter,  $(2R_c+0.35B)/H_s$ , taking into account both the crest free board and width. It is concluded that the influence of oblique

waves on the wave overtopping discharge can be described by an influence factor for wave obliquity. A slight increase in the scatter is found including the data for oblique waves, see **Figs. 10 and 11**.

**Fig. 9** Dimensionless overtopping discharge,  $Q$ , as function of dimensionless free board,  $R_c/H_s$ . Crest width,  $B=0.16$  m.

**Fig. 10** Dimensionless overtopping discharge,  $Q$ , as function of the dimensionless parameter,  $(2R_c + 0.35B)/H_s$ . Angle of wave attack,  $\beta = 0^\circ$ .

**Fig. 11** Dimensionless overtopping discharge including an influence factor to take into account wave obliquity,  $Q/\text{factor}$ , as function of the dimensionless parameter,  $(2R_c + 0.35B)/H_s$ .

## Conclusions

A wide range of parameters influence wave overtopping of coastal structures. The present research study on overtopping of a traditional rubble mound breakwaters with an armour layer slope of 1:2.0 has concentrated on the angle of wave attack, the crest free board, crest width, and the general wave parameters ( $H_s$ ,  $T_p$ , and  $s_{op}$ ).

Model tests were carried out in a wave basin for measuring the mean overtopping discharge,  $q$  ( $m^3/m/s$ ), and covered angles of wave attack ranging from  $0^\circ$  (perpendicular waves) up to  $50^\circ$  in step of  $10^\circ$ .

The significant wave height and the crest free board are the most important parameters with respect to wave overtopping. The crest width is found to have some smaller influence.

Testing with four wave steepnesses show that this parameter has an influence on the wave overtopping for perpendicular waves, whereas the influence is decreasing for oblique waves. However, the influence is small compared to the influence of the other tested parameters.

From analyses of the test results, it can be concluded that the reduction factor for wave obliquity (described by the ratio between the overtopping for oblique waves and perpendicular waves) is dependent on the crest free board. In case of a low-crested breakwater, the average of the tests show a maximum in the mean overtopping discharge for an angle of  $10^\circ$ . A pronounced decrease is found increasing the angle to  $20^\circ$  and  $30^\circ$ . For an angle of  $50^\circ$ , an average reduction factor of 0.1 is estimated. For breakwaters with a higher crest free board, the influence of the angle is larger, eg for the high-crested breakwater a reduction factor of about 0.2 is found for  $20^\circ$ .

The dimensionless overtopping discharge data for perpendicular waves (including all four wave steepnesses) show to fit well when plotted against a dimensionless parameter combining the influence of the crest free board and width  $(2R_c + 0.35B)/H_s$ . Dividing the dimensionless overtopping discharges with average reduction factors for wave obliquity, it is found that the same dimensionless parameter gives a reasonable fit also for oblique waves. This means that for rubble mound breakwaters with a slope of 1:2.0, the dimensionless overtopping discharge including a reduction factor for wave obliquity can be described by an exponential function of  $(2R_c + 0.35B)/H_s$ .

In order to establish a general overtopping formula for rubble mound breakwaters, it will be required to include the influence of, for instance, alternative breakwater geometries, water depth, artificial armour units, and superstructures.

## Acknowledgement

The research has been funded by the Danish Research Council and the Danish Hydraulic Institute. The authors would like to thank Ms Kirsten Bossen, Mr Christian Paulsen, Mr Andreas Roulund and Mr Micael Aamann for carrying out the model tests and making the preliminary analysis, which were part of their B.Sc. dissertations at the Danish Academy of Engineering.

# Coastal Engineering 1994

Proceedings of the  
twenty-fourth international conference

October 23-28; 1994  
Kobe, Japan

Conference held under the auspices of the  
Coastal Engineering Research Council of the  
American Society of Civil Engineers

Organized by the Japan Society of Civil Engineers

Edited by Billy L. Edge

Published by the  
American Society of Civil Engineers  
345 East 47th Street  
New York, New York 10017-2398

## ABSTRACT

This proceedings contains over 200 papers presented at the 24th International Conference on Coastal Engineering which was held in Kobe, Japan, October 23-28, 1994. The book is divided into six parts: 1) Characteristics of coastal waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) coastal processes and sediment transport; 5) coastal, estuarine and environmental problems; and 6) case studies. The individual papers include such topics as the effects of wind, waves, storms and currents as well as the study of sedimentation and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and related fields with a broad range of information on coastal engineering.

Coastal engineering 1994: proceedings of the twenty-fourth international conference, October 23-28, 1994, Kobe, Japan  
edited by Billy L. Edge.

# CONTENTS

## PART I

Plenary Session THE PRESENT AND FUTURE OF COASTAL ENGINEERING IN JAPAN.....	1
<i>Yuichi Iwagaki</i>	
Chapter 1 ON THE CHARACTERISTICS OF ONE-DIMENSIONAL SPECTRA AND NON-DIMENSIONAL PARAMETERS OF WIND WAVES.....	12
<i>Toshio Aono, Chiaki Goto</i>	
Chapter 2 SWASH MOTION DUE TO OBLIQUELY INCIDENT WAVES.....	27
<i>Toshiyuki Asano</i>	
Chapter 3 LABORATORY COMPARISON OF DIRECTIONAL WAVE MEASUREMENT SYSTEMS AND ANALYSIS TECHNIQUES .....	42
<i>Michel Benoit, Charles Teisson</i>	
Chapter 4 ACCURACY OF WIND AND WAVE EVALUATION IN COASTAL REGIONS.....	57
<i>Luciana Bertotti, Luigi Cavaleri</i>	
Chapter 5 A SPECTRAL MODEL FOR WAVES IN THE NEAR SHORE ZONE.....	68
<i>R.C. Ris, L.H. Holthuijsen, N. Booij</i>	
Chapter 6 WIND VARIABILITY AND EXTREMES STATISTICS.....	79
<i>Luigi Cavaleri, Luciana Bertotti</i>	
Chapter 7 MEAN FLUX IN THE FREE SURFACE ZONE OF WATER WAVES IN A CLOSED WAVE FLUME.....	86
<i>Witold Cieslikiewicz, Ove T. Gudmestad</i>	
Chapter 8 VERTICAL VARIATIONS OF FLUID VELOCITIES AND SHEAR STRESS IN SURF ZONES .....	98
<i>Daniel T. Cox, Nobuhisa Kobayashi, Akio Okayasu</i>	

Chapter 9	
VORTICITY EFFECTS IN COMBINED WAVES AND CURRENTS .....	113
<i>I. Cummins, C. Swan</i>	
Chapter 10	
WAVES IN AN ANNULAR ENTRANCE CHANNEL .....	128
<i>Robert A. Dalrymple, J.T. Kirby</i>	
Chapter 11	
WAVE DAMPING BY KELP VEGETATION .....	142
<i>Alfonse Dubi, Alf Tørum</i>	
Chapter 12	
NONLINEAR COUPLING IN WAVES PROPAGATING OVER A BAR .....	157
<i>Y. Eldeberky, J.A. Battjes</i>	
Chapter 13	
AN ABSORBING WAVE-MAKER BASED ON DIGITAL FILTERS .....	168
<i>Peter Frigaard, Morten Christensen</i>	
Chapter 14	
WAVE CLIMATE STUDY IN WADDEN SEA AREAS .....	181
<i>Ralf Kaiser, Günther Brandt, Joachim Gärtner, Detlef Glaser, Frerk Jensen, H.D. Niemeyer, Joachim Grüne</i>	
Chapter 15	
FALSE WAVES IN WAVE RECORDS AND NUMERICAL SIMULATIONS .....	192
<i>Marcos H. Giménez, C.R. Sánchez-Carratalá, J.R. Medina</i>	
Chapter 16	
MEASURING WAVES WITH MANOMETER TUBES .....	207
<i>David J. Hanslow, P. Nielsen, K. Hibbert</i>	
Chapter 17	
QUANTITY OF SPRAY TRANSPORTED BY THE STRONG WIND OVER BREAKING WAVES .....	219
<i>Nobuhiro Matsunaga, Misao Hashida, Hiroyuki Mizui, Yuji Sugihara</i>	
Chapter 18	
EXTENSION OF THE MAXIMUM ENTROPY PRINCIPLE METHOD FOR DIRECTIONAL WAVE SPECTRUM ESTIMATION .....	232
<i>Noriaki Hashimoto, Toshihiko Nagai, Tadashi Asai</i>	

Chapter 19	
A REGRESSION MODEL FOR ESTIMATING SEA STATE PERSISTENCE .....	247
<i>Yoshio Hatada, Masataka Yamaguchi</i>	
Chapter 20	
THE MAXIMUM SIGNIFICANT WAVE HEIGHT IN THE SOUTHERN NORTH SEA .....	261
<i>L.H. Holthuijsen, J.G. de Ronde, Y. Eldeberky, H.L. Tolman, N. Booij, E. Bouws, P.G.P. Ferier, J. Andorka Gal</i>	
Chapter 21	
IMPROVED BOUNDARY CONDITIONS TO A TIME-DEPENDENT MILD-SLOPE EQUATION FOR RANDOM WAVES .....	272
<i>Toshimasa Ishii, Masahiko Isobe, Akira Watanabe</i>	
Chapter 22	
TIME-DEPENDENT MILD SLOPE EQUATIONS FOR RANDOM WAVES .....	285
<i>Masahiko Isobe</i>	
Chapter 23	
MODELLING MOVEABLE BED ROUGHNESS AND FRICTION FOR SPECTRAL WAVES .....	300
<i>L.M. Kaczmarek, J.M. Harris, B.A. O'Connor</i>	
Chapter 24	
DIFFERENCE BETWEEN WAVES ACTING ON STEEP AND GENTLE BEACHES .....	315
<i>Kazumasa Katoh</i>	
Chapter 25	
WAVE BREAKING UNDER STORM CONDITION .....	330
<i>Yoshiaki Kawata</i>	
Chapter 26	
APPLICATION OF MAXIMUM ENTROPY METHOD TO THE REAL SEA DATA .....	340
<i>Taerim Kim, Li-Hwa Lin, Hsiang Wang</i>	
Chapter 27	
PROBABILITY OF THE FREAK WAVE APPEARANCE IN A 3-DIMENSIONAL SEA CONDITION .....	356
<i>Akira Kimura, Takao Ohta</i>	

Chapter 28	
ON THE JOINT DISTRIBUTION OF WAVE HEIGHT, PERIOD & DIRECTION OF INDIVIDUAL WAVES IN A 3-DIMENSIONAL RANDOM SEAS.....	370
<i>J.G. Kwon, Ichiro Deguchi</i>	
Chapter 29	
SPECTRAL WAVE-CURRENT BOTTOM BOUNDARY LAYER FLOWS.....	384
<i>Ole Secher Madsen</i>	
Chapter 30	
TIME DOMAIN MODELLING OF WAVE BREAKING, RUNUP AND SURF BEATS .....	399
<i>Per A. Madsen, O.R. Sørensen, H.A. Schäffer</i>	
Chapter 31	
ORTHONORMAL WAVELET ANALYSIS FOR DEEP-WATER BREAKING WAVES .....	412
<i>Nobuhito Mori, Takashi Yasuda</i>	
Chapter 32	
A FULLY DISPERSIVE-NONLINEAR WAVE MODEL AND ITS NUMERICAL SOLUTIONS .....	427
<i>Kazuo Nadaoka, Serdar Beji, Yasuyuki Nakagawa</i>	
Chapter 33	
A GENERALIZED GREEN-FUNCTION METHOD FOR WAVE FIELD ANALYSIS .....	442
<i>Hitoshi Nishimura, Michio Matsuoka, Akira Matsumoto</i>	
Chapter 34	
COUPLED VIBRATION EQUATIONS FOR IRREGULAR WATER WAVES.....	455
<i>Masao Nochino</i>	
Chapter 35	
NONLINEAR EVOLUTION OF DIRECTIONAL WAVE SPECTRA IN SHALLOW WATER .....	467
<i>Okey Nwogu</i>	
Chapter 36	
NON-GAUSSIAN PROBABILITY DISTRIBUTION OF COASTAL WAVES .....	482
<i>M.K. Ochi, K. Ahn</i>	

Chapter 37		
PROBABILITY CHARACTERISTICS OF ZERO-CROSSING WAVE HEIGHT .....		497
	<i>Takao Ohta, Akira Kimura</i>	
Chapter 38		
NUMERICAL SIMULATION AND VALIDATION OF PLUNGING BREAKERS USING A 2D NAVIER-STOKES MODEL.....		511
	<i>H.A.H. Petit, P.Tönjes, M.R.A. Van Gent, P. Van Den Bosch</i>	
Chapter 39		
WAVE VELOCITY FIELD MEASUREMENTS OVER A SUBMERGED BREAKWATER .....		525
	<i>Marco Petti, Paul A. Quinn, Gianfranco Liberatore, William J. Easson</i>	
Chapter 40		
VELOCITY FIELD MEASUREMENTS AND THEORETICAL COMPARISONS FOR NON-LINEAR WAVES ON MILD SLOPES .....		540
	<i>Paul A. Quinn, Marco Petti, Michele Drago, Clive A. Greated</i>	
Chapter 41		
THE CONCEPT OF RESIDENCE TIME FOR THE DESCRIPTION OF WAVE RUN-UP, WAVE SET-UP AND WAVE RUN-DOWN .....		553
	<i>Holger Schüttrumpf, Hendrik Bergmann, Hans-Henning Dette</i>	
Chapter 42		
BOTTOM SHEAR STRESSES UNDER RANDOM WAVES WITH A CURRENT SUPERIMPOSED.....		565
	<i>Richard R. Simons, Tony J. Grass, Wameidh M. Saleh, Mehrdad M. Tehrani</i>	
Chapter 43		
EFFECTS FROM DIRECTIONALITY & SPECTRAL BANDWIDTH ON NON-LINEAR SPATIAL MODULATIONS OF DEEP-WATER SURFACE GRAVITY WAVE TRAINS .....		579
	<i>Carl Trygve Stansberg</i>	
Chapter 44		
SHEAR STRESSES AND MEAN FLOW IN SHOALING AND BREAKING WAVES .....		594
	<i>Marcel J.F. Stive, Huib J. De Vriend</i>	

Chapter 45	
PREDICTION OF THE MAXIMUM WAVE ON THE CORAL FLAT .....	609
<i>Dede M. Sulaiman, Shigeaki Tsutsui, Hiroshi Toshioka,</i>	
<i>T. Yamashita, S. Oshiro, Y. Tsuchiya</i>	
Chapter 46	
DEVELOPMENT OF A SUBMERGED DOPPLER-TYPE DIRECTIONAL	
WAVE METER .....	624
<i>Tomotsuka Takayama, Noriaki Hashimoto, Toshihiko Nagai,</i>	
<i>Tomoharu Takahashi, Hiroshi Sasaki, Yoshiki Ito</i>	
Chapter 47	
BRAGG SCATTERING OF WAVES OVER POROUS RIPPLED BED .....	635
<i>Hijime Mase, Ken Takeba</i>	
Chapter 48	
NON-REFLECTIVE MULTI-DIRECTIONAL WAVE GENERATION	
BY SOURCE METHOD .....	650
<i>Masahiro Tanaka, Takumi Ohyama, Tetsushi Kiyokawa, Kazuo Nadaoka</i>	
Chapter 49	
THE GROWTH OF WIND WAVES IN SHALLOW WATER .....	665
<i>L.A. Verhagen, I.R. Young</i>	
Chapter 50	
ESTIMATION OF TYPHOON-GENERATED MAXIMUM WAVE	
HEIGHT ALONG THE PACIFIC COAST OF JAPAN BASED ON	
WAVE HINDCASTING .....	674
<i>Masataka Yamaguchi, Yoshio Hatada</i>	
Chapter 51	
RUN-UP OF IRREGULAR WAVES ON A GENTLY SLOPING BEACH .....	689
<i>Yoshimichi Yamamoto, Katsutoshi Tanimoto, Karunarathna Harshinie</i>	
Chapter 52	
SOLITON-MODE WAVEMAKER THEORY AND SYSTEM FOR	
COASTAL WAVES .....	704
<i>Takashi Yasuda, Takeshi Hattori, Seirou Shinoda</i>	
Chapter 53	
ON A METHOD FOR ESTIMATING REFLECTION COEFFICIENT	
IN SHORT-CRESTED RANDOM SEAS .....	719
<i>Hirumune Yokoki, Masahiko Isobe, Akira Watanabe</i>	

Chapter 54	
THE DIRECTIONAL WAVE SPECTRUM IN THE BOHAI SEA.....	731
<i>Yuxiu Yu, Shuxue Liu</i>	

Chapter 55	
IRREGULAR WAVES OVER AN ELLIPTIC SHOAL.....	746
<i>Xiping Yu, Hiroyoshi Togashi</i>	

Chapter 56	
PERFORMANCE OF A SPECTRAL WIND-WAVE MODEL IN SHALLOW WATER.....	761
<i>Gerbrant Ph. van Vledder, John G. de Ronde, Marcel J.F. Stive</i>	

## PART II

Chapter 57	
THE GENERATION OF LOW-FREQUENCY WAVES BY A SINGLE WAVE GROUP INCIDENT ON A BEACH.....	776
<i>Gary Watson, Timothy C.D. Barnes, D. Howell Peregrine</i>	

Chapter 58	
INFLUENCE OF LONG WAVES ON SHIP MOTIONS IN A LAGOON HARBOUR.....	791
<i>Volker Barthel, Etienne Mansard</i>	

Chapter 59	
RESONANT FORCING OF HARBORS BY INFRAGRAVITY WAVES.....	806
<i>Gordon S. Harkins, Michael J. Briggs</i>	

Chapter 60	
NUMERICAL SIMULATION OF THE 1992 FLORES TSUNAMI IN INDONESIA: DISCUSSION ON LARGE RUNUP HEIGHTS IN THE NORTHEASTERN FLORES ISLAND.....	821
<i>Fumihiko Imamura, Tomoyuki Takahashi, Nobuo Shuto</i>	

Chapter 61	
A COMPARATIVE EVALUATION OF WAVE GROUPING MEASURES.....	832
<i>E.P.D. Mansard, S.E. Sand</i>	

Chapter 62	
RELATIONSHIP OF A MOORED VESSEL IN A HARBOUR AND LONG WAVE CAUSED BY WAVE GROUPS.....	847
<i>Toshihiko Nagai, N. Hashimoto, T. Asai, I. Tobiki, K. Ito, T. Toue, A. Kobayashi, T. Shibata</i>	

Chapter 63	
COHERENT STRUCTURE OF TIDAL TURBULENCE IN A ROTATING SYSTEM OF OSAKA-BAY .....	861
<i>Tsukasa Nishimura, Tomonao Kobayashi, Goichi Furuta</i>	

Chapter 64	
DEVELOPMENT OF A PARTIALLY THREE-DIMENSIONAL MODEL FOR SHIP MOTION IN A HARBOR WITH ARBITRARY BATHYMETRY .....	871
<i>Takumi Ohyama, M. Tsuchida</i>	

Chapter 65	
THE MEASURED AND COMPUTED HOKKAIDO NANSEI-OKI EARTHQUAKE TSUNAMI OF 1993 .....	886
<i>Tomoyuki Takahashi, Nobuo Shuto, Fumihiko Imamura, Hideo Matsutomi</i>	

Chapter 66	
QUASI-THREE-DIMENSIONAL MODEL FOR STORM SURGES AND ITS VERIFICATION .....	901
<i>Takao Yamashita, Yoshito Tsuchiya, Hiroshi Yoshioka</i>	

### PART III

Chapter 67	
ANALYSIS OF PRACTICAL RUBBLE MOUNDS .....	918
<i>N.W.H. Allsop, R.J. Jones, P. Besley, C. Franco</i>	

Chapter 68	
FRICTION AND CLAMPING FORCES IN WAVE LOADED PLACED BLOCK REVETMENTS .....	932
<i>Adam Bezuijen</i>	

Chapter 69	
A FIELD EXPERIMENT ON THE INTERACTION WAVES-REFLECTING WALL .....	945
<i>Paolo Boccotti</i>	

Chapter 70	
THE APPLICATION OF LOAD-CELL TECHNIQUE IN THE STUDY OF ARMOUR UNIT RESPONSES TO IMPACT LOADS .....	958
<i>Hans F. Burcharth, Zhou Liu</i>	

Chapter 71	
STEEP WAVE DIFFRACTION BY A SUBMERGED CYLINDER.....	973
<i>J.T. Aquije Chacaltana, A.F.T. da Silva</i>	
Chapter 72	
WAVE STRESSES ON RUBBLE-MOUND ARMOUR .....	986
<i>Andrew M. Cornett, Etienne Mansard</i>	
Chapter 73	
DAMAGE ANALYSIS FOR RUBBLE-MOUND BREAKWATERS .....	1001
<i>Michael H. Davies, Etienne P.D. Mansard, Andrew M. Cornett</i>	
Chapter 74	
NUMERICALLY MODELING PERSONNEL DANGER ON A PROMENADE BREAKWATER DUE TO OVERTOPPING WAVES .....	1016
<i>Kimihiko Endoh, Shigeo Takahashi</i>	
Chapter 75	
WAVE OVERTOPPING ON VERTICAL AND COMPOSITE BREAKWATERS.....	1030
<i>L. Franco, M. de Gerloni, J.W. van der Meer</i>	
Chapter 76	
AN INVESTIGATION OF THE WAVE FORCES ACTING ON BREAKWATER HANDRAILS .....	1046
<i>Atsushi Hujii, Shigeo Takahashi, Kimihiko Endoh</i>	
Chapter 77	
RUBBLE MOUND BREAKWATER STABILITY UNDER OBLIQUE WAVES: AN EXPERIMENTAL STUDY .....	1061
<i>J.-C. Galland</i>	
Chapter 78	
WAVE LOADS ON SEADYKES WITH COMPOSITE SLOPES & BERMS .....	1075
<i>Joachim Grune, Hendrik Bergmann</i>	
Chapter 79	
COMPUTERISED METHODOLOGY TO MEASURE RUBBLE MOUND BREAKWATER DAMAGE .....	1090
<i>Bruno Chilo, Franco Guiducci</i>	

Chapter 80	
WAVE BREAKING OVER PERMEABLE SUBMERGED BREAKWATERS .....	1101
<i>Masataro Hattori, Hiroyoki Sakai</i>	
Chapter 81	
WAVE FORCES ACTING ON A VORTEX EXCITED VIBRATING	
VERTICAL CYLINDER IN WAVES .....	1115
<i>Kenjirou Hayashi, Futoshi Higaki, Koji Fujima,</i>	
<i>Toshiyuki Sigemura, John R. Chaplin</i>	
Chapter 82	
OVERTOPPING OF SEA WALLS UNDER RANDOM WAVES .....	1130
<i>D.M. Herbert, N.W.H. Allsop, M.W. Owen</i>	
Chapter 83	
STABILITY OF HIGH-SPECIFIC GRAVITY ARMOR BLOCKS .....	1143
<i>Masahiro Ito, Y. Iwagaki, H. Murakami, K. Nemoto, M. Yamamoto,</i>	
<i>M. Hanzawa</i>	
Chapter 84	
ROCK ARMoured BEACH CONTROL STRUCTURES ON	
STEEP BEACHES .....	1157
<i>R.J. Jones, N.W.H. Allsop</i>	
Chapter 85	
EFFECT ON ROUGHNESS TO IRREGULAR WAVE RUN-UP.....	1169
<i>Jea-Tzyy Juang</i>	
Chapter 86	
WAVE OVERTOPPING OF BREAKWATERS UNDER OBLIQUE WAVES.....	1182
<i>Jørgen Juhl, Peter Sloth</i>	
Chapter 87	
CONSTRUCTION OF OFFSHORE FISHING PORT FOR PREVENTION	
OF COASTAL EROSION .....	1197
<i>Takeshi Kawaguchi, O. Hashimoto, T. Mizumoto, A. Kamata</i>	
Chapter 88	
TOPOGRAPHICAL CHANGE AROUND MULTIPLE LARGE	
CYLINDRICAL STRUCTURES UNDER WAVE ACTIONS.....	1212
<i>Chang-Je Kim, Koichiro Iwata, Yoshihito Miyaike, Hong-Sun Yu</i>	

Chapter 89	
STABILITY OF RUBBLE MOUND FOUNDATIONS OF COMPOSITE BREAKWATERS UNDER OBLIQUE WAVE ATTACK .....	1227
<i>Katsutoshi Kimura, Shigeo Takahashi, Katsutoshi Tanimoto</i>	
Chapter 90	
ANALYSIS OF NONLINEAR COEFFICIENTS OF REFLECTION AND TRANSMISSION OF WAVES PROPAGATING OVER A RECTANGULAR STEP .....	1241
<i>Wudhipong Kittitanasuan, Yoshimi Goda</i>	
Chapter 91	
OSCILLATORY MOTIONS AND PERMANENT DISPLACEMENTS OF CAISSON BREAKWATERS SUBJECT TO IMPULSIVE BREAKING WAVE LOADS.....	1255
<i>P. Klammer, H. Oumeraci, H.-W. Partenscky</i>	
Chapter 92	
HYDRAULIC CHARACTERISTICS AND FIELD EXPERIENCE OF NEW WAVE DISSIPATING CONCRETE BLOCKS (ACCROPODE) .....	1269
<i>Masanori Kobayashi, Sumio Kaihatsu</i>	
Chapter 93	
EXPERIMENTAL STUDY ON DEVELOPING PROCESS OF LOCAL SCOUR AROUND A VERTICAL CYLINDER.....	1284
<i>Tomonao Kobayashi, Kenji Oda</i>	
Chapter 94	
WAVE-INDUCED UPLIFT LOADING OF CAISSON BREAKWATERS .....	1298
<i>Andreas Kortenhaus, Hocine Oumeraci, Søren Kohlhase, Peter Klammer</i>	
Chapter 95	
LINEAR AND NONLINEAR WAVE FORCES EXERTED ON A SUBMERGED HORIZONTAL PLATE.....	1312
<i>Haruyuki Kojima, A. Yoshida, T. Nakamura</i>	
Chapter 96	
MODERN FUNCTIONAL DESIGN OF GROIN SYSTEMS.....	1327
<i>Nicholas C. Kraus, Hans Hanson, Sten H. Blomgren</i>	
Chapter 97	
RESHAPING BREAKWATERS IN DEEP AND SHALLOW WATER CONDITIONS.....	1343
<i>A. Lamberti, G.R. Tomasicchio, F. Guiducci</i>	

Chapter 98	
DESIGN OF BREAKWATERS AND BEACH NOURISHMENT .....	1359
<i>Christian Laustrup, Holger Toxvig Madsen</i>	
Chapter 99	
CIRCULAR CHANNEL BREAKWATER TO REDUCE WAVE OVERTOPPING AND ALLOW WATER EXCHANGE .....	1373
<i>Dal Soo Lee, Woo Sun Park, Nobuhisa Kobayashi</i>	
Chapter 100	
INCREASED DOLOS STRENGTH BY SHAPE MODIFICATION .....	1388
<i>S.A. Luger, D.T. Phelp, A. Van Tonder, A.H. Holtzhausen</i>	
Chapter 101	
INFLUENCE OF WAVE DIRECTIONALITY ON STABILITY OF BREAKWATER HEADS.....	1397
<i>Y. Matsumi, E.P.D. Mansard, J. Rutledge</i>	
Chapter 102	
COST-EFFECTIVENESS OF D-ARMOR BREAKWATER.....	1412
<i>Josep R. Medina</i>	
Chapter 103	
THE CORE-LOC: OPTIMIZED CONCRETE ARMOR.....	1426
<i>Jeffrey A. Melby, George F. Turk</i>	
Chapter 104	
STABILITY OF ARMOR STONES OF A SUBMERGED WIDE-CROWN BREAKWATER .....	1439
<i>Norimi Mizutani, Teofilo Monge Rufin, Jr., Koichiro Iwata</i>	
Chapter 105	
WAVE INDUCED FLOW AROUND SUBMERGED SLOPING PLATES .....	1454
<i>Hitoshi Murakami, Sadahiko Itoh, Yoshihiko Hosoi, Yoshiyuki Sawamura</i>	
Chapter 106	
SECOND-ORDER WAVE INTERACTION WITH ARRAYS OF VERTICAL CYLINDERS OF ARBITRARY CROSS SECTION .....	1469
<i>Keisuke Murakami, Akinori Yoshida</i>	
Chapter 107	
HYDRODYNAMIC FORCES ON BOTTOM-SEATED HEMISPHERE IN WAVES AND CURRENTS.....	1484
<i>Hidenori Nishida, A. Tada, F. Nishihira</i>	

Chapter 108	
THE PRESSURE FIELD DUE TO STEEP WATER WAVES INCIDENT ON A VERTICAL WALL .....	1496
<i>D.H. Peregrine, M.E. Topliss</i>	
Chapter 109	
RESULTS OF EXTENSIVE FIELD MONITORING OF DOLOS BREAKWATERS.....	1511
<i>D. Phelps, S. Luger, A. Van Tonder, A. Holtzhausen</i>	
Chapter 110	
FAILURE OF RUBBLE MOUND STRUCTURES DUE TO THE STORM DURATION AND THE IRREGULARITY OF OCEAN WAVES .....	1526
<i>Cheong-Ro Ryu, Hyeon-Ju Kim</i>	
Chapter 111	
BLOCK SUBSIDENCE UNDER PRESSURE AND FLOW .....	1541
<i>T. Sakai, H. Gotoh, T. Yamamoto</i>	
Chapter 112	
STABILITY OF ROCK ON BEACHES.....	1553
<i>Gerrit J. Schiereck, Henri L. Fontijn, Wout V. Grote, Paul G.J. Sijstermans</i>	
Chapter 113	
SHORT TERM WAVE OVERTOPPING RATE OF BLOCK ARMORED SEAWALL .....	1568
<i>Tsunehiro Sekimoto, Hiroshi Kunisu, Tsuyoshi Yamazaki</i>	
Chapter 114	
ESTIMATING THE SLIDING DISTANCE OF COMPOSITE BREAKWATERS DUE TO WAVE FORCES INCLUSIVE OF IMPULSIVE FORCES .....	1580
<i>Kenichiro Shimosako, S. Takahashi, K. Tanimoto</i>	
Chapter 115	
BED SHEAR STRESS AND SCOUR AROUND COASTAL STRUCTURES .....	1595
<i>B.M. Sumer, J. Fredsøe, N. Christiansen, S.B. Hansen</i>	
Chapter 116	
LABORATORY MEASUREMENT OF OBLIQUE IRREGULAR WAVE REFLECTION ON RUBBLE-MOUND BREAKWATERS.....	1610
<i>Charles Teisson, Michel Benoit</i>	

Chapter 117	
STONE MOVEMENT ON A RESHAPED PROFILE .....	1625
<i>G. Roberto Tomasicchio, A. Lamberti, F. Guiducci</i>	
Chapter 118	
THE LARGE SCALE DOLOS FLUME STUDY.....	1641
<i>George F. Turk, Jeffrey A. Melby</i>	
Chapter 119	
H <sub>0</sub> PARAMETER FOR PRELIMINARY DESIGN OF CONVENTIONAL BREAKWATER STRUCTURAL HEAD: DATA ANALYSIS OF SPANISH NORTH COAST HARBOURS .....	1657
<i>Vincente Negro Valdecantos, Ovidio Varela Carnero</i>	
Chapter 120	
NUMERICAL MODELLING OF BREAKING WAVE IMPACTS ON A VERTICAL WALL .....	1672
<i>N.T. Wu, H. Oumeraci, H.-W. Partenscky</i>	
Chapter 121	
WIND EFFECTS ON RUNUP AND OVERTOPPING.....	1687
<i>Donald L. Ward, Christopher G. Wibner, Jun Zhang, Billy L. Edge</i>	
Chapter 122	
MODELLING OF WAVE OVERTOPPING OVER BREAKWATER.....	1700
<i>F. Zhuang, C. Chang, J.J. Lee</i>	
Chapter 123	
STRESSES IN TETRAPOD ARMOR UNITS INDUCED BY WAVE ACTION....	1713
<i>Kees d'Angremond, J.W. van der Meer, C.P. van Nes</i>	
Chapter 124	
PORE PRESSURES IN RUBBLE MOUND BREAKWATERS.....	1727
<i>M.B. de Groot, H. Yamazaki, M.R.A. van Gent, Z. Kheyruri</i>	
Chapter 125	
WAVE ACTION ON AND IN PERMEABLE STRUCTURES.....	1739
<i>M.R.A. van Gent, P. Tönjes, H.A.H. Petit, P. Van Den Bosch</i>	
Chapter 126	
PROBABILISTIC CALCULATIONS OF WAVE FORCES ON VERTICAL STRUCTURES.....	1754
<i>J.W. van der Meer, K. d'Angremond, J. Juhl</i>	

## PART IV

Chapter 127	
VELOCITY AND PRESSURE BOUNDARY CONDITIONS FOR FLOW OVER THE PERMEABLE BOUNDARY OF A POROUS MEDIUM.....	1770
<i>Ismail Aydin</i>	
Chapter 128	
PHYSICAL EXPERIMENTS ON THE EFFECTS OF GROINS ON SHORE MORPHOLOGY.....	1782
<i>Peyman Badiei, J. William Kamphuis, David G. Hamilton</i>	
Chapter 129	
LINE-MODELING OF SHOREFACE NOURISHMENT .....	1797
<i>Willem T. Bakker, Nico F. Kersting, Hanz D. Niemeyer</i>	
Chapter 130	
STATISTICAL VARIATIONS IN BEACH PARAMETER CHANGE RATES FOR WALLED & NON-WALLED PROFILES AT SANDBRIDGE, VA.....	1812
<i>John M. Hazelton, David R. Basco, D. Bellomo, G. Williams</i>	
Chapter 131	
A BOTTOM BOUNDARY LAYER SEDIMENT RESPONSE TO WAVE GROUPS .....	1827
<i>J. Lee, S. O'Neil, K. Bedford, R. Van Evra</i>	
Chapter 132	
GEOMORPHOLOGICAL ANALYSIS OF A BEACH AND SANDBAR SYSTEM.....	1837
<i>Chen-Shan Kung, Marcer Stive, Geffery Toms</i>	
Chapter 133	
SUSPENDED SEDIMENT TRANSPORT IN INNER SHELF WATERS DURING EXTREME STORMS.....	1849
<i>O.S. Madsen, T.A. Chisholm, L.D. Wright</i>	
Chapter 134	
SEA BED STABILITY ON A LONG STRAIGHT COAST.....	1865
<i>E. Christensen, R. Deigaard, J. Fredsoe</i>	
Chapter 135	
THE RESPONSE OF GRAVEL BEACHES IN THE PRESENCE OF CONTROL STRUCTURES .....	1880
<i>T.T. Coates, N. Dodd</i>	

Chapter 136	
THE ROLE OF ROLLERS IN SURF ZONE CURRENTS.....	1895
<i>William R. Dally, Daniel A. Osiecki</i>	
Chapter 137	
THREE DIMENSIONAL MORPHOLOGY IN A NARROW WAVE TANK: MEASUREMENTS AND THEORY .....	1906
<i>Robert G. Dean, Tae-Myoung Oh</i>	
Chapter 138	
NUMERICAL SIMULATION OF FINITE AMPLITUDE SHEAR WAVES & SEDIMENT TRANSPORT .....	1919
<i>Rolf Deigaard, Erik Damgaard Christensen, Jesper Svarrer Damgaard, Jørgen Fredsøe</i>	
Chapter 139	
BEACH NOURISHMENT AND DUNE PROTECTION.....	1934
<i>Hans H. Dette, Arved J. Raudkivi</i>	
Chapter 140	
PROFILE CHANGE OF A SHEET FLOW DOMINATED BEACH.....	1946
<i>Mohammad Dibajnia, Takuzo Shimizu, Akira Watanabe</i>	
Chapter 141	
A NONLINEAR SURF BEAT MODEL.....	1961
<i>Zhili Zou, Nicholas Dodd</i>	
Chapter 142	
PIV MEASUREMENTS OF OSCILLATORY FLOW OVER A RIPPLED BED....	1975
<i>H.C. Earnshaw, T. Bruce, C.A. Greated, W.J. Easson</i>	
Chapter 143	
SHEAR INSTABILITY OF LONGSHORE CURRENTS: EFFECTS OF DISSIPATION AND NON-LINEARITY .....	1983
<i>Albert Falqués, Vicente Iranzo, Miquel Caballería</i>	
Chapter 144	
INTERPRETATION OF SHORELINE POSITION FROM AERIAL PHOTOGRAPHS .....	1998
<i>John S. Fisher, Margery F. Overton</i>	

Chapter 145	
SETTLING COLUMNS PARAMETRIC TESTS APPLIED TO COASTAL SEDIMENT CONSOLIDATION.....	2004
<i>Stephane Gallois, Alain Alexis, Pierre Thomas</i>	
Chapter 146	
SEDIMENT-CLOUD BASED MODEL OF SUSPENSION OVER RIPPLE BED DUE TO WAVE ACTION .....	2013
<i>Hitoshi Gotoh, Tetsuro Tsujimoto, Hiroji Nakagawa</i>	
Chapter 147	
WAVE OVERTOPPING AND SEDIMENT TRANSPORT OVER DUNES.....	2028
<i>Mark W. Hancock, Nobuhisa Kobayashi</i>	
Chapter 148	
SEDIMENT TRANSPORT OVER RIPPLES IN WAVES AND CURRENT .....	2043
<i>Gilles Perrier, Erik Asp Hansen, C. Villaret, Rolf Deigaard, Jorgen Fredsøe</i>	
Chapter 149	
IN-SITU DETERMINATION OF THE CRITICAL BED-SHEAR STRESS FOR EROSION OF COHESIVE SEDIMENTS.....	2058
<i>Erik-Jan Houwing, Leo C. van Rijn</i>	
Chapter 150	
CONTROL OF CROSS-SHORE SEDIMENT TRANSPORT BY A DISTORTED RIPPLE MAT.....	2070
<i>Isao Irie, N. Ono, S. Hashimoto, S. Nakamura, K. Murakami</i>	
Chapter 151	
HOW MUCH VELOCITY INFORMATION IS NECESSARY TO PREDICT SEDIMENT SUSPENSION IN THE SURF ZONE? .....	2085
<i>Bruce E. Jaffe, David M. Rubin, Asbury Sallenger, Jr.</i>	
Chapter 152	
BEACH PROFILE SPACING: PRACTICAL GUIDANCE FOR MONITORING NOURISHMENT PROJECTS.....	2100
<i>Timothy W. Kana, Christopher J. Andrassy</i>	
Chapter 153	
WATERTABLE OVERHEIGHT DUE TO WAVE RUNUP ON A SANDY BEACH.....	2115
<i>Hong-Yoon Kang, P. Nielsen, D.J. Hanslow</i>	

Chapter 154	
A MODEL FOR CROSS SHORE SEDIMENT TRANSPORT .....	2125
<i>Irene Katopodi, Nikos Kitou</i>	
Chapter 155	
NUMERICAL MODELLING OF FLOW OVER RIPPLES USING SOLA METHOD.....	2140
<i>Hyoseob Kim, Brian A. O'Connor, Youngbo Shim</i>	
Chapter 156	
SWASH DYNAMICS UNDER OBLIQUELY INCIDENT WAVES .....	2155
<i>Nobuhisa Kobayashi, Entin A. Karjadi</i>	
Chapter 157	
WAVE RUN-UP AND SEA CLIFF EROSION .....	2170
<i>S.-M. Shih, P. Komar, K.J. Tillotson, W.G. McDougal, P. Ruggiero</i>	
Chapter 158	
MEASUREMENT OF PARAMETERS, DIRECTION AND RATE OF BEDFORM MIGRATION .....	2185
<i>Ruben D. Kos'yan, I.S. Podymov</i>	
Chapter 159	
BREACH-GROWTH RESEARCH PROGRAMME AND ITS PLACE IN DAMAGE ASSESSMENT FOR A POLDER.....	2197
<i>Arie W. Kraak, W.T. Bakker, J. van de Graaff, H.J. Steetzel, P.J. Visser</i>	
Chapter 160	
SWASH ZONE WAVE CHARACTERISTICS FROM SUPERTANK .....	2207
<i>David L. Kriebel</i>	
Chapter 161	
MORPHOLOGICAL MONITORING OF A SHOREFACE NOURISHMENT NOURTEC EXPERIMENT AT TERSCHELLING, THE NETHERLANDS.....	2222
<i>Aart Kroon, Piet Hoekstra, Klass Houwman, Gerben Ruessink</i>	
Chapter 162	
NUMERICAL MODEL FOR LONGSHORE CURRENT DISTRIBUTION ON A BAR-TROUGH BEACH .....	2237
<i>Yoshiaki Kuriyama</i>	

Chapter 163	
PREDICTION OF BEACH PROFILE CHANGE AT MESOSCALE UNDER RANDOM WAVES .....	2252
<i>Magnus Larson</i>	
Chapter 164	
A QUASI-3D SURF ZONE MODEL .....	2267
<i>Jung Lyul Lee, Hsiang Wang</i>	
Chapter 165	
QUANTIFICATION OF LONGSHORE TRANSPORT IN THE SURF ZONE ON MACROTIDAL BEACHES .....	2282
<i>Franck Levoy, Olivier Monfort, Helene Rousset, Claude Larssonneur</i>	
Chapter 166	
A THREE DIMENSIONAL MODEL FOR WAVE INDUCED CURRENTS .....	2297
<i>Bin Li, Roger J. Maddrell</i>	
Chapter 167	
INFLUENCE OF OFFSHORE BANKS ON THE ADJACENT COAST .....	2311
<i>N.J. MacDonald, B.A. O'Connor</i>	
Chapter 168	
WAVE RUNUP ON COMPOSITE-SLOPE AND CONCAVE BEACHES .....	2325
<i>Robert H. Mayer, D.L. Kriebel</i>	
Chapter 169	
SIMULATION OF NEARSHORE WAVE CURRENT INTERACTION BY COUPLING A BOUSSINESQ WAVE MODEL WITH A 3D HYDRODYNAMIC MODEL .....	2340
<i>Roberto Mayerle, Andreas Schröter, Werner Zielke</i>	
Chapter 170	
EXPERIMENTAL RESULTS OF WAVE TRANSFORMATION ACROSS A SLOPING BEACH.....	2350
<i>Constantine D. Memos</i>	
Chapter 171	
A RELATIVE INTERCOMPARISON BETWEEN VARIABLE WAVE SHOALING, BREAKING AND TRANSITION ZONE FORMULATIONS .....	2365
<i>G.P. Mocke, F. Smit</i>	

Chapter 172	
ANALYSIS OF COASTAL PROCESSES AT TORONTO ISLANDS.....	2380
<i>R.B. Nairn, R.D. Scott, C.D. Anglin, P.J. Zuzek</i>	
Chapter 173	
STABILITY AND MANAGEMENT OF AN ARTIFICIAL BEACH.....	2395
<i>Naofumi Shiraishi, Hoiku Ohhama, Taiji Endo,</i> <i>Patricia G. Pena-Santana</i>	
Chapter 174	
SUSPENDED SEDIMENT PARTICLE MOTION IN COASTAL FLOWS.....	2406
<i>Peter Nielsen</i>	
Chapter 175	
LONG-TERM MORPHODYNAMICAL DEVELOPMENT OF THE EAST FRISIAN ISLANDS AND COAST .....	2417
<i>Hanz D. Niemeyer</i>	
Chapter 176	
FIELD OBSERVATION AND NUMERICAL SIMULATION OF BEACH AND DUNE SCARPS.....	2434
<i>Ryuichiro Nishi, Michio Sato, Hsiang Wang</i>	
Chapter 177	
EFFECTS OF CONTROLLED WATER TABLE ON BEACH PROFILE DYNAMICS .....	2449
<i>Tae-Myoung Oh, R.G. Dean</i>	
Chapter 178	
LABORATORY EXPERIMENTS ON 3-D NEARSHORE CURRENTS AND A MODEL WITH MOMENTUM FLUX BY BREAKING WAVES.....	2461
<i>Akio Okayasu, Koji Hara, Tomoya Shibayama</i>	
Chapter 179	
SUSPENDED SEDIMENT CAUSED BY WAVES AND CURRENTS .....	2476
<i>Masanobu Ono, Kyu Han Kim, Toru Sawaragi, Ichiro Deguchi</i>	
Chapter 180	
DEVELOPMENT OF A DUNE EROSION MODEL USING SUPER TANK DATA.....	2488
<i>Margery F. Overton, John S. Fisher, Kyu-Nam Hwang</i>	

Chapter 181	
NUMERICAL MODELLING OF THREE-DIMENSIONAL WAVE-DRIVEN CURRENTS IN THE SURF-ZONE.....	2503
<i>Philippe Péchon, Charles Teisson</i>	
Chapter 182	
SEDIMENT TRANSPORT IN VARIOUS TIME SCALES .....	2513
<i>Zbigniew Pruszek, Ryszard B. Zeidler</i>	
Chapter 183	
SEDIMENT TRANSPORT UNDER (NON)-LINEAR WAVES AND CURRENTS .....	2527
<i>Jan S. Ribberink, Irene Katopodi, Khaled A.H. Ramadan, Ria Koelewijn, Sandro Longo</i>	
Chapter 184	
WAVES AND CURRENTS AT THE EBRO DELTA SURF ZONE: MEASUREMENTS AND MODELLING .....	2542
<i>A. Rodriguez, A. Sánchez-Arcilla, F.R. Collado, V. Gracia, M.G. Coussirat, J. Prieto</i>	
Chapter 185	
A NUMERICAL SIMULATION OF BEACH EVOLUTION BASED ON A NONLINEAR DISPERSIVE WAVE-CURRENT MODEL .....	2557
<i>Shinji Sato, Michael B. Kabiling</i>	
Chapter 186	
AN EXPERIMENTAL STUDY ON BEACH TRANSFORMATION DUE TO WAVES UNDER THE OPERATION OF COASTAL DRAIN SYSTEM.....	2571
<i>Michio Sato, Sadakatsu Hata, Masahiro Fukushima</i>	
Chapter 187	
WAVE BREAKING AND INDUCED NEARSHORE CIRCULATIONS .....	2583
<i>Ole R. Sørensen, Hemming A. Schäffer, Per A Madsen, Rolf Deigaard</i>	
Chapter 188	
ACCURACY AND APPLICABILITY OF THE SPM LONGSHORE TRANSPORT FORMULA.....	2595
<i>J.S. Schoones, A.K. Theron</i>	

Chapter 189	
FIELD VERIFICATION OF A NUMERICAL MODEL OF BEACH TOPOGRAPHY CHANGE DUE TO NEARSHORE CURRENTS, UNDERTOW AND WAVES .....	2610
<i>Takuzo Shimizu, Masahito Tsuru, Akira Watanabe</i>	
Chapter 190	
AN ATTEMPT TO MODEL LONGSHORE SEDIMENT TRANSPORT ON THE CATALONIAN COAST .....	2625
<i>J.P. Sierra, A.I. Presti, A. Sánchez-Arcilla</i>	
Chapter 191	
EROSION AND OVERTOPPING OF A GRASS DIKE LARGE SCALE MODEL TESTS .....	2639
<i>G.M. Smith, J.W.W. Seiffert, J.W. van der Meer</i>	
Chapter 192	
CALCULATION OF TOMBOLO IN SHORELINE NUMERICAL MODEL.....	2653
<i>Kyung Duck Suh, C. Scott Hardaway, Jr.</i>	
Chapter 193	
BEACH IMPROVEMENT SCHEMES IN FALSE BAY .....	2668
<i>D.H. Swart, J.S. Schoonees</i>	
Chapter 194	
BEACH EROSION IN KUTA BEACH, BALI & ITS STABILIZATION .....	2683
<i>Abdul R. Syamsudin, Yoshito Tsuchiya, Takao Yamashita</i>	
Chapter 195	
FUNDAMENTAL CHARACTERISTICS OF A NEW WAVE ABSORBING SYSTEM UTILIZING SAND LIQUEFACTION .....	2698
<i>Shigeo Takahashi, S. Yamamoto, H. Miura</i>	
Chapter 196	
LABORATORY STUDY OF SURF-ZONE TURBULENCE ON A BARRED BEACH .....	2712
<i>Francis C.K. Ting</i>	
Chapter 197	
BEACH EROSION AROUND A SAND SPIT—AN EXAMPLE OF MIHONO-MATSUBARA SAND SPIT .....	2726
<i>Takaaki Uda, Koji Yamamoto</i>	

Chapter 198	
SHORECIRC: A QUASI 3-D NEARSHORE MODEL .....	2741
<i>A.R. Van Dongeren, F.E. Sancho, I.A. Svendsen, U. Putrevu</i>	
Chapter 199	
A MODEL FOR BREACH GROWTH IN SAND-DIKES .....	2755
<i>Paul J. Visser</i>

## CHAPTER 87

### Construction of Offshore Fishing Port for Prevention of Coastal Erosion

T. Kawaguchi<sup>1</sup>, O. Hashimoto<sup>1</sup>, T. Mizumoto<sup>2</sup>, A. Kamata<sup>2</sup>

#### Abstract

When constructing a small fishing port along sandy beach, the most important considerations are how to prevent sand deposition at the port entrance and beach erosion along the down-drift side of the port. To solve these problems, an offshore fishing port connected to the shore by a bridge was planned at Kunnui, Hokkaido Prefecture. The port was designed to allow littoral drift to pass between the port and the shore. The appropriate shape and offshore distance of the port to restrict the development of tombolo was determined by hydraulic model tests and numerical simulations of wave-induced current near the port. Bottom sounding was carried out in parallel with the construction work. As a result, development of tombolo was restricted to some extent and no serious beach erosion occurred. This port seems to have generated unexpected strong cell-like circular currents on both sides, and sand deposits deposited by these currents. There are, however, no problems at present concerning the shape, offshore distance and location of the port entrance.

#### Introduction

In planning a small fishing port along sandy beach, the most important points to be taken into consideration are how to prevent shoaling of the port entrance by drift sand and how to eliminate adverse effects of the structures on coastal topography such as down stream erosion and excessive accretion at the updrift beach. Movement of sea bottom materials is very active in the littoral zone, and even a small sized fishing port must be designed to avoid littoral sand deposits at the port entrance. Extended breakwaters, however, act as a dam and intercept the flow of sediments, and accretion occurs at the updrift side. This creates in some cases deficiency in material supply to the down coast, where erosion occurs. Out of about 3,000 fishing ports in Japan, seventy five percent are in the category of type I according to Japanese classification, which is small scale, used only by fishermen from several adjoining fishing communities and serving an average of 100 boats less than 3 Gross Tonnages.

<sup>2</sup>Fishing Port Div., Fisheries Dept., Hokkaido Prefecture, 7, Kita-Sanjyo-Nishi, Chuo-Ku, Sapporo, Hokkaido 060, JAPAN.

The offshore fishing port discussed here was constructed with its entrance out of the surfzone, and thus free of sediment deposition, and connected by a bridge so as to allow littoral drift to pass behind. In case of such a small port, it is not necessary to locate the port very far from the coast, and construction costs are reasonable. The problem is to determine the offshore distance needed to restrict development of tombolo to the extent to allow the passage of drift sand. From this standpoint, this offshore fishing port was planned at Kunnui, in Uchiura Bay, southern part of Hokkaido in 1985 and completed in 1994. This report represents the characteristics of drift sand in the Bay of Uchiura, several investigations to determine the layout of the port, and changes in the bathymetry of the site during the construction.

## Outline of The Project Site Conditions

### Topography

Kunnui fishing port is located at the head of Uchiura Bay along the eastern side of the Oshima Peninsula. As shown in Fig. 1, the bay is almost a circle, 50 km in diameter and 150 km in length along the coastline. The entrance is open to Pacific Ocean at the southeast side and the width of this entrance is 28 km. The bay is roughly divided into three sections from the viewpoint of the geographical, meteorological and oceanographical conditions such as wind, wave and littoral current.

#### ① Northeast Coast

This section is between Muroran and Shizukari, consisting of coastal cliff made of igneous rock which has strong resistance against erosion and narrow coastline between the cliff and sea. The coastline is generally monotonous and slightly concave or bow-shaped.

#### ② Northwest Coast

This section, between Shizukari and Yakumo, is located in front of the bay entrance. The coast is monotonous, bow-shaped and of sand. The particle diameter of sand at the foreshore is almost uniform. This coast is topographically of emergent, caused by land upheaval. Especially between Shizukari and Kunnui, there is a flat coastal plain. Kunnui fishing port is located at around the middle of this coast.

#### ③ Southwest Coast

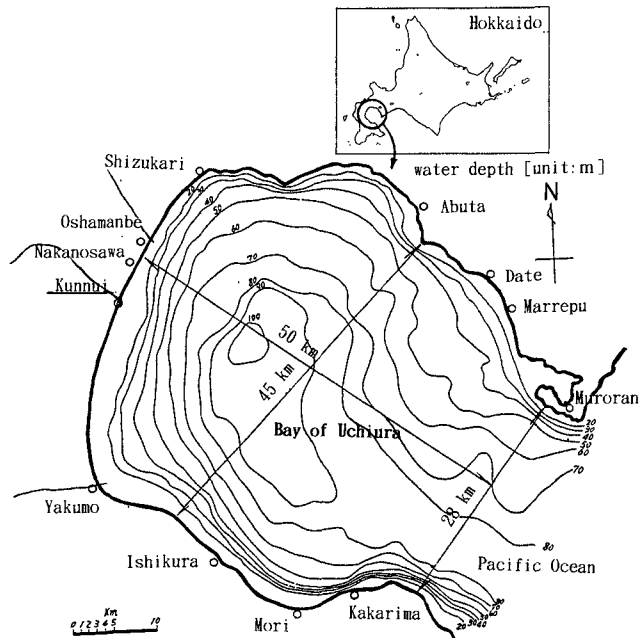

Fig.1 Uchiura Bay

This region, between Yakumo and Mori, has eroding beaches approached by hills. Sandy coast is limited with, one to two kilometers sandy beaches between capes that exist at intervals. Capes are made of sedimentary rock and considerably eroded. Recently, the construction of a coastal seawall is serving to protect and preserve this coast.

**Sea Waves**

In this bay, there is hardly any seasonable change in waves, but there are occasional higher waves caused by typhoons in autumn, and low atmospheric pressures passing through the Sea of Japan in winter.

Along the northwest coast, where Kunnui fishing port is located, principal wave direction is ENE~SE, and mostly at a right angle to the coastline. Wave observation is conducted at Nakanosawa, located 5 kilometers north-north-east of Kunnui. Probability of non-exceedance on wave height and period from 1968 to 1981 are shown in Fig. 2. Waves less than 0.5 m account for 90 percent. Frequency distribution of waves is shown in Fig. 3. This figure indicates predominant wave periods are around 5 sec. and over 9 sec. This shows two types of waves, one generated in the bay and the other from the Pacific Ocean. As shown in Table 1, incident waves range from ENE to SSE, but predominant wave direction is from ESE to SE, and is almost at a right angle to the coastline.

Fig.2 Non-exceedance Probability of Waves (Nakanosawa Observation Point)

Fig.3 Frequency Distribution of Observed Waves (1968~1981, at Nakanosawa)

Table 1 Wave Height[H] Distribution by Directions (1968~1981, at Nakanosawa)

Wave Height H(m)	Direction					Total
	ENE	E	ESE	SE	SSE	
0.0~0.5	-	39	2157	1889	30	4115
0.5~1.0	-	1	682	736	-	1419
1.0~1.5	70	-	33	11	2	116
1.5~2.0	-	-	3	-	-	3
2.0~2.5	-	-	3	-	-	3
2.5<	-	-	-	-	-	0
Total	70	40	2878	2636	32	5656
%	1.24	0.71	50.88	46.60	0.57	100.00

Average wave height is 0.4 meters, and average wave period is 7.5 sec.

According to the significant design wave investigations for the port conducted by Hokkaido prefecture, maximum yearly wave height is for storm wave coming from the Pacific Ocean, and wave heights with some return periods were obtained by

Table 2 Wave Height with a Return Period of N years

Direction	Return Period of N years		1 year	3 years	5 years	10 years	20 years
E S E	Wave Height	H(m)	2.1	3.7	4.5	5.6	6.8
	Period	T(sec)	6.4	7.8	8.5	9.4	10.4
S E	Wave Height	H(m)	2.9	5.0	5.9	7.0	8.0
	Period	T(sec)	7.1	8.9	9.6	10.6	11.4

Table 3 Equivalent Deepwater Wave

Condition	Direction	Deep Sea Wave		Equivalent Deepwater Wave Height $H_o'$ (m)	Direction	Breaker Depth $h_b$ (m)
		$H_o$ (m)	$T_o$ (sec)			
Ordinal Storm (in 1 year)	E S E	2.1	6.0	1.3	E S E	2.15
	S E	2.9	8.0	1.7	E S E	2.89
Storm (in 20 years)	E S E	6.8	10.0	3.5	E S E	5.67
	S E	8.0	11.0	4.1	E S E	6.64

statistical analysis on 20 waves each for ESE and SE, applying the Weibull Distribution Method. The result is as per Table 2.

Deep sea significant design wave was decided as wave height of 8.0 m and wave period of 11.4 sec with return period of 20 years. The bay entrance is not very wide, so equivalent deepwater wave height is calculated based on angular spreading of wave energy and refraction coefficient. For these effects, equivalent deep sea wave height of design wave 4.1 m and breaker depth is 6.6 m from ESE, as per Table 3.

**Tidal and Littoral Current**

Highest water level on record is +2.00 meters, mean monthly-highest water level is 1.4 meters, mean water level is 0.5 meters and mean monthly-lowest water level is 0.0 meters above datum level. As for littoral and tidal currents, field investigations conducted by Civil Laboratory of Hokkaido Development Bureau, for 2 years 1963 to 1965, were available, as per Fig. 4. Characteristics are as follows:

① Tidal current in the bay becomes a loop current, clockwise in summer and counter clockwise in winter, influenced by ocean currents outside the bay.

② Correlation between direction of littoral current and incident wave direction is high, and the dominant direction of littoral current corresponds to prevailing direction of incident wave.

③ In normal weather, littoral current in the bay depends on season. Along northeast and southwest coasts, direction is towards the head of bay in summer, and from head forward the entrance in winter. But along the northwest coast, direction is opposite on the Shizukari side and Yakumo side, with the neighborhood of Oshamanbe as a border.

④ Velocity of tidal current is about 16 cm/sec.

**Bottom Slope**

Contour lines are almost parallel to coastline. Bottom slope is approx. 1/90 as far as -7.0 meters. Depending on season, a step is formed, in some cases at water depth of 2 to 3 meters.

**Bottom Materials**

Fig.4 Currents in Uchiura Bay

This coast is emergent, and the existing coastline is assumed to have been deposited at about -20 m sea bottom. Particle diameter of sand is less than 0.22 mm, and well sorted. Median grain size ( $d_0$ ) has a smaller value depending on water depth toward offshore. Median grain size and coefficient of screening by water depth is shown in Table 4.

Table 4 Median Grain Diameter[ $d_{50}$ ] and Sorting Coefficient[ $S_0$ ] by Water Depth

Date	Offshore Distance (m)	- 60	+ 60	+300	+500	+700
	Water Depth (m)	+1.0	-1.0	-4.5	-7.0	-8.5
Nov., 1984	$d_{50}$ (mm)	0.25	0.21	0.17	0.15	0.08
	$S_0=(d_{75}/d_{25})^{1/2}$	1.48	1.43	1.21	1.38	1.42
Jul., 1985	$d_{50}$ (mm)	0.29	0.22	0.16	0.15	0.14
	$S_0=(d_{75}/d_{25})^{1/2}$	1.19	1.23	1.21	1.20	1.33

**Drift Sand**

**Changes of Coastline**

According to field interviews, the shoreline around Kunnui fishing port retreated about 25 m during the 40 years from 1925 to 1965, and yearly average retreat was 0.6 m/year. Further, according to the coastal deformation map based on topographical maps (1/50,000) made by the Geographical Survey Institute from 1896 to 1975 at Oshamanbe, 10 km from the port, shoreline retreat continued up to around 1969

Fig.5 Changes of Shoreline from a Reference Line (at Nakanosawa)

but there was little retreat afterwards. Today, a balanced situation is maintained, but considerable seasonal changes seem to be occurring. Fig. 5 shows the investigation results on change of coastline at Nakanosawa from June 1963, to June 1965. Distances to coastline measured from 21 key piles installed at 50 meters intervals are

plotted monthly. Average distance is shown by a dotted line and the total trend by a solid line. The trend is forwards coastline advance in summer and retreat in winter. For those 2 years, the coastline retreated by about 20 meters on an average but seasonal change was also substantial, from 10 to 15 meters. From this figure the following features are recognized;

- ① Throughout the year, accretion and erosion repeat alternately and a seasonal cycle is observed.
- ② Erosion trend is observed from October to February and deposition from March to September, though there exist some variations depending on the annual wave conditions.
- ③ Retreat of shoreline is, in most cases, sudden rather than gradual. It is assumed that coastal erosion is caused by waves generated by typhoon around autumn and cyclones passing through the Sea of Japan in winter, and that in such cases erosion is not completely recovered even after a long period of calm sea.

• Relation among Wave Energy, Average Length to Coastline and Foreshore Sand Volume

Assuming that  $E_h$  is wave energy transmitted across a plane of unit width perpendicular to the direction of wave advance at water depth  $h$ ; and  $E_b$  is wave energy at breaker position;  $E_b = (b_n/b_b)E_h$ ; and  $E_a$  is energy passing through unit width parallel to coastline per unit time, therefore  $E_a = E_b \cdot \sin \alpha \cdot \cos \alpha$ . In these equations  $b_n/b_b$  is sq. of refraction coefficient and  $\alpha$  is wave crest angle with shoreline at breaker position. Assuming that at water depth  $h$ ,  $H$  is wave height,  $L$  is wave length and  $T$  is wave period, from Small Amplitude Waves Theory,  $E_h = n H L \gamma / 8T$ , and  $\gamma$  is unit weight of sea water and  $n$  is ratio between wave velocity and group velocity. Therefore, incident angle is divided to  $+\alpha$  and  $-\alpha$ , if right angle direction against coastal line is set as 0. Assuming that  $E_L$  is the energy of waves come in from left hand side and  $E_R$  from right hand side. Fig. 6 shows change of length and foreshore sand volume up to coastline from key pile and the relation with  $\sum E_L$  as well as  $\sum E_R$  and also  $(\sum E_L - \sum E_R)$ . For calculation of  $\sum E$ , it was assumed that the measured waves at noon continued until the following noon, and the energies from the both sides are added up separately for each month. Shoreline advance occurred when  $(\sum E_L - \sum E_R)$  is within the range of  $E_R$ , and shoreline retreated when this is within the  $E_L$  range. As a result of this survey, it was concluded that in this area, onshore-offshore sand transport is dominant under usual wave occurrence, and under unusual weather conditions, longshore littoral transport

Fig.6 Relationship between Average Shoreline, Sand Volume and Wave Energy(at Nakanosawa)

parallel to the coast is predominant. The coastline thus advances when  $E_R$  surpasses  $E_L$ , and vice-versa. Direction of predominant littoral transport is from right to left.

### Coastal Changes of the Adjoining Fishing Port and Coastal structures

#### Yakumo Fishing Port

Yakumo fishing port is located at 23 km from Kunnui. Construction work began in 1951. Fig. 7 shows the coastal changes of this port. Due to drift sand moving from right to left, sand was deposited along the upstream shore, and it became difficult to maintain water depth at the port entrance. Considering the smallness of particle diameter at this coast, and the changing direction of dominant longshore current depending on season,

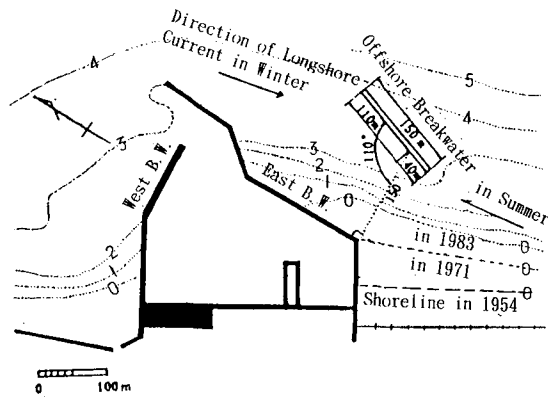

Fig.7 Shoreline Changes at Yakumo Fishing Port

as shown in this figure was installed. Sand accumulates at the back of the offshore breakwater in summer and when wave and flow change direction in winter, flushing of sand by natural forces acts as a counter-measure. Consequently, this counter-measure succeeded in preventing excessive sedimentation at the port entrance.

However, as water depth at the port entrance had already been reduced to 3 meters, and onshore drift sand is flowing in from the port entrance, maintenance dredging is still carried out every year.

#### Offshore Breakwaters for Shellfish Propagation Ground at Yakumo

From 1976 to 1981, three offshore breakwaters had been constructed with the purpose of "sakhalin surf-cram" propagation grounds about 13 km from Kunnui. The specifications of these offshore breakwaters are; 200 m in length, 50 m between successive breakwaters, 200 m of offshore distance and -3.0 m as site depth. As this area is very near and topographically similar to Kunnui, bottom materials and slope are similar to that at Kunnui. Fig. 8 shows coastal changes caused by the construction of these offshore breakwaters. The type of the breakwater is of permeable riprapping tetrapod with crown height of D.L.+3.0 m.

As shown in Fig. 8, as the construction work progressed, extensive tombolo developed behind the breakwaters and the coastline advanced by about 100 m at low water level. The adjoining coast was eroded, and at the left-hand coast even the foundation of the existing seawall was eroded. Accretion was remarkable and three tombolo were connected to each other. Fig. 9 shows bathymetry in August of 1984. As the development of the right-side tombolo is greater and coastal erosion is greater than on the left side, the dominant direction of drift sand is supposed to be from right to left.

#### Plan of the Fishing Port

In the past, before Kunnui fishing port was developed, fishing boats were hauled

Fig.8 Changes of Shoreline behind Offshore Breakwater at Yakumo

Fig.9 Bathymetry of Yakumo Shell-Fish Propagation Ground (Aug., 1984; Two and Half Years after the Completion of Offshore Breakwater)

up on the foreshore, much man power and time was needed for lifting and launching fishing boats. Major catches are scallop, flatfish, salmon and tuna. The fisheries are managed under stable conditions with gillnet, small setnet and salmon large setnet fisheries, and shallow water aquaculture of scallop. Kunnui fishing port was designed to serve as a vessel mooring area and a base for preparing and managing fishery operation.

**Shape of the Port**

Merits and demerits of detached fishing ports are discussed by Sakai. In case of small-scale ports, a large area for port facilities is not required, but if a plan be conducted only directing our attention to the scale of a plane layout, or the port design is concentrated only on facility layout, ignoring the presence of littoral drift,

and the port entrance is set inside the breaker zone where drift sand movement is heavy, then the function of the port may be impaired. On the other hand, if the port layout is determined from a viewpoint of preventing sedimentation at the port entrance, a rather large-scale port design is indispensable in order to set the port entrance far offshore side beyond the breaker zone. In this respect, however, a port constructed at a properly selected offshore site as a kind of man-made island may not require higher total costs than a conventional port.

Several draft plans were examined, considering the influence on adjoining coast, sedimentation at port entrance, ease of construction and construction cost. Two basic configurations were considered; one was a conventional type extending offshore; and the other was a detached island type. Further, two detached types were considered; one with a curved shape to decrease wave dumping effect by the port, and the other with an angular form. Fig. 10 shows these types;

Fig.10 Layout Plan of Kunnui Fishing Port

① Plan 1 : Conventional type of port ② Plan 2 : Island type of port with angular lines ③ Plan 3 : Island type with curved breakwater to produce rough waves behind the sheltered area. Although Kunnui is a small port, if the port was constructed based on the conventional method of installing shore-connected breakwaters, it was assumed that longshore transport would be interrupted and beach accretion up-coast as well as erosion down-coast would occur. Further, if the port entrance was set in the surf zone, there was a risk of sedimentation at the port entrance. In fact, these troubles occurred at Yakumo port, as already mentioned. In order to prevent the influence of drift sand as much as possible, an offshore island type fishing port was adopted.

From a standpoint of coastal structure, an island fishing port is considered to be very similar to an offshore breakwater. In this case, the point was how to balance the need to prevent development of tombolo with construction costs. The longer the offshore distance, the smaller the development of tombolo, but the higher the construction cost. Therefore, the following conditions are key for determination;

① Water depth at the port entrance is deep enough to prevent being blocked by drift sand under adverse wave conditions. ② Port is designed such as to decrease formation of tombolo. ③ Offshore distance has to be great enough to prevent the port from being connected to shore by development of tombolo. ④ Reasonable construction cost based on comparison with costs estimated for conventional port, including relation between offshore distance, maintenance and management cost if longshore drift transport were totally interrupted and beach erosion occurred.

Offshore distance was initially set at around 200 m, and investigations were carried out for several different distances.

#### Scale of the Fishing Port

Port scale was planned according to the forecasted number of fishing boats which would utilize the port, as per Table 5. Pursuant to Fishing Port Planning Criteria, the facilities and scale are as per Table 6.

#### • Entrance Water Depth

If a port is constructed offshore, the risk for sedimentation at the entrance

becomes lower as the entrance water depth gets deeper, but cost increases. For deciding the depth of the port entrance, critical depth for sediment movement is adopted as a yardstick. This critical depth is classified into two types; critical water depth for surface sediment movement and critical water depth for complete sediment movement. The former concerns mass movement of surface sand at the bottom along wave direction; and the latter indicates movement which can cause change of water depth. According to the formula developed by Sato and Tanaka, these depths are expressed as follows;

Table 5 Usage of Kunnui Fishing Port[G.T.: gross tonnage]

(Complete Sediment Movement)

$$\frac{H_0}{L_0} = 2.4 \left( \frac{d}{L_0} \right)^{\frac{1}{3}} \left( \sinh \frac{2\pi h_c}{L} \right) \left( \frac{H_0}{H} \right)$$

Where,

Affix o : offshore wave

$h_i$  : Critical water depth for surface sediment movement

$h_c$  : Critical water depth for complete sediment movement

As a result of bottom survey, median diameter of bottom sand is  $d_{50} = 0.08-0.26$ . During investigation period,  $H_0 = 2.2$  m and  $T = 12.3$  sec were observed. After storm wave subsided, recognized isobath was up to  $-6.5$  m, with  $d_{50}$  of 0.26 mm. The calculated values were  $h_i = 6.6$  m and  $h_c = 3.1$  m. For wave with return period of one year, equivalent deep water wave height  $H_0$  is 1.7 m, with  $h_i = 7.7$  m-12.5 m and  $h_c = 3.7$  m-5.7 m. According to these results, the entrance depth was determined to be deeper than D.L-5.7 m.

These factors were established based on the analysis of existing materials, site investigations and simulations, and thus may not represent in full the actual site conditions. Consequently, an hydraulic model test was conducted, and the results were compared.

### Layout of the port

#### • Model Test

To compare the angular and curved offshore fishing ports, a hydraulic model test was carried out. As bottom slope is gentle, the distorted model was applied through trial and error. Model Scale was 1/100 in horizontal and 1/70 in vertical. Tests were carried out for the angular type (Plan 2) and the curved type (Plan 3) with waterdepth  $-5.5$  m,  $-6.5$  m,  $-7.0$  m. Offshore distance was initially set at 200 m and tests were conducted for several distances around this figure. Sand used in the tests has a

median grain size of 0.22 mm. The purpose of the tests was qualitative comparison of tombolo development.

Test Waves were for waves with return period of 1 year and 20 years, and wave direction was ESE and SE. As a verification method, sand movement by tracer in the Model was arranged to correspond to the move of fluorescent sand at the site. As it is difficult to reproduce actual site conditions in the model, only qualitative comparisons were conducted.

A total of 24 hydraulic model tests were performed for various wave conditions and offshore distances.

As a qualitative comparison between angular type and circle type, tests showed no tombolo protruding from water surface for the circle type, because of higher wave height and rougher water behind the port compared to the angular type. Two examples of the results of the tests are shown in Fig. 11 and Fig. 12.

In this case of the angular type, conspicuous tombolo was observed, while no tombolo appeared in the circle type even though incident wave was a little higher. A long and slender shoal, however, elevation of which was the same as the water surface, was formed along the center line behind the port, where waves from both sides collided with each other. Another characteristic was local scouring along and at the corners of breakwaters in the angular type, in contrast to that deposition area appeared along breakwaters up to water depth of  $-5.0$  m to  $-6.0$  m in the circle type. This phenomena seemed to be caused by strong return flow along the structures.

#### • Numerical Simulation of Wave Induced Current

For Plan 3, numerical calculation of wave induced offshore current was conducted to confirm the speed of return flow. The result of the computation is shown in Fig. 13.

The wave conditions in this case are; wave direction ESE, equivalent deep water wave height is 2.2 m (at depth of  $-6.0$  m it is about 2.0 m), and wave period 8.0 sec. The range of computation is 1,000 m, along the coast and offshore. Mesh interval is 20 m. In this case, a circular current with velocity 10 to 30 cm/sec developed behind the port. Part of this current flows offshore along outlying facilities as return flow. This flow might result in sediment transport and deposition along port outlying facilities as seen in the model test. If the  $-2$  m isobath reaches the port entrance, the entrance may not be maintained. In the hydraulic model test, this phenomenon occurred until initial water depth of  $-3.5$  m.

These qualitative tests, however, were unable to confirm what would occur at the actual site. Furthermore, although conspicuous tombolo was not formed in the model

Fig.11 Example of Sea Bottom Change by Hydraulic Model Test[Plan(2)]

test, a considerable size of tombolo was assumed to develop from this calculation. Putting all these various results together, along with last but not least, consideration of total cost, layout shown in Fig. 14 was adopted.

**Topographic Changes During Construction**

The construction work commenced in 1988, and proceeded in the following order:  
 ① Road bridge  
 ② West side seawall  
 ③ Bridge approach

Fig.12 Example of Sea Bottom Change by Hydraulic Model Test[Plan(3)]

Fig.13 Nearshore Current by Numerical Simulation [H<sub>0</sub>=3.6m, T=8.0sec.: H=2.0m at h=-6.0m]

- ④ Southern seawall ⑤ Southern breakwater ⑥ Eastern breakwater ⑦ Northern seawall
- ⑧ Northern breakwater
- ⑨ Mooring facilities ⑩ Reclamation of land for facilities. During the construction, sounding survey was conducted every year around August and September. The coastal configuration at each stage of work was compared against with the base survey conducted in August, 1985. As was predicted, a tombolo was formed at the rear of the port. Fig. 15 shows changes of coastline (development of tombolo) at

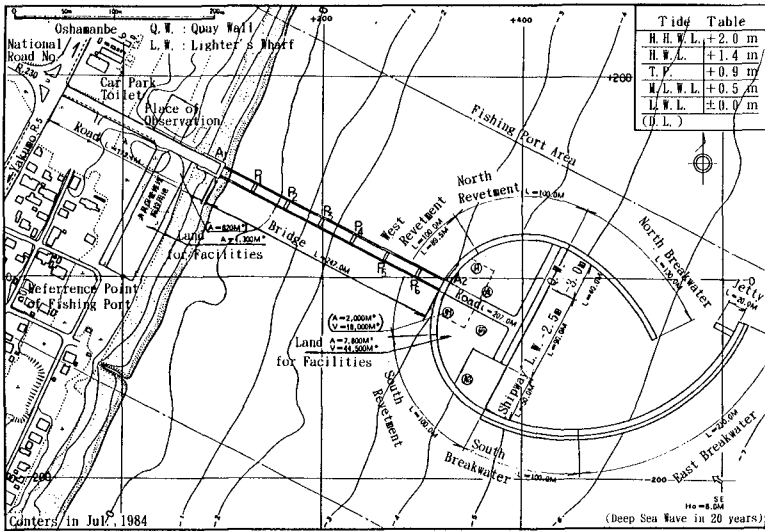

Fig.14 Final Plan of Kunnui Fishing Port

M.W.L. (D.L.+0.5 m). The tip of the tombolo advances seaward with the progress of the construction work. But maximum length of advancement is only about 60 m and the size is not so great. Fig. 16 illustrates the changes of shoreline at L.W.L. (D.L.+0.0 m). The seaward tip of the coastline is long and sharp but changes its shape adapting to imposed wave conditions much like a kind of cusped spit, and almost touches the port in recent years. Fig. 17 shows bathymetric changes. Since this port consists of impermeable breakwater and a coastal structure 300 m long and 200 m wide, bathymetric change is, in general, different from that of a conventional offshore breakwater shown in Fig. 9, which is of permeable type with low crown height. In the case of common offshore breakwaters, local scouring is generally observed at both ends, but in the case of an offshore fishing port, there exists no scouring because of the smooth linear change in the line of the structure. Due to influence of return flow, sand deposition occurs as far as -6 m on the right-side and -5 m on the left-side along the port and shape of the isobath becomes convex near the port.

At the planning stage of this port, we considered only the similarities with an offshore breakwater, but in reality, coastal changes adjoining the port also show similarities with the changes usually caused by a long jetty.

Bathymetric changes since 1992 hint at the existence of large scale and strong cell-like circular currents on both sides of the port. Along this current, scouring of sea bottom occurs in the onshore direction and deposition in the offshore direction. The width of this circular current is approximately 400 m, and this results in the start of tombolo 300 m - 350 m on both sides from the center line of the port. Retreat of the coastline is 30 m at right and 10 m at left and stable. In comparison with yearly shoreline changes by attacking waves before the construction of the port, this retreat is small and stable and thus there are no problems concerning coastal erosion, even though there is no seawall at this beach. Over a distance of 400 m from the center line, no particular change can be seen in the coast except for seasonal changes.

The point is whether we have obtained the desired results or not. At this coast,

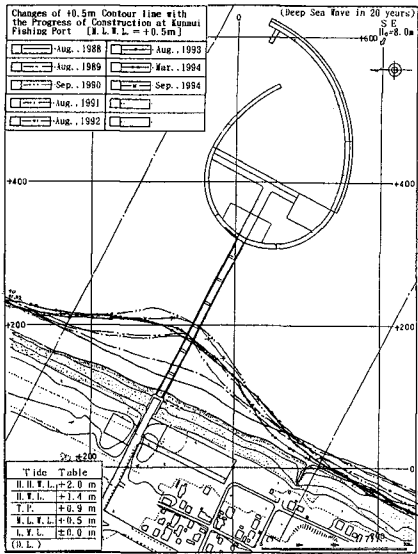

Fig.15 Change of +0.5m Contour line with the Progress of Construction at Kunnuui Fishing Port [M.L.W.L.=+0.5m]

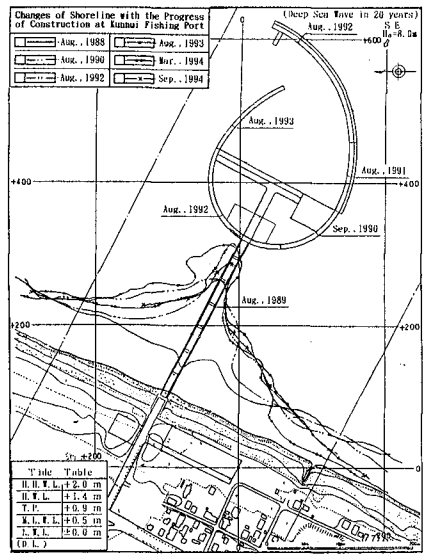

Fig.16 Changes of Shoreline with the Progress of Construction at Kunnuui Fishing Port [at L.W.L.=±0.0m]

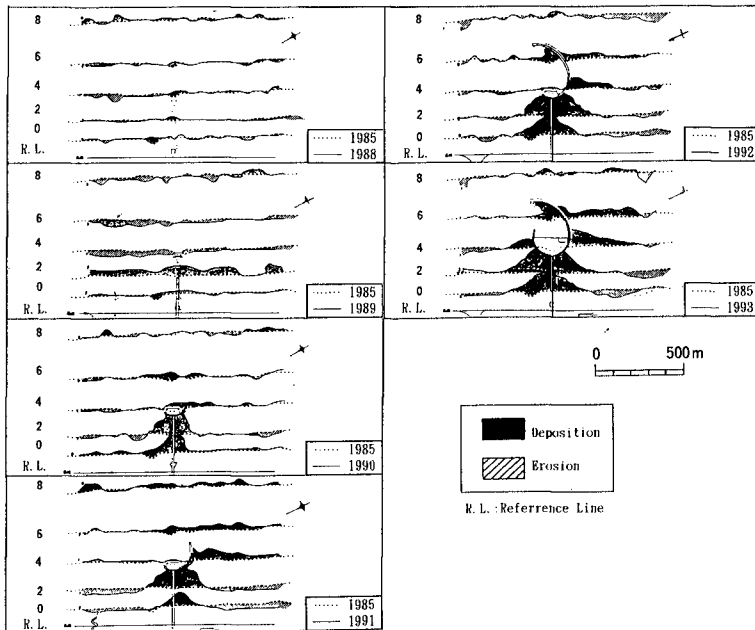

Fig.17 Changes of Contours with the Progress of Construction at Kunnuui Fishing Port

onshore-offshore sand drift dominates under normal conditions and longshore sand drift during high waves, but except for low water, there remains a channel at the rear, and we thus think it stands to reason that littoral current flows behind the port. It is only 3 years, however, since the port took shape, and we are thus going to continue field observations and make a final decision in the future.

### **Conclusion**

Our research focused on how to prevent beach erosion and sand deposition at the port entrance. For the time being, this purpose seems to be satisfied at Kunnui fishing port, but careful examination of bathymetric charts conducted in parallel with the construction work indicated that there occurred large scale cell-like circular currents at both side of the port. This current transports sand onshore and scours the sea-bottom en-route and deposits sand behind and along the port when it is flowing in the offshore direction. In this sense, the location of port entrance at the depth of -6.5 m, and over 400 m offshore from the coastline is supposed to be adequate in this case. We learned that it is important not only to restrict tombolo generation but also to predict the scale and strength of cell-like circular currents in planning this type of fishing port.

## CHAPTER 88

# Topographical Change around Multiple Large Cylindrical Structures under Wave Actions

Chang-Je KIM<sup>1</sup>, Koichiro IWATA<sup>2</sup>, Yoshihito MIYAIKE<sup>3</sup> and Hong-Sun YU<sup>4</sup>

### Abstract

This paper is aimed to investigate theoretically and experimentally the topographical change and the local scouring around multiple large cylindrical structures under wave actions. It is revealed from laboratory experiments that the bottom configuration, the local scouring area and its depth around the cylindrical structures are changed largely according to the number of cylindrical structures, the structure's diameter, the incident wave angle and the sediment size. The theoretical model which developed newly is shown to predict well the topographical change around the structures.

### 1. Introduction

Cylindrical structures are one type of the widely-used coastal and offshore structures such as large volumed gravity platforms or water intake towers for power plants. Very recently, multiple large cylindrical structures have been constructed in shallow water depth and have been reported to suffer from local scouring around the cylindrical structures under wave actions in Japan. It goes without saying that the prediction of topographical change and the evaluation of local scouring area and depth around structures are indispensable for safety design of the structures. The accumulated knowledge of bottom topographical change around multiple large cylinders is, however, little compared with that of one large cylinder or small cylinders.

This paper is to discuss theoretically and experimentally the bottom topographical change and local scouring around the two or three large cylinders under wave actions. First, the theoretical model is newly developed to evaluate the topographical change and to predict the scouring area and depth. Next, elaborate laboratory experiments are conducted to investigate the change of bottom configuration due to changes of the number of the large cylinders, their diameters, the incident wave and angle, and the sediment size. Comparing with laboratory experiments, the theoretical model proposed in this paper is shown to be very useful to evaluate the bottom topographical change and the local scouring around multiple large cylindrical structures.

## 2. Theoretical model

### 2.1 Diffraction theory

The diffraction theory is applied to evaluate the wave kinematics and wave deformation around the circular cylinders, since the ratio of the cylinder's diameter to the wavelength (diffraction parameter),  $D/L$  is more than 0.2. The source distribution function method using a vertical line wave source Green's function (Issacson, 1978) is employed in this paper under the assumptions of inviscid and incompressible fluid, and irrotational wave motion. The water particle velocities can be described with velocity potential  $\Phi (= \Phi_I + \Phi_S$ ;  $\Phi_I$  is the incident velocity potential,  $\Phi_S$  the scattered velocity potential), which satisfies Laplace equation.  $\Phi$ ,  $\Phi_I$ , and  $\Phi_S$  are all functions of  $x$ ,  $y$ ,  $z$ , and  $t$ , and  $(x, y, z)$  are the Cartesian coordinates of a point in the fluid field at which the potentials ( $\Phi$ ,  $\Phi_I$ , and  $\Phi_S$ ) are calculated at time  $t$ . When it is assumed that the wave height is sufficiently small for linear wave theory to apply, the incident wave velocity potential  $\Phi_I$  is a known value, and the scattered wave velocity potential  $\Phi_S$  is obtained from the source distribution function method (see, Kim and Iwata, 1993).

The wave height  $H$  around structures is given as

$$H = 2 \left| \frac{i\sigma}{g} \{ \phi_I(x, y) + \phi_S(x, y) \} \right| \quad (1)$$

where  $i = \sqrt{-1}$ ,  $\sigma$  denotes the wave angular frequency,  $g$  the gravitational acceleration,  $\phi_I$  the complex amplitude of the incident velocity potential  $\Phi_I$ ,  $\phi_S$  the complex amplitude of the scattered velocity potential  $\Phi_S$ , and  $| \quad |$  the absolute value.

The water particle velocities  $U_b(x, y; t)$ ,  $V_b(x, y; t)$  in the  $x$ -,  $y$ - directions near bottom around structures are as follows, respectively.

$$U_b = \text{Real}\left[\frac{\partial\Phi}{\partial x}\Big|_{z=-h}\right] = \text{Real}[U_0(x, y) \exp(-i\sigma t)] \quad (2)$$

$$V_b = \text{Real}\left[\frac{\partial\Phi}{\partial y}\Big|_{z=-h}\right] = \text{Real}[V_0(x, y) \exp(-i\sigma t)] \quad (3)$$

in which Real denotes the real part of the expression following,  $h$  the still water depth,  $U_0$  and  $V_0$  are the complex amplitudes of  $U_b$  and  $V_b$ , respectively.

It has been reported that the wave height and the bottom velocity evaluated with the source distribution function method using a vertical line wave source Green's function, were in good agreement with those by experiments (Kim and Iwata, 1993, Kim et al., 1994).

## 2.2 Mass transport velocity

Taking constant viscosity into account, Lagrangian mass transport velocities  $\overline{u_L}$ ,  $\overline{v_L}$  in the  $x$ -,  $y$ - directions in the bottom boundary layer combined Stokes' mean drift with Eulerian mean drift are given as (Carter et al., 1973)

$$\overline{u_L} = \frac{1}{4\sigma} \text{Real} \left\{ F_5 U_0 \frac{\partial U_0^*}{\partial x} + F_6 V_0 \frac{\partial U_0^*}{\partial y} + F_7 U_0 \frac{\partial V_0^*}{\partial y} \right\} \quad (4)$$

$$\overline{v_L} = \frac{1}{4\sigma} \text{Real} \left\{ F_5 V_0 \frac{\partial V_0^*}{\partial y} + F_6 U_0 \frac{\partial V_0^*}{\partial x} + F_7 V_0 \frac{\partial U_0^*}{\partial x} \right\} \quad (5)$$

where \* means the complex conjugate,  $F_5$ ,  $F_6$  and  $F_7$  are expressed as

$$F_5 = -8i \exp\{-(1-i)\xi\} + 3(1+i) \exp\{-2\xi\} - 3 + 5i \quad (6)$$

$$F_6 = -4i \exp\{-(1-i)\xi\} + (1+2i) \exp\{-2\xi\} - 1 + 2i \quad (7)$$

$$F_7 = F_5 - F_6 \quad (8)$$

where  $\xi = z_1/\delta$ ,  $z_1$  is the distance away from the bottom and points normally into the inviscid region,  $\delta (= \sqrt{2\nu/\sigma})$ ;  $\nu$  is the kinematic viscosity) the thickness of the boundary layer.

With the known expressions of  $U_0$ ,  $V_0$  or  $U_0^*$ ,  $V_0^*$  in Eqs.(2) and (3), Lagrangian mass transport velocities  $\overline{u_L}$ ,  $\overline{v_L}$  in the bottom boundary layer in Eqs.(4)and(5) can be evaluated.

2.3 The sediment transport rate model

From the sediment transport field, the development of the topographical change or the local scouring around structures is calculated by the continuity equation for the sediment given as

$$\frac{\partial h(x, y; t)}{\partial t} = \left\{ \frac{\partial q_x(x, y; t)}{\partial x} + \frac{\partial q_y(x, y; t)}{\partial y} \right\} \tag{9}$$

in which  $h$  is the above-mentioned still water depth,  $q_x$  and  $q_y$  are the sediment transport rates in volume of material per unit time and width in the  $x$ - and  $y$ - directions, respectively.

Consider the sediment transported in the  $s$ - direction by mass transport  $V(= \sqrt{u_L^2 + v_L^2})$ , as shown in Fig. 1. The sediment transport model  $q_s$ , proposed by Watanabe(1981) is widely used in and out the surf zone.

$$q_s = \frac{A_1 w_f}{(1 - \lambda_0) s_0 g \sqrt{s_0 g d_{50}}} (u_*^2 - u_{*c}^2) u_* \tag{10}$$

in which  $A_1$  represents dimensionless parameter,  $w_f$  the sediment settling velocity,  $\lambda_0$  the porosity of the bed material,  $s_0$  the specific weight of the sediment in water,  $d_{50}$  the median diameter of the sediment,  $u_*$  the friction velocity and  $u_{*c}$  the critical shear velocity.

Fig. 1 Simplified model of the sediment transport rate

The sediment transport rate of Eq. (10) is generally based on the sediment transported by breaking wave over the slope bed. Therefore, Eq. (10) is applied to the sediment transport over the plane bed like the present study, the sediment transport rate may be overestimated. Consequently, the new model for the sediment transport applicable to the cases that the spatial change of the wave height is dominant, is proposed on the approximation described in the following.

Equation (10) can be approximated by

$$q_s \sim u_*^3/g \sim V_{bmax}^3/g \sim \frac{H^3}{gT^3 \sinh^3 kh} \quad (11)$$

where  $V_{bmax} = \sqrt{(U_b^2 + V_b^2)}|_{max}$ ,  $T$  is the period of the incident wave,  $k$  the wave number.

Similarly, the mass transport velocity  $V$  can also be approximated as follows.

$$V \sim \frac{1}{\sigma} U_{0s} \frac{\partial U_{0s}}{\partial s} \sim \frac{H^2}{gT^3 \sinh^3 kh} \quad (12)$$

where  $U_{0s}$  indicates the water particle velocity in the  $s$ -direction near the bed.

The following Eq. (13) is obtained by combining Eq. (11) with (12).

$$q_s \sim VH \quad (13)$$

Equation (13) means that the sediment transport rate is proportional to  $VH$ . The wave height  $H$  in the vicinity of large scale structures changes largely in space due to the scattered wave superimposed on the incident wave, and since the wave height  $H$  corresponds to the dynamic pressure, its magnitude represents the extent of the sediments suspension. From this point of view, it seems to be more reasonable that the wave height  $H$  is explicitly included in the sediment transport rate. In the present study, consequently, the sediment transport rate  $q_s$  at an equilibrium state is given as

$$q_s = \frac{A}{1 - \lambda_0} (\Psi_m - \Psi_c) VH \quad (14)$$

where  $A$  indicates the dimensionless parameter,  $\Psi_m (= f_w V_{bmax}^2 / (2s_0 g d_{50})$ ;  $f_w$  is the wave friction factor) the Shields parameter,  $\Psi_c$  the critical Shields parameter.

In calculating Eq. (14), the wave height  $H$  is evaluated with Eq. (1), the water particle velocities  $U_0$  and  $V_0$  are evaluated with Eqs. (2) and (3) using

the source distribution function method, and the mass transport velocities  $\overline{u_L}$  and  $\overline{v_L}$  are also evaluated with the values  $(U_0, V_0, U_0^*$  and  $V_0^*)$  by means of Eqs. (4) and (5).

### 2.4 Topographical change at an equilibrium state

It is assumed that the wave field has little change after the bottom profile change, that is, the sediment transport rates at the equilibrium condition can be evaluated with those  $q_x(x, y; 0)$ ,  $q_y(x, y; 0)$  at  $t=0$ , and the acting time  $T_c$  of wave when the bottom topography reaches an equilibrium state is determined from the experimental results, since the present study aims to establish the simple method that is able to predict the topographical change, the local scouring depth around structures.

From Eq. (9),

$$\begin{aligned} \Delta h_c(x, y) &= \int_0^{t_c} \left\{ \frac{\partial q_x(x, y; t)}{\partial x} + \frac{\partial q_y(x, y; t)}{\partial y} \right\} dt \\ &\cong \left\{ \frac{\partial q_x(x, y; 0)}{\partial x} + \frac{\partial q_y(x, y; 0)}{\partial y} \right\} T_c \\ &= \left\{ \frac{\partial(q_s \cos \theta')}{\partial x} + \frac{\partial(q_s \sin \theta')}{\partial y} \right\}_{t=0} T_c \end{aligned} \tag{15}$$

in which,  $\Delta h_c(x, y)$  represents the change of the still water depth, and  $\Delta h_c > 0$ ,  $\Delta h_c < 0$  and  $\Delta h_c = 0$  correspond to, respectively, the scouring, the deposition and no-change. Eq. (14) is applied to Eq. (15) to evaluate  $\Delta h_c$ . The pattern of the bottom configuration around structures is divided into three parts such as the scouring area ( $\Delta h_c > 0$ ), the deposition area ( $\Delta h_c < 0$ ) and no change area ( $\Delta h_c = 0$ ).

### 2.5 Numerical computation

In Eq. (14), the values of the dimensionless parameter  $A$ , the porosity of the bed material  $\lambda_0$ , the specific weight of the sediment in water  $s_0$ , and the critical Shields parameter  $\Psi_c$ , respectively, were taken as 0.02~0.05, 0.4, 1.65, and 0.08 for the relatively fine sand ( $d_{50}=0.015\text{cm}$ ) and 0.07 for the relatively coarse sand ( $d_{50}=0.038\text{cm}$ ). Then, the mass transport velocity  $V$  at a middle point ( $\xi=1/2$ ) within the boundary layer were used. In the case of the wave friction factor  $f_w$ , Eq. (16) presented by Swart(1974) was applied.

$$f_w = \exp\{-5.977 + 5.213(a_m/k_s)^{-0.194}\} \tag{16}$$

in which  $a_m$  is the amplitude of the orbital motion at the bottom,  $k_s$  the bed roughness and took the median diameter  $d_{50}$  of sand.

In calculating Eq. (15),  $T_c=5200 \times T$  was chosen from the experimental results as will be mentioned later.

### 3 Laboratory experiments

#### 3.1 Dimensional analysis

Taking the structures installed in a line with the same diameters into consideration, the non-dimensional bottom configuration change  $\Delta h_c/H_I$  around the three large cylindrical structures at an equilibrium state is mainly governed by the following 9 parameters.

$$\frac{\Delta h_c}{H_I} = \phi_1 \left\{ \frac{r}{D}, \theta, \frac{D}{L}, \frac{e_1}{D}, \frac{e_2}{D}, \alpha, \frac{H_I}{L}, \frac{h}{L}, \frac{d_{50}}{L} \right\} \quad (17)$$

where  $r$  is the radial distance,  $\theta$  the clockwise angle along the structures measured from the first point of the structures where the incident wave contacts,  $e_1$  the distance between structures I(the right one from the incident wave) and II(the center one),  $e_2$  the distance between structures II and III(the left one) and  $\alpha$  the incident wave angle.  $e_2/D = \infty$  corresponds to the case of two structures and  $e_1/D = e_2/D = \infty$  does to one structure. In the present paper, the effects of the following 6 parameters on the topographical change are mainly discussed.

$$\frac{\Delta h_c}{H_I} = \phi_2 \left\{ \frac{r}{D}, \theta, \frac{D}{L}, \frac{e_1}{D}, \alpha, \frac{d_{50}}{L} \right\} \quad (18)$$

#### 3.2 Experimental equipments and conditions

Laboratory experiments were carried out in a wave basin(28m in length, 11m in width and 0.8m in depth) with a flat bottom. A piston-type wave generator was installed at one end and the wave dissipating sandy beach with the slope of 1/10 was constructed at the other end. And the wave absorbing filters were set up on the both sides of the basin to diminish wave reflection from side walls as small as possible. The surface piercing cylindrical structures with the same diameters, were installed in a line on a sandy bed(400cm in length 500cm in width and 7cm in depth). Test conditions for the movable bed are listed in

Table 1 Test conditions for the topographical change

Table 1, in which  $n$  means the number of structures. The experimental waves satisfied with the live bed state for all the cases, were continuously generated until the bottom topographical change seemed to close to an equilibrium state. The bottom topographical changes were carefully measured with point gauges at all the 2cm-interval mesh points within the sandy bed. The water particle velocities near the bottom and water surface profiles around the structures were measured with electromagnetic type velocity meters and capacitance-type wave gauges, respectively, for the same conditions as the movable bed ones to examine the validity of the employed theory regarding the wave kinematics and the wave heights.

## 4 Results and discussion

### 4.1 Topographical change around structures

Figure 2 represents the time evolution  $t/T$  of the non-dimensional topographical change  $\Delta h/H_I$  at four locations where the comparatively larger scouring depth occurred. In Fig. 2,  $x'$  is the offshoreward distance measured from the structure surface. As shown in Fig. 2, it can be judged that the number  $t/T$  of waves reached the equilibrium state is approximately more than 5000,

Fig. 2 Time evolution of the topographical change  
 $(D/L = 0.26, e_1/D = 1.0, H_I/L = 0.03, h/L = 0.11, \alpha = 0^\circ)$

regardless of the places and the sediment sizes. This result is almost the same as that of Xie(1981) in front of breakwater, or of Katsui and Toue(1992) around one large cylinder. In the present paper, the topographical change at  $t/T=5200$  is taken to be the equilibrium state, and the experimental results at  $t/T=5200$  are compared with the computed ones(Eq. (15) with  $T_c=5200 \times T$ ).

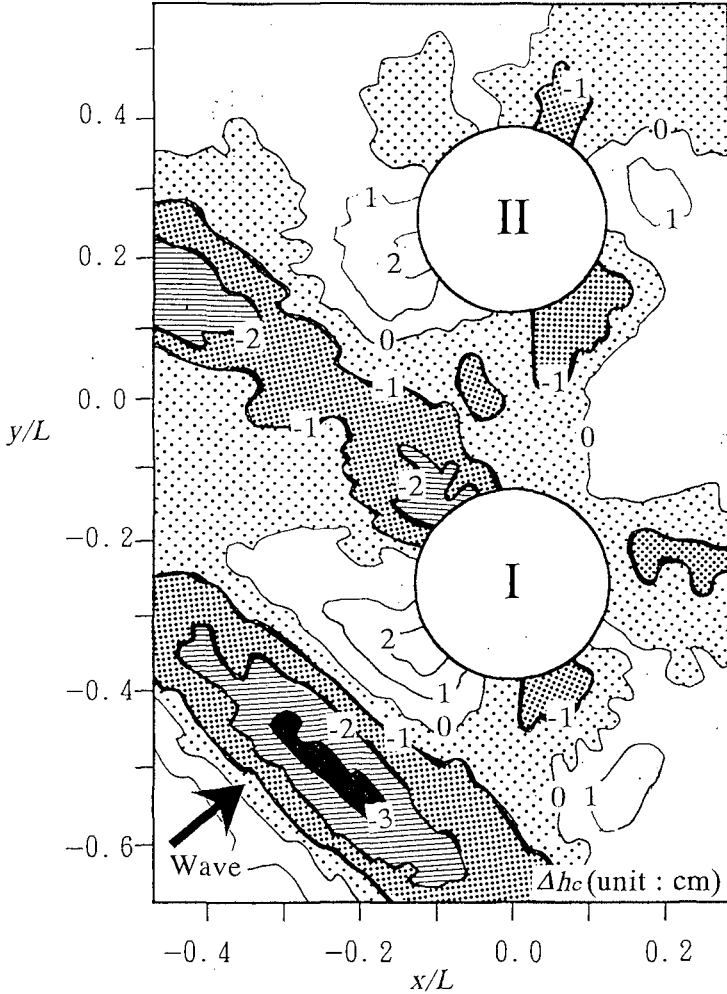

Fig. 3(a) Topographical change around two structures  
 ( $D/L = 0.26, e_1/D = 1.0, H_1/L = 0.03, h/L = 0.11, \alpha = 45^\circ, d_{50}/L = 0.00008$ )

In general, the bottom configuration, the local scouring area and its depth around cylindrical structure are changed according to the number of structures, the structure's diameter, the incident wave angle and the sediment size.

Fig. 3(b) Topographical change around two structures(computed)  
 $(D/L = 0.26, e_1/D = 1.0, H_1/L = 0.03, h/L = 0.11, \alpha = 45^\circ, d_{50}/L = 0.00008)$

Figure 3(a) and (b), respectively, show the experiment result and the computed one of the bottom configuration  $\Delta h_c$  around the two structures in the case of  $\alpha = 45^\circ$ ,  $e_1/D = 1.0$  and  $D/L = 0.26$ . In Fig. 3(a) and (b), the digits indicate the values of the topographical change  $\Delta h_c$ , and the signs of - and +, respectively, indicate the scouring (black area in Fig. 3(a)) and the deposition (white area in Fig. 3(a)). Experiments with the sediment size of  $d_{50} = 0.038\text{cm}$  in place of  $d_{50} = 0.015\text{cm}$  were also conducted and their results were reported by Kim and Iwata (1993). In the case of the relatively fine sediment (this study), the scouring depth and its area are larger and wider than those of the case of the relatively coarse one (Kim and Iwata, 1993). In the cases of obliquely incident waves like  $\alpha = 45^\circ$ , since the onshore structure II is located at the sheltered area of the offshore structure I, a little change or no change is generally found around onshore structure I. Comparing the experimental result with the computed one, it is seen that the bottom configuration around structures can be well estimated with the present theory.

## 4.2 Topographical change along structures

Figure 4 illustrates the non-dimensional topographical change  $\Delta h_c/H_I$  at  $r/D = 0.53$  along the structures with parameter of  $e_1/D$ . In Fig. 4, the solid line represents the experimental result and the dashed line the computed one. The maximum scouring depth takes place at  $\theta = 45^\circ \sim 135^\circ$  (see Fig. 4 and 5) and in Fig. 4, the maximum scouring depth becomes smaller in order of  $e_1/D = 1.0$  (Fig. 4(a)),  $e_1/D = 3.0$  (Fig. 4(b)) and  $e_1/D = \infty$  (Fig. 4(c)). It is inferred that the influence of diffracted wave from one structure on the other one can not be neglected for  $e_1/D = 3.0$ . It is also seen that theoretically estimated values are in good agreement with experiments.

Figure 5 shows the effect of the sediment size on the non-dimensional topographical change  $\Delta h_c/H_I$  for the case of  $D/L = 0.49$ . When the sediment size is smaller (see Fig. 5(a)), the scouring depth and its area are larger and wider, as mentioned above. And the maximum scouring depth for the case of larger diffraction parameter  $D/L = 0.49$  (see Fig. 5(a)) is larger than that of smaller one  $D/L = 0.26$  (see Fig. 4(a)). The reason for this is inferred as follows. When the  $D/L$  becomes large, the spatial difference of the wave height  $H$  also becomes large. As explained before, the sediment is easy to be suspended and to be transported due to mass transport velocity and its large change in space caused by the large difference of the wave height  $H$  in space. Consequently, the scouring depth for the case of larger diffraction parameter becomes larger.

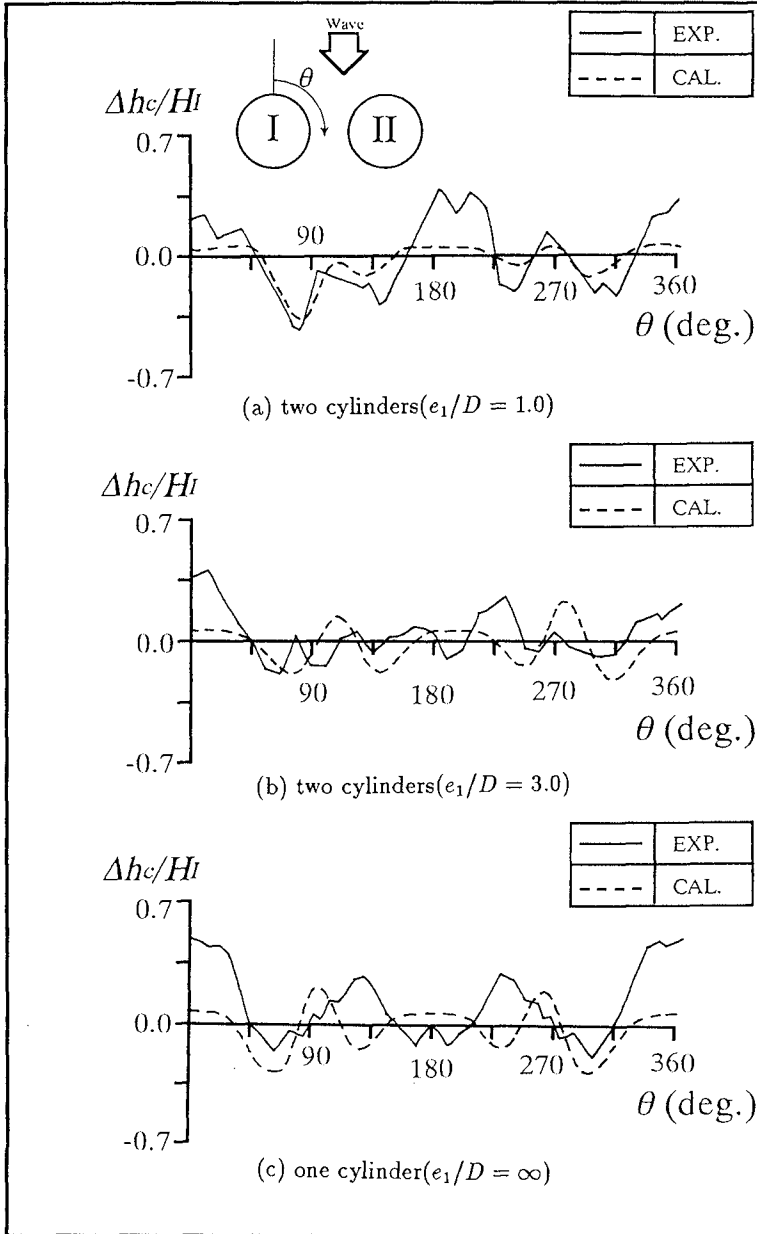

Fig. 4 Topographical change along structures  
 ( $D/L = 0.26, H_1/L = 0.03, h/L = 0.11, \alpha = 0^\circ, d_{50}/L = 0.00008, r/D = 0.53$ )

Fig. 5 Topographical change along two structures  
 ( $D/L = 0.49, e_1/D = 1.0, H_1/L = 0.03, h/L = 0.11, \alpha = 0^\circ, r/D = 0.53$ )

### 5 Concluding remarks

The bottom configuration changes around cylindrical structures under wave actions have been discussed. Main conclusions obtained in the present study are summarized as follows.

(1) The bottom configuration, the local scouring area and its depth around cylindrical structure are changed according to the number of structures, the structure's diameter, the incident wave angle and the sediment size.

(2) The bottom topographical change around structures can be well evaluated with the present theory.

(3) Under the obliquely incident wave, the scouring depth along the offshore structure I is larger than that along the onshore structure I.

(4) With increasing of the diffraction parameter  $D/L$ , the scouring depth becomes larger.

## CHAPTER 89

### Stability of Rubble Mound Foundations of Composite Breakwaters under Oblique Wave Attack

Katsutoshi KIMURA<sup>1</sup>  
Shigeo TAKAHASHI<sup>2</sup>  
Katsutoshi TANIMOTO<sup>3</sup>

#### ABSTRACT

The armor stability of composite breakwaters has been investigated by large 3-D model experiments using oblique irregular waves. The characteristics of wave-induced flow near the mound, which directly affect the armor stability, are disclosed theoretically and numerically. The stability number of armor units in breakwater trunk, head and tail sections is formulated for oblique wave angles less than 60°. The applicability of the proposed methods is confirmed by prototype failure data, and the analyses of case studies are shown for some practical conditions.

#### INTRODUCTION

Rubble mounds of composite breakwaters are usually covered with armor units heavy enough to withstand severe wave actions. Methods to calculate the minimum weight due to irregular waves have been proposed by Tanimoto et al. (1982) and by Wu et al. (1983). However, these techniques apply only for 2-D conditions, such as armor unit stability in breakwater trunks for normal incident waves.

The scouring of rubble mound foundations caused by neglect of the 3-D effects has been one major reason for composite breakwater failures in Japan. According to the 3-D model test data for irregular waves, Ito et al. (1966) suggested that armor damage increases rapidly under oblique wave attack.

Caissons at breakwater heads and tails were sometimes tilted by the scouring of rubble mound foundations. Conventional design procedures recommend that armor units at breakwater heads be 1.5 times heavier than those in breakwater trunks. However, the effect of incident wave angle and the extent of heavy armoring required are not obvious.

In this paper, the minimum weight of armor units required to withstand oblique incident waves is formulated for breakwater trunk, head and tail sections, based on stability tests, considering peak values of wave-induced water particle velocity on the mound.

## ARMOR STABILITY AND WAVE-INDUCED FLOW NEAR MOUND

### Stability Number of Armor Units

Figure 1 shows a standard cross section of a composite breakwater with a vertical wall and a rubble mound foundation. Wave forces acting on the vertical wall can be calculated for the breakwater's trunk, head and tail considering wave directions.

Rubble mound foundations have been however designed on the basis of engineer's experience, according to the following formula:

$$W = \frac{\gamma_d H_{1/3}^3}{N_s^3 (S_r - 1)^3} \quad (1)$$

where  $W$  is the stable weight of armor units (tf);  $\gamma_d$  the unit weight of armor units;  $S_r$  the specific gravity of armor units in sea water;  $H_{1/3}$  the wave height used in design (m); and  $N_s$  the stability number determined by wave factors, mound forms and characteristics of armor units. Equation (1) was developed by Hudson (1959) and has been in general use since Brebner and Donnelly (1962) modified it to estimate the stable weight of rubble mound foundation for vertical walls. Based on experimental results with irregular waves, Tanimoto et al. (1982) proposed the formula below to estimate the stability number of armor

Figure 1 Standard Cross-Section of Composite Breakwater

units (two-layered settlement) against normal incident waves in breakwater trunks:

$$N_s = \max \left\{ 1.8, 1.3 \frac{1-\kappa}{\kappa^{1/3}} \frac{h'}{H_{1/3}} + 1.8 \exp \left[ -1.5 \frac{(1-\kappa)^2}{\kappa^{1/3}} \frac{h'}{H_{1/3}} \right] \right\} \quad (2)$$

where  $\kappa$  is non-dimensional flow speed. Peak horizontal speed of water particle motion  $U$  near the bottom is defined as;

$$U = \sqrt{\frac{gH^2\kappa}{h'}} \quad (3)$$

where,  $H$  is incident wave height,  $h'$  is water depth above the rubble mound foundation and  $g$  is gravitational acceleration. As for wave forces on armor units, it is assumed that drag forces predominate over inertial forces. For the 3-D conditions,  $\kappa$  is formulated considering peak flow of water particle motions as described below.

In breakwater trunk sections for oblique wave attack,  $\kappa$  is defined by the small amplitude wave theory as follows:

$$\kappa = \kappa_1 \cdot (\kappa_2)_B \quad (4)$$

$$\kappa_1 = \frac{2kh'}{\sinh 2kh'} \quad (5)$$

$$(\kappa_2)_B = \max \{ \alpha_s \sin^2 \beta \cos^2(kl/\cos\beta), \cos^2 \beta \sin^2(kl/\cos\beta) \} \quad (6)$$

where  $\beta$  is the incident wave angle defined as the angle between the wave direction and the normal line of the breakwater alignment,  $k$  is wave number ( $= 2\pi/L'$  :  $L'$  is wave length for depth  $h'$ ), and  $l$  is the distance from the vertical wall,  $\kappa_1$  is the parameter of relative depth, and  $(\kappa_2)_B$  expresses the effect of mound shape and wave direction. The first and second terms of  $(\kappa_2)_B$  correspond to the peak flows, components parallel and orthogonal to the alignment, respectively. The slope factor  $\alpha_s$  is determined to be 0.45 from the measured data and is multiplied only by the first term of Eq.(6), as the slope effect does not exist along the breakwater alignment.

Figure 2 shows the relationship between  $(\kappa_2)_B$  and  $l/L'$  for three wave directions;  $\beta=0^\circ$ ,  $45^\circ$  and  $60^\circ$ . For  $\beta = 0^\circ$ ,  $(\kappa_2)_B$  is determined by the second term of Eq.(6), and armor units with wider berm mounds become more unstable.

Figure 2 Non-Dimensional Flow Speed in Breakwater Trunk

For oblique incident 60° conditions,  $(\kappa_2)_B$  is determined by the first term of Eq.(6) and slightly decreases away from the vertical wall.

Formulae for Breakwater Head and Tail

For breakwater head and tail sections,  $\kappa$  is formulated from the flow speed at the bottom using the small amplitude wave theory as follows;

$$\kappa = \frac{\kappa_1 \alpha_s \tau^2}{4} \tag{7}$$

Figure 3 Non-dimensional Flow Speed at Breakwater Head and Tail

Figure 4 Flow Patterns at Breakwater Head and Tail

where  $\tau$  is the correction factor for local rapid flow around corners. Figure 3 shows the relationship between  $\kappa$  and the relative water depth  $h'/L'$  using  $\tau$  as a parameter. For longer period conditions with smaller relative depth, flow speed becomes larger.

Figure 4 shows numerical results of the mild slope equations. Flow pattern is analyzed for flat bottom conditions with  $h = 30$  cm. The length of breakwater is three times that of incident wave length. The wave condition is  $T = 3.0$  s and  $H = 10$  cm. The peak speed of rapid flow  $U$  is divided by  $U_{p0}$ , the peak water particle velocity at bottom in progressive wave conditions without breakwaters. Rapid flow occurs locally around the offshore- and onshore-corners for normal incident conditions. The oblique  $60^\circ$  incidence leads to remarkable

Figure 5 Rapid Flow Area

local flow around corners projecting towards the wave direction at breakwater tails as the standing wave height increases along the breakwater for the wave direction.

Wave-induced flow on the rubble mound is measured by electromagnetic current meters for regular wave conditions. The curved lines in Fig. 5 show the limit of rapid flow areas. Since the stability tests proved that the area to be protected is within the range of  $1.0H$  from the corner,  $\tau=1.4$  can be used for  $\beta=0^\circ$  and  $\beta=45^\circ$  conditions, and  $\tau=2.5$  can be used for  $\beta=60^\circ$  conditions

## STABILITY TESTS

### Experimental Setup

The tests were carried out in a 50m-long, 20m-wide 3-D wave basin. The basin bottom slopes at a gradient of 1/50, as shown in the lower part of Fig.6 (d). The incident wave angles  $\beta$  were  $0^\circ$ ,  $45^\circ$  and  $60^\circ$ , varied by changing the layout of the breakwater model as shown in Fig. 6 (a) ~ (c). The length of the breakwater alignment is more than 2.5 times the wave length for oblique incident conditions.

The standard cross section of the model breakwater was a relatively low mound condition. Water depth  $h$  was 65 cm, mound depth  $h'$  was 45 cm and mound berm width  $B_M$  was 40 cm.

Stability tests of armor units were carried out under irregular wave conditions. The wave range was limited to the non-breaking conditions,  $H_{1/3}/h$  is less than 0.35. Three types of wave period ( $T_{1/3} = 1.64, 2.19$  and  $2.92$  s) were prepared, and the relative depth  $h/L$  was varied from 0.08 to 0.15. The spectrum of the irregular waves was the modified Bretschneider-Mitsuyasu type, and the wave number was about 150 for each experiment.

Standing wave heights in front of vertical wall vary along the breakwater alignment due to diffraction waves. Armor stabilities in the breakwater trunk were examined in front of caissons No. 10 ~ 12 ( Fig. 6(a):  $\beta=0^\circ$ ), No.12~14 ( Fig. 6 (b):  $\beta=45^\circ$ ) and No.9 ( Fig.6 (c):  $\beta=60^\circ$ ), where the standing wave height is approximately twice the incident wave height.

Four types of stones with mean weights of 15, 30, 60 and 100 gf were used as a model of armor units. Physical characteristics of armor stones are shown in Table 1. The wave height was gradually increased without changing the arrangement of armor units.

The inspection area was divided into a 20-cm-square grid, and differently colored armor stones were placed in each square. The number of stones moving out of the grid was counted by visual observation. The damage rate defined as the ratio of moved stones to the total, and maximum damage ratios are used in the following analyses.

### Armor Stability at Breakwater Trunk

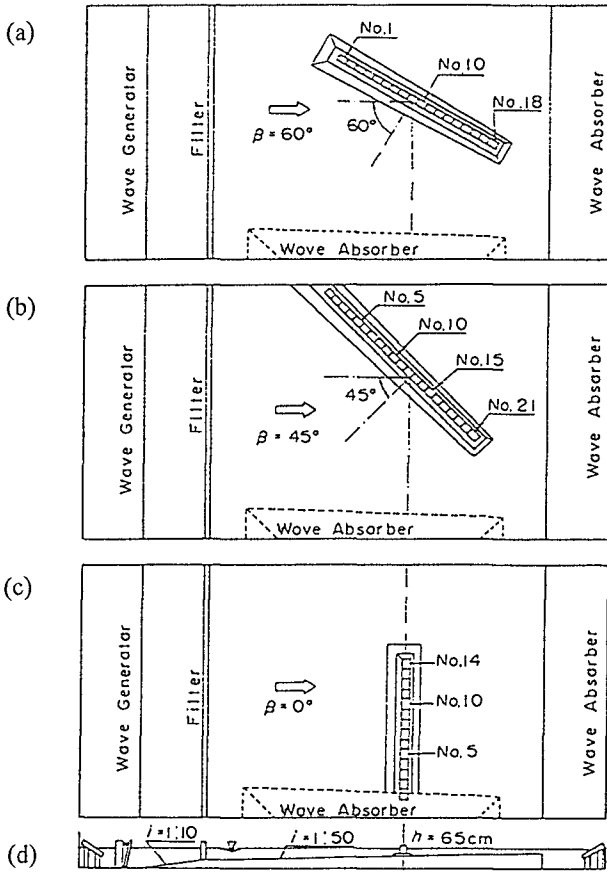

Figure 6 Model Breakwaters in a Three-Dimensional Wave Basin

Table 1 Model Armor Stones

Grade	Weight (gf)		Density ( $\text{gf}/\text{cm}^3$ )
	Average	Standard Div.	
I	15.0	2.05	2.60
II	29.9	3.51	2.59
III	57.3	5.99	2.62
IV	105.5	12.5	2.75

Photo 1 Damage Pattern: Oblique 60° Condition

Photo 1 shows damage patterns for the oblique 60° condition in breakwater trunk. The left part shows the armor conditions before wave action, the right shows them after the wave action of  $T_{1/3} = 2.92$  s and  $H_{1/3} = 23.0$  cm. Armor units of 15 gf were heavily scoured near the vertical wall by the wave-induced rapid flow along the breakwaters.

Figure 7 shows damage ratio, with the incident wave height on the abscissa. The results for normal and 45° oblique waves are very similar, and the damage does not extend with the increase in the wave height. However, when the wave angle  $\beta = 0^\circ$ , the damage starts at small wave heights, and then increases remarkably. This is because the non-dimensional flow speed  $(\kappa_2)_B$  for  $\beta = 60^\circ$  is larger than that for  $\beta = 0^\circ$  and  $\beta = 45^\circ$  when  $l/L' \leq 0.07$  as shown in Fig. 2.

Figure 8 shows the relationship between wave heights and the minimum weights for three wave directions, when  $T_{1/3} = 2.92$  s. The circles show the

Figure 7 Relationship between Damage and Wave Height

Figure 8 Minimum Armor Weight (Trunk)

limits of damage, with the short, solid horizontal lines indicating the 5% damage range. The curved lines are calculated by the proposed method and agree well with the experimental values. This results confirm the applicability of formulating the wave-induced flow based on the small amplitude wave theory.

Armor Stability at Breakwater Head and Tail

Figure 9 shows scouring patterns at the breakwater head and tail for each of the wave directions with  $T_{1/3} = 2.92$  s. For the normal incident waves, the damage is larger at the shoreward corner of the caisson. For oblique waves, the scouring occurs at projecting corners of the breakwater tail.

Figure 9 Scouring at Breakwater Head and Tail

Figure 10 Relationship between Damage and Wave Height

Figure 11 Minimum Armor Weight (Head and Tail)

patterns agree well with the positions where the wave-induced flow speed near the mound is larger as shown in Fig. 4.

Figure 10 shows the damage ratio for breakwater head and tail sections under waves with  $T_{1/3} = 2.92$  s. The results for the normal and 45° oblique waves are very similar. With the 60° oblique waves, the damage begins to occur at small wave heights and then increases remarkably.

Figure 11 shows the relationship between the wave height and the minimum armor weight for each wave direction, when  $T_{1/3}$  is 2.19 s and 2.92 s. No armor damage was recorded for the wave condition of  $T_{1/3} = 1.64$  s. Armor units for

Figure 12 Comparison with Prototype Failures

longer wave periods become more unstable and should be made heavier than those used for shorter wave period.

The curved lines are calculated by the proposed method and agree well with the experimental values. It is shown that the effect of incident wave angles can be expressed by the correction factor  $\tau$  in the calculation of minimum armor weights.

#### Comparison with Prototype Failures

Figure 12 compares the prototype armor failures (1965 ~ 1990) and the proposed methods. The x-axis represents the ratio of the mean weight of armor units  $W$  to the weight calculated by the proposed method  $W_c$ , and the y-axis represents the damage percent of the prototype armor units  $D_e$ .

When  $W/W_c < 1$ , damage is expected, and the applicability of the proposed calculation method is confirmed by the above comparisons.

### EXAMPLE OF ARMOR DESIGN

#### Design Conditions

A composite breakwater, in Fig. 13, is used for the case studies. Design conditions are as follows;

Depth :  $h = 13.0$  m,  $h' = 9.0$  m

Wave Conditions :  $H_{1/3} = 5.0$  m,  $T_{1/3} = 13.0$  s

$B_M = 8.0$  m

$\beta = 0^\circ$  and  $60^\circ$

Armor units : Two layers of stones,  $\gamma_d = 2.65$  tf/m<sup>3</sup>

#### Armor Units for Breakwater Trunk

Figure 13 Design Conditions

## (1) Normal incident condition

Substituting  $h'/L' = 0.076$  for Eq.(5),  $\kappa_1$  is calculated as follows;

$$\kappa_1 = \frac{2 \times 2 \times 3.14 \times 0.076}{\sinh(2 \times 2 \times 3.14 \times 0.076)} = 0.863$$

For normal incident conditions, the mound shoulder becomes critical for the stability of armor units.

Substituting  $l = B_M$  for Eq.(6),

$$(\kappa_2)_B = \sin^2 \left( \frac{2 \times 3.14 \times 8.0}{118} \right) = 0.171$$

$$\kappa = \kappa_1 \cdot (\kappa_2)_B = 0.863 \times 0.171 = 0.148$$

Using Eqs.(1) and (2), the stability number and the necessary minimum weight are calculated as follows:

$$N_s = 1.3 \times \frac{1 - 0.148}{0.148^{1/3}} \times \frac{9.0}{5.0} + 1.8 \exp \left[ -1.5 \times \frac{(1 - 0.148)^2}{0.148^{1/3}} \times \frac{9.0}{5.0} \right] = 3.79$$

$$W = \frac{2.65 \times 5.0^3}{3.79^3 \times (2.65/1.03 - 1)^3} = 1.56 \text{ (tf)}$$

## (2) Oblique 60° Condition

Armor stability should be checked; at the outside of foot protection blocks ( $l = 4.0$  m),

$$\begin{aligned} (\kappa_2)_B &= \max \left\{ 0.45 \sin^2 60 \cos \left( \frac{2 \times 3.14 \times 4.0}{118} \right), \cos^2 60 \sin^2 \left( \frac{2 \times 3.14 \times 4.0}{118} \right) \right\} \\ &= \max \{ 0.322, 0.011 \} = 0.322 \end{aligned}$$

$K$ ,  $N_S$  and  $W$  are calculated as follows:

$$\kappa = 0.278, N_S = 2.80, W = 3.88 \text{ (tf)}$$

For the breakwater trunk, the necessary weight of armor units for oblique  $60^\circ$  waves is 2.5 times that for normal incident conditions.

#### Armor Units for Breakwater Head and Tail

##### (1) Normal incident condition

Substituting  $\kappa_1 = 0.863$  and  $\tau = 1.4$  for Eq.(7),  $\tau$  is calculated as follows:

$$\kappa = 0.863 \times \frac{0.45 \times 1.4^2}{4} = 0.190$$

Using Eqs.(1) and (2), the stability number and the necessary minimum weight are calculated as follows:

$$N_S = 3.38, W = 2.20 \text{ (tf)}$$

##### (2) Oblique $60^\circ$ Condition

Substituting  $\tau=2.5$  for Eq.(7),  $K$ ,  $N_S$  and  $W$  are calculated for breakwater tails as follows:

$$K = 0.607, N_S = 2.19, W = 8.11 \text{ (tf)}$$

At the breakwater tail, the necessary weight for oblique  $60^\circ$  waves becomes 3.7 times than that for normal incident waves. Under oblique  $60^\circ$  conditions, the tail section requires armor units two times heavier than the trunk section does.

## CONCLUSIONS

The characteristics of the wave-induced flow near the mound of composite breakwaters, which directly affect the armor stability, were investigated for 3-D conditions. The results of numerical analyses and physical model tests confirmed that armor damages in prototype failures occurred in the rapid flow areas.

The stability number can be calculated by Eq.(2) for oblique wave conditions of non-dimensional flow speed  $\kappa$ . For breakwater trunk sections,  $\kappa$  is formulated by Eqs.(4) through (6). For breakwater head and tail sections,  $\kappa$  is formulated by Eq.(7), and the area to be heavily protected is within the range of  $1.0 H$  from the corner of caissons. The applicability of proposed methods was confirmed by stability model tests and prototype failure analyses.

## CHAPTER 90

# ANALYSIS OF NONLINEAR COEFFICIENTS OF REFLECTION AND TRANSMISSION OF WAVES PROPAGATING OVER A RECTANGULAR STEP

Wudhipong Kittitanasuan<sup>1</sup> and Yoshimi Goda<sup>2</sup>

### Abstract

A mathematical model for nonlinear wave propagation over a rectangular step is formulated based on the boundary element method. The wave profile computed by this model gives a more realistic wave profile than that of linear wave theory. The calculation of the height of nonlinear waves is studied, and as a results of the study the reflection and transmission coefficients are computed based on the technique which considered the higher harmonic components in the computation of wave height. The solutions of these coefficients are presented and compared with laboratory experiments.

## 1 Introduction

A land reclamation has been recommended to provide an artificial shallow ledge around its periphery in order to mitigate adverse effects on the environment. This shallow ledge can be considered as a rectangular step placed in finite depth water. A breakthrough of knowledge of the transformations of waves on this marine structure is necessary so that we can design and construct all related structures properly. Transformations of waves on a rectangular step were originally studied by Lamb (1932), who solved this kind of problem by applying basic continuity requirements at the point of discontinuity. Up to now, Bartolomeusz (1958), Newman (1965), Mei and Black (1969), Ijima (1971), *etc.*, have proposed various solutions for the prediction of wave reflection and transmission coefficients. Most of these solutions were derived based on linear wave theory. In

many applications, however, it is the waves of large amplitude which are of primary importance. It is because the large amplitude waves exercise vast influence on the aquatic environment, owing to their strong movements of water particle.

As illustrated by Ohyama and Nadaoka (1991) and Kittitanasuan *et al.* (1993) waves on the step exhibit highly nonlinear behavior exemplified by the enhancement of the higher harmonic components, and therefore, the effect of these nonlinear components should be considered in the computation of the coefficients of wave reflection and transmission of rectangular step. In this study, an attempt is made to provide the solutions of wave reflection and transmission coefficients based on the nonlinear computation.

## 2 Mathematical Formulation

### 2.1 Governing Equation

The nonlinear boundary value problem based on the velocity potential theory is formulated by assuming that the fluid is inviscid and incompressible, and the fluid motion is irrotational. The two-dimensional continuity equation in the fluid domain  $\Omega$  can be written as follows :

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial z^2} = 0 \quad (\text{in } \Omega) \quad (1)$$

where  $\phi$  is the velocity potential,  $x$  is the horizontal axis, and  $z$  is the vertical axis taken upward the mean water level.

Figure 1: Definition sketch

### 2.2 Boundary Conditions

Along the solid boundaries,  $S_h$ ,  $S_q$ , and  $S_v$  sketched in Fig. 1, the boundary conditions are formulated as shown below.

$$\frac{\partial \phi}{\partial z} = 0 \quad (\text{on } S_h) \quad (2)$$

$$\frac{\partial \phi}{\partial z} = 0 \quad (\text{on } S_q) \quad (3)$$

$$\frac{\partial \phi}{\partial x} = 0 \quad (\text{on } S_v) \quad (4)$$

For the incident boundary,  $S_s$ , at the left-hand side of Fig. 1, the velocity normal to this boundary is equal to the moving velocity of a wave paddle.

$$-\frac{\partial \phi}{\partial n} = \frac{\partial \phi}{\partial x} = U \quad (\text{on } S_s) \quad (5)$$

where  $U$  is the moving velocity of a wave paddle, which is calculated according to the wave maker theory for a given wave height and period. It should be noted that the depth-dependent velocity computed from the orbital velocity of water particle can also be utilized as the velocity  $U$ .

Two free-surface boundary conditions must be satisfied; the first condition is the kinematic boundary condition Eq. (6), and the second condition is the Bernoulli equation Eq. (7) with the assumption of constant pressure everywhere on the free surface.

$$\frac{\partial \phi}{\partial n} = \dot{\eta} \cos \beta \quad (\text{on } S_f) \quad (6)$$

$$\dot{\phi} + \frac{1}{2} \left\{ \left( \frac{\partial \phi}{\partial n} \right)^2 + \left( \frac{\partial \phi}{\partial s} \right)^2 \right\} + g\eta = 0 \quad (\text{on } S_f) \quad (7)$$

where  $\dot{\eta} = \partial \eta / \partial t$ ,  $\dot{\phi} = \partial \phi / \partial t$ ,  $g$  is the acceleration of gravity,  $n$  and  $s$  show the directions of normal and tangent vectors respectively, and  $\beta$  is the angle between the normal vector and the vertical axis.

Both of the free surface boundary conditions are nonlinear and are applied on the free surface, the elevation of which is not known *a priori*.

In order to simulate wave motions for a long duration, an appropriate boundary condition has to be introduced at the vertical boundary  $S_e$ , at the right-hand side of Fig. 1 so that the waves can pass through the boundary without undergoing significant distortion and without influencing the interior solution. A variety of methods have been developed to achieve the non-reflectivity at the boundary for wave propagation problems. Among various methods proposed, use of the Sommerfeld boundary condition appears most appropriate. In this study, we shall utilize the Sommerfeld boundary condition at the boundary  $S_e$ ; therefore, the boundary condition at  $S_e$  can be defined as:

$$\frac{\partial \phi}{\partial x} = -\frac{1}{C} \frac{\partial \phi}{\partial t} \quad (\text{on } S_e) \quad (8)$$

where  $C$  is the phase speed of the wave, and is approximated with that derived by the linear wave theory.

## 3 Numerical Results

### 3.1 Propagating Wave Profile

A study of wave deformation on the step was made through the numerical analysis by the present model and experiment. A numerical flume composed of 105 elements on the free surface and 63 elements on the bottom and lateral boundaries was created. The water depth was set at 0.376 m in front of the step and 0.113 m on the step, the step height of 26.3 cm was utilized. A wave period of 1.74 s was utilized in the computation. On the free surface, the element size of 20 cm was used in the deep water region and 10 cm was used in the shallow water region; these element sizes were equal to  $L/15.3$  and  $L/17.9$ , respectively. A time step of  $T/16$  were utilized in the computation. The spatial profile of wave propagation is computed by the present model and is plotted in Fig. 2. We can see from this figure that when waves enter into the shallow zone, the wave height increases, and the wave crest becomes much sharper than the wave trough, and the secondary crest is developed. The location of this secondary crest on the wave profile changes gradually as the wave propagates into the shallow water zone.

### 3.2 Comparison of Numerical and Experimental Results

In order to verify the results of the present model, a laboratory experiment was conducted in a 17 m long wave flume, equipped with a computer controlled piston-type wave generator. A rectangular step of the same height 26.3 cm as used in the numerical computation was installed in this flume. At the end of the flume, a flat plate of 2.0 m long was installed with a slope of 1/10. On the top of this plate, a wave absorber was placed to reduce wave reflection at the end of the flume. A wave period of 1.74 s was utilized for this experiment. A single wave gage was used to measure time-history wave profiles at 4 measuring points, at the distances of 1.0 m offshoreward from the tip of the step, and 1.0 m, 2.0 m, and 3.0 m inshoreward from the tip of the step.

The wave profiles computed by the present model are compared with the experimental results for four different locations as mentioned above. The comparisons are shown in Figs. 3. In the comparisons of wave profiles about 20 wave cycles were employed in order to have stable wave profiles. The profile of waves computed by the present model illustrates similar wave profiles in the both regions, in front of the step and on the step. The secondary wave crest is also well simulated having a similar shape compared with the experiments. Therefore, it is clear that the present model can accurately predict the wave profile of wave propagation over the rectangular step.

Both results have indicated that the wave profile on the rectangular step is different from that of sinusoidal waves; *i.e.*, the wave crest is much sharper than the wave trough, and a secondary crest is developed.

### 3.3 Higher Harmonic Components

The effect of finite amplitude on the amount of energy transferred to higher harmonic components of waves on the step was numerically and experimentally investigated. For this analysis, the water depth was set at 0.376 m in front of the step and 0.113 m on the step. The wave height was varied at three levels,

Figure 2: Wave propagating profile

Figure 3: Comparison of wave profiles

while the wave period was fixed at 1.74 s. From the results of wave profiles by numerical model and experiment, the FFT analysis are made to computed the amplitudes of all frequency components. In order to separate the transmitted waves from the reflected waves at the end of the flume, the resolution technique introduced by Goda and Suzuki (1976) is employed. Then, the potential energy of the first, second and third harmonics are computed. In Fig. 4, the ratios of maximum energy of the second and third harmonics to that of the first harmonic are plotted against the relative wave height, the ratio of the height of incident waves  $H_{in}$  to the water depth on the step  $h_2$ . The relative energy is found to be 0.2~0.4 for the second harmonic and 0.01~0.09 for the third harmonic. Therefore, the energy transferred to higher harmonic components is very significant compared with that of the first harmonic.

Figure 4: Relative energy of higher harmonic components

## 4 Analysis of the Height of Nonlinear Waves

### 4.1 Conventional Methods

The reflection of water waves is known to associate with every problem of wave and structure interaction. In order to estimate wave heights of incident and reflected waves, we need to have an information of reflection coefficient, or the ratio of reflected to incident wave heights. Up to now, many techniques have been proposed by various researchers, Healy (1953), Thornton and Calhoun (1972), Goda and Suzuki (1976), Morden *et al.* (1976), Mansard and Funke (1980), and others for the estimation of wave reflection. The method introduced by Healy is based on a measurement of wave profile with a single wave gage which is traversed over a distance of more than a half wave length. The methods of Thornton and Calhoun,

Goda and Suzuki, and Morden *et al.* are based on a simultaneous measurement of wave profile at two positions on a line parallel to the direction of wave propagation. Meanwhile, the method by Mansard and Funke employs three-points measurements of the wave profile.

The first method to be described herein is based on the assumption that the total energy is equal to the summation of the energies of incident and reflected waves. The method is later referred as the method (a) in the calculation of wave height of experiments. The formulation of this method can be summarized as follow :

$$E = E_{in} + E_{rf} = \frac{1}{8} \rho g (H_{in}^2 + H_{rf}^2) = (1 + K_{rf}^2) \frac{1}{8} \rho g H_{in}^2 \quad (9)$$

where the subscripts "in" and "rf" refer to the incident and reflected waves respectively, and  $K_{rf}$  is the reflection coefficient. This reflection coefficient is estimated as the ratio of the amplitude of the fundamental component of reflected waves to that of incident waves which are computed by utilizing the resolution technique of Goda and Suzuki (1976).

From Eq. (9), the incident wave height can be computed as

$$H_{in} = \sqrt{\frac{8E}{\rho g(1 + K_{rf}^2)}} = \sqrt{\frac{4(E_1 + E_2)}{\rho g(1 + K_{rf}^2)}} = \sqrt{\frac{4}{\rho g} [(E_1)_i + (E_2)_i]} \quad (10)$$

where

$$(E_1)_i = \frac{E_1}{1 + K_{rf}^2}, \quad E_1 = \frac{1}{2} \rho g \sum_{i=1}^{n/2} (a_i^2 + b_i^2)_1$$

$$(E_2)_i = \frac{E_2}{1 + K_{rf}^2}, \quad E_2 = \frac{1}{2} \rho g \sum_{i=1}^{n/2} (a_i^2 + b_i^2)_2$$

and  $E_1$  and  $E_2$  are the energy calculated from all fourier components of the first and second wave gages, respectively.  $a_i$  and  $b_i$  are the amplitudes of sine and cosine terms obtained from the Fourier analysis of recorded wave profiles, respectively. The subscripts 1 and 2 represent the first and second wave gages, respectively.

The second method, to be referred as the method (b), is the method introduced by Goda and Suzuki (1976) for the calculation of wave heights of incident and reflected waves of irregular waves. The method is based on two main assumptions. The first one is that the energy of composite waves is represented with the sum of the energies of individual wave trains. The second one is that the proportionality of representative wave heights to the square root of wave energy holds for such composite wave too, regardless of the directions of individual wave trains. In general, the basic concept of the approach is similar to that the first method, except that the energy is estimated from the wave height of zero-crossing method. The wave height of incident waves of this method can be computed as

$$H_{in} = \frac{1}{2\sqrt{1 + K_{rf}^2}}(\bar{H}_1 + \bar{H}_2) \quad (11)$$

where  $\bar{H}_1$  and  $\bar{H}_2$  are the average wave heights computed by the zero-downcrossing method of the first and second wave gages, respectively.

## 4.2 Method by Kittitanasuan et al. (1993)

In the calculation methods of wave heights of incident and reflected waves described above, the reflection of waves is treated as a single value of the reflection of fundamental component, but the harmonic components of incident and reflected waves are not given appropriate consideration. As illustrated by Kittitanasuan *et al.* (1993), the second and third harmonic components play an important role on waves propagating in the shallow water. Therefore, these harmonic components should be considered in the calculation of the height of waves exhibiting nonlinear behavior. In this study, the method proposed by Kittitanasuan *et al.* for the calculation of wave height when waves contain enhanced higher harmonic components will be reviewed. The basic concept of this method is the conservation of energy density over a range of frequencies. The energy is considered to preserve within the range of major frequency components, *i.e.* the first, second and third harmonic components. In this method, the reflection of each harmonic component is treated individually. That means the energy density of incident and reflected waves are computed from the summation of energies of all resolved components of incident and reflected waves, respectively. In the resolution of incident and reflected components, the technique introduced by Goda and Suzuki (1976) is utilized.

According to this method, the wave height is calculated by converting the energy of all resolved incident and reflected components as shown in the following.

$$H_{in}^* = 2\sqrt{\frac{2E_{in}}{\rho g}} \quad ; \quad H_{rf}^* = 2\sqrt{\frac{2E_{rf}}{\rho g}} \quad (12)$$

where

$$E_{in} = \frac{1}{2}\rho g \sum_{i=f_{min}}^{f_{max}} (a_{in})_i^2 \quad ; \quad E_{rf} = \frac{1}{2}\rho g \sum_{i=f_{min}}^{f_{max}} (a_{rf})_i^2 \quad (13)$$

in which  $(a_{in})_i$  is the amplitude of a resolved component of incident waves and  $(a_{rf})_i$  is that of reflected waves.  $f_{min}$  and  $f_{max}$  are the minimum and maximum frequencies corresponding to the resolution technique.

Use of the whole energy is made to minimize the effect of energy spreading around the harmonic frequencies by the FFT analysis. In fact, the energy of frequency components outside the three consecutive frequencies around the harmonics was less than 5% in the present analysis.

By knowing these wave heights, the reflection coefficient can be calculated as follow :

$$K_{rf} = \frac{H_{rf}^*}{H_{in}^*} \quad (14)$$

The transmission coefficient,  $K_{tr}$ , can also be calculated as the ratio of the representative incident wave height on the step to the representative incident wave height in front of the step.

Figure 5: The comparison of computed wave heights

The three methods, methods (a), (b) and method by Kittitanasuan *et al.* (1993), were applied for the experimental data on the step. The water depths were set at 0.376 m in front of the step and 0.113 m on the step. A wave period of 1.74 s are utilized. The comparison of results of these three methods are illustrated in Fig. 5. The wave height computed by the method by Kittitanasuan *et al.* give a slight fluctuation of wave height along the shallow zone, and meanwhile the other two conventional methods give considerable fluctuations of wave heights. Among the three methods, it is evident that the method proposed by Kittitanasuan *et al.* yields the smallest fluctuation of the wave height on the step. Therefore, this method will be utilized for the computation of wave height through out the present study.

If we compare the wave heights computed from the methods (a) and (b) with that of Kittitanasuan *et al.* (1993), the method (a) is seen to under-estimate, and the method (b) tends to over-estimate the wave height. In the partial standing wave system, the maximum and minimum vertical displacements are results of the superposition of the profiles of the incident and reflected waves. When the wave height is measured directly by these maximum and minimum displacements as in the zero-crossing method, there is a possibility of over-estimation of the wave height.

The fluctuation of the wave heights computed by the two conventional methods was investigated. A relatively high reflection of waves from the wave absorber at the end of rectangular step is considered to be the reason of the fluctuation. The maximum wave reflection coefficient computed at all measuring points is found to be 0.26. The variation of wave height shown in Fig. 5 is considered to be corresponding to the wave height envelope in the partial standing wave system. Therefore, the wave length estimated by the wave height envelope was examined to confirm the assumption. The estimated wave length is 1.80 m, and this length corresponds to the wave length computed from the dispersion relationship of linear wave theory which is 1.79 m for this case. Therefore, we can conclude that the fluctuation of wave heights computed by the two conventional methods is caused by the reflection of waves at the end of rectangular step.

## 5 Reflection and Transmission Coefficients

### 5.1 Coefficients of Nonlinear Wave Reflection and Transmission

The numerical model based on the boundary element method described earlier is used to compute the profile of wave propagating over a rectangular step. The free surface boundary was discretized into 104 elements, 36 elements in the deep water side and 68 elements in the shallow water side. Besides the free surface boundary, there were 63 elements on the bottom and lateral boundaries. The element size on the free surface is selected to include the first three major harmonic components in the resolution of reflected waves. This element size is ranged between  $L/18.1$  to  $L/16.1$ . Three levels of water depth ratio  $q$ , the ratio of water depth on the step to the water depth in front of the step, were setup. The computations were conducted for 45 cases, 15 cases for each water depth ratio  $q$ . Three values of the relative wave depth on the step  $h_2/L_0$ , 0.025, 0.05 and 0.1, are utilized in the computations. The incident wave height is varied from 1% of water depth on the step to 26% of water depth on the step for the maximum case. A time step of  $T/16$  is used for all the computations. After obtaining time-history displacement of all nodal points, the wave height of incident, reflected and transmitted waves are computed by using the technique proposed by Kittitanasuan *et al.* (1993). Because of the spatial variation of wave heights on the step, the reflection and transmission coefficients are computed based on their average values.

The reflection coefficients of a rectangular step computed by the present model are illustrated in Fig. 6. The reflection coefficients computed by the analytical solutions derived by using Ijima's technique, are also included in these figures. The reflection coefficients computed by the present model give nearly the same values as those computed from the analytical solutions for  $q = 0.5$  and  $0.3$ . For  $q = 0.1$ , the reflection coefficients computed by the model give smaller values than those computed from the analytical solution for  $h_2/L_0$  less than 0.05. From these figures, it is seen that the incident wave height has a rather small effect on the reflection coefficients.

The transmission coefficients of waves propagating over a rectangular step computed by the present model are exhibited in Fig. 7. The transmission coefficients computed by the present model give nearly the same values as those computed by the analytical solution for the water depth ratio  $q$  of 0.5 and 0.3.

However, the coefficients by the present model yield lower values than those of the analytical solution for  $q=0.1$ . From the results of these transmission coefficients, the coefficients increase as the incident wave height increases for the relative depth  $h_2/L_0$  less than 0.05. However, the effect of this wave height is quite small.

Figure 6: Comparisons of nonlinear and linear reflection coefficients

Figure 7: Comparisons of nonlinear and linear transmission coefficients

Figure 8: Comparisons of wave reflection and transmission coefficients,  $K_{rf}$  and  $K_{tr}$  ( $h = 0.376$  m,  $qh = 0.113$  m,  $T = 1.74$  s)

Figure 9: Comparisons of wave reflection and transmission coefficients,  $K_{rf}$  and  $K_{tr}$  ( $h = 0.376$  m,  $qh = 0.113$  m,  $T = 1.30$  s)

## 5.2 Comparison of Reflection and Transmission Coefficients with Experimental Data

Laboratory experiments were conducted to verify the reflection and transmission coefficients computed by the present model. The wave flume installed with a rectangular step of 26.3 cm high was used in these experiments. The water depth was set at 0.376 m in front of the step and 0.113 m on the step, the water depth ratio  $q$  is equal to 0.3. Comparisons between the reflection and transmission coefficients by the present model, Ijima's solution, and the experiments were made for two different cases of wave period. For the first case, a wave period of 1.74 s was utilized. In the comparison of the coefficients shown in Fig. 8, both Ijima's solution and the present numerical model show an identical prediction of the reflection coefficient  $K_{rf}$  which almost agree with the experimental results. For the transmission coefficient  $K_{tr}$ , the result from the present model gives a better agreement with the experimental result than that of Ijima's solution.

For the latter case, the water depths were 0.376 m offshoreward and 0.113 m inshoreward from the tip of the step and the wave period was 1.3 s. In the comparison of the reflection coefficient with Ijima's solution and experiments shown in Fig. 9, the reflection coefficient computed from the present model and Ijima's solution are almost the same. They are in agreement with the experimental data, with the exception of under-prediction for the wave height ratio,  $H_{in}/h_2$ , less than 0.2. In the comparison of transmission coefficient with Ijima's solution and experiment, the result of the present model shows a better agreement with the experiment than that of Ijima's solution.

## 6 Conclusions

Analysis of the coefficients of nonlinear wave reflection and transmission has been made through the present numerical model and experiments, and major conclusions can be described as follows:

1. The numerical model utilizing the boundary element method has been confirmed to accurately predict the profiles of nonlinear waves propagating over a rectangular step, as demonstrated by comparison with experimental data.
2. Waves propagating over a rectangular step are found to exhibit highly nonlinear behavior exemplified by the enhancement of the energy of the second and third harmonic components.
3. A representative wave height based on the assumption of the conservation of energy density is proposed for a situation in which higher harmonic components maintain a significant amount of wave energy. This definition provides a consistent estimate of wave heights on a rectangular step, where the conventional definitions produce a considerable fluctuation of wave heights.
4. The wave reflection and transmission coefficients computed by the model of nonlinear wave propagation over the step are close to the coefficients computed by the solution of Ijima (1971) with the exception of the water depth ratio  $q$  equal to 0.1. For this case of water depth ratio, the coefficients computed by the model yield smaller values than those of the analytical solutions.

5. The effect of finite amplitude on the reflection and transmission coefficients of wave propagation over the step is found small as long as the energies of higher harmonic components are taken into account.

## CHAPTER 91

# Oscillatory Motions and Permanent Displacements of Caisson Breakwaters Subject to Impulsive Breaking Wave Loads

P. Klammer <sup>1)</sup>; H. Oumeraci <sup>2)</sup>; H.-W. Partenscky <sup>3)</sup>

### Abstract

Small-scale model tests were recently conducted in a wave flume at the University of Hannover in order to study in more detail the relationship between impulsive loading induced by waves breaking on a caisson breakwater and subsequent displacements of the latter. These experiments are briefly described and some first results are discussed. Thereby, particular emphasis is put on the relationships between (i) oscillatory motions and permanent displacements, (ii) wave loading and oscillatory motions and (iii) wave loading and permanent displacements.

The findings presented in this paper are intended to improve the understanding of the stability of caisson breakwaters subject to impulsive breaking wave loads and to help developing proper tools for the dynamic analysis of such structures.

### Introduction

When a monolithic breakwater is subject to a sequence of breaking wave loads, both oscillatory and permanent displacements develop. The peak amplitudes of the former may exceed the ultimate resistance of the foundation, thus resulting in relatively smaller but residual deformations. The latter cumulate, leading to large permanent displacements which may cause the structure to collapse.

<sup>3)</sup> Prof. Dr.-Ing. Dr. phys., formerly Director of Franzius-Institut, University of Hannover, SFB 205

In this respect, hydraulic model tests on the impulsive loading and dynamic response of caisson breakwaters using improved measuring techniques for the motions of the structure were conducted at the University of Hannover, SFB 205/TP B3. These tests principally aim at establishing relationships as shown in Fig. 1, i.e. (i) between incident wave parameters and impulsive loading (TF1), (ii) between impulsive loading and dynamic response (TF2), and (iii) directly between incident wave parameters and dynamic response (TF3).

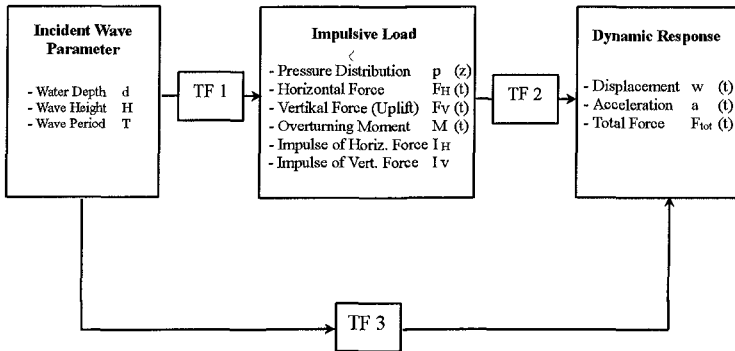

Fig. 1- Definition of Relationships under Study

With the present paper it is intended to discuss some of the results of these investigations, particularly the relationship between the oscillatory motions and the permanent displacements, as well as those between the loading and the response of the structure.

Additional calculations of the safety factor against sliding and overturning and comparison with measurements of the permanent displacements are also presented.

### **Experimental Set-Up, Measuring Techniques, Tests-Conditions and Procedures**

The tests were conducted in a wave flume with 110 m length, 2.2 m width and 2.0 m depth in which both regular and random waves with maximum wave heights up to 40 cm and periods up to 4 s can be generated. The caisson model consists of two distinct parts which can move independently of each other. The first part of the caisson model, for which a cross-section is shown in Fig. 2, is used for the measurement of the impact pressure on the front of the caisson, the uplift pressure on the caisson bottom, as well as the acceleration and displacements of the caisson.

For the pressure measurements piezo-electric pressure transducers of type PDCR 830 from Natec Schultheiss were used which a natural frequency of 28 - 360 kHz and a pressure range from 0.35-5 bar. For the measurement of the acceleration of the caisson three high output accelerometers of type Seitner Model JA-5-M19 with a range of  $\pm 1$  g and  $f_{max} = 200$  Hz are installed at the front top (one vertical) and at the rear top (one vertical and one horizontal) of the caisson.

For the measurement of the caisson motions, a displacement meter of type W2 ATK from Hottinger Baldwin Meßtechnik with the range of  $\pm 2$  mm and a failure of  $\pm 0.2$  %. The displacement transducer is able to record permanent and oscillatory motions of the caisson, while the accelerometers are intended to measure only the latter.

Fig. 2- Instrumented Model Caisson Breakwater

On the second caisson part only total horizontal force measurements behind the structure were performed (shear forces). For this purpose two 20 kN force transducers of type U2 A from Hottinger Baldwin Meßtechnik were used. All these measurements (waves, pressure, total forces, accelerations and displacements), as well as video records were performed simultaneously.

For three different water depths (0.90, 1.00 and 1.10 m) regular and irregular wave tests were conducted with wave heights ranging from 0.10 up to 0.3 m and wave periods from 1.9 - 3.2 s.

**Experimental Results**

**(a) Relationship Between Oscillatory Motion and Permanent Displacements**

A typical time series of the oscillatory motions and permanent displacements of the model caisson breakwater induced by waves ( $H_{max} = 0.30$  m,

$T = 2.4$  s,  $d = 1.00$  m) plunging on the structure front is shown in Fig. 3. The related horizontal force  $F_H$  and uplift force  $F_V$  which induce the permanent displacement  $a_r$  and the oscillatory motion  $x_t$  are shown in Fig. 4.

Fig. 3- Oscillatory Motions and Permanent Displacements of the Caisson Breakwater

Fig. 4- Horizontal Force  $F_H$  and Uplift Force  $F_V$  Responsible for Caisson Motion in Fig. 3

In order to get an idea about the relations between  $x_t$  and  $a_r$ , the peak values of the oscillatory motions are plotted against the permanent displacements (Fig. 5).

Fig. 5- Peak Values of Oscillatory Motions vs. Permanent Displacements

It is seen from Fig. 5, that:

- for smaller peak amplitudes  $x_t$  of the oscillatory motions (generally  $x_t < 0.1$  mm), almost no permanent displacements  $a_r$  occur;
- for amplitudes  $x_t > 0.1-0.15$  cm, relatively larger permanent displacements  $a_r$  start to occur, suggesting that there is some threshold value of  $x_t$  for which a permanent displacement is initiated;
- despite the scatter of the recorded values, there is a clear tendency of the amplitudes  $a_r$  of the permanent displacements to increase "exponentially" with increasing peak amplitudes  $x_t$ . This relationship strongly depends on the weight of the caisson.

**(b) Relationship Between Wave Loading and Oscillatory Motions of Caisson Breakwater**

A typical result is given by Fig. 6 showing the horizontal impact force, the uplift force, the total overturning moment around the caisson heel and the resulting motions of the caisson in non-dimensional form ( $H = 0.30$  m,  $T = 2.4$  s, water depth  $d = 1.00$  m)

Fig. 6- Simultaneously Recorded Impact Loading and Motions of Caisson Breakwater

For the study of the relation between wave loading and the magnitude of the peak amplitude of the caisson motions  $x_t$ , the horizontal impact force, the uplift force and the total overturning moment around the caisson heel are considered.

Despite the large scatter of the measured values it is seen from Fig. 7 that the peak amplitude  $x_t$  first increase at a higher than at a lower rate with increasing peak of the horizontal force  $F_{hmax}$ .

Fig. 7- Peak Amplitude of Oscillatory Motions vs. Horizontal Impact Force

Fig. 8- Peak Amplitude of Oscillatory Motions vs. Uplift Force

Fig. 9- Peak of Oscillatory Motions vs. Peak of Total Overturning Moment

Almost the same tendency is depicted in Fig. 8 for the relationship between the peak values of the oscillatory motions and the peak values of the uplift forces. The resulting effect of the uplift and the horizontal impact force is shown in Fig. 9 as peak values of the total overturning moment vs. the peak amplitudes of the permanent displacements.

### **(c) Relationship Between Wave Loading and Permanent Displacements**

For the study of the relationship between wave loading and permanent displacements  $a_r$ , the horizontal impact force, the uplift force and the total overturning moment around the caisson heel are considered.

The permanent displacements  $a_r$  are plotted against the peak amplitudes of the horizontal impact force, the uplift force and the total overturning moment in Figs. 10, 11 and 12, respectively.

As compared to Figs. 7, 8, and 9 for the oscillatory motion there is no clear relationship between the wave loading and the permanent displacements. A large scatter is present on the peak values of the critical loading at which a permanent displacement starts to occur, illustrating the fact other characteristics of the loading may also be determinant for the initiation and the magnitude of the permanent displacements.

Fig. 10- Permanent Displacements vs. Horizontal Impact Forces

Fig. 11- Permanent Displacements vs. Uplift Forces

Fig. 12- Permanent Displacements vs. Peak of Total Overturning Moment

#### d) “Safety Factor“ against Sliding

A kind of “safety factor“ against sliding  $\eta_s$  is defined as the ratio of  $F_R/F_{hmax}$  in which the shear resistance or friction force is expressed as

$$F_R = \mu \cdot (W_{cai} - F_V),$$

where  $\mu$  is a “dynamic“ friction coefficient ( $\mu=0.5$ ),  $W_{cai}$  is the weight of the caisson (dry and submerged part) and  $F_V$  is the maximum uplift force (Fig. 13). The horizontal impact force  $F_{hmax}$  is obtained by integrating the pressure recorded on the front face of the caisson.

Plotting the related time history of the measured caisson motions (scaled on the left y-axis) and the calculated safety factor  $\eta_s$  (right y-axis) in Fig. 14 for one event, it can be seen that the displacement of the caisson is initiated for  $\eta_s < 1$ .

Fig. 13- Definition Sketch

Plotting the related time history of the measured caisson motions (scaled on the left y-axis) and the calculated safety factor  $\eta_s$  (right y-axis) in Fig. 14 for one event, it can be seen that the displacement of the caisson is initiated for  $\eta_s < 1$  (test conditions:  $H= 0.30$  m,  $T= 2.4$  s,  $d= 1.0$  m).

Fig. 14- Related Time History of Measured Displacement and Calculated “Safety Factor“  $\eta_s$

This result is confirmed by a set of more than 40 impacts caused by regular waves where the ratio of  $F_R$  and  $F_{Hmax}$  is plotted against the permanent displacement of the caisson (Fig. 15). It is seen that permanent displacement occurs only for  $\eta_s < 1$ .

Fig. 15- "Safety Factor" vs. Permanent Displacement

The ratio  $\eta_R = M_R / M_{tot}$  is also considered in analogy to the safety coefficient against overturning, where  $M_R$  is the resistive moment (due to the weight of the caisson) and  $M_{tot}$  the maximum overturning moment around the caisson heel induced by the horizontal peak force  $F_{Hmax}$  and the maximum uplift force  $F_{vmax}$ . It can be seen from Fig. 16 that permanent displacement may occur even for values  $\eta_R > 1$ .

Fig. 16- "Safety Factor"  $\eta_R$  against vs. Permanent Displacements of the Caisson

**e) Cumulative Effect of Permanent Displacements**

As already mentioned above the effect of the impulsive loading induced by waves breaking on the structure is not only limited to small amplitude oscillatory motions of the caisson breakwater. It also consists in incremental small permanent displacements which may cumulate and lead to the collapse of the structure.

Fig. 17 shows the total overturning moments calculated from the horizontal and uplift forces on the caisson induced by a sequence of breaking wave loads and the resulting oscillatory motions and permanent displacements.

Fig. 17- Cumulative Effect of Permanent Displacements Induced by a Sequence of Breaking Wave Loads (see Fig. 18)

The cumulative effect of permanent displacements may lead to a stepwise failure of the caisson (Fig. 18). This effect is very important and should be taken into account in future design methods, analysis and numerical modelling.

Fig. 18- Stepwise Failure of Caisson Breakwaters Induced by a Sequence of Breaking Wave Loads (see Fig.17)

#### **4. Concluding Remarks**

Although the analysis of the results of the hydraulic model tests is not yet completed they clearly show that the effect of the impulsive loading induced by waves breaking on the structure is not only limited to small amplitude oscillatory motions of the caisson breakwater. It also consists in incremental small permanent displacements which may cumulate and lead to the collapse of the structure.

On the other hand, these first results show that future analysis and numerical models to be developed for the prediction of the stability of caisson breakwaters should also necessarily account for the stepwise failure resulting from the incremental residual displacements (plastic deformations) induced by successive breaking waves on the structure.

#### **5. Acknowledgements**

This study is part of a research programme on breakwaters within the Coastal Engineering Research Unit "SFB 205" at the University of Hannover which is supported by the German Research Council (DFG), Bonn.

## CHAPTER 92

### Hydraulic Characteristics and Field Experience of New Wave Dissipating Concrete Blocks (ACCROPODE)

Masanori Kobayashi<sup>1</sup>, Sumio Kaihatsu<sup>1</sup>

#### ABSTRACT

More than 30,000 pcs. of the ACCROPODE blocks have been applied for the wave dissipator of the breakwaters and the revetments at the Haramachi thermal power station where construction works of the harbor started about four years ago.

Since the ACCROPODE has not been used in Japan beforehand, hydraulic model tests were needed to examine its characteristics and to confirm the feasibility to the project, although extensive tests have been made in the world.

This paper describes the results of tests on the stability, reflection and transmission coefficients of the ACCROPODE blocks and the field experience at the Haramachi power station. Much reduction of the construction costs and good stability against storm waves attacked were obtained which showed its super usage as the wave dissipator.

#### INTRODUCTION

Tohoku Electric Power Company in Japan is now constructing the Haramachi thermal power station. This power station has 2 units of 1,000 MW coal fired thermal power plants, and a port facility capable of mooring a 60,000 DWT class coal carrier ship (Fig.1).

The total length of breakwaters and of revetments are 3.0 kms and 2.5 kms respectively. For the breakwaters two types were employed, one is the rubble-mounded type of 0.7 kms long for the coast shallower than 10 meters and the other is the caisson composite type of 2.3 kms long for the

1. Civil Engineering Dept., Tohoku Electric Power Co., Inc.  
3-7-1 Ichiban-cho Aoba-ku Sendai 980, JAPAN

Fig.1 Plan View of The Haramachi Thermal Power Station

deeper zone than 10 meters. Selection was made mainly by the reason of construction costs.

Since 1984 until 1989 the staff members of the civil engineering department of Tohoku Electric Power Company had continued the contact with SOGREAH on the ACCROPODE blocks to be used for the mound of breakwaters and revetments because of the high stability, the financial benefit and the easy construction method. Final decision of employing the ACCROPODE was made through the hydraulic model tests conducted independently by the company itself which confirmed the preceding tests in the world with the detailed data of the reflection and transmission coefficients not supplied beforehand.

This paper describes the results of the tests and the field experience of the Haramachi project exposed to the ocean storm waves up to date without any harm.

## DESCRIPTION OF TESTS

### *Experimental Equipment*

The wave flume in which the model tests were conducted, is shown in Fig.2. It is a two dimensional wave flume, 34 meters long, 5 meters wide, and 1.2 meter deep. The scale was 1:50, following the Froude similarity. The foreshore slope was uniform with 1:100, simulating the sea bottom of the Haramachi field. The tests were carried out by waves generated with the power spectra of the Bretschneider-Mitsuyasu type.

Fig.2 Wave Flume

Fig.3 Cross Section of Rubble-mound Breakwater Model

*Test Conditions*

The cross section of the rubble-mound breakwater model is shown in Fig.3. The test conditions are shown in Table 1. More than 20 tests were conducted under various combination of these conditions which are probably expected in the project site.

Table 1 Test Conditions

	Model	Field
Water depth at the structure	20 cm, 30 cm, 40 cm	10 m, 15 m, 20 m
Wave period	1.2 sec, 1.7 sec 2.0 sec, 2.3 sec	8.5 sec, 12.0 sec 14.1 sec, 16.3 sec
Armour layer (ACCROPODE)	74.0 g, 166.3 g	9.3 t, 20.8 t
Filter layer (gravel)	20-30 g	3-4 t
( $\gamma\ell$ block)	32.8 g, 73.6 g	4.1 t, 9.2 t
Core (gravel)	0.5-4 g	50-500 kg

The ACCROPODE blocks were installed in the armour layer, and two types of the ACCROPODE blocks, 74.0 g and 166.3 g, were used.

In the filter layer, gravels and two types of the  $\gamma\ell$  blocks 32.8 g and 73.6 g were used. The  $\gamma\ell$  block is the artificial concrete block, used in lieu of the large rubble stone.

The core was made of gravels which weight was from 0.5 g to 4 g equivalent to 50 kgs to 500 kgs in the field.

The slope of armour face was fixed as 1:1.33 as shown in Fig.3. Owing to the report by CSIR (Holtzhausen and Zwamborn, 1991, Ref.1), the 1:2 slope was more stable than the 1:1.33 slope and the 1:1.5 slope but the rocking displacement before the failure was more remarkable than the latters. On the other hand interlocking by the initial shake down causes units to pack more densely for the 1:1.33 slope while units do not pack much closer during shifting on a flat slope. This was the main reason of this slope which was strongly recommended by SOGREAH.

The tests were carried out with three types of the water depth at the structure, from 20 cm to 40 cm deep, and four types of the significant wave period, from 1.2 sec to 2.3 sec.

In the Haramachi project, design conditions are as follows that the maximum water depth at the breakwater is 10 meters, equivalent to 20 cm in the model, and the design wave period for the significant wave is 16 sec, equivalent to 2.3 sec in the model.

In each cases the crest height of the model above the sea level was 11 cm, equivalent to 5.5 meters in the field.

#### *Arrangement of the ACCROPODE*

The arrangement of the ACCROPODE in the tests is shown in Fig.4. The centers of gravity of each block are plotted in white and black, where H is the height of the block.

The horizontal spacing is 1.24H along horizontal lines, and the distance between each horizontal lines is 0.6H. The thickness of the armour layer is 0.9H.

Fig.4 Arrangement of The ACCROPODE

*Definition of damage*

In order to estimate the stability of the ACCROPODE, the damage ratio of the armour layer is defined as follows,

$$D = (n/N) \cdot 100 \tag{1}$$

where,

- D: the damage ratio (%)
- N: the total number of blocks in the test area
- n: the actual number of blocks displaced more than the height of the block

The definition of the test area is shown in Fig.5. The area, from 1.5Hs ( Hs:significant wave height ) below the still-water level to the crest of the model, and 1.0 meter wide, is the test area. In this test area from 200 pcs. to 300 pcs. of the ACCROPODE blocks were included.

According to this definition, 2% of the damage ratio is nearly equivalent to the condition of severe damage.

Fig.5 Test Area

## RESULTS OF TESTS

### *KD and Ns values*

The damage ratio  $D$  versus  $KD$  and  $N_s$  values are plotted in Fig.6. The  $KD$  value is the Hudson stability factor. The  $N_s$  value is the stability number given by the following relation with the  $KD$  value.

$$N_s = H_s / \Delta D_n = (KD \cdot \cot \alpha)^{1/3} \quad (2)$$

where,

- $H_s$ : significant wave height in front of the structure
- $\Delta$ : relative mass density of the unit
- $D_n$ : nominal diameter of the unit
- $\alpha$ : slope angle of the structure

In these figures the filter layer is composed of gravels.

At 0% of the damage ratio, the  $KD$  value is estimated in the range of 30 to 50, from 3.5 to 4.0 equivalent in the  $N_s$  value. From these  $KD$  or  $N_s$  value, it can be said the initial stability of the ACCROPODE, in other words the stability against the start of damage is very high compared with the other artificial armour units.

In the region under 2% or 3% of the damage ratio, the  $N_s$  value increases with the rate much higher than that of the damage ratio. But in the region over 2% or 3% of the damage ratio, the  $N_s$  value scarcely increases with the increase of the damage ratio. The  $N_s$  values at the condition of no damage and severe damage (or failure) are very close with each other. This means that the structure fails progressively after damage started.

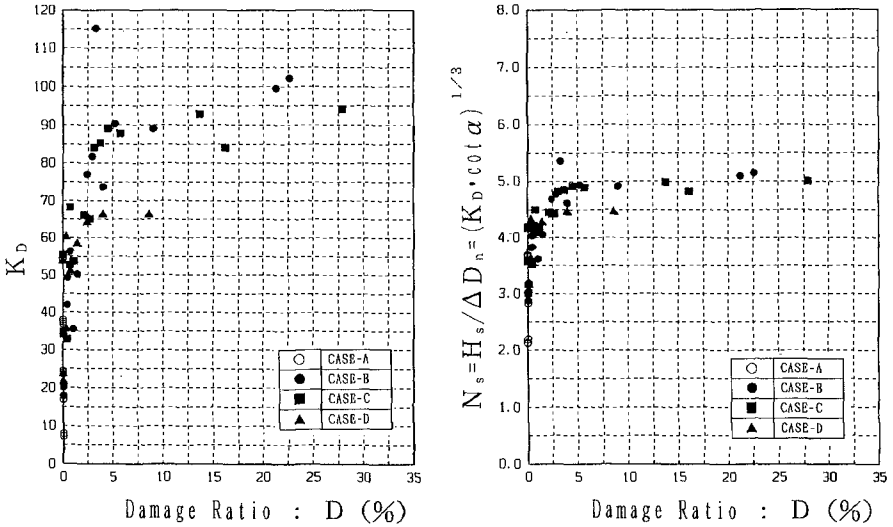

Fig.6 Damage Ratio vs.  $K_D$  &  $N_s$  Values  
(Filter Layer : Gravel)

All the tests carried out under the design condition of water depth at the structure (20 cm in the model) in the Haramachi project, could be found no damage at all.

*Influence of the wave period*

The Iribarren number, or the surf similarity parameter  $\xi z$  is defined as,

$$\xi z = \tan \alpha / (H_s / L_o)^{0.5} \tag{3}$$

where  $L_o$  is the deep water wave length derived by the wave period with zero up-crossing. Fig.7 shows the relation between the  $N_s$  values and the surf similarity parameter  $\xi z$  where the damage ratio is 0% or 2%. The filter layer is composed of gravels. In our tests,  $\xi z$  was in the range of 3 to 5.

In case of 0% of the damage ratio, even though the data is scattered, the  $N_s$  value has a tendency to decrease with the increase of  $\xi z$ . And in case of 2% of the damage ratio, such tendency is not so remarkable in compare to the cases of 0% of the damage ratio. We could find the influence of the wave period in case of the gravel filter.

In case of the  $\gamma \ell$  blocks used for the filter layer, the relation between  $\xi z$  and  $N_s$  is shown in Fig.8. From this figure, the influence of the wave period is not found.

Fig.7 Stability of The ACCROPODE  
(Filter Layer : Gravel)

*Effect of the filter layer's material*

From Fig.7 and Fig.8, it is found that the difference of the filter layer's material, gravels or the  $\gamma\ell$  blocks, has the influence on the stability of the armour layer. At the condition of no damage, the KD value will be estimated in the range of 30 to 50 in case of the gravel filter, showing higher stability than in case of the  $\gamma\ell$  block's filter in which case the KD value will be at only 20.

It could be estimated to choose the most favorable weight (or size) of the  $\gamma\ell$  blocks for the weight of the ACCROPODE units. However such relationship was not recognized since the unevenness of the filter setting seemed to be another origin of data scattering.

*Comparison of results with other investigations*

Fig.9 shows the comparison of results with other investigations, carried out by SOGREAH (Perdreau, 1983, Ref.4) and DELFT hydraulics laboratory (Van der Meer, 1987, Ref.2). Although the influence of wave period was found in case of the gravel filter, our present studies show similar results and tendency of the  $N_s$  value to other investigations.

It should be noted that the difference of the stability number between no damage and severe damage is very much small where  $\xi_z$  was 3 and increases with the increase of  $\xi_z$ . Holtzhausen and Zwamborn (Ref.1) gave caution that the time from start of damage to failure is shorter for steeper slopes.

Fig.9-1 Stability of The ACCROPODE by Different Investigations (at No Damage)

Fig.9-2 Stability of The ACCROPODE by Different Investigations (at Severe Damage)

*Reflection coefficient*

The reflection coefficient KR , as a function of the wave steepness is shown in Fig.10. All the data are distributed in the range of 0.25 to 0.6 of the reflection coefficient. It is found that the reflection coefficient increases with the increase of the water depth and the wave period. This tendency is similar to the characteristics of the other artificial armour blocks.

*Transmission coefficient*

Fig.11 shows the wave height transmission coefficient KT , as a function of the wave steepness in case of 40 cm water depth at the structure. Under the same condition of the wave steepness, the transmission coefficient had a tendency to become larger when the wave period became longer. The transmission coefficient was highly affected by the wave overtopping. Under non-overtopping condition the transmission coefficient was less than 0.2, but when overtopping started it increased up to 0.4.

In Fig.12 the transmission coefficient are plotted as a function of the relative crest height hc/Hs , where hc is the crest height above the sea level. In this figure, the typical curve of the transmission coefficient can be drawn.

Fig.10 Reflection Coefficient vs. Wave Steepness

Fig.11 Wave Transmission Coefficient vs. Wave Steepness

Fig.12 Wave Transmission Coefficient vs. Relative Crest Height ( $h_c/H_s$ )

### *Design conditions*

We decided the weight of the ACCROPODE blocks by the Hudson formula. The design wave height and the weight of the ACCROPODE are shown in table 2.

In the Haramachi project, three types of the ACCROPODE blocks, 14.5 t, 20.7 t, and 27.6 t, are applied to the rubble-mound breakwaters and revetments. As the filter layer, 9 t type of the  $\gamma\ell$  blocks are applied, mainly because of the difficulty of obtaining large stones as many as feeding to the site. The summation of these stones for the filter layer amounted to about 250,000 cubic meters.

The KD value of 10 was applied in our design. In case of the gravel filter, the KD value was estimated from 30 to 50 at no damage condition. But we reduced design KD value, considering the application of the  $\gamma\ell$  blocks in the filter layer, the failure mode, the randomness of installed blocks especially below the sea level, and the unprecedented experience in Japan.

The KD value could be increased even up to 15.

Table 2 Design Conditions

Water depth at the structure	2.0 m	6.0 m	8.0 m
	- 6.0 m	- 8.0 m	- 10.0 m
Slope angle ( $\cot \alpha$ )	1.25	1.33	1.33
Design significant wave height	4.9 m	5.9 m	6.7 m
ACCROPODE's weight (by Hudson's formula)	10.8 t	18.9 t	27.6 t
ACCROPODE's weight (applied)	14.5 t	20.7 t	27.6 t

FIELD EXPERIENCE*Installation of the ACCROPODE*

Total number of blocks which will be installed to the rubble-mound breakwaters and revetments, is about 12,000 pcs. in which about 11,000 pcs. were placed already.

In addition, we have a plan to place the ACCROPODE blocks, 9.2 t and 14.5 t, to the caisson-type composite breakwaters as armour units of the rubble foundation, and 3,000 pcs. have been already installed.

In the Haramachi project more than 30,000 pcs. of the ACCROPODE blocks will be installed in total.

1993. 3. 8.	4.94	10.8	Low Pressure
1993. 8.27.	4.61	10.9	Typhoon
1992.10.21.	4.11	10.2	Low Pressure

### *Experienced storm wave*

About four years have passed since we began to install the ACCROPODE blocks. Table 3 shows the 5 highest storm wave conditions attacked the construction site after installation. But we have experienced no harm thus far. The stability of the ACCROPODE blocks in the field were very much excellent.

The highest wave was 9.41 meters in the maximum wave height and 5.52 meters in the significant wave height, which occurred on Feb. in 1991.

The design wave conditions at the point of the wave observatory, about 1.8 km offshore, are following : The significant wave height is 7.6 meters, the maximum wave height is 11.9 meters, and the wave period is 16 sec.

As shown in Fig.1, waves attacked obliquely which showed the excellent characteristics even tests were conducted in two dimensional conditions.

### *Results in the field experience*

By applying the ACCROPODE blocks, the followings were recognized in the Haramachi project.

- 1) The area of the fabrication yard was rather small.
- 2) The moulding process was fairly easy, because of the simplicity formed by two symmetrical shells.
- 3) The settlement of blocks in the armour layer was almost completed in the range of 15 cm to 20 cm, after 7 days to 30 days following installation.
- 4) The void ratio of installed blocks was from 45% to 50%.
- 5) The strength of the block element was very high. Few or no blocks were broken.
- 6) The stability of the ACCROPODE in the armour layer against the wave force was good enough.
- 7) In comparison with other artificial blocks, quantity of concrete was saved about 30%, and the total construction costs for armour units, from production to installation to the rubble-mound breakwaters and revetments were reduced about 30%.

### CONCLUSIONS

For the Haramachi project, the hydraulic model tests were carried out on the rubble-mound breakwaters armoured with the ACCROPODE blocks. The followings were observed as conclusions.

- 1) The stability of the ACCROPODE at no damage was very high, but the criteria of no damage and failure were very close.
- 2) The filter layer's material had an influence on the stability of the ACCROPODE in the armour layer. In case of the gravel filter, the KD value was estimated in the range of 30 to 50, but in case of the  $\gamma \ell$  block's filter,

it was 20.

- 3) It was found that the wave period had an influence on the stability of the ACCROPODE in case of the gravel filter.
- 4) The reflection and the wave transmission coefficients were similar to the other artificial armour units.

Field experience showed successful achievement for the expense, the easy construction and the stability of the blocks.

#### ACKNOWLEDGEMENTS

The model of the ACCROPODE blocks were lent by SOGREAH, and their assistance is acknowledged with thanks.

## CHAPTER 93

### Experimental Study on Developing Process of Local Scour around a Vertical Cylinder

Tomonao Kobayashi<sup>1</sup> and Kenji Oda<sup>2</sup>

#### ABSTRACT

Time evolution of scoured seabed profiles around a vertical slender cylinder under waves has been investigated by means of laboratory experiments. The characteristics of the scoured bed profiles on the developing process is discussed considering the flow features. The local scoured bed profiles are classified with the location of the maximum scoured point. And the developing scouring process of each classified type is discussed. We found that for each scour type, the scoured bed retains a similar profile during its whole developing process. The ultimate scour depth on the vicinity of the cylinder surface is related to the Keulegan-Carpenter number, and it is independent of the sand bed condition.

#### 1. INTRODUCTION

Local scouring is an important factor to consider when the stability of offshore and onshore structures is analyzed, and different aspects of this have already been investigated by various researchers. Among them, Well and Sorensen (1970) based on laboratory experiments found relations of the ultimate scour depth to the Shields number, Reynolds number, etc. Sumer *et al.* (1992), also based on laboratory tests, proposed the scour depth as a function of the Keulegan-Carpenter (K.C.) number on the live bed, *i.e.* the bottom with continuous sediment motion. Nishizawa and Sawamoto (1988) studied the flow around a vertical slender cylinder under waves using flow visualization techniques, and reported relations between the flow characteristics and the K.C. number. Kobayashi (1993) measured in the laboratory the velocity distributions around a cylinder near the bed on both flat bottom and scoured bed, and discussed about the effect of the scoured seabed configuration on the vortex behavior near the bed around the cylinder.

In most of the available literature about the local scouring phenomenon around a vertical slender cylinder under waves, only the ultimate scoured bed

TABLE 1. Incident Wave Conditions at The Cylinder

Wave Height	$H$	13~60mm
Wave Period	$T$	1.3~3.0s
Water Depth	$h$	120mm
K.C. number	K.C.	3.95 ~ 30.0

is considered. To recognize this physical phenomenon, however, the developing process of the local scouring should also be studied.

The intent of the present study is therefore to recognize the characteristics of the developing process of the local scour around a cylinder under waves. For this purpose, first, the scoured bed profiles are classified into several typical scour types. Then, for each scour type the characteristics of the time evolution of the scoured bed profiles are discussed by considering the flow features on the bed. Finally, relations of the ultimate scour depth to the typical parameters are also discussed.

2. EXPERIMENTAL APPARATUS

Figure 1 shows a sketch of the wave flume employed. The size of this flume is 8 m in length, 300 mm in width and 150 mm in height. Both flume lateral walls are made of glass to facilitate the observations. Part of the bottom flume was lifted to make a movable bed, and in the transition from the bottom flume to the sand bed a slope was located. The bottom of a cylinder was inserted on the movable bed. To classify the local scoured bed profiles, a cylinder of 30 mm diameter was used for the experiments, and in the case of the time evolution of the local scouring experiments, the cylinder diameter was 22 mm.

The wave conditions at the cylinder are shown in Table 1. The maximum

(Unit : mm)

FIG. 1. Side View of Flume

TABLE 2. Sand Type

Sand type (Collected place)	Diameter $d_{50}$ (mm)	Specific weight $s$
Toyoura	0.17	2.569
Toyouni	0.16	2.556
Makuhari	0.20	2.525
Komesu	0.43	2.695
Oarai	0.17	2.643

velocity at the bottom, that is used to calculate the value of the K.C. number, is evaluated from the wave conditions shown in Table 1 by applying the linear wave theory. During the experiments, the five types of sand shown in Table 2 were employed, and the waves were produced until the scoured bed was considered to be almost stable.

All experiments were done under the clear water condition, because in this way, only the sand near the cylinder moves due to the secondary flow driven by the existence of the cylinder. Hence the characteristics of the flow near the bed around the cylinder are easy to recognize. This is an important matter to understand the local scouring process.

Scoured bed profiles were measured in two dimensions with a sand profile meter.

### 3. CLASSIFICATION OF SCOUR TYPE

The contour maps of the bed profiles around the cylinder in Fig. 2 show typical scour types that were observed during the experiments performance. In this figure, hatched areas indicate scoured regions. The Twin-Horn-Shaped and Cone-Shaped scoured bed profiles in this figure have already been studied by Nishizawa and Sawamoto (1988) among others. In this study, we found the following same results as those reported by them: in the Twin-Horn-Shaped bed the lee side of the cylinder is scoured, and in the case of the Cone-Shaped bed the scouring takes mainly place around the cylinder. When we were performing the experiments, we observed an additional scoured bed type as shown in Fig. 2 (b). Here, both the lee side of the cylinder and the vicinity of the cylinder are scoured. We classified this scour type as Transient-Shaped scoured bed. In this study therefore the scour bed profiles are classified into the categories: Twin-Horn-Shaped, Transient-Shaped and Cone-Shaped bed profiles. An example of each of these bed profiles is shown in Fig. 2. The classification mentioned above, based on the scoured bed profiles, is rather subjective. So, to classify objectively the scour types we introduce the use of the location of maximum scoured point.

Figure 3 shows the distribution of the maximum scoured points of all experimental cases. In this figure, the marks indicate the scour types classified with the scoured bed profile. Here, the Twin-Horn-Shaped bed profiles have two maximum scoured points which are located at both right and left lee sides of the

cylinder. In the case of Cone-Shaped bed profiles the maximum scoured point is located either in front of or beside the cylinder. The location of the maximum scoured point depends on the scour type, and we conclude therefore that this location can be applied to classify objectively the scour type. The maximum scoured point concept is applied for the following discussions.

To investigate the flow pattern near the bed around a cylinder, laboratory experiments were performed for several K.C. numbers. We observed that for low K.C. numbers, flow separation from the cylinder or a pair of symmetric vortices was generated, and this scoured the bed at the lee side of the cylinder. Finally, a Twin-Horn-Shaped scoured bed profile was formed. For large KC numbers, the Cone-Shaped scoured bed profiles were formed and an asymmetric vortex, similar to the Karman vortex appeared. Nishizawa *et al.* (1988) also observed the flow pattern under similar conditions. In general, our observations coincide with theirs. Except that they did not have any horseshoe vortex formation in any cases, even for the Cone-Shaped scored bed profile.

Based on these observations, we conclude that each scour type corresponds to a different flow pattern or vortex structures.

Figure 4 shows the relation of local scour type to the K.C. number. The

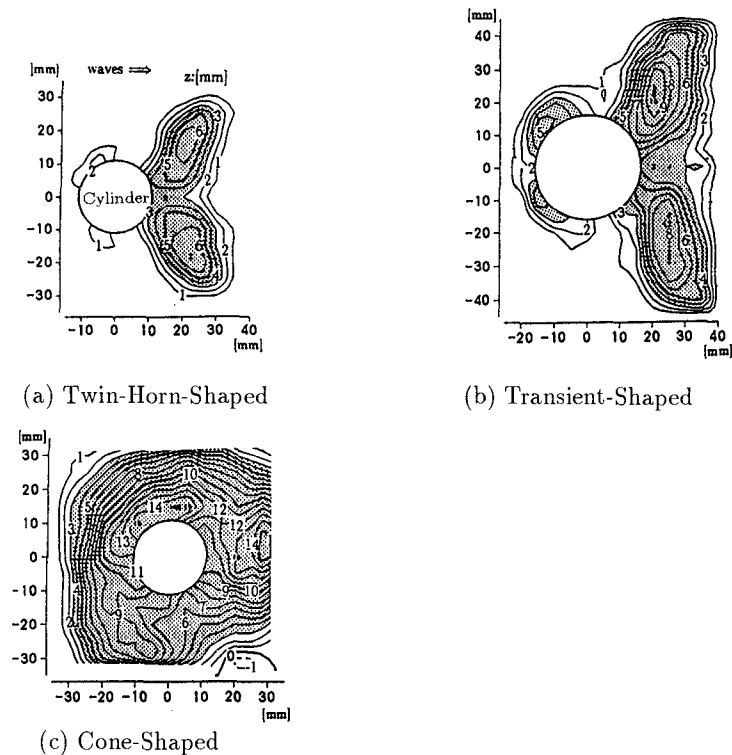

FIG. 2. Typical Scour Bed Profiles

FIG. 3. Distribution of Maximum Scoured Points of All Experimental Cases

FIG. 4. Relation of Scour Type to The K.C. Number

ordinate in this figure indicates the scour type that is classified with the scoured bed profiles. From this figure it is clear that the flow pattern is well represented by the K.C. number. This relation has already been investigated (c.f. by Nishizawa and Sawamoto; 1988). The results reported by these authors and ours coincide in the following characteristics: the scour type changes from the Twin-Horn-Shaped to the Cone-Shaped as the K.C. number increases. The borders between the bed profiles Twin-Horn-Shaped and Transient-Shaped, as well as Transient-Shaped and Cone-Shaped are about 8.0 and 20.0 in K.C. number, respectively. These borders are independent of the sand diameter.

Figure 4 depicts the relation of scour type to the K.C. number. As the scour type is related to the flow pattern, represented by the K.C. number, and since the location of maximum scoured points are related to the scour types, as we showed previously, we conclude that the flow pattern can be explained in terms of the location of maximum scoured point.

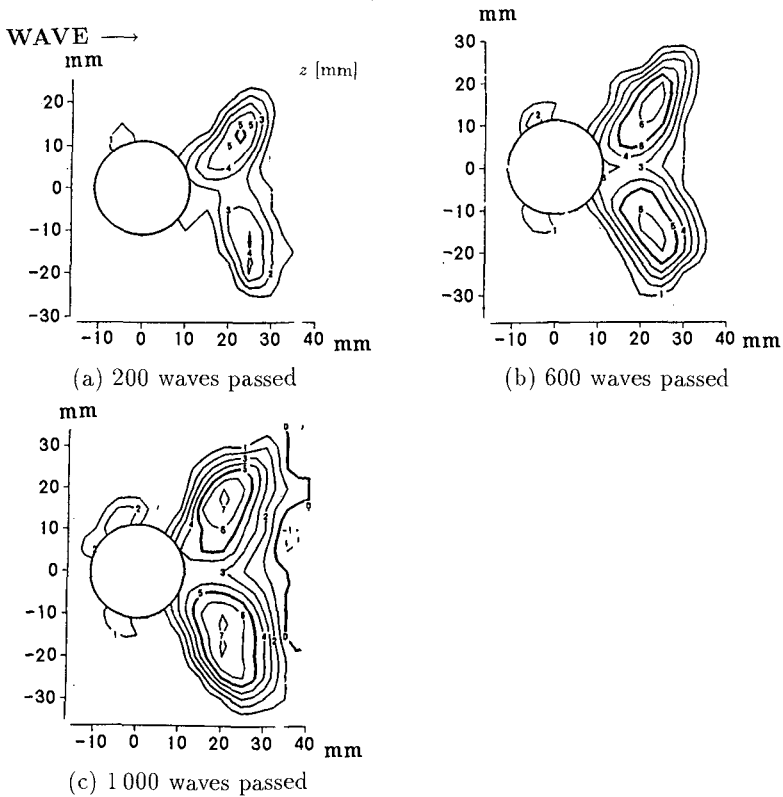

FIG. 5. Bottom Bed Profiles in The Local Scour Developing Process. (K.C. Number: 9.0, Scour Type: Twin-Horn-Shaped)

### 4. SCOUR DEVELOPING PROCESS

The time evolution of the local scour bed profiles around a cylinder was measured in 8 experimental cases. In the experiments, the range of the K.C. number varied from 4.38 to 30.9. The bottom bed profiles around the cylinder were measured every 200 waves passing the cylinder, until we considered that the bottom bed became almost stable. For all experimental cases, the initial bed was flat, and the scoured bed became almost stable after 1000 waves passed the cylinder. The typical developing bed profiles measured are shown in Figs. 5 to 7. Figure 5 shows the Twin-Horn-Shaped scour type. Here, the bed at the lee side of the cylinder was scoured during each developing stage. The bed profiles after 200 and 600 waves passed the cylinder correspond to local scour developing stages. They show similar features to those of the profiles obtained after 1000 waves

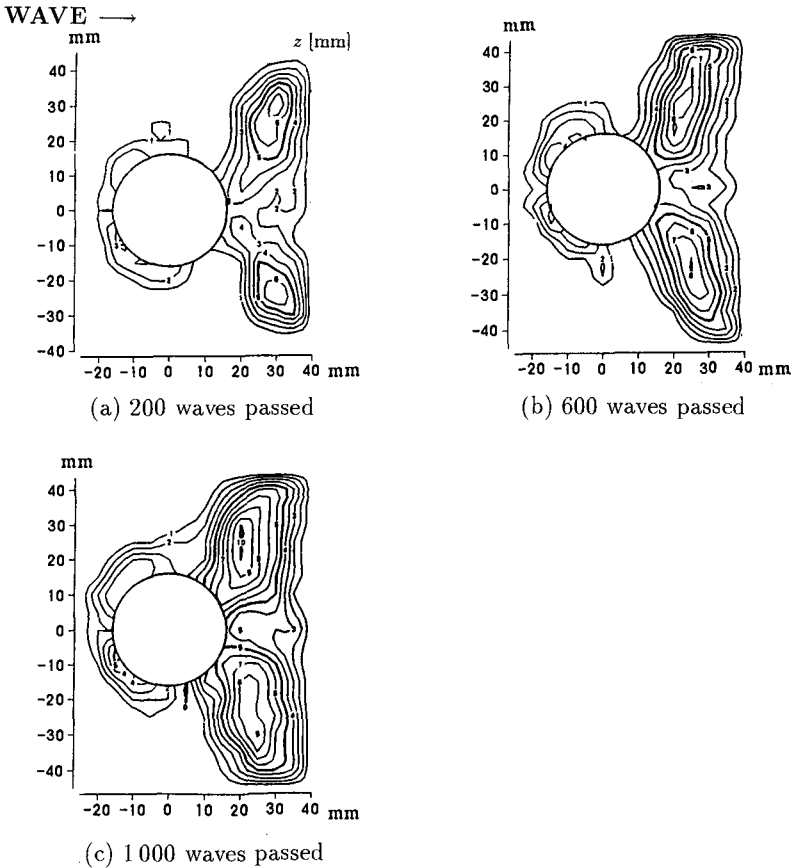

FIG. 6. Bottom Bed Profiles in The Local Scour Developing Process. (K.C. Number: 11.0, Scour Type: Transient-Shaped)

passed, which is considered the equilibrium stage. The maximum scoured point remains located almost in the same place with respect to the cylinder, during every developing stage shown in this figure.

In Fig. 6 the Transient-Shaped scoured bed profile is depicted. This figure shows that the scouring develops at both the lee side of the cylinder and beside this one, during every developing stage. And, as in the case of the Twin-Horn Shaped bed profile, similar shape of bed scouring is retain during the whole developing process.

Figure 7 shows the Cone-Shaped bed profile. Here as in the two previous cases, the scour shape found at the final equilibrium stage is the same that was formed during the earlier stages of the scour developing process. As mentioned in the previous section, the Cone-Shaped bed profile is associated with a horseshoe vortex, and the Twin-Horn-Shaped bed profile is with flow separation from the cylinder or a pair of separated vortices.

No matter however what the flow pattern is, the respective scour bed

**FIG. 8. Location of Maximum Scoured Points in Each Developing Stage. *N* Represents the Number of Waves That Passed The Cylinder.**

shapes appearing in the final equilibrium stage of the scour developing process is formed already at the earlier stages. This was confirmed in all experiments performed, and was found to be independent of the scour type.

Next, the developing process of local scour around a cylinder is discussed with the location of maximum scoured point. Figure 8 shows the distribution of maximum scoured points at each developing stage of local scouring for the cases corresponding to Figs. 5 to 7. The maximum scoured points in Figs. 8 (a) and (b) correspond to the cases of Twin-Horn-Shaped and the Transient-Shaped bed profiles, respectively. In both cases, these points are located at the right and left lee side of the cylinder, and they are apart from the cylinder contour. Fig. 8 (c) corresponds to the Cone-Shaped bed profile. Here, the maximum scoured points are located beside the cylinder. During the experiments performance, we observed

that in all cases the location of the maximum scoured points was almost fixed during the whole scouring process. We conclude therefore that the flow pattern near the bed around a cylinder is practically the same during all the local scouring developing process.

Kobayashi (1993) measured velocity distributions around a vertical cylinder on both flat bed and scoured bed, and computed the vorticity distribution shown in Fig. 9. In this figure, the phase  $\theta$  is defined as 0 when a wave crest passes the cylinder axis, these vorticity distribution corresponds then to an instant just after the wave crest passes. Figures 9 (a) and (b) show the vorticity distribution in the initial and equilibrium stage of the developing process of local scouring, respectively. In Fig. 9 (a), the axis of the vortex formed apart from the cylinder contour is almost vertical and parallel to the cylinder axis. And in Fig. 9 (b) the vortex is deformed due to the scoured bed topography, and has an arch shape. From Figures 9 (a) and (b) this author concluded that the scoured bed profile changes the flow pattern near the bed around a cylinder, which contradicts the results obtained in this study. A reason for such contradiction may be attributed to the nonlinearity waves effect. This is because in Kobayashi (1993) study, non-

FIG. 9. Vorticity Distribution Near The Bottom Around a Cylinder (Kobayashi, 1993) K.C. Number : 5.2, Phase  $\theta : \pi/4$

linearity of waves could be very important since Ursell number was 83.8. On the other hand, in this study linear waves were reproduced with maximum Ursell number of about 4. This is however just a supposition and studies to clarify the effect of nonlinearity of waves on the local scouring process are required.

**5. ULTIMATE SCOUR DEPTH**

The prediction of the ultimate local scour stage is very important for planning and maintenance of onshore and offshore structures. The predominant parameters in this ultimate stage are the depth and the scoured bed profile. The scoured bed profile has already been examined with the K.C. number: In this section, the local scour depth on the equilibrium stage is discussed.

Figure 10 shows the relation of the ultimate scour depth to the K.C. number. The ordinate in this figure represents the maximum scour depth  $S$  divided by the cylinder diameter  $D$ . Six series of experimental results are shown in this figure. Five of them are results of this study, and one corresponds to experimental results obtained by Sumer *et al.* (1992). The solid line drawn in this figure indicates the relation evaluated empirically by these authors. Their experiments were performed on the live bed condition, and those of this study in clear water condition. In spite of this difference, most experimental results of this study agree well with the solid line. Only the results obtained for K.C. number less than 10 are in relative disagreement with this line; they show deeper maximum scour depths than the solid line does.

The scour bed profile for K.C. number less than 10 is of the Twin-Horn-

FIG. 10. Relation Between Ultimate Scour Depth and K.C. Number

Shape type, as shown in Fig. 4. For this type of scour profile the maximum scoured points are located apart from the cylinder contour, as observed in Fig. 2(a) or 3. Since for engineering purposes, the local scour just at the vicinity of a cylinder is most serious than that apart from this, the maximum scour depth was reevaluated by considering a reduced area surrounding the cylinder, and excluding the maximum scoured points.

The results obtained after reevaluation are shown in Fig. 11. In this figure, the ordinate represents the ultimate scour depth on the vicinity of the cylinder surface  $S'$  divided by the cylinder diameter  $D$ . In Fig. 11 better agreement of the reevaluated results, for low K.C. numbers, with the solid line estimated by Sumer *et al.* (1992) is observed, comparing with Fig. 2 (a). From this results, we conclude that the maximum scour depth at the vicinity of the cylinder is related with the K.C. number, and is independent of the bed condition, live bed or clear water, as well as the sand diameter.

The reason why in the Twin-Horn-Shaped scoured bed the very near vicinity of the cylinder was not scoured is that, in this case the flow pattern did not show clear formation of the horseshoe vortex. Only flow separation on the lee side of the cylinder or a pair of separated vortices were visible. Sumer *et al.* (1992) reported that horseshoe vortices were absent for K.C. numbers less than 6, and therefore the bed around the cylinder was not scoured under the live bed condition.

Figure 12 shows the relation of the maximum scour depth in the ultimate

FIG. 11. Relation Between Ultimate Scour Depth on The Vicinity of The Cylinder surface and K.C. number

**FIG. 12. Relation Between Ultimate Scoured Depth to Shields Parameter**

stage to Shields parameter  $\Psi_m$ . The ordinate in this figure indicates the maximum scour depth in the ultimate stage  $S$  divided by the cylinder diameter  $D$ . The Shields parameter  $\Psi_m$  is calculated from the incident wave conditions shown in Table 1, and the sand characteristics listed in Table 2. In Fig. 12 the relation of the maximum scour depth to the Shields parameter is shown. We observe here that the maximum scour depth has a poor relation with the Shields parameter.

## 6. CONCLUSIONS

In this study, local scour around a vertical cylinder and its developing process were investigated experimentally with the flow pattern near the bed. Local scoured bed profiles were classified into the types: Twin-Horn-Shaped, Transient-Shaped and Cone-Shaped. The location of the maximum scoured points was introduced to classify objectively the bed profiles. This location was found to be related to the flow pattern near the bed around the cylinder. In the case of Twin-Horn-Shaped scoured bed profile a pair of maximum scoured points are located at the right and left lee side of the cylinder, and they are apart from the cylinder contour. This type of bed profile is associated with the formation of flow separation or a pair of separated vortices. In the case of the Cone-Shaped scoured bed profile, one maximum scoured point is found, and this is located in front or beside the cylinder. During the whole local scour developing process the bed profiles have a similar shape, and the location of the maximum scoured point or points is almost fixed. These features are independent of the scour type. Finally, we found that

the maximum scour depth has a close relation to the K.C. number, and a very poor relation to the Shields parameter. Also that, this depth is independent of the bottom bed condition, live bed or clear water, and the sand diameter.

## Wave-induced Uplift Loading of Caisson Breakwaters

Andreas Kortenhaus<sup>1</sup>, Hocine Oumeraci<sup>2</sup>, Søren Kohlhase<sup>3</sup> & Peter Klammer<sup>1</sup>

### ABSTRACT

Wave induced uplift pressures and forces have been investigated by small- and large-scale model tests. Detailed analyses of waves at the structure, forces and structure motions showed that conventional design formulae neglect details of pressure development which contribute to the total uplift force. Direct comparison between quasi-static, dynamic forces and the commonly used formulae show that dynamic effects exhibit a significantly different behaviour in comparison to those observed during quasi-static wave attack. The most relevant of the effects which may be useful for setting up a numerical model for the prediction of uplift pressures are described.

### 1. INTRODUCTION

Wave induced uplift forces for design purposes are commonly calculated by empirical or semi-empirical formulae based on the assumption that the maximum uplift pressure occurs at the seaward bottom edge of the caisson and decreases linearly to zero at the shoreward edge. Generally, it is also implicitly assumed that the maximum horizontal peak force occurs simultaneously with its maximum uplift counterpart and that the caisson structure is fixed and does not exhibit any motion during wave loading. Moreover, the influence of the characteristics of the rubble foundation (permeability, thickness etc.) is totally ignored.

The wave induced flow in the rubble foundation has been studied in a large-scale and a small-scale-model by using a fixed and a movable caisson break-

water. The tests principally aim at a better understanding of the generation of uplift pressure under standing, breaking and broken wave conditions and at the establishment of a basis for the development of a conceptual model for the calculation of uplift pressures.

The present paper primarily intends to discussing some of the experimental results. Based on these results an attempt is made to explain the physical processes underneath a vertical caisson structure subject to breaking and nonbreaking wave attack.

## 2. EXPERIMENTAL SET-UP

Small-scale and large-scale model tests have been conducted on a caisson breakwater supported by a rubble foundation (Fig. 1). These investigations were

AM = Acceleration meter; DM = Displacement meter; FT = Force transducer; WO = Wave gauge

Fig. 1: Large-scale model of caisson breakwater

principally directed towards the examination of the effect of the motions of the caisson on the uplift pressure development. For this purpose, five pressure gauges were installed underneath the structure and two displacement meters were placed at the rear and front top of the caisson, respectively. Further seven pressure gauges were installed along the toe berm in front of the caisson in order to determine the impact pressure gradients along the rubble toe, and hence to better understand the mechanisms associated with the uplift generation. Tests with a fixed and a movable caisson were performed. Further simultaneous measurements of waves, accelerations, total forces and pore pressures in the rubble foundation were conducted.

Since the small-scale model tests are not suitable for the quantitative evaluation of the uplift pressure, flow in the porous rubble foundation is subject to scale effects due to too large viscous forces, large-scale model tests were also performed for different water depths and wave conditions.

Three different wave types were generated throughout the tests: solitary waves, regular waves and random waves (TMA spectra). The wave heights, wave periods and water depths used in the large-scale model tests are summarized in Table 1.

**Table 1: Test programme for large-scale model tests**

<b>SOLITARY WAVES</b>					
<b>Wave heights</b>	<b>steps</b>	<b>Wave periods</b>	<b>steps</b>	<b>Water depth</b>	<b>steps</b>
0.40 - 0.60 m	0.10 m	-	-	3.10 - 3.50 m	0.10 m
0.65 - 1.10 m	0.05 m	-	-	3.50 - 3.90 m	0.20 m
<b>REGULAR WAVES</b>					
<b>Wave heights</b>	<b>steps</b>	<b>Wave periods</b>	<b>steps</b>	<b>Water depth</b>	<b>steps</b>
0.30 - 1.10 m	0.20 m	3.50 - 6.50 s	1.00 s	3.70 - 4.30 m	0.20 m
<b>RANDOM WAVES (TMA spectra)</b>					
<b>Wave heights</b>	<b>steps</b>	<b>Wave periods</b>	<b>steps</b>	<b>Water depth</b>	<b>steps</b>
0.30 - 1.10 m	0.20 m	3.50 - 6.50 s	1.00 s	3.70 - 4.30 m	0.20 m

The small-scale model was about four times smaller than the large-scale model.

### 3. CLASSIFICATION OF BREAKER TYPES

Three major breaker types were identified from the experiments leading to essentially different response of the structure (Fig. 2). All these breaker types could be observed - independently from the type of waves generated. Generally there are more than three different breaker types (*Schmidt et al., 1992*). However, only the three main types shown in Fig. 2 for two time steps  $t_1$  and  $t_2$  are considered below in order to make more clear the physical processes involved.

Four parameters were found suitable to describe the main features of the force histories of both impact and uplift pressures (Fig. 3). These parameters are:

- $t_r$ : rise time of impact force
- $\Delta t$ : time difference between maximum of impact force and maximum of uplift force

Fig. 2: Main breaker types considered

- $\eta_{F_{m,q}}$ : ratio of quasi-static impact force  $F_{h, qus}$  and maximum impact force  $F_{h, max}$
- $\eta_{F_{h,v}}$ : ratio of maximum uplift force  $F_{v, max}$  and maximum impact force  $F_{h, max}$

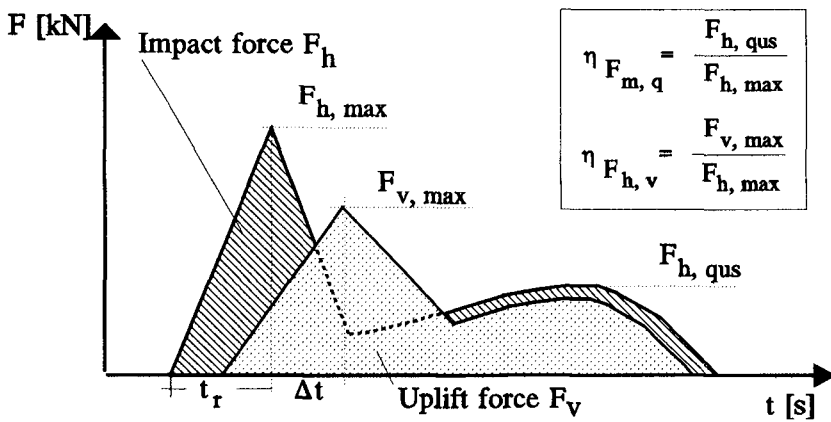

Fig. 3: Parameters for identification of loading cases

## 4. TYPICAL TEST RESULTS

### Force histories

Typical force histories for impact and uplift forces for the three different loading cases can be seen in Figs. 4 to 6 where the aforementioned descriptive parameters are given.

Fig. 4: Typical force histories for loading case 1 (turbulent bore)

The force histories show a high force peak ( $F_{h,max}$ ) caused by the wave hitting the structure and a lower force maximum  $F_{h,qus}$  which occurs when the water of the wave running up the wall falls down again. Between these maxima there is a minimum force (trough) which coincides with the maximum wave run-up.

In loading case 1 (turbulent bore) the wave breaks before reaching the structure, inducing a turbulent air-water mixture. This can be observed from the high frequency oscillations in the time history of the impact forces. There is no time lag between the maxima of impact and uplift force.

The uplift force in loading case 2 shows a double peak for the vertical force which however do not always occurs when a plunging breaker hits the structure. This double peak force is due to the uplift of the structure, which will be discussed in the next chapter.

Loading case 3 shows a very sharp and high peak in the impact force history followed by high frequency oscillations which are due to oscillations of the

Fig. 5: Typical force histories for loading case 2 (plunging breaker)

Fig. 6: Typical force histories for loading case 3 (plunging breaker with air entrapment)

entrapped air pocket at the vertical face of the structure. Very often a double peaked force in the impact force history occurs. The first peak is induced by the beaker tongue hitting the structure whereas the second occurs when the rest of the wave front impinges on the structure.

### Pressure distributions

Typical horizontal impact pressure distributions on the front and the bottom of the caisson caused during loading case 2 are given in Fig. 7. In this figure the motion of the structure is amplified by a factor of 200 to make clear:

- whether the structure moves at all,
- the comparison of all loading cases,
- at which time the structure starts to move.

The following typical features of impact and uplift pressures are observed for loading case 1:

- there are almost no temporal changes in the figures (quasi-static behaviour)
- maximum impact pressure is approximately at still water level
- measured impact pressure distribution is very close to the theoretically predicted (SAINFLOU) distribution for a standing wave with little scatter due to reflection coefficients which are actually less than 100%.
- uplift pressures are almost linear but not decreasing to zero pressure at the shoreward edge of the structure
- velocity flow in the rubble foundation has been estimated by an improved Forchheimer equation (*Van Gent, 1993*) to about 5 to 10 cm/s. Therefore, pressures due to velocity head can be neglected

For loading case 2 (Fig. 7), the typical features which are worth to mention are:

- point of application of impact force is in the range of still water level, but the magnitude of the force is much higher
- there are mainly horizontal motions of the structure, but only some slight rotational motions
- compression wave underneath the structure
- lever arm of uplift force is at 2/3 of the width of the structure from its heel

Loading case 3 is an extreme example for plunging breakers with air entrapment inducing a very high short time impact peak followed by high amplitude oscillations. Impact and uplift pressures exhibit the following typical distribution:

- maximum impact is reached within a very short time
- pressure oscillations due to air entrapment occur about 0.2 s after maximum peak
- no motions of structure is induced since peak pressures are too short
- relatively low uplift pressures (showing phenomenon of compression wave)

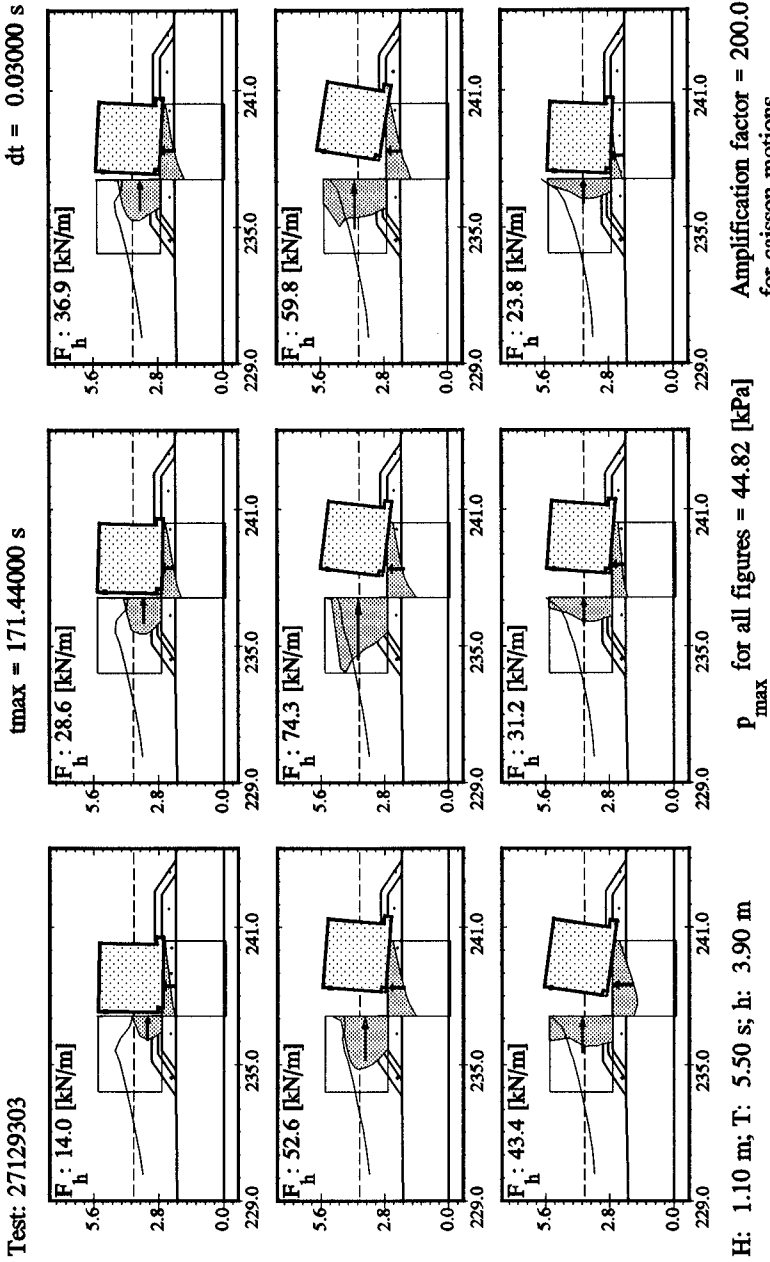

Fig. 7: Typical pressure distribution for loading case 2

**Comparison to Goda formulae**

For the prediction of horizontal wave and uplift forces the Goda formulae are widely used (Goda, 1985). Calculations using these formulae have been performed for the loading cases described in section 3 to show the range of quasi-static and dynamic loads. The results of these calculations are compared to the measurements for each of the loading cases in Figs 8 to 10.

**Fig. 8:** Comparison of loading case 1 with GODA's formulae

**Fig. 9:** Comparison of loading case 2 with GODA's formulae

For quasi-static loads (loading case 1) the results obtained by Goda formulae are conservative whereas the pressure peaks in the case of highly dynamic loads exceed the calculated pressure by a factor up to 5. Goda's formulae predict approximately correct uplift pressure values at the seaward edge of the breakwater for loading cases 1 and 3, but not for dynamic loading case 2. In this case the maximum uplift force occurs when the compression wave is underneath the structure and has reached 2/3 of the width of the structure from its heel.

Fig. 10: Comparison of loading case 3 with GODA's formulae

### 5. OBSERVED UPLIFT PHENOMENA

#### Compression wave

For loading cases 2 and 3 a compression wave is induced beneath the structure by the wave impact on the vertical face of the breakwater. To obtain more information about the propagation, velocity of this wave underneath the structure and its effect on the porous rubble foundation the uplift pressure recorded beneath the structure have been plotted for a single wave in Fig. 11. The maxima of the obtained curves were determined and time differences have been plotted versus the

Fig. 11: Analysis of compression wave underneath the structure

spacial difference  $dx_i$  between the respective pressure gauges. This procedure was repeated several times for a test with regular waves (Fig. 12). Similar results have been found for further regular and random waves, showing that the velocity of the compression wave is not affected by the wave parameters.

Fig. 12: Velocity of compression wave beneath the structure

**Suction underneath the structure**

Due to the very high impacts inducing a strong horizontal and rotational motion of the structure a gap forms at the front base (Fig. 13). Pressure decreases

$d_{vf}$  = vertical displacement at the front

Fig. 13: Suction beneath a rotating caisson structure

immediately and water flows with relatively high velocities into the gap thus increasing the risk of erosion of the rubble materials (suction). This phenomenon was only observed for high impacts and cannot be considered as typical for normal impact loading. However, it may be a very critical case, due to the aforementioned erosion potential of the high velocity gap flow.

Fig. 14 shows simultaneously recorded uplift forces and displacements at the vertical face front of the structure. It can be seen that the increase of the displacement suddenly leads to a decrease in the uplift force (dashed line in Fig. 14). The uplift force is obtained from the integration of all pressure records at the bottom of the structure. Similar decrease can also be observed in the pore pressure records.

Fig. 14: Time histories of uplift force and vertical displacement at the caisson front

The reduction of uplift force caused by the suction is shown in Fig. 15 where an increase of vertical displacements at the front for small values creates an almost linear increase of uplift forces. Three almost parallel lines were plotted to show this dependency. Furthermore, it can be seen that there is a clear relationship between the water depth and the uplift force where higher water depths at the toe of the rubble mound in front of the structure will result in smaller uplift forces. However, for larger displacement values a sudden bend can be found leading to an increase of uplift forces at a lower rate with increasing displacements. A more detailed analysis in the near future will show whether there are similar relations with respect to different water depths. To obtain quantitative statements more variations in wave parameters have to be considered.

Fig. 15: Reduction of uplift force by suction underneath the structure

**Pressure at shoreward edge**

In all measurements of both breaking and nonbreaking waves the pressure at the shoreward edge of the breakwater was different from zero. This phenomenon was also observed under model and prototype conditions, but could not be explained (Marchi *et al.*, 1975). Several reasons may be considered to explain this phenomenon:

- water level variations behind the breakwater were induced by a flow through the rubble foundation thus leading to hydrostatic pressures at the shoreward edge
- flow induced velocities are responsible for this pressure (velocity head  $v^2/2g$ )
- pressures may be induced by flow resistance in the rubble foundation, since the rubble structure at the rear is higher than the bottom level of the caisson

Since water level variations and flow through the rubble foundation induces pressures which are in the range of 5% of the measured pressures at the rear edge, the latter reason seems to provide the most reasonable explanation. This has to be confirmed by further model tests or numerical modelling.

**6. SUMMARY OF RESULTS AND FUTURE RESEARCH TASKS**

- The widely used assumption of linear pressure distribution underneath the structure is almost valid for quasi-static wave loading. For impulsive loading, however, a non linear distribution occurs. This is due to the effect of com-

pression waves beneath the structure where the maximum uplift pressure no longer occurs at the seaward edge of the structure;

- the assumption of zero pressure at the shoreward edge of the structure seems to be only valid for very low rubble foundation and should be more thoroughly examined for higher rubble substructures;
- for extreme wave conditions suction at the seaward bottom edge of the structure may occur leading to lower uplift pressures and forces at the base of the structure and in the rubble foundation, thus increasing the risk of erosion due to high velocities of the gap flow.

The influencing parameters to be investigated in the future are:

- permeability of the rubble foundation
- geometry of the structure and the rubble foundation (thickness and height)

A numerical model should be developed which accounts for a) the (turbulent) flow and pressures in the rubble mound; b) breaking and nonbreaking wave conditions and c) variations in geometry and permeability of the rubble foundation. This numerical model could be calibrated by the experimental results obtained by this study and might be used for an extensive parameter study. The results of this parameter study will help to develop simple prediction formulae for both uplift pressure distribution and forces as a function of various parameters (water depth, wave parameters, breaker type, properties of rubble material and geometry of structure and rubble foundation).

## CHAPTER 95

# LINEAR AND NONLINEAR WAVE FORCES EXERTED ON A SUBMERGED HORIZONTAL PLATE

Haruyuki Kojima <sup>1</sup>, Akinori Yoshida <sup>2</sup> and Tetuya Nakamura <sup>3</sup>

## ABSTRACT

Linear and Nonlinear wave forces exerted on a submerged horizontal plate are studied using the method of matched eigenfunction expansions for velocity potential together with the perturbation technique up to second order. Energy damping coefficients are introduced in the formulation to incorporate the effects of vortices and wave breaking. The theoretical results are compared with experimental data to obtain validity and limits of the second-order solution. The theory with proper energy damping coefficients can well simulate the wave forces even when wave breaking occurs over the plate. The second-order oscillatory wave force is relatively small as compared to the first-order one, while time-independent, steady wave force becomes comparable with the first-order one at small relative water depth and its direction is always upward.

## 1 INTRODUCTION

Wave interactions with a submerged horizontal plate have been extensively studied both theoretically and experimentally. Most of the studies, however, deal with linear wave interactions, namely, reflection and transmission characteristics of waves from the submerged plate (e.g., Ijima *et al.*, 1970, and Patarapanich *et al.*, 1989). These studies concluded that the submerged horizontal plate might be one of the promising wave attenuation devices. There is however little information available on the characteristics of wave forces exerted on the plate except for a work by Patarapanich (1984), especially of nonlinear wave forces. Since wave motion over the plate placed at small submergence depth is highly nonlinear, higher harmonic generation usually occurs; the second harmonic wave increases

significantly over the plate and at the end of the plate the second harmonic sometimes becomes greater than the first one (Kojima *et al.*, 1990). It is of great interest to study the contribution of the higher harmonic forces to the total wave force. The information on these forces and the overturning moment is essential in designing such a structure.

The main objective of this study is to present a theoretical solution of linear and nonlinear wave forces exerted on a submerged horizontal plate and to understand their characteristics. The solution obtained is valid to second order. Numerical results are compared with experimental data to show the validity and limitation of the second-order solution. The characteristics of wave forces under the extreme condition such as breaking waves are also examined. The study is restricted to the two-dimensional cases of regular waves approaching normal to the thin plate fixed at various submergence below the water surface.

## 2 THEORETICAL FORMULATION

### 2.1 Governing Equations

The nonlinear interaction problem is treated as the water wave boundary value problem for the second-order velocity potential since potential flow assumptions may be valid. Let us consider the second-order Stokes' wave, with its first-order amplitude  $\zeta_0$ , wave number  $k$ , and angular frequency  $\sigma$ , incident upon a submerged horizontal plate from the positive  $x$  direction, as shown in Fig. 1. Since the fluid motion may be assumed to be irrotational, incompressible and inviscid, the governing equations for this problem are as follows:

Laplace equation,

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial z^2} = 0 \tag{1}$$

the kinematic free surface boundary condition,

$$\frac{\partial \zeta}{\partial t} + \frac{\partial \Phi}{\partial x} \frac{\partial \zeta}{\partial x} - \frac{\partial \Phi}{\partial z} = 0 \quad \text{on } z = \zeta(x, t) \tag{2}$$

the dynamic free surface boundary condition with the Bernoulli constant  $Q$ ,

$$\frac{\partial \Phi}{\partial t} + g\zeta + \frac{1}{2} \left\{ \left( \frac{\partial \Phi}{\partial x} \right)^2 + \left( \frac{\partial \Phi}{\partial z} \right)^2 \right\} = Q \quad \text{on } z = \zeta(x, t) \tag{3}$$

and the kinematic no-flux condition on the plate surface and sea bottom,

$$\frac{\partial \Phi}{\partial z} = 0 \quad \text{on } z = -h_2, -h_d, -h \tag{4}$$

Figure 1 Fluid regions and definition sketch.

### 2.2 Solutions of first and second order

To obtain solutions for the first- and second-order velocity potential, the velocity potential, water elevation and Bernoulli constant are expanded by the perturbation approach in terms of power series in a small parameter  $\epsilon (= k\zeta_0)$  and the combined free surface boundary condition is applied on the still mean water level with help of the Taylor expansion. Then, the velocity potential  $\Phi(x, z, t)$  can be given by

$$\Phi(x, z, t) = \frac{g}{k\sigma} \text{Re} \left[ \epsilon \phi_1^{(1)}(x, z) \exp(i\sigma t) + \epsilon^2 \{ \phi_0^{(2)}(x, z) + \phi_2^{(2)}(x, z) \exp(i2\sigma t) \} + \dots \right] \quad (5)$$

in which  $\phi_1^{(1)}(x, z)$ ,  $\phi_0^{(2)}(x, z)$ ,  $\phi_2^{(2)}(x, z)$  are nondimensional complex functions (hereafter referred to as a potential function) and the subscripts 0, 1 and 2 indicate the degree of harmonic components and the indices (1) and (2) denote the first- and second-order solutions, respectively.

The potential functions  $\phi_1^{(1)}$ ,  $\phi_2^{(2)}$ ,  $\phi_0^{(2)}$  in the regions (1), (2) and (4) with the free water surface can be expressed in terms of a power series as

$$\phi_1^{(1)}(x, z) = \sum_{n=0}^{\infty} \{ C_{in} \exp(k_{in}x) + D_{in} \exp(-k_{in}x) \} Z(k_{in}z) \quad (6)$$

$$\begin{aligned} \phi_2^{(2)}(x, z) = & \sum_{n=0}^{\infty} \{ C_{in}^{(2)} \exp(k_{in}^{(2)}x) + D_{in}^{(2)} \exp(-k_{in}^{(2)}x) \} Z(k_{in}^{(2)}z) \\ & + \sum_{m=0}^{\infty} \sum_{p=0}^{\infty} \Pi_{mp}(x, z) \end{aligned} \quad (7)$$

$$\begin{aligned} \phi_0^{(2)}(x, z) = & \overline{C_0^{(2)}} \frac{x}{b} + \overline{D_0^{(2)}} \\ & + \sum_{n=1}^{\infty} \left\{ \overline{C_n^{(2)}} \exp\left(\frac{n\pi}{h} x\right) + \overline{D_n^{(2)}} \exp\left(-\frac{n\pi}{h} x\right) \right\} \cos \frac{n\pi}{h} z \\ & + \sum_{m=0}^{\infty} \sum_{p=0}^{\infty} \Pi_{mp}^*(x, z) \end{aligned} \tag{8}$$

where  $C_{in}^{(q)}, D_{in}^{(q)}, \overline{C_{in}^{(q)}}, \overline{D_{in}^{(q)}}$  indicate unknown coefficients of  $O(\epsilon^q)$ , the subscript  $i$  denotes the corresponding fluid regions, and the eigenfunction  $Z(k_{in}^{(q)} z)$  is written by

$$Z(k_{in}^{(q)} z) = \frac{\cos k_{in}^{(q)}(z + h_i)}{\cos k_{in}^{(q)} h_i} \tag{9}$$

The eigenvalues  $k_{in}^{(q)}$  can be found from the following dispersion relationship.

$$\frac{(q\sigma)^2 h_i}{g} = -k_{in}^{(q)} h_i \tan k_{in}^{(q)} h_i \quad (i = 1, 2, 4 \quad q = 1, 2) \tag{10}$$

When  $n = 0$ , it becomes an imaginary number ( $k_{i0}^{(q)} = i k_i^{(q)}$ ) and a real number when  $n \neq 0$ .  $\Pi_{mp}(x, z)$  and  $\Pi_{mp}^*(x, z)$  in Eqs. (7) and (8) are given by

$$\left. \begin{aligned} \Pi_{mp}(x, z) &= \frac{\lambda(k_m, k_p)}{\mu_1(k_{mp})} Q_{mp}(x) Z(k_{mp} z) + \frac{\overline{\lambda}(k_m, k_p)}{\mu_1(\overline{k_{mp}})} \overline{Q}_{mp}(x) Z(\overline{k_{mp}} z) \\ \Pi_{mp}^*(x, z) &= \frac{\Upsilon(k_p)}{\mu_2(k_{mp}^*)} Q_{mp}^*(x) Z(k_{mp}^* z) + \frac{\overline{\Upsilon}(k_p)}{\mu_2(\overline{k_{mp}^*})} \overline{Q}_{mp}^*(x) Z(\overline{k_{mp}^*} z) \end{aligned} \right\} \tag{11}$$

where

$$\left. \begin{aligned} Q_{mp}(x) &= C_m C_p \exp(k_{mp} x) + D_m D_p \exp(-k_{mp} x) \\ \overline{Q}_{mp}(x) &= C_m D_p \exp(\overline{k_{mp}} x) + C_p D_m \exp(-\overline{k_{mp}} x) \\ Q_{mp}^*(x) &= C_m C_p^* \exp(k_{mp}^* x) + D_m D_p^* \exp(-k_{mp}^* x) \\ \overline{Q}_{mp}^*(x) &= C_m D_p^* \exp(\overline{k_{mp}^*} x) + C_p^* D_m \exp(-\overline{k_{mp}^*} x) \end{aligned} \right\} \tag{12}$$

$$\left. \begin{aligned} \lambda(k_m, k_p) &= \frac{i}{2k} (3\Gamma^2 + 2k_m k_p + k_p^2), \quad \Upsilon(k_p) = \frac{i}{2k} (\Gamma^2 + k_p^2) \\ \overline{\lambda}(k_m, k_p) &= \frac{i}{2k} (3\Gamma^2 - 2k_m k_p + k_p^2) \end{aligned} \right\} \tag{13}$$

$$\left. \begin{aligned} \mu_1(k_{mp}) &= 4\Gamma + k_{mp} \tan k_{mp} h, \quad \mu_2(k_{mp}^*) = k_{mp}^* \tan(k_{mp}^* h) \\ \mu_1(\overline{k_{mp}}) &= 4\Gamma + \overline{k_{mp}} \tan \overline{k_{mp}} h, \quad \mu_2(\overline{k_{mp}^*}) = \overline{k_{mp}^*} \tan(\overline{k_{mp}^*} h) \end{aligned} \right\} \tag{14}$$

$$\left. \begin{aligned} k_{mp} &= k_m + k_p, \quad \overline{k_{mp}} = k_m - k_p, \quad \Gamma = \sigma^2/g \\ k_{mp}^* &= k_m + k_p^*, \quad \overline{k_{mp}^*} = k_m - k_p^* \end{aligned} \right\} \quad (15)$$

The index \* designates the complex conjugate of the variables. Note that  $\phi_0^{(2)}(x, z)$ , given by Eq.(8) and representing the steady component of the second-order potential function, contributes to neither the second-order water surface displacement nor wave pressure exerted on the plate. The interpretation of the solution for  $\phi_2^{(2)}(x, z)$  is discussed elsewhere (Kojim *et al.*, 1994).

The first- and second-order solutions for the fluid region beneath the plate are assumed to have the following form:

$$\begin{aligned} \phi_3^{(q)}(x, z) &= C_{30}^{(q)} \frac{x}{b} + D_{30}^{(q)} \\ &+ \sum_{n=1}^{\infty} \left\{ C_{3n}^{(q)} \exp(\nu_n x) + D_{3n}^{(q)} \exp(-\nu_n x) \right\} \cos \nu_n(z + d) \end{aligned} \quad (16)$$

in which  $\nu_n = n\pi/h_3$  and  $q = 1, 2$ .

The unknown coefficients in the first- and second-order solutions should be determined by satisfying the no-flux conditions along the vertical faces of the plate as well as flow continuity conditions over the vertical planes separating the fluid regions. Instead of using a conventional technique employing the orthogonality of the eigenfunctions (Ijima, 1971, and Massel, 1983), a "collocation" method of matching is applied in determining unknown coefficients in the expansions. A detailed explanation of the procedure is presented by Kojima *et al.* (1994) and Yoshida *et al.* (1990).

## 2.3 Linear and Nonlinear Wave Forces

### 2.3.1 Expressions for dynamic wave pressures

The dynamic pressure due to wave action against a submerged horizontal plate can be obtained from the unsteady Bernoulli equation. Like the velocity potential  $\Phi(x, z, t)$ , the dynamic pressure  $p(x, z, t)$  may be expanded in terms of power series in  $\epsilon$ , and substituting the determined velocity potential into the Bernoulli equation and collecting terms of each order in  $\epsilon$  yield the non-dimensional dynamic pressure  $p(x, z, t)$  to second order in the following form.

$$\begin{aligned} \frac{p(x, z, t)}{\rho g \zeta_0} &= p^{(1)}(x, z, t) + \epsilon p^{(2)}(x, z, t) \\ &= R\epsilon \left[ p_1^{(1)}(x, z) \exp(i\sigma t) + \epsilon \left\{ p_0^{(2)}(x, z) + p_2^{(2)}(x, z) \exp(i2\sigma t) \right\} \right] \end{aligned} \quad (17)$$

where

$$p_1^{(1)}(x, z) = -i\phi_1^{(1)} \quad (18)$$

$$p_0^{(2)}(x, z) = -\frac{g}{4k\sigma^2} \left\{ \frac{\partial \phi_1^{(1)}}{\partial x} \frac{\partial \phi_1^{(1)*}}{\partial x} + \frac{\partial \phi_1^{(1)}}{\partial z} \frac{\partial \phi_1^{(1)*}}{\partial z} \right\} + Q^{(2)} \quad (19)$$

$$p_2^{(2)}(x, z) = -2i\phi_2^{(2)} - \frac{g}{4k\sigma^2} \left\{ \left( \frac{\partial \phi_1^{(1)}}{\partial x} \right)^2 + \left( \frac{\partial \phi_1^{(1)}}{\partial z} \right)^2 \right\} \tag{20}$$

In the above equations  $p_1^{(1)}(x, z), p_0^{(2)}(x, z), p_2^{(2)}(x, z)$  are non-dimensional dynamic pressure where the superscripts (1) and (2) denote the first- and second-order dynamic pressures, respectively, and  $Q^{(2)}$  is the Bernoulli constant.

### 2.3.2 Vertical wave force

The vertical wave forces exerted on a horizontal plate located at an arbitrary depth  $z$  can be obtained by integrating wave pressures in regions (2) and (3) from  $-b$  to  $b$  in the direction of  $x$

$$F_Z(z, t) = \frac{f_Z(z, t)}{\rho g \zeta_0 B} = \int_{-b}^b \{p_3(x, z, t) - p_2(x, z, t)\} dx \tag{21}$$

By using Eq. (18) through Eq. (20), the normalized wave forces  $f_Z(z, t)/\rho g \zeta_0 B$  can be expressed as

$$F_Z = \frac{f_Z(z, t)}{\rho g \zeta_0 B} = Re \left[ \{F_{Z31}^{(1)}(z) - F_{Z21}^{(1)}(z)\} \exp(i\sigma t) + \epsilon \left\{ \left( F_{Z30}^{(2)}(z) - F_{Z20}^{(2)}(z) \right) + \left( F_{Z32}^{(2)}(z) - F_{Z22}^{(2)}(z) \right) \exp(i2\sigma t) \right\} \right] \tag{22}$$

Since the first-order term is well-known, only the second-order ones are given as follows:

$$F_{Z20}^{(2)}(z) = \int_{-b}^b p_{20}^{(2)}(x, z) dx = \sum_{m=0}^{\bar{n}_2} \sum_{p=0}^{\bar{n}_2} \left[ \alpha(k_m, k_p^*) Z(\overline{k_{2mp}z}) R_{mp}^* + \bar{\alpha}(k_m, k_p^*) Z(k_{2mp}z) \overline{R_{mp}^*} \right] + Q^{(2)} \tag{23}$$

$$F_{Z30}^{(2)}(z) = \int_{-b}^b p_{30}^{(2)}(x, z) dx = -\frac{g}{4k\sigma^2} \left[ \frac{C_{30} C_{30}^*}{b^2} + \frac{C_{30}}{2b^2} \sum_{m=1}^{n_3} \{A(\nu_m)\} \{C_{3m}^* - D_{3m}^*\} Z(\nu_m z) + \frac{C_{30}^*}{2b^2} \sum_{n=1}^{n_3} \{A(\nu_n)\} \{C_{3n} - D_{3n}\} Z(\nu_n z) + \sum_{n=1}^{\bar{n}_3} \sum_{m=1}^{\bar{n}_3} \nu_n \nu_m \left\{ \widehat{R}_{nm}^* Z(\overline{\nu_{nm}z}) - \overline{\widehat{R}_{nm}^*} Z(\nu_{nm}z) \right\} \right] + Q^{(2)} \tag{24}$$

$$F_{Z22}^{(2)}(z) = \int_{-b}^b p_{22}^{(2)}(x, z) dx = -2i \sum_{n=0}^{n_2^{(2)}} \frac{A(k_{2n}^{(2)})}{2k_{2n}^{(2)} b} \{C_{2n}^{(2)} + D_{2n}^{(2)}\} Z(k_{2n}^{(2)} z)$$

$$\begin{aligned}
 & -2i \sum_{m=0}^{\bar{n}_2} \sum_{p=0}^{\bar{n}_2} \left\{ \frac{\lambda(k_m, k_p)}{\mu_1(k_{mp})} R_{mp} Z(k_{2mp}z) + \frac{\bar{\lambda}(k_m, k_p)}{\mu_1(\bar{k}_{mp})} \overline{R}_{mp} Z(\overline{k_{2mp}z}) \right\} \\
 & + \sum_{m=0}^{\bar{n}_2} \sum_{p=0}^{\bar{n}_2} \left\{ \alpha(k_m, k_p) R_{mp} Z(\overline{k_{2mp}z}) + \bar{\alpha}(k_m, k_p) \overline{R}_{mp} Z(k_{2mp}z) \right\} \quad (25)
 \end{aligned}$$

$$\begin{aligned}
 F_{Z_{32}}^{(2)}(z) &= \int_{-b}^b p_{32}^{(2)}(x, z) dx \\
 &= -2i \left[ \{-C_{30}^{(2)} + D_{30}^{(2)}\} + \sum_{n=1}^{n_3} \frac{A(\nu_n)}{2\nu_n b} \{C_{3n}^{(2)} + D_{3n}^{(2)}\} Z(\nu_n z) \right] \\
 &\quad - \frac{g}{4k\sigma^2} \left[ \frac{1}{b^2} C_{30}^2 + \frac{1}{b^2} C_{30} \sum_{n=1}^{n_3} A(\nu_n) \{C_{3n} - D_{3n}\} Z(\nu_n z) \right. \\
 &\quad \left. + \sum_{n=1}^{\bar{n}_3} \sum_{m=1}^{\bar{n}_3} \nu_n \nu_m \left\{ \widehat{R}_{nm} Z(\overline{\nu_{nm}z}) - \overline{\widehat{R}}_{nm} Z(\nu_{nm}z) \right\} \right] \quad (26)
 \end{aligned}$$

where

$$R_{mp}^* = \begin{cases} C_{2m} C_{2p}^* + D_{2m} D_{2p}^* & (m = p = 0) \\ \frac{A(2k_{2mp})}{2k_{2mp}^* b} \{C_{2m} C_{2p}^* + D_{2m} D_{2p}^*\} & \begin{pmatrix} m = p \neq 0 \\ m \neq p \end{pmatrix} \end{cases} \quad (27)$$

$$\overline{R}_{mp}^* = \begin{cases} \exp(-2k_{2m}b) \{C_{2m} D_{2p}^* + C_{2p}^* D_{2m}\} & (m = p \neq 0) \\ \frac{B(k_{2p}, k_{2m})}{2k_{2mp}^* b} \{C_{2m} D_{2p}^* + C_{2p}^* D_{2m}\} & \begin{pmatrix} m = p = 0 \\ m \neq p \end{pmatrix} \end{cases} \quad (28)$$

$$\widehat{R}_{nm}^* = \frac{A(\nu_{nm})}{2\nu_{nm} b} \{C_{3n} C_{3m}^* + D_{3n} D_{3m}^*\} \quad (29)$$

$$\overline{\widehat{R}}_{nm}^* = \begin{cases} \exp(-2\nu_n b) \{C_{3n} D_{3m}^* + C_{3m}^* D_{3n}\} & (n = m) \\ \frac{B(\nu_m, \nu_n)}{2\nu_{nm} b} \{C_{3n} D_{3m}^* + C_{3m}^* D_{3n}\} & (n \neq m) \end{cases} \quad (30)$$

$$R_{mp} = \frac{A(k_{2mp})}{2k_{2mp} b} \{C_{2m} C_{2p} + D_{2m} D_{2p}\} \quad (31)$$

$$\overline{R}_{mp} = \begin{cases} \exp(-2k_m b) \{C_{2m} D_{2p} + C_{2p} D_{2m}\} & (m = p) \\ \frac{B(k_{2p}, k_{2m})}{2k_{2mp} b} \{C_{2m} D_{2p} + C_{2p} D_{2m}\} & (m \neq p) \end{cases} \quad (32)$$

$$\widehat{R}_{nm} = \frac{A(\nu_{nm})}{2\nu_{nm} b} \{C_{3n} C_{3m} + D_{3n} D_{3m}\} \quad (33)$$

$$\overline{\hat{R}}_{nm} = \begin{cases} \exp(-2\nu_n b) \{C_{3n}D_{3m} + C_{3m}D_{3n}\} & (n = m) \\ \frac{B(\nu_m, \nu_n)}{2\nu_{nm}b} \{C_{3n}D_{3m} + C_{3m}D_{3n}\} & (n \neq m) \end{cases} \quad (34)$$

In the above equations,  $A(k_{2mp})$ ,  $B(k_{2p}, k_{2m})$ ,  $Z(k_{2p}^{(2)}z)$ ,  $Z(\nu_n z), \dots$  can be given for each variable in the following forms.

$$\left. \begin{aligned} A(k_{2mp}) &= 1 - \exp(-2k_{2mp}b) \\ B(k_{2p}, k_{2m}) &= \exp(-2k_{2p}b) - \exp(-2k_{2m}b) \\ Z(k_{2p}^{(2)}z) &= \frac{\cos k_{2p}^{(2)}(z + h_2)}{\cos k_{2p}^{(2)}h} \\ Z(\nu_n z) &= \cos \nu_n(z + h_d) \end{aligned} \right\} \quad (35)$$

### 2.3.3 Horizontal wave forces

The horizontal wave forces exerted on the horizontal plate can be obtained by integrating over the plate thickness from  $-h_d$  to  $-h_2$ . The wave force coefficient  $F_x = f_x(z, t)/\rho g \zeta_0 D$  can be expressed as

$$F_X = \frac{f_x(x, t)}{\rho g \zeta_0 D} = Re \left[ \left( F_{X_{i1}}^{(1)}(x) - F_{X_{i1}}^{(1)}(x) \right) \exp(i\sigma t) + \epsilon \left\{ \left( F_{X_{i0}}^{(2)}(x) - F_{X_{i0}}^{(2)}(x) \right) + \left( F_{X_{i2}}^{(2)}(x) - F_{X_{i2}}^{(2)}(x) \right) \exp(i2\sigma t) \right\} \right] \quad (36)$$

$F_{X_{i1}}^{(1)}(x)$ ,  $F_{X_{i0}}^{(2)}(x)$ , and  $F_{X_{i2}}^{(2)}(x)$  can be given by the following equations:

$$F_{X_{i1}}^{(1)}(x) = -2i \sum_{n=0}^{n_i^{(1)}} \left\{ C_{in}^{(1)} \exp(k_{in}^{(1)}x) + D_{in}^{(1)} \exp(-k_{in}^{(1)}x) \right\} Y_n^{(1)} \quad (37)$$

$$F_{X_{i0}}^{(2)}(x) = \sum_{m=0}^{\bar{n}_i} \sum_{p=0}^{\bar{n}_i} \left\{ \alpha(k_m, k_p^*) Q_{imp}^*(x) \overline{Y_{mp}^*} + \bar{\alpha}(k_m, k_p^*) \overline{Q_{imp}^*}(x) Y_{mp}^* \right\} + Q^{(2)} \quad (38)$$

$$\begin{aligned} F_{X_{i2}}^{(2)}(x) &= -2i \sum_{n=0}^{n_i^{(2)}} \left\{ C_{in}^{(2)} \exp(k_{in}^{(2)}x) + D_{in}^{(2)} \exp(-k_{in}^{(2)}x) \right\} Y_n^{(2)} \\ &\quad - 2i \sum_{m=0}^{\bar{n}_i} \sum_{p=0}^{\bar{n}_i} \left\{ \frac{\lambda(k_m, k_p)}{\mu_1(k_{mp})} Q_{imp}(x) Y_{mp} + \frac{\bar{\lambda}(k_m, k_p)}{\mu_1(k_{mp})} \overline{Q_{imp}(x)} \overline{Y_{mp}} \right\} \\ &\quad + \sum_{m=0}^{\bar{n}_i} \sum_{p=0}^{\bar{n}_i} \left\{ \alpha(k_m, k_p) Q_{imp}(x) \overline{Y_{mp}} + \bar{\alpha}(k_m, k_p) \overline{Q_{imp}(x)} Y_{mp} \right\} \end{aligned} \quad (39)$$

where

$$Y_{mp}^* = \begin{cases} 1.0 & (m = p = 0) \\ \frac{2 \cos k_{mp}^* (h_3 + D/2) \sin k_{mp}^* D/2}{k_{mp}^* D \cos k_{mp}^* h} & \begin{pmatrix} m = p \neq 0 \\ m \neq p \end{pmatrix} \end{cases} \quad (40)$$

$$\overline{Y}_{mp}^* = \begin{cases} 1.0 & (m = p \neq 0) \\ \frac{2 \cos \overline{k}_{mp}^* (h_3 + D/2) \sin \overline{k}_{mp}^* D/2}{\overline{k}_{mp}^* D \cos \overline{k}_{mp}^* h} & \begin{pmatrix} m = p = 0 \\ m \neq p \end{pmatrix} \end{cases} \quad (41)$$

$$Y_n^{(2)} = \frac{2 \cos k_n^{(2)} (h_3 + D/2) \sin k_n^{(2)} D/2}{k_n^{(2)} D \cos k_n^{(2)} h} \quad (42)$$

$$Y_{mp} = \frac{2 \cos k_{mp} (h_3 + D/2) \sin k_{mp} D/2}{k_{mp} D \cos k_{mp} h} \quad (43)$$

$$\overline{Y}_{mp} = \begin{cases} 1.0 & (m = p) \\ \frac{2 \cos \overline{k}_{mp} (h_3 + D/2) \sin \overline{k}_{mp} D/2}{\overline{k}_{mp} D \cos \overline{k}_{mp} h} & (m \neq p) \end{cases} \quad (44)$$

The subscript  $i$  is 1 and 4, denoting regions (1) and (4). Since the water depths in regions (1) and (4) are same, the wave numbers  $k_m, k_p$  are equal in these regions.

## 2.4 Incorporation of the effects of energy damping

To incorporate the effects of energy losses due to vortices generated at the plate ends and wave breaking over the plate, the energy losses are assumed to be expressed in terms of flow resistance proportional to square of local flow velocity and to local flow acceleration. The pressure continuity condition along the vertical plane at  $x = b$  may then be written as

$$\frac{1}{\rho}(p_1 - p_2) = -\frac{1}{2}C_D|v_1|v_1 - C_M \frac{\partial v_1}{\partial t} \quad (45)$$

where  $C_D$  and  $C_M$  are energy loss coefficients. By using the Lorentz concept, linearizing a nonlinear term with respect to time and expressing the dynamic wave pressure and velocity in the velocity potential yield the following boundary condition for the potential continuity.

$$\phi_1 - \phi_2 = \beta \left| \frac{\partial \phi_1}{\partial x} \right| \frac{\partial \phi_1}{\partial x} - C_M \frac{\partial \phi_1}{\partial x} \quad (46)$$

where

$$\beta = i \frac{4}{3\pi} \frac{g}{\sigma^2 h} \frac{\zeta_0}{h} C_D \quad (47)$$

### 3 Hydraulic Experiments

Two-dimensional hydraulic experiments are performed to measure the vertical and horizontal wave forces as well as the dynamic pressure along the upper and lower surfaces of the plate using pressure transducers. Fig. 2 illustrates the devices used for these measurements. For horizontal wave forces, as shown on the left-hand side of the figure, two pairs of strain gages were mounted on four steel cylinders attached to the horizontal plate. The horizontal forces may then be obtained through a calibrated strain-force relationship. For vertical wave forces, pressure transducers were mounted on both the top and bottom surfaces of the plate, as shown on the right-hand side of the figure. Integrating pressure distributions along the plate yields vertical wave forces exerted on the plate top and bottom surfaces, and adding these forces gives the resultant vertical wave forces. The height and period of incident waves are varied to investigate the effects of wave breaking over the plate on wave forces.

## 4 RESULTS AND DISCUSSIONS

### 4.1 The first- and second-order wave pressures and forces

The components induced by the nonlinear interactions of the second-order theory include a time-independent, steady component and second-harmonic component which constitute the second-order wave pressure and force. Fig. 3 shows comparison between the computed and measured pressure amplitude distributions along the top surface (upper figure) and the bottom surface (lower figure) of the plate. The lines indicate the computed results and the marks the measured. When energy damping is not taken into consideration, i.e.  $C_D = C_M = 0.0$ , an agreement between the computed and measured pressure distributions is poor, especially for the first harmonic pressure component, as shown in the left-hand side of Fig. 3. This may thus be due to the effects of energy losses caused by the generation of vortices at the two ends of the plate. With proper energy loss coefficients, which are 0.8 for  $C_D$  and 0.0 for  $C_M$  in this case, both 1st- and 2nd-order solutions agree quite well with the experimental results, as seen in the right-hand side of Fig 3. However, the computed 2nd-order steady component somehow deviates from the measured.

The amplitude of the first- and second-order non-dimensional oscillatory wave forces is shown in Fig. 4, where the thin lines indicate the computed results without consideration of energy damping and the thick lines with consideration of energy damping. By comparing the measured wave forces with the computed, an agreement between them is remarkably good when the submergence depth is not so small and the wave height is fairly small. The effects of energy loss indicated by the thick lines affect the normalized vertical force  $F_z$  more than the normalized horizontal one  $F_x$ . The computed second-order oscillatory forces  $F^{(2)}$ , indicated by the broken line, are also consistent with the measured, indicated by

Figure 2 Schematic description of measuring devices for horizontal and vertical wave forces.

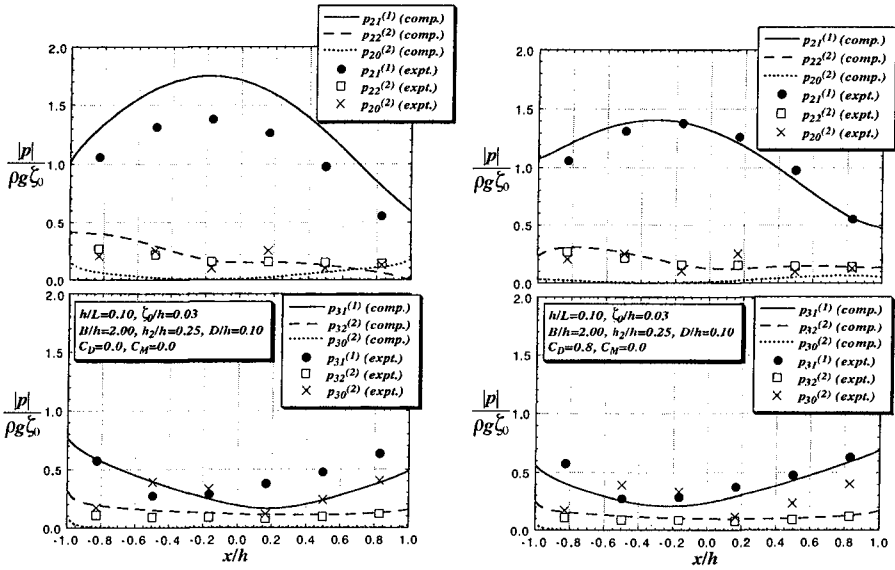

Figure 3 Comparison between computed and experimental wave pressure along the top and bottom surfaces of the plate with and without energy damping consideration.

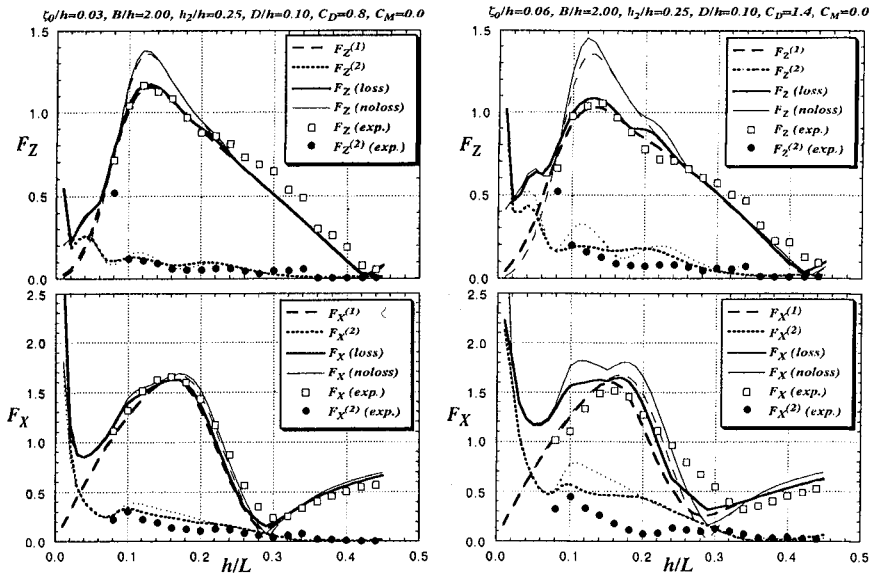

Figure 4 Comparison between computed and measured wave forces exerted on a submerged horizontal plate with  $\zeta_0/h = 0.03$  and  $\zeta_0/h = 0.06$ .

the black circle. Both the vertical and horizontal second-order oscillatory forces are small compared with the first-order ones  $F^{(1)}$  and decrease monochromatically with increase in  $h/L$

The right-hand side of Fig. 4 shows the result of a higher incident wave amplitude ( $\zeta_0/h = 0.06$ ), where wave breaking takes place over the plate when the relative water depth is greater than  $h/L = 0.14$ . The theory with greater  $C_D$  value can simulate the total wave forces fairly well even when wave breaking occurs over the plate. Although the theory overpredicts the 2nd-order oscillatory force, the actual values become quite small. Thus the first-order or linear wave forces dominate the total wave forces.

### 4.2 Variation of wave forces due to the submergence depth

Fig. 5 shows the variations of the normalized 1st-order vertical and horizontal wave forces with relative water depth for three different submergence depths. As the submergence depth  $h_2/h$  decreases, the computed results disagree not only quantitatively but also qualitatively with the measured, as depicted in Fig 5. The theory can fairly well predict the value of the maximum vertical and horizontal wave forces up to  $h_2/h = 0.15$ . At a smaller submergence depth the theoretical values fluctuate with the variation of relative water depth, but the experimental

Figure 5 Variations of the first-order wave forces with submergence depth.

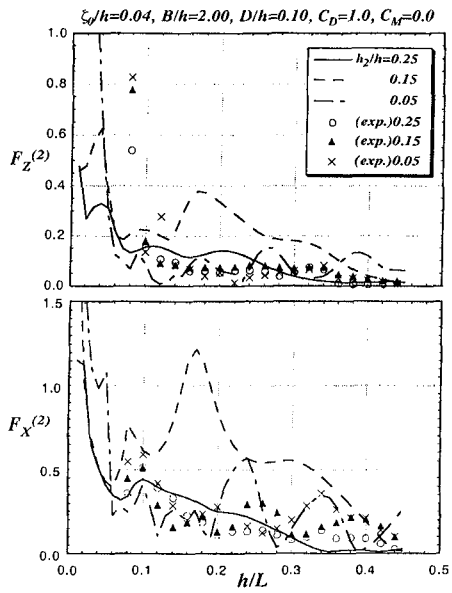

Figure 6 Variations of the second-order wave forces with submergence depth.

ones somewhat flatten over the whole range of relative water depth. The theory also overpredicts the amplitude of the second-harmonic force, as depicted in Fig. 6.

### 4.3 Variation of time-independent, steady wave forces

Another important wave force for design of a submerged horizontal plate is time-independent, steady force. The variations of normalized vertical steady forces for three different incident waves are delineated in Fig. 7, where a rectangular mark indicates the force exerted on the plate's top surface, a triangular mark on the plate's bottom surface, and a black circle the resultant force. When an incident wave height is relatively small, say  $\zeta_0/h = 0.03$ , upward steady forces act on the plate's bottom surface, while downward steady forces act on the plate's top. Since the upward forces are almost always greater than the downward forces, the resultant steady forces become uplift ones. The net steady forces exerted on the plate become comparatively large in magnitude at smaller relative water depth, decreasing almost monochromatically with the increase in relative water depth, and at larger relative water depth the forces come closer to zero. As an incident wave height increases, the normalized steady forces exerted on the both top and bottom surfaces become smaller and the direction of the forces exerted on the top surface changes to the upward at smaller relative water depth.

Figure 7 Variations of the steady wave forces with relative water depth for different incident wave heights.

## 5 CONCLUSIONS

The following conclusions are obtained from this study:

1. Linear and nonlinear dynamic wave pressures and forces exerted on a submerged horizontal plate are explained through the non-transient, finite amplitude wave theory that is valid to second order.
2. The theory with proper energy damping coefficients can well simulate the wave forces even when wave breaking occurs over the plate. The second-order wave forces are relatively small as compared to the first-order ones.
3. For the plate placed close to the water surface, the computed wave forces are qualitatively inconsistent with the measured; the computed first-order oscillatory wave forces fluctuate with relative water depth, while the measured vary almost linearly.
4. When wave height is relatively small, an upward steady force acts on the plate bottom surface, while a downward steady force acts on the plate top surface; the direction of the resultant force depends on their magnitude. The steady net uplift force becomes comparatively large in magnitude at smaller relative water depth, decreasing almost monochromatically with increase in relative water depth.

## CHAPTER 96

### MODERN FUNCTIONAL DESIGN OF GROIN SYSTEMS

Nicholas C. Kraus<sup>1</sup>, Hans Hanson<sup>2</sup>, and Sten H. Blomgren<sup>3</sup>

**ABSTRACT:** Coastal zone management policy in the United States and many other countries discourages use of groins for shore protection, even though properly designed groins can maintain beach width, increase longevity of beach fills, and prevent loss of sand into inlets, navigation channels, and submarine canyons. A lack of a systematic approach to groin functional design and a poor image from incorrect applications are probably responsible for the aversion to groins. In this study, a modern approach to groin functional design is demonstrated by applying the shoreline response model GENESIS to simulate the action of single and multiple groins. Groin bypassing and permeability, evolution of the shoreline in a groin field, and groin tapering are discussed. The balance between net and gross sand longshore transport rates emerges as an important factor controlling groin functioning. A criterion is introduced for judging groin success, and an example design diagram is developed based on this criterion to demonstrate the feasibility of developing a general and rational functional design procedure. Predictions are tested in reproducing shoreline change observed at the 15 groins at Westhampton, Long Island, New York.

#### INTRODUCTION

Coastal zone management policy in the United States and many other countries strongly discourages use of groins for shore protection, despite observations of good performance and their potential for maintaining beach width, increasing longevity of beach fills, and preventing loss of sand into inlets, navigation channels, and submarine canyons. No guidance on groin functional design is available other than rules of thumb, and many examples of poor performance of groins caused by mis-judgments in either design or in planning have turned this structure into a cliché representing automatic beach destruction. The result, however, is that society is losing a valuable shore-protection structure that can function effectively and economically under certain conditions, in particular for increasing the longevity of beach fills (e.g., Truitt et al. 1993) and for stabilizing beaches adjacent to inlets. The purpose of the present work is to demonstrate a framework for groin functional design by use of modern coastal engineering predictive tools and knowledge.

This paper concerns the functional design of groins, specifically their interaction with the beach through interruption of longshore sand transport – the "gating" or valve effect of groins (Hanson & Kraus 1989). Sand bypassing, groin permeability, and the balance between net and gross longshore transport will be shown to be key factors entering groin functional design and are central to this study. The functioning of a groin, which at first sight appears to be a simple structure, is governed by a surprising number of parameters, discussed in the next section. We exploit the shoreline change numerical simulation model GENESIS (Hanson & Kraus 1989) to quantify the influence of several of these parameters. For this study, representation of groins in GENESIS was refined based on qualitative observations in the field and laboratory, numerical testing, and data on groin functioning at Westhampton Beach, Long Island, New York (Nersesian et al. 1992). Although the dependence of groin functioning on longshore sand transport is the main focus, cross-shore transport processes are considered qualitatively.

## REVIEW AND SYNTHESIS

Here, groins are defined as shore-perpendicular structures emplaced for the purpose of either (1) maintaining the beach behind them, or (2) controlling the amount of sand moving alongshore. Previous definitions have stated the purpose as "building a beach" or as "trapping littoral drift" (SPM 1984), which implies the removal of sand from the littoral system by entrapment. Because modern coastal engineering practice includes a regional perspective that considers the stability of adjacent beaches (Kraus 1989), groin emplacement may involve beach nourishment so that sand bypasses the system. Therefore, we emphasize *maintaining a beach* for Purpose 1. The second purpose primarily refers to terminal structures built to anchor the beach by limiting removal of sand (Dean 1993), as onto an ebb-tidal shoal or into a navigation channel. Here we focus on the first purpose, maintenance of beaches, i.e., providing a certain minimum beach width.

As a shore-normal structure, groins may not function well (a) if there is a large tidal range, allowing sand to bypass the structures at low tide or to overpass at high tide, or (b) if cross-shore sediment transport is dominant, such as is typical in shallow bays and lagoons, and along portions of the U.S. Great Lakes (Hanson & Kraus 1991a) where strong winds and relatively small fetches make steep (erosive) waves predominate over swell. Undesirable updrift buildup and offshore transport of sediment may be promoted if groins extend too far offshore in relation to the wave average breaker line or if they are not sufficiently permeable, potentially causing sand to be jetted seaward.

Groins are a possible component of shore-protection, beach-saving, and sand-management alternatives in the following situations:

1. Where there is a divergent nodal region in longshore transport, such as in the central area of a crenulate pocket beach, in the border region of a diffraction shadow zone of a harbor breakwater or jetty, or where the curvature of the coast changes greatly.
2. Where there is no source of sand, such as on the down-drift side of a large harbor breakwater or jetty.
3. Where intruding sand is to be managed, such as at the updrift side of an inlet entrance, harbor entrance, or navigation channel (for preventing sand intrusion and for stabilizing or anchoring the beach at the groin, or for stockpiling material for bypassing across the inlet).
4. Where sand movement alongshore is to be controlled or gated, such as to prevent undue loss of beach fill, while providing material to downdrift beaches.

5. Where an entire littoral reach is to be stabilized, such as along a spit, near a submarine canyon, or along a barrier island, for which sand is lost without return in an engineering time frame.
6. Where stabilization of the shoreline is required in the face of extreme sand-transporting conditions, such as on the banks of inlets, where the current alongshore is strong.

### Synthesis of Present Knowledge

Reviews of groin functional design have been given by Bruun (1952, 1972), Balsillie and Berg (1972), Balsillie and Bruno (1972), Nayak (1976), Fleming (1990), and the U.S. Army Corps of Engineers (USACE 1992). These reviews provide some rules of thumb but no method for systematic functional design under a wide range wave, structure, and beach conditions. Although the literature on groins appears to be substantial, most papers describing the functioning of groins tend to restate conclusions from other studies with and without quoting sources. To the unwary reader, the literature may appear to assign validity to certain concepts and conclusions by weight of repetition and not by independent confirmation. Many laboratory tests appear to suffer so severely from scale distortions that the results are questionable or misleading. Some laboratory studies contain interpretations that confuse cross-shore processes with longshore processes. For example, change in wave steepness may change the breaking wave angle and longshore transport while causing either shoreline advance or recession by cross-shore transport. Almost no well-documented field case studies exist that involve shoreline evolution at groins.

The response of the shoreline to groins can be expressed schematically as an unknown functional relation  $Response = F[groin(s); beach; waves, wind, \& tide]$  that involves at least 27 parameters (Table 1), more than the number found for shoreline response to detached breakwaters (Hanson & Kraus 1990). The engineer can control parameters related to the structure(s), such as groin length, spacing, and permeability (elevation, porosity). Grain size may also be controlled somewhat by selection of beach nourishment material.

Major properties that can be attributed to groins and the authors' reasoning behind accepting or questioning the validity of those properties are summarized in Table 2. Laboratory studies and field performance suggest that groins on sandy beaches function best if their spacing is two to four times the groin length (the *SPM* suggests a spacing ratio of two to three). Optimal spacing and groin functioning depend upon: groin length (depth at the groin tip, which controls sand bypassing); groin permeability or porosity (controlling sand throughpassing); groin elevation and tidal range (controlling sand overpassing); predominant wave direction and height; net and gross longshore transport; and sediment grain size (mode of transport as suspended load or bed load).

Field observations reveal that single groins, groin fields, and jetties that function as groins rarely fill to capacity (to their seaward tips). Typically, the updrift shoreline reaches only a modest distance to the tip, indicating that sand bypassing and permeability, as well as variability in wave direction, play an important role in determining transport around the groin and resultant local and regional shoreline change. In a study of a groin field that has been active for almost three decades, Nersesian et al. (1992) found that the 14 groin compartments were still slowly filling in the predominant direction of the littoral drift. Such behavior can be explained by the process of bypassing, whereby each compartment deprives sand to neighboring downdrift compartments until it is filled to the point that bypassing can occur to the adjacent downdrift compartments or beach. If bypassing is not complete, a groin will act as a headland and impound sand far updrift, reducing the supply of sand downdrift along the remaining portion of the littoral cell.

<b>Table 1. Parameters governing beach response to groins.</b>		
<b>Groin(s)</b>	<b>Beach and Sediment</b>	<b>Waves<sup>1</sup>, Wind, &amp; Tide</b>

1) Long-term wave statistics or time series, and storms. 2) Standard deviation (representing variability in the given quantity). 3) Can be obtained by beach profile survey or estimated from wave information.		

### Judging Success

How should groins be judged successful in performing their intended function of preserving the position of the (local) shoreline? The criterion imposed here is preservation of shoreline position in a groin compartment or next to a groin such that the shoreline never recedes landward of half the effective groin length. This definition is arbitrary and simply addresses the aim to provide a certain minimum width of beach – others might choose, say, one-fourth the effective length. The effective length of a groin is the distance (on either side) from its seaward tip to the design shoreline, which would normally be formed by beach fill at the time the groins were constructed.

### GROIN BOUNDARY CONDITION

Groins have been represented in GENESIS throughout its development (Hanson 1989, Hanson & Kraus 1989), and shoreline change has been successfully simulated numerically for jetties and groins in the field (e.g., Kraus & Harikai 1983, Hanson & Kraus 1991a) and in physical models (Hanson & Kraus 1991b). However, predicted shoreline response adjacent to groins has been regarded by its developers as needing improvement (Gravens & Kraus 1989), particularly for groins that are permeable as well as diffract waves. The groin boundary condition was revised in this study based upon the following three requirements:

1. Bypassing should be represented such that the shoreline response to a groin, including evolution of the shoreline in time and its equilibrium plan form, depend on groin length (depth at tip of groin), with an increase in length increasing the impact of the structure on the shoreline.
2. Different groin permeabilities should produce different equilibrium plan forms, with increasing permeability decreasing the impact of the structure on the shoreline.
3. A permeability of 100% should result in longshore sand transport and shoreline evolution identical to that with no groin present.

<b>Table 2. Functional properties attributed to groins and critical evaluation.</b>	
<b>Property</b>	<b>Comment</b>
1. Wave angle and wave height are leading parameters (longshore transport).	Accepted. For fixed groin length, these parameters determine bypassing and the net and gross longshore transport rates
2. Groin length is a leading parameter for single groins. (Length controls depth at tip of groin.)	Accepted, with groin length defined relative to surfzone width.
3. Groin length to spacing ratio is a leading parameter for groin fields.	Accepted. See previous item.
4. Groins should be permeable.	Accepted. Permeable groins allow water and sand to move alongshore, and reduce rip current formation and cell circulation.
5. Groins function best on beaches with a predominant longshore transport direction.	Accepted. Groins act as rectifiers of transport. As the ratio of gross to net transport increases, the retention functioning decreases.
6. The updrift shoreline at a groin seldom reaches the seaward end of the groin.  (This observation was not found in the literature review and appears to be original to the present paper.)	Accepted. Because of sand bypassing, groin permeability, and reversals in transport, the updrift shoreline cannot reach the end of a groin by longshore transport processes alone. On-shore transport is required for the shoreline to reach a groin tip, for a groin to be buried, or for a groin compartment to fill naturally.
7. Groin fields should be filled (and/or feeder beaches emplaced on the downdrift side).	Accepted. Filling promotes bypassing and mitigates downdrift erosion.
8. Groin fields should be tapered if located adjacent to an unprotected beach.	Accepted. Tapering decreases the impoundment and acts as a transition from regions of erosion to regions of stability.
9. Groin fields should be built from the downdrift to updrift direction.	Accepted, but with the caution that the construction schedule should be coordinated with expected changes in seasonal drift direction.
10. Groins cause impoundment to the farthest point of the updrift beach and erosion to the farthest point of the downdrift beach.	Accepted. Filling a groin field does not guarantee 100% sand bypassing. Sand will be impounded along the entire updrift reach, causing erosion downdrift of the groin(s).
11. Groins erode the offshore profile.	Questionable and doubtful. No clear physical mechanism has been proposed.
12. Groins erode the beach by rip-current jetting of sand far offshore.	Questionable. Short groins cannot jet material far offshore, and permeable groins reduce the rip-current effect. However, long impermeable jetties might produce large rips and jet material beyond the average surfzone width.
13. For beaches with a large predominant wave direction, groins should be oriented perpendicular to the breaking wave crests.	Tentatively accepted. Oblique orientation may reduce rip current generation.

In GENESIS, the fraction  $F$  of sand that passes a groin by being transported over and through it is represented by a permeability factor  $P$ , and the amount passing around the seaward end is represented by a bypassing factor  $B$  (Hanson & Kraus 1989), such that

$$F = P(1 - B) + B \quad (1)$$

where  $0 \leq P \leq 1$ , and  $0 \leq B \leq 1$ . In the new version of GENESIS, the actual transport rate at the groin  $Q_G^*$ , denoted with an asterisk, is related to the calculated potential rate at the groin  $Q_G$  as

$$Q_G^* = F \cdot Q_G \quad (2)$$

In the original version of GENESIS, the factor  $F$  was applied to the transport rate at the updrift cell, as  $Q_G^* = F Q_{G \pm 1}$ . However, to satisfy Criterion 3, that, in the limit  $P \rightarrow 0$ , the calculation should give the same result as for "no groin present," Eq. 2. is required. The permeability factor is assigned based on groin elevation, groin porosity, and tide range, and the bypassing factor  $B$  is calculated in the model at each time step as (using the present shoreline position to calculate present depth)

$$B = 1 - D_G / D_{LT} \quad (3)$$

where  $D_G$  is the depth at the groin at a particular time step, and  $D_{LT}$  is the depth of active longshore sand transport, taken to be about 1.6 times the significant breaking wave height (Hanson & Kraus 1989). Eq. 3 shows the importance of depth at the groin tip, a parameter related to but more fundamental than groin length, and the form of Eq. 3 suggests that the parameter  $D_G / H_o$  should characterize groin bypassing, where  $H_o$  is the deep-water wave height.

The reasoning behind use of this simple formula, Eq. 3, in development of GENESIS was pragmatic: the cross-shore distribution of longshore transport on a natural beach takes many forms not readily predicted, including peaks in the swash zone and near the breaker line (Kraus et al. 1982), and the presence of a groin in the surf zone will also modify the distribution in some, as yet, unpredictable way. Therefore, a rectangular distribution across shore was originally taken as an easily calculated representative shape. In the new version of GENESIS, the depths in Eq. 3 are calculated from the equilibrium profile with  $y^{2/3}$  shape, where  $y$  is distance offshore.

## Single-Groin Tests

**Time Dependence of Bypassing.** Shoreline change predictions at a single groin were compared for four distributions of transport; rectangular on a plane-sloping profile, triangular with peak at the shore on a plane-sloping profile, and two similar distributions on an equilibrium profile shape. In the test, median grain size was 0.25 mm, used to determine the equilibrium profile shape, the groin was 100 m long on an initially straight shoreline, and waves were constant with deep-water height of 1 m, period of 8 sec, and angle of 20 deg. The model was run for 15 years, and calculated positions of the shoreline directly updrift of the groin divided by the groin length are plotted in Fig. 1. The general trend is for rapid initial buildup followed by a more gradual growth after about two years. The calculated gradual buildup agrees with the qualitative observation that groins seldom fill to capacity, and an influential factor is the increased amount of material bypassing a groin as the shoreline grows. The rectangular distribution based on the equilibrium profile falls between the two extremes and was selected for the new version of GENESIS.

Fig. 1. Shoreline change at groin calculated with different distributions for bypassing.

**Influence of Gross Longshore Transport.** Shoreline change in the vicinity of disturbances that alter transport alongshore is controlled by the gross transport rate as well as the net (Bodge 1992). A single groin was placed on the beach of the previous example, and the directions of hindcast waves from the Westhampton project, discussed below, were modified to change the ratio of the net transport rate  $Q_n$  to the gross  $Q_g$  as  $Q_n/Q_g = 1, 0.5, 0.33,$  and  $0.25$ . The ratio  $Q_n/Q_g$  varies between 0 and 1 for the limiting conditions of perfectly balanced transport (no net) and unidirectional transport, respectively. The ratio  $Q_n/Q_g = 0.5$ , with  $Q_n = 300,000$  cu m is the design condition for Westhampton. The length of the groin  $Y_G$  was also varied in relation to the width of the surfzone (to the breakpoint)  $Y_B$  on the initially straight beach  $Y_G/Y_B = 0.5, 1,$  and  $2$ . Fig. 2 plots calculated shoreline change on the updrift side of the groin for  $Y_G/Y_B = 1$ . Over the 5-year calculation interval, the shoreline approaches the tip of the groin only if the gross and net rates are equal. As the gross rate exceeds the net, the growth decreases, confirming Property 5 in Table 2. Shoreline change with  $Q_n/Q_g = 0.5$  for the three dimensionless groin lengths is plotted in Fig. 3. The updrift shoreline moves seaward more rapidly as the relative groin length increases.

### Multiple-Groin Tests

Shoreline change was calculated for a field of seven groins with  $P = 10\%$  placed on an initially straight beach. The groins were 100 m long with spacing of 400 m. Waves were Raleigh-distributed in height with significant  $H_o = 1$  m, period 8 sec, and deep-water direction 10 deg. Grid spacing was 50 m and time step was 6 hr. Fig. 4 shows calculated shoreline change after 5 and 10 years. The groins slowly filled in the direction of transport, but the shoreline did not reach the tip of the most updrift groin. Updrift groins deprived the downdrift compartments and downdrift (unprotected) beach of sand until substantial bypassing occurred. At 10 years, the most downdrift compartment did not yet benefit from the gradual bypassing, and it lost sand because of groin permeability. Tracking of shoreline position through time (Fig. 5) downdrift of the most updrift groin in the first compartment shows that it first retreated because sand could not enter. Over time, bypassing began to occur and the shoreline advanced.

Fig. 2. Shoreline change updrift of groin for different ratios of net to gross transport rate

Fig. 3. Shoreline change updrift of groins of different relative length when the net rate equals half the gross rate

Fig. 4. Shoreline change in a groin field showing gradual filling of compartments in the direction of net drift.

Fig. 5. Evolution of shoreline within most updrift groin compartment.

**Example Design Diagram.** The final example, which demonstrates numerical modeling capability to develop general functional design guidance, concerns a pair of groins placed on a 0.25-mm sand beach. Waves with constant significant deep-water height, period of 8 sec, and deep-water direction of 30 deg were applied for one year. Initial depth at the groin tip was specified for groin lengths of 50, 75, 100, 150, and 200 m, and simulations were also done for  $D_G/H_o = 0.5$  and 1.0 to give groin lengths of 10 and 27 m. The groin spacing  $X_G$  divided by groin length  $Y_G$  was also changed. The resultant shoreline response was classified as either satisfying or not the criterion that the calculated landward-most shoreline position  $Y$  be less than half the effective groin length, where filled circles in Fig. 6 indicate satisfaction of the criterion.

Fig. 6 shows that shorter groins, indicated by smaller  $D_G/H_o$  values, satisfy the criterion with a larger relative groin spacing, suggesting that shorter groins will be more cost effective. For the longest groin tested, the criterion was met for all groin spacings, explained by the fact that for a relative groin spacing exceeding about 8, the two groins no longer interact as a system but function independently. Thus, very long groins satisfy the criterion as a single groin. Care must be used in interpreting a plot such as Fig. 6 which involves non-dimensional parameters. The figure implies, by the imposed success criterion, that a spacing of  $X_G/Y_G = 1/1$  is satisfactory, but only as far as maximum recession is concerned; maximum accretion or filling capacity (by nourishment) for smaller ratios is also much smaller. For example, with longshore spacing of  $X_G = 200$  m, the ratio  $X_G/Y_G = 1/1$  gives a maximum advance of about 14 m, whereas the ratio 1/11 gives a maximum advance of 106 m. Effectiveness in holding a certain width of beach, reduction of down-drift impacts, and initial and maintenance costs must be kept in mind when developing groin functional designs. Shorter relative groin spacing may also increase cost. In using longer groins, relative erosion is limited, whereas absolute erosion increases with groin length.

## SIMULATION FOR WESTHAMPTON BEACH

### Background

Westhampton Beach faces the Atlantic Ocean and is located on a portion of a 24.6-km long barrier island of the southeast shore of Long Island, New York, between Shinnecock Inlet to the east and Moriches Inlet to the west. This coast was devastated by a hurricane in 1938 and further damaged by at least seven other hurricanes and extra-tropical storms that struck the area from 1944 to 1962. As a result, the U.S. Government authorized storm-protection planning for much of the south shore. Groins were constructed initially at Westhampton Beach because it was the section judged to be most vulnerable to breaching and inlet formation to the Great South Bay. Nersesian et al. (1992) describe the regional setting, history of the Westhampton Beach shore-protection project, and the functioning of the groins there. The work described in this section is a continuation of the paper of Nersesian et al. to modeling of shoreline change at Westhampton.

The original plan developed by the U.S. Army Corps of Engineers (USACE 1958) provided for construction of dunes, fronting protective beaches, together with 23 groins if needed. Owing to political and economic considerations (Heikoff 1976) (with law suits against the three levels of Government (Federal, State, County) by private land owners settled in October, 1994), eleven groins were constructed without placement of the dune and beach fill on the eastern 3.8 km of shore extending westerly from a point 10.6 km east of Moriches Inlet. This work was supplemented in 1970 by construction of four groins extending 1.8 km west of the 11 groins, including beach fill in the four new compartments. The groins are made of large quarry stone, and are 146 m long with average spacing of 400 m. The chronology of fills as implemented in the shoreline change simulation is: 1969-1970, 1.49 million cu m placed in last four compartments during and after completion of construction (USACE 1980); 1974, 31,400 cu m (probably dredged beach-quality material from channel maintenance) placed directly downdrift of Groin 15 (assumed to be a rectangular fill 400 m long); and 1977, 44,700 cu m, placed similarly as the 1974 fill.

Westhampton Beach is composed of fine to medium sands, and the net transport rate has been estimated to be on the order of 300,000 cu m/year to the west (Panuzio 1968). Fig. 7 is an oblique aerial view of the Westhampton groin field, looking east, with Groin 15 in the foreground. Over the years, the groin field has very successfully performed its intended *local* function of reinforcing the historically weak section of barrier beach by building a wide beach at the groin field and to the east (updrift) (Nersesian et al. 1992). However, the beach immediately to the west has eroded significantly and was breached on December 18, 1992, during a strong subtropical storm.

### Simulation of Shoreline Change

The shoreline change model was driven with data generated from a recent Corps of Engineers Wave Information Study (WIS) hindcast (Hubertz et al. 1993) that provides wave parameters at 3-hr intervals for the 20-year period 1956-1975. Using representative coefficient values of  $K_1 = 0.54$  and  $K_2 = 0.27$  in the CERC/GENESIS longshore sand transport rate (LSTR) formula (Kraus et al. 1982, Kraus & Harikai 1983), a shoreline orientation of 70 deg from north, and wave shadowing by land masses to achieve a 20-year average annual net of approximately 300,000 cu m (the WIS hindcast gives waves from all directions), GENESIS produced statistics as shown in Table 3, using both the WIS sea and swell components. With the average annual LSTR constrained to approximate the empirically determined rate (Panuzio 1968), the corresponding gross rate was about twice that amount. In the simulations, the grid spacing was 61 m, and the time step was 3 hr. The lateral boundary conditions were a pinned beach located approximately 4 km east of Groin 1 on the east, and a gated boundary defined by the Moriches Inlet jetty about 4 km to the west of Groin 15.

Fig. 7. Aerial view of Westhampton groin field, looking east, Dec. 1992

<b>Table 3. Variability in annual potential longshore sand transport rates (1,000 cu m) calculated from the 20-year WIS wave hindcast (positive net transport to the west).</b>			
<b>Quantity</b>	<b>Net Rate</b>	<b>Gross Rate</b>	<b>Year</b>
Minimum Net	117	471	1967
Maximum Net	685	842	1958
Minimum Gross	189	434	1957
Maximum Gross	685	842	1958
Average	321	610	—
Standard Dev.	130 <sup>1</sup>	114	—
1) Note that ratio of std. dev. over average for the net transport is much greater than for the gross.			

**Variability in Wave Input.** Simulations were performed using four different sequences of ten years of record from the 20-year hindcast wave time series. The series were 1956-1965 and 1966-1975, taken in chronological order by year and in reverse chronological order by year. The resultant calculated shoreline positions showed little difference among each other, which may be explained by the groin system having more control (as through bypassing) than do reasonable variations in wave conditions. The only notable difference produced by the wave sequencing was in position of the shoreline directly west of Groin 15 (downdrift of the groin field), depending on whether the most recent waves arrived more out of the south than out of the north.

**Model Calibration.** Fig. 8 shows measured and calculated shoreline change in December 1989 starting from the February 1966 measured shoreline, which was the pre-construction shoreline. The overall trend in simulated shoreline change follows well that of the actual change. Of particular note is the reproduction in the model of the gradual infilling of the groin compartments from east to west (left to right in the figure). Reproduction of the observed gradual infilling of the groin field in the direction of predominate transport is considered a major success of the model. No attempt was made to adjust the transport coefficient  $K_T$  or otherwise tune the model.

The hump in the measured 1989 shoreline around distance 14 km (east of Groin 1) is anomalous from the perspective of longshore transport processes and may be a result of irregular nearshore bathymetry. The model overpredicts erosion on the west side of Groin 15. Depth soundings made by the first author in reconnaissance of the site in June 1991 indicated that the water adjacent to the west side of Groin 15 was much deeper than at comparable distances offshore of the groin field and the distant unprotected beach. The steeper nearshore profile west of Groin 15 alters wave transformation and sediment transport processes, and it is not accounted for in the shoreline change simulations. Also, occasional strong reversals in direction of longshore transport in the summer, not necessarily accounted for in the hindcast, can create a fillet on the east side of Groin 15. Such fillets are present in autumn/winter 1979 and 1994 aerial photographs. Sand volume in the system increased; we believe the extra volume to be associated with onshore wind-blown sand transport on the wide beach in the groin field, creating lush high dunes and a wide berm.

Fig. 8. Calibration of the shoreline change model for Westhampton

**Groin Tapering and Shortening - Alternative Designs.** Tapering and shortening of groins reduce their gating capacity and promote transport of sand out of the groin field in transition of the groins to the unprotected beach. Tapering of the westward-most groins at Westhampton would increase bypassing and movement of sand to the west. Shortening of the groins would release sand to the system, reduce updrift impoundment, and provide stone for constructing additional groins to the west, if needed. Moderate tapering and shortening of the groins would cause a minor decrease in level of protection to the properties in their lee by decreasing berm width.

As a simple example of the use of a shoreline response model in groin functional design, three alternatives were examined to estimate the shoreline plan form at and west of the groin field 20 years into the future. The simulations started from the measured shoreline of March 1989 and finished in July 2009 (Fig. 9). Alternative 1 simulated the existing condition to provide a baseline for comparison. Alternative 2 involved shortening of Groins 14 and 15 to 129.5 and 85.3 m, respectively (groins shortened by 16.8 m and 61.0 m), with addition of a groin between them of 107.4-m length to maintain groin spacing to length ratio, and placement of 2,500,00 cu m in the westernmost eight compartments (including the intermediate groin). Alternative 3 involved shortening all groins by 30.5 m or to the existing shoreline, with addition of 300,000 cu m west of Groin 15 for a distance of 1,600 m. Each year of the WIS wave hindcast was used in the 20-year simulation.

Fig. 9 shows after 20 years, the groin field will be effectively filled, except for the most westward compartment, because it can receive sand from the east, but not from the west (because of the great effective groin length on the west side) during times of reversal from the predominant direction of transport. Tapering plus fill provides maximum benefit to the downdrift beach; clearly, the model could be used to optimize the preferred alternative design to meet planning objectives.

Fig. 9. Comparison of groin shortening and tapering alternatives

## CONCLUSIONS AND RECOMMENDATIONS

1. This paper has demonstrated that modern numerical simulation models can reproduce the main features of shoreline change at single groins and at groin fields, and thus are powerful tools for groin functional design.
2. Bypassing (parameterized by the ratio  $D_G/H_o$ ), structure permeability, and the balance between net and gross longshore transport rates (parameterized by the ratio  $Q_n/Q_g$ ) are three key factors that determine the functioning of groins. These three factors succinctly incorporate many fundamental parameters, such as wave height, direction, period (and their variability), equilibrium beach slope (or grain size), and groin length. Ratio of groin separation distance to groin length is a key controlling factor for groin systems, as found in previous studies.
3. There is great need for comprehensive project-level monitoring of groin behavior, including periodic shoreline surveys (as through aerial photography), and periodic beach profile and sediment surveys together with long-term wave and current monitoring.
4. Field and large-scale laboratory studies are required to quantify groin bypassing, distribution of transport in the presence of a groin, groin permeability, seasonality of waves in inducing both longshore and cross-shore transport, and the offshore jetting effect of groins.
5. Cross-shore sediment transport processes and their intricate and unknown interaction with longshore sediment processes need to be investigated to understand how beach elevation and width can build beyond what can be presently calculated with shoreline change models. It is postulated here that cross-shore transport, such as a strong accretionary event in summer, is a potentially important mechanism for groin filling, because longshore transport alone cannot fill groins to their tips owing to bypassing and variability in direction of transport.

## ACKNOWLEDGEMENTS

This study was supported by the Conrad Blucher Institute for Surveying and Science, Texas A&M University-Corpus Christi, and the Department of Water Resources Engineering, University of Lund. Some concepts developed in this paper were stimulated in coastal engineering studies conducted by the authors for the New York District and the Jacksonville District, U.S. Army Corps of Engineers. The major portion of this work was performed while the second and third authors were in residence as visiting scholars at the Blucher Institute over February to June, 1994. We appreciate discussions with Mr. Gilbert K. Nersesian, Senior Coastal Engineer of the New York District, and Dr. Tsuguo Sunamura, Tsukuba University, Japan. Ms. Rebecca Brooks and Robin Hoban of the Coastal Engineering Research Center provided the wave hindcast data used in this study.

## Reshaping breakwaters in deep and shallow water conditions

A. Lamberti<sup>1</sup>, G.R. Tomasicchio<sup>2</sup>, F. Guiducci<sup>3</sup>

### Abstract

In order to investigate the influence of water depth on the profile of reshaping breakwaters, model tests have been performed in deep, intermediate and shallow water conditions. The results show that the reduction factor for the dimensions of a reshaped profile in intermediate and shallow water conditions does not depend only on the wave height reduction. Other influencing factors are identified as breaking depth, wave steepness and foreshore slope. Moreover, at any water depth condition, the characteristic wave height corresponding to the frequency of stone movements on a reshaped profile is larger than the significant wave height. In the present tests, good results are obtained using the 1/50 wave height. Finally, whereas the offshore evaluated reflection coefficient increases with the water depth at the structure, the same coefficient evaluated in front of the structure shows an opposite trend.

### Introduction

In the last decade researchers have paid great attention to the characteristics of berm breakwaters (Burcharth & Frigaard, 1987; van der Meer, 1988; Juhl & Jensen, 1990; Hall & Kao, 1991). Such structures are also named sacrificial or reshaping breakwaters, as sometimes a berm is present also in the armor layer of a conventional non reshaping breakwater. In a reshaping breakwater, if a sufficient amount of material is provided, a stable S-shape profile is eventually developed. During the reshaping phase, the material is removed from zones where it is unstable and relocated into more stable positions; a sorting process is also active during reshaping since the less stable units in the mound are removed first; at the end of reshaping if a low mobility remains active throughout the phase, a profile with a uniform distribution of mobility is naturally formed. The self armoring response of reshaping breakwaters to wave forces makes them economically attractive because finer rock material can be used than for a conventional breakwater; construction and maintenance can also use less expensive equipments.

Most laboratory investigations aimed to foresee the behavior of the reshaping profiles under deep water conditions. In particular, laboratory investigations have considered 2- and 3-dimensional stability of reshaping breakwaters, referring mainly to the trunk section, but also to the rear side (Andersen & al., 1992) and to the roundhead (Burcharth & Frigaard, 1987). Only few tests have considered reshaping of the seaward profile in shallow water conditions. A large number of breakwaters in the Mediterranean area operate in shallow water conditions and moderate tidal excursion; in these conditions waves, before hitting the structure, undergo a relevant energy decay and an even more pronounced decay of extreme wave height.

This paper investigates the influence of water depth in front of the structure on the seaward profile development of a reshaping breakwater, comparing results of 2-dimensional model tests performed at Danish Hydraulic Institute (DHI) and Estramed laboratories for deep, intermediate and shallow water conditions.

## Description of the model tests

### Flumes

Physical model tests were carried out using the facilities at DHI (Spring 1992) and Estramed (Summer 1993, Summer 1994) laboratories. Tests were performed in glass walled flumes.

In deep water tests (referred to as DHI-92) the flume presented a horizontal foreshore with water depth 0.60 m. Intermediate and shallow water tests were performed using two different flumes. The first flume (referred to as Estramed-93) presented a bottom (fig. 1a) consisting of a foreshore slope 1:20 from 0.60 to 0.36 m water depth, followed by a milder 1:100 slope reaching 0.30 m water depth at structure toe. The second (referred to as Estramed-94) presented a bottom (fig. 1b) with a foreshore slope 1:20 from 0.60 to 0.34 m water depth, followed by a milder 1:100 slope; on this slope the structures were placed at depth 0.30 and 0.14 m. Characteristics of the flume are summarized in table 1.

Table 1. Tests set-up characteristics (measures in m)

No.	Test series	Width	Effective length	Toe depth	Foreshore slope
1	DHI-92	0.60	16.0	0.60	0
2	Estramed-93	1.50	22.6	0.30	1:100
3	Estramed-94	0.75	13.2	0.30	1:100
4	Estramed-94	0.75	33.6	0.14	1:100

### Materials

For present tests, armor materials and wave characteristics were chosen in order to obtain values of the stability number  $H_s/\Delta D_{n50}$ , the index of the armor layer mobility, close to 3. Moreover, water depth was varied in order to obtain values of

the ratio  $h/H_{so}$  as low as 0.85. Values of  $h/H_{so}$  larger than 3.0 provided deep water conditions; values of  $h/H_{so}$  around 2.0 gave intermediate water conditions.

All tested structures were built with crushed stones whose characteristics for the armor and the core are given in table 2. Gradation curves were based on samples of more than 200 stones.

Table 2. Rock material characteristics (measures in cm)

No.	Test series	Armor $D_{n50}$	Armor $D_{n85}/D_{n15}$	Core $D_{50}$	Core $D_{85}/D_{15}$	$\Delta$	Shape
1	DHI-92	3.4	1.42	1.1	2.8	1.68	Angular
2	Estramed-93	2.5	1.50	0.9	2.5	1.65	Angular
3	Estramed-94	2.6	1.66	0.9	2.5	1.65	Angular
4	Estramed-94	1.5	1.66	0.9	2.5	1.65	Angular

**Structure shapes**

Berms were built approximately 0.1 m above mean water level (fig. 2) and a certain amount wider than the foreseen erosion. Seaward slopes of as built structures were in the range 1:1.1 to 1:1.5. The geometrical characteristics of the structures are summarized in table 3.

Table 3. Berm breakwaters sections (measures in cm)

No.	Test series	Toe depth	Berm width	Berm freeboard	Crest width	Crest freeboard
1	DHI-92	60	70	10	30	20
2	Estramed-93	30	55	10	30	20
3	Estramed-94	30	55	10	30	20
4	Estramed-94	14	35	6	20	12

**Wave attacks**

In all the tests irregular waves of the Pierson-Moskowitz spectral shape were generated by hydraulically actuated piston-type wave makers without re-reflection absorption system.

In DHI tests, where depth was constant everywhere offshore the breakwater, 4 wave gauges were installed half way between the wave paddle and the breakwater and some further ones closer to the toe of the structure. The four gauges were used to estimate incident and reflected spectra, while the gauges at the structure toe were used as phase reference for velocity measurements. In Estramed tests, 3 gauges were installed in front of the breakwater and 3 offshore, not far from the wave paddle. In this way both offshore and inshore incident and reflected waves were measured. Waves were recorded continuously throughout all the tests. Wave gauges were statically calibrated (in green water); non linear effects are stronger in shallow water conditions and are not accounted for by the adopted separation method between

incident and reflected spectra (Goda & Suzuki, 1976; Mansard & Funke, 1980). Measures of incident and reflected wave height in shallow water conditions should be regarded as affected by greater experimental uncertainties.

Offshore wave characteristics were measured at 0.60 m water depth and are summarized in table 4.

All tests consisted of a reshaping phase during which design wave conditions were applied lasting 6x1000 waves. Profiles were surveyed by a mechanical sounding, i.e. measuring the depth of the profile relative to a horizontal reference plane. Profile surveys were repeated at least 3 times during reshaping; after 1000, 3000 (or 2000) and 6000 waves. Data were digitized and visually analyzed in order to estimate the characteristic dimensions of the profile according to Vellinga (1986) parameterization scheme. It was observed that the largest portion of berm erosion occurred during the attack of the first few hundreds waves. After this phase, stones moved singularly and rarely.

A small amount of wave overtopping occurred during tests at DHI and no overtopping at all was observed during the other tests.

*Table 4. Offshore wave characteristics (measures in cm, s)*

## Waves on the structures

### Incident waves

Data from present tests have been compared with values computed according to Goda (1985) for a foreshore slope 1:100. Data are presented (fig. 3) as a reduction factor, i.e. as a ratio between characteristic values having the same exceeding frequency in offshore and inshore conditions. Our data present some differences from values foreseen by Goda's formulae; this is probably due to the evaluation procedure and to reflection at present tests. However, mentioned differences do not influence the wave height ratios.

Fig. 1. Bottom conditions at Estramed tests

Fig. 2. Cross section of the as built structures (measures in m)

Because inshore wave characteristics were measured at a small but finite distance from the structure, on a water depth larger than at the structure toe, incident wave height on the structure was obtained from measured data applying a small correction which was evaluated according to Goda's formulae. Table 5 gives the observed and calculated inshore wave characteristics.

### Wave height distribution

For deep water conditions, in the case of irregular waves with a narrow spectrum (which is a very frequent case in nature and is almost certainly the case for the highest waves affecting the breakwater in deep water conditions) the wave height distribution is of Rayleigh type, or at least it shows a Rayleigh type upper tail of such an extension that the whole third of highest waves fits the Rayleigh distribution well. As a consequence, the ratio between any characteristic wave height and the significant one is a constant. For instance,  $H_{1/10}/H_{1/3} = 1.27$ ,  $H_{1/50}/H_{1/3} = 1.55$  and  $H_{max}/H_{1/3} = 1.8$ .

Fig. 3. Wave height reduction factors against relative water depth

In shallow water breaking acts selectively on the highest waves and produces super- and sub-harmonics, broadening the spectrum. For the range of relative water depths of our intermediate and shallow water tests, the ratio between the characteristic wave heights was significantly lower than the mentioned values

derived from Rayleigh distribution. The observed ratios in shallow and intermediate water conditions are:

$$H_{1/10}/H_{1/3} = 1.19 \pm 0.04$$

$$H_{1/50}/H_{1/3} = 1.33 \pm 0.12$$

Table 5. Inshore wave characteristics (measures in m and s)

No.	Test series	$h$ at point of measure	$H_s$	$H_{1/50}$	$T_m$	$C_R$	$h$ at toe	$H_s$	$H_{1/50}$

In shallow water the wave height distribution is distorted compared to the Rayleigh one, and a different distribution must be considered (Glukhovskiy, 1966; Klopman & Stive, 1989). In general no 1-parameter distribution will describe the wave height statistics both in shallow water and in deep water conditions. Only for particular purposes a unique characteristic wave height can be used; for instance, aiming to assess the safety of a brittle structure, the maximum wave height may be considered, as in fact it is normally done for vertical wall breakwaters.

### Characteristic wave height

Reshaping of the seaward profile of a berm breakwater is a result of stone movements. During our laboratory investigation, it was observed that their frequency ranged from few single events, when movement starts, to about 50 events in 1000 waves, for the assumed reshaping conditions, producing contemporary movements in more than one place. Therefore we have assumed that a good representative wave height for describing this phenomenon for any water condition is  $H_{1/50}$ .

The frequency of stone movements is described by the *surface damage level* which is defined as:

$$S = N_d \cdot D_{n50}^2/A \tag{1}$$

representing the probability of moving of a generic stone from a one-grain thick layer of the reshaped profile.

The wave height and wave steepness effects on stone movement frequency (Tomasicchio & al., 1994) along a reshaped profile can be described, both in deep and shallow water conditions, by a unique relation if  $H_{1/50}$  is considered (fig. 4). Wave attack intensity is described by the *modified stability number* defined as:

$$N_s^{**} = \frac{H_k}{C_k \Delta D_{n50}} \cdot \left( \frac{s_m}{s_{mk}} \right)^{-1/5} \quad (2)$$

$N_s^{**}$  is a modification of the traditional stability number  $N_s$  accounting for the effect of a non-Rayleighian wave height distribution and of wave steepness. If we assume  $H_{1/50}$  as the wave height  $H_k$ ,  $C_k = 1.55$ . As reference wave steepness we assume  $s_{mk} = 0.03$ . For this wave steepness and for deep water conditions the values of  $N_s$  and  $N_s^{**}$  are equal.

An interpretation of eqn. (2) comes from consideration that, in the case of an orthogonal wave attack, the assumptions that onshore wave energy flux is conserved and that waves break as shallow water waves can be translated as:

$$\frac{1}{8} \rho g H_o^2 c_{go} = \frac{1}{8} \rho g H_b^2 c_{gb} \quad (3)$$

where

$$c_{go} = \frac{1}{2} \sqrt{g/k_o}, \quad c_{gb} = \sqrt{g h_b}$$

and

$$H_b = \gamma \cdot h_b \quad (4)$$

They imply:

$$\frac{H_b}{H_o} = \left( \frac{\gamma}{4k_o H_o} \right)^{1/5} \propto \left( \frac{H_o}{L_o} \right)^{-1/5} \quad (5)$$

According to Komar & Gaughan (1972) the best agreement with reality is obtained assuming  $\gamma = 1.4$  or the proportionality constant in the last relation = 0.56. The comparison of eqn. (2), (3) and (5) shows that the modified stability number  $N_s^{**}$  assumes as relevant wave intensity parameter the onshore energy flux or, if preferred, the breaker height provided the above assumptions hold.

## Scale effects

Reynolds number referred to the mound where waves break on is usually defined combining the characteristic length  $D_{n50}$  with the typical breaking wave velocity  $\sqrt{g H_s}$ :  $Re = D_{n50} \sqrt{g H_s} / \nu$ . With the kinematic viscosity,  $\nu$ , equal to  $10^{-6}$  m<sup>2</sup>/s we obtain in our tests  $2.1 \cdot 10^4 < Re < 4.6 \cdot 10^4$ . Jensen and Klinting (1983) found that in rubble mound breakwater models there is no evident viscosity scale effect if  $Re > 0.6 \cdot 10^4$ .

## Profile dimensions in shallow water

A reshaped or dynamically stable profile for a given wave climate can be described by a small number of geometrical parameters (van Hijum & Pilarczyk, 1982; van der Meer, 1988). Empirically based numerical models to determine such a profile in deep water conditions are available (van der Meer, 1988, 1992 and 1993).

Depth induced breaking cause a reduction in every characteristic wave height and in the dimensions of the developed profile (fig. 4), compared to a breakwater attacked by the same waves in deep water.

Fig. 4. Parameters for describing the developed profile in shallow water conditions

Accounting for the wave height reduction just in front of the structure is however not sufficient and, as shown first by van der Meer (1988), in order to evaluate the profile parameters, a further reduction factor must be applied.

The relation providing step dimensions suggested by van der Meer (1988) are:

$$h_s = H_{si} \cdot N^{0.07} \cdot 0.22 \cdot s_m^{-0.3} \tag{6}$$

$$l_s = D_{n50} \cdot N^{0.07} \cdot (H_0 T_0 / 3.8)^{1/1.3} \tag{7}$$

Based on very few experimental data, van der Meer proposed the following functional relationship for the reduction factor of the step dimensions,  $r$ , depending on the water depth to incident wave height ratio  $h/H_s$ :

$$r = 1 - 0.75 \left(2.2 - \frac{h}{H_s}\right)^2 \quad \text{if } \frac{h}{H_s} < 2.2 \tag{8.1}$$

$$r = 1 \quad \text{if } \frac{h}{H_s} > 2.2 \tag{8.2}$$

Comparing the two sets of experimental data, the differences between van der Meer's and our test conditions and analysis procedure must be pointed out, see table 6:

Table 6. Differences in laboratory investigations and in the analyses

	van der Meer tests	our tests
Mobility range	$3.5 < N_s < 12$	$2.9 < N_s < 3.4$
Foreshore slope	1:30	$\leq 1:100$
Shape of the built structure	1:3 uniform slope	berm type
Wave measurements	without structure	with the structure in place
Wave analysis	in the time domain	reflection analysis in frequency domain

Figure 5 shows some of the surveyed profiles. After the first few thousands waves if wave conditions are kept constant, the reshaped profile conserves a poor memory of the built profile. The main trace of the original shape observed in our tests refers to the crest: in fact in our tests the crest was usually not clearly above the original berm elevation; therefore the crest position may not depend only on wave intensity but also on the original shape.

The observation of the profiles from our and from other Authors tests suggests the following comments on the qualitative behavior:

- for a breakwater in shallow water, the reshaped profiles can certainly be described by a reduced number of parameters than described by Vellinga (1986): the step height  $h_s$ , the step length  $l_s$ , the crest height  $h_c$  and/or the crest length  $l_c$ ;
- the crest elevation above the original berm was in our tests not evident, not even after a very long reshaping phase; in such case the independent parameters identifying the crest are reduced to only one;
- the step dimensions are reduced in the breaker zone much more than the significant wave height does and therefore a correction factor is necessary;
- the correction cannot be interpreted only as the effect of the reduction of the characteristic wave height ( $H_{1/50}$ ) compared to the significant one, which is not more pronounced than 25%;
- the reduction seems to be due to the change of the kinematic behavior of waves hitting the breakwater: the wave action on the armor stones changes from that of an irrotational green-water breakers plunging on the rubble mound to the action of a white-water roller-shaped bore running up the mound;

Fig. 5. Surveyed as built and reshaped profiles

- the *corner* separating the step from the lower slope is rather rounded and the mentioned slope is relatively short, therefore sometime the position of the corner is not well defined and the relevance of the slope angle is usually modest;
- the quantification of the dimensions related to stone size is relevant; table 7 gives the observed ratios between typical profile dimensions and the nominal diameter of the armor material.

*Table 7 Relative size of step dimensions*

$h$ at toe, m	$h/H_s$	$h_s/D_{n50}$	$l_s/D_{n50}$
0.30	$2.3 \pm 0.1$	$4 \div 5$	$12 \div 13$
0.14	$1.8 \pm 0.1$	$3 \div 4$	$8 \div 12$

Table 8 presents the dimensions of the profiles surveyed in our tests at the end of each reshaping phase. The following figures present also results relative to surveys performed during the reshaping progress.

*Table 8. Relevant dimensions of the profile at reshaping end*

In figures 6 data from present tests are reported according to van der Meer's interpretation scheme. Inspection of figs 6 indicates that the data scatter is relatively large and that apparently the relative water depth is not the unique relevant parameter explaining the physical process which results in the reduction of  $l_s$  and  $h_s$ ; other possible parameters influencing the reduction factor are wave period, foreshore slope and breaking depth and probably the mobility conditions.

Figures 7 show the observed values of the reduction factor against the ratio between the depth at structure toe and the depth at breaking point of the characteristic wave (1/50). The figures indicate that the reduction of profile dimensions  $l_s$  and  $h_s$  are highly influenced by breaking of the characteristic waves, which, compared to significant wave breaking, occur at a water depth proportionally greater.

Quantitative results show that:

- our reduction factor are more pronounced than those observed by van der Meer;
- the reduction of the step length is more pronounced than of the step height; average limit values in shallow water conditions are around 0.3 and 0.5, respectively;
- test do not show a perfect repeatability even in the same experimental set-up: compare for instance the results of tests 1 to 3 carried out under very similar wave conditions, or the 5 collectively represented as test no. 4, or test no. 7 which reproduce conditions similar to test no. 4 in a different channel;
- part of the scatter in the reduction coefficient may be interpreted as the effect of the imperfection of the formulae which are actually used below the range of mobility conditions in which they were calibrated; the formulae proposed later by van der Meer (1992) for lower mobility are strongly sensitive to the equivalent slope angle  $\alpha_1$  and  $\alpha_2$ , which are not always well defined (for instance for a very wide berm lower than the significant wave height they become both very small, raising the mobility threshold to unrealistic values), and are no more robust than the original ones; the original ones, (6) and (7), were actually used;

Fig. 6. The reduction factor  $r$  of the step dimensions  $h_s$  and  $l_s$  as function of the water depth to local wave higher ratio  $h/H_s$ .

- the effect of the different evaluation procedure of the significant wave height between our and van der Meer tests has been evaluated in some of our cases where

measurements were performed both in presence and absence of the breakwater; the relation  $H_s = 4.0\sqrt{m_0}$  is experimentally well satisfied at 0.30 and 0.60 m water depth, whereas at 0.14 m depth the coefficient should be reduced to 3.9; the decomposition of incident and reflected waves by the least square method provides a measure of the accuracy of the assumed model: 95-96% of the total variance is represented in intermediate and deep water conditions, whereas the percentage decreases to 87% in shallow water; the resultant wave height is underestimated by few percentage points (from 2% in intermediate and deep water up to 5% in shallow water); the effect should not be disregarded, but it seems however less important than the control of reflection: i.e., when waves are measured in the absence of the structure, waves reflected by the structure should be accurately absorbed in order to obtain a better estimate of the incident wave height than provided by the spectral reflection analysis.

Fig. 7. The reduction factor  $r$  of the step dimensions  $h_s$  and  $l_s$  as function of water depth to breaking depth ratio:  $h/h_b$

### Wave reflection at reshaping breakwaters

Reflection coefficients observed in our tests are summarized in table 9. Wave reflection from berm breakwaters in shallow water conditions is rather heavy

( $\approx 60\%$ ) if measured in front of the structure but it is highly reduced when evaluated offshore the breakers. A comparison of at toe and offshore values indicates that in shallow water conditions reflected waves loose approximately 1/3 of their height through the breaker zone.

*Table 9. Observed reflection coefficient*

Test series	Depth, m	$H_s/H_{s0}$	$C_R$ at toe	$C_R$ offshore
DHI-92	0.60	1.00	$0.32 \pm 0.02$	$0.32 \pm 0.02$
Estramed-93	0.34	0.74	$0.54 \pm 0.04$	$0.31 \pm 0.02$
Estramed-94	0.32	$0.61 \pm 0.09$	$0.62 \pm 0.05$	$0.30 \pm 0.02$
Estramed-94	0.16	$0.42 \pm 0.04$	$0.63 \pm 0.06$	$0.18 \pm 0.05$

## Conclusions

The behavior of reshaping breakwaters in deep and shallow water conditions is qualitatively similar but quantitatively different.

For a reshaping breakwater located in the breaker zone, the profile of the breakwater can be described by a reduced number of parameters.

The step and crest dimensions decrease with  $H_s$ , but  $H_s$  is not the unique influencing factor, since the dimensions of the step are evidently smaller than those expected according to deep water relations and to  $H_s$  incident on the breakwater.

The major cause of the difference between expected and actual dimensions is shown to be the change of kinematics of waves breaking on the structure.

Water depth at the structure toe influences by the breaking process the wave height distribution; its shape changes through the breaker zone. A characteristic wave height, including the effect of limited water depth and representing stone movements in the typical mobility range of breakwaters, is greater than  $H_s$ ; good results were obtained adopting  $H_{1/50}$ .

In particular, consideration of data from present and from van der Meer tests confirms the relevance of the breaking process on the reduction of the profile dimensions, which is well represented by a factor depending on the position of the structure relative to characteristic breakers, quantified as the ratio between the depth at structure toe and the breaking depth of characteristic waves.

Reflection of the breakwater increases with decreasing water depth reaching remarkably high values. Reflected waves are however attenuated through the breaker zone, whereas the encountered incident waves become greater. The offshore apparent reflection coefficient is therefore much lower and decreases with the depth at the structure.

## Acknowledgments

The present study was partially supported by the research and technological development programme in the field of Marine Science and Technology (MAST) financed by the Commission of the European Community, MAST contract 0032.

## List of symbols

$A$	= area of the reshaped profile;
$C_R$	= reflection coefficient;
$c_{go}, c_{gb}$	= offshore and at breaking group velocity;
$D_{\#}$	= sieve diameter of which # % of the material is finer;
$D_{n\#}$	= nominal (volume) diameter of which # % of the material is finer;
$h$	= water depth;
$h_c, h_s$	= crest and step height of the reshaped profile;
$H_k$	= characteristic wave height;
$H_s$	= inshore incident significant wave height;
$H_{so}$	= offshore incident significant wave height;
$H_{1/50}$	= average of the highest 1/50 wave heights;
$k$	= wave number;
$l_c, l_s$	= crest and step length of the reshaped profile;
$N$	= number of waves in a wave attack;
$N_d$	= number of displaced stones after 1000 waves;
$N_s$	= stability number: $H_s/\Delta D_{n50}$ ;
$N_s^{**}$	= modified stability number;
$r$	= reduction factor;
$R_e$	= Reynolds' number;
$s_m$	= fictitious wave steepness, $\frac{2\pi H_s}{gT_m^2}$ ;
$T_m$	= mean wave period;
$S$	= surface damage level;
$\Delta$	= relative mass density of rock;
$\nu$	= kinematic viscosity of water;
$\rho$	= water density.

## CHAPTER 98

### DESIGN OF BREAKWATERS AND BEACH NOURISHMENT

Christian Laustrup<sup>1</sup> and Holger Toxvig Madsen<sup>2</sup>

#### Abstract

The subject of this paper is to compare the design forecast and the actual performance of a coastal protection scheme combining segmented near shore breakwaters and beach nourishment.

#### Introduction

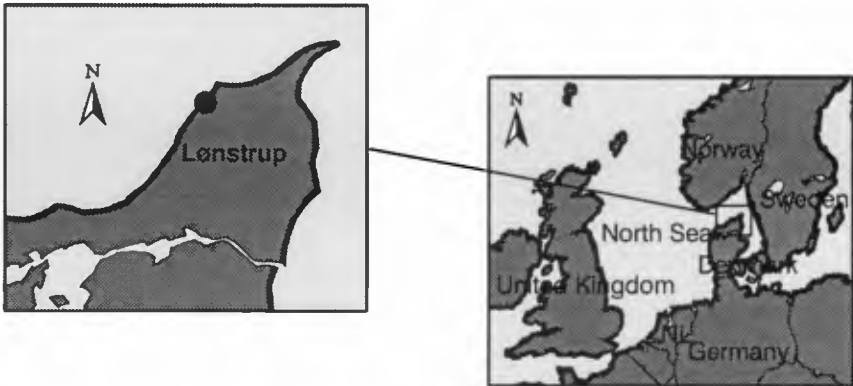

Figure 1. Area Map

The location is a 1100 m coastline at Loenstrup on the Danish North Sea coast. The long term erosion at Loenstrup is 1.4 m per year and the tidal range is 0.3 m.

-----  
1 Deputy Director

2 Head of Department

Danish Coastal Authority, Box 100, DK7620 Lemvig, Denmark.

Figure 2. The Beach and the Cliff

During a storm in 1981, 5–15 m of the cliff was eroded and it was decided to protect the town.

#### Design Method

The design layout was a combination of near shore breakwaters and beach nourishment. The reasons behind this layout were psychological and economical. At that time there was a feeling among the local population that the main component of a coastal protection scheme should be a rigid structure and not "only" beach nourishment. The use of hard structures in this area to stabilize the beach can be justified by the fact that nourishment costs were and are quite high. The cheapest way to get the sand was to transport it by lorries from a harbour 15 km away. The project aims to stop the retreat of the profile and to protect the cliff from further erosion during storm surge. Consequently the scheme should include a revetment. Furthermore it should be taken into

consideration that the beach is used by many tourists in the summer season.

In the design phase a c/b study was carried out with the purpose to determine the combination of breakwater design and beach nourishment volumes with the lowest total costs during the lifetime of the project. The idea of the analyses is that the further off shore and the higher the breakwaters are and the smaller the gaps are, the less nourishment is needed but also the higher the construction costs are.

To do that, the costs and effects of a large number of designs of segmented breakwaters were calculated. The parameters were the breakwater height, the position of the breakwaters relative to the coastline and the gaps between the breakwaters.

For each set of breakwater parameters a wave frequency table for long term wave impact was calculated based on wave recordings and calculations of refraction, shoaling breaking and transmission. The wave decay in the breaker zone was calculated according to Goda (1975).

Figure 3. Wave Transformation

For each wave component the wave energy flux per m coast perpendicular to the coast is

$$\frac{1}{8}\gamma H_i^2 c_g \cos^2 \alpha_i f \sim \text{constant} * f * H_i^2 * d_s^{1/2} * \cos^2 \alpha_i$$

$H_i$  = incoming wave height

$c_g$  = group velocity  $\sim (g * d_s)^{1/2}$  at the structure

$\alpha_i$  = incoming wave angle

$f$  = frequency of the wave component

$d_s$  = depth at the structure

To calculate the transmitted wave energy flux,  $H_t$  replaces  $H_i$ . The transmitted wave height over the breakwaters was calculated according to Saville (1963). It was assumed that wave energy would pass the gaps without reduction. By use of the frequency tables, the energy reduction by the breakwaters for average weather conditions could be calculated.

We then assumed that the long term erosion of the profile segment landward of the breakwaters would be reduced with the same percentage as the percentage of energy reduction caused by the breakwaters. The still remaining erosion of the profile out to a certain closing depth should be compensated for by beach nourishment. For different combinations of breakwater parameters the associated building costs and the need for beach nourishment to compensate for erosion were calculated. Only breakwaters that could be built using land based equipment were considered which limited the water depth to be used in the study to apr. 2 m. It was clear from the start that using sea based equipment would be far too expensive.

The present value of the total costs (building + maintenance + nourishment) in the lifetime was calculated for each alternative layout.

Figure 4. Present Value as a Function of Height and Depth (distance from the beach).

Figure 4 shows examples of design curves where the case of no breakwaters and only nourishment is the intersection with the y - axis. This example represents a case where 50% was breakwaters and 50% was gaps. It shows that down to a water depth of about 1.7 m there is a minimum of costs for certain breakwater heights.

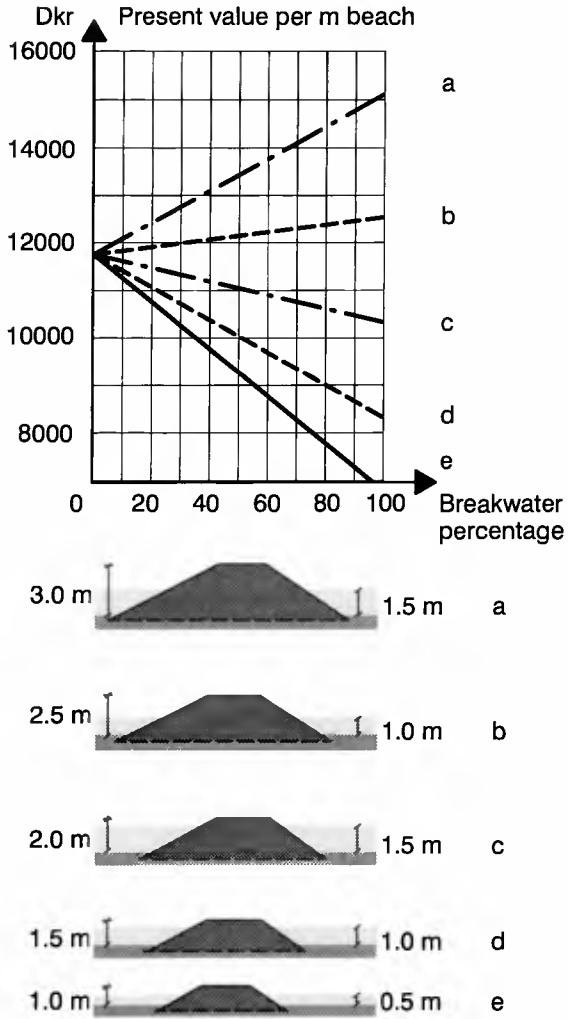

Figure 5. Present Value as a Function of the Percentage of Breakwaters Versus Total Length.

On figure 5 the variation of costs as a function of the percentage of breakwaters is presented and not surprisingly this shows a linear variation. When the total costs are below the costs of only nourishment, the most cost effective solution theoretically is to have 100% breakwaters and no gaps.

Project Layout

When selecting the practical solution we had to consider the need for a certain width of the beach for recreational use. This led to a minimum construction depth of 0.5 m. Furthermore, the gaps should at least be 50% of the total length to allow for swimming. The necessary dimension of the stones in the cover layer resulted in a breakwater height of 1.8 m above sea bed equivalent to a freeboard of 1.3 m relative to normal sea level. The total present value is read from figure 4. It is 10,650 Dkr (1,600 US\$) which is still below the case of no structures.

Figure 6. Cross Section.

Figure 7. Aerial Photo of Breakwater Group.

Figure 8. Single Breakwater.

#### Monitoring and Results

The breakwaters were built in 1983 and annual beach nourishment has been carried out since then. The annual nourishment volume has been decided by the need to maintain the beach behind the breakwaters. The profile seaward of the breakwaters was not nourished, so it could be expected that the profile would eventually stabilize in a steeper position.

To find out if the breakwaters have had the expected effect i.e. if they have reduced the erosion behind the breakwaters with the calculated percentage, a monitoring programme was set up. The chosen design should according to our calculations give a reduction of the erosion of about 49.9% in a year with normal weather conditions.

Figure 9. Time Variation of Depth Contours.

Figure 9 shows the time variation of the location of the depth contours. They seem to respond to the new situation a couple of years after the breakwaters were built and the nourishment had started. The 4 and 2 m contours seem to stabilize their position around 1985 resulting in a steeper equilibrium profile.

If the weather had been average since 1983, it would be easy to compare the design forecast of the nourishment volume with the actual annual volumes. The weather has, however deviated significantly from normal since 1983.

Elevation, cm

Figure 10. Statistics of Extreme Water Levels

On figure 10, the statistics of extreme water levels are shown. They show a significant difference between the period before and the period after 1983.

The question is if the actual nourishment volumes and the actual weather conditions since 1983 could be expected to result in the measured time variation of volumes in the control box behind the breakwaters when we use the design theory of energy reduction and erosion. To verify this, we have hindcasted this variation of volumes using the actual volumes, the theoretical erosion on the unprotected beach and the theory of energy reduction.

Figure 11. Theoretical Development of Volume Behind Breakwaters

This hindcast of volume development is shown on figure 11. The nearly vertical lines represent the nourishment. The length of the lines represent the actual sand volumes. The sloping lines represent the erosion that would theoretically have occurred in the periods between nourishments if the design theory of the breakwater effect is correct. The slope of the lines is calculated as the rate of erosion that would have occurred if the breakwaters had not been built. Since this rate is unknown the erosion rate of an unprotected reference beach is applied. This erosion rate is then reduced according to the theory of energy reduction caused by the breakwaters developed in the design phase. Since it is the nourishment sand and not the native sand which is eroded, a correction is made using the renourishment factor method (James 1975).

On figure 12, the hindcasted volume curve and the measured volume curve are both shown. It appears, that there is a good agreement between the curves.

Figure 12. Theoretical(— —)and Measured Volume (——)Development Behind Breakwaters.

### Conclusions

Based on measurements and hindcast calculations it can be concluded, that the effect of the near shore breakwater group in terms of reducing erosion behind the breakwaters is proportional to the ability of the breakwater group to reduce the wave energy flux perpendicular to the coast. However this conclusion should probably be used with caution in cases where the conditions differ significantly from the conditions described in this paper.

### CIRCULAR CHANNEL BREAKWATER TO REDUCE WAVE OVERTOPPING AND ALLOW WATER EXCHANGE

Dal Soo LEE<sup>1</sup> Associate Member of ASCE,  
Woo Sun PARK<sup>2</sup>, and Nobuhisa KOBAYASHI<sup>3</sup> Member of ASCE

#### Abstract

A new type of breakwater caisson is presented for improving water quality in a harbor. Circular resonance channels connected with flow conduits in the caisson cause clear sea water inflow into a harbor through the conduits. The hydraulic characteristics of this caisson with respect to wave reflection, overtopping and transmission appear excellent compared with those of conventional caissons. The potential of water quality improvement is great due to its high efficiency in normal wave conditions. A simple resonance model is developed to identify an important dimensionless parameter. Experimental results show that the new concept of circular channel breakwater is promising in terms of its hydraulic performance.

#### Introduction

The main function of existing breakwaters is to reduce waves propagating onshore, and for normal wave conditions, the breakwaters are designed for no wave overtopping to secure harbor tranquility. However, it is normally overlooked that the breakwaters usually block sea water exchange at the cost of the harbor

tranquility. This often causes water pollution problems due to the stagnation of sea water inside the harbors if tidal ranges are not sufficiently large.

Several kinds of breakwaters have already been developed to allow water exchange (Kataoka and Saida, 1986; Tanimoto et. al, 1987; Korea Ocean Research and Development Institute, 1989; Tanimoto et. al, 1989), but most of them are normally effective only in the presence of currents. No breakwater type with water quality improving capability mainly under weak wave action appears to exist at the present. Hence, there is a practical need to develop a breakwater type that causes clear sea water inflow into a harbor through the breakwater using incoming waves as a driving force. In addition, the performance of the breakwater with respect to wave reflection, overtopping and transmission should be improved as much as possible.

The circular channel breakwater(CCB) equipped with flow conduits presented herein has been devised to attain the capability of wave-induced sea water inflow into a harbor as well as low wave reflection and overtopping at the same time. The resonance phenomena of water level in the circular channel is shown to be important in increasing water flow rates for short period waves. A simple resonance model is developed to identify an important dimensionless parameter for the analysis of experimental data. Experimental results show that the concept of CCB is promising.

### Conceptual Description of CCB

Figure 1 shows a conceptual diagram of the Circular Channel Breakwater(CCB). The caisson has circular channels at its front part and flow conduits at its rear part. When incident waves impinge on the CCB, water passes through the channel. Water inflow into a harbor occurs through the conduits due to the pressure difference between the inlet and outlet of these conduits. The inflow induces a small rise of mean water level behind the breakwater, and the pressure driven weak current is subsequently introduced into the harbor but occurs essentially continuously under normal wave conditions. A reverse flow is restricted because the inlets of the conduits are placed near the still water level in the circular channels to create one way flow into the harbor.

The water inflow does not make any significant disturbance of water surface in the harbor under normal wave conditions because

Figure 1. Conceptual diagram of the Circular Channel Breakwater (CCB).

the outlet of the conduits are well submerged. The back face of the caisson may be used as a wharf for small ships under moderate wave conditions when the outlets of the conduits are placed well below the draft of a ship.

Resonant oscillations occur in the circular channel for short period waves and hence enhance the flow rate. On the other hand, when wave overtopping occurs, the outflow issuing from the circular channel collides with the overtopping water flow above the caisson, resulting in increased wave energy dissipation and reduced wave overtopping.

### Simple Resonance Model

A simple resonance model is developed to gain insight into the complicated hydrodynamic process in the circular channel and to identify an important dimensionless parameter for the following experimental data analysis.

Figure 2 shows the geometric parameters and cylindrical coordinate system( $r, \theta$ ) used in the following linear potential flow analysis, where  $R_c$  and  $b$  are the circular channel radius and its width, respectively,  $\eta_c(t)$  is the free surface elevation in the channel,  $\theta_s$  is the value of  $\theta$  at still water level in the channel,

$P_e(t)$  is the pressure at the channel entrance, and  $d$  is the water depth. It is assumed that the circular channel radius  $R_c$  is much larger than its width  $b$ , and that no overflow occurs from the exit of the channel.

Figure 2. Diagram showing geometric parameters in cylindrical coordinate system.

The Laplace equation for the velocity potential  $\phi$  in the circular channel is expressed as

$$\frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \phi}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 \phi}{\partial \theta^2} = 0 \quad (1)$$

The boundary conditions may be expressed as

$$-\rho \frac{\partial \phi}{\partial t} = P_e(t) \quad \text{at } \theta = -\frac{\pi}{2} \quad (2)$$

$$\frac{\partial \eta_c}{\partial t} = \frac{1}{R_c} \frac{\partial \phi}{\partial \theta} \cos \theta_s \quad \text{at } \theta = \theta_s \quad (3)$$

$$-\frac{\partial \phi}{\partial t} = -g\eta_c \quad \text{at } \theta = \theta_s \quad (4)$$

$$\frac{\partial \phi}{\partial r} = 0 \quad \text{at } r = R_c \quad \text{and} \quad r = (R_c + b) \quad (5)$$

where,  $\phi(r, \theta, t)$  = velocity potential inside the circular channel  
 $P_e(t)$  = dynamic pressure at the entrance of the channel  
 as shown in Figure 2  
 $\rho$  = water density  
 $\eta_c$  = free surface elevation in the channel  
 $\theta_s$  = value of  $\theta$  at the still water level in the channel

Equations (3) and (4) correspond to the linearized kinematic and dynamic free surface boundary conditions.

To satisfy the no flux boundary condition on the curved solid walls given by Equation (5), the solution  $\phi$  of Equation (1) should be independent of  $r$  as

$$\phi(\theta, t) = C_1(t)\theta + C_2(t) \quad (6)$$

Using Equation (3),

$$C_1(t) = \frac{R_c}{\cos \theta_s} \frac{\partial \eta_c}{\partial t} \quad (7)$$

From Equations (2) and (4),

$$\frac{dC_1(t)}{dt} \left(-\frac{\pi}{2}\right) + \frac{dC_2(t)}{dt} = -\frac{1}{\rho} P_e(t) \quad (8)$$

$$\frac{dC_1(t)}{dt} \theta_s + \frac{dC_2(t)}{dt} = -g\eta_c \quad (9)$$

Eliminating  $C_1(t)$  and  $C_2(t)$  from Equations (7), (8) and (9), we get

$$\frac{R_c(\theta_s + \frac{\pi}{2})}{\cos \theta_s} \frac{d^2 \eta_c}{dt^2} + g\eta_c = \frac{1}{\rho} P_e(t) \quad (10)$$

which indicates the free surface oscillation in the channel forced by the dynamic pressure  $P_e(t)$  at the channel entrance.

Assuming simple harmonic motions for  $\eta_c(t)$  and  $P_e(t)$  expressed as

$$\eta_c(t) = R_e[\bar{\eta}_c e^{-i\omega t}] \quad (11)$$

$$P_e(t) = R_e[\bar{P}_e e^{-i\omega t}] \quad (12)$$

where  $R_e$  indicates the real part,  $\bar{\eta}_c$  and  $\bar{P}_e$  are the complex valued amplitudes, and  $\omega$  is the angular frequency. Substituting Equations (11) and (12) into (10) yields :

$$\bar{\eta}_c = \left[ 1 - \frac{R_c(\theta_s + \frac{\pi}{2})\omega^2}{g \cos \theta_s} \right]^{-1} \cdot \frac{1}{\rho g} \bar{P}_e \quad (13)$$

In order to find  $\bar{P}_e$ , the solution in the channel will need to be matched with the solution in front of the caisson. Nevertheless, this simple solution indicates that resonance occurs in the circular channel when,

$$\frac{R_c(\theta_s + \frac{\pi}{2})\omega^2}{g \cos \theta_s} = 1 \text{ for infinite } \eta_c.$$

In reality,  $\eta_c$  will not be infinite due to energy loss especially at the channel entrance.

For the following data analysis the dimensionless parameter  $\omega^*$  is defined as

$$\omega^* \equiv \frac{R_c(\theta_s + \frac{\pi}{2})\omega^2}{g \cos \theta_s} \quad (14)$$

where  $\omega^* = 1$  corresponds to the resonance condition.

### Experiments and Data Analyses

Experiments on the circular channel breakwaters(CCB) were conducted to examine the hydrodynamic characteristics of wave reflection, overtopping, transmission and water discharge through the flow conduits. The experiments were performed with regular waves in a wave flume (53.3 m long, 1.0 m wide, and 1.25 m high)

with a model caisson as shown in Figure 3, where the water depth on the horizontal bottom is  $d=40.5\text{ cm}$ , the caisson crest height above the still water level is  $h_c=8.5\text{ cm}$ , the radius of the front wall of the channel is  $r_{c1}=8.5\text{ cm}$ , the radius of the rear wall of the channel is  $r_{c2}=15\text{ cm}$ , the width of the channel at the entrance is  $b_e=10\text{ cm}$ , and the diameter of the flow conduit is  $D=3.2\text{ cm}$ . The incident wave height  $H_i$  was 3 and 5 cm in these experiments. In this model the channel width was designed to be decreased gradually upward to produce higher runup inside the channel. Additional experiments were also carried out for the solid wall breakwater (SWB, conventional caisson breakwater) for the purpose of comparisons.

Figure 3. Cross-sectional diagram of model setup without rubble mound foundation(unit : cm).

Figure 4 shows the measured wave runup  $\eta_{c\text{ max}}$  inside the channel normalized by the incident wave height  $H_i$  as a function of  $\omega^*$  defined by (14). Comparing the measured values of  $\eta_{c\text{ max}}/H_i$  with the value of 1.0 in front of a perfectly reflective vertical wall, this runup in the vicinity of  $\omega^*=1$  serves as an amplified potential

for driving inflow into the harbor through the flow conduits.

The occurrence of the peak at the resonance frequency (at the value of  $\omega^*=1$  in Figure 4) means that the resonance plays a major role in the enhancement of runup in the channel. In shelter coastal areas, the waves of short periods and small wave heights prevail, as a result, the energy of normal waves can be effectively used to induce water inflow into a harbor by the use of this type of breakwater.

Figure 4. Maximum wave runup inside the circular channel shown in Figure 3 for  $H_i=3cm$  (WC1) and  $H_i=5cm$  (WC2).

Figure 5 shows that the reflection of the CCB is lower than that of the SWB. The occurrence of the lowest reflection near the resonance frequency (near the value of  $\omega^*=1$  in Figure 5) means that the resonance reduces significantly reflection from CCB. The resonance peak in this figure is shifted to slightly higher frequency for the tests with  $H_i=3cm$ .

Figure 6 shows the measured net flow rate  $Q$  normalized by  $\sqrt{2gH_i}A$  with  $g$ =gravitational acceleration and  $A=(\pi/4)D^2$  through one flow conduit of diameter  $D=3.2cm$  for the model caisson shown in Figure 3. The resonant peak in this figure is shifted to slightly lower frequency for the tests with  $H_i=5cm$ .

Figure 5. Comparison of reflection coefficients between CCB shown in Figure 3 and SWB for  $H_i=3cm$  (WC1) and  $H_i=5cm$  (WC2).

Figure 6. Net inflow rate through one flow conduit with  $D=3.2cm$  for  $H_i=3cm$  (WC1) and  $H_i=5cm$  (WC2).

Figures 7 and 8 show model setup with a rubble mound and the different positions ( $C1$ ,  $C2$  and  $C3$ ) of flow conduit inlets in the circular channel, respectively. The crest elevation  $h_c$  above the still water level was chosen as  $12\text{ cm}$  and  $8\text{ cm}$  by changing the water depth in the tank. In Figures 7 and 8,  $h_c=12\text{ cm}$ , while the water depths on the bottom and above the foundation are  $d=50\text{ cm}$  and  $h=30\text{ cm}$ :

Figure 7. Cross-sectional diagram of model setup with rubble mound foundation.

Figure 8. Schematic diagram showing different positions ( $C1$ ,  $C2$  and  $C3$ ) of flow conduit inlets in the circular channel in Figure 7.

Only some of the many geometric parameters involved in the caisson were changed. It should therefore be noted that the experimental results presented hereafter are not general and limited to the adopted model configuration and experimental conditions. For the experimental setup shown in Figure 7 wave overtopping occurred for the incident wave height  $H_i=13\text{ cm}$  and the simple model discussed in the previous section is not applicable.

Figure 9 shows the comparison of the net flow rate  $Q$  through one conduit of diameter  $D=3.2\text{ cm}$  where  $l$  is the length of the flow conduit. At position C3 (below the still water level), the net flow rate is generally low for the longer period waves due to the occurrence of reverse flow in the conduit under the minimum free surface elevation in the channel. At position C1 (above the still water level), the net flow rate is generally low for shorter period waves due to the short duration of the head difference between the inlet and outlet of the flow conduit. At position C2 (at the still water level) the net flow rate remains to be large for any wave period. The variation pattern of the net flow rate with respect to the inlet position may vary if the configuration of the channel is changed.

Figure 10 shows that the reflection from the CCB is lower for all frequencies than that from the SWB. The relative difference increases with the increase of  $\omega^2 d/g$ . This means that CCB retains the merit of low reflection of perforated wall caisson breakwaters.

Figures 11 and 12 show measured values of overtopping rate and transmission coefficient for the water depth condition different from that shown in Figure 7. The caisson crest height above the still water level is  $h_c=8\text{ cm}$ , and the water depths on the bottom and above the foundation are  $d=54\text{ cm}$  and  $h=34\text{ cm}$ , respectively. Figure 11 shows that the overtopping rate  $q$  of CCB per unit width is always lower than that of SWB. This means that the outflow issuing from the exit of the circular channel plays an important role in reducing wave overtopping due to its collision with the landward overtopping water above the caisson. Figure 12 shows the resulting difference in the wave transmission coefficient between CCB and SWB.

The characteristics of low reflection together with low

Figure 9. Variations of net inflow rate  $Q$  through one flow conduit in Figure 8 with  $d=50\text{ cm}$ ,  $h=30\text{ cm}$ ,  $h_c=12\text{ cm}$  and  $D=3.2\text{ cm}$  for  $H_i=13\text{ cm}$ .

Figure 10. Comparison of reflection coefficients between CCB and SWB with  $d=50\text{ cm}$ ,  $h=30\text{ cm}$ ,  $h_c=12\text{ cm}$  in Figure 7 for  $H_i=7$  and  $13\text{ cm}$ .

Figure 11. Comparison of overtopping rates between CCB and SWB with  $d=54\text{ cm}$ ,  $h=34\text{ cm}$  and  $h_c=8\text{ cm}$  in Figure 7 for  $H_i=13\text{ cm}$ .

Figure 12. Comparison of transmission coefficients between CCB and SWB with  $d=54\text{ cm}$ ,  $h=34\text{ cm}$  and  $h_c=8\text{ cm}$  in Figure 7 for  $H_i=13\text{ cm}$ .

transmission imply that the hydraulic performance of CCB is superior to that of SWB.

### Conclusions

A circular channel breakwater (CCB) connected with flow conduits was proposed. The performance of CCB in terms of wave reflection, overtopping and transmission is excellent compared with that of conventional solid wall caisson breakwaters.

The capability of inducing clear water inflow through the conduits of CCB into a harbor is enhanced by the resonant oscillations in the circular channel under normal wave conditions. A great potential for improving water quality in harbors is expected under normal wave conditions when water quality problems may become serious. At the same time, CCB maintains the merits of caisson type breakwaters in that the upper and back faces of the caisson can be utilized.

Further studies are needed to reveal the dynamic characteristics related to the pressure distribution and resulting caisson stability.

## CHAPTER 100

### Increased Dolos Strength by Shape Modification

S. A. Luger<sup>1</sup>, D. T. Phelp<sup>1</sup>, A. van Tonder<sup>1</sup> and A. H. Holtzhausen<sup>1</sup>

#### Abstract

A survey of prototype dolos breakages was performed to determine the distribution of failure modes. The results showed that 89% of the failures originate near the fluke-shank intersection. A series of static and dynamic finite element analyses was subsequently performed with the aim of improving the resistance of the dolos against the most commonly observed modes of failure. Of the six dolos shapes analysed, a large fillet extending from the fluke to the centre of the shank was found to be the most effective in reducing the stress in the critical fluke-shank intersection. Compared to a sharp intersection, the large fillet reduces the stress by more than 60%.

#### Introduction

A number of dolos-armoured breakwaters constructed in the 1960's and 1970's in South Africa now require repair work. This repair work generally involves placing additional layers of somewhat heavier dolosse on top of the damaged dolos slope.

A number of methods are available to improve the strength of these repair dolosse. These include an increase in waist ratio, the use of reinforcement (conventional, prestressed, rail or fibre) or a modification to the fluke-shank intersection. Increasing the waist ratio has the disadvantage of reducing the hydraulic stability (Holtzhausen and Zwamborn, 1992), while reinforcing increases the unit cost and there is

---

<sup>1</sup>Ematek, CSIR, P O Box 320, Stellenbosch 7599, South Africa

the potential for corrosion problems. In this paper the method of modifying the fluke-shank intersection is investigated. The initial phase of the study was to perform a survey of prototype dolos breakages. Various modifications to the fluke-shank intersection were then tested using static and dynamic finite element analysis.

### Survey of Prototype Dolos Breakages

The objective of the survey was to identify the main failure modes and determine the relative frequency of each mode. Use was made of close-range photographs taken from a crane on the breakwater crest or from a helicopter. Seven breakwaters were surveyed in this way and each of the 357 observed breakages were classified as one of six failure modes. The dolos masses ranged from 5 to 30 t and the waist ratios from 0,31 to 0,36. The fluke-shank intersections were either sharp or had a small fillet (radius approximately  $0,04H$ , where  $H$  is the dolos height) or a small chamfer (size approximately  $0,057H$ ).

Figure 1. Distribution of prototype dolos failures

The six failure modes and the distribution of the failures are illustrated in Figure 1. The most common failure mode is a failure through the shank adjacent to a fluke. The four failure modes that originate near to the fluke-shank intersection account for 89% of the breakages.

The data set also indicated that dolosse with smaller waist ratios were more susceptible to failures through the shank. The dolosse with waist ratios of 0,31 had 86% shank failures and 14% fluke failures, while the dolosse with waist ratios of 0,34 to 0,36 had only 52% shank failures and 48% fluke failures. The chamfered or filleted units displayed proportionally more torsional failures (16% of all failures) than the dolosse with a sharp fluke-shank intersection (8% of all failures).

**Modifications to the Fluke-Shank Intersection**

The original dolos shape had a sharp fluke-shank intersection (Merrifield and Zwamborn, 1966). Based on photo-elastic stress analysis Lillevang and Nickola (1976) suggested a fillet with a radius of 0,04H, while Tait and Mills (1980) performed fatigue tests on model dolosse including one with a fillet radius of 0,175H. The shape given in the Shore Protection Manual (CERC, 1984) has a chamfer with a dimension of 0,057H. Rosson and Tedesco (1992) performed finite element simulations of the drop test using chamfer sizes of both 0,06H and 0,10H.

Based on the prototype breakages, it is expected that a stronger and more structurally-balanced dolos shape can be developed by further strengthening the fluke-shank intersection. Finite element models were therefore generated for six geometries of fluke-shank intersection. Each model had approximately 1900 quadratic elements and 8500 nodes. The six meshes are illustrated in Figure 2.

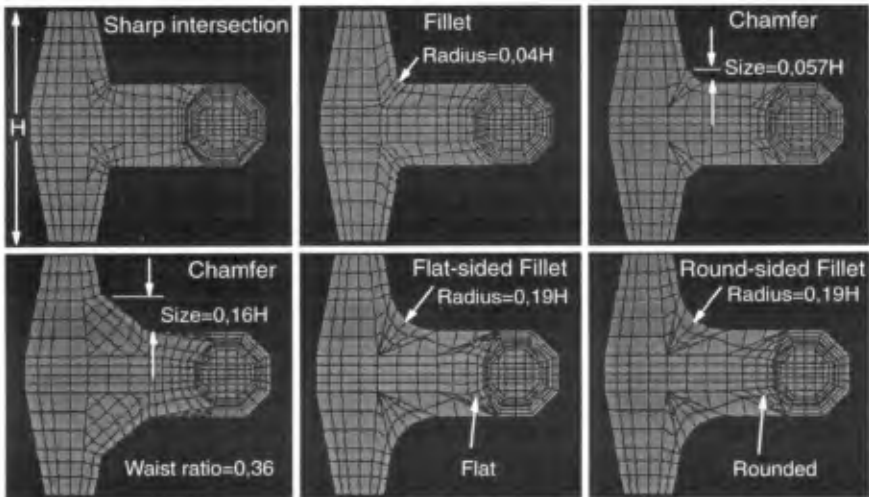

Figure 2. Shapes modelled in F E analyses

The top three shapes in Figure 2 are existing designs representative of the broken prototype dolosse analysed above. The bottom three shapes are new shapes aimed at strengthening the fluke-shank intersection. The dolosse all have a waist ratio of 0,36 while the height (H) was varied to ensure that all shapes had the same mass. The large chamfer extends to the middle of the shank and the angle between the chamfer and the shank is equal to the angle between the chamfer and the fluke. This gives a chamfer size of approximately 0,16H at a waist ratio of 0,36. The large fillet also extends to the middle of the shank which results in a radius of approximately 0,19H at a waist ratio of 0,36. Two different shapes incorporating the large fillet were tested. For the first shape the sides of the fillet consist of flat surfaces while for the second shape the sides of the fillet are rounded to intersect the shank and fluke smoothly.

### Static Finite Element Analyses

A series of static finite element analyses was performed in order to compare the maximum principal tensile stresses for each of the six dolos shapes. Linear elastic material behaviour was assumed and the results are thus only applicable up to the initiation of cracking. The following material properties were used: Density 2400 kg/m<sup>3</sup>, Young's modulus 27 GPa, Poisson's ratio 0,17.

The loading and boundary conditions applying to dolosse on a breakwater are extremely varied and complex and cannot therefore be reproduced in a deterministic finite element analysis. Only three simplified loading conditions (Figure 3) were analysed. The hanging load case was assumed to represent the shank fractures near to a fluke (40% of prototype fractures - refer to Figure 1). The fluke load represents the straight and diagonal fluke fractures (38% of prototype fractures) while the torsional load represents the torsional shank failures (11% of prototype fractures).

The surface stress distributions for the six dolos shapes due to the hanging load case are shown in Figure 4. The stress concentration in the sharp intersection can clearly be seen. The larger 0,16H chamfer does not reduce the stress compared to the 0,057H chamfer, due to the stiffer response of the larger chamfer. The lowest stress occurs for the 0,19H fillet with flat sides, due to the fact that this shape results in a slightly wider fillet than the 0,19H fillet with rounded sides. The torsional plots (Figure 5) show that the 0,16H chamfer again performs poorly. The 0,19H fillet with rounded sides shows the lowest stress. The 0,19H fillet with flat sides has a relatively sharp intersection between the flat sides and the shank which increases the stress in this area.

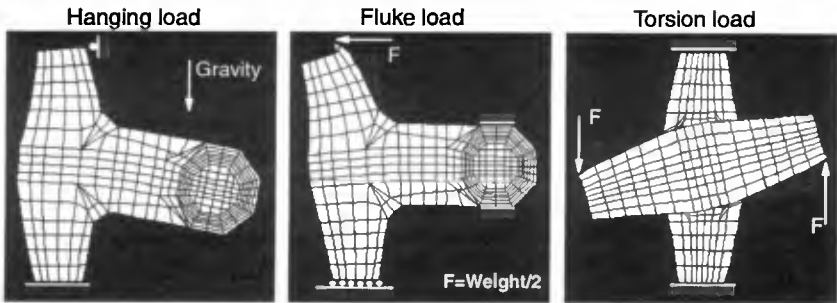

Figure 3. Static load cases

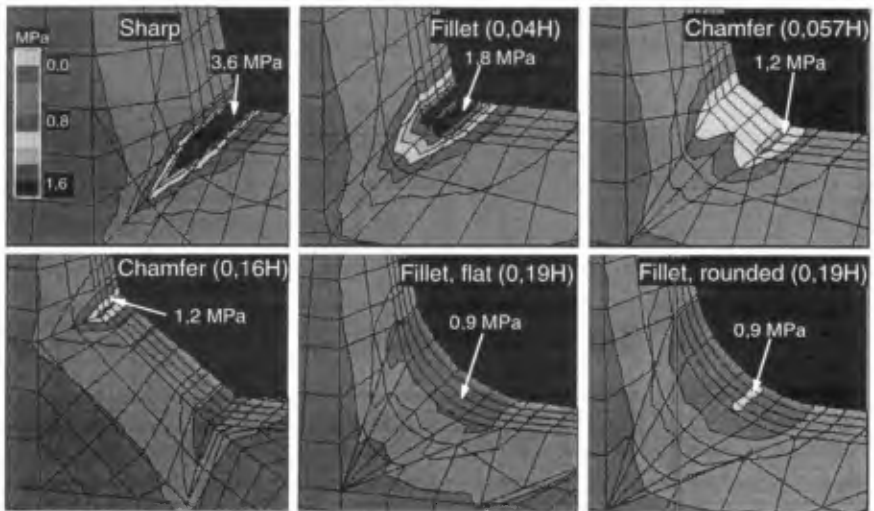

Figure 4. Principal tensile stresses - Hanging load case

Stress reduction factors were determined for each shape relative to the sharp intersection. These reduction factors were then weighted based on the relative frequency of each failure mode. 11% of the prototype failures occurred away from the fluke-shank intersection and this weighting was therefore applied to all the shapes. The results are summarised in Table 1.

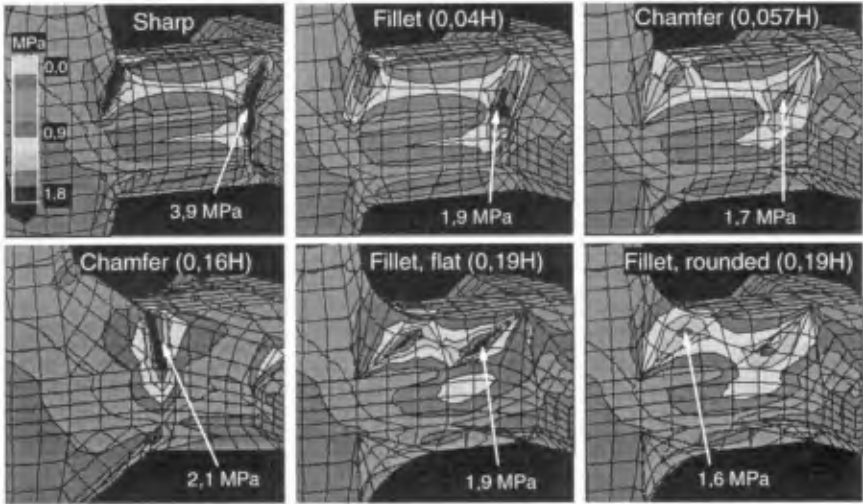

Figure 5. Principal tensile stresses - Torsional load case

	Load case	Geometry of fluke-shenk intersection					
		Sherp	Fillet (0,04H)	Chemfer (0,057H)	Chamfer (0,16H)	Fillet,flat (0,19H)	Fillet,round (0,19H)
Stress reduction factor relative to sherp shape	Shenk	1,00	0,51	0,33	0,34	0,24	0,26
	Fluke	1,00	0,52	0,38	0,47	0,29	0,30
	Torsion	1,00	0,49	0,44	0,52	0,49	0,41
Weighted reduction factor (weighting in brackets)	Shank (0,40)	0,40	0,20	0,13	0,14	0,09	0,10
	Fluke (0,38)	0,38	0,20	0,15	0,18	0,11	0,11
	Torsion (0,11)	0,11	0,05	0,05	0,06	0,05	0,04
	Other (0,11)	0,11	0,11	0,11	0,11	0,11	0,11
Total reduction factor	All	1,00	0,56	0,44	0,48	0,37	0,37

Table 1: Stress reduction factors for static loading

The two 0,19H fillet shapes show total static reduction factors of 0,37 compared to the sharp shape, 0,66 compared to the 0,04H fillet and 0,84 compared to the 0,057H fillet. In general, these modifications to the fluke-shank intersection do not reduce the torsional stresses as significantly as the stresses due to the hanging and fluke loads. This corresponds to the prototype breakages, where fillets or chamfers were found to increase the relative proportion of torsional failures.

**Dynamic Finite Element Analyses**

The response of the six dolos shapes to dynamic impact loading was also compared. The load case selected was the drop test (Burcharth, 1981). The material was modelled as linear elastic and no yield of the impacted surface was allowed. The implicit method of time integration was used with a constant time step of 5  $\mu$ s, which is approximately a quarter of the time required for a stress wave to travel between the integration points in an element.

The maximum principal tensile stresses occurred at the fluke-shank intersection, as illustrated in Figure 6. The computed stress reduction factors relative to the sharp intersection are presented in Table 2. These factors are similar to those computed for the static loads.

1,1 ms after impact, magnification factor = 1000

**Figure 6. Tensile stress distribution during drop test.**

	Geometry of fluke-shank intersection					
	Sharp	Fillet (0,04H)	Chamfer (0,057H)	Chamfer (0,16H)	Fillet,flat (0,19H)	Fillet,round (0,19H)
Drop test reduction factor	1,00	0,54	0,45	0,51	0,32	0,34

**Table 2: Stress reduction factors for dynamic loading**

## Conclusions

89% of prototype dolos breakages were found to occur near to the fluke-shank intersection. The static and dynamic tensile stresses at the fluke-shank intersection can be reduced by more than 60% by incorporating a large fillet extending to mid-shank. Although little difference in performance was found between the flat-sided and the round-sided fillet, the round-sided fillet is preferred due to its superior torsion resistance.

## Applications and Future Developments

The 0,19H fillet with round sides is being used for the repair of a number of breakwaters; the dolos sizes range from 7,5 to 30 t. A series of prototype drop tests has also been performed using 7,5 t dolosse with different fluke-shank intersections.

An aspect that has not been tested is the influence of the 0,19H fillet on the hydraulic stability of the dolos. A comparison between the profile of this shape and the 0,057H chamfer does reveal a large difference - the effect on the interlocking is thus expected to be small. This assumption must, however, still be tested by means of physical model studies.

## CHAPTER 101

### Influence of Wave Directionality on Stability of Breakwater Heads

Y. Matsumi <sup>1</sup>, E.P.D. Mansard <sup>2</sup> and J. Rutledge <sup>3</sup>

#### Abstract

An experimental investigation was undertaken to investigate the stability of breakwater heads under uni and multidirectional wave attacks. Waves of normal and oblique incidence were used in the investigations and the stability results were assessed along with relevant measurements of wave surface elevation, measured in the proximity of breakwater heads.

#### INTRODUCTION

In spite of the growing number of multidirectional wave facilities around the world, breakwater designs are still evaluated using unidirectional regular or irregular waves, because it is widely believed that testing under unidirectional wave provides conservative results (i.e. overdesigned breakwaters). This may be true for the trunk section of the breakwater where the directional spread associated with the multidirectional seas tends to reduce the wave loads imparted on the structure. For the breakwater heads, this assumption is perhaps not valid. Because of the directional characteristics in multidirectional waves (i.e. 3D waves), some sections of breakwater heads may be exposed to larger wave heights than normally encountered under unidirectional waves (i.e. 2D waves).

Generally, under unidirectional waves of normal or oblique incidence, the head sections of breakwaters are more susceptible to damage than their trunk sections owing to the large wave heights and velocities that result from processes such as refraction, diffraction and shoaling on and around the head sections. Because of this, researchers such as Jensen (1984) and Vidal et al. (1991) suggest that the weight of stones for the heads should be about 1.5 to 4 times the weight of armour stones in the trunk section.

Under multidirectional waves, the wave heights that a breakwater head section encounters through the various processes described above, are possibly made even larger due to waves directly attacking the breakwater from other directions. Therefore more wave loads are expected on the heads, resulting thereby in lower stability.

## EXPERIMENTAL SETUP

### Layout of the basin

The physical model tests were carried out, at the National Research Council of Canada, in the multidirectional basin of the Coastal Engineering Laboratory of the Institute for Marine Dynamics.

The basin used for this purpose has a length of nearly 20m and a width of 30m. Figure 1 shows a plan view of the experimental set-up. A sixty-segment wave generator is located along one of the 30m sides of the basin. Perforated expanded sheet absorbers, capable of limiting wave

Figure 1. Plan view of the experimental set-up

reflections to 5% for most frequencies of interest, are installed along the remaining three sides of the basin. A 5m long gate and a closure plate of similar length at the two extremities of the wave generator are generally used for techniques that intentionally use corner reflection for increasing the size of the homogeneous area (see Figure 1).

#### Layout of wave gauges

The water surface elevations were measured at 17 different locations indicated by dots in Figure 1. Eight offshore wave gauges were mounted on two frames as a three-gauge and a five-gauge arrays. The three gauge array was set up to analyze the reflection of unidirectional waves of normal incidence by the methodology of Mansard and Funke (1987). The five gauge array was used to analyze the directional characteristics of normal and oblique incidence multidirectional waves with and without the structure in position. The remaining nine wave gauges were placed in the proximity of the model at a distance of 0.5m away from the toe of the structure, at locations shown in Figure 1. (Note that St stands for wave gauge station).

#### Layout of breakwater model

The layout of the breakwater model had to be designed carefully in this study, for the reasons indicated below.

Although sophisticated techniques have been developed to simulate the directional characteristics of the natural sea states inside laboratory environments, the area over which the sea state can be homogeneous in a wave basin is limited because of processes such as diffraction and reflection (see Sand and Mynett, 1987). Therefore careful consideration had to be given in order to ensure similar sea state severities along the entire breakwater section. For this purpose, use was made of the WAGEN model which could predict the water surface elevation and kinematics of the sea states prevailing at different locations in the basin. This model, developed by Isaacson (1992), is based on the boundary integral equation and linear diffraction theory and can account for partial reflection from structures such as breakwaters. A sample output resulting from this program is presented in Figure 2. It illustrates the spatial distribution of wave heights in the basin without the breakwater model, under a multidirectional sea state. The expected wave heights presented in this figure were normalized with respect to target wave heights. Note that their maximum value is only 0.9. This is due to diffraction processes and can be increased by applying an amplification factor. It can be seen from this figure that the useful test area, over which the sea state is homogeneous, is limited by a triangular boundary. According to this figure, the best location for the model would be close to the paddle. However, since this wave basin is not yet equipped with active absorption, an optimum location which would simultaneously ensure an homogeneous sea state

and minimize re-reflections from the paddle had to be chosen.

Since the model breakwater occupied only a portion of the basin width, reflected waves were expected to dissipate through diffraction processes before they are re-reflected by the paddles. Furthermore, since the proposed breakwater geometry had a symmetrical layout, it was considered justifiable to study only one of its head sections. Based on these different criteria, the model was located, as shown in Figure 1, at a distance of 9m from the paddle, and it was also offset by 2m from the center line.

Figure 2. Spatial distribution of wave heights in the basin without the breakwater in place

#### Characteristics of breakwater model

Figure 3 shows both plan and profile views of the breakwater model. In order to achieve a better insight into the individual performance of the various breakwater components, nine sections of interest were separated from the total structure by using a steel frame with different components. Figure 3 shows the six trunk and the three head sections included in the study. The three head sections, called Front Head (FH), Middle Head (MH) and Back Head (BH), cover an area enclosed by an angle of  $60^\circ$  as shown in Figure 3. The remaining parts of the breakwater were covered with a steel mesh having square openings of 1x1cm in size, in order to avoid rebuilding the entire breakwater after every test.

The breakwater was of conventional type, composed of two layers of armour, a filter layer and a relatively porous core. Its height was 80cm and it performed as a non-overtopping structure in a water depth of 50cm. The

front and rear slopes were 1:2. Similar stone weights were used both in the trunk and head sections intentionally, in order to ensure high damage on the head section. One of the main reasons for this is that an accurate assessment of the wave height that causes small degrees of damage is generally difficult because of the experimental variability associated with effects such as interlocking (see Davies et al., 1994).

Figure 3. Plan and elevation views of the breakwater model

The characteristics of the core, filter and armour stones used in the experiments are presented in Table 1. The gradations of the armour stone were meticulously checked and the resulting  $D_{n85}/D_{n15}$  ratio for the armour was 1.3. In order to differentiate the various layers, each layer of armour stone and the filter layer were painted with a unique color. With this color scheme, the level of damage in each section could be easily ascertained by visual observation and photographs.

### Measurement techniques

The profiles of the trunk and head sections of the breakwater were measured using the electro-mechanical profiler described in Davies et al. (1994). The profiles taken in the direction normal to the wave paddle, were generally spaced 10cm apart in the trunk and head sections. The head section profiles were then converted into polar coordinates to obtain profiles every  $5^\circ$ . Since the head was subdivided into 3 sections, each covering an

area enclosed by 60°, an average of 11 profiles was used to quantify the damage in these sections.

The eroded area in the head and trunk sections was computed after each test using average profiles of original and final cross-sections. The damage index,  $S$ , was then calculated by normalizing the eroded area with the square of the armour stone's nominal diameter.

Besides establishing damage values by profile data, visual observations were also used to classify the degree of damage according to the four classifications suggested by Vidal et al. (1991): Initial damage, Iribarren's damage, start of destruction and destruction.

To further assist the estimation of damage, color photographs of each individual section were taken after each test. In addition, video pictures were used to record the entire experiment.

Table 1. Summary of the breakwater characteristics

$W_{50}$ weight of armour (g)	118
$W_{50}$ weight of filter (g)	15
$W_{50}$ weight of core (g)	2
$D_{n50}$ nominal diameter of armour (cm)	3.54
porosity	0.45
length of trunk (cm)	600
diameter of head (cm)	333
crest breadth (cm)	13
height of breakwater (cm)	80

$$D_{n50} = (W_{50} / \rho_s)^{1/3}, \rho_s : \text{unit weight of armour unit}$$

## TEST SERIES

Table 2 indicates the characteristics of the waves used in the experiments. The spectra were of the JONSWAP type with two different peak periods ( $T_p = 1.4s$  and  $T_p = 1.7s$ ). The peak enhancement factor  $\gamma$  was chosen to be equal to 3.3. The multidirectional waves were simulated using the well known Single Summation Method in order to eliminate spatial variability of sea states. Since the objective of this study was to assess the sensitivity of damage to spreading of the wave energy, the commonly used  $\cos^{2s}$  model was chosen for directional distribution. Values of  $s=2$  resulting in  $\cos^4$  and  $s=\infty$  were applied to simulate multi and unidirectional waves respectively. In order to assess the influence of obliqueness, two different mean angles of incidence  $\bar{\theta}=0^\circ$  and  $-15^\circ$  were used, ensuring at the same time homogeneity of the sea state at all sections of interest.

In order to minimize statistical variability associated with short lengths of wave records, a recycling period of 20 minutes (in model scale) was used in the synthesis by the Random Phase Method. This length corresponded to about 1000 waves when  $T_p=1.4s$  and 850 for  $T_p=1.7s$ . The ratios of diameter of the head over wave length and length of trunk over wave length are indicated in Table 2.

Eight test series were carried out using different combinations of spreading index and mean angle of incidence. In each series, the spectrum-based significant wave heights  $H_{m0}$  were increased from 5 to 15cm in steps of 2.5cm. Most of these sea states were pre-calibrated in the basin without the structure in position, while keeping all 17 gauges in place.

Tests under each value of  $H_{m0}$  were run until the stabilization of damage. This was achieved in about 2000 to 5000 waves.

Table 2. Characteristics of waves in experiments

Spectrum	$T_p$ (s)	$\gamma$	$\bar{\theta}$ (deg.)	s	$T_R$ (min.)	N	D/L	TL/L
JONSWAP	1.4	3.3	0, -15	$2, \infty$	20	1028	1.3	2.3
JONSWAP	1.7	3.3	0, -15	$2, \infty$	20	847	1.0	1.8

### RE-REFLECTIONS IN THE TEST SET-UP

The reflection characteristics of the breakwater were estimated by the NRC algorithm, under unidirectional waves of normal incidence. Figure 4, which summarizes these results, shows the reflection coefficient,  $C_r$ , to be in the order of 20 to 25%. Although the steepness parameter,  $H_{m0}/L$ , used in the abscissa of the figure, incorporates the relevant wave length of the sea state, longer periods result in higher reflection coefficients.

Table 3 provides a summary of wave heights measured under different experimental combinations for one particular severity of the sea state (i.e.  $H_{m0}=12.5cm$ ).

The description of the various parameters presented in this table is given below.

- $H_{m0}$  is the target significant wave height;
- $H_{m0\_no}$  is the significant wave height measured without the structure at the gauge 2. (This is the middle gauge in the 5 probe array);
- $H_{m0\_with}$  is the significant wave height measured during the experiments by the gauge 2; and
- $H_{m0,i}$  is the incident wave height resolved by reflection analysis.

This table shows that the estimation of the incident wave heights is within an accuracy of 2.5%, while the build-up of wave heights due to re-reflections is in the order of 3.6%. (This small degree of re-reflection was also confirmed by running some regular wave tests and monitoring the build-up). Because the reflection and the re-reflection were small in this set-up, it was considered justifiable to use the wave heights measured by gauge 2 with the structure in position, as the reference wave height in the stability analysis.

Figure 4. Reflection characteristics of the breakwater

Table 3. Comparison between different estimates of the significant wave heights when the target  $H_{m0}=12.5\text{cm}$

Wave condition	$H_{m0}$ (cm)	$H_{m0\_no}$ (cm)	$H_{m0\_with}$ (cm)	$H_{m0,i}$ (cm)
2D normal waves	12.5	12.83	13.30	12.53
2D oblique waves	12.5	12.83	13.71	-----
3D normal waves	12.5	12.81	12.33	-----
3D oblique waves	12.5	13.04	13.25	-----

RESULTS OF BREAKWATER STABILITY

The analysis of the results from these eight test series, on the stability of the relatively large number of test sections is still proceeding. This paper presents some of the first findings on the stability of head sections. A complete presentation of the results will be given in Matsumi et al. (1995).

### Influence of wave periods

Given the difference in wave lengths under the two peak periods, substantially different patterns of wave diffraction were found in the two cases. In fact, along the trunk section, the non-uniform pattern of damage reported by Vidal et al. (1991) was also found in this study under unidirectional waves. (All results related to trunk sections will be presented in Matsumi et al., 1995). For the head sections, the difference in stability between uni and multidirectional waves was relatively small when  $T_p$  was equal to 1.4s. Numerical simulation of wave heights and kinematics is required to provide a better insight of the influence of wave period. Therefore in the next section, only those results that correspond to 1.7s will be discussed.

### Comparison between the damage under unidirectional waves with normal and oblique incidence

In order to facilitate the interpretation of stability results, the significant wave heights measured at different locations in the proximity of the heads were computed and normalized with respect to the significant wave height measured at gauge 2. (The rationale for using the 2<sup>nd</sup> gauge was discussed earlier).

Figure 5 shows the results of the wave height ratios and the resulting stabilities for unidirectional waves under normal and oblique incidence. Although the difference in the values of significant wave heights realized under normal and oblique wave conditions is small, the stability results show more damage under oblique waves with  $\bar{\theta} = -15^\circ$ .

In order to achieve a better understanding of these results, the numerical model WAGEN, described earlier, was used. Assuming a partial reflection of 30% from the breakwater, the horizontal velocity components in the x and y directions were computed using a regular wave of 1.7s. (Note that x direction is normal to the wave machine, and y direction is parallel to it).

Figures 6a and 6b show the resolutions of the dominant directions of velocity components under normal and oblique wave conditions respectively. It can be seen that these are directed towards the FH section under oblique waves, while under normal waves they wrap around the section. This focussing pattern is believed to be responsible for causing higher damage in FH section when  $\bar{\theta} = -15^\circ$ .

In order to explore the reasons for similar increase in the damage of MH and BH sections, a refraction analysis was carried out using simple cases of regular waves. The intervals between wave rays were found, in this analysis, to be narrower under oblique waves, implying more concentration of energy and thus resulting in lower stability.

The higher damage on the front head under unidirectional waves is however not common for traditional structures. According to Jensen (1984)

Figure 5. Comparison of significant wave heights around the head, and of damage index, under unidirectional normal and oblique waves

the most susceptible section for damage is at angle of about  $90^\circ$  to  $135^\circ$  relative to the incident wave direction. However for berm breakwaters, which are generally composed of smaller stones than those used in conventional structures, Jensen and Sørensen (1991) report damage to the front head sections. It is therefore possible that the reason for the higher damage in this study is the small gradation of stones used intentionally to cause larger degrees of damage.

Figure 6. Dominant directions of velocity components under normal and oblique waves (Regular wave  $T=1.7s$ )

#### Comparison between damage under normal uni and multidirectional waves

Figure 7 shows a comparison of the significant wave heights around the head for normal uni and multidirectional waves. It can be seen that the directional spread under multidirectional waves has increased the wave heights on the head sections. This implies higher wave loading under these waves, and the stability results presented in this figure also confirm this fact. However, the difference in damage between uni and multidirectional waves is largest in the MH section when  $H_{m0}$  was equal to 12.5cm. Under

Figure 7. Comparison of significant wave heights around the head, and of damage index, under uni and multidirectional normal waves

Figure 8. Uniform damage pattern in MH section under unidirectional normal waves

Figure 9. Spot damage pattern in near boundary between MH and BH sections under multidirectional normal waves

unidirectional wave attack, the damage is found to be uniform near the waterline because of the high velocities generated by refraction, shoaling and diffraction processes. In the case of multidirectional waves, the co-existence of the above processes added to the incidence of oblique waves, has resulted in severe spot damage near the boundary between the MH and BH sections (i.e.  $90^\circ$  to  $135^\circ$ ). Figures 8 and 9 present the photographs corresponding to these damages.

For  $H_{m0}=10\text{cm}$ , it is difficult to find any difference between the results of uni and multidirectional waves. The reasons for it are unclear, but are possibly due to experimental variabilities found under low degrees of damage.

To achieve a better insight into the reasons for the increased damage, some velocity measurements were made at St9 and St11, as a continuation of the present study, by the principal author at the Tottori University. The results indicate that the y-component velocities under 3D waves are larger by nearly 1-1/2 to 2 times the values measured under 2D waves. These findings support the stability results presented above.

#### Comparison between damage under oblique uni and multidirectional waves

Under oblique incidence, the multidirectional waves result in large significant wave heights on the middle and back head sections in comparison to the heights obtained under 2D seas. The resulting damages do not display a consistent trend except in the MH section where higher damage was observed under 3D waves when  $H_{m0}$  was equal to 12.5cm. However, the velocity measurements described earlier clearly display larger y-component velocities under 3D waves.

For the FH section, the damages under unidirectional waves are larger than those caused by multidirectional waves (see Matsumi et al. 1995).

#### CONCLUSIONS

In this particular test program, some correspondence was found between the wave heights measured in the proximity of the heads and the resulting damage. A clearer picture emerged when the x and y components of the velocity field were analyzed.

The front head section of the breakwater suffered substantial damage under all combinations of sea states owing to the small gradation of stones used in the tests. For waves of normal incidence, damage on FH section was larger under 3D waves due to directional spreading. However, with  $\bar{\theta}=-15^\circ$ , the trend was opposite (i.e. unidirectional waves induced more damage).

The MH section is more prone to damage under 3D waves because of the co-existence of processes such as refraction, diffraction and shoaling, along with the possibility of direct attack from other directions.

Further analysis of wave kinematics at the Tottori University as a continuation of this test program is expected to provide a better insight into the damage pattern.

### ACKNOWLEDGMENTS

The authors are very grateful to the Institute for Marine Dynamics of the National Research Council of Canada for generously providing the facilities for these experiments.

## CHAPTER 102

### COST-EFFECTIVENESS OF D-ARMOR BREAKWATER

Josep R. Medina,<sup>1</sup> Member ASCE

#### ABSTRACT

The cost-effectiveness of conventional and D-armor breakwaters are compared. Initial cost and capitalized anticipated damage during the lifetime of the structure are the basic elements to be considered in the economic optimization problem. A four level structural response function and a linear initial construction cost estimation are used to define the economic function. An exponential approximation to the return period of the design wave storm with an uncertainty factor is used to estimate the economic impact of the wave climate uncertainty. Finally, the adaptative design concept is introduced considering the advantages of designing for repairing and monitoring breakwaters after construction.

#### INTRODUCTION

During the last two decades, a variety of large mound breakwaters have failed in many regions of the world. The Working Group PIANC-PTCII (1985) analyzed more than 160 mound breakwaters all over the world. 28% of the large breakwaters (depth > 10 m., and  $H_s > 6.5$  m.), and 60% of the very large breakwaters (depth > 12 m., and  $H_s > 8.5$  m.) reported, were damaged after or during construction. Most of them were built with special concrete armor units. The position of mound breakwaters worldwide may be worse, because some of the most famous breakwater failures were not analyzed in the report (see Farrow, 1988). Some breakwaters like Sines (Portugal) at 50 m. depth were totally destroyed; other breakwaters like Bilbao (Spain) were partially damaged forcing expensive reparation and reinforcement works. These experiences generated a worldwide lack of confidence in the optimistic extrapolation of the design techniques of the sixties to new deep water conditions. The last decade has been characterized by the critiques

---

<sup>1</sup>Professor, Director of the Lab. of Ports and Coasts, Dep. of Transportation, Univ. Polit cnica de Valencia, Camino de Vera s/n, 46022 Valencia, SPAIN.

and controversy among different designers, constructors, researchers, and laboratories about the collapse of the old design techniques and the necessity of a significantly improved updated methodology to design mound breakwaters. We are now in a transitional phase between a traditional design methodology with a weak scientific and technical support, and a variety of new methodologies with weak real experimental support.

The cost-effective optimization of rubblemound cross sections requires an estimation of a variety of economic factors during the structural life cycle: initial construction cost, maintenance cost, economic losses due to the functional performance, capitalized costs to cover structural damages, and economic losses associated with total failure. Medina(1992a) presented a new design of a rubblemound breakwater cross section named the "D-armor breakwater", which showed similar resistance in the laboratory to the initiation of damage than conventional design but a significant increase of resistance to total failure. The characteristics of the D-armor design appears to be cost-efficient to face high uncertainties of the design wave conditions at the construction site. In this paper, a comparative analysis of the cost-efficiency of conventional and D-armor cross sections is presented. The D-armor breakwater shows a higher cost-effectiveness when uncertainty of design wave conditions and economic losses due to breakwater destruction increase.

A continuous effort has been developed towards a better understanding of the structural and hydrodynamic factors affecting the stability of rubble-mound breakwaters. There are two main goals of the research effort: a) New calculation procedures for a more reliable and accurate estimation of the structural response during the lifetime to optimize the designs; and b) New designs to reduce the construction cost, maintenance and risk of failure in its lifetime.

The design waves of a variety of maritime projects can only be estimated assuming large uncertainties. On the other hand, there are still significant differences in the calculation procedures proposed by different authors to estimate the structural response of conventional breakwaters for given wave conditions (see Medina, 1992a). Additionally, a number of concrete armor unit designs have been proposed and used in conventional cross sections. However, some of the most costly failures involved the use of special concrete armor units (Sines, San Ciprián, Tripoli, Arzew, Giona Tauro, etc.). Finally, some new breakwater cross sections are being proposed to reduce construction cost or to increase armor resistance. However, some failures have been reported recently (St. Paul berm breakwater) with only a few unconventional breakwaters actually built. This paper focuses the attention on the economic evaluation problem associated to breakwater cross sections.

A variety of alternative designs to the conventional rubblemound breakwater cross section have been proposed. The S-shape and berm type breakwaters are the most popular unconventional designs. In spite of the limited number of prototypes

built according to these new designs. There is an increased number of laboratory results which indicate some of their advantages. However, the current practice for the design and construction of mound breakwaters is conservative. The frequent breakwater failures, the unknown risks associated with designs that lack experimental verification, and a general aversion to risk of most decision makers, may explain the general opposition of designers to adopt radical changes in the classic mound breakwater cross section. This paper describes the economic comparative analysis of conventional and the D-armor breakwater concept that could be extended to other breakwater designs. The general goal is to provide an objective evaluation of the economic niche of each design concept. The D-armor breakwater seems to be a robust solution to face large uncertainties associated with long term wave actions at a construction site.

### D-ARMOR: A ROBUST DESIGN

Fig. 1 shows the cross sections corresponding to the Conventional (SPM, 1984), S-Shape (Ergin et al., 1989), and D-armor breakwater (Medina, 1992a). This paper compares the cost-effectiveness of D-armor and conventional mound breakwaters; the D-armor section reshapes to an efficient S-shape armor near the total failure point, and appears to be a reasonable first step towards a convenient evolution from the old conventional breakwater to more efficient designs.

**Figure 1.- Rubble-Mound Breakwater Cross Sections: a)Conventional; b)D-Armor; and c)S-Shape.**

The D-armor model showed a similar initiation of damage, but a significant higher resistant capacity to total failure. Using the definition of armor damage proposed by Medina(1992a), for a structure with as much as 50% more armor erosion capability before total failure, it may be reasonable to consider a "initiation of damage" range as the identifiable damage below the extra active armor area of the D-armor section. Fig. 2 shows the failure functions corresponding to conventional and D-armor breakwater with a 2/3 reduction in the armor weight to equalize the total failure point. On the other hand, the failure function suggested by SPM(1984) for rough quarrrystones fits the line

$$\frac{H_{10}}{H_d} = \left[ \frac{D}{1.6} \right]^{\frac{1}{5}} \tag{1}$$

Figure 2.- Equalized Failure Functions of D-Armor and Conventional Breakwaters.

The sensitivity analysis included in the methodologies proposed by Medina(1989, 1992b) for the optimization of rubblemound breakwater cross sectional designs, increases the cost-efficiency of the resistant capacity to total failure, and the flexible structural response to wave attack shown by D-armor. On the contrary, a cost-efficient breakwater design, having brittle structural response, requires a reliable estimation of design wave conditions during its lifetime. From a structural point of view, the D-armor breakwater is similar to a conventional design with a significant increase of the armor thickness in the area where the mean water level crosses the external armor profile of uniform slope. Figs. 1-a and 1-b show the cross sections corresponding to the conventional and D-armor breakwaters.

Before damage, the external profile is the same; however, when armor erosion increases, the D-armor design progressively transforms to an S-shape breakwater (see Fig. 1-c). Because of this characteristic, the structural performance is similar to the conventional breakwater at low levels of armor erosion, but the reshaping process significantly increases the resistance capacity as an S-shape breakwater. Therefore, the D-armor design has the large structural response flexibility required to face the high levels of uncertainty usually associated with the design wave storms. Contrary to the conventional or S-shape breakwaters, the D-armor breakwater is designed to reshape significantly during its lifetime.

From the economic point of view, the structural response of conventional and D-armor breakwaters may be classified in four levels: (I) No armor movement, (II) Identifiable but acceptable armor movement (no repair needed), (III) Partial damages (repair needed but no port disruption), and (IV) Total failure (port disruption and breakwater reconstruction needed). Table 1 shows the  $H_{10}/H_{D=0}$  limits defining the structural response of conventional and D-armor breakwaters.

<b>RESPONSE</b>	<b>Conventional</b>	<b>D-Armor</b>
<b>I - II</b>	<b>0.87</b>	<b>0.87</b>
<b>II - III</b>	<b>1.00</b>	<b>1.25</b>
<b>III - IV</b>	<b>1.65</b>	<b>1.89</b>

**Table 1.-  $H_{10}/H_{D=0}$  Corresponding to the Threshold Levels Between Different Structural Response Stages.**

Most breakwaters are built at a construction site where the long term wave climate or the maximum water depth (MSL to sea bed) can only be estimated with large uncertainties. In those cases, low risk and economically-efficient solutions demand robust designs with a flexible structural response having a wide margin between initiation of damage and total destruction. To face large uncertainties in wave action, economic optimization leads to very conservative and expensive designs for brittle structural responses, and to less expensive and safer designs for flexible structural responses. In those conditions, the D-Armor breakwater seems to be a reasonable first step for a safe migration from the inefficient conventional breakwater to new structural and cost-efficient designs. It appears to have about the same construction cost at prototype scale, with higher stability and structural flexibility, making it appropriate to face high uncertainties in the design wave conditions at the construction site. Therefore, it seems to be a reasonable economically-efficient alternative to the conventional design in both deep and shallow waters.

## BREAKWATER COST-EFFECTIVENESS

Three decades ago, Van der Kreeke and Paape(1964) proposed a methodology to optimize breakwaters, considering initial construction cost and capitalized anticipated damage. The optimum design was dependent on the lifetime, the failure function and the long term wave climate. Mol et al.(1983) analyzed the failure of the breakwater at Port Sines (Portugal) and found the uncertainty of the wave climate to be an important factor to be taken into consideration when designing large breakwaters. A similar conclusion was found by C.E.L.(1983), demonstrating the impact of the uncertainty of long term wave climate on the cost of breakwaters in deep water conditions. Recently, Burchart(1991) reviewed design innovations and research contributions, remarking the importance of the procedures for estimating the uncertainties associated with wave data sets, extrapolation from short data samples and lack of knowledge of the long term distributions.

The uncertainty of the long term wave climate, not taken into account in breakwater design, has been found to be responsible of major breakwater failures in the past decades. The estimation of the wave climate uncertainty and the use of safety coefficients, is a first step towards a better rationalization of the optimum breakwater design problem. More elaborate probabilistic methods, considering estimated uncertainties of the principal wave climate parameters, are the natural evolution of the methods for optimization the breakwater design. During the next decades a significant effort will be made worldwide to reduce the uncertainty of the long term wave climate. Therefore, right now it is necessary to use methods and breakwater designs to face large uncertainties in deep waters.

The cost-effectiveness of alternative breakwater cross sections have to take into account not only estimated initial cost and risk to failure during the lifetime, but also the estimated uncertainty of the principal wave climate variables and the procedures to take advantage of monitoring programs for updating the estimated anticipated capitalized damage during the lifetime. The cost-effectiveness of structures with brittle response in deep waters is critically dependent on the reliability and uncertainty of long term wave climate. On the contrary, the structures with a flexible response are not so critical to a precise description of wave climate. Furthermore, an adequate monitoring program after construction can provide valuable information for a precise evaluation of risk during the lifetime, including additional works of repair and reinforcement.

If it is not possible to minimize the uncertainties of the wave climate which critically affects the risk of failure during the lifetime, it is reasonable to face those uncertainties with robust designs and reinforcement strategies based on adequate monitoring programs. The first years after construction may be the best one to one scale test, since most failures of most breakwaters occurs during this period. An adequate design and monitoring program may be useful to limit the risk of failure and to optimize the breakwater design.

## Initial Construction Cost

The initial construction cost of a breakwater depends critically on the technological and geological conditions. Although the model tests referred to rubblemound breakwaters of quarrystone, it will be assumed that the failure functions are also a reasonable first approximation for large mound breakwaters with robust concrete armor units. Some of the largest mound breakwaters with robust concrete armor units (cubic or parallelipedic blocks) are built on the Spanish coast. Two typical Spanish breakwaters are selected to define a reasonable initial construction cost function: 1)"Dique del Este" in the Mediterranean Port of Valencia, and 2)"Dique de Zierbana" in the Atlantic Port of Bilbao.

Del Moral and Berenguer(1980) published the optimization methodology applied to the "Dique del Este" of the Port of Valencia. The water depth was about 14 m and the  $H_{s100} \approx 8.5$  m. The authors proposed several cross sections following the Iribarren's design criteria for different design wave conditions ( $H_{sd}$ ). Because both monetary and wave climate parameters have different meaning in different countries and years, the costs have been made dimensionless by the cost corresponding to the design for one hundred year return period. The design wave storm have been made dimensionless by that corresponding to one the hundred year return period. In the case of Valencia, the following linear function was fitted:

$$C_0(H_{sd}) \approx C_0(H_{s100}) \left[ 1 + 1.1 \left( \frac{H_{sd} - H_{s100}}{H_{s100}} \right) \right] \quad (2)$$

where  $C_0(H_{sd})$  is the initial construction cost for a design significant wave height of  $H_{sd}$ , and  $H_{s100}$  is the significant wave height for one hundred year return period. In the Cantabric Sea open to the Atlantic Ocean, Uzcanga and González(1992) defined pre-designs for the "Dique de Zierbana" in the Port of Bilbao. The water depth was about 25 m. and the  $H_{s100} \approx 12$  m.. The function that fitted the cost estimation provided by the authors was:

$$C_0(H_{sd}) \approx C_0(H_{s100}) \left[ 1 + 1.5 \left( \frac{H_{sd} - H_{s100}}{H_{s100}} \right) \right] \quad (3)$$

Fig. 3 shows the dimensionless initial construction cost functions for the cases of Valencia and Bilbao. In the following, the initial construction cost of Bilbao will be used for the economic analysis of conventional and D-armor breakwaters. The economic function used to analyze the cost-effectiveness will be based on the initial construction cost function and the long term wave climate function containing an uncertainty factor. With these two basic elements, the economic problem will be reduced to define an economic function with the capitalized anticipated damages due to damages and risk to failure during the lifetime.

Figure 3.- Dimensionless Initial Construction Cost Functions Corresponding to Mound Breakwaters Built in Valencia and Bilbao.

## Wave Climate

There are a variety of statistical methods for estimating the long term wave climate to be considered in breakwater design. However, both data and methods have an evolution in time changing the "best" estimation to be considered in design. As an example, Copeiro(1978) published a long term wave climate for Bilbao which may be approximated by the following exponential approximation for the return period:  $R \approx \exp(H_s - 7.5)$ . Some years later, the Spanish Ministry of Public Works published a recommended manual for maritime design (ROM 0.3-91) with a long term wave climate for Bilbao which may be approximated by:  $R \approx \exp(H_s - 6.8)$ . In the future, it is reasonable to assume that both methods and data will contribute to modify the recommended long term wave climate for different locations.

In a specific location, in a given year, only an approximation to the real long term wave climate will be available, if that long term wave climate really exists. In addition to the number of sources of risk and uncertainty affecting the long term wave climate of a specific location, some doubts still remain about the interannual stationarity of the wave climate. Therefore, a reasonable way to take into consideration the global uncertainty in the long term wave climate, is to define a model for the return period affected by an uncertainty factor,  $\beta$ . The higher the  $\beta$ , the higher uncertainty on the estimated return period for the given location is

considered: If  $\beta=0$ , no uncertainty is considered for the wave climate.

Figure 4.- Return Periods of Conventional and D-Armor Responses.

Taking as a basis an exponential approximation of the return period with a reasonable parameter, say  $R \approx \exp(H_s - 7.5)$ , an ensemble of possible scenarios with different return period functions may be considered. Eq. 4a shows the family of return period functions to be considered and Eq. 4b the return periods to be considered depending on the uncertainty factor.

$$R_i (H_s) \approx \exp(H_s - 7.5 + \beta \omega_i H_{s100}) \tag{4a}$$

$$R(H_s, \beta) = \frac{1}{E \left[ \frac{1}{R_i} \right]} ; E[\omega_i \cdot \omega_{i+k}] = 0, k \neq 0 ; \sigma_\omega^2 = 1 \tag{4b}$$

Eqs. 4a,b defines a one-parameter exponential function for the return period in which the parameter is considered a Gaussian random variable with a mean given by usual wave climate estimations and a standard deviation,  $\sigma(\beta\omega_i) = \beta$ , given by qualitative assessment considering all sources of risk and uncertainty involved in the

designing process. Figure 4 shows the return periods corresponding to the structural response limits shown in Table 1 for conventional and D-armor breakwaters.

## Economic Function

Using the design guidelines of Iribarren, Del Moral and Berenguer(1980) proposed a number of economic ratios that were considered in the economic evaluation of the Valencia breakwater. The most important ratios were: 1)Cost of the conventional armor  $\approx 45\%$  cost of the conventional breakwater, 2)Value of properties defended by the breakwater  $\approx 400\%$  cost of the breakwater, 3)Cost of partial repair  $\approx$  three times the initial construction cost, and 4)Cost of total reconstruction  $\approx$  twice the initial construction cost. In addition, comparing the volume of armor stones used by Medina(1992a) in the conventional and D-armor breakwater, two additional ratios may be used in the economic function: 5)Cost of D-armor  $\approx 50\%$  cost of the conventional breakwater, and 6)Cost of the D-armor breakwater  $\approx 105\%$  cost of the conventional breakwater.

In this paper, the economic function of both conventional and D-armor breakwaters are based on the economic ratios given above, the initial construction cost given by Eq. 3, the structural responses given by Eq. 1 and Table 1, the long term wave climate given by Eqs. 4a,b and the following anticipated capitalized formula to cover risk of failure

$$C_L(H_{sd}) = C_0(H_{sd}) + ac \left[ \frac{(1+i)^L - 1}{i(1+i)^L} \right] \quad (5)$$

in which  $L$  is the lifetime of the structure,  $ac$  is the annual cost to cover the risk of failure,  $C_0$  is the initial construction cost (including maintenance and monitoring in lifetime),  $C_L$  is the total cost (including repair and risk of failure), and  $i$  is the interest rate. The first component of Eq. 5 is an increasing function with the design significant wave height, because a larger and more expensive breakwater is required to resist a stronger design wave storm. On the contrary, the second component of Eq. 5 is a decreasing function, because the risk to failure decreases when the design significant wave height increases. Eq. 5 have a minimum value which corresponds to the optimum economic design point; however, the optimum design point depends on the selection of  $\beta$ ,  $i$ , and  $L$ , which are based on engineering judgement. Fig. 5 shows the economic functions ( $L=100$  and  $i=5\%$ ) of conventional and D-armor breakwater for different values of  $\beta$ . The total cost has been normalized by the initial construction cost of the conventional breakwater for the one hundred year return period significant wave height,  $C_0(H_{s100})$ . The design wave height,  $H_d$ , is related with the design significant wave height by  $H_d = 1.27 H_{sd}$ , which corresponds to the  $H_{10}$  of the design storm.

**Figure 5.- Dimensionless Total Cost of Conventional and D-Armor Breakwaters ( $L=100$ ,  $i=5\%$ ).**

The optima points with minima costs shown in Fig. 5 are sensitive to the subjective selection of  $L$ ,  $i$  and  $\beta$ . Therefore, the economic description of the conventional and D-armor alternatives would require not only the economic functions, but also a sensitivity analysis of the factors decided on the basis of judgement, specially  $\beta$ . A preliminary qualitative analysis of the economic functions shown in Fig. 5, shows an increase in the total cost for both the D-armor and conventional breakwaters when  $\beta$  increases. However, D-armor is more efficient because its economic function for  $\beta=0.2$  (high uncertainty) is similar to the economic function of conventional breakwater when  $\beta=0.0$  (no uncertainty).

## UNCERTAINTY AND ADAPTATIVE DESIGNS

According to Medina et al. (1994), most breakwater failures occurred during construction or within a few years after construction. It is obvious that the construction phase and the few years after construction, offers a unique opportunity for a reliable estimation of the risk of failure during the lifetime. An adequate monitoring program may provide a reliable basis for a decision of re-design or structural reinforcement or repair program during the lifetime. Robust designs with

flexible structural responses, like those shown in Table 1, are appropriate to put a limit on the risk to total failure during the monitoring phase. On the basis of robust designs, adaptative designs could be considered in advance to take full advantage of the information obtained during the monitoring phase after construction.

The adaptative design concept may be associated with designing for repairs. In other words, if it seems impossible to design for no damage during the lifetime, the best alternative is to design for having damage during the first years after construction. If the damage actually occurs, a structure designed to be repaired will have to be repaired. In addition, a reliable estimation of risk of failure will have been obtained during the monitoring phase during and after construction until partial damages were reported. If no damage is observed after construction, the reliable estimation of risk of failure during the lifetime obtained from the monitoring phase, will provide the guarantee that a supposed underdesigned breakwater is safe enough for the given lifetime. The economic advantage of the adaptative design concept is so evident than some engineering design strategies applied in practice may be considered in this category.

Two adaptative design alternatives were evaluated on the basis of the D-armor cross section, which was found to be robust enough to be appropriate for testing the new concept. Figs. 6 show the cross sections of the conventional and the two D-armor sections with short and long berm. The sections were very efficient in economic terms with 1.5:1 slope and less armor stone than the conventional breakwater. In order to analyze the structural performance of the two adaptative D-armor designs of Figs. 6, series of 2-D experiments were conducted at the UPV wave flume (30x1.2x1.2 m), divided in two parts to test simultaneously a conventional and a D-armor cross section with berm. A transparent glass divider was used for the verification of the same wave attack on the two cross sections during the experiments. Seven minutes of random wave generation of PM using the DSA-FFT method produced between 200 and 300 waves depending on the  $Ir$  value of the run. An Iribarren's number for random waves defined as  $Ir = [\tan \beta] / [2\pi H_{m0} / g T_{02}^2]^{0.5}$  was constant for all the runs of each test; two different values of  $Ir$  were used for each test ( $Ir = 2.5, 3.0$ ). Starting from the zero-damage design wave height,  $H_{10} = H_d = 12$  cm, the wave height was increased 10% each run ( $H_{10} = H_d [1.1]^k$ ;  $k = 1, 2, \dots, 7$ ). After the seventh run, the sections were re-built to a 2/1 slope, to continue the experiment until total failure of the armor layer.

The berm were found to be reasonably stable, but the behavior of the armors were different than expected in the pre-design phase. The section with short berm showed more resistance to total failure than the section with long berm. After the reinforcement, neither the section with short berm nor the section with long berm show a significant increase of the resistance to total failure shown by the D-armor breakwater with a 2/1 slope (Medina, 1992a). On the contrary, the conventional breakwater increased the resistance to failure after the reinforcement. Additionally, the volume of armor stones required to reinforce the conventional breakwater was significantly lower than the volume required for the sections with berm. Therefore,

the preliminary analysis of results, of the experiments on the two adaptative designs shown in Figs. 6, suggests than both the conventional and the original D-armor breakwater with no berm may be a better adaptative design alternative than those shown in Figs. 6.

Figure 6.- Breakwater Cross Sections: a)Conventional, b)D-Armor with Short Berm, and c)D-Armor with Long Berm.

## CONCLUSIONS

The cost-effectiveness of conventional and D-armor breakwaters are compared considering different uncertainty levels on the wave climate. In deep water conditions, robust designs with flexible structural responses, monitoring programs and adaptative design strategies after construction, appears to be the rational elements for economic optimization of breakwater design.

## CHAPTER 103

### THE CORE-LOC: OPTIMIZED CONCRETE ARMOR

Jeffrey A. Melby, A.M. ASCE and George F. Turk<sup>1</sup>

**ABSTRACT:** This paper outlines the development and initial testing of a new optimized armor shape, called CORE-LOC, that balances and optimizes engineering performance features such as hydraulic stability, strength, and layer porosity. The new shape has significantly reduced design stresses over many existing shapes, yet has superior interlocking and therefore greater stability. The unit has internal maximum tensile stress levels of approximately half that of dolosse and, therefore, should not need reinforcement. For over 1000 flume tests, the core-loc has demonstrated two-dimensional no-damage stability numbers over 7 and Hudson stability coefficients over 250. In nearly all tests, the core-loc layer could not be damaged up to the wave height-period capacities of the flumes. A site-specific three-dimensional stability test of the proposed Noyo, California, offshore breakwater showed a stable no-damage stability number of 2.7 for  $H_s$  or a Hudson stability coefficient of 13 when the core-loc armor layer was exposed to repeated attack of a very severe design-level storm. The unit has been designed to be used alone or as a repair unit for dolosse. Core-loc-repaired dolos model slopes showed improved stability over the original dolos slopes. Finally, through reduced volumes, the core-loc layer is substantially more economical than all other commonly-used randomly-placed armor.

## INTRODUCTION

The U.S. Army Corps of Engineers (USAE) maintains over 1500 rubble

---

1) Research Hydraulic Engineers, Coastal Engineering Research Center, USAE Waterways Experiment Station, Vicksburg, MS, 39180

structures, 17 of which are protected by concrete armor units. Seven additional concrete armor layer projects are planned or are in the preliminary design phase. The Corps has primarily used dolos and tribar armor units but has also used tetrapods, quadripods, blocks, and tetrahedrons. Interest in concrete armoring has increased in the U.S. recently because stone quarries are becoming inaccessible due to increasing environmental constraints. Also, the existing armor shapes have not performed well, with significant breakage due to instability and structural fragility (Melby and Turk 1994a).

Recently, significant inroads into understanding slender armor unit structural response have been made. Terao et al. (1982), Burcharth (1981), and Melby and Turk (1994b, 1994c) developed and verified armor impact scaling criteria. Zwamborn and Phelp (1990) made measurements of prototype impact response. Timco and Mansard (1982) discussed scaled tensile strength modeling. Howell (1988), Melby and Howell (1989), Howell et al. (1990), and Kendall and Melby (1990, 1992), discussed the first measurements of internal strains in in-situ prototype dolosse as part of the Crescent City Prototype Dolos Study. These measurements led to the calibration for hydrodynamic loading of load cell instrumentation, similar to that developed by Scott et al. (1986), for laboratory measurement of dolos structural response (Markle 1990).

One of the primary conclusions from the Crescent City study was that the maximum wave loading-induced stresses were less than the static mean stress, for large dolosse. So static stresses dominate the structural design of stable non-rocking dolosse. This made accurate measurements of static strains very important; but the prototype data were insufficient to quantify static response because only 17 prototype dolosse were sampled and accurate quantification of the static response statistics requires a tremendous number of permutations of random boundary conditions, slope, and armor unit position on the slope.

Melby and Turk (1994b, 1994c, 1995) made large-scale measurements of 26-kg dolos static, wave loading, and impact strains to fill in the missing pieces in the dolos structural response quantification. Although these data are still being analyzed, they showed that the impact strains are very large and dolos movement should be avoided.

Recently, reasonable design methods for stable dolosse have been proposed based on the prototype and large scale measurements discussed above (Melby 1990, 1993, Melby and Turk 1992). Yet concrete armor breakage surveys of USAE breakwaters and jetties, combined with the existing structural data, have produced conclusive evidence that armor unit structural and hydraulic stability response can be improved significantly through small modifications in armor shape (Melby and Turk 1994a). This is therefore the focus of the research reported herein.

## **DEVELOPING NEW ARMOR SHAPES**

The Corps has an ongoing research effort to develop optimized concrete armor shapes. The optimal armor engineering characteristics are summarized as

follows:

- a.* High hydraulic stability in a single-unit-thickness layer on any slope. Reserve stability for wave conditions exceeding the design event.
- b.* Hydraulically stable with no rocking, even when broken or following reneasting resulting from local instability.
- c.* Efficient combination of porosity and slope roughness to dissipate the maximum amount of wave energy with the minimum armor volume over a critical range of wave periods.
- d.* Hydraulically stable when placed as a repair with other shapes.
- e.* Low internal stresses, so no reinforcement required.
- f.* Constructable casting yard forms and armor layers (need to be able to construct armor layer in low visibility water.)
- g.* Uses minimal casting yard or barge space.
- h.* Utilizes conventional construction materials and techniques.

A new series of concrete armor units, called the CORE-LOC, was recently developed at the USAE Waterways Experiment Station Coastal Engineering Research Center with the above features as prerequisite (Melby and Turk 1993, 1994d). The unit has a balance of the above engineering features such that the armor layer performance is maximized while the armor layer costs are minimized. The core-loc appears to have improved engineering performance due to a balance of the hydraulic stability, structural strength, wave energy dissipation, and constructability. The armor layer costs are reduced through less concrete and fewer and smaller units. The core-loc was designed to be placed in a single-unit-thick layer on steep or shallow slopes. The unit interlocks well on any slope and even interlocks well with dolosse, providing an efficient repair unit for those dolosse slopes in need of repair.

### **CORE-LOC ENGINEERING CHARACTERISTICS**

The core-loc armor unit and its engineering characteristics are shown in Table 1 and Figure 1. Table 1 also gives a comparison with dolos. The design parameters, such as the packing density and volumes, are defined using the traditional Shore Protection Manual (SPM 1984) methodology.

Table 1. Engineering Characteristics of the Core-loc							
Unit	Volume	Number of Layers <sup>1</sup>	Porosity	Layer Coefficient	Packing Density	Typical Slope	Number of Units <sup>2</sup>
	V	n	P as %	k <sub>A</sub>	φ	cotα	N/C <sup>2</sup>
Cora-loc	0.2240C <sup>3</sup>	1	66	1.6	0.54	1.5	1.46
Dolos	0.1561C <sup>3</sup>	2	56	0.94	0.83	2.0	2.86

Footnotas

- The two dolos armor layers are always constructed as a single layer but n = 2 corresponds to k<sub>A</sub> = 0.94 in equations 2 and 3.
- Here the number of units is given per square armor unit dimension.

Figure 1. Core-loc Dimensions and Engineering Characteristics

### CORE-LOC STRUCTURAL RESPONSE

Finite element method (FEM) structural analyses have been done to compare the structural response of core-locs to dolos, accropode, and tribar for several loading modes. The model and analysis specifications are shown in Table 2 for the FEM analysis. The FEM grid is shown in Figure 2. An example loading, shown in Figure 2, imposed the worst case flexural condition with one outer member fixed rigidly along the outside surface and the load applied to the end of the opposing member. This condition generated the maximum flexural stresses at the internal intersection on the units. The load was equal to the armor weight, which was 9 tonnes. Another pure flexural loading, a pure torsion loading, and a combined torsion and flexural loading were also analyzed. For the other pure flexure load condition, the load of 9 tonnes was applied transversely at the center of the outer member while the opposing member was held rigid. For the torsion loading, four 4.5-tonne loads were applied to the four outer member tip ends to generate the maximum twisting force on the unit. The unit was pinned at the center for this case. For the combined loading case, two 9-tonne loads imposing torsion and flexure, were applied to one outer member end while the opposing member was held rigid along its entire length. FEM results are shown in Table 3.

Table 2. Finite Element Model Properties	
Model Properties	Fully three-dimensional linear elastic model with about 2000 nodas and 1500 alaments, depending on the unit shepe.
Armor end Material Properties	Armor Weight, $W = 9$ tonnes Modulus of Elasticity, $E = 3.5 \cdot 10^4$ MPe Poisson Ratio, $\nu = 0.21$ Specific Greivity, $S = 2.33$ relative to fresh water

Table 3. FEM Static Stress Comparison				
Load Case	Stress, $\sigma$ , MPe			
	Core-loc	Dolos	Accropoda	Tribar
Torsion	1.12	2.08	1.52	2.98
Flexure - fluke tip load	1.12	2.41	1.52	3.36
Flexure - fluke center load	2.10	3.42	-	-
Combined flexure end torsion	1.91	3.83	-	-

Figure 2. Loading and Boundaries for Flexural Stress Comparison of Core-loc, Tribar, Accropode, and Dolos.

As illustrated in Table 3, for equivalent weight units, the core-loc maximum tensile stress for static loads ranges from 34% to 62% that of dolos. The maximum core-loc tensile stress is 74% for torsion and 74% for flexure that of accropode, and 38% for torsion and 33% for flexure that of tribar.

## CORE-LOC HYDRAULIC STABILITY TEST RESULTS

### *Two-Dimensional Hydraulic Stability*

The first *proof-of-concept* tests of core-loc hydraulic stability were two dimensional and showed the unit to be exceptionally stable, with no damage

measured for Hudson stability coefficients over 300 (stability numbers,  $N_s$ , over 7). The tests were done in a 0.6-m-wide flume with the structure 30 m from the wave generator. A wide range of monochromatic wave conditions were tested. The waves were generated by an electro-hydraulic powered, computer-controlled, bottom-hinged paddle. The approach slope was 1V:20H for 5 m seaward of the structure, 1V:16H for 2.4 m, flat for 6.7 m, and 1V:33.3H to the generator pit. Two three-electrical-capacitance-gage arrays were used to measure water surface elevations near the wave generator and at a position 3 m from the structure toe. The incident and reflected waves were resolved using the method of Goda and Suzuki (1976). The armor layer was composed of 220 g core-locs (Table 4) on a slope of 3V:4H with a stone underlayer mean weight of 41 g and a stone core mean weight of 2 g. The core had a very low permeability and was therefore more critical to armor stability. The maximum wave conditions are summarized in Table 5. The armor could not be damaged up to the limit of the wave generator for nearly all tests. The only instability, the first entry in the table, appeared to be due to low randomness in the armor placement. It was noted during all tests that only a few of the units on the slope were rocking, and then only slightly, even for the most severe wave conditions.

Table 4. Model Core-loc Specifications

* Wave generation capacity limited, no instability						

Carver and Wright (1994) carried out a much more comprehensive series of two-dimensional hydraulic stability tests of the core-loc and also could not damage the armor layer for significant wave heights corresponding to stability numbers over 7 (Hudson stability coefficients over 250). These tests were done in a 1-m-wide section of an 3.3-m-wide flume 75 m long. The remainder of the flume width was left clear for waves to be dissipated on a rock wave absorber on the rear wall of the flume. A second section of 1 m width was filled with an identical dolos structure for comparative tests partially through this test series. Monochromatic and irregular waves were generated by an electro-hydraulic powered, computer-controlled, horizontal-displacement paddle. For the irregular waves, the spectra were of the TMA type. Incident and reflected waves were resolved from water surface measurements made with two sets of three electrical capacitance wave gages, again using the methods of Goda and Suzuki. The test parameters are summarized in Table 6. The approach slope was at 1V:100H for 6.5 m seaward of the structure, 1V:75H for 34 m, and flat for 15.2 m to the generator pit. The wave gage arrays were positioned near the wave generator and 3.3 m from the structure toe.

<b>Table 6. Flume Stability Test Parameters</b>	
Structure Height	0.9 m
Structure Base Width	2.7 m for 1V:1.33H and 3.0 m for 1V:1.5H
Structure Slopes	1V:1.33H and 1V:1.5H
Mean Armor Mass	219 g
Mean Underlayer Mass	45 g
Mean Core Mass	1 g
Number of Waves per Test	~1000
Water Depths at Structure Toe	36 and 61 cm
Incident Wave Heights, $H_{mo}$	4.6 to 39 cm (61 cm depth)
Peak Period, $T_p$	1.5 to 4.7 sec
Surf Sim. Param, $\xi$	2.13 to 15.9
Relative Depth, $d/L_o$	0.012 to 0.175
Wave Steepness, $H_{mo}/L_o$	0.001 to 0.098

For these tests, several parameters of relative measure were calculated including the surf similarity parameter or Irribarren number,  $\xi = \tan \alpha / (H_{mo}/L_o)^{1/2}$ , the relative depth,  $d/L_o$ , and the wave steepness,  $H_{mo}/L_o$ . Here  $\alpha$  is the structure front slope angle,  $H_{mo}$  is the incident wave height at the shallow gage array,  $L_o = 2\pi/gT_p^2$  is the deep water wave length computed from the peak period at the shallow gage array, and  $d$  is the structure toe depth. The ranges of these

parameters are also summarized in Table 6.

The researchers made note of the fact that the units showed almost no movement on the slope, including in-place rocking. It seems likely that the units would therefore have a very low probability of experiencing impact stresses. Also, in the dolos and core-loc side-by-side tests, the reflection coefficients from the core-loc slope were almost indistinguishable from those of dolosse, indicating that existing dolos reflection and runup design information could be used for preliminary estimation of reflection and runup on core-loc slopes.

These early tests showed that the core-loc armor layer was two-dimensionally stable for wave heights far exceeding those causing damage to most other armor shapes. It was noted that a conservative design would never specify armor weights using very high stability coefficients, such that the non-interlocked armor stability was significantly different from the interlocked stability, because of the risk of catastrophic failure. Therefore these tests show that the core-loc armor, when designed conservatively for two dimensional situations, such as on a revetment, will have considerable reserve stability beyond the design wave or when repeatedly subjected to the design wave.

### *Three-Dimensional Stability*

Although generic three-dimensional stability tests have not been done, several site-specific studies have been completed. Smith et al. (1994) carried out three dimensional stability tests of a core-loc armor layer for a site-specific test of the proposed Noyo, California Harbor offshore breakwater. This site is subjected to depth limited 7 to 9 m breaking waves repeatedly each winter, and therefore provided a very good test of core-loc stability. Also, the breakwater is subjected to very high flow velocities that are due to wave focussing from several surface-piercing pinnacles just off the seaward toe.

Three-dimensional stability tests of the Noyo breakwater were carried out at a geometrically undistorted scale of 1:50 with molded bathymetry. The model offshore breakwater was scaled from prototype dimensions of 122 m length between two round head centers and initial crown widths of 9 m on the large head, 6.1 m on the small head, and 7 m in between. The slope of the breakwater was 1V:1.5H. The initial storm series consisted of 17 tests of 15 minutes model, 106 minutes prototype, each with a succession of 13, 17, and 20 second peak period waves of increasing significant wave heights from 3.4 to 8.4 m (Storm I). The maximum wave height was depth limited. The primary armor tested consisted of approximately 500 28-tonne core-locs on the large head and 500 17-tonne core-locs on the small head.

The core-locs were stable for two successive Storm IA wave series (the 10 highest energy series from storm I) and began to unravel after being subjected to an additional three Storm IB series, each consisting of the 3 highest energy series in Storm I. It appeared that the primary damage was instigated by toe instability, particularly in areas of wave focussing, due to erosion of the toe apron. The stability number corresponding to the larger core-loc was 2.7 for the highest  $H_s$

(Hudson stability coefficient of 13).

The design waves tested above were considered to be quite conservative, so a somewhat more realistic wave condition was also tested. The final storm series consisted of a five-Storm-IB sequence, except that the 20 sec, 8.4 m test was omitted from the middle three series. The apron was mostly stable for this sequence of storms, and only 4 core-loc units, or 0.4%, were displaced. In summary, the core-locs were stable for very high stability coefficients when repeatedly subjected to this very high energy design storm event. The core-loc structure was the only alternative to meet the required economic benefit-to-cost ratio and was accepted as the final design.

### ***Dolos Repair Tests Using Core-loc***

A short series of two-dimensional stability tests was conducted to determine the comparative stability between dolos and a dolos slope repaired with core-locs. The tests were done in shallow water with a 1.5-m-wide fronting reef in the same 0.6-m-wide flume described above. The structure was 17 cm high with a front slope of 1V:1.5H. Monochromatic waves were generated producing a maximum incident wave height of 22 cm and period of 3.75 sec in a depth of 17 cm at the structure. A very high wave height-to-depth ratio occurred at the structure because the fronting reef was narrow relative to the wavelength; therefore, the wave height was not stabilizing before it hit the structure. Approximately 180 waves were generated per run. The number of wave cases and complexity of this experiment were kept to a minimum for this *proof-of-concept* test.

For the dolos stability tests, 97 dolosse were placed at a packing density of 0.83. The armor mass was 125 g. For these tests, 15 units were displaced and most of the dolosse were mobile during the tests. The Hudson stability coefficient for this case was approximately 61, but represented excessive damage.

For the repair tests, the damaged dolos slope was repaired with 15 core-locs. The repair units were 145 g and were placed rather haphazardly along the toe and in two pockets on the slope. The remaining dolosse were not touched. This is not a recommended repair procedure but represents a worst case emergency spot repair. For this test series, 3 core-locs were displaced off the slope and 3 additional dolosse were displaced. It was noted that the core-locs had interlocked and stabilized the original damaged regions on the slope. The displaced units were near the cap and were never interlocked. The additional core-loc weight contributed some to the increased stability of the dolos slope; but the effect was small because the incident wave heights were far greater than those corresponding to the non-interlocked stability threshold. The primary stabilization was from interlocking. For an actual repair, the same weight units would likely be used and the existing armor near the repair region would be removed from the slope so the core-locs could be interlocked with the dolos units as they were placed. It is expected that this more careful repair procedure would have resulted in a much more stable armor layer.

Although very brief, these tests showed that the core-loc-repaired areas

were qualitatively more stable than the original dolos slope, and the higher structural strength of the core-loc further justify its use as a repair unit for dolos slopes. More extensive tests are being done to systematically quantify the stability of a core-loc-repaired dolos slope and to determine the most effective repair methods.

## CONCLUSION

A new armor unit, called the core-loc, was discussed which solves the primary problems of existing randomly-placed units. The core-loc appears to have a unique balance such that the primary engineering performance criteria are maximized while the amount of concrete and number of units are minimized. These primary performance criteria are structural integrity, hydraulic stability, armor porosity, and constructability. A finite element study showed the core-loc maximum tensile stress for combined loading to be approximately 62% that of an equivalent-sized dolos. The study showed the core-loc maximum flexural and torsional tensile stresses to be slightly lower than those in an equivalently sized accropode. Several stability studies are discussed which show two-dimensional flume stability numbers over 7 (Hudson stability coefficients over 300) for long slopes. A three-dimensional site-specific study of the proposed Noyo, California, breakwater showed no-damage stability numbers of 2.7 (Hudson stability coefficients of 13 for  $H_s$ ) for repeated exposure to severe design storms. A simple hydraulic stability test showed that core-locs would be effective at repairing dolos slopes.

Finally, for general design based on  $H_s$ , Hudson stability coefficients of 13 for the head and 16 for the trunk are preliminarily and conservatively recommended for core-locs. Using the stability coefficient of 13, for breaking waves on a head, and the recommended packing density of 0.54, the core-loc armor layer requires 47% less total volume than a dolos armor layer, 57% less than tetrapod, 51% less than tribar, and 24% less than accropode.

## ACKNOWLEDGEMENT

The work described in this paper was conducted as part of both the Coastal Research and Development Program and the Repair, Evaluation, Maintenance, and Rehabilitation Research Program of the US Army Engineer Waterways Experiment Station, US Army Corps of Engineers. Permission to publish this paper was granted by the Chief of Engineers.

## CHAPTER 104

# STABILITY OF ARMOR STONES OF A SUBMERGED WIDE-CROWN BREAKWATER

Norimi MIZUTANI,<sup>1</sup> Teofilo Monge RUFIN Jr.,<sup>2</sup> and Koichiro IWATA<sup>3</sup>

### Abstract

The stable weight of armor rubbles of a submerged wide-crown breakwater was analyzed in relation to the wave force acting. At first, stability models for armor rubble were derived based on the idealized spherical armor unit; then, the shape effect of armor stones on acting wave forces and stability was investigated experimentally. Based on the results, the proper modification of the stability models for spherical armor unit gives good estimate of the stable weight of armor rubbles. Furthermore, the shape effect on wave forces and stability is significant; whereas, the shape effect of armor rubble on the stable weight is relatively small.

### 1. INTRODUCTION

The submerged breakwater is a nature-conscious coastal protection work which takes the essential role in providing an agreeable environment of safety in coastal areas. This structure creates a calm sea and scarcely harms the coastal scenery nor obstruct the utilization of the sea for recreational and residential developments. In the design of submerged breakwater, an accurate estimation of stable weight of armor unit is deemed necessary. The stable weight of a rubble structure such as the rubble-mound breakwaters (e.g., Hudson et al. 1958, 1959; Hedar 1986), composite rubble-mound breakwater (Brebner and Donnelly 1962), and artificial reef (Uda et al. 1989) were discussed and stability models were subsequently proposed. Most of the existing stability formulae are intended to correlate the stable weight with the wave height, and the relation between the stable weight and wave forces acting have not been discussed in detail. However, the stable weight of the armor unit depends largely on the acting wave forces; thus, it is necessary to relate the stability to the acting wave forces and its pertinent characteristics. Although there have been some studies

on wave forces acting on rubble stones of a rubble-mound slope breakwaters (Iwata et al. 1985; Tørum 1994), still the accumulated knowledge on wave force on rubble stones are very limited because of the complexity of the shape of stones. The present authors analyzed the wave force acting on a spherical armor unit which is an ideal shape of rubble stone, and then discussed and proposed a model for the stable weight in relation to the acting wave force (Mizutani et al. 1992; Rufin et al. 1993). This method, however, cannot be directly applied for the case of actual rubble stones without first clarifying the shape effect of rubble stone on stability and wave force. Hence, this paper aims to present the wave force and stability of armor stones in relation to the shape effect, and then develop a method of evaluating the stable weight of armor rubble of a submerged wide-crown breakwater.

## 2. EXPERIMENTAL SET-UP AND PROCEDURE

The stability tests and the laboratory observations of wave forces acting on spherical armor unit and armor rubble stones on a submerged breakwater were carried out using an indoor wave tank (25m long x 0.7m wide x 0.9 m deep). The model of the breakwater was prepared using spheres and then performed with one made of natural stones, as shown in Fig. 1. Regular waves with different wave periods ( $T = 1.0, 1.4, \text{ and } 1.8\text{s}$ ) were generated in this experiment.

For the stability measurement, the critical wave height of each sample of

Figure 2: Stones samples.

armor unit in each wave period was determined for every designated locations on the submerged breakwater. The critical wave height is defined as the minimum wave height required to move a given sample of armor unit. The samples of armor units were spheres with  $D/d = 0.35, 0.28,$  and  $0.28$  and stones, as shown in Fig. 2, with the same volume with that of the equivalent sphere of three different shapes (round-type, flat-type, and edged-type), where  $D$  is the diameter of sphere and  $d$  is the crown water depth. Table 1 gives the characteristics of the sample armor units used in the investigation, where  $S_1$  and  $S_2$  are the maximum and minimum lengths, respectively, and  $L_1$  and  $L_2$  are the maximum tangential and normal lengths, respectively. The determination was made by generating series of experimental trials with different values of wave height until the critical wave height is attained. The armor sample was placed on the structure surface with the maximum cross-section parallel to the horizontal plane and the minimum cross-section normal to the wave incident direction.

For wave force measurement, the horizontal and vertical wave forces ( $F_x, F_z$ ) of each sample were measured for a given incident wave height ( $H_I$ ) and critical wave height conditions. The corresponding water surface elevations and horizontal and vertical water particle velocities ( $u$  and  $w$ ) were also measured. Table 2 gives the experimental conditions. The wave forces were measured for the same placement except for a very small gap between the wave force meter and the surface of the structure. In the measurement of wave force acting on rubble stones, a prototype of the actual stone of interest with exactly the same shape was prepared by plaster cast and used as sensor on the wave force meter.

### 3. WAVE FORCE ACTING ON ARMOR UNIT

Regardless of wave period, shape, and size of armor units, the nondimen-

dimensional maximum wave force,  $Fx_m/\rho g D^2 H_I$ , shows similar variation with the dimensionless distance,  $x/L$ , where  $\rho$  is the density of water,  $g$  is the gravitational acceleration,  $x$  is the horizontal distance referred from the leading crown-edge, positive in onshore direction, and  $L$  is the wavelength at the toe of the structure. As shown in Fig. 3,  $Fx_m/\rho g D^2 H_I$  increases with  $x/L$  and  $H_I/h_t$  on the slope ( $x/L < 0$ ) and attains a maximum value near the crown-edge (Rufin et al. 1994), where  $h_t$  is the still water depth at the toe of the structure. On the crown ( $x/L > 0$ ),  $Fx_m/\rho g D^2 H_I$  decreases rapidly for wave breaking condition; whereas,  $Fx_m/\rho g D^2 H_I$  decreases gradually for non-breaking condition. Therefore, the nondimensional maximum wave force,  $Fx_m/\rho g D^2 H_I$ , for non-breaking condition is larger than the wave breaking condition. This may be attributed to the disturbance due to the wave breaking and higher harmonic wave component generated on the crown. Similar tendency was observed for nondimensional maximum wave force in the vertical direction,  $Fz_m/\rho g D^2 H_I$ , however, the variation with  $x/L$  and  $H_I/h_t$  is not clear as compared with the horizontal wave force. Moreover, the figure shows that the onshore wave force is generally larger than the offshore wave force.

The shape effect of stones is not sensitive in the variations of nondimensional wave forces with  $x/L$ . However, shape effect is very significant on the magnitude of wave forces. Figure 4 gives the comparison of wave force among various shapes of armor unit. For the horizontal wave force, the wave force on round-type stone is almost the same magnitude with the equivalent sphere. The wave force on edged-type stone, however, is much larger than the sphere and round-type stone. For edged-type shape, flow separation takes place easier than the round-shape body because of the edges of stone, consequently, resulting to a larger drag force. On the other hand, the horizontal wave force on flat-type stone is generally small compared to the other types of stones. The method of placement wherein the smallest cross-sectional area faces the horizontal flow gives the flat-type stone the smallest projected area which results to a smaller horizontal wave force. However, the vertical wave force on flat-type stone is much larger than the other types of stone, because of very large projected area. This significant property is attributed to the variation of

Figure 3: Variations of  $F_{x_m}/\rho_w g D^2 H_1$  and  $F_{z_m}/\rho_w g D^2 H_1$  with  $x/L$ .

the cross-sectional area in the flow direction.

#### 4. STABILITY MODEL OF SPHERICAL ARMOR UNIT

The stability models for spherical armor unit were derived by the present authors (Mizutani et al. 1992); however, the proposed models were applicable only for a given experimental conditions and not suitable for the case of the actual rubble stones. Therefore, in this study, a more general stability model for spherical armor unit for various types of movements were derived in the following manner. By considering an element consisting of four spherical units of the most densely packed arrangement, as shown in Fig. 5, the possible movements of the sphere resting on top of the pyramid formed by the assemblage of these four spheres are rolling, sliding, and uplifting. For sliding and rolling movements, a maximum external force is required to move the sphere along the median line connecting the vertex of the triangle; whereas, a minimum external force is necessary to move the sphere along the median line connecting the base of the triangle. Furthermore, the case of the most movable arrangement of the exposed armor unit also depends on the direction of movement (onshore and offshore). Based on these methodologies, the theoretical models were developed for these two typical cases, CASE-I and CASE-II, as shown in Fig. 6. The uplifting motion was not observed in the experiment proper for the given samples of armor unit, thus, the succeeding models were derived based on rolling and sliding movements only.

By considering the balance of moments for rolling movement and balance of forces for sliding movement, as shown in Fig. 7, the following stability models for spherical armor unit on a submerged breakwater are summarized as follows:

- Stability model for offshore rolling (CASE-I)

$$W_1' \geq \{(\tan \beta)Fn - [1 + (2\epsilon/D)/\cos \beta] Ft\}_m / (\tan \beta - \tan \theta)(\cos \theta) \quad (1)$$

- Stability model for offshore rolling (CASE-II)

$$W_2' \geq \{(\tan \beta)Fn - 2[1 + (2\epsilon/D)/\cos \beta] Ft\}_m / (\tan \beta - 2 \tan \theta)(\cos \theta) \quad (2)$$

Figure 6: Methods of placement.

Figure 7: Balance of moments and forces.

- Stability model for onshore rolling (CASE-I)

$$W'_3 \geq \{(\tan \beta)Fn + 2[1 + (2\varepsilon/D)/\cos \beta]Ft\}_m / (\tan \beta + 2 \tan \theta)(\cos \theta) \quad (3)$$

- Stability model for onshore rolling (CASE-II)

$$W'_4 \geq \{(\tan \beta)Fn + [1 + (2\varepsilon/D)/\cos \beta]Ft\}_m / (\tan \beta + \tan \theta)(\cos \theta) \quad (4)$$

- Stability model for offshore sliding (CASE-I)

$$W'_5 \geq \frac{\{(\sin \beta + \mu \cos \beta)Fn - (\cos \beta - \mu \sin \beta)Ft\}_m}{(\cos \theta \sin \beta - \sin \theta \cos \beta) + \mu(\cos \theta \cos \beta + \sin \theta \sin \beta)} \quad (5)$$

- Stability model for offshore sliding (CASE-II)

$$W'_6 \geq \frac{\{(\sin \beta + 2\mu \cos \beta')Fn - (\cos \beta - \mu \sin \beta')2Ft\}_m}{(\cos \theta \sin \beta - 2 \sin \theta \cos \beta) + 2\mu(\cos \theta \cos \beta' + \sin \theta \sin \beta')} \quad (6)$$

- Stability model for onshore sliding (CASE-I)

$$W'_7 \leq \frac{\{(\sin \beta + 2\mu \cos \beta')Fn + 2(\cos \beta - \mu \sin \beta')Ft\}_m}{(\cos \theta \sin \beta + 2 \sin \theta \cos \beta) + 2\mu(\cos \theta \cos \beta' - \sin \theta \sin \beta')} \quad (7)$$

- Stability model for onshore sliding (CASE-II)

$$W'_8 \leq \frac{\{(\sin \beta + \mu \cos \beta)Fn + (\cos \beta - \mu \sin \beta)Ft\}_m}{(\cos \theta \sin \beta + \sin \theta \cos \beta) + \mu(\cos \theta \cos \beta - \sin \theta \sin \beta)} \quad (8)$$

where subscript  $_m$  indicates the maximum value,  $Fn$  and  $Ft$  are the normal and tangential wave forces, respectively,  $\beta$  and  $\beta'$  are the contact angles defined in Fig. 6,  $\mu$  is the coefficient of friction,  $\theta$  is the slope angle of the submerged breakwater ( $\theta = 0^\circ$  on the crown), and  $\varepsilon$  is the eccentricity and location of the center of action of wave force. In this study, the treatment of offshore rolling and offshore sliding for both CASE-I and CASE-II is the same with the work of Lee et al. (1990).

Figure 8 shows the concept of the stability conditions. The domain bounded by the critical stability lines is the stable range; thus, in the case that the trace of wave force is inside the domain, the armor unit is said to be stable. However, as the trace of wave force touches the critical stability lines, the corresponding incipient movement occurs. And beyond the critical stability lines, unstable state of the armor unit is attained.

The comparison between the calculated and experimental values of stable weight for CASE-I on the crown is shown in Fig. 9(a). By following the video-movement analysis, all movements were observed to be onshoreward rolling; thus, the corresponding critical weight given by Eq. 3 is used for the computed values. The calculated value, neglecting the eccentricity and friction, is obtained by substituting the time-varying wave forces into Eq. 3 and taking the maximum value, then, the maximum value for each run was plotted. Some scattering for each period was observed in the maximum wave force, and this

Figure 8: Concept of stability conditions.

Figure 9: Estimated and experimental values for spherical armor unit.

scattering is significant in the movement of the armor unit. On the slope, as shown in Fig. 9(b), both onshore and offshore rolling movements were observed; thus, the calculated values are based on these two movements. These two directions of rolling movements occurred because on the slope, downward movement is likely to prevail; however, the onshore wave force is generally greater than the offshore wave force, as described in Fig. 3, thus, onshore movement is also evident. Although there are some discrepancies between the calculated and experimental values because of the non-uniformity of the slope of the structure, the calculated values generally agree well with the experimental value. Thus, the models derived in this study express well the stable weight of the spherical armor unit.

### 5. STABILITY MODEL OF ARMOR RUBBLE STONE

A straightforward application of the stability formulae of the spherical armor unit to the armor rubble stone is quite difficult because the shape effect and contact angle vary for a given stone. Thus, some modifications with theoretical consideration and engineering point of view are considered. In this study, only the physical quantities which has a major influence on the movement of the armor stone were included.

For rolling-type movement, the important quantities considered were the acting wave force and the moment-arm lengths. Representing the arm lengths

of the overturning and restoring moments by the maximum tangential and normal lengths, the following models were summarized and given as:

- Stability model for offshore rolling (CASE-I)

$$W'_1 \geq \frac{\{Fn - L_e S(1 + \varepsilon/L_2 K)Ft\}_m}{(\cos \theta - L_e S \sin \theta)} \quad (9)$$

- Stability model for offshore rolling (CASE-II)

$$W'_2 \geq \frac{\{Fn - 2L_e S(1 + \varepsilon/L_2 K)Ft\}_m}{(\cos \theta - 2L_e S \sin \theta)} \quad (10)$$

- Stability model for onshore rolling (CASE-I)

$$W'_3 \geq \frac{\{Fn + 2L_e S(1 + \varepsilon/L_2 K)Ft\}_m}{(\cos \theta + 2L_e S \sin \theta)} \quad (11)$$

- Stability model for onshore rolling (CASE-II)

$$W'_4 \geq \frac{\{Fn + L_e S(1 + \varepsilon/L_2 K)Ft\}_m}{(\cos \theta + L_e S \sin \theta)} \quad (12)$$

For sliding-type movement, the acting wave force, friction and contact angles were considered important. However, the accurate estimation of the contact angle is complicated for the case of the actual stone. Thus, in the computation, the contact angle can be assumed equal to zero for conservative estimation. The following sliding models are summarized and given as:

- Stability model for offshore sliding (CASE-I)

$$W'_5 \geq \frac{\{Fn(\sin \beta + \mu \cos \beta) - Ft(\cos \beta - \mu \sin \beta)\}_m}{(\cos \theta \sin \beta - \sin \theta \cos \beta) + \mu(\cos \theta \cos \beta + \sin \theta \sin \beta)} \quad (13)$$

- Stability model for offshore sliding (CASE-II)

$$W'_6 \geq \frac{\{Fn(\sin \beta + 2\mu \cos \beta') - 2Ft(\cos \beta - \mu \sin \beta')\}_m}{(\cos \theta \sin \beta - 2\sin \theta \cos \beta) + 2\mu(\cos \theta \cos \beta' + \sin \theta \sin \beta')} \quad (14)$$

- Stability model for onshore sliding (CASE-I)

$$W'_7 \geq \frac{\{Fn(\sin \beta + 2\mu \cos \beta') + 2Ft(\cos \beta - \mu \sin \beta')\}_m}{(\cos \theta \sin \beta + 2\sin \theta \cos \beta) + 2\mu(\cos \theta \cos \beta' - \sin \theta \sin \beta')} \quad (15)$$

- Stability model for onshore sliding (CASE-II)

$$W'_8 \geq \frac{\{Fn(\sin \beta + \mu \cos \beta) + Ft(\cos \beta - \mu \sin \beta)\}_m}{(\cos \theta \sin \beta + \sin \theta \cos \beta) + \mu(\cos \theta \cos \beta - \sin \theta \sin \beta)} \quad (16)$$

where  $L_e = L_2/L_1$ ,  $S = \cot \beta$ ,  $K = \cos \beta/2$ , and the relation between the contact angles,  $\beta$  and  $\beta'$ , is given by  $\tan \beta = 2 \tan \beta'$ ; for sphere,  $L_e = 1.0$ . In the above mentioned formulae,  $W'$  is the weight of stone in water, and for the weight of armor rubble stone in air,  $W$ , the following equation is given.

$$W = W' + \rho V = W' \left( 1 + \frac{\rho}{\rho_s} \right) \quad (17)$$

where  $V$  is the volume of stone and  $\rho_s$  is the density of stone.

## 6. APPLICATION OF STABILITY MODEL

The movements observed for armor stone were rolling and sliding with no uplifting movements. The type of movement depends largely on shapes of stones and location on the structure. On the crown, onshoreward rolling was generally observed for round-type and edged-type of stones. For the case of flat-type stones, onshoreward sliding was generally observed for  $D/d = 0.236$  and  $0.353$ ; whereas, for  $D/d = 0.277$  onshore rolling was always observed. Regardless of shape and size of stone, offshoreward movement was not observed on the crown. On the slope, only rolling motion was generally observed for round-type and edged-type of stones, the direction of movement was almost onshoreward because the onshore wave force is predominant over the offshore wave force. However, there are some cases that offshoreward movement was observed, since armor unit is easily moved in offshoreward direction (down the slope) due to gravitational effect.

The validity of the derived models was examined by comparing the weight of each sample with the estimated weight. Although there is no clear classification of CASE-I and CASE-II for the actual stones, comparison between these two arrangements is made for analysis.

For round-type stones on the crown, the model given by Eq. (11), as shown in Fig. 10(a), for onshoreward rolling for CASE-I generally gives a good estimate although small scattering of data was observed. Figure 10(a) also shows the comparison for the case of the edged-type of stones; the model based on CASE-I arrangement overestimates the actual value. This is attributed to the effect of interlocking between stones, thus, movement is relatively difficult for the same acting wave force. However, the model based on CASE-II arrangement can estimate well the stable weight of the edged-type stone. Therefore, the stable weight of the round-type and edged-type stones can be estimated by Eq. (11) and (12), respectively. The present results suggest that the shape effect is clearly recognized by referring to the arrangement of the spherical armor unit which is the basis of the models derived for rubble stones. Figure 10(b) gives the comparison of stable weight for onshoreward sliding, in this study,  $\mu = 0.60$  is used. The model based on the contact angle of sphere,  $\beta = 35.26^\circ$ , underestimates the actual values; whereas, the model with  $\beta = 0.0^\circ$  gives good agreement. Therefore, the model based on CASE-I for onshore sliding with  $\beta = 0.0^\circ$  can estimate well the stable weight of flat-type stone.

The onshore movements on the slope were also analyzed. Figure 11(a) shows the comparison between the actual value and the estimated weight based on CASE-I for round-type and edged-type of stones. Although the number of data is limited, the model estimate well the stable weight. The estimated weight based on CASE-II overestimates the stable weight. On the slope, the

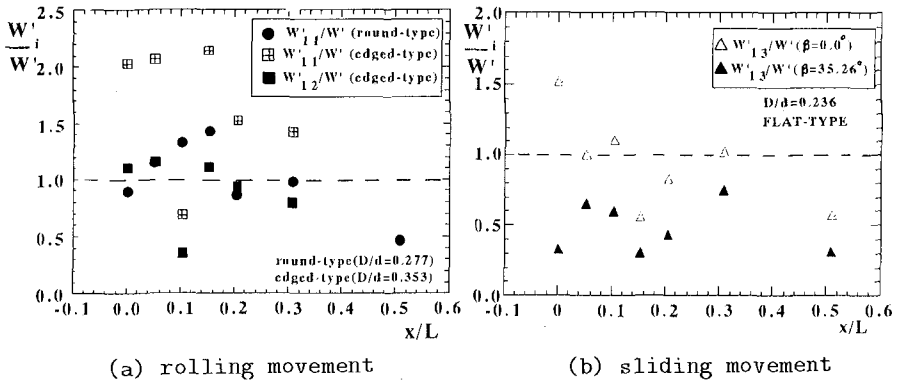

Figure 10: Estimated and experimental values for armor stones on the crown.

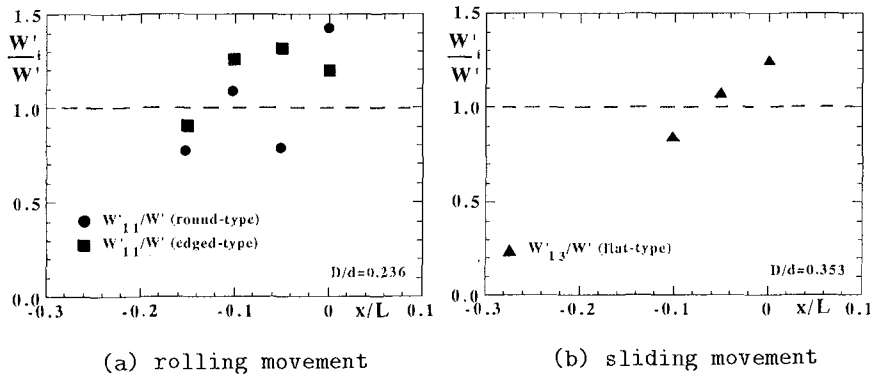

Figure 11: Estimated and experimental values for armor stones on the slope. shape effect of the edged-type stone was not so clear as in the case on the crown. This can be attributed to the contribution of the vertical wave force because on the slope the acting vertical wave force is almost upward when the onshoreward wave force takes its maximum value at incipient motion; consequently, the weight of stone is reduced, thereby, reducing the resistance against rolling. For flat-type stone, the model for offshoreward sliding based on CASE-I gives a good estimate of the stable weight, as shown in Fig. 11(b).

Summarizing these results, the recommended models for each shape of stone are given in Table 3.

7. SIMPLIFICATION OF STABILITY MODEL

The proposed models express the stable weight as a function of both the tangential and normal wave force components. Thus, it is convenient to express the stable weight as a function of only one wave force component. The orthogonal wave forces are correlated by a linear relationship as given in the following equation.

Table 3 Summary of recommended stability models.

STONE SHAPES	LOCATION	MOVEMENT	DIRECTION	STABILITY FORMULA	REMARKS
ROUND TYPE	SLOPE	ROLLING	ONSHORE	Equation 11	
			OFFSHORE	Equation 9

$$Fn_m = \phi Ft_m \tag{18}$$

where  $\phi$  is the coefficient. This assumption is based on the experimental results that the movement occurs at the phase that the tangential wave force takes almost a maximum value. Then, if the normal wave force at the phase is expressed in terms of the tangential wave force, the normal wave force can be eliminated. Based on the result, the coefficient  $\phi$  is taken equal to unity for engineering point of view. This means that the normal wave force is almost the same magnitude with the tangential wave force, a phenomenon which corresponds to the most dangerous condition for armor stability. This result was confirmed in some cases but in other cases, the vertical wave force is overestimated. However, the variations of the maximum wave force for each wave period exist even in the case of the regular wave train, and this effect has a significant contribution in the stability of armor unit. On the other hand, it is very difficult to estimate such variation of maximum wave force and mean value of the maximum wave force may be available as an input data. Consequently, the assumption,  $Fn_m \simeq Ft_m$ , does not overestimate the stable weight, as shown in Fig. 12, where  $W'(t)_m$  is the computed stable weight using the maximum time varying quantity of the right-hand side of the corresponding model, and  $W'(Ft)_m$  is the computed stable weight using the relation that the maximum normal is approximately equal to maximum tangential wave force.

Substituting the variation of maximum wave forces into the respective models, depending on the arrangement, the distribution of the stable weight of typical shape of stone along the submerged breakwater is obtained, as given in Fig. 13. It is noted that there is no significant differences among the three shapes of stones, although the shape effect was evident in wave force and stability. This implies that the shape effect of armor unit has a significant influence on wave force and moving limitations, but, for the case of stable weight, the shape effect due to the wave force and moving limitations cancel each other.

Figure 12: Validity of the assumption,  $F_{n_m} \simeq Ft_m$ .

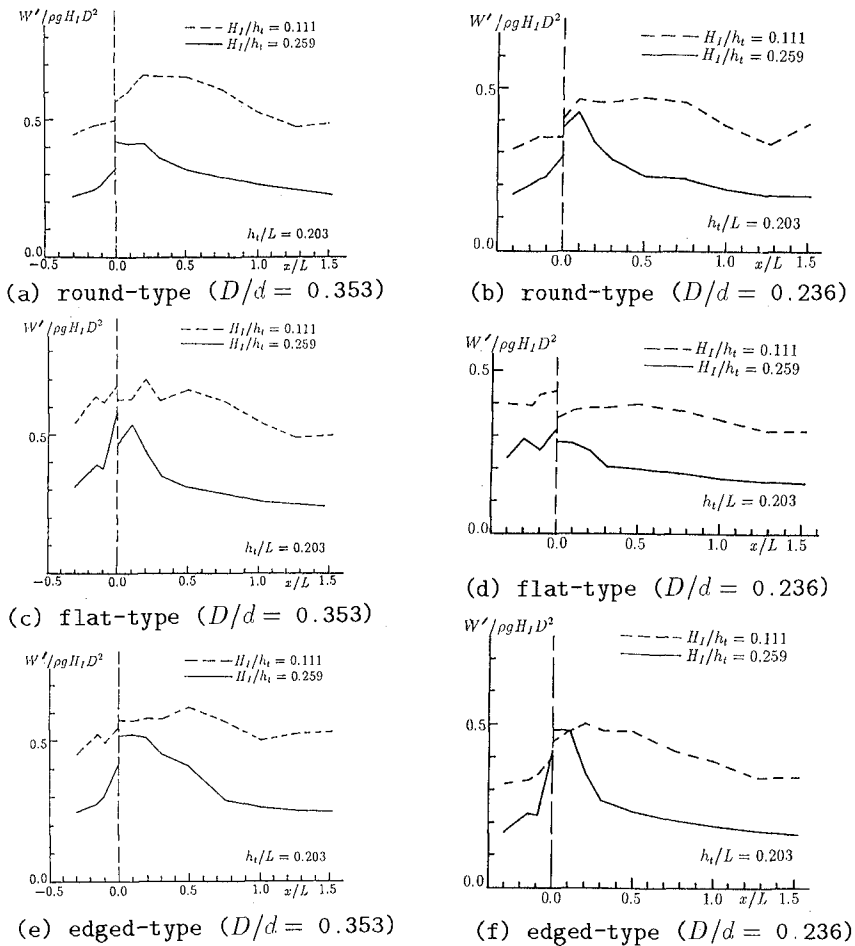

Figure 13: Stability distribution of armor stones.

## 8. CONCLUSIONS

Significant results are summarized as follows:

- (1) A general stability models were derived based on acting wave forces, moment-arm lengths and contact angles.
- (2) The vicinity around the crown-edge is revealed to be the most critical location on the submerged breakwater.
- (3) Large cross-sectional area enlarges the wave force.
- (4) To consider the moment-arm length and contact angle, the stability model for spherical armor unit can be applicable to the armor stone.
- (5) The stable weight is not so affected by the stone shape since the shape effect on the stability is offset by the shape effect of the acting wave force.

### ACKNOWLEDGMENT

The grant awarded by the Japan Society for the Promotional of Science (JSPS) to Mr. Teofilo Monge Rufin, Jr., one of the authors, is deeply appreciated. The contribution of Ms. Natsuko Totsuka is also acknowledged.

## CHAPTER 105

# Wave Induced Flow around Submerged Sloping Plates

Hitoshi Murakami<sup>1</sup>, Sadahiko Itoh<sup>2</sup>,  
Yoshihiko Hosoi<sup>3</sup> and Yoshiyuki Sawamura<sup>4</sup>

### Abstract

This paper deals with the hydraulic characteristics of two kinds of submerged plate type breakwaters. One is a plate with a gradual upward slope, the other is with a downward slope. The characteristics of the temporal and spatial wave induced flow and turbulence around a plate are discussed in detail on the basis of the result of the water particle velocity measured by the Laser Doppler Velocimeter. In addition, the effects of the plate length, the submerged depth of the crown and the inclination angle of a plate on the wave transmission, reflection and wave energy dissipation are discussed.

Finally it is suggested that a plate with a gradual upward slope is effective not only for the control of wave absorption but also for water purification.

### Introduction

For improvement of a much better environment in the coastal zone, various kinds of breakwaters have been designed in full consideration of the conservation of water quality, sediment and non-injury to the landscape. The artificial reef is a typical example of the breakwater designed for this purpose. However, it has been known that its crown width should

be constructed widely in comparison with regular submerged breakwaters, if we expect the reduction of wave energy in an artificial reef. In covering the sea bed with the rubble mound in order to set up an artificial reef, the destruction of a good environmental condition of habitat would be a worry. Such fear will be removed in the case of submerged plate type breakwater.

In recent years, the characteristics of wave reflection and transmission in submerged sloping plate type breakwaters have been actively investigated experimentally and theoretically (Aoyama et al, 1988, Takahashi et al, 1989, Yu et al, 1989, 1991, Yamashita et al, 1990). Unfortunately, we have no information on the characteristics of wave induced flow and the turbulence around a plate, though it would be important to understand the motion of water particles and behavior of eddies not only from the hydraulic viewpoint but also from an ecological point of view.

Prior to this study, we have experimentally investigated the characteristics of the flow around both the vertical and horizontal plate type breakwaters (Murakami et al., 1992).

Two kinds of submerged sloping plate type breakwaters are chosen in this study. First, the characteristics of wave transmission, reflection and wave energy dissipation are investigated for the two kinds of breakwaters which comprise the plate with a gradual upward slope and one with a gradual downward slope. Second, based on the results of the two direction components of water particle velocities measured by the Laser Doppler Velocimeter, the characteristics of the flow and the turbulence around a plate are discussed.

## Experimental Method

A wave tank with a flap-type wave generator at one end, which was 15m long, 20cm wide and 30cm deep, was used as shown in Fig.1. The submerged plate models were placed at a distance of 9.15m from the wave generator.

For convenience, the plate models with a gradual upward slope were named the A-type and ones with a gradual downward slope the B-type. The rear edge of the plate was in water. It did not touch the sea bottom in all of the experiments. The submerged depth  $d$  was defined as the water depth from the front edge of the plate. The water depth  $h$  and the wave period  $T$  were kept at a constant of 15cm and 0.65sec, respectively. Consequently, the wave length  $L$  was 60cm.

The wave heights were measured at the points **a**, **b** and **c** to obtain the reflection and the transmission coefficients.

Fig.1 Experimental Apparatus

On the other hand, both the horizontal and the vertical water particle velocities were measured separately by the Laser Doppler Velocimeter (SYSTEM9100-3, KANOMAX) at 93-94 points around the plate. The change of water surface elevation was also measured at the same time above a measured point of the velocity.

Experimental conditions were shown in Table 1. In the table, the minus sign for the inclination angle of the plate  $\theta$  was assigned to the A-type, a plus sign to the B-type.

Table 1 Experimental Conditions

$T=0.65\text{sec}$ ,  $h=15\text{cm}$ ,  $L=60\text{cm}$ ,  $h/L=0.25$

1) Experiment of Wave Absorption    2) Experiment of Water Particle Velocity

H/L	0.029	0.062	0.075
d(cm)	1.5	3.0	4.5
d/h	0.1	0.2	0.3
l(cm)	15	20	30
l/L	1/4	1/3	1/2
$\theta(^{\circ})$	-10,-5, 0, 10, 20, 30, 40	-10,-5, 0, 10, 20, 30	-5, 0, 10, 20

H/L	0.062	
d/h	0.2	
l/L	1/3	1/2
$\theta(^{\circ})$	-10, -5, 0, 10, 20, 30	10

The effect of the relative plate length  $l/L$  and the relative submerged depth  $d/h$  on the wave energy dissipation have already been discussed for the horizontal plate (Murakami et al, 1992). The dimensions of the models were determined with reference to these studies in this paper.

## Analytical Method

The incident and the reflected wave heights were separated by Goda's method from the wave record at point **a** and **b** in Fig.1 (Goda et al, 1976). Using these results and the transmitted wave height, the coefficients of the transmission  $k_T$  and the reflection  $k_R$  were obtained. The wave energy dissipation rate  $\varepsilon$  was calculated by the following equation.

$$\varepsilon = 1 - k_T^2 - k_R^2 \quad (1)$$

Let's describe how to obtain the water particle velocity and the turbulent intensity at a measured point.

From the data of each velocity component which consists of the horizontal velocity  $U$  and the vertical one  $V$ , the data corresponding to a train of 30 waves were used for the analysis. Each averaged velocity component ( $U, V$ ) and each turbulent component ( $u' = U - \bar{U}, v' = V - \bar{V}$ ) at an arbitrary phase of a wave period were obtained as mentioned hereunder.

First, one wave with  $T=0.65$ sec was divided into 50 phases, the components of the velocity and the turbulence at each phase were obtained by calculating the average value of 30 waves at each phase. Second, the velocity ( $\sqrt{\bar{U}^2 + \bar{V}^2}$ ) and the turbulent intensity ( $\sqrt{u'^2 + v'^2}$ ) at a measured point were obtained by the composition of each component.

## Characteristics of Wave Absorption

### 1) Wave Profile Transformation

Fig.2(1) shows only one example of the spacial wave profile transformation with time in the case of  $l/L=1/3$ ,  $d/h=0.2$ ,  $\theta = -5^\circ$  in the A-type.

With the installation of the plate, the wave profile gradually changes with regard to time. By the wave breaking on the plate, the wave height decreases immediately. After that, the wave induced flow rolls beneath the plate. Then, an eddy with air bubbles can be observed there. Such patterns are periodically repeated.

The transmitted wave height is attenuated from this figure.

Fig.2(2) shows this in the case of the B-type. When an incident wave reaches right at the front edge of the plate, the wave profile is compulsorily

transformed there. Though the wave crest becomes sharp for a while, the wave does not break and the transmitted wave height does not decrease so much as in the A-type.

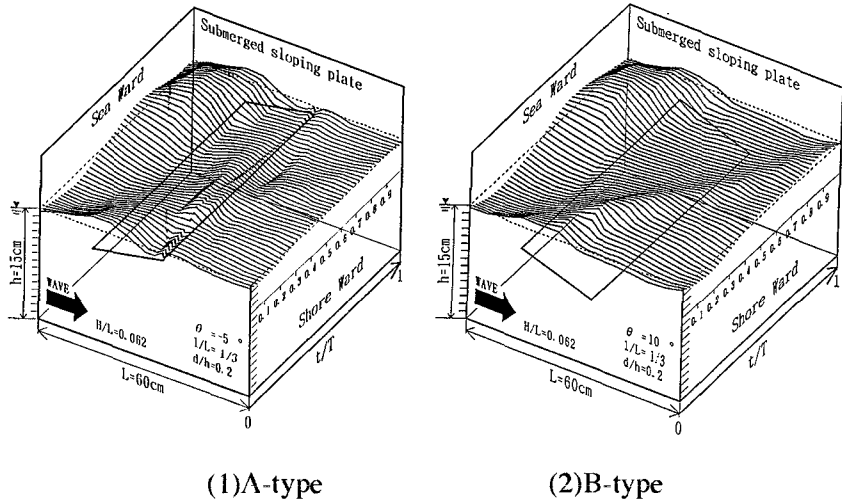

Fig.2 Wave Profile Transformation

**2) Characteristics of Transmission, Reflection and Wave Energy Dissipation**

Fig.3 shows the characteristics of the transmission coefficients  $k_T$  in  $d/h=0.2$ . The results in the A-type and the B-type are plotted in the minus and the plus region of the inclination angle  $\theta$ , respectively. The plate with  $\theta=0^\circ$  represents the horizontal plate.

In the A-type, the transmission coefficient  $k_T$  decreases with the increase of the inclination angle  $\theta$ . Such a tendency is remarkable as this relative plate length  $l/L$  increases.

In the case of  $l/L=1/2$ , the value of the  $k_T$  could be controlled 0.1 even for  $\theta=-5^\circ$ .

In the B-type, if the horizontal plate ( $\theta=0^\circ$ ) is inclined downward  $\theta=10^\circ$ , the value of the  $k_T$  increases steeply. However the effects of the  $l/L$  and the  $\theta$  on the  $k_T$  are not so remarkable in the range of  $\theta \geq 10^\circ$ .

Fig.4 shows the characteristics of the reflection coefficient  $k_R$  in  $d/h=0.2$ . It can be considered that there is no effect of the  $l/L$  on the  $k_R$  for each

type of plate .

In the A-type with a range of  $-10^\circ \leq \theta \leq 0^\circ$  , the  $k_R$  decreases with the increase of the  $\theta$  ,because the wave is easy to break on at the plate as the  $\theta$  increases. The  $k_R$  takes the small values 0.3-0.4 in this experiment.

Fig.3 Transmission Coefficient

Fig.4 Reflection Coefficient

Fig.5 Wave Energy Dissipation Rate (d/h=0.2)

Fig.6 Wave Energy Dissipation Rate (I/L=1/3)

In the B-type, the  $k_R$  increases slightly with the increase of the  $\theta$  for  $I/L=1/2$ . Contrary to this , the tendency of the  $k_R$  decreases slightly for  $I/L=1/4$ . In this experiment, the  $k_R$  takes the values 0.3-0.45. These values of the  $k_R$  are not so big in comparison with the reflection coefficients in some other types of breakwaters.

Fig.5 shows the characteristics of the wave energy dissipation rate  $\varepsilon$  in  $d/h=0.2$ .

In the A-type with the range of  $-10^\circ \leq \theta \leq 0^\circ$ , the  $\varepsilon$  increases with the increase of both the  $\theta$  and the  $l/L$ . For  $\theta=-5^\circ$ , the incident wave energy is dissipated about 60% in the case of  $l/L=1/4$ , 80% in  $l/L=1/3$  and 90% in  $l/L=1/2$ .

It is effective for wave energy dissipation to incline the rear edge of the plate upward.

In the B-type with the range of  $0^\circ \leq \theta \leq 10^\circ$ , the  $\varepsilon$  decreases steeply with the increase of the  $\theta$  and with the decrease of the  $l/L$ . However, the values of the  $\varepsilon$  in the range of  $10^\circ \leq \theta \leq 40^\circ$  do not remarkably change regardless of the  $l/L$ . It means that effective dissipation of wave energy can not be expected regardless of the plate length, when the  $\theta$  exceeds a given value.

Fig.6 shows the effect of the relative submerged depth  $d/h$  on the  $\varepsilon$  in the case of  $l/L=1/3$ . The values of the  $\varepsilon$  in  $d/h=0.3$  are smallest of the three cases, the difference between the values of the  $\varepsilon$  in  $d/h=0.1$  and in  $d/h=0.2$  is not so big.

## Characteristics of Wave Induced Flow and Turbulence

### 1) Spatial Distribution of Velocity and Turbulence at Arbitrary Phase

The spacial distribution of the mean velocity and turbulent intensity was obtained at every  $1/50$  phase of a wave period.

Fig.7 and Fig.8 show only two examples of the spacial distribution at the phases  $t/T=0$  and  $0.52$  of in the case of  $l/L=1/3$ ,  $d/h=0.2$ ,  $\theta=-5^\circ$  in the A-type.

The  $U_{\max}$  in a figure represents a maximum horizontal velocity at the still water surface calculated by the small amplitude wave theory. The value of  $U_{\max}=19.6$  cm/s is obtained in this experiment.

Pay attention to the upper figure of Fig.7. At this phase of  $t/T=0$ , the wave breaks intensely at the region from the front edge to the center part on the plate. Then the velocity at the forehead of the wave crest is about two times as large as the  $U_{\max}$ . The wave induced flow plunges into the rear part of the plate, and the shoreward flow is generated at the upper part of the inner basin overtopping the plate edge. However, the velocity along the back of the plate is very small in contrast to the velocity at the upper part of the plate.

(1) Velocity

(2) Turbulent Intensity

Fig.7 A-type( $t/T=0$ )

The values of turbulent intensity are shown by the nondimensional expression in the lower figure. It can be found that the large value of turbulent intensity appears at the forehead of the wave crest and at the rear edge of the plate where the overtopping flow plunges into it.

At the phase after the time of a half of a wave period  $t/T=0.52$ , the surge after a wave breaking climbs up the slope and jumps over the rear edge of the plate as shown in Fig.8. So, the region with a large velocity is

can be seen at the upper part of the inner basin. On the other hand, the seaward flow with a small velocity is generated at both sides of the plate. The direction and the size of these velocities near both edges are very complicated. As a consequence, comparative strong turbulence is generated there as in the lower figure. Generally, we can say the turbulence at the under region of the plate is very weak at any phase in the A-type.

(1)Velocity

(2)Turbulent Intensity

Fig.8 A-type( $t/T=0.52$ )

Fig.9 and Fig.10 show the spacial distribution in the case of  $1/L=1/3$ ,

$d/h=0.2, \theta =10^\circ$  in the B-type. At  $t/T=0$  as shown in Fig.9, the region with a large velocity exists at the upper part of the front edge of the plate.

(1) Velocity

(2) Turbulent Intensity

Fig.9 B-type( $t/T=0$ )

As the velocities along both sides of the plate are different, the turbulence due to the strong eddy is generated at the rear edge of the plate as shown in the lower figure.

At  $t/T=0.52$ , the upward flow with a large velocity is generated at the rear edge as in Fig.10. It could be observed that the eddy existing at the

lower part of the rear edge gradually expanded and moved upward. In the lower figure, we can see the result of the behavior of the eddy. It is noticeable that the influence of the turbulence extends to the lower part of the plate, though the turbulent intensity is not so strong.

(1)Velocity

(2)Turbulent Intensity

Fig.10 B-type(t/T=0.52)

**2) Spatial Distribution of Averaged Value of Velocity and Turbulence of a Wave Period**

Fig.11 shows the spatial distribution of both the averaged velocity and

turbulent intensity of a wave period in the case of  $l/L=1/3$ ,  $d/h=0.2$ ,  $\theta = -5^\circ$  in the A-type.

(1)Residual Velocity

(2)Averaged Turbulent Intensity

Fig.11 A-type

Each velocity vector in the upper figure means the residual velocity. The shoreward residual flow with comparative large velocities generated at the limited region of the upper part of the inner basin can be seen. Then, the strong turbulence can be found at the rear edge of the plate as in the lower figure. However, it is clear that strong turbulence is not generated

at the under region of the plate as already pointed out.

Fig.12 shows the case of  $l/L=1/3$ ,  $d/h=0.2$ ,  $\theta = 10^\circ$  in the B-type.

(1)Residual Velocity

(2)Averaged Turbulent Intensity

Fig.12 B-type

The shoreward residual flow is generated only at the region of the water surface behind the front edge of the plate. Furthermore, the complicated residual flow can be seen at the rear edge of the plate. It can be found that weak turbulence is scattered at the surface, the rear edge and at the bottom of the rear edge as shown in the lower figure.

Fig.13 shows the change of the flow rate  $Q$  through a cross section of the rear edge of the plate in the case of  $l/L=1/3$ ,  $d/h=0.2$  in the A-type with  $\theta=-5^\circ$  and the B type with  $\theta=10^\circ$ . The  $Q$  was calculated by the product of the averaged velocity in 5-6 points of the cross section and the water depth from the water surface to the bottom. Though the seaward flow is generated for a short time at some phases in the A-type, the one directional shoreward flow is almost always generated in both types of plates. It means that seawater with pure water quality flows into the inner basin through these types of breakwaters. Furthermore, if we suppose the reflected wave at a seawall in the A-type again acts upon an A-type plate, the seawater in the inner basin must flow out smoothly into the sea through the breakwater by the seaward residual flow. This is because the reflected wave seaward in the A-type corresponds to the incident wave shoreward in the B-type.

Fig.13 Change of Flow Rate

## Conclusion

The mechanism of wave absorption and the characteristics of wave induced flow around two kinds of submerged plate type breakwaters were discussed experimentally.

Results are summarized as follows.

1) it could be certified that the validity of a sloping plate type breakwater for wave absorption, especially a plate with a gradual upward slope is

effective for the control of wave absorption.

2) The behavior of temporal and spacial water particle velocity and turbulence around a plate type breakwater could be understood.

3) The submerged sloping plate is effective for water quality purification producing a one directional flow, regardless of the raising and lowering of the rear edge of the plate.

Through this knowledge, we could give information to make a good environmental habitat for aquatic biota.

# Second-order wave interaction with arrays of vertical cylinders of arbitrary cross section

Keisuke Murakami\*      Akinori Yoshida†

## ABSTRACT

This paper proposes an approximate calculation method for the second-order wave interactions with arrays of vertical cylinders of arbitrary cross section. In mathematical formulations, the first- and the second-order boundary value problems are derived by perturbation method, and Green's Identity Formula is used to express the distribution of the velocity potentials on horizontal plane. Second-order water surface elevations near the cylinders and wave forces acting on the cylinders are computed, and the results are verified by comparing with wave tank experiments in the valid range of the Stokes second-order wave theory.

## 1. INTRODUCTION

Nonlinear wave interactions with structures are important under severe wave conditions, and the developments of a numerical method for calculating nonlinear wave forces and wave deformations are needed. A numerical calculation method of the second-order wave forces utilizing Hskind's reciprocal relationship has been proposed (e.g., Molin, 1979), and this method has been further applied to the case of plural vertical cylinders (e.g., Masuda et al., 1986). Nonlinear wave field near the structures, however, can not be calculated by this method because the second-order velocity potential in a fluid region is not determined. On the other hand, great efforts have been made to predict

†Associate Professor, Ditto

the nonlinear wave field near the structure by solving the second-order boundary value problem. For examples, Yamaguchi and Tsuchiya(1974) derived a second-order solution of closed form for a vertical cylinder, Garrison(1979) proposed a numerical solution based on a source distribution method using Green's function. Recently, Kriebel(1987) proposed an analytical solution of the second-order diffraction problem for a single circular cylinder and Kim and Yue(1989) showed the complete second-order diffraction solution for an axisymmetric body. However, these methods are difficult to be applied to the case of plural cylinders of arbitrary cross section.

The main purpose of this study is to develop an approximate calculation method for the second-order interaction between water waves and the arrays of vertical cylinders of arbitrary cross section. The validity of the method are confirmed through comparison with experiments and other numerical results. In mathematical formulations, perturbation method is used to derive the first- and second-order boundary value problems, and Green's Identity Formula is also used to express the distribution of the velocity potentials on a horizontal plane(Ijima et al.,1974). A particular solution for scattered waves of the second-order problem is approximately expressed on the assumption that it has the same form of an eigenfunction in the vertical direction as that of the second-order Stokes solution.

## 2. FORMULATION OF THE BOUNDARY VALUE PROBLEM

### 2.1 General formulation

Fig.1 shows a coordinate system,  $x$  and  $y$  being the horizontal axes and  $z$  the vertical axis taken upward from the undisturbed still water surface. Fixed vertical cylinders of arbitrary cross section in water of uniform depth  $h$ , are subject to the incident waves with first-order wave amplitude  $\zeta_0$ , and angular frequency  $\sigma$ , propagating with an incident angle  $\theta$ , measured from positive  $x$  direction. It is assumed that the fluid is both inviscid and incompressible, and its motion is irrotational. The velocity potential  $\Phi(x, y, z, t)$  satisfy following Laplace equation in the whole fluid region.

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} + \frac{\partial^2 \Phi}{\partial z^2} = 0 \quad (1)$$

The kinematic boundary condition and the dynamic boundary condition on the free water surface, and bottom boundary conditions are written as:

$$\frac{\partial \zeta}{\partial t} - \frac{\partial \Phi}{\partial z} + \frac{\partial \Phi}{\partial x} \frac{\partial \zeta}{\partial x} + \frac{\partial \Phi}{\partial y} \frac{\partial \zeta}{\partial y} = 0 \quad (z = \zeta(x, y, t)) \quad (2)$$

$$\frac{\partial \Phi}{\partial t} + g\zeta + \frac{1}{2} \left\{ \left( \frac{\partial \Phi}{\partial x} \right)^2 + \left( \frac{\partial \Phi}{\partial y} \right)^2 + \left( \frac{\partial \Phi}{\partial z} \right)^2 \right\} = Q \quad (z = \zeta(x, y, t)) \quad (3)$$

Fig.1 Definition sketch.

$$\frac{\partial \Phi}{\partial z} = 0 \quad (z = -h) \tag{4}$$

where  $Q$  is a constant and  $g$  is a gravity acceleration.

In order to obtain the first- and the second-order boundary value problems, perturbation method is employed. The velocity potential  $\Phi(x, y, z, t)$ , the water surface elevation  $\zeta(x, y, t)$ , and the constant value  $Q$  are expressed in power series by introducing a parameter  $\epsilon$  ( $\epsilon = k\zeta_0$ , where  $k$  is the incident wave number).

$$\left. \begin{aligned} \Phi(x, y, z, t) &= \frac{g}{k\sigma} Re \left[ \epsilon \phi_1^{(1)}(x, y, z) \exp(-i\sigma t) \right. \\ &\quad \left. + \epsilon^2 \left\{ \phi_2^{(0)}(x, y, z) + \phi_2^{(2)}(x, y, z) \exp(-i2\sigma t) \right\} \right] \\ \zeta(x, y, t) &= \frac{1}{k} Re \left[ \epsilon \eta_1^{(1)}(x, y) \exp(-i\sigma t) \right. \\ &\quad \left. + \epsilon^2 \left\{ \eta_2^{(0)}(x, y) + \eta_2^{(2)}(x, y) \exp(-i2\sigma t) \right\} \right] \\ Q &= \frac{g}{k} Re \left[ \epsilon Q_1 + \epsilon^2 Q_2 \right] \end{aligned} \right\} \tag{5}$$

The time independent component  $\phi_2^{(0)}$  in the second-order potential function does not contribute to the second-order wave forces and water surface elevation. Since the main purpose of this study is to develop the numerical calculation method of the second-order wave forces and wave height, we consider the time dependent component  $\phi_2^{(2)}$  only in the following formulations.

By expanding both Eqs.(2) and (3) in Taylor series about  $z=0$ , and substituting Eq.(5) into them, the first- and the second-order combined free surface boundary conditions are obtained.

## 2.2 First-order problem

The first-order boundary value problem is given as follows:

$$\nabla^2 \phi_1^{(1)}(x, y, z) = 0 \quad (6a)$$

$$\frac{\partial \phi_1^{(1)}}{\partial z} - \frac{\sigma^2}{g} \phi_1^{(1)} = 0 \quad (z = 0) \quad (6b)$$

$$\frac{\partial \phi_1^{(1)}}{\partial z} = 0 \quad (z = -h) \quad (6c)$$

The solution is obtained by separating the potential function  $\phi_1^{(1)}$  into the incident plane waves and the scattered waves. A general solution of Eq.(6a), which satisfies free surface boundary condition and bottom boundary condition simultaneously, is given as (Ijima et al., 1974)

$$\phi_1^{(1)}(x, y, z) = \{\varphi_{1I}(x, y) + \varphi_{1S}(x, y)\} \frac{\cosh k(z+h)}{\cosh kh} \quad (7)$$

In Eq.(7),  $\varphi_{1I}$  and  $\varphi_{1S}$  represent the potential of the first-order incident plane waves and the scattered waves respectively, and  $\varphi_{1I}$  is given as

$$\varphi_{1I}(x, y) = -i \exp \{-ik(x \cos \theta + y \sin \theta)\} \quad (8)$$

where  $i = \sqrt{-1}$  and  $k$  satisfies the following dispersion relationship.

$$\frac{\sigma^2 h}{g} = kh \tanh kh \quad (9)$$

$\varphi_{1S}$  must satisfy the following Helmholtz equation since  $\phi_1^{(1)}$  satisfies Laplace equation.

$$\nabla^2 \varphi_{1S}(x, y) + k^2 \varphi_{1S}(x, y) = 0 \quad (10)$$

## 2.3 Second-order problem

The second-order boundary value problem is given as follows:

$$\nabla^2 \phi_2^{(2)}(x, y, z) = 0 \quad (11a)$$

$$\frac{\partial \phi_2^{(2)}}{\partial z} - 4 \frac{\sigma^2}{g} \phi_2^{(2)} = \frac{i}{k} \left\{ \left( \frac{\partial \phi_1^{(1)}}{\partial x} \right)^2 + \left( \frac{\partial \phi_1^{(1)}}{\partial y} \right)^2 + \left( \frac{\partial \phi_1^{(1)}}{\partial z} \right)^2 \right\} + \frac{\eta_1^{(1)}}{2k} \left\{ \frac{\sigma^2}{g} \frac{\partial \phi_1^{(1)}}{\partial z} - \frac{\partial^2 \phi_1^{(1)}}{\partial z^2} \right\} \quad (z = 0) \quad (11b)$$

$$\frac{\partial \phi_2^{(2)}}{\partial z} = 0 \quad (z = -h) \quad (11c)$$

The second-order free surface boundary condition ,Eq.(11b), is nonhomogeneous because the quadratic forcing terms appear in the right hand side. The solution may be obtained by the separation of potential function  $\phi_2^{(2)}$  as

$$\phi_2^{(2)}(x, y, z) = \phi_{2I}(x, y, z) + \phi_{2L}(x, y, z) + \phi_{2F}(x, y, z) \tag{12}$$

where  $\phi_{2I}$  represents the second-order incident plane waves expressed as

$$\left. \begin{aligned} \phi_{2I} &= \varphi_{2I}(x, y) \frac{\cosh 2k(z + h)}{\cosh 2kh} \\ \varphi_{2I}(x, y) &= -\frac{3i}{8} \frac{\Gamma}{k \sinh^4 kh} e^{-i2k(x \cos \theta + y \sin \theta)} \end{aligned} \right\} \tag{13}$$

where  $\Gamma = \sigma^2 h/g$ .

In Eq.(12),  $\phi_{2L}$  represents a phase-locked wave which satisfies the nonhomogeneous free surface boundary condition and  $\phi_{2F}$  represents a free wave which satisfies the homogeneous free surface boundary condition. The boundary value problems of  $\phi_{2L}$ , and  $\phi_{2F}$  are obtained by a substitution of Eqs.(12) and (13) into Eqs.(11a),(11b) and (11c).

Firstly, the boundary value problem for  $\phi_{2L}$  is given as follows:

$$\nabla^2 \phi_{2L}(x, y, z) = 0 \tag{14a}$$

$$\frac{\partial \phi_{2L}}{\partial z} - 4 \frac{\sigma^2}{g} \phi_{2L} = \frac{i}{k} \left\{ \frac{3\Gamma^2 - k^2}{2} \varphi_{1s} (\varphi_{1s} + 2\varphi_{1I}) + \frac{\partial \varphi_{1s}}{\partial x} \left( \frac{\partial \varphi_{1s}}{\partial x} + 2 \frac{\partial \varphi_{1I}}{\partial x} \right) + \frac{\partial \varphi_{1s}}{\partial y} \left( \frac{\partial \varphi_{1s}}{\partial y} + 2 \frac{\partial \varphi_{1I}}{\partial y} \right) \right\} \quad (z = 0) \tag{14b}$$

$$\frac{\partial \phi_{2L}}{\partial z} = 0 \quad (z = -h) \tag{14c}$$

By assuming that the  $\phi_{2L}$  has the same form of an eigenfunction for z direction as the Stokes second-order solution has(Sabuncu et al.,1985), the particular solution of  $\phi_{2L}$  is approximately expressed as follows:

$$\phi_{2L}(x, y, z) = \gamma f(x, y) \frac{\cosh 2k(z + h)}{\cosh 2kh} \tag{15}$$

where  $\gamma$  and  $f(x, y)$  are given as follows:

$$\gamma = \frac{i}{2k^2 \tanh 2kh - 2 \tanh kh} \tag{16}$$

$$f(x, y) = \frac{3\Gamma^2 - k^2}{2} \varphi_{1s} (\varphi_{1s} + 2\varphi_{1I}) + \frac{\partial \varphi_{1s}}{\partial x} \left( \frac{\partial \varphi_{1s}}{\partial x} + 2 \frac{\partial \varphi_{1I}}{\partial x} \right) + \frac{\partial \varphi_{1s}}{\partial y} \left( \frac{\partial \varphi_{1s}}{\partial y} + 2 \frac{\partial \varphi_{1I}}{\partial y} \right) \quad (17)$$

Secondary, the boundary value problem for  $\phi_{2F}$  is given as follows:

$$\nabla^2 \phi_{2F}(x, y, z) = 0 \quad (18a)$$

$$\frac{\partial \phi_{2F}}{\partial z} - 4 \frac{\sigma^2}{g} \phi_{2F} = 0 \quad (z = 0) \quad (18b)$$

$$\frac{\partial \phi_{2F}}{\partial z} = 0 \quad (z = -h) \quad (18c)$$

The solution of Eq.(18a), which satisfies the homogeneous free surface boundary condition and bottom boundary condition simultaneously, can be expressed in much the same way as the first-order problem as

$$\phi_{2F}(x, y, z) = \varphi_{2F}(x, y) \frac{\cosh k^{(2)}(z + h)}{\cosh k^{(2)}h} \quad (19)$$

where  $k^{(2)}$  satisfies the following dispersion relationship.

$$\frac{(2\sigma)^2 h}{g} = k^{(2)} h \tanh k^{(2)} h \quad (20)$$

$\varphi_{2F}$  must satisfy the following Helmholtz equation since  $\phi_{2F}$  satisfies Laplace equation.

$$\nabla^2 \varphi_{2F}(x, y) + (k^{(2)})^2 \varphi_{2F}(x, y) = 0 \quad (21)$$

### 3. NUMERICAL CALCULATION METHOD

As shown in **Fig.1**, the boundaries  $C_1$  and  $C_2$  are defined as the intersection of still water surface and the vertical structures, and  $\nu$  as an unit vector normal to the boundary.  $X_i$  and  $X_j$  are the coordinates taken in the fluid region and on the boundary respectively. Since the potentials of the first-order scattered waves and the second-order free waves satisfy the Sommerfeld's radiation condition respectively, each potential at  $X_i$  can be expressed by means of Green's Identity Formula as follows (Ijima et al.,1974):

$$\varphi_{1S}(\mathbf{X}_i) = \alpha \oint_{C_1+C_2} \left\{ \varphi_{1S}(\mathbf{X}_j) \frac{\partial}{\partial \nu} H_0^{(1)}(kr_{ij}) - H_0^{(1)}(kr_{ij}) \frac{\partial}{\partial \nu} \varphi_{1S}(\mathbf{X}_j) \right\} ds \tag{22}$$

$$\varphi_{2F}(\mathbf{X}_i) = \alpha \oint_{C_1+C_2} \left\{ \varphi_{2F}(\mathbf{X}_j) \frac{\partial}{\partial \nu} H_0^{(1)}(k^{(2)}r_{ij}) - H_0^{(1)}(k^{(2)}r_{ij}) \frac{\partial}{\partial \nu} \varphi_{2F}(\mathbf{X}_j) \right\} ds \tag{23}$$

where  $r_{ij}$  represents a distance between  $\mathbf{X}_i$  and  $\mathbf{X}_j$  and  $H_0^{(1)}$  represent the first kind of Hankel function, and  $\alpha = -i/2$  ( $\mathbf{X}_i$  is on the boundary) and  $\alpha = -i/4$  ( $\mathbf{X}_i$  is in the fluid region)

For the first- and the second-order potential functions, no-flow conditions around the cylinders are written as follows:

$$\frac{\partial \phi_1^{(1)}}{\partial \nu} = 0 \quad (-h \leq z \leq 0) \tag{24}$$

$$\frac{\partial \phi_2^{(2)}}{\partial \nu} = 0 \quad (-h \leq z \leq 0) \tag{25}$$

By substituting Eq.(7) into Eq.(24) and Eq.(12) into Eq.(25), and by integrating Eq.(24) and Eq.(25) over the water depth after multiplying by eigenfunctions  $\cosh k(z+h)$  and  $\cosh 2k(z+h)$  respectively, the boundary conditions of  $\varphi_{1S}$  and  $\varphi_{2F}$  on  $C_1$  and  $C_2$  are derived as follows:

$$\frac{\partial \varphi_{1s}}{\partial \nu} = -\frac{\partial \varphi_{1l}}{\partial \nu} \tag{26}$$

$$\frac{\partial \varphi_{2F}}{\partial \nu} = -\frac{i}{4k\Gamma} \frac{1}{M_0} \frac{1}{\gamma} \frac{(k^{(2)})^2}{(2k)^2 - (k^{(2)})^2} \left( \frac{\partial \varphi_{2l}}{\partial \nu} + \gamma \frac{\partial f}{\partial \nu} \right) \tag{27}$$

where  $M_0 = (1 + 2k^{(2)}h / \sinh 2k^{(2)}h) / 2$

In order to obtain the numerical solutions of the integral equations written as Eqs.(22) and (23), the boundaries  $C_1$  and  $C_2$  are discretized into elements  $\Delta S_j$  of  $N_1$  and  $N_2$  numbers, and the coordinate  $\mathbf{X}_i$  is set on them. On each element, the potential and its normal derivative are assumed to be constant. By applying Eqs.(26) and (27) to Eqs.(22) and (23) respectively, the linear matrix equations for  $\varphi_{1s}$  and  $\varphi_{2F}$  are obtained as follows:

$$\sum_{j=1}^{N_1+N_2} \left( \overline{G_{ij}^{(1)}} - \delta_{ij} \right) \varphi_{1S}(\mathbf{X}_j) = - \sum_{j=1}^{N_1+N_2} G_{ij}^{(1)} \overline{\varphi_{1I}}(\mathbf{X}_j) \quad (i = 1 \sim N_1 + N_2) \tag{28}$$

$$\sum_{j=1}^N \left( \overline{G_{ij}^{(2)}} - \delta_{ij} \right) \varphi_{2F}(\mathbf{X}_j) = -\beta \sum_{j=1}^N G_{ij}^{(2)} \left\{ \overline{\varphi_{2I}}(\mathbf{X}_j) + \gamma \overline{f}(\mathbf{X}_j) \right\} \quad (i = 1 \sim N_1 + N_2) \tag{29}$$

$$\left. \begin{aligned} G_{ij}^{(1)} &= -\frac{i}{2} \int_{\Delta S_j} H_0^{(1)}(kr_{ij}) & \overline{G_{ij}^{(1)}} &= -\frac{i}{2} \int_{\Delta S_j} \frac{\partial}{\partial \nu} H_0^{(1)}(kr_{ij}) ds \\ G_{ij}^{(2)} &= -\frac{i}{2} \int_{\Delta S_j} H_0^{(1)}(k^{(2)}r_{ij}) & \overline{G_{ij}^{(2)}} &= -\frac{i}{2} \int_{\Delta S_j} \frac{\partial}{\partial \nu} H_0^{(1)}(k^{(2)}r_{ij}) ds \end{aligned} \right\} \tag{30}$$

where  $\overline{\varphi_{1I}}$ ,  $\overline{\varphi_{2I}}$  and  $\overline{f}$  mean a normal derivative of  $\varphi_{1I}$ ,  $\varphi_{2I}$  and  $f$  on the boundaries.

From Eq.(15),  $f(\mathbf{X}_i)$  must satisfy the following Helmholtz equation.

$$\nabla^2 f + (2k)^2 f = 0 \tag{31}$$

By assuming that  $\varphi_{2L}$  satisfies the same radiation condition as  $\varphi_{1s}$  and  $\varphi_{2F}$ ,  $f(\mathbf{X}_i)$  can be also expressed by means of Green's Identity Formula as follows:

$$f(\mathbf{X}_i) = \alpha \oint_{C_1+C_2} \left\{ f(\mathbf{X}_j) \frac{\partial}{\partial \nu} H_0^{(1)}(2kr_{ij}) - H_0^{(1)}(2kr_{ij}) \frac{\partial}{\partial \nu} f(\mathbf{X}_j) \right\} ds \tag{32}$$

From Eq.(32),  $\overline{f}(\mathbf{X}_j)$  can be computed without numerical differentiations of  $f(\mathbf{X}_j)$  on the boundaries.

The first-order potential function  $\varphi_1^{(1)}$  expressed in Eq.(7) is obtained by solving the linear matrix equation. After solving the first-order equation,  $\varphi_{2L}$  is determined from the first-order solution and thus  $\varphi_{2F}$  is obtained by solving the linear matrix equation given as Eq.(29). By applying these second-order solutions to Eq.(12), the second-order potential function  $\varphi_2^{(2)}$  is determined.

### 3. RESULTS OF CALCULATIONS

To verify the numerical calculation method, we conducted the wave tank experiments for single and double vertical circular cylinders. The vertical circular cylinders of radius  $a = 18.5\text{cm}$  are placed in the center of the wave tank of  $18\text{m}$  long and  $10\text{m}$  wide, and the water depth is maintained at  $h = 40\text{cm}$ .

Table-1 Incident wave conditions for single and double circular cylinders

Single Circular Cylinder			Double Circular Cylinder		
$kh$	$T(sec.)$	$\zeta_0/h$	$kh$	$T(sec.)$	$\zeta_0/h$
1.0	1.46	0.081	0.8	1.74	0.178
1.4	1.14	0.109	1.0	1.46	0.202
			1.4	1.14	0.179
			1.6	1.05	0.175

Fig.2 Wave runup and rundown around single circular cylinder.

Table-1 shows the incident wave conditions. The water surface elevations around the cylinders are measured by the wave gages. In the case of the double circular cylinders, the cylinders are placed in a row with spacing  $B = 1m$  normal to the incident wave direction.

Fig.2 and Fig.3 show the wave runup and rundown around the single cylinder for  $kh = 1.0$  and  $kh = 1.4$ . The incident wave propagates from positive  $x$  direction and  $\alpha$  is measured counterclockwise from positive  $x$  direction. In the experimental results, the secondary effects are observed at front side and rear side of the vertical cylinder and the second-order results show good agreements with experimental ones.

Fig.3 Wave runup and rundown around single circular cylinder.

Fig.4 and Fig.5 show the wave runup and rundown around the double cylinder for  $kh = 0.8$  and  $1.0$ . In the experiments, the waves become very steep between the cylinders and the wave patterns around the cylinders are more complicate than the case of single cylinder. The linear results are largely different from experimental ones especially at the front side( $\alpha = 0$ ), rear side( $\alpha = 180$ ) and inner side( $\alpha = 270$ ) of the cylinders. On the other hand, the second-order results show good agreements with experimental ones.

Fig.6 and Fig.7 show the computed maximum wave amplitude distribution around the double and the triple circular cylinders. The wave with  $kh = 1.0$  and  $\zeta_0/h = 0.1$  propagates from positive  $y$  direction normal to the row of the cylinders( $a/h = 0.5$ ,  $B/h = 2$ ;  $a$  is the cylinder radius and  $B$  is the space between cylinders) The second-order results show more complicated pattern than linear ones and secondary effects are clearly observed around the cylinders. The maximum differences of wave amplitude between linear results and second-order ones around the cylinders are about 20%.

Fig.8 shows the maximum wave forces acting on the single and double circular cylinders, and Fig.9 also shows the maximum wave forces acting on the center of the triple circular cylinders. The cylinders are placed in a row normal to the incident wave direction. The differences between linear results and second-order ones become small as the  $ka$  increase.

Fig.4 Wave runup and rundown around double circular cylinder.

Fig.6 Maximum wave amplitude distribution near double circular cylinders.  
 $[B/h = 2, a/h = 0.5, \zeta_0/h = 0.1, kh = 1.0]$

Fig.7 Maximum wave amplitude distribution near triple circular cylinders.  
 $[B/h = 2, a/h = 0.5, \zeta_0/h = 0.1, kh = 1.0]$

Fig.8 Maximum wave forces acting on double circular cylinders

Fig.9 Maximum wave forces acting on triple circular cylinders

On the other hand, the differences become large as the  $ka$  decrease for  $ka < 0.5$ . The divergence of the present method in small value of  $ka$  ( $ka < 0.3$ ), small value of  $ka$  means large Ursell parameter in this case, is caused by the failure of the Stokes second-order theory (Isaacson, 1978). In  $0.6 < ka < 1.3$ , the wave forces acting on the single cylinder are always larger than those on the double cylinders and the center cylinder of the triple ones, but with increase of  $ka$ , the wave forces acting on those plural cylinders are converged to the value of single cylinder.

## 5. CONCLUSIONS

An approximate calculation method for the second-order wave interactions with array of vertical cylinders of arbitrary cross section is proposed by using both Green's Identity Formula and perturbation method in combination. The validity of the present method is confirmed by comparing the computed results with experimental ones. Though the present method includes approximation that the second-order potential function for phase-locked wave has the same form of an eigenfunction of the second-order Stokes solution, the nonlinear wave field and wave forces are estimated with good accuracy in the valid range of the Stokes second-order wave theory.

## CHAPTER 107

### HYDRODYNAMIC FORCES ON BOTTOM-SEATED HEMISPHERE IN WAVES AND CURRENTS

H. Nishida<sup>1</sup>, A. Tada<sup>2</sup> and F. Nishihira<sup>3</sup>

#### Abstract

The characteristics of hydrodynamic forces acting on a bottom-seated hemisphere in waves only, in currents only and in waves & currents are presented from the viewpoint of the design of an artificial reef. A large number of regular wave experiments were conducted in order to find the empirical formulas of the hydrodynamic coefficients for the bottom-seated hemisphere. It is shown that the proposed empirical formulas are sufficiently accurate for predicting the hydrodynamic forces. The effects of the normalized water depth and hemisphere spacing relative to its diameter are also elucidated experimentally.

#### Introduction

In order to provide a continued supply of marine products, the Japanese fishing industry has been shifting from fish catching to fish farming. Various artificial reefs have been used to attract fish by producing coherent eddies with upward flow as well as by providing hiding places for fish. Most of these reefs have rectangular shapes and caused tearing of fishing nets. In order to reduce entanglement of fishing nets, the authors have proposed bottom-seated hemispherical reefs. For the design of such a reef against waves and currents, the hydrodynamic forces acting on the reef need to be predicted.

### Hydraulic Experiments

Regular wave experiments were conducted in a wave flume which was 65m long, 1.0 m wide and 1.6 m high. The flume was capable of generating steady currents in both directions relative to the direction of wave propagation. As a first attempt, plastic hemispheres without any opening were used in the experiments. The experimental results presented herein may hence be of interest to researchers working on the design of quarry stone armor units. The three-dimensional hydrodynamic force acting on an individual hemisphere was measured using a three-component waterproof load cell with a water pressure adjustment. Fluid velocities at the location of the hemisphere were measured using a two-component electromagnetic current meter. Free surface oscillations above the hemisphere are measured using a capacitance wave gage. For limited tests, flow visualization was performed to examine the flow pattern and eddy formation using a laser and a high speed camera, as shown in Photo.1. A large number of tests were performed for a single hemisphere and three hemispheres in a row.

Fig.1 shows the experimental setup for three hemispheres, where  $X$ =horizontal coordinate taken to be positive in the direction of wave propagation with  $X=0$  at the center of the middle hemisphere;  $Z$ =vertical coordinate taken to be positive upward with  $Z=0$  at the still water level(SWL);  $h$ =water depth below SWL;  $H$ =height of incident regular waves whose period is denoted by  $T$ ;  $D$ =diameter of the hemisphere; and  $L_f$ =distance between the centers of two adjacent hemispheres. The experiments were conducted for the following conditions;

- 1)  $h=40,60$  and  $80$  cm
- 2)  $H=3.0,6.0$  and  $9.0$  cm
- 3)  $T=1.2,1.6,2.0,2.4$  and  $2.8$  sec
- 4)  $D=15.0$  and  $20.0$  cm
- 5)  $L_f/D=1.0,1.5,2.0,2.5$  and  $3.0$
- 6)  $U=\pm 5.0, \pm 10.0, \pm 20.0, \pm 30.0$  and  $\pm 40.0$  cm/sec

where  $U$ =depth-averaged steady current velocity which is negative for opposing currents.

### Data Analysis

The measured horizontal and vertical hydrodynamic forces acting on the hemisphere are assumed to be expressed in the form proposed by Morison (Morison et al. 1950).

$$F_x = \frac{1}{2} \rho C_D \left( \frac{\pi D^2}{8} \right) (u + U) |u + U| + \rho C_M \left( \frac{\pi D^3}{12} \right) \frac{du}{dt} \quad (1)$$

$$F_{z_m} = \frac{1}{2} \rho C_L \left( \frac{\pi D^2}{8} \right) (u_m + U)^2 \quad (2)$$

where  $F_x$  = horizontal force ;  $\rho$  = fluid density ;  $u$  = oscillatory horizontal fluid velocity ;  $U$  = steady fluid velocity ;  $C_D$  = drag coefficient ;  $C_M$  = inertia coefficient ; and  $C_L$  = lift coefficient .The velocities  $u$  and  $U$  are at the location of the hemisphere. The constant values of  $C_D$  and  $C_M$  for each test were determined using the method of least squares (Reid 1957). The constant value of  $C_L$  was estimated such that the maximum vertical force  $F_{z_m}$  could be predicted by Eq.(2) accurately. This was because Eq.(2) with constant  $C_L$  did not reproduce the entire variation of  $F_z$  with respect to time  $t$  very well.

### Drag, Inertia and Lift Coefficients

The efforts for developing the empirical relationships for  $C_D$ ,  $C_M$  and  $C_L$  were separated into;

- single hemisphere in waves only
- single hemisphere in currents only
- single hemisphere in waves & currents
- middle hemisphere among three hemispheres in waves only
- middle hemisphere among three hemispheres in currents only

For these tests, the inertia force was generally dominant in Eq.(1) and the horizontal force was normally greater than the vertical force. In addition, it was judged that there was little scale effect on hemispherical models because the influence of Reynolds number  $Re=u_m D/\nu$  on the wave force coefficients were negligible under adopted experimental conditions, refer to Figs.2 and 3.

Fig.4 shows the relationship between the wave force coefficients and Keulegan-Carpenter number( $K.C.=u_m T/D$ ) for the single hemisphere in the water depth of 40 cm, where  $u_m$  is the maximum value of  $u$ . As shown in Fig.4,  $C_M$  in waves only is on the order of 1.35 and  $C_D$  in waves only varies with  $K.C.$  in a manner similar to a sphere (Jenkins and Inman 1976).

Eqs.(3), (4) and (5) are the empirical formulas of  $C_D$ ,  $C_M$  and  $C_L$  in waves only, respectively. They are statistically derived by means of the method of least squares.

$$C_D = 6.79 \cdot (K.C.)^{-0.89} \quad \text{for } U=0 \quad (3)$$

$$C_M = 1.35 \quad \text{for } U=0 \quad (4)$$

$$C_L = 3.3 \cdot (K.C.)^{-0.98} \quad \text{for } U=0 \quad (5)$$

Eqs.(6) and (7) are the empirical formulas of the drag and lift coefficients in currents only for the single hemisphere in the depth of 40 cm, respectively. The effect of Reynolds number  $Re=UD/\nu$  on these coefficients seems to be also negligible for the case of currents only as shown in Fig.5.

$$C_D = 0.48 \quad \text{for } u_m=0 \quad (6)$$

$$C_L = 0.8 \quad \text{for } u_m=0 \quad (7)$$

Fig.2 Drag coefficient  $C_D$  versus  $Re(=u_m D/\nu)$  in waves only

Fig.3 Inertia coefficient  $C_M$  versus  $Re(=u_m D/\nu)$  in waves only

Fig.4 Drag coefficient  $C_D$ , inertia coefficient  $C_M$  versus  $K.C.$  in waves only

Fig.5 Drag coefficient  $C_D$  versus  $Re(=UD/\nu)$  in currents only

Fig.6 shows the relationship between  $C_D$  in waves & currents and the modified Keulegan-Carpenter number  $K=(|U|+u_m)T/D$  for the single hemisphere in fair currents for which  $U>0$  (Iwagaki et al . 1983). The water depth is 40 cm. The parameter  $\alpha$  shown in the figure is defined as  $\alpha=|U|/u_m$  and two solid lines in this figure indicate the empirical formulas of  $C_D$  in waves only [Eq.(3)] and in currents only [Eq.(6)] , respectively.  $C_D$  is slightly affected by  $K$  and  $\alpha$  and also approximately approaches 0.48 for large  $\alpha$ , corresponding to the value of  $C_D$  for currents only.

On the basis of these characteristics shown in Fig.6, the following empirical formula of  $C_D$  for the single hemisphere in waves & currents with  $U>0$  have been proposed;

$$C_D = 6.97 \cdot e^{-\beta} \cdot K^{-0.89} + 0.48(1 - e^{-\beta}) \text{ for } U>0 \quad (8)$$

with  $\beta = 0.019\alpha^2 + 0.99\alpha - 0.07$

When  $\alpha$  is equal to zero and  $K=K.C.$ , Eq.(8) yields almost the same value of  $C_D$  in waves only. On the other hand, this formula corresponds to  $C_D$  in currents only when  $\alpha$  tends to infinity. The broken lines in Fig.6 indicate Eq.(8) for  $\alpha$  in the range of 0.25 to 2.5. In order to evaluate the accuracy of Eq.(8), Fig.7 compares  $C_D$  calculated by Eq.(8) with  $C_D$  obtained from the experiments. It is realized that the former agrees fairly with the latter, regardless of  $\alpha$ .

Fig.8, for the case of water depth 40 cm, shows the relationship between the inertia coefficient in waves & currents and  $K$  for the single hemisphere in fair currents. It is obvious that  $C_M$  increases with increasing  $K$  in the region  $C_M>1.35$  , whereas  $C_M$  decreases with increasing  $K$  in the region  $C_M<1.35$ . Furthermore ,  $C_M$  decreases with increasing  $\alpha$  if  $K$  is assumed to be constant.

Considering the above characteristics, the following empirical formula of  $C_M$  as a function of  $\alpha$  and  $K$  is derived from the method of least squares.

$$C_M = 1.35 \cdot \exp \left[ 0.084(1.18 - \alpha)K \right] \text{ for } U>0 \quad (9)$$

Eq.(9) is equivalent to  $C_M$  in waves only if  $\alpha$  is equal to 1.18. Broken lines in Fig.8 indicate the above formula for  $\alpha$  in the range of 0.25 to 3.5. It is found that Eq.(9) coincides fairly with the experimental values.

The relationship between  $C_M$  calculated by Eq.(9) and  $C_M$  obtained from the experimental results is also shown in Fig.9. The reason why the accuracy of Eq.(9) is lower as the parameter  $\alpha$  becomes larger is that the drag force is more predominant than the inertia force and it is hard to estimate  $C_M$  accurately for large  $\alpha$ .

Fig.6 Drag coefficient  $C_D$  versus  $K$  in waves & currents(fair current)

Fig.7 Drag coefficient  $C_D(\text{EXP})$  versus Drag coefficient  $C_D(\text{CAL})$

Fig.8 Inertia coefficient  $C_M$  versus  $K$  in waves & currents(fair current)

Fig.9 Inertia coefficient  $C_M$ (EXP) versus inertia coefficient  $C_M$ (CAL)

Fig.10 shows the relationship between  $C_L$  in waves & currents and  $K$  for the single hemisphere in the water depth of 40 cm . The variations of  $C_L$  with respect to these dimensionless parameters were similar to those associated with  $C_D$ . The following formula in fair currents is introduced.

$$C_L = 3.3 \cdot e^{-0.5\alpha} \cdot K^{-0.98} + 0.8(1 - e^{-0.5\alpha})^{0.16} \text{ for } U > 0 \quad (10)$$

The relationships between the hydrodynamic coefficients and  $K$  for the single hemisphere in adverse currents for which  $U < 0$  and  $\alpha$  are shown in Figs.11 and 12. Moreover, the following empirical formulas for adverse currents are derived using the same procedure .

$$C_D = 6.97 \cdot e^{-\beta} \cdot K^{-0.89} + 0.48(1 - e^{-\beta}) \text{ for } U < 0 \quad (11)$$

$$\text{with } \beta = -0.08\alpha^2 + 1.05\alpha - 0.1$$

$$C_M = 1.35 \cdot \exp \left[ 0.063(1.34 - \alpha)K \right] \text{ for } U < 0 \quad (12)$$

$$C_L = 3.3 \cdot e^{-0.6\alpha} \cdot K^{-0.98} + 0.8(1 - e^{-0.6\alpha})^{0.43} \text{ for } U < 0 \quad (13)$$

Those formulas should be reevaluated because free surface oscillations became larger and more irregular as waves propagated over a long distance in adverse currents.

Fig.10 Lift coefficient  $C_L$  versus  $K$  in waves & currents(fair current)

Fig.11 Drag coefficient  $C_D$  versus  $K$  in waves & current(adverse current)

Fig.12 Inertia coefficient  $C_M$  versus  $K$  in waves & currents(adverse current)

Applicability of Empirical Formulas

The above experimental results were for the water depth of 40cm. It is very important to study the effect of the variation of water depth on  $C_D$  and  $C_M$  in waves & currents. Figs.13 and 14 show the effects of the water depth normalized by the diameter  $D$  on  $C_D$  and  $C_M$ , respectively. These coefficients are almost constant, regardless of the dimensionless parameter  $h/D$ . In other words,  $C_D$  and  $C_M$  in waves & currents are not practically affected by the effect of the water depth in the range  $h/D=2.0\sim 4.0$  tested here.

Fig.15 shows the relationship between the dimensionless  $C_{MG}/C_M$  and  $L_f/D$ , where  $C_{MG}$  is the inertia coefficient of the middle hemisphere among three hemispheres and  $L_f$  is defined in Fig.1.  $C_{MG}/C_M$  approximately approaches 1 for large  $L_f/D$ . The empirical formulas on the inertia coefficient proposed in this paper are valid for the range  $L_f/D > 2.0$ . The effect of the adjacent hemispheres on the drag coefficient was also negligible for  $L_f/D > 2.0$ .

Conclusions

The experimental results in this paper are summarized as follows;

- (1)The empirical formulas of  $C_D$  and  $C_M$  in waves & currents are derived using the modified Keulegan-Carpenter number  $K$  and the parameter  $\alpha$  indicating the current strength relative to the wave velocity. These formulas are accurate enough to estimate the hydrodynamic forces.
- (2)These hydrodynamic coefficients in waves & currents are not affected by the normalized water depth  $h/D$  in the range  $h/D=2.0\sim 4.0$ .
- (3)The empirical formulas proposed in this study are valid for the range  $L_f/D > 2.0$  for the conditions shown in Fig.1.

Fig.13 Drag coefficient  $C_D$  versus  $h/D$

Fig.14 Inertia coefficient  $C_M$  versus  $h/D$

Fig.15  $C_{MG}/C_M$  versus  $L_f/D$

Acknowledgment

The authors would like to express their gratitude to Prof. Nobuhisa Kobayasi at the University of Delaware, whose insight and guidance were of great assistance in the preparation of this manuscript.

## CHAPTER 108

# The Pressure Field due to Steep Water Waves Incident on a Vertical Wall

D.H.Peregrine<sup>1</sup> & M.E.Topliss<sup>2</sup>

### Abstract

The entrained air present when a wave impacts upon a vertical wall is modelled. A numerical boundary-integral method is applied, with appropriate initial conditions giving a prescribed surface profile and corresponding velocity potential, to model an overturning wave trapping a single air pocket between the oncoming wave front and the vertical wall. The resulting detailed computations provide suitable initial parameters for a simple theoretical model of the trapped air pocket as described in Topliss, Cooker & Peregrine (1992). The fundamental frequencies, and pressures on the impact wall due to the bubble can thus be estimated from the numerical computations. Video frames of small-scale experiments by Hattori & Arami (1992 and private communications) are also examined in detail and similar use of the model provides further pressure estimates. The resulting frequencies and maximum pressures are compared with the measured values. The peak pressures on the impact wall are within 30% of those measured and the frequencies are generally closer. Scaling with wave size is also discussed.

### Introduction

Much attention has been given to the peak pressures developed when storm waves meet sea walls and breakwaters, e.g. experimental studies by Kirkgöz (1991), Hattori & Arami (1992), Oumeraci & Partensky (1992) and theoretical studies by Cooker & Peregrine (1990,1992). These breaking-wave impacts can

---

<sup>2</sup>Research Student

have substantial aeration, either as air trapped at the wall or as pre-entrained air.

Aeration in wave impacts has been described in the laboratory experiments as either a cloud of small air bubbles in the water adjacent to the vertical structure or as a single air pocket trapped between the overturning wave and the impact wall. Numerical computations presented in this paper can simulate the motion of an overturning wave against a vertical structure on a finite depth, up until point of impact. This provides detailed data which can be used with theoretical analysis to describe the initial motion of an air pocket. Comparison of the analytic theory with the computations and experimental data, in particular that of Hattori & Arami (1992 and private communications) and Hattori, Arami & Yui (1994), has led to fairly good agreement with the various parameters. Three experimental data sets have been compared with computations that produce the same size air pockets.

The majority of experiments undertaken to study wave impact are performed in small-scale tanks and a discussion of scaling from model to prototype completes the paper.

## Numerical Method

The numerical method used in this paper for computing the unsteady two-dimensional motion of a water surface, including that for breaking waves, is described in Dold & Peregrine (1986) and Dold (1992).

The fluid is taken to be incompressible and the flow irrotational so that a velocity potential can be defined such that  $\mathbf{u} = \nabla\phi$  and  $\phi$  satisfies Laplace's equation with the fully nonlinear free surface boundary conditions. We have taken the pressure immediately above the free surface to be a constant and neglected surface tension.

The surface profile and velocity potential are prescribed on the free surface as initial data. The domain is reflected about the bed  $y = -h$  to form a symmetric image flow where a point on the upper free surface has an image on a lower free surface. The free surface boundary conditions are satisfied at the free surface which moves with time. The surface of the fluid is considered to be a smooth continuous profile approximated by a set of discrete points. A truncated Taylor series is used to perform explicit time-stepping. Cauchy's integral theorem is used to obtain a boundary integral equation for the evaluation of velocities and multiple derivatives of the surface motion. After the unsteady surface motion is calculated, the velocity and pressure beneath the surface can be evaluated at points over a rectangular grid. Variables are scaled accordingly:  $y^* = y/h$ ,  $x^* = x/h$ ,  $p^* = p/\rho gh$ ,  $t^* = t\sqrt{g/h}$ ,  $u^* = u/\sqrt{gh}$  and  $A^* = Ag$  where  $h$  is a chosen value and  $*$  represents the scaled variables.

## Computations for an overturning 'tanh' wave.

Using this boundary-integral method for a non-periodic surface, Cooker (1990) has described the motion of a wave overturning immediately before a vertical wall (with a finite depth), trapping a pocket of air against the wall. This was achieved by allowing two equal waves propagating in opposite directions towards each other to form a flow which is symmetric about a point. This is equivalent to a single wave approaching a vertical wall at this point. The initial data used obtained from a tanh expression describing a long wave of elevation:

$$u(x) = -\frac{1}{2}u_o \left\{ 1 + \tanh \left[ \frac{(x - x_o)}{s} \right] \right\} \quad (1)$$

where  $x_o$  is the initial centre of the wave,  $u_o$  is the initial maximum velocity, and  $s$  is a constant. The wave elevation is of the form  $\eta(x) = |u| + \frac{1}{4}u^2$  which gives a wave propagating towards the wall by shallow water theory. This long shallow water wave steepens and breaks as it propagates into water of constant depth, for an example see the surface profiles in figure 1. The computations have to stop just before the wave jet comes into contact with the wall and so the results only describe the motion immediately before impact.

Three examples have been studied of a wave overturning immediately in front of a vertical wall. Different initial positions of the wave give different size air pockets to illustrate the varying characteristics of the motion due to the volume of air trapped. In this section,  $h$  is the lowest water depth at the wall. Approximately 250-350 discretisation points were used for the surface of the wave. The wave is taken to have a large initial amplitude of 1.7 with  $s = 2.0$ , chosen to obtain large air pockets. Accuracy tests with more discretisation points have been very satisfactory. Surface profiles are presented for several timesteps and the pressure contours below the free surface have been evaluated in each case for the final computed time.

The first example (example 1) presented has an initial distance from the wall of  $x_o = 8.0$ .

The wave steepens and begins to overturn as it comes nearer to the wall as portrayed in the time history of the surface profiles in figure 1. The timesteps are reduced as the wave becomes steeper and the motion more violent. The computations stop just before impact with a small pocket of air is trapped between the wave front and the wall.

The pressure field at the final computed time shown in figure 2 has pressure contours in increments of 0.4. The thickened line represents the water surface. As well as high pressures at the foot of the wall, a region of much higher pressure is found just below the waterline with very tightly packed contour lines. Note that no direct impact between the water and the wall has yet occurred. The high pressures are spread over a substantial area of the fluid domain.

For a similar wave of amplitude 1.7, the initial distance of wave from wall

Figure 1: Surface profiles for a tanh waveform of amplitude 1.7, initial distance 8.0 at times 1.53, 2.81, 3.45, 3.77, 3.93 and 4.01 - 4.17 in steps of 0.04.

Figure 2: Pressure contours for a tanh waveform of amplitude 1.7, initial distance 8.0 at time 4.17 with increments of 0.4.

is now increased to  $x_o = 9.0$  in example 2. The time history of the surface profiles of the wave is displayed in figure 3. The waterline at the wall now lower and a larger amount of air is trapped. As can be seen in figure 4, the isobars, are at the same intervals, and show much lower pressures and pressure gradients than in example 1. Now the greatest pressures are at the bed.

Figure 3: Surface profiles for a tanh waveform of amplitude 1.7, initial distance 9.0 at times 1.48, 2.76, 3.40, 3.72, 4.04, 4.36 and 4.44 - 4.56 in steps of 0.04.

Example 3 has a further increase of initial distance of the wave from wall to  $x_o = 10.0$ . The wave now overturns further from the wall and produces the largest air pocket. The surface profiles in figure 5 show the time history of the wave. Figure 6 shows the pressure distribution under the free surface for the final profile before impact has lower values than for the previous two examples. The pressure field is now in sharp contrast with the pressures of example 1, as the isobars are almost horizontal, indicating that pressures are not much in excess of hydrostatic. These three examples show that as the amount of air trapped increases, the pressures decrease and the characteristics of the pressure field change. Other examples have confirmed this trend.

The numerical data from the final computed times enables the characteristics of the three examples to be studied and compared. A representative set of numerical data includes the incident wave amplitude be  $H_o$ , the vertical height of the water above the bed after the final computational time be  $H$ , the vertical height of the water line in contact with the wall at the final computed time be  $H_w$ , and the vertical velocity, acceleration at this point be  $u_p, a_p$  respectively as shown in figure 7. The initial wave amplitude  $H_o$  is 1.7 in all three cases, but with three different size air pockets resulting from the original placing of the wave with regard to the wall. Let the horizontal velocity at the centre line of

Figure 4: Pressure contours for a tanh waveform of amplitude 1.7, initial distance 9.0 at time 4.56 with increments of 0.4.

Figure 5: Surface profiles for a tanh waveform of amplitude 1.7, initial distance 10.0 at times 2.0, 3.28, 3.92, 4.24 and 4.44 - 4.92 at steps of 0.04.

the pocket be  $u_f$  and the horizontal velocity at the tip of the jet be  $u_t$ . The respective parameters for the three examples from the numerical results of the final computed time are shown in table 1. The horizontal velocity at the centre line of the bubble becomes much smaller as the radius of the pocket increases with the horizontal velocity of the tip of the jet not significantly altered. Thus in the first two examples, the velocity of the jet tip is larger than the velocity of the centreline as noted by Hattori, Arami & Yui (1994). In addition the upward velocity of the waterline at the wall decreases rapidly with the formation of larger pockets leading to the forward velocity  $u_f$  becoming greater than the upward velocity  $u_p$ .

For very small bubble sizes, large values are obtained for the vertical velocity and acceleration of the waterline. This shows an approach to the violent conditions reported by Cooker & Peregrine (1990) in their report of the "flip through" phenomenon. The vertical height of the waterline at the wall becomes much lower as the amount of air trapped increases resulting in the ratio  $H_w/H$  becoming smaller. These ratios are in agreement with those presented by Oumeraci, Klammer & Partenscky (1993).

## Comparison of numerical and experimental data

The numerical method for an overturning wave provides many parameters allowing different sizes of air pockets to be studied. Given experimental results,

Figure 6: Pressure contours for a tanh waveform of amplitude 1.7, initial distance 10.0 at time 4.92 with increments of 0.2.

	Example 1	Example 2	Example 3
Wave amplitude $H_o$	1.7	1.7	1.7
Initial distance from wall	8.0	9.0	10.0
Pocket radius	0.071	0.445	0.784
Vertical height $H$	2.75	2.85	2.84
Vertical height $H_w$	2.390	1.823	1.522
Vertical velocity $u_p$	15.821	2.368	1.345
Vertical acceleration $a_p$	1700.7	10.93	4.09
Horizontal velocity $u_f$	5.35	2.69	1.99
Horizontal velocity $u_t$	3.06	2.81	2.77
Ratio $H_w/H$	0.869	0.640	0.536

Table 1: Comparison of dimensionless numerical data from the final computed times for the three tanh waveform examples.

Figure 7: Parameters for an overturning wave

either with data showing the size of a trapped air pocket and its position under the free surface or photographs from which these parameters can be measured, a computation can be used to model the overturning wave by producing a resulting trapped air pocket of the same dimensions. We choose a computation to compare with an individual experiment by varying the initial wave height  $H_o$  and distance from the wall  $x_o$  until the computation gave a trapped air pocket which was a good match with the values for the radius  $r$ , the distance  $d$  of the bubble centre from the bed and the height  $H$  of the water after impact measured from the experimental data. We have compared with video frames from Hattori & Arami (1992). For a bubble nearer the bed than the free surface, a higher incident wave amplitude is required to obtain a correct  $d/H$  ratio. For a larger bubble, the initial distance of the wave from the wall needs to be increased as shown in the above examples. The numerical data for the final computed time gives values for the normal velocities around the curved surface which can then be averaged to give a radial velocity  $u_r$ .

The subsequent motion of the trapped air pocket has been modelled as a two-dimensional semi-circular bubble using Topliss, Cooker & Peregrine's (1992) result for the fundamental frequency. To a first approximation, it is

$$\omega^2 = -\frac{2\gamma p_o}{\rho_l a^2 \log\left[\frac{1}{4}(\pi a/H) \tan\left(\frac{1}{2}(\pi d/H)\right)\right]} \quad (2)$$

where  $\rho_l$  is the density of water,  $p_o$  the atmospheric pressure,  $\gamma$  the ratio of specific heats and  $\omega = 2\pi f$  where  $f$  is the fundamental frequency of the bubble. Once values for  $a, d, H$  and  $u_r$  have been obtained, either from a computation or, as in the next section, from experimental measurements, the frequencies and amplitudes of oscillation of the bubble can be predicted using equation 2, the linearised kinematic boundary condition,  $u_r = \omega\epsilon_o$ ,  $\alpha_o = a\epsilon_o\omega$  and the corresponding expression for maximum pressure,

$$p_{max} = -\rho\omega\alpha_o \log\left(\frac{\lambda a}{2} \tan(\lambda d)\right) \quad (3)$$

Hattori & Arami have provided us with many details of their experiments to investigate the importance of a trapped air pocket between the breaking wave and the wall. The experiments were undertaken in a small wave tank with a 1:20 bed slope to cause the wave to break. In each case the still water depth was five centimetres. High-speed video frames were taken of the fluid motion with simultaneous pressure histories. The experimental data sets with large clear trapped air pockets were chosen for comparison.

The histories of the pressure, measured on the impact wall immediately after impact exhibit three stages when air is trapped. Initially the pressure rises to a peak value and is followed by an interval of regular smooth oscillations, of decreasing amplitude. These oscillations are displayed with the same frequency in all six pressure gauges. This finally develops into a more confused signal, consisting of higher frequencies with lower amplitudes, and which carries on for an indefinite time.

The photographs show a cylindrical air pocket trapped between the wave front and the structure immediately after impact. In the video frames following the impact, it can be seen that the free surface rises and a thin jet of water shoots up the wall. We neglect this since it is usually much thinner than the bubble until a later stage and assume a flat surface in our models. The damped oscillations recorded by Hattori & Arami decay exponentially like  $e^{-\beta t}$ . The peak pressure is presented in the dimensionless form  $p^* = p/\rho g H_o$  where  $H_o$  is the incident wave height above the bed.

Three sets of experimental data on the formation of an air pocket by Hattori & Arami have been examined in detail. In each case measurements have been taken from the video frames to obtain values for  $a, d, H, u_f$ , where  $u_f$  is the forward velocity as previously defined. The bubble surface in the frames is not sufficiently well defined to take measurements around the surface and so the value obtained for  $u_f$  is used for the average radial velocity  $u_r$ . The video frames indicate a horizontal free upper surface at impact and so the computations of a tanh waveform should provide a good numerical model. For each of the cases studied, a table below shows the values of  $a, d, H$  and  $u_r$  obtained from both measuring the video frames of the experiments and from the corresponding computation. The table also gives the *estimated* values of  $f, \epsilon_o, \alpha_o$  and maximum

$p^*$  using the theoretical analysis for a semi-circular bubble and the measured values of peak pressure and oscillation frequency.

In experiment No. 132-3 the bubble radius was measured to be 7.5 mm from the video frames. Comparisons are made with a computation using a wave of initial dimensionless amplitude 8.0 and at an initial distance 6.5 from the impact wall. The corresponding dimensional value is 72 mm for wave height and there are comparable values for  $d$  and  $H$ . The radial velocity given by the numerical computations also gives agreement with that measured from the photographs. The top line in the table gives the maximum experimentally measured pressure and the frequency of its oscillation.

	$d$	$H$	$f$	$u_r$	$\epsilon_o$	$\alpha_o$	$p^*$
Hattori & Arami			190				38.1
From video	0.0295	0.066	221	1.0	0.00072	0.0075	43.5
Computation	0.0219	0.055	222.2	0.95	0.00068	0.0070	35.4

Table 2: Comparison of theory with experiment and computation for a pocket of radius 7.5 mm.

In experiment No. 172-3 the trapped air pocket, from the video frames, had radius 9.5mm. The computation producing a trapped pocket of the same size uses a wave of initial dimensionless height 5.0 and initial distance of 7.4, corresponding to 62 mm dimensional wave height .

	$d$	$H$	$f$	$u_r$	$\epsilon_o$	$\alpha_o$	$p^*$
Hattori & Arami			210				55.7
From video	0.029	0.063	186.5	1.1	0.00093	0.01	49.0
Computation	0.03	0.061	191.5	0.99	0.00082	0.0094	39.7

Table 3: Comparison of theory with experiment and computation for pocket of radius 9.5 mm.

The third data set, experiment No. 178-3, has the largest trapped air pocket, radius 20 mm, and produces the lowest pressures. The computation of initial dimensionless wave amplitude 7.0 with an initial distance from the impact wall of 9.0 corresponds to an incident wave height of 86 mm.

As can be seen from the comparisons, reasonable agreement is obtained between the experimental and theoretical results with larger bubble sizes producing lower frequencies. The measurements from the frames show that the lower surface rises more rapidly up the wall for a smaller pocket in agreement with the numerical computations. The damping of the oscillations appears to

	$d$	$H$	$f$	$u_r$	$\epsilon_o$	$\alpha_o$	$p^*$
Hattori & Arami			106				22.5
From video	0.026	0.067	99	0.8	0.0014	0.015	28.7
Computation	0.029	0.069	101.2	0.76	0.0012	0.015	20.0

Table 4: Comparison of theory with experiment and computation for a pocket of radius 20 mm.

be not as strong for the largest bubble and the oscillations last the longer. The slow rise of the pocket and mass of small bubbles in the video frame during the oscillations indicate little air loss initially through the surface of the water. The damping of pressure oscillations is yet to be modelled.

difference with Hattori & Arami	pressure from video	pressure from computation	frequency from video	frequency from computation
132-3	+12 %	-7 %	+16%	+17%
172-3	-12 %	-29 %	-11%	-9%
178-3	+22 %	-11 %	-7 %	-5%

Table 5: Comparison of the maximum pressure and oscillation frequency estimates for the three data sets.

The pressures predicted by the theory give reasonable agreement for both the experimental and computational parameters. Table 5 shows the differences in the pressures and frequencies estimated compared to those those measured by Hattori & Arami in each of the three experiments. The pressure differences are the percentage change between the peak pressures recorded in the data and the predicted values from the theory. Differences with those from the computations are all lower. The frequencies are generally closer to the experimental values.

## Scaling

Most experiments undertaken to investigate wave impact on vertical structures involve laboratory model-scale wave flumes. Scaling from model to prototype remains a complex and not fully understood problem. The number of parameters concerning the motion need to be identified and mathematical relationships established between the dimensionless scaling parameters.

When modelling the entrained air as either a single air pocket or a uniform bubbly mixture, expressions for the resonant frequencies have been obtained in

each case. Peregrine (1994) has suggested, to get order of magnitude estimates, a simpler approximation, similar to

$$\omega = (\gamma g H_a / C)^{1/2} \tag{4}$$

but without  $\gamma$ , where  $C$  is the volume of trapped air per unit length of wall ( $r^2$  for a single bubble or  $LH$  for a mixture of bubbles in a layer of width  $L$  at the wall),  $H_a$  is the hydrostatic head of water equal to atmospheric pressure. The comparison of this formula with  $\gamma=1.0$  (for isothermal bubbles) and 1.4 with the analytical expressions in each case is shown in figure 8. As can be seen

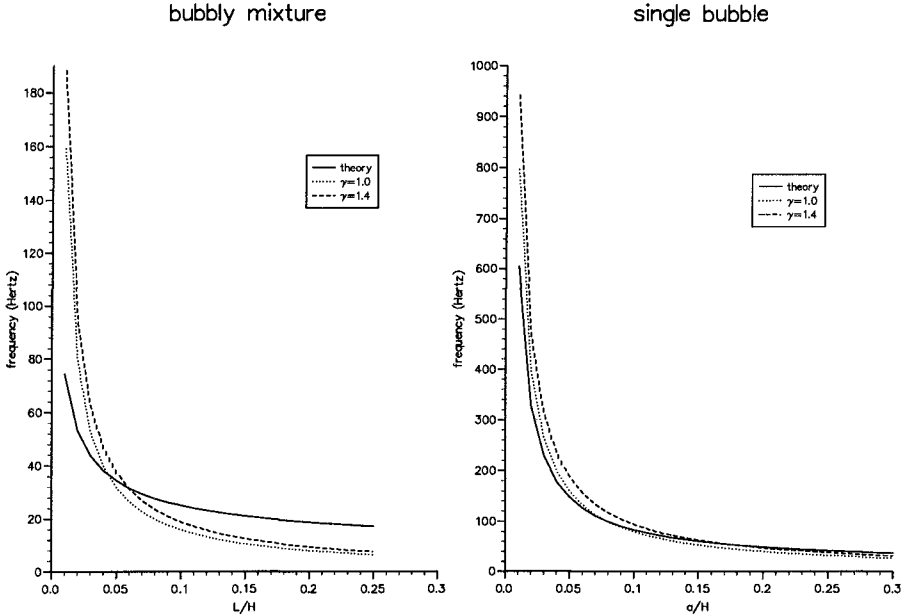

Figure 8: Comparison of the estimated fundamental frequencies, for a single cylindrical bubble with  $d/H=0.5$  (right) and for a column of bubbles next to a wall with  $\alpha=0.1$  (left).

from figure 8, the simplified formula presented by Peregrine is within a factor 2, particularly for the single air bubble, except for small pockets or very thin columns of bubbles.

Peregrine (1994) also presents a simple expression to estimate the maximum pressures:

$$\frac{p_{max}}{\rho g h} = \beta \left( \frac{h H_a}{C} \right)^{1/2} \tag{5}$$

where  $\beta$  is the fraction of the wall over which this impact occurs. For a reasonable ranges of  $\beta$ , 0.1 to 1.0, and  $C$ ,  $0.01 h^2$  to  $0.25 h^2$ , this gives

$$0.2 \left( \frac{H_a}{h} \right)^{1/2} \leq \left( \frac{p_{max}}{\rho g h} \right) \leq 10 \left( \frac{H_a}{h} \right)^{1/2}. \quad (6)$$

To assess these formulas, the maximum pressures for the three experimental data sets studied in have been evaluated using equation (5) with the data taken from the computational parameters and compared with the results obtained previously in tables 2, 3 and 4.

	$C$	$h$	$\beta$	$f$	$f$	$p^*$	$p^*$
	$m^2$	m		eq(2)	eq(4)	eq(3)	eq(5)
No 132-3	$(0.0075)^2$	0.072	0.27	222.2	212.2	35.4	30.8
No 172-3	$(0.0095)^2$	0.062	0.31	191.5	167.5	39.7	25.8
No 178-3	$(0.02)^2$	0.086	0.58	101.2	79.6	20.0	26.9

Table 6: Comparison of estimated frequencies and pressures evaluated earlier for the data sets from Hattori et. al. using the computational parameters, and the simple estimates for frequencies and maximum pressures given by Peregrine.

The maximum pressures predicted by equation (5) show agreement with those predicted by equation (3) to within 30 percent and thus this equation gives a very simple calculation for rough estimates. Looking at the range for the pressures given by equation (5), the values  $C = 0.01$ ,  $0.02$  and  $0.05 h^2$  are obtained for No 132-3, 172-3 and 178-3 respectively, giving  $p_{max}/\rho g h$  to be 3.2, 4.4 and 2.1  $(H_a/h)^{1/2}$  respectively, well within in the range given by (6).

## CHAPTER 109

### RESULTS OF EXTENSIVE FIELD MONITORING OF DOLOS BREAKWATERS

D PHELP\*, S LUGER\*, A VAN TONDER\* and A HOLTZHAUSEN\*

#### ABSTRACT

The entrances to most of the ports in South Africa are protected by rubble mound breakwaters which have dolos armouring. As part of their maintenance programme, Portnet, the local Port Authority, has commissioned the CSIR to annually monitor the main breakwaters. A minimum of five years of photographic and other monitoring data have now been accumulated. This paper presents a brief description of the dolos breakwaters in South Africa, and the field monitoring techniques used to record the annual damage to the armouring. The results and analysis of the photographic monitoring are given in more detail. The application of these results are also presented, and some exciting new developments in breakwater monitoring are discussed.

#### INTRODUCTION

The conclusions of the report of the PIANC Working Group no. 12 on the Analyses of Rubble Mound Breakwaters, (PIANC, 1992), stated:

**'Finally, it is worth repeating that the experience of this working group has shown again, as others have found before us, that there is a great need for more detailed monitoring of existing rubble mound breakwaters including records of the wave conditions to which they are subjected in service. Collection and publication of data on this subject would greatly assist the advancement of engineering knowledge.'**

---

\* Ematek, CSIR, P O Box 320, Stellenbosch 7600 South Africa

The long-term stability of, and the intermittent storm damage to rubble-mound breakwaters are of considerable interest to the designers, builders and authorities responsible for maintenance. Depending on the severity of the wave attack, the breakwater armouring will deteriorate in time if not properly maintained. Gradual deterioration can often pass unnoticed until weak areas give way to major damage. Early detection of deterioration such as displaced, broken or lost armour units is therefore essential.

Annual monitoring of a breakwater provides an early warning system to identify any weak spots in the armouring which can then be repaired before the overall stability of the breakwater is threatened. The accumulation of data on damage which can be linked to the prevailing sea conditions during the monitoring period can also be used to improve breakwater design techniques and calibrate the design formulae which are mostly based on the results of hydraulic model tests. Breakwater monitoring also offers the potential for increasing our understanding of failure mechanisms associated with rubble-mound structures which are difficult to simulate accurately by way of physical model tests.

## DESCRIPTION OF BREAKWATERS

The seven harbours, where the breakwaters are monitored, are spread out along the east and south coast of South Africa, from Richards Bay in the north-east to Cape Town and Saldanha Bay in the south-west, as shown in Figure 1. All but one of these ports are protected by rubble mound breakwaters, which are covered with dolos armour units. Saldanha Bay, which is also monitored on an annual basis, lies in a large natural bay, and is protected by an artificial spending beach breakwater across the entrance to the bay.

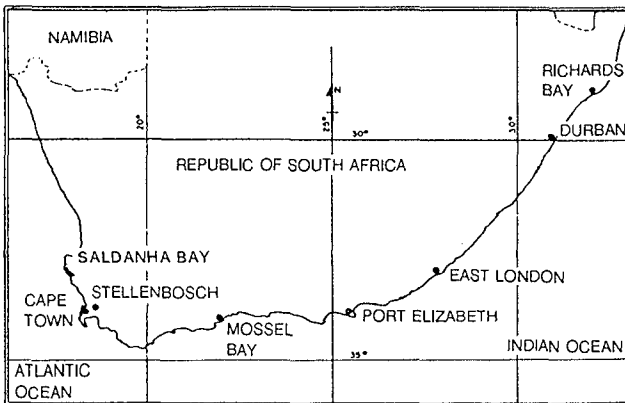

Figure 1. Location of Breakwaters

The main dolos breakwaters lie on the southern sides of the port entrance channels and the water depths at the toe of the breakwaters vary between 3 m and 15 m. The extreme wave conditions at most of the harbours are therefore depth limited. At the east coast ports the breakwaters have a dual function of reducing wave heights and preventing siltation in the entrance channels. At these ports maintenance dredging is necessary to intercept the littoral drift which is predominantly from south to north. Table I summarises the details of each of the dolos breakwaters (CSIR, 1981). The calculation of percentage damage, as given in the table, is described later in this paper.

Richards Bay has two dolos breakwaters, a shorter straight breakwater on the northern side and a longer curved breakwater on the southern side. East London, the only river port, is the oldest dolos structure which still has the original dolosse designed by Mr E Merrifield, the port engineer, in 1964. The main reason for the very high percentage damage to armouring on this breakwater, is that the dolosse were placed directly over randomly placed 35 ton blockwork. In some areas, there is only the blockwork left to protect the concrete mass-capping. Although the original breakwater was founded in 10 m water depth, a sand-bank, of 5 m depth, has formed just off-shore, which gives added protection from severe wave attack.

At the commencement of the regular monitoring programme for Portnet in 1989, a base-line damage status had to be calculated for those breakwaters which were already extensively damaged (specifically East London and Mossel Bay). This was done using a combination of visual inspection (of broken dolosse) and crane and ball survey. Cross-sectional plots compared the difference between the original as-built profiles and the existing profiles, and percentage damage was based on section areas.

Harbour	Length	No Dolosse	Year constructed	Monitored Years	Dolos size	Waiste ratio	Design Hs	Max % Damage	Average Damage
Richards Bay North	600 m	1000 (Head) 8800 (Trunk)	1973-1975	1987-1994	15t 5t	0,33 0,33	7,9 m	17% 16%	8,5% 6,5%
Richards Bay South	1400 m	2200(Head) 13400(Trunk)	1973-1976	1979-1994	30t 20t	0,36 0,33	7,9 m	10% 17%	3,9% 7,5%
Durban	585 m	2100	1982-1987	1989-1994	20 t	0,33	6,5 m	20%	6,1%
East London	600 m	2000	1964	1987-1994	18 t	0,34	8,5 m	71%	39%

Cape Town	500 m	2900	1988	1989-1994	25 t	0,355	7,5 m	16%	2,6%

Table I. Summary of Breakwater Damage

## MONITORING METHODS

Most of the breakwater monitoring methods, used by the CSIR in South Africa, are listed briefly below, together with descriptions of their usefulness and applicability. Detailed descriptions of these methods are available in various reports (CSIR, 1988a and Kluger, 1982).

- **Visual inspections** are useful for checking specific damage. The number of broken units per section of breakwater, and the type of break (important for structural analysis of armour units) can be checked visually but this is more time consuming than photographic methods and is not suitable for monitoring the entire slope. More broken units can usually be located using the visual method, and it is therefore useful at the start of a monitoring programme to get the base-line damage figures.
- **Close up photography** merely records the results of visual inspection and is useful for checking detailed progress of localised damage such as cracks in the mass capping. Camera type and position should be kept constant for good comparisons of subsequent photographs. Valuable information can also be obtained from photographs taken during extreme sea conditions. Areas of focused wave action can often be identified in this way, and related to the resulting damage to the breakwater. Aerial photography is normally not possible during storm events, but photographs, taken from the closest possible safe vantage point, have proven to be very useful.
- **Diver inspections** are just an extension of visual inspections to below water, provided visibility is good. Recording can be done by video or still photography but position fixing is more difficult and the whole operation more time consuming. This type of monitoring is normally only done if damage is already indicated by other methods such as crane and ball surveys.
- **Photographic surveys** from fixed positions to produce overlapping photographs covering the entire above-water condition of the breakwater (viewed at low spring tide) are the most useful and cost effective methods of breakwater monitoring. This method which involves the use of overlay techniques to check damage, should not be confused with photogrammetric survey methods, described below. The photographs may be taken from a boat (horizontal view), or crane or aircraft (vertical view), whichever is available. The helicopter was found to be most suitable, in that it could hover (wait for wave drawdown) and move quickly between monitoring stations. Position fixing of the helicopter is normally done by the use of Differential GPS, which is accurate to within 1m. The height can be set to suit the camera lens being used (the

greater the height, the better the accuracy, but once chosen, the equipment should be standardised for subsequent surveys). For South Africa's dolos breakwaters the above method was found to be generally adequate for monitoring the above-water damage to the armour units. A new development, however, is to substitute the helicopter photographs with video, which is equivalent to taking 25 images per second (at the TV frame rate of 25 Hz for the PAL standard).

- **Photogrammetric surveys** can also be done from a crane or aircraft, although position fixing of the camera is more critical and accurate benchmarks are required to properly reference each section of breakwater being stereographically photographed. This method is time consuming and expensive and is only used where very accurate three-dimensional recording of armour unit positions are required. This method is more applicable to the monitoring of small armour units or rock where the individual movements are more difficult to identify. As with the photographic surveys, a spring low tide and good wave drawdown are essential to get maximum exposure of the breakwater slope.

- **Crane and ball surveys** are used to monitor the breakwater profile (above and below water) at predefined intervals. A mobile crane is normally used to position the ball, and the level of the ball is measured from a theodolite station on the breakwater. The size of the ball which must obviously be kept constant from one survey to the next is normally around  $r = 1,14 V^{1/3} / \sin 45^\circ$  where  $r$  is the ball radius and  $V$  is the dolos volume. The above survey method was found to be the most successful in recording underwater damage, but the reach of the crane could be a limiting factor in the seaward extent of the survey. During construction of the breakwater, this method is essential to monitor the as-built rock and dolos profiles.

- **Seismic, sidescan sonar and bathymetric surveys** can be used to supplement the crane and ball survey by extending the monitoring seaward. Seismic profiling can even be used to check the profile of the original breakwater which may now be buried by sand. This detail is very important for the design of breakwater repairs including the toe berm. The survey equipment can be operated from either a crane or boat depending on the sea conditions adjacent to the breakwater. Provided visibility is good, any unusual features indicated by the above methods can be investigated by divers.

- **Standard tacheometric survey methods** may be used to accurately monitor levels of predetermined positions on the capping slab and specific armour units to identify general deterioration by settlement of the entire structure. Cracks in the capping slabs usually indicate settlement.

This method can be used to obtain cross section profiles by pre-marking (studs or drill holes) and surveying points up and down the breakwater slope. This survey data should be referenced to a stable benchmark located on shore.

Although a number of different breakwater monitoring methods have been listed above, not all these surveys, except possibly the photographic survey, need to be done on an annual basis. It is, however important that 'base-line' surveys using each of the different methods, listed above, are done as soon as possible after construction of the breakwater to provide a reference level to compare future damage against.

Other forms of monitoring which are complimentary to the breakwater monitoring techniques presented above, are:

- wave recording (by wave buoy - height, period and direction)
- bathymetric surveys around the breakwater to monitor toe erosion
- sediment sampling adjacent to the breakwater to check grain size
- water/sediment movement through the breakwater (dye tests)
- monitoring of concrete decay (possible alkali aggregate reaction)
- monitoring of cracks in capping slab (linked to settlement)

The results of these surveys are then linked to the breakwater damage analysis.

## ANALYSIS OF MONITORING DATA

Only the photographic survey will be described here, but the analysis principles are the same for the other methods of breakwater monitoring listed above. With the aim of the monitoring being the assessment of the deterioration of the breakwaters, the cumulative damage per monitoring station is calculated by comparing photographs taken before and after the monitoring period (usually annual) and adding the new damage to the previous cumulative damage per station. Provided the camera position and type of lens are kept constant for consecutive surveys, it is possible to use the overlay (or stereo-comparator) technique to quickly compare respective photographs to detect individual armour unit movements of less than 0,5 m. New, digital image analysis techniques are presently being investigated, and are presented later in this paper.

Both annual and cumulative damage are given in the monitoring reports. The visible damage has been categorised into three degrees of dolos movement (A) < 0,5 m, (B) 0,5 - 1,5 m and (C) > 1,5 m, (D) dolos breakage and (E) disappearance (loss) of the dolos from the visible slope. The damage per monitoring station, which normally cover 20 m to 25 m of breakwater length, are expressed as percentages, which are calculated by adding (C) + (D) + (E) and dividing by the total number of dolosse per station (N).

The movement of pieces of dolosse, which have already broken are also monitored, but do not contribute further to the damage calculation. In the same way, the smaller dolos movements (A) and (B) are recorded for information purposes, but do not contribute to the damage total. The movement history of a particular dolos is also tracked, so that the cumulative movement can be measured. Once this cumulative movement reaches more than 1,5 m (C), or  $h/2$  where  $h$  is the height of a dolos, it is then added to the damage total. Although some experts only consider prototype dolos breakage as 'damage', it was found that once a dolos had moved more than half its length ( $h/2$ ), the gap left by this movement often resulted in focused wave action, which in turn resulted in further damage (movement or breakage), especially under severe wave conditions. Monitoring results have shown that unrepaired localised damage causes an increase in the rate of damage in that localised area.

Because the main purpose of breakwater monitoring is to warn of potential failure areas which need to be maintained, it was decided to include these dolos movements (C), in the damage criteria given in the table. This theory is also more in line with the definition of damage of dolosse in scaled model tests, where movements more than  $h$  are generally recorded as damage (together with an observation of the number of rocking dolosse, to represent dolos breakage without displacement). The broken dolosse have however been listed separately to allow further analysis of damage, using dolos breakage as the only criteria.

It is recommended that the moved, broken or lost units be highlighted on the photographs which should be included in the monitoring report for easy reference. Weak areas or 'holes' in the armouring, which are more easily identified from photographs than in prototype, should also be highlighted to assist maintenance planning. When a hole is repaired with new units, the cumulative damage is reduced by the number of new units placed ( $n$ ), but when the new units are just added to the slope and are not particularly filling any 'holes', only the total number of units per section ( $N$ ) are increased.

The results of annual monitoring exercises at each port have been presented in reports issued to the port authority. The monitoring report also includes a brief description of the survey methods used, including camera details, and position and heights of camera stations to ensure continuity and ease of comparison for future monitoring. The wave data from wave buoys off each harbour, covering the monitoring period, are analyzed and included in each report so that annual damage can be linked to the prevailing sea conditions or significant storm events. Graphs are also plotted showing the rate of increase of damage per station which highlights those areas of the breakwater which may need urgent repairs.

## APPLICATION OF RESULTS

The results of these breakwater monitoring surveys have been found to be vitally important for a better understanding of, design of, and appropriate maintenance planning of dolos structures. Prototype monitoring results are presently being used for both structural (Zwamborn and Phelps 1989) and hydraulic damage analysis. The ultimate objective is to have sufficient prototype breakwater data (of dolos structures in this case), to combine with the recorded wave conditions, to create a basis for validating design formulae which are, thus far, predominantly based entirely on the results of small scale model tests.

Some of the uses to which these results have been applied in South Africa, include the following:

- **Planning of breakwater maintenance** - On-going maintenance is carried out on those breakwaters with permanently mounted breakwater cranes (Durban and East London have hammerhead cranes mounted on rails along the length of the mass-capping). At these ports it is economically feasible to carry out spot repairs, as needed and indicated by monitoring surveys. Gaps in the armouring are filled, and the percentage damage is kept low. For this purpose, a stockpile of spare dolosse is required at the root of the breakwater, within reach of the crane. As explained above, the damage at the East London breakwater was already high before the monitoring programme was started.

At other breakwaters, without permanent cranes, or spare dolosse, it is more feasible to let the damage rise to higher levels, before the planning of more major repairs. This critical level of damage depends on the importance of the breakwater in protecting the harbour entrance, and in the importance of the harbour itself. At Richards Bay, a major exporting port, planning for repairs to the southern breakwater commenced when the percentage damage per station exceeded 15 per cent. While at Mossel Bay, a small fishing harbour with a shallow water breakwater (-4 m), the maximum percentage damage per station was allowed to rise above 30 per cent before temporary repairs were done, and major repairs planned. As for East London, the damage to the Mossel Bay breakwater was already high when detailed monitoring commenced. Both dolos breakwaters are approximately 30 years old.

- **Age of breakwater vs damage (history of damage after construction)** - The Durban and Cape Town harbour breakwaters, which have been carefully monitored since construction, have shown that the initial 'settling in' of dolosse during the first major storm event, can result in more than double the normal annual damage. The rate of damage at any station, after initial settling-in, is generally related to the cumulative damage total at that station; this tended to increase after 20 per cent.

The damage history of the Port of Cape Town breakwater is shown in Figure 2, below. This graph is based on 6 years of monitoring data on the breakwater trunk, which consists of approximately 2 400 25 ton dolosse over a length of 500 m. The cumulative damage (movement and breakage, and breakage only) is plotted as a line graph against the left Y-axis, whilst the four worst storms (during the annual monitoring period) are plotted as bar graphs against the right Y-axis. The 1989 survey showed very high 'settling in' damage.

Figure 2. Damage History of Port of Cape Town Breakwater

- **Ratio of dolos movement vs breakage** - All visible dolos movements (above water) were recorded to within an accuracy of 0,1 m by the photographic survey method. Of all the recorded movements:
  - 52 per cent were less than 0,5 m,
  - 32 per cent were between 0,5 m and 1,5 m, and
  - 16 per cent were above 1,5 m

In this case, 1,5 m is approximately  $h/2$  where  $h$  is the height of a 25 ton dolos. This means that on average, only 16 per cent of all recorded dolos movements contribute to the recorded damage total. After the initial 'settling in' of the breakwater after construction, which normally involves a high percentage of small movements, approximately 55 per cent of the recorded movements, were new movements while 45 per cent had moved before. Besides rocking units, many dolosse move, or are displaced more than once, before becoming stable.

Based on a sample of 233 events (dolos movements including breakage), recorded on the Table Bay breakwater over a 5 year period:

- 75 per cent moved (without breakage) less than  $h/2$ , and
- 15 per cent moved more than  $h/2$  (also without breakage).
- 10 per cent of all the movements resulted in breakage.

Fewer than half the dolosse which moved more than  $h/2$ , actually broke, while some dolosse were seen to rotate up to  $270^\circ$  without breaking. Breakage of dolosse which had moved less than  $h/2$ , were usually the result of either rocking, impact from other dolosse or cold joints.

■ **Effect of rail reinforcing in dolosse** - The results of swing tests (with yield cushions) on 9 t dolosse using rail reinforcing (Zwamborn and Phelp, 1989) compared well with the results of monitoring the 25 t rail reinforced units which were used to repair the Cape Town breakwater (Zwamborn, Claassens and Van Tonder, 1990). The three types of rail reinforcement tested are shown in Figure 3. The test results showed that X-type rail reinforced dolosse could withstand approximately double the fall height, compared to unreinforced dolosse. A near design storm which occurred in July 1989, resulted in damage (as monitored photographically), of the same order as that predicted by the swing tests and hydraulic model tests, thereby validating the design.

**Figure 3: Types of Rail Reinforcement**

Prototype reinforced units were observed to have moved more than  $h/2$  without breakage, and many of those units which did break, were still held together by the rail reinforcing, and thus continued to be functional in providing protection to the breakwater. Monitoring surveys of Cape Town breakwater revealed that rail reinforcing reduces both shank and fluke failure, but was not effective in reducing torsional failure (especially the double-V type, Figure 3). Torsional loading of reinforced dolosse tended to shatter concrete on the shank of the dolos, leaving the rails exposed. However, this is not considered too significant, because torsional failures constituted only 11 per cent of all observed dolos breakage (based on a sample of 357 broken dolosse).

■ **Improvement of dolos shape to reduce breakage** - As part of the breakwater monitoring exercises done in South Africa, a detailed study has been made of the number and type of broken dolos armour units, with a view to improving the shape to reduce breakage (Luger, 1993).

An analysis of these prototype dolos breakages has identified the fluke-shank intersection of the dolos as a region of structural weakness. Over 80 per cent of the dolosse breakages were found to originate from this point. Finite element analysis has been used in an attempt to improve the stress distribution in the dolos by modifying the dolos shape in the region of the fluke-shank intersection. Three of the shapes which have been analyzed are shown in Figure 4. This work is aimed at developing a dolos shape which is structurally superior to the existing shape, without significantly reducing the excellent hydraulic stability of the existing shape. The improved shape should be suitable for use on new projects as well as for the repair of existing breakwaters.

Figure 4: Evolution of Improved Dolos Shape

The continued monitoring of breakwaters where improved armour units are used will provide valuable data to determine the improved performance of the prototype units and confirm the theoretical advantages. The curved filleted dolos (Figure 4) are presently being used in the repair of existing breakwaters at Richards Bay and Mossel Bay, and in coastal protection works in Table Bay near the entrance to the Port of Cape Town. One advantage of using the improved dolosse for the repair of older dolos structures, is that there is still good interlocking between the new and old shaped units of the same weight.

■ **Effect of dolos size and waist ratio** - As a general rule, it was found that a larger waist ratio reduces the percentage of shank failure but increases the percentage of fluke failure. Independent of the waist ratio,

the introduction of even the smallest fillet, reduces breakage at the fluke/shank intersection. This was observed on some of the older breakwaters which have both dolosse with no fillet and dolosse with small rounded fillets and the original chamfer (SPM, 1984).

No relation could be found between breakwater damage and dolos size. It is the author's opinion however that dolosse, being slender units, are not suitable for deep water applications, and become structurally unstable above 35 ton to 40 ton, even with higher waist ratios. In South Africa, where most of the breakwaters lie in relatively shallow water, the dolos is still considered to be the most suitable armour unit.

■ **Calibration of site-specific model tests** - The Port of Richards Bay breakwaters, have been monitored by various techniques since completion in 1976, but regularly since 1987 using photographic survey from a mobile crane. The results of these surveys indicated that it was necessary to consider doing repairs to the 20 ton dolosse on the trunk of the south breakwater (CSIR, 1988b). Both 3D basin and 2D flume scale model tests were undertaken in 1991 to optimise the proposed breakwater repairs and check the effect of sand trap dredging adjacent to the breakwater (CSIR, 1992).

Because the breakwaters had already experienced storms with wave heights in excess of the 1:50 year design wave height of  $H_{mo} = 7,9$  m, it was decided to calibrate the 'design damage' in the model to equate the existing prototype damage. Each test consisted of a sequence of wave height steps from 2,5 m to 8,5 m in increments of 1,5 m, run for an equivalent of six hours (prototype) each. The model damage was determined using the photographic survey method to record dolos movements. These dolos movements were divided into the number of movements less than the height of a dolos ( $<h$ ) and the number of movements greater than the height of a dolos ( $>h$ ). The calibration factor  $0,4 (<h) + (>h)$  was found to give the best model approximation of prototype damage. Figure 5 shows the prototype and calibrated model damage for monitoring stations 5 to 17, which were spaced 25 m apart.

Figure 5: Prototype versus Calibrated Model Damage

By applying the same calibration factor to the model tests of different repair options, the expected design damage could be determined and the most effective repair option chosen.

Figure 5 also shows, both in model and prototype results, that the worst damage occurred between stations 7 and 9. Hydrographic surveys of the sand trap between 1977 and 1991 have shown that, almost since completion of the breakwater, the deepest area of the sand trap was located opposite stations 7 to 9 (Figure 6). This also coincided with the area where the sides of the sand trap were steepest and closest to the toe of the breakwater. One model test which was carried out with a larger deeper sand trap resulted in an increase in damage proportional to the extension of the sand trap, which indicated that the increased breakwater damage could be linked to the sand trap dredging (CSIR, 1992).

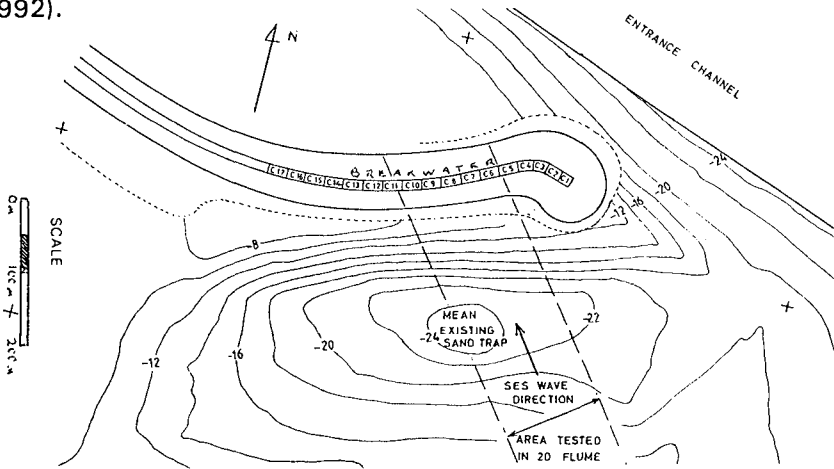

Figure 6: Mean Existing Sand Trap

## FUTURE DEVELOPMENTS

Future developments, in the field of breakwater monitoring, include improved correlation of damage with wave data, and video scanning for digital analysis, storage and presentation of monitoring results. The former involves the installation of directional wave recorders off the breakwaters. A brief description of the latter follows below:

A disadvantage of the photographic monitoring technique which is presented above, is the tedious manual comparison of photographs, even if the overlay or stereo comparator are used, to identify dolos movement and breakage. A recent new development is the replacement of the photograph of the breakwater by a digital image, captured by video recording or a live video camera signal. Flicker Optics<sup>1</sup> is a digital image processing technique which is then used to interlace, in real time, the image with a preview of the same breakwater station before the damage occurred. Any changes are then detected as a stroboscopic flashing of just that portion of the screen where the change has taken place.

A dynamogram (Figure 7) is then generated by simply subtracting the video image in which movement has been detected, from the initial or reference video image. The dolos that has moved shows up clearly while the background, which has not changed, is almost featureless. Three main areas of application of the above technique are as follows:

- Digitizing of archived photographic records (via CCD camera and frame grabbing card) for re-analysis and inclusion in a database.
- Aerial monitoring of prototype breakwater using video camera.
- Real time monitoring of scale model tests on breakwaters.

Figure 7. Digital Image Processing

Direct image subtraction assumes an invariant image geometry, illumination and reflectance. Initial testing of this new monitoring technique was carried out under ideal conditions, achievable in the laboratory at small scale. By real time video monitoring, even the small 'settling in' movements of the scaled dolosse were detected. For analysis of the photographic and prototype video record, however, the images need the following manipulation to overcome certain variables:

- Translation, rotation, scaling and warping to allow for errors in camera position (even with DGPS position fixing).
- Contrast stretching and histogram equalisation to allow for changes in illumination (sun and shadow) during consecutive surveys.
- Spatial intensity gradient image formats and edge detection techniques to allow for surface variation such as sea growth.

Advantages of digital images, include the ability to store only the necessary data (ie dolos movements and breakage), for the database and later presentation of survey results. By using a screen overlay grid and the cursor to scale known positions on the image, the dolos movements can be quantified. this information is then added to the data base.

## CONCLUSION

Breakwater monitoring in general, at South African ports and photographic monitoring in particular, have been successfully used as useful tools to identify damage, provide an early warning system (giving time for model tests of the repairs to be carried out) and assist in the planning of maintenance.

In this paper, the various methods of breakwater monitoring were covered and the use of monitoring results to calibrate model test results and improve repair designs were presented. Three projects involving two breakwater repairs and one new breakwater, soon to be undertaken, have been designed using mathematical and physical model tests, aided directly by the results of prototype breakwater monitoring. Ongoing monitoring of these structures will prove the performance of their design and of improvements made to the shape of the dolosse which are to be used.

## ACKNOWLEDGEMENTS

The author is indebted to Portnet for their support for the continued monitoring of the breakwaters at South Africa's seven major ports. G Hough and M J Alport of Space Physics Research Institute, University of Natal, are acknowledged for the digital (video) image analysis software. <sup>1</sup>Flicker Optics has a patent pending (December 1994).

## CHAPTER 110

# FAILURE OF RUBBLE MOUND STRUCTURES DUE TO THE STORM DURATION AND THE IRREGULARITY OF OCEAN WAVES

Cheong-Ro Ryu<sup>1</sup> and Hyeon-Ju Kim<sup>2</sup>

### Abstract

Failure mechanism and destruction processes of rubble mound structures under the irregular wave attack are discussed in considering with the effects of wave grouping, storm duration, and structural conditions using the model test results. In the analysis of the stability, a new irregular force parameter that affect the failure of rubble mound structures is defined by combining wave grouping characteristics, storm duration effects and wave-structure interaction mechanisms. Using the external force parameter, a modified rubble mound design formula is suggested, and its applicability is proved by the results of comparative studies with the conventional results.

### 1. Introduction

Wave climate, irregularities and uncertainty of ocean waves, and wave-structure interactions are the important parameters in the design of rubble mound structures. Remarkable efforts to develop design formulas of rubble mound structures considering irregular ocean waves have been made by Ryu and Sawaragi (1986), van der Meer (1988), and many of other researchers. Sawaragi et al. (1985) and Ryu et al. (1984) developed the design formula introducing the irregularity of ocean waves. Ryu and Sawaragi (1986) improved it considering allowable damage, material and/or block characteristics, spectral shape effects of ocean waves on the stability of rubble mound structures. Van der Meer (1988) proposed similar advanced design formula considering

the storm duration, allowable damage, and the permeability of rubble mound structures. However, any of the results can't explain sufficiently the destruction mechanism and processes of rubble mound structures by the effects of storm duration and the irregularity of ocean waves including wave-structure interactions.

In the study, define a modified irregular force parameter that can consider the spectral shapes, wave-structure interactions and storm duration effects on the stability. Using the experimental data (Ryu, 1984), the destruction processes will be analyzed with the conception of storm duration effects, and combining the relation between the damage level increase and the irregular force parameter, a new design formula of rubble mound structures will be developed, and the applicability will be discussed by comparing with conventional results.

## 2. Conventional Design Formulas and Problems

The parameters considered in the conventional design formulas to estimate stable rubble weight ( $W$ ) for the monochromatic wave can be summarized as:

$$W = \begin{aligned} &f_1(H, \theta, \gamma_w, \gamma_s, f) \\ &+ f_2(T(L), \beta, D, P, i, h, \gamma_a, h_c) \\ &+ f_3(\dots) \end{aligned} \quad (1)$$

where  $H$  = wave height

$\theta$  = slope angle

$\gamma_w, \gamma_s$  = relative weight of sea water and cover material,  
respectively

$f$  = friction coefficient

$T(L)$  = wave period (length)

$\beta$  = incident wave angle

$D$  = allowable damage ratio (%)

$P$  = permeability coefficient

$i$  = slope of sea bottom

$h$  = water depth

$\gamma_a$  = thickness of cover layer

$h_c$  = crest height.

The most design formulas considered only the parameters in the  $f_1$  of Eq. (1), and the effects of parameters in  $f_2$  and  $f_3$  were introduced as a constant to correct the stability. Since the variety of the constant, the design results are varied by the career of designer and selection of design formula, however, the design rubble weight ( $W$ ) are presented to be proportional to the  $H^3$  (Ryu, 1984).

$$W \geq \alpha H^3 \tag{2}$$

where  $\alpha$  represents the proportional constant.

The variation of the design results will be largely increased, if the irregularity of ocean waves are introduced in the design concept. As shown in Fig. 1, the degree of rubble weight change can be pointed out as an important technical problem to develop a new design conception that minimize the scattering. In the figure, Ryu's (Ryu and Sawragi, 1986) and Meer's (van der Meer, 1988) formulas are to the irregular waves, and others are to the regular waves. It can easily found that the design rubble weights changed to 2 times or more due to the difference of coefficients and formulas.

In the case of irregular waves, following irregularity parameters of ocean waves should be considered additionally in Eq. (1).

$$W = f_{irr.} ( H_{1/n}, \xi_{1/n}, E_{sum} j(), Q_p, N, D, P, \theta, \phi, \gamma_w, \gamma_s, \dots ) \tag{3}$$

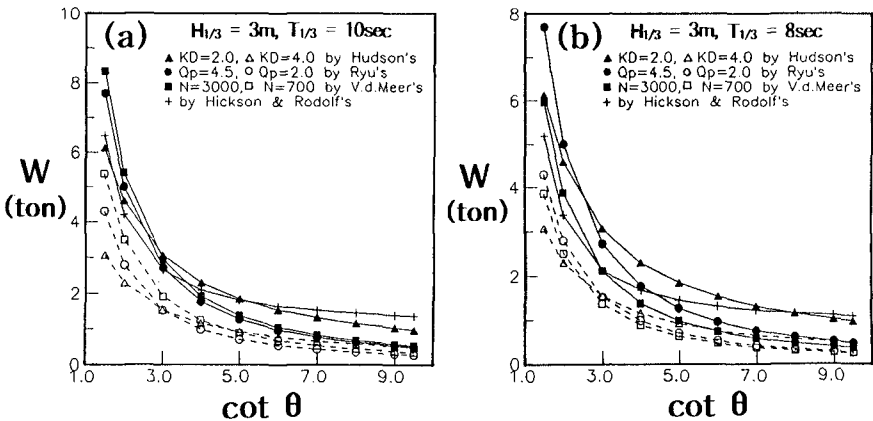

Fig. 1. Design weights of rubble units in relation to the slope angle by various formulas.

where  $H_{1/n}$  is the statistic wave heights,  $\xi_{1/n}$  the surf similarity parameter using  $1/n$  significant waves,  $Q_p$  the spectral peakedness parameter (Goda, 1985),  $N$  the number of incident waves,  $\phi$  repose angle of cover material.  $E_{sum}()$  denotes the concept of run-sum which is defined as the mean energy level of group formed waves as Eq. (7).

The representative design formula for irregular waves was proposed by parameterization of the effects of wave grouping/spectral shapes, wave periods/wave-structure interactions and the allowable damage level considering equilibrium slope formation as follows (Ryu and Sawaragi, 1986):

$$W_r \geq \left[ \frac{\gamma_w (6.15 Q_p + 20.0)}{\gamma_s^{1/3} (D + 30.1)} \frac{\tan \theta}{\tan \phi} \right]^{3/2} H_{1/3}^3 \quad (4a)$$

for the uniform slopes

$$W_r \geq \left[ \frac{\gamma_w (5.46 Q_p + 17.73)}{\gamma_s^{1/3} (D + 36.3)} \frac{\tan \theta'}{\tan \phi} \right]^{3/2} H_{1/3}^3 \quad (4b)$$

for the composite slopes

$$Q_p = \frac{2}{m_0^2} \int_0^\infty f S^2(f) df$$

in which  $W_r$  denotes the design rubble weight by Ryu's formula, allowable damage ratio  $D$  denotes percentage of eroded volume of cover layer to the total eroded volume until the damage level directly affects the stability of filter layer stones,  $m_0$  the zero-th spectral moment,  $S(f)$  the spectral density function,  $f$  the frequency.

Another design formula on irregular waves was proposed by van der Meer (1988) considering the permeability and storm duration etc. as follows:

$$W_v \geq \frac{\xi_m^{3/2} \gamma_s H_{1/3}^3}{[6.2 P^{0.18} (D_v / \sqrt{N})^{0.2}]^3 \left(\frac{\gamma_s}{\gamma_w} - 1\right)^3} \quad (5a)$$

for  $\xi_m < \xi_c$

$$W_v \geq \frac{\gamma_s H_{1/3}^3}{[P^{-0.13} (D_v/\sqrt{N})^{0.2} (\cot \theta)^{0.5} \xi_m]^3 \left(\frac{\gamma_s}{\gamma_w} - 1\right)^3} \quad (5b)$$

$$\text{for } \xi_m > \xi_c$$

where  $\xi_m$  is surf similarity parameter using mean wave period,  $D_v$  is the damage level defined by van der Meer (1988) that has the relation of  $D_v = 0.08 D$ . Eqs. (5a) and (5b) correspond to plunging and surging breakers, respectively classified with transition value of surf similarity parameter  $\xi_c$  given by

$$\xi_c = (6.7 P^{0.31} \sqrt{\tan \theta})^{\frac{1}{P+0.5}} \quad (6)$$

Though these design formulas are the most advanced, each has not included important parameters in Eq. (3). Ryu's formula (Ryu and Sawaragi, 1986) did not account for the effects of storm duration effect and structural permeability, and van der Meer (1988) neglected the wave grouping characteristics. To overcome before mentioned shortcomings and scatterings, the improved formula is needed to develop. It can be pointed out that such storm duration and wave grouping statistics is not clarified statistically as design parameters to introduce in actual design. However, it can be emphasized that the irregularities should be considered in the experiments on the stability and reliability check for the reasonable design.

### 3. Analysis of Available Data

#### 3.1 Experimental Features and Analysis

Destruction mechanism and damage processes are investigated used the results of hydraulic model tests in addition to previous works of Ryu (1984), and Ryu and Sawaragi (1986). The tests were carried out with 3 kinds of structural slopes 1:1.5, 1:2.0, 1:3.0 on a uniformly sloping beach of 1/40 with controlling the permeability of core layer to correct the scale effects. Irregular waves are generated with various spectral shapes of 200 cases. The destruction processes were

visualized simultaneously with incident waves by the 16 mm high speed cine camera (50 frames/sec) during the experiments.

Destruction mechanism is reanalyzed to investigate the effects of irregular wave parameters and correct the effects of resonance phenomena on the slope by introducing the tolerable destruction concept. And storm duration effect on destruction process is analyzed by measuring the destruction history to the irregular wave trains.

### 3.2 Analysis of Wave Irregularities as a Design Force Index

Waves used in the experiments were analyzed by wave by wave analysis and spectral analysis methods, and wave grouping parameters that is important to stability of rubble mound structures were evaluated. The wave grouping parameters such as run-length  $j(\ )$  and run-sum were defined same as Ryu (1984). The mean run-sum ( $E_{sum}$ ) is defined as the mean of energy-sum of group formed waves shown in Eq. (7). In the study, the mean run-sum of conditional run of  $\xi_o^*$  under the condition of significant wave height,  $E_{sum} j(\xi_o^*|H_{1/3})$  is introduced as a grouping parameter that affects to the stability. From the previous work by an author (Ryu and Sawaragi, 1985) on relations among the mean run-sum and  $Q_p$ , it can be estimated by the following formula.

$$E_{sum} j(\ ) = \sum_{j=1}^{\infty} \sum_{k=1}^{\infty} \frac{1}{8} \gamma_w H_k^2 / \sum_{j=1}^{\infty} N_{j(\ )} \quad (7)$$

$$E_{sum} j(\xi_o^*|H_c) = \gamma_w H_c^3 (0.04 Q_p + 0.13) \quad \text{for } H_c=H_{1/3} \quad (8)$$

$$\xi_o^* = \{1.5 \leq \xi_{1/3} \leq 2.5\} \quad (9)$$

$$\xi_{1/3}^* = \frac{\xi_{1/3}}{\xi_{max}} = \frac{\tan \theta / \sqrt{H/L_o}}{\tan \theta / \sqrt{(H/L_o)_{max}}} \quad (10)$$

where  $H_k$  ( $k=1,2,3,\dots$ ) is  $k$ -th wave of run-length  $j(\ )$ ,  $j(\ )$  denotes the run-length  $j$  of the run of  $(\ )$ ,  $N_j$  is number of wave group with the run-length  $j$ . The breaker types could be classified by surf-similarity parameters  $\xi$ , and the range of Eq. (9) makes the

resonance phenomena on the slope by wave by wave interaction.

Ryu and Sawaragi (1986) defined irregular force parameter [X] including wave grouping and resonance phenomena, and arranged the correlation with destruction ratio  $D(\%)$  as follows:

$$[X] = \left[ \frac{E_{sum} j(\xi_{ol}^* H_{1/3})}{\gamma_s l_a^2} \frac{\tan \theta}{\tan \phi} \right] \tag{11}$$

$$D(\%) = 153.8[X] - 30.1 \tag{12}$$

in which  $l_a$  is the characteristic length of stone/block. Eq. (12) did not consider the effects of storm duration and permeability of structures.

### 3.3 Analysis of Destruction Processes

Destruction mechanism and processes of rubble mound structures can be explained with combining the effects of storm duration time, resonance phenomena and wave force parameter [X] shown as Eq. (13). The contribution of the effects to the damage level illustrated schematically in Fig. 2.

$$D(\%) = AN^{0.25}[X] \tag{13}$$

Fig. 2. Schematic definition of weighting function.

Fig. 3. Variation of modified stability number according to relative surf-similarity number.

Damage of rubble mound structures is strongly related with the waves in the range of  $1.5 < \xi_{1/3}^* < 2.5$  where the minimum point of modified stability number ( $N'_s$ ) is appeared as shown in Fig. 3. From Fig. 3 by Ryu and Sawaragi (1986), it can be pointed out that critical surf similarity parameter  $\xi_c^*$  with the minimum point of modified stability number decrease with the damage level increase.

$$N'_s = \frac{\gamma_w^{1/3} H_{D(\%)}}{(\gamma_{s/\gamma_w} - 1) W^{1/3}} \frac{\tan \theta}{\tan \phi} \tag{14}$$

where  $H_{D(\%)}$  is the design wave height for the damage level in percent  $D(\%)$ . In the case of tolerable destruction ratio  $D = 0\%$ , minimum point of  $N'_s$  located at about 2.3 of relative surf similarity parameter  $\xi_{1/3}^*$ , in  $D = 100\%$ , about 1.8. If the critical surf similarity parameter  $\xi_c^*$  can be assumed to be linearly changed according to tolerable damage ratio, it is represented as follows:

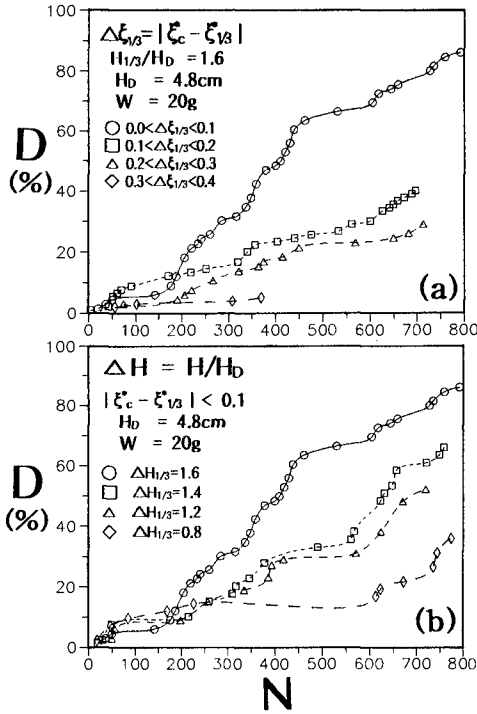

Fig. 4. Storm duration effects on the failure of rubble mound structures with the resonance indexes  $\Delta \xi_{1/3}^*$  (a) and  $\Delta H_{1/3}$  (b).

$$\xi_c^* = 2.3 - 0.005 D \tag{15}$$

Dimensionless damage level to irregular force parameter has a peak around critical surf similarity parameter  $\xi_c^*$  and decrease with increase of  $\Delta \xi_{1/3}^*$  ( $= \xi_c^* - \xi_{1/3}^*$ ) in Fig. 3. This was proved by investigating of the effects of the resonance indexes,  $\Delta \xi_{1/3}^*$  and  $\Delta H_{1/3}$  to the failure of rubble mound structures as shown in Fig. 4. In the figure, it is clarified that the damage level increase is affected by decrease of  $\Delta \xi_{1/3}^*$  and increase of  $\Delta H_{1/3}$  with the storm duration time  $N$ . Considering the characteristics, a weighting function was introduced as Eq. (16) by trial and error method with storm duration effect.

$$A = C_1 \cos\left(\frac{\xi_c^* - \xi_{1/3}^*}{2}\right) = C_1 \cos\left(\frac{(2.3 - 0.005 D) - \xi_{1/3}^*}{2}\right) \tag{16}$$

Fig. 5. Damage level increase of rubble mound structures according to the resonance indexes and the storm duration effects.

Combining Fig. 4(a) and (b), the damage level change due to storm duration under the condition of various  $\Delta\xi_{1/3}^*$  is shown in Fig. 5. It can be said that the severe damage will occur at smaller  $\Delta\xi_{1/3}^*$ .

Dimensionless damage level to the force parameter  $[X]$  and weight function  $A$  was compared versus the storm duration. The result of this analysis presented in Fig. 6. The variance of the results is considerable, however, if one wants to design more reliable structures considering uncertainty of damage processes, the upper limit of the figure will be applied, and the trend of damage increase whose resonance index is close to 0 can be presented as follows:

$$\frac{D}{A[X]} = C_2 N^{0.25} \tag{17}$$

Using the relations, the destruction processes can be summarized and formulated combining constants  $C_1$  and  $C_2$  to  $C$  as follows:

$$A N^{0.25} = C \cos\left(\frac{(2.3 - 0.005D) - \xi_{1/3}^*}{2}\right) N^{0.25} \tag{18}$$

where  $C$  is a constant of 0.194 from the data.

Fig. 6. Variation of damage level according to the storm duration.

### 4. Development of Design Formula

To develop a design formula considering the effects of irregularity of ocean waves and storm duration time on destruction processes as written in Eq. (18), the relationships between damage level ( $D$ ) and modified irregular force parameter  $[X]'$  were investigated by comparing with previous result used  $[X]$ . Fig. 7 shows the results,

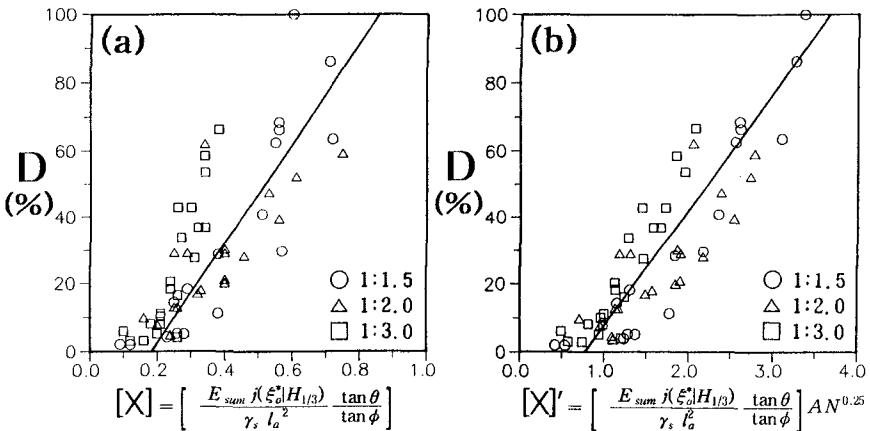

Fig. 7. Comparisons between failure characteristics with respect to the previous irregular force parameter (a) and the modified parameter (b).

and it can be clarified that the modified force parameter  $[X]'$  represents very well the damage processes than  $[X]$ . The correlation between the damage ratio and the new force parameter can be derived empirically as:

$$D = 29.84 [X]' - 5.82 \tag{19}$$

$$[X]' = A N^{0.25} [X] \tag{20}$$

By the relation, the formula to calculate the design weight of a rubble unit can be rearranged to as follow:

$$W_{new} \geq \left[ \frac{\gamma_w(1.19 Q_p + 3.88)}{\gamma_s^{1/3} (D/A N^{0.25} + 5.82)} \frac{\tan \theta}{\tan \phi} \right]^{3/2} H_{1/3}^3 \tag{21}$$

Using the new design formula and conventional formulas, the variation of design weight of a rubble unit is compared according to the storm duration under the same conditions of other parameters. Fig. 8 shows a typical example of variation of design weight of rubble unit. The design weight becomes heavier according to the longer storm duration, and the difference between new formula and others are significant by irregular wave conditions and allowable

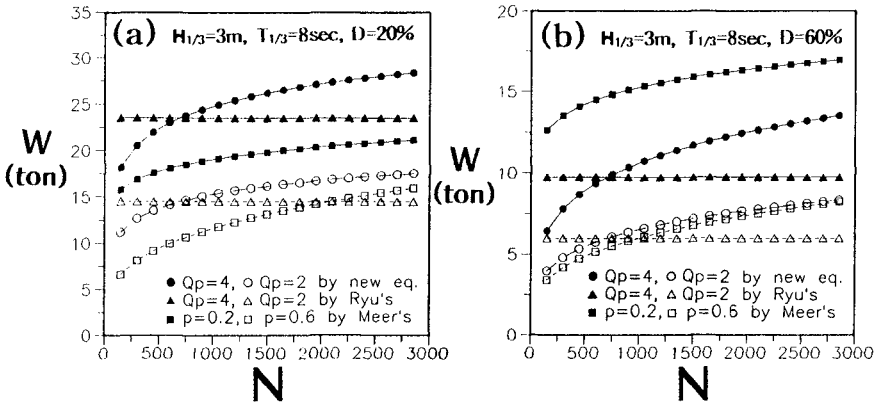

Fig. 8. An example of design weight of rubble unit in relation to storm duration.

damage level( $D$ ). This point out the importance of storm duration as well as the force parameter. It is emphasized that the wave grouping effects/spectral shape effects is one of the most important parameter in the new formula while neglected in van der Meer's formula.

Many researchers including authors pointed out the importance of permeability in rubble mound structures, but it is difficult to formulate using effective parameters on the stability. Kaku et al. (1991) developed a design formula using the experiments by van der Meer (1988), which was simplified as function of  $P$  and  $\xi_m$ , however, it has also problems for sensitivity analysis to the irregularity of waves.

To expand the new formula to the variable permeability, stability analysis parameter  $Q_s$  can be defined by combining the experimental results by author(1984) and van der Meer(1988).

$$Q_s = \frac{\xi_m \cot \alpha}{7.3 C_k^2 P^{0.36}} - 3.32 \quad (22a)$$

$$\text{for } \xi_m < \xi_c$$

$$Q_s = \frac{P^{0.26}}{0.19 C_k^2 \xi_m^{2P}} - 3.32 \quad (22b)$$

$$\text{for } \xi_m > \xi_c$$

where  $C_k$  denotes constant as introduced by Kaku et al. (1991). This formula represents the effect of  $Q_b$  to the stability in use of the new formula by introducing  $\xi_m$  and  $P$  of van der Meer's formula Eq. (5).

Stability analysis method could be formulated with regard to the storm duration, wave grouping characteristics, resonance phenomena and permeability, however, the parameters can not easily get in the field data. In future, field measurement to get a design parameter should be designated to satisfy the estimation of the force parameter, and the experiments should be designed to cover the effects. It is needed to consider the effects of crown height and wave-structures-soil interactions in the design.

These methods and data will be contributed to database as design constraints with numerical models on wave-structure interactions in the applications of the optimal design algorithm developed by Ryu et al.(1992).

## 5. Conclusions

Destruction processes of rubble mound structures are investigated by the hydraulic experiments considering irregularities of ocean waves and storm durations. The main results obtained in the study are:

- 1) From the analysis of destruction mechanism and its process, the effects of wave grouping and spectral shapes of irregular ocean waves, storm duration and wave-wave interaction on the slopes are emphasized as the important parameters in the analysis of stability of rubble mound structures.
- 2) The destruction processes are formulated empirically introducing the new irregular force parameter included the storm duration and resonance phenomena in addition to the irregular force parameter. And a modified design formula is proposed by rearranging the relationship between the damage level and the modified force parameter to calculate weight of rubble units.
- 3) By the comparative study with previous works, it can be emphasized that the new formula represents reasonably the effects of storm duration, wave irregularities, damage increasing processes, and wave-wave interaction on the slope. Applicability of the formula and research needs were discussed to the comprehensive optimal design algorithm of rubble mound structures.
- 4) The effect of permeability to the stability can be applied by a correct parameter to expand the use of the new formula.

## CHAPTER 111

### BLOCK SUBSIDENCE UNDER PRESSURE AND FLOW

T. Sakai<sup>1</sup>, M. ASCE, H. Gotoh<sup>2</sup> and T. Yamamoto<sup>3</sup>

#### Abstract

The block subsides gradually into sandy bed under water pressure fluctuation. In actual coast the oscillatory flow also acts on the block. The block subsidence is reproduced qualitatively in a laboratory. The subsidence occurs even under the oscillatory flow. Under some combinations of water pressure fluctuation and oscillatory flow, the subsidence is larger than any of the subsidence under the pressure fluctuation only and the subsidence under the oscillatory flow only.

#### Introduction

In sandy coast armour blocks gradually subside into the bed. Fig.1 shows an example of the block subsidence and dispersion of an offshore breakwater off the west coast of Niigata facing the Japan Sea(Nakata, H. et al., 1991). There are several mechanisms proposed : for example, the rocking of the block and the porewater flow in the sand bed under the block.

One more explanation for this phenomenon is that the porewater pressure fluctuates due to the wave pressure, the vertical effective stress decreases at each wave trough phase, the block subsides slightly and it is repeated wave and wave. Already the subsidence was reproduced under a water pressure fluctuation in a laboratory(for example, Zen et al., 1990. See Fig.2). The behaviour of a sand bed during a block subsidence was observed in a laboratory(Nago et al., 1993. See Fig.3).

Fig.1 Subsidence and dispersion of block of offshore breakwater(Nakata, H. et al., 1991)

Fig.2 Reproduction of block subsidence due to water pressure fluctuation(Zen, K. et al., 1990)

In actual coasts, however, the oscillatory flow is also induced by waves and the scour around the blocks occurs. Here the subsidence of a model block on a sand bed is reproduced under a simultaneous action of a water pressure fluctuation and an oscillatory flow by a

laboratory experiment. The effects of the pressure and flow on the block subsidence are examined qualitatively.

Fig.3 Behaviour of sand bed during block subsidence (Nago, H. et al., 1993)

### Experimental setup, procedure and conditions

#### experimental setup

An oscillatory tank, which can generate a water-pressure fluctuation and an oscillatory flow simultaneously, was used. It consists of a U-shaped tank (30cm x 30cm cross section) with both ends closed and

Fig.4 Experimental setup

a sand pit(200cm wide and 100cm deep) attached to the horizontal part of the tank.

The medium grain size of the sand was 0.25mm. A rectangular block(10cm wide, 5.5cm high and 20.5cm long) was set on the sand-bed surface(Fig.4).

#### experimental procedure and conditions

Three kinds of experiments were done, water-pressure fluctuation only, oscillatory flow only and both water-pressure fluctuation and oscillatory flow simultaneously. The periods of the pressure fluctuation and the oscillatory flow are same(3.0s and 6.0s). Fig.5 shows the combination of the total pressure fluctuation amplitude head and the average oscillatory flow amplitude for the case of wave period = 3.0sec. Fig.6 shows the combination for the case of wave period = 6.0sec. The phase between the pressure and the flow could not be controlled arbitrarily. It varied around 90 degrees. After 100 waves loaded, the amount of subsidence was measured.

The average head of water pressure was about 2.0m, the maximum total pressure-fluctuation amplitude head was 1.3m, and the maximum amplitude of oscillatory flow was 60cm/s. The void ratio of the sand bed was estimated several times during the experiment.

#### Experimental results

##### water-pressure fluctuation only

Fig.7 shows an increase of the amount of subsidence for the case of the period = 6.0sec and the total pressure fluctuation amplitude head = 141cm. Even after 300 waves(30min.) the subsidence continues.

Fig.8 shows a relation between the amount of subsidence after 100 waves and the total pressure-fluctuation amplitude head for the period = 3.0sec. The relation between the amount of subsidence and the total pressure fluctuation amplitude is roughly linear. The result for the period = 6.0sec shown in Fig.9 is nearly the same. No clear difference from that of the period = 3.0sec is seen.

##### oscillatory flow only

Under the oscillatory flow, the block was inclined generally. The amount of subsidence of the gravity center of the block was measured. Fig.10 shows a relation between the amount of subsidence after 100 waves and the average amplitude of oscillatory flow for the period = 3.0sec.

Fig.5 Combination of pressure fluctuation amplitude and oscillatory flow amplitude for wave period = 3.0sec

Fig.6 Combination of pressure fluctuation amplitude and oscillatory flow amplitude for wave period = 6.0sec

Fig.7 Increase of amount of subsidence in time

When the average oscillatory flow amplitude becomes larger than about 30cm/sec, the block begins to subside. The relation between the amount of subsidence and the flow amplitude is roughly linear. The result for the period = 6.0sec shown in Fig.11 is nearly the same. No clear difference from that of the period = 3.0sec is seen.

#### pressure fluctuation and oscillatory flow simultaneously

Fig.s 12 and 13 shows the amount of subsidence in the parentheses for the period = 3.0sec and 6.0sec respectively. The data on the horizontal axis are for the case of pressure fluctuation only. The data on the vertical axis are for the case of oscillatory flow only.

### Discussions

#### pressure fluctuation only

In the experiment of Zen et al.(1990), the width, height and length of the block were 6.9cm, 19.0cm and 6.9cm respectively(Table 1). The weight per unit area of the sand surface was 52.0g/cm<sup>2</sup> in the experiment of Zen et al., while it was 9.7g/cm<sup>2</sup> in this experiment. The void ratio of the sand bed, the period of pressure fluctuation and the total pressure fluctuation amplitude head were 0.80, 3.0sec and 566cm respectively. The amount of se after 100 waves was 0.5cm.

Fig.8 Amount of subsidence after 100 waves under pressure fluctuation only(wave period = 3.0sec)

Fig.9 Amount of subsidence after 100 waves under pressure fluctuation only(wave period = 6.0sec)

Fig.10 Amount of subsidence after 100 waves under oscillatory flow only(wave period = 3.0sec)

Fig.11 Amount of subsidence after 100 waves under oscillatory flow only(wave period = 6.0sec)

Fig.12 Amount of subsidence after 100 waves under both pressure fluctuation and oscillatory flow (wave period = 3.0sec)

Fig.13 Amount of subsidence after 100 waves under both pressure fluctuation and oscillatory flow (wave period = 6.0sec)

Table 1 Comparison with Zen et al.'s experiment(1990)

	Zen et al.(1990)	this study
width(cm)	6.9	10.0
height(cm)	19.0	5.5
length(cm)	6.9	20.5
weight/bottom area (g/cm <sup>2</sup> )	52.0	9.7
void ratio	0.80	0.93
degree of saturation	high	low
period(sec)	3.0	3.0
total pressure amplitude head(cm)	566	131
subsidence(cm)	0.5	1.2

In this experiment, the amount of subsidence under total pressure fluctuation amplitude head of 131cm is 1.2cm. In the experiment of Zen et al., the amount of subsidence is less than half of that of this experiment under about 4 times larger pressure fluctuation. The void ratio of the sand bed of this experiment was 0.93 and fairly larger than 0.80 of the experiment of Zen et al. This is one reason of the large amount of subsidence of this experiment.

One more possible reason may be the low degree of saturation of porewater. The lower the degree of saturation of porewater, the larger the attenuation and the phase lag of the porewater pressure(Zen et al., 1990). It induces the larger decrease of the vertical effective stress under the wave trough.

#### pressure fluctuation and oscillatory flow simultaneously

For convenience' sake, the data in each figure of Fig.12 are divided into several groups. The group (a) consists of the data for the case of pressure fluctuation only. The group (b) consists of the data for the case of oscillatory flow only.

The scatter of data is large, but the following can be said. In the case of 3.0sec, the amount of subsidence under the pressure fluctuation and the oscillatory flow, the average flow amplitude of which is less than 35cm/sec, group (c), is roughly the same as that of group (a). In other words, under the average flow amplitude less than 35cm/sec, in which no subsidence occurs in group (b) of

oscillatory flow only, there is no effect of oscillatory flow on group (c).

In group (d), in which the average flow amplitude is larger than 35cm/sec, the amount of subsidence is larger than that of group (a) for the same pressure fluctuation amplitude. Some data show the amount of subsidence larger than any of those of the cases of the same pressure fluctuation only and the same oscillatory flow only.

In the case of 6.0sec shown in Fig.13, the similar trend is seen. There are the data in which the average flow amplitude is less than 35cm/sec and the total pressure fluctuation amplitude head is less than 40cm, group (c<sub>1</sub>). In the case of 3.0sec, there is no such data. Under the average flow amplitude less than 35cm/sec, in which no subsidence occurs in the case of flow only, the amount of subsidence is larger than that expected from the pressure fluctuation amplitude. This is one of the additive effects of the pressure fluctuation and the oscillatory flow.

### Conclusions

The amount of subsidence of a model block(10.0cm wide, 5.5cm high and 20.5cm long) on a sand bed was measured after 100 waves under a water pressure fluctuation and an oscillatory flow in a U-shaped oscillatory tank. The tank generated a water pressure fluctuation and an oscillatory flow simultaneously. The maximum total water pressure fluctuation head was 1.3m. The maximum average oscillatory flow amplitude was 60cm/sec. The period was 3.0sec and 6.0sec.

- (1) Under the water pressure fluctuation, the relation between the fluctuation amplitude and the amount of subsidence is roughly linear and independent on the period.
- (2) The amount of subsidence under the water pressure fluctuation is fairly large compared with that of Zen et al.(1990). This is thought to be due to the larger void ratio and the lower degree of saturation of the porewater.
- (3) Even under the oscillatory flow, the subsidence occurs. The relation between the flow amplitude and the amount of subsidence is roughly linear and independent on the period.
- (4) Under both the water pressure fluctuation and the oscillatory flow simultaneously, the subsidence is larger than any of the subsidence under the pressure

fluctuation only and the subsidence under oscillatory flow only for some combinations of the pressure and the flow.

## CHAPTER 112

# STABILITY OF ROCK ON BEACHES

by

Gerrit J. Schiereck, Henri L. Fontijn, Wout V. Grote, Paul G. J. Sistermans<sup>1</sup>

### ABSTRACT

Stability relations for rock on a mild slope are derived and compared with experimental results. It appears that for non-breaking waves the stability on a mild slope can be described with existing relations for stability on a horizontal bottom in oscillatory flow. For breaking waves, no existing relation can be used and a provisional empirical design rule was established. The results can be applied in designing outfall protections.

### 1. INTRODUCTION

Figure 1 Outfall protection

Pipelines on the sea bottom are usually protected in order to prevent damage by anchors or erosion. When a pipeline crosses a beach, it often lays in a dredged trench, see Figure 1, is covered with stones including a filter layer and is again covered with the original sand. The protection then acts as a last defence in case of severe wave attack on the beach. For the design of such a protection, which can be seen as an armour layer on a mild slope, no design rule is available at the moment.

---

<sup>1</sup>Delft University of Technology, Faculty of Civil Engineering,  
P.O. Box 5046, 2600 GA Delft

Much information is available on static stability of rock on steep slopes, as occurring at breakwaters and revetments, see e.g. Hudson (1959) or van der Meer (1988). Information is also available on static stability in oscillating flow on a horizontal bottom, see e.g. Sleath (1978) or Rance & Warren (1968), while Naheer (1977) investigated the stability under breaking solitary waves. For mild slopes much is known about dynamic stability, e.g. for sand and pebble beaches, where the profile is reshaped when conditions change. About static stability on mild slopes, which is a rather unusual combination in coastal engineering, practically nothing is known. At Delft University of Technology two studies were done (Sisternans (1993) and Grote (1994)) to find a static stability relation for rock on mild slopes which can be used as a design rule for outfall protections.

2. LOAD AND STRENGTH

Figure 2 Orbital velocity and wave friction

The basic phenomenon in stability under waves on a mild slope, at least under non-breaking waves, is assumed to be the shear stress due to oscillatory flow:

$$\hat{\tau}_b = \frac{1}{2} \cdot \rho_w \cdot f_w \cdot \hat{u}_b^2 \tag{1}$$

with:

$$\hat{u}_b = \omega a_b = \frac{\omega H}{2} \frac{1}{\sinh kh} \tag{2}$$

$f_w$  and  $u_b$  depend on the wave height,  $H$  and period,  $T$ . Given a certain wave height, the longer the period, the larger the orbital velocity at the bottom,  $u_b$ , (Figure 2a).

With  $f_w$ , the friction coefficient, the relation is opposite: the shorter the period, the larger the friction coefficient, see Figure 2b, derived from Jonsson (1966) where  $f_w$  is given as a function of the orbital stroke at the bottom, related to the bottom roughness. This is caused by the fact that the boundary layer, ( $\delta$ , see Figure 2a) under a longer wave is more developed, leading to a lower velocity gradient, causing a smaller shear stress (given a certain velocity). In CUR/CIRIA (1991) an expression by Swart is given to describe the relation of Figure 2b:

$$f_w = \exp[-6 + 5.2 \left(\frac{a_b}{k_s}\right)^{-0.194}] \quad (f_{w \max} = 0.3) \quad (3)$$

For the stability relation between shear stress and stone dimensions, the critical Shields parameter, as adapted by Sleath (1978) for turbulent flow is:

$$\frac{\hat{\tau}_b}{(\rho_s - \rho_w) \cdot g \cdot d} = 0.056 \quad (4)$$

$d$  is the equivalent spherical diameter, in this paper approximated with  $d_{50}$ , the median sieve diameter, which is easily available and differs only a few percent from the spherical diameter. Equation (4) is partly based on experimental data by Rance & Warren (1968) from experiments in an oscillating flow tunnel. In this research, their results are, as an alternative for equation, (1), (3) and (4), described with:

$$\frac{a_b}{T^2 \Delta g} = 0.025 \left[\frac{a_b}{d}\right]^{-\frac{2}{3}} \quad (5)$$

In breaking waves, for the time being, the same mechanism is assumed to work. But due to a complete change in the velocity field and the turbulence in a breaking or broken wave, it can be expected that some amplification factor on the computational results has to be applied to fit experimental data.

### 3. EXPERIMENTS

#### Set up

Experiments were done in a wave tank (length 40 m, width 0.8 m, depth 0.9 m) at the Laboratory of Fluid Mechanics at Delft University of Technology (DUT). On the concrete surface of a slope 1:25, stones were laid with dimensions ranging from  $d_{50} = 7$  mm to 17 mm and densities ranging from 2400 to 2900 kg/m<sup>3</sup>. The width of the sieve curves of the stones ( $d_{85}/d_{15}$ ) used in the experiments was about 1.5. 3 to 4 layers of stone were used, in order to ascertain a proper roughness between

the stones and the slope. The difference with the geometry of a real pipeline cover, which has a filter layer under the top layer, is assumed to be negligible with respect to stability of the top layer.

The stones were laid in coloured strips of 0.2 m (in the wave direction) over the full width of the flume. By counting the number of stones displaced,  $n$ , after every test, the damage  $S$  was determined as a percentage of the total number of stones available in a strip:  $S = n * d_{s0}^2 / A$  (%). For every strip a relation between  $n$  and the wave height at the toe of the slope was established and from these curves, the level  $S = 0.5$  % was arbitrarily chosen as incipient motion.

The maximum number of waves in regular wave tests was 750. Irregular waves were generated according to a JONSWAP-spectrum; the number of waves was 2000 in irregular wave tests. The wave heights and spectra were determined at the toe of the slope. The water depth at that location varied from 0.7 m for regular waves to 0.6 m for irregular waves.

#### Scale effects

The flume in the laboratory is considered as a physical reality in itself, not as a model of some prototype with a scale 1:X. Computations are made for that reality and compared with the experimental results. However, in the end, the relations thus found have to be used for prototype circumstances. This is permissible only if no scale effects are present in the relations. Sources of scale effects in small flumes using water as a fluid, can be the viscosity of the water, the surface stress and air entrainment in breaking waves.

To avoid viscosity effects, the particle **Re**-number in the Shields-graph ( $u_* d / \nu$ ), should be more than about 600, indicating that the flow around the stones is turbulent. The minimum stone size of 7 mm was chosen to meet this demand.

Stive (1985) investigated the scale effects in breaking waves on a 1:40 slope and found no significant scale effects in wave heights and velocities on the slope for a wave height range from 0.1 to 1.5 m. The wave heights in the authors' experiments ranged from 0.1 m to 0.35 m.

## 4. COMPUTATIONS

Orbital velocities were computed with the linear wave theory. Although the circumstances on the slope are beyond the validity-range of this theory, LeMéhauté (1968) already showed that for orbital velocities at the bottom, the theory predicts measured values quite well. Figure 3 shows for various locations along the slope and wave steepnesses,  $s$ , in the authors' experiments, the comparison between

**Figure 3** Comparison computed and measured orbital velocities in DUT wave flume

computed and measured maximum orbital velocities at the bottom. The measured values are in the upslope direction, since it appeared from the experiments that the first movement of the stones is in upslope direction. The agreement between computed and measured values is remarkably good.

The wave heights on the slope were determined, applying the shoaling coefficient:

$$K_{sh} = \frac{1}{\sqrt{\tanh kh \left[ 1 + \frac{2kh}{\sinh 2kh} \right]}} \tag{6}$$

The water depth at the toe of the slope in the flume cannot be considered as deep water. Hence the local wave height is computed as:

$$H_L = K_{sh,L} * H_0 = K_{sh,L} * \frac{H_{Toe}}{K_{sh,Toe}} \tag{7}$$

For irregular waves the same procedure is followed, now with respect to a significant wave height,  $H_s$ , and a peak period of the wave spectrum,  $T_p$ .

Tests were done with various stone sizes. For each water depth along the slope, the (local) wave height for the threshold of motion for the stone dimensions in a certain test, and the corresponding wave height at the toe of the slope were determined with the above mentioned relations and compared with the measurements.

5. NON-BREAKING REGULAR WAVES

Figure 4 Wave height at toe of slope for incipient motion with constant T

Figure 5 Wave height at toe of slope for incipient motion with constant  $s = 3\%$

Figure 4 shows the results for constant wave period (2 s and 3.5 s). The differences between the computation according to Jonsson/Sleath and Rance & Warren are small. The agreement for  $T = 2$  s is quite good. For  $T = 3.5$  s there is a deviation for water depths around 0.3 m. The wave steepness for which the threshold of

motion was determined was 1 % or less, and the corresponding wave appeared to be unstable in the flume: the waves fell apart into two separate waves. Figure 5 shows the stability for a constant steepness,  $s_r = H_r/1.56 \cdot T^2 = 3 \%$  and various stone sizes and densities. The difference between Jonsson/Sleath and Rance & Warren is again small for the smaller stones in relatively deep water. For larger stones the difference increases. This is caused by the fact that a large stone diameter gives a large friction coefficient,  $f_w$ , which is computed iteratively in Jonsson/Sleath.

In general it can be said that the assumed mechanism describes reasonably well the experimental results. In the following, all computations have been done with the method of Rance & Warren, being simpler than that of Jonsson/Sleath while the differences are small.

## 6. NON-BREAKING IRREGULAR WAVES

The stability mechanism in irregular waves does not differ from that in regular waves, but it is obvious that the higher waves cause the damage. In this research, the irregular wave field is described with a significant wave height and the peak period of the wave spectrum. From a first comparison between the results for regular and irregular waves, it appeared that, for incipient motion, in regular waves the wave height was about 50% higher than the significant wave height in irregular waves. Taking the Rayleigh-distribution as basis for the wave height distribution, this would mean that the 1% highest waves are responsible for the incipient motion ( $H_{1\%} \approx 1.5H_s$ ). In shallow water, the wave height distribution is going to deviate from the Rayleigh-distribution. An expression for this deviation is given by Stive, see CUR/CIRIA (1991). This expression is, however, independent of the wave period, while in the experiments the difference between regular and irregular waves was larger for lower wave steepness.

A magnifying factor for the significant wave height,  $K_I$ , is now defined with a lower limit 1 and an upper limit depending on the water depth and the wave period:

$$H_{ML} = K_I * H_{SL} = \left[ 1 + \text{Constant} * \tanh \left( \frac{H_M}{H_{S0}} \right) \right] * H_{SL} \quad (8)$$

$$= \left[ 1 + \text{Constant} * \tanh \left( \frac{0.14 * L * \tanh(kh)}{H_{S0}} \right) \right] * H_{SL}$$

$H_M$ , is the breaker height according to Miche, see CUR/CIRIA (1991). For the constant in  $K_I$ , a value 0.6 was chosen. The result is a magnifying factor for  $H_{SL}$  along the slope between 1 and 1.6 depending on the depth and the wave steepness.

**Figure 6** Regular non-breaking waves,  $\Delta = 1.7$

**Figure 7** Regular non-breaking waves,  $\Delta = 1.4$

**Figure 8** Regular non-breaking waves,  $\Delta = 1.9$

Figure 6, Figure 7 and Figure 8 show the results for non-breaking irregular waves. It appears that for all stone densities investigated, the computations follow the trend

of the experiments rather well; the influence of the wave steepness, however, is underestimated. The constant (0.6) in  $K_1$  was chosen such that it fitted the experimental results for irregular waves with  $s = 1\%$ , being a practical lower limit for irregular waves. It appears that the representation of an irregular wave field with  $H_s$  and  $T_p$ , as used in shoaling computations, combined with the proposed magnifying factor,  $K_1$ , is too simple to describe correctly the whole process. For this first round, however, this is taken for granted, since the trend is indicated quite well and the final values to be used in the design rule are on the conservative side.

Note: The use of  $H_M$ , the local breakerheight according to Miche, seems somewhat peculiar in a formula for non-breaking waves. This is however deemed acceptable because, in an irregular wave field, there is a very gradual transition from non-breaking to breaking, while the mechanism at the point of breaking is not necessarily completely different. Moreover, the use of  $K_1$ , including  $H_M$ , has no other pretention than being a sensible way of curve-fitting.

## 7. BREAKING REGULAR WAVES

The assumed mechanism for the stability in breaking waves is again the shear stress under a wave. Starting with a given wave at the toe of the slope, the local wave parameters are computed and from these the stone diameter needed.

Figure 9 Computation of stone diameter in breaking wave

Figure 9 shows the computed wave heights due to shoaling and the breaker height according to Miche. The maximum of these two is used in the computation of the diameter, yielding a maximum value along the slope. It can be expected that this procedure will underestimate the necessary diameter, since the shape of the wave, the velocity field and the turbulence in a breaking or broken wave are unfavourable compared with non-breaking waves. Therefore, a second tuning parameter,  $K_B$ , comes in:

$$d_{\text{Breaking}} = K_B * d_{\text{Non-Breaking}} \quad (9)$$

The diameter that finally results from this procedure is taken as the diameter in breaking regular waves.

**Figure 10** Comparison measured and calibrated values for regular breaking waves

Figure 10 gives the results of the comparison between computation and experiment, in which the above mentioned procedure was performed in a reversed order and iteratively (starting with a given diameter, which is the case in a flume experiment, computing the local wave height for incipient motion and hence the wave height at the toe of the slope).  $K_B = 2$  is used in the figure, giving the best fit.

Here again it can be seen that a larger wave steepness leads to a more stable situation (larger wave height for incipient motion, see Figure 10). This can also be explained from the way of breaking of the waves. According to the common classification, all these waves belong to the spilling type ( $\xi < 0.4$ , see Battjes (1974)). There is, however, a gradual change in breaking characteristics and the lower the steepness of the waves in the experiments, the more they showed a

plunging behaviour. In a plunging breaker the bottom is attacked by a jet, giving a more unfavourable situation compared to a "real" spilling breaker. The energy dissipation in a plunging breaker is more concentrated than in a spilling breaker, see Figure 11.

Figure 11 Energy dissipation in spilling and plunging breakers

### 8. BREAKING IRREGULAR WAVES

With a magnifying factor,  $K_i$ , for the irregularity of the waves and an amplification factor,  $K_B$ , to take the effect of breaking into account, the stability in breaking irregular waves is computed and the results are given in Figure 12.

Figure 12 Comparison computed and measured values for irregular breaking waves

In this figure the stability is expressed as  $H_{S0} / \Delta d_{n50}$  in order to compare it with the stability of rock on breakwaters or revetments.  $H_{S0}$  is a fictitious deep water wave

height, derived from equation (7) in order to have an unambiguously defined wave height. The nominal diameter ( $d_{n50}$ ) is used instead of the sieve diameter because this is a more practical measure for large stones. The relation between  $d$  and  $d_n$  can be taken as an average for normal rock, see CUR/CIRIA (1991):  $d_n = 0.84*d$ .

From Figure 12 the following can be seen:

- The dimensionless parameter  $H/\Delta d$ , computed according to the procedure outlined above, still shows variation with  $\Delta$ . This means that either the mechanism assumed in the computation is not correct or the use of this dimensionless parameter is not allowed.
- The rather scarce data do not fit very well with the computations.
- Typical values of  $H/\Delta d$  for a wave steepness of 3 %, lie around 6 compared to 2 for revetments with steep slopes.

For the time being, the lower limit of the experimental results is taken as a conservative approach for a provisional design rule:

$$\frac{H_{s0}}{\Delta d_{n50}} = 4.5 + 50 * s_0 \quad (10)$$

The tendency of this result is conformable to van der Meer's equation for stability on steep slopes, see van der Meer (1988). For a given slope angle, van der Meer's equation for plunging breakers gives an increasing stability number  $H/\Delta d$  for an increasing wave steepness or a decreasing  $\xi$ . In Figure 13 both relations are given for a slope angle 1:25 (this is far beyond the range for which the van der Meer equations are valid, but it is just to show the mentioned tendency).

Figure 13 Comparison experimental results with van der Meer's equation

## 9. DESIGN RULE

The proposed design rule is now to be applied as follows:

- Start with the significant deep water wave height ( $H_{s0}$ ), measured or from equation (7) and a wave height measured at any relatively deep water location
- Compute the shoaling of  $H_{s0}$  along the slope with equation (6) using the peak period of the spectrum,  $T_p$
- Determine  $H_{ML}$  along the slope with equation (8)
- Compute the necessary diameter along the slope with equation (2) and (5)
- Compute the maximum diameter with equation (10)

Figure 14 gives the result for  $H_{s0} = 5$  m,  $T_p = 10$  s and  $\Delta = 1.65$ .

Figure 14 Design example

### NOTES:

- 1 Equation (10) expresses the stability as a function of the wave steepness,  $s$ . Since the stability is closely related to breaking, it would be more appropriate to relate the stability parameter  $H/\Delta d$  to the breaking parameter  $\xi$ . Only one slope was investigated (1:25). Using  $s$  instead of  $\xi$  is on the safe side for all slopes milder than 1:25, since a milder slope yields lower  $\xi$ -values leading to a more stable situation.
- 2 In the figure some limits of stone classes are given, which are common in the Netherlands. These are not essential, but are presented to show that for a practical case, a choice has to be made from material available.

## 10. RECOMMENDATIONS

The design rule, presented in the previous section, is the best approach available at the moment for stability of rock on mild slopes. Conservative choices had to be made; improvements are possible. Therefore the following is needed:

- A more complete description of the velocities and shear stresses on the slope in irregular waves. This can probably be obtained with a model that describes the behaviour of irregular waves on a slope, including bottom friction and breaking, see e.g. van der Meer (1990).
- A physical description of the breaker zone itself with a model that includes the shape of the waves, the velocity field and the turbulence. This could give more and better information on the attack on the slope than is possible with the orbital movement according to the linear wave theory.
- More systematic experimental data on stability in breaking waves, including other slope angles. In doing so, also an attempt can be made to make a better link between the relations in Figure 13, giving a complete picture of stability of rock on mild and steep slopes.

## CHAPTER 113

### Short Term Wave Overtopping Rate of Block Armored Seawall

Tsunehiro Sekimoto\* Hiroshi Kunisu\* and Tsuyoshi Yamazaki\*

#### Abstract

The characteristics of short term over topping rate for a deepsea block armored seawall are investigated experimentally. Two series of experiments were conducted. One is a series that seawall has low crown height and a wave grouping effect is investigated. Another experiment is a series that it has a high crown height and slope effect of armor unit is studied. From these experiments, we have to consider the short term wave overtopping rate for the design of drainage facilities of deepsea structure such as an artificial island.

#### Introduction

Recently, Many ideas of offshore artificial island have been planning in Japan and many studies on a design method for deepsea seawall or deepsea breakwater have been started. In a concerning research, it is pointed out that excess wave overtopping maybe lead artificial island to ruin. Therefore it is very important in the construction of artificial island to estimate accurately of overtopping rate of seawall.

Usually, In order to estimate the wave overtopping rate, the Goda's diagrams (Goda, 1987) are used. This diagram illustrates the relationship between a mean overtopping and a crown height. It has been pointed out that short term overtopping rate is important for the design of drainage facilities behind the seawall (Kimura and Seyama, 1984). Moreover it is suggested that the short term overtopping rate become several ten times of mean wave overtopping rate and large amount of water comes into the drainage facilities in short time (Inoue et al., 1989).

---

\* Penta-Ocean Construction Institute of Technology, 1534-1 Yonku-cho Nishinasuno-machi Nasu-gun Tochigi 329-27 Japan

However, Goda's diagram is illustrated only for the time average of total overtopping quantity and this diagram dose not include an effect on the slope of block armor unit. In this study, we study the characteristics of short term wave overtopping rate on the block armored seawall experimentally.

**Experiments**

Experiments were conducted by using the wave flume with dimension of 0.6m in width, which is partly divided from a wave basin of 5m in wide, 34m in length and 1.2m in depth. At an end of basin, rubbles banked in 1: 5 slope in order to reduce reflected waves. The wave flume shows in Figure 1. Model seawall were set up in the flume.

Two series of experiments for the wave overtopping were carried out. In these experiments, it is supposed that a prototype water depth in front of the seawall is 22.5m. Considering the wave flume dimensions, the model scale of series one and two are assumed to 1/85.7 and 1/87.5 respectively.

One of two experiments is a series that seawall has low crown height and a wave grouping effect is investigated. A typical model section in Series-one is shown in Figure 2. Both a vertical and a block armored seawall are used in this series. The water depth in front of a model seawall was 26.3 cm. Sea bed slope in front of a model seawall is 1/100. The tetrapods (58.9g) were used as armored blocks and the same size blocks

Figure 1 Experimental setup.

were used in all section. A crown height was 10.5 cm. It is 9m in prototype scale and the slope of armor units is 1:4/3.

Figure 2 Typical model seawall (for series 1)

Irregular waves which have Wallops type spectrum were act on model seawall.

Wallops type wave spectrum is shown below.

$$S(f) = \beta H_{1/3}^2 T_p (T_p f)^{-m} \exp \left[ -\frac{m}{4} (T_p f)^4 \right] \quad (1)$$

$$\beta \equiv \frac{0.6238 m^{(m-2)/4}}{4^{(m-5)/4} \Gamma[(m-1)/4]} \left[ 1 + 0.7458(m+2)^{-1.057} \right] \quad (2)$$

$$T_p \equiv T_{1/3} / \left[ 1 - 0.283(m-1.5)^{-0.684} \right] \quad (3)$$

where  $m$  : Spectral shape factor,  $H_{1/3}$  : Significant wave height,  $T_{1/3}$  : Significant wave period,  $T_p$  : Peak wave period,  $\Gamma()$  : Gamma function.

The shape factor  $m$  become small, the bandwidth of wave spectrum becomes narrow, while the  $m$  is large, the band widths of wave spectra become wide. In the case that  $m$  is 5, Wallops type wave spectrum corresponds to Modified Bretschneider-Mitsuyasu type wave spectrum modified by Goda.

The experimental cases were shown in Table 1. In this series, 24 runs of experiment were conducted. The three types of spectral shape factor  $m= 3, 5$  and  $9$  were selected. The wave period was 1.73 second and

five kinds of wave height were used. The wave height normalized by the crown height were changed from 0.65 to 1.42.

	0.730	○				
	0.821	○	○	○	○	○
	0.913	○	○	○	○	○

Another experiment is a series that it has a high crown height and slope effect of armor unit is studied. Assuming an actual wave overtopping condition, the mean wave overtopping rate set below  $0.05\text{m}^3/\text{m}/\text{s}$  in prototype scale in the condition that the significant wave height normalized by crown height is 0.684, and significant wave period is 16s in this series. The crown height was 16 cm in experimental scale (it is 14m in prototype scale). Therefore these experiments were conducted under the relatively high crown height and low wave overtopping rate condition. The slopes of armor units which were used in the experiment were 1:4/3, 1:1.6, 1:1.8, 1:2.0 and 1:2.5. The tetrapods (36.8g) were used as armored blocks and the same size of block was used in all section. The Wallops type wave spectra were also used in this series. In this series, the shape factor of incident wave spectra is selected  $m = 5$ . The wave heights normalized by the crown height were changed from 0.46 to 0.91 and three wave periods 1.28s, 1.71s and 2.14s in experimental scale were used, which were 12s, 16s and 20s second in prototype scale respectively. Experimental condition is shown in Table 2. Eighty-four runs of experiments were conducted.

#### Short term over topping rate measurement.

In order to get the short term overtopping rate, a time dependent weight of water was measured using the measurement apparatus which was used by Sekimoto et al. (1994). This apparatus is consist of a water tank which was supported by four load-cells and was set just behind the seawall. The instantaneous wave over topping rate was defined as a change rate of water weight per unit time.

We defined a maximum wave overtopping rate as a maximum value of moving average of instantaneous overtopping rate over a time interval as shown below. The duration of average is to be  $n$  times significant wave period, where  $n$  is 1,3 and 5 in this study. Using this instrument, the short term wave overtopping rate can be measured accurately (Sekimoto et al., 1994).

$$q_n(t) = \frac{1}{nT_{1/3}} \int_{-nT_{1/3}/2}^{nT_{1/3}/2} q_i(t + \tau) d\tau \quad , n = 1, 3, 5 \quad (4)$$

$$q_{n-\max} = \text{Max}[q_n(t)] \quad (5)$$

where,  $q_i(t)$  : Instantaneous wave overtopping quantity,  $q_n(t)$  :  $n$ -waves mean overtopping rate,  $q_{n-\max}$  :  $n$ -waves maximum overtopping rate (short term wave overtopping rate),  $T_{1/3}$  : Significant wave period.

Figure 3 The relationship between spectral shape factor  $m$  and groupiness factor.

Results

Figure 3 shows the relationship between spectral shape factor  $m$  and groupiness factor. There is no clear relationship in both. In the case of high wave height, wave breaking is occurred and groupiness factor is relatively small.

In Figure 4, the mean wave overtopping rate normalized by wave height is plotted against the spectral shape factor  $m$ . In this figure, the wave height is measured on the position of seawall in the condition that the model seawall dose not set up. On the left hand side of this figure, the results of vertical wall type seawall are shown and on the right hand side the results of block armored seawall are shown. The mean wave overtopping rate have tendency of increase while spectral band width become narrow. However, this tendency is not so strong.

Figure 4 The relationship between the mean wave overtopping rate and the spectral shape factor.

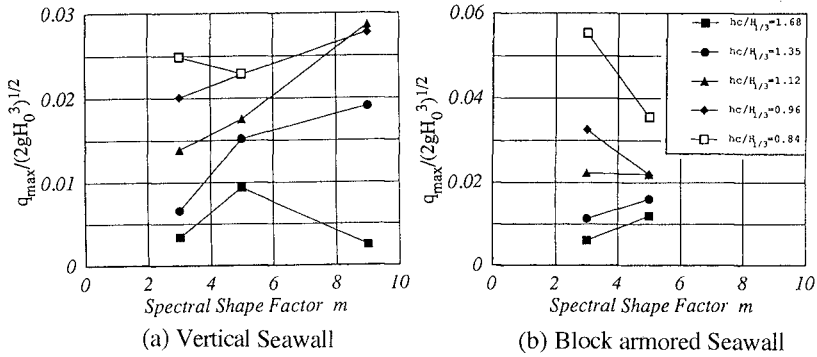

Figure 5 The relationship between the maximum wave overtopping rate and the spectral shape factor.

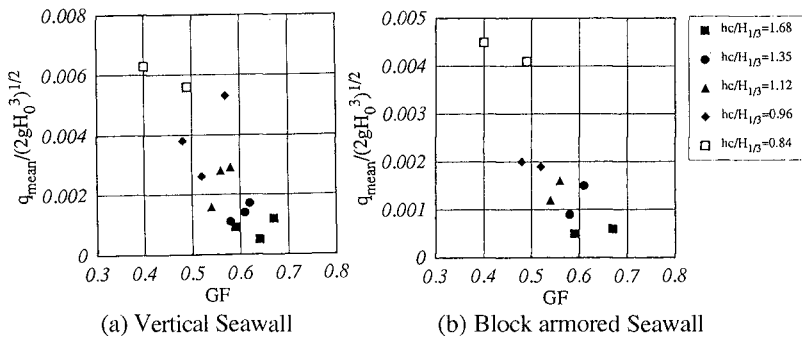

Figure 6 The relationship between the mean wave overtopping rate and the groupiness factor.

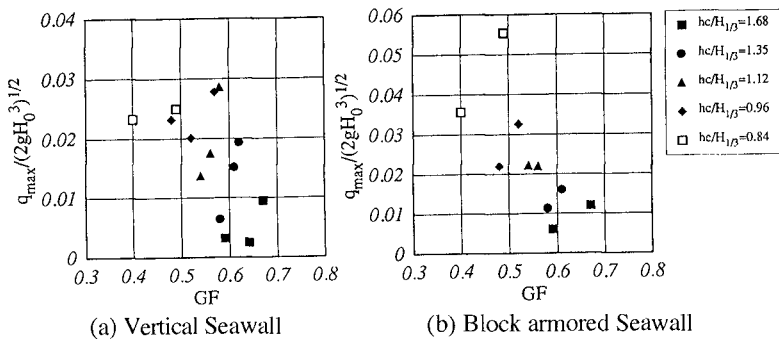

Figure 7 The relationship between the maximum wave overtopping rate and the groupiness factor.

Figure 5 shows the maximum wave overtopping rate in the same manner as Figure 4. The maximum wave overtopping seems depends on the shape factor except for the case of high waves. In the case of high wave height, wave breaking effect may be appeared.

The relationship between wave-overtopping rate and groupiness factor is compared in Figure 6 and Figure 7. On the left hand side of this figure, the results of vertical wall type seawall are shown and on the right hand side the results of block armored seawall are shown. The results show the strong relationship between both is available. In the case of the same wave height, the wave overtopping also increase as the wave groupiness increase.

We also compared the maximum wave height in a wave train with wave overtopping rate. The maximum wave height in this figure is measured at the location of model seawall before the model seawall was set up. The left-hand side and right-hand side of this figure are indicated in the same manner as previous figures.

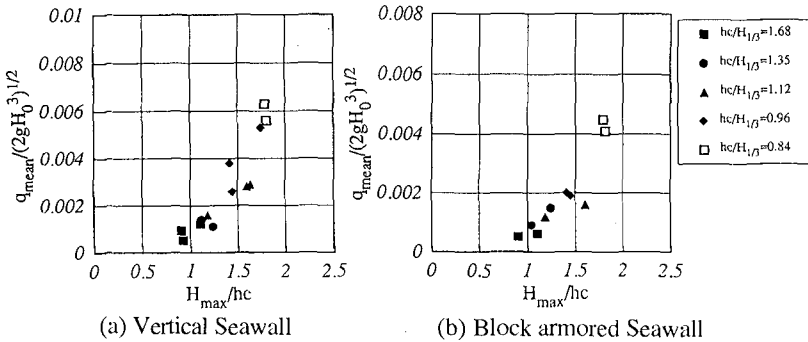

Figure 8 The relationship between the mean wave overtopping rate and the maximum wave height.

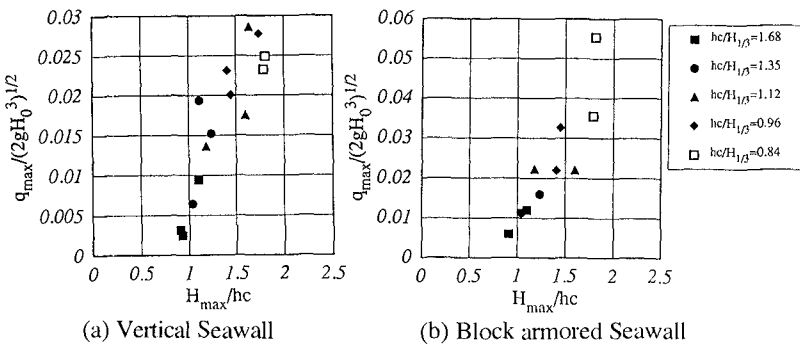

Figure 9 The relationship between the maximum wave overtopping rate and the maximum wave height.

Figure 8 shows the case of mean wave overtopping rate. The mean wave overtopping rate has one to one correspond to maximum wave height. In the results of maximum wave overtopping rate (Figure 9), we can clearly see the same relationship. This relationship is very natural and shows that once we know the maximum wave height in front of seawall, we can accurately estimate the wave overtopping rate not only the mean overtopping rate but also the short term wave overtopping rate.

Next, we investigated the slope effect on the wave over topping.

The relationship between the mean wave overtopping rate and an inverse of the slope in each wave period had investigated by Sekimoto et al. (1994). According to this study, the tendency of these relationships is similar to the results of Saville's runup experiment(1952). That is the mean overtopping rate is small when the slope is steep. As the slope becomes mild, the mean overtopping rate becomes large. The slope further becomes mild, the mean overtopping rate decreases.

This reason can be accounted for the wave deformation on the slope of blocks. In the case of steep slope, wave deformation does not occur on the slope because of the short slope length. As the slope becomes mild, the wave height increases due to wave shoaling. In the case that slope is further mild, the wave energy is dissipated due to the wave breaking on the slope and the energy loss in the armor units. In the case that the same wave act on the seawall, the mean overtopping rate has not same volume when the slope of armor units is not same. Especially in the case of the 1: 1.8 slope, the mean overtopping rate was seven times as large as that in the case of the 1: 2.5 slope.

We investigated the relationship between the maximum wave overtopping rate and the slope of armor unit in Figure 10. In this figure, the wave overtopping rate was indicated in prototype scale. The almost same relationship to the mean wave overtopping rate is available in this figure. However, the maximum wave overtopping rate is more variable quantity than the mean wave overtopping rate, in the sense of statistics.

Figure 10 The relationship between the maximum wave overtopping rate and the slope of armor unit.

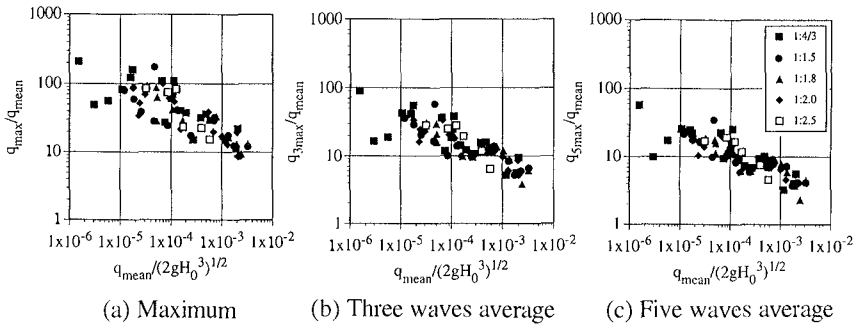

Figure 11 The relationship between the short term wave overtopping rate and the mean wave overtopping rate.

Therefore the maximum wave overtopping rate shows more complicated feature than mean wave overtopping rate.

Figure 11 shows the relationship between the short term wave overtopping rate and the mean wave overtopping rate. In this figure, vertical axis is the ratio of short term overtopping rate to the mean wave overtopping rate and horizontal axis is taken normalized mean wave overtopping rate. Three types of short term wave overtopping rate were taken in these figures. The  $q_{max}$  means the maximum wave overtopping rate which is the maximum value of the average of wave overtopping quantities during one wave. The  $q_{3max}$  means the maximum value of the average of wave overtopping quantities during three waves. The  $q_{5max}$  means during five waves.

From this figure, we find that the ratio becomes large as the mean wave overtopping rate becomes small. The maximum wave overtopping rate shows 10 to 170 times the mean wave overtopping rate. The maximum overtopping rate during three waves shows 5 to 100 times the mean wave overtopping ratio. The maximum overtopping rate during five waves indicated 3 to 50 times.

It shows that the large amount of water flows over seawall in short time and we have to consider short term wave overtopping in the design of drainage facilities just behind the seawall.

Figure 12 shows the relationship between the short term wave overtopping rates against the mean wave overtopping rate. The data of maximum overtopping rate during three waves were distributed from 0.333 to 0.8 times the maximum wave overtopping rate. In the case of maximum overtopping rate during five waves, it becomes from 0.2 to 0.5. It is natural that scattering of this ratio become small when the duration time for average is large. In the case of small rate of wave overtopping, the number of overtopped waves including the wave by which the maximum wave overtopping rate was occurred is only one. In the case of large rate of

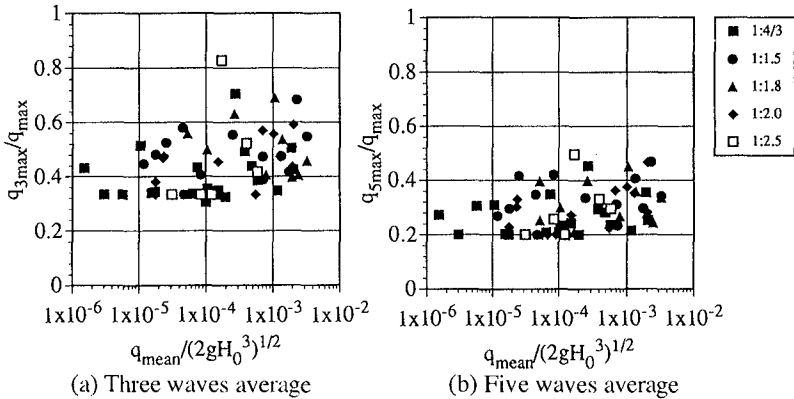

Figure 12 The relationship between the short term wave overtopping rates against the mean wave overtopping rate.

wave overtopping, the number of overtopped waves including the wave when the maximum wave overtopping rate was occurred is one to three.

## Conclusions

The main results obtained from this study were shown below.

(1) The mean wave overtopping rate is not so affected by the spectral band width in this experiment.

(2) The short term wave overtopping rate is affected by the spectral band width, except for the case that the wave breaking obviously occurred.

(3) The wave overtopping rate strongly related to the Groupiness Factor.

(4) The wave periods become longer, the short term wave overtopping rate become larger.

These results were similar to the case of mean overtopping rate.

(5) The maximum wave overtopping quantity, which is defined as the maximum value of wave overtopping for one wave, becomes more than 100 times of the mean wave overtopping rate in the case of high crown height. In the design of drainage facilities, it has to be considered that huge amount of water flows in short time.

(6) The mean overtopping rate and the maximum wave overtopping rate were clearly affected by the slope of block armor unit. This is a same tendency of previous experiments of Saville's wave run-up on composite slopes. The slope effect in the wave overtopping has to be considered in design of sea wall.

## CHAPTER 114

### Estimating the Sliding Distance of Composite Breakwaters due to Wave Forces Inclusive of Impulsive Forces

Kenichiro Shimosako<sup>1</sup>, Shigeo Takahashi<sup>2</sup>, Katsutoshi Tanimoto<sup>3</sup>

#### Abstract

Estimating the sliding distance is essential in the future probabilistic design of caisson breakwaters. In this paper, characteristics of the sliding phenomena are described, and a method based on the equivalent sliding forces to calculate the sliding distance is proposed. This calculation method is applicable for both impulsive and ordinary wave forces considering the shear force at the bottom of the caisson.

#### 1. Introduction

Composite type breakwaters consisting of a rubble mound foundation and upright section have several advantages over conventional rubble mound breakwaters, since they are more stable, can be constructed faster and easier, and also reduce wave transmission.

In the conventional design process of a composite breakwater, the sliding stability of the caisson is evaluated by the sliding safety factor (S.F.). However, even if the S.F. is below 1.0, the breakwater can still maintain its function if the sliding distance is small. Consequently, to ensure economical design, it is necessary to determine the expected sliding distance occurring in the return period of the caisson.

Ito, Fujishima, and Kitatani (1966) conducted the research on the stability of breakwaters and proposed the concept of the expected sliding distance. Horikawa, Ozawa, and Takahashi (1972) also discussed the expected sliding distance of high mound composite breakwater. However, it was difficult to estimate the wave pressure precisely, much more the sliding distance at that time.

Tanimoto, Kimura, and Miyazaki (1988) calculated the sliding distance based on the fourth order finite standing wave theory. This calculation is applicable for non-breaking wave conditions in deepwater area.

Goda (1974) developed a new wave pressure formula which included an impulsive pressure. This formula is quite useful and has become the standard method to obtain wave pressure against a vertical wall, although discrepancies arise under some impulsive pressure conditions. Takahashi, Tanimoto and Shimosako (1993, 1994b) proposed an impulsive pressure coefficient obtained by a re-analysis of the results of comprehensive sliding tests, which is introduced into the Goda pressure formula.

Takayama and Fujii (1991) carried out the probabilistic estimation of stability of sliding which considered the probabilistic property of wave height, wave pressure and friction coefficient between caissons and rubble mound. However, caisson's sliding distance was not included.

In order to estimate the caisson's sliding distance, the complex phenomena including the dynamic response of a breakwater caisson due to impulsive wave forces must be quantified. In the present study, model experiments with some non-linear FEM calculations to elucidate the characteristics of the dynamic response are described. A method is proposed to calculate the sliding distance, which is applicable for both impulsive and ordinary wave forces considering the shear force.

## 2. Present Design Method and Formulation of Caisson's Sliding

### Present Design Method

The design wave forces acting on the caisson's upright section can be obtained using the Goda pressure formula. The present design method for determining the sliding stability is shown as follows:

$$S.F. = \mu(W' - U) / P \quad (1)$$

The safety factor for sliding  $S.F.$  is represented by the ratio of the friction resistance  $\mu(W' - U)$  to the horizontal wave force  $P$ , where  $\mu$  is the friction coefficient between the caisson and rubble mound,  $W'$  is the caisson weight in water, and  $U$  is the uplift force. When  $S.F.$  is less than 1.0, the caisson is considered to be in an unstable condition. However, even if  $S.F.$  is less than 1.0, the breakwater can still maintain its function providing the sliding distance is small.

In order to optimize the design from an economical standpoint, we must determine the expected sliding distance occurring in the return period of the caisson. However, the sliding distance cannot be estimated using the present design method.

Equation of Motion of Caisson

Figure 1 shows the forces that act on the caisson when it is sliding.  $M_a$  is the added mass,  $F_R$  is the frictional resistance force, and  $F_D$  is the force related sliding velocity including the wave-making resistance force.

The equation of motion representing caisson sliding is presented as follows:

$$(W/g + M_a) \ddot{x} = P - F_R - F_D \tag{2}$$

where

$$F_R = \mu(W' - U) \tag{3}$$

In Eq.(2),  $P$  represents horizontal wave force, but the effective force producing caisson's sliding, that is the shear force at the caisson bottom,  $F_T$ , should be used instead of  $P$  in order to include the effect of dynamic response of caisson. Although the magnitude of impulsive pressure intensity is quite large, the shear force is greatly reduced due to the caisson's dynamic response which is discussed later. If wave pressure is not impulsive, the shear force is equal to the horizontal wave force.

Figure 1 Forces acting on the caisson in sliding.

In our simplified sliding model, it is assumed that  $\mu$  is constant before and during sliding, and that  $M_a$  and  $F_D$  are small enough to be neglected. Consequently, Eq.(2) is rewritten as follows:

$$(W/g)\ddot{x} = F_T + \mu U - \mu W' \quad (4)$$

### Caisson's Dynamic Response due to Impulsive Wave Forces

The magnitude of impulsive pressure intensity is quite large, being several times that of ordinary wave pressure. However, the shear force at the caisson bottom, which is the effective pressure producing caisson sliding, is greatly reduced due to the caisson's dynamic response. Figure 2a shows the experimentally determined impulsive wave force  $P$ , inertia force  $m\ddot{x}_G$ , shear force  $F_T$ , and displacement  $x_G$ , where the peak shear force is about 80% of the peak impulsive force. The ratio of the peak shear force to the peak impulsive force varies according to the peak value and duration time of  $P$ . Note that the stability of the sliding is not dependent on  $P$  itself, but instead on  $F_T$ .

To reproduce the dynamic response of the caisson, we adopted a FEM calculation method named "the Bank Earthquake Analysis with Dynamic Water Pressure (BEAD)" (Uwabe, 1983). One advantage of the BEAD method is that it takes into account the pore water in the seabed and the surrounding water of the caisson. The equations utilized are a kind of Biot's equations. The BEAD program can simulate the behavior of the caisson, as well as that of the rubble mound and soil bed. The input data consists of the shear modulus, the Poisson ratio, and the permeability of the rubble mound and soil bed, as well as the input force on

Figure 2a Experimental caisson response.

Figure 2b. Calculated caisson response.

the caisson. At each time step in the simulation, the acceleration, velocity, displacement, stress, and strain are evaluated. Figure 2b shows the corresponding FEM-calculated results using the same impulsive wave force, where good agreement is present with experimental results. (Takahashi, Tanimoto, and Shimosako, 1994a)

In actuality, sand bed and rubble mound are relatively soft in comparison with those of the model, and therefore, the dynamic response is much more significant. For instance, when applying the same impulsive force profile, the FEM-calculated ratio of the peak shear force to peak impulsive force under field conditions is about 40%, whereas about 75% in the 1/20 scale model.

#### Calculation Method of the Sliding Distance

The sliding distance of the caisson can be calculated by integrating the acceleration twice. Figure 3 shows the acceleration  $\ddot{x}$ , velocity  $\dot{x}$ , and displacement  $x$  over time.  $x$  can be calculated from Eq.(4) if the shear force  $F_T$ , uplift force  $U$ , friction coefficient  $\mu$ , caisson weight in water  $W'$  and in the air  $W$  are known. In the proposed model, we defined the equivalent sliding wave force  $F_s$  as follows:

$$F_s = F_T + \mu U \quad (5)$$

The time series of  $F_s(t)$  is considered to be a triangular pulse having a duration of  $\tau_0$ , which becomes smaller as the wave force increases. Figure 4 shows the time-dependent mathematical model used to simulate caisson displacement, where  $F_s(t)$  is defined as follows:

$$F_s(t) = \begin{cases} (2t/\tau_0) F_{Smax} & (0 \leq t < \tau_0/2) \\ 2(1-t/\tau_0) F_{Smax} & (\tau_0/2 \leq t < \tau_0) \\ 0 & (t \geq \tau_0) \end{cases} \quad (6)$$

Figure 3 Acceleration, velocity, and displacement of the caisson.

Figure 4 Proposed calculation model of the sliding distance.

The caisson begins to slide when  $F_s(t)$  becomes larger than  $\mu W'$ .  $S_1$  indicates the sliding distance while  $F_s(t)$  is larger than  $\mu W'$ , and  $S_2$  is that after  $F_s(t)$  becomes smaller than  $\mu W'$ . The total sliding distance  $S$  is evaluated as follows:

$$S = S_1 + S_2 = \frac{g\tau_0^2 (F_{S_{\max}} - \mu W')^3 (F_{S_{\max}} + \mu W')}{8\mu W' W' F_{S_{\max}}^2} \quad (7)$$

$F_{S_{\max}}$  can be obtained by the Goda pressure formula, but we still must determine  $\tau_0$  to evaluate  $S$ . We used theoretical analysis and model experiments to determine  $\tau_0$ . Consequently,  $\tau_0$  is represented as follows:

$$\tau_0 = k\tau_{0F} \quad (8)$$

$$k = 1/((\alpha^*)^{0.3} + 1)^2 \quad (9)$$

$$\alpha^* = \max \{ \alpha_1, \alpha_2 \} \quad (10)$$

$$\tau_{0F} = (0.5 - H/(8h))T \quad (0 \leq H/h \leq 0.8) \quad (11)$$

where  $\alpha_1$  is an impulsive pressure coefficient (Takahashi, Tanimoto and Shimosako, 1993),  $\alpha_2$  is a coefficient indicating the effect of impulsive pressure in Goda pressure formula,  $H$  is wave height,  $h$  is water depth, and  $T$  is wave period. In non-breaking wave,  $\tau_0$  is almost the same as  $\tau_{0F}$ , whereas for impulsive wave,  $\tau_0$  is 0.1~0.2 s in the model experiment. Note that  $\tau_0$  is determined based on the duration time of shear force. Actually, the duration time of impulsive pressure is much smaller than  $\tau_0$ .

### 3. Experiments

#### Experimental Procedure

Figure 5 shows a cross section of the caisson model which is made of synthetic acrylic plates and has its bottom comprised of a concrete slab that simulates the friction factor. Additional concrete blocks were placed in front of the caisson to generate impulsive wave pressures. Seven pressure transducers and a load cell are attached to the front plate to measure the applied wave pressure and force. Two acceleration meters and two displacement meters measure caisson movement. The caisson was mainly subjected to regular waves with a period  $T = 3.04$  s.

Sliding tests using both impulsive and non-breaking waves were conducted with the same caisson model and wave conditions. Based on the wave force, caisson weight was accordingly adjusted by putting lead weights inside it.

Figure 5 Cross section of the model experiment.

Sliding due to Non-breaking Wave Forces

Figure 6 shows typical recorded profiles of non-breaking wave.  $P$  is the horizontal wave force,  $U$  is the uplift force, and  $F_s$  is the equivalent sliding wave force as mentioned before.  $x_{GEXP}$  indicates the displacement of the caisson's center of gravity, while  $S_{CAL}$  is the calculated sliding distance.  $S_{CAL}$  is calculated from the measured  $F_{Smax}$  and  $\tau_0$  calculated from Eq.(8)-(11). The caisson starts to move before when  $F_s$  becomes larger than  $\mu W'$ . This is because  $x_{GEXP}$  includes the elastic displacement of rubble mound and soil bed. Actually, it is considered that the caisson starts to slide when  $F_s$  becomes larger than  $\mu W'$ , and it stops when  $x_{GEXP}$  is

Figure 6 Recorded profiles of the non-breaking wave.

Figure 7 Wave pressure distribution of the non-breaking wave.

maximum. Notice that the elastic displacement continues until  $F_s$  becomes 0. Theresidual displacement of  $x_{GEXP}$  is slightly smaller than  $S_{CAL}$ .

Figure 7 shows a typical wave pressure distribution for a non-breaking wave as measured by a model experiment. The solid lines show the design wave pressure distributions calculated by the Goda pressure formula. Note the horizontal wave pressure distribution is almost uniform, except near the top of the caisson. In addition, the measured and calculated pressures indicate good agreement.

#### Sliding due to Impulsive Wave Forces

Figure 8 shows typical profiles recorded for an impulsive wave force hitting the caisson, where  $m\ddot{x}_G$  indicates the inertia force, and  $F_T$  is the shear force ( $= P - m\ddot{x}_G$ ). The peak value of  $F_T$  is smaller than that of  $P$ , and when  $m\ddot{x}_G$  is negative peak,  $F_T$  is larger than  $P$ . Displacement begins at the same time when impulsive pressure starts, and it peaks after  $P$  becomes smaller than  $\mu W'$ . The elastic motion is found just as non-breaking wave, however, it stops before  $F_T$  becomes 0. Therefore, the caisson does not move in the wave period, but the oscillation period of it. Good agreement is present between  $S_{CAL}$  and  $x_{GEXP}$ , although the residual displacement of  $x_{GEXP}$  is slightly smaller than  $S_{CAL}$ .

Figure 8 Recorded profiles of the impulsive wave.

Figure 9 Wave pressure distribution of the impulsive wave.

Figure 9 shows a typical wave pressure distribution for an impulsive wave. The solid lines and the dotted lines are design wave pressure distributions calculated by the Goda pressure formula using and not using the "Impulsive Pressure Coefficient" respectively. Note the calculated value by the Goda pressure formula is much smaller than measured pressure. However, the shear force at the caisson bottom, which is the effective pressure producing caisson sliding, is greatly reduced due to the caisson's dynamic response as described before. The "Impulsive Pressure Coefficient" is determined based on the result of sliding experiments in order to represent the effective sliding force.

### Sliding Distance

Figure 10a compares the experimental and calculated results of sliding distance  $S$  versus the sliding safety factor  $S.F.$  for a non-breaking wave. Calculated results is obtained from the peak value of the measured equivalent sliding wave force  $F_s$  and the calculated of  $\tau_0$  (not measured  $\tau_0$ ). Note that the sliding distance increases as the sliding safety factor decreases, and also that good agreement exists between the experimental and calculated results.

In the present design method, the friction coefficient  $\mu$  is considered as 0.6. However, as  $\mu$  scatters in the experiment, the sliding distance  $S$  also scatters. Most of the experimental results are close to the calculations using  $\mu = 0.5 \sim 0.7$ .

Figure 10b shows the corresponding results for an impulsive wave. Notice it has almost the same general characteristics as the non-breaking wave. However, at the same sliding safety factor value, the sliding distance for the impulsive wave is smaller.

Figure 10a Sliding distance as a function of the sliding safety factor.  
( Non-breaking wave)

Figure 10b Sliding distance as a function of the sliding safety factor.  
( Impulsive wave)

#### 4. Estimation of Expected Sliding Distance

##### Calculation Procedure of Expected Sliding Distance

In the future breakwater designs, calculation method of expected sliding distance should be established to allow some sliding of the caisson. In that case, the proposed method should be extended to estimate the expected sliding distance.

Goda pressure formula with the impulsive pressure coefficient and the calculation model of the sliding distance can be applied as they were mentioned. In addition, all wave data during its return period are needed to calculate the expected sliding distance, and the probabilistic property of wave height, wave force, water level, friction coefficient, and caisson weight should be taken into consideration.

##### Sample Calculation

As a example, using 9-year wave data observed at a certain point, the expected sliding distance is calculated for a caisson breakwater. Figure 11 shows the cross section of the designed breakwater. The return period of the breakwater is usually 50 years, however, only 9-year observed wave data is used, and the fluctuation of wave force, friction coefficient, etc. are not considered.

Figure 12 shows the wave height distribution expressed in the form of probability density. Using the significant wave height, each wave height is reproduced according to the Rayleigh distribution. The number of waves which is larger than a certain wave height can calculate from this distribution. For instance, the number of waves which is larger than 12.1 m is 3.7, and that larger than 10.5 m is 36.3, where 12.1 m is the maximum significant wave height, and 10.5 m is the

Figure 11 Cross section of the prototype calculation.

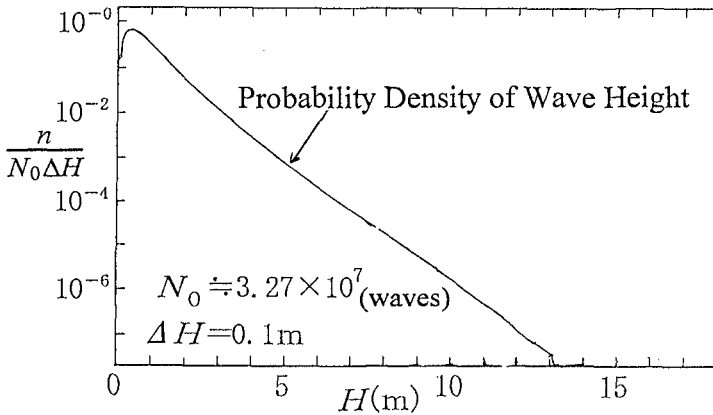

Figure 12 Probability density of wave height.

average value of the annual maximum significant wave heights for 9 years. The total number of waves during 9 years is almost 32.7 million.

Figure 13 shows the relation between wave height and sliding distance for one wave in various design wave heights. When the design wave height  $H_D = 12.1$  m and sliding safety factor  $S.F. = 1.0$ , the sliding distance at  $H = 18.0$  m is 72 cm.

The expected sliding distance for 9 years can be obtained using the sliding distance for one wave and the probability density of wave height. Figure 14 shows the relation between the design wave height and the expected sliding distance caisson for 9 years. The wave height distribution and the sliding distance for one wave are also shown in this figure. For instance, when the design wave heights  $H_D$  are 12.1 m and 10.5 m, the probable sliding distances are 0.6 cm and 45 cm, respectively.

Figure 13 Sliding distance for one wave.

Figure 14 Expected sliding distance.

**5. Concluding Remarks**

A practical method was derived to estimate the sliding distance due to wave forces including impulsive ones. In future breakwater designs, probabilistic design method should be adopted to ensure economical considerations are optimized. Subsequent research will be directed at extending the proposed sliding model to estimate the sliding distance of the caisson during its return period considering the fluctuation of wave force, friction coefficient, and caisson weight.

## CHAPTER 115

### BED SHEAR STRESS AND SCOUR AROUND COASTAL STRUCTURES

B.M. Sumer<sup>1</sup>, J. Fredsøe<sup>1</sup>, N. Christiansen<sup>1</sup> and S.B. Hansen<sup>1</sup>

#### Abstract

Two kinds of experiments were made: 1) Rigid-bed experiments and 2) erodible-bed experiments. In the former experiments, bed shear stresses were measured around three kinds of structures: 1) a vertical circular cylinder, 2) a cone-shaped structure and 3) the head of a breakwater (with and without side slopes). The results are presented in terms of amplification in the bed shear stress for the structures considered.

In the erodible-bed experiments, actual scour tests were carried out with the aforementioned structures. The results regarding the scour tests are related to the measured bed shear stress.

#### 1. Introduction

Considerable knowledge may be gained on scour around coastal structures by studying the bed shear stress on the unscoured bed, one of the hydrodynamic quantities directly related to scour.

The purpose of the present study is to investigate the bed shear stress around three kinds of coastal structures, namely a vertical pile, a cone-shaped structure and a breakwater, and to relate it to the resulting scour. The cone-shaped structure has been selected, to study the effect of side slopes on the complex vortex system responsible for scour around the structures. As regards the breakwater structure, attention is concentrated on the three-dimensional scour around the head of the breakwater.

---

<sup>1</sup> Institute of Hydrodynamics and Hydraulic Engineering (ISVA), Technical University of Denmark, 2800 Lyngby

## 2. Experiments

### 2.1. Bed-shear stress measurements

The experiments were conducted in a flume facility the size of  $26.5 \times 0.6 \times 0.8$  m. In most of the cases, the model structures were exposed to both waves and steady currents.

A two-component hot-film probe (DANTEC 55R46 spec.) was used in the experiments. The probe was flush-mounted with the rigid bed of the flume. It enabled the magnitude and the heading of the bed shear stress vector to be measured. The details about the probe and the other pertinent information have been reported elsewhere (Sumer et al., 1993).

Three kinds of structures were implemented in the tests (Fig. 1): 1) A vertical cylinder with a circular cross section (one with diameter  $D = 4$  cm and the other with  $D = 9$  cm), 2) a cone-shaped structure (one with  $\beta = 45^\circ$  side slope and the other with  $\beta = 30^\circ$  side slope; both with the same base diameter, namely  $D = 9$  cm), and finally 3) a breakwater with and without side slopes. In the case of the breakwater with side slopes, simulating a rubble-mound breakwater, the angle of the side slopes was  $45^\circ$ . The relatively high value of the side slope was due to experimental constraints. The base width of the breakwater was  $B = 3$  cm in the vertical wall breakwater case and  $B = 11.5$  cm in the rubble-mound case.

The bed shear stress measurements were supported in a few cases with velocity measurements where a one-component DANTEC Laser Doppler Anemometer was used.

Fig. 1 Structures considered in the present study. a: Vertical cylinder. b: Cone ( $\beta = 30^\circ$  and  $45^\circ$ ). C1: Vertical-wall breakwater. C2: Rubble-mound breakwater (side slope = 1:1 in the bed shear stress meas., and 1:1.5 in the scour expts.).

## 2.2. Scour experiments

The scour processes around the structures were videotaped, using an underwater mini video camera in most of the cases. These experiments were carried out in three facilities, namely in a small scale flume (the same as that used in the bed shear stress measurements) and in two medium scale flumes (one with dimensions 28 × 4 × 1 m and the other 23 × 2 × 0.5 m).

In all the wave tests, the orbital velocity of the undisturbed flow at the bottom was measured. In the current tests, the undisturbed velocity profile over the depth was measured. Similar to the bed shear-stress measurements, three kinds of structures were used in the scour experiments: 1) Vertical circular cylinders, 2) cone-shaped structures and 3) breakwaters. Table 1 summarizes the test conditions of the scour experiments.

In the table,  $V$  is the mean flow velocity in the case of steady current and  $U_m$  is the amplitude of the orbital velocity at the bed in the case of waves, while  $U_f$  and  $U_{fm}$  are the corresponding friction velocities in the case of steady current and in the case of waves, respectively.  $\theta$  is the Shields parameter defined by

$$\theta = \frac{U_f^2}{g(s-1)d} \quad (1)$$

in which  $g$  is the acceleration due to gravity and  $s$  is the relative density of sand grains.  $U_f$  is replaced by  $U_{fm}$  in the case of waves. In the table,  $KC$ , the Keulegan-Carpenter number, is defined by

$$KC = \frac{U_m T}{D} \quad \text{or} \quad KC = \frac{U_m T}{B} \quad (2)$$

and  $Re$ , the Reynolds number,

$$Re = \frac{U_m D}{\nu} \quad \text{or} \quad Re = \frac{U_m B}{\nu} \quad (3)$$

From the table, it is seen that all the scour experiments were conducted under live-bed conditions,  $\theta > \theta_{cr}$ , in which  $\theta_{cr}$  is the critical value of  $\theta$  corresponding to the initiation of motion on the sand bed.

## 3. Results and discussion

### 3.1 Bed shear stress

#### Cylinder

The bed shear stress around a vertical cylinder placed on

a plane bed is increased due to the following three effects: 1) the contraction of streamlines near the structure 2) the horse-shoe vortex and 3) the vortex shedding (Fig. 2).

Fig. 2 Definition sketch. Near-bed flow structures around a vertical cylinder.

The mechanisms related to these effects and their role in the scour processes have been discussed in Breusers et al. (1977), Hjorth (1975), Baker (1979), Dargahi (1987) in steady current and Sumer et al. (1992) in waves.

Fig. 3 illustrates the distribution of the bed shear stress along the principal axes  $x$  and  $z$  in the case of steady current. In the figure,  $\alpha$  is the amplification in the bed shear stress

$$\alpha = \frac{\tau_0}{\tau_{0\infty}} \quad (4)$$

in which  $\tau_0$  is the bed shear stress and  $\tau_{0\infty}$  is that corresponding to the undisturbed flow. The figure includes also the results of Baker (1979) who obtained the bed shear stresses from the measured velocity profiles. (It is seen that the present results and the results of Baker agree fairly well despite the differences in the test conditions and in the flow environment). While Fig. 3b illustrates the amplification in  $\tau_0$  near the side edges of the cylinder due to contraction of the flow, Fig. 3a shows the amplification in  $\tau_0$  both in front of the cylinder (beneath the horse-shoe vortex) and at the rear side of the cylinder (in the lee-wake region).

It is seen that the increase in the bed shear stress near the cylinder can be as much as by a factor 10 or even larger. Similar results were obtained also by Hjorth (1975) (Fig. 4a).

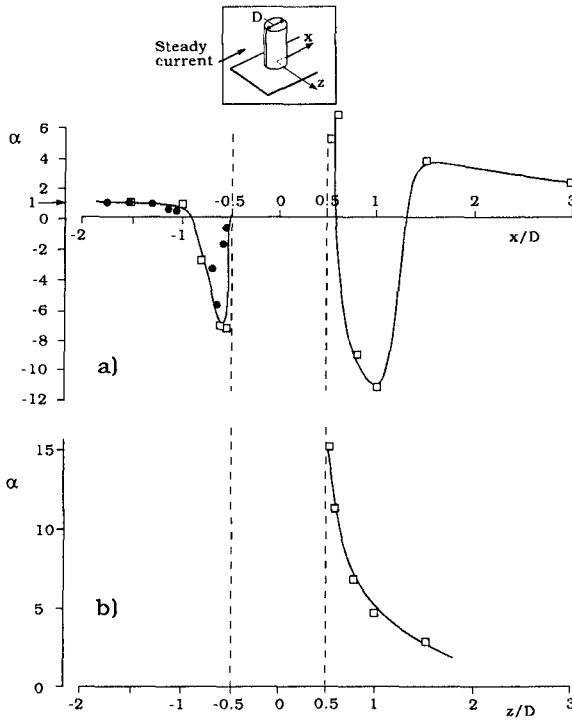

Fig. 3 Amplification in the shear stress along the principal axes  $x$  and  $z$  around a vertical cylinder. Squares: Present experiments (flow-depth,  $h = 40$  cm,  $D = 9$  cm and  $V = 8.7$  cm/s and  $Re = 7800$ ). Circles: Baker's (1979) experiments in air ( $D = 7.6$  cm,  $V = 51$  cm/s,  $D/\delta^* = 14.8$  and  $Re = 2610$ ,  $\delta^*$  being the displacement thickness of the boundary layer on the bottom).

Fig. 4 compares the distribution of the bed shear stress near the cylinder in the case of steady current (Hjorth, 1975) with that measured in the present study in the case of waves (where  $KC$ , the Keulegan-Carpenter number, is 10) while Fig. 5 gives a 3D illustration of the latter flow, at the phase value  $\omega t = 0$ , corresponding to the passage of the wave crest. In Fig. 4,  $\alpha$  is the amplification in the bed shear stress defined by

$$\alpha = \frac{|\bar{\tau}_0|}{\tau_{0\infty}} \quad ; \quad \text{steady-current case} \quad (5)$$

and

$$\alpha = \frac{Max|\bar{\tau}_0|}{\tau_{0m}} \quad ; \quad \text{wave case} \quad (6)$$

in which  $\tau_{0m}$  is the maximum value of the bed shear stress corresponding to the undisturbed flow.

Fig. 4 Amplification in the bed shear stress. a: Steady current ( $D = 7.5$  cm,  $V = 30$  cm/s,  $h = 20$  cm) (from Hjorth (1975)). b: Waves ( $D = 4$  cm,  $U_m = 9.2$  cm/s,  $T = 4.4$  s,  $h = 40$  cm).

Fig. 4 indicates that, in the case of waves, the amplification factor is not as large as in steady currents; the increase in the bed shear stress with respect to its undisturbed value is only a factor 3-4 in the best condition. Measurements show that this is the case also for other  $KC$  numbers (up to  $KC = 100$ ), see Sumer et al. (1992). Fig. 6 depicts the distribution of amplification along the principal axes  $x$  and  $z$ . It seems that the measurements as regards the  $z$ -variation of  $\alpha$  apparently agree quite well with the potential-flow prediction (Fig. 6b).

As seen from Fig. 4, there is a factor 3 difference between the amplification in steady currents and that in waves. This may be attributed to the rather thin boundary layer developing

Fig. 5 Three-dimensional vector-diagram illustration of near-bed flow around a vertical circular cylinder at the phase value  $\omega t = 90^\circ$ , i.e. at the time of crest passing ( $D = 4$  cm,  $U_m = 9.2$  cm/s,  $T = 4.4$  s,  $h = 40$  cm).

Fig. 6 Amplification in the bed shear stress around a vertical circular cylinder along the principal axes  $x$  and  $z$  ( $D = 9$  cm,  $U_m = 31.8$  cm/s,  $T = 1.9$  s,  $h = 40$  cm).

Fig. 7 Comparison of the bed-shear stress amplification around the cylinder and the cone. (Test conditions are the same as in Fig. 3 for the cylinder test. For the cone test:  $D = 9$  cm,  $V = 8.7$  cm/s,  $h = 40$  cm).

Fig. 8 Comparison of the bed-shear stress amplification around the cylinder and the cone. (Test conditions are the same as in Fig. 6 for the cylinder test. For the cone test:  $D = 9$  cm,  $U_m = 31.8$  cm/s,  $T = 1.9$  s,  $h = 40$  cm).

over the bed in the case of waves. The previously mentioned agreement between the measurements and the potential-flow prediction substantiates the latter argument. In the case of steady current, however, the combined action of the horse-shoe vortex and the contraction of flow near the side edges of the cylinder amplifies the bed shear stress tremendously, to give an  $\alpha$  value of  $O(10)$  (Figs. 3b and 4a). The strong presence of horse-shoe vortex in the steady-current situation accounts for also the large increase in the bed shear stress in front of the cylinder (Fig. 3a).

### Cone

Figs. 7 and 8 compare the cone results with the cylinder results along the principal axes  $x$  and  $z$ . It is clear that the net effect of side slopes (the cone case) is to decrease the bed shear stress. From the preceding figures, the following conclusions may be drawn.

1) Fig. 7a shows that  $\tau_0$  decreases by a factor of about 4 underneath the *horse-shoe* vortex (in the area extending over  $-1 \leq x/D \leq -0.5$ ) in the case of cone. (It is interesting to note that the horse-shoe vortex is still existent in the cone case, but its strength is greatly reduced with respect to the cylinder situation).

The decrease in  $\tau_0$  is due to the large decrease in the adverse pressure gradient which builds up at the upstream side of the structure and is known to be responsible for the formation of horse-shoe vortex. This decrease in the adverse pressure gradient is simply because of the favourable cone geometry.

It may be noticed that the cone and the cylinder results are almost identical in the case of waves at the upstream side of the structure (Fig. 8a). This is simply because no horse-shoe vortex exists for this KC number, not even in the case of cylinder (Sumer et al. (1992)). So, the results will obviously be the same. The 45°-cone experiments exhibited the same behaviour.

The results in Fig. 8a are not symmetric with respect to  $x = 0$  due to the asymmetry in waves.

2)  $\tau_0$  decreases considerably also near the *side edges* of the structure in the case of cone; this decrease is about a factor 10 in the steady-current situation (Fig. 7b), while it is a factor 2-3 in the case of waves (Fig. 8b). Two effects are responsible for this large decrease in  $\tau_0$ : 1) the contraction of streamlines near the side edges of the cone structure is rather small; and also, 2) the horse shoe vortex is rather weak in this case, as mentioned above.

3) Similar observations can be made also in the *lee-wake* area. Tremendous decrease (by an order of magnitude) takes place in  $\tau_0$  in this area ( $x \geq 0.5$ ) in the case of steady current (Fig. 7a), while practically no change takes place in the case of waves (Fig. 8a). This reduction in the bed shear stress

Fig. 10 Amplification in the bed shear stress around the head of a breakwater with side slopes. ( $B' \approx 11.5$  cm,  $U_m = 12$  cm/s,  $T = 1.3$  s,  $h = 40$  cm).

Fig. 9 Amplification in the bed shear stress around the head of a vertical-wall breakwater. ( $B = 3$  cm,  $U_m = 12$  cm/s,  $T = 1.3$  s,  $h = 40$  cm).

is obviously related to the rather weak occurrence of vortex shedding in the case of cone.

### Breakwater

Fig. 9 depicts the contour plot of the bed-shear-stress amplification,  $\alpha$ , in the case of vertical-wall breakwater for  $KC = 8$ . As seen, the  $\alpha$  values can be as high as 14 near the head of the breakwater. Similar behaviour was obtained for  $KC = 1$  where a value of about 10 was measured for the maximum value of  $\alpha$ .

Fig. 11 Sketch illustrating the steady streaming around a large cylinder in waves. S: Scour. D: Deposition.

In a previous study undertaken at ISVA (Gökçe et al., 1994), the flow around the head of a vertical-wall breakwater was found to occur in the following three regimes: 1) Unseparated-flow regime when  $KC < 1$ , 2) separated-flow regime when  $1 < KC \leq 12$  and 3) separated-flow regime with a horse-shoe type vortex in front of the breakwater when  $KC \geq 12$ .

Since the tested  $KC$  numbers, namely  $KC = 1$  and  $8$ , are well below the  $KC$  number beyond which the horse-shoe vortex emerges, no horse-shoe vortex was present in the present tests. This means that the only factor behind the extensive increase in  $\tau_0$  at the head of the breakwater is the effect of flow contraction including the one experienced during the flow reversal where the separation vortex is washed around the breakwater. This explains why  $\alpha$  is a factor 3-4 larger in the present case (Fig. 9) than in the corresponding case of a circular cylinder (Fig. 4b) where the contraction effect is not as severe as in the case of breakwater.

Fig. 10 illustrates the effect of side slopes on the bed shear stress. The model used in the tests was exactly the same as that used in the vertical-wall breakwater tests (Fig. 9). The only difference is that the model was encircled with a sloping side wall on the bottom (as sketched in Fig. 10) with a slope 1:1. As seen, the effect is a large drop in the bed shear stress at the head of the breakwater. The maximum value of  $\tau_0$  is reduced by a factor 7 with respect to its value in the case of vertical-wall breakwater.

This large reduction is obviously related to the small flow contraction in the present case due to the geometry of the structure, similar to that when the structure is changed from a circular cylinder to a cone (Figs. 7b and 8b).

**3.2 Scour**

The scour data obtained in the case of cone (both with  $\beta = 30^\circ$  and  $45^\circ$ ) indicated that the smaller the side slope, the smaller the scour depth.

Secondly, it was apparent from the results that the scour depth in the case of cone ( $\beta = 30^\circ$  and  $45^\circ$ ) in steady current was one order of magnitude smaller than in the case of cylinder.

Fig. 12 Normalized scour depth at the head of breakwater as function of KC. For test conditions, see Table 1. x: Maximum scour or deposition

Thirdly, the cone results corresponding to the wave case have been compared with the cylinder scour reported in Sumer et al. (1992). It was found that, for KC numbers above 5, the cone scour is on average below the cylinder scour. For very small KC numbers ( $KC = O(5)$ ), however, the maximum scour depth appeared to be in the same order of magnitude as that measured in Sumer et al. (1992). This may be related to the not very extensive drop in the bed shear stress in the case of cone in waves (Fig. 8).

For extremely small KC numbers such as  $KC(1)$  (i.e., large structures), the scour is caused not by the vortex shedding but rather by various forms of steady streaming which build up around the structure. The steady streaming around a large cylinder is an example for this kind of streaming (Fig. 11). Here, the streaming is caused by the difference in the response of the cylinder boundary layer to the two successive half periods of the wave motion. This kind of steady streaming may cause a scour-and-deposition pattern around the structure, as sketched in Fig. 11.

The data related to the present breakwater-scour experiments are plotted in Fig. 12. As seen from the sketches in the figure, the scour hole occurring at the tip of the breakwater in the case of large KC-number situations disappears when KC becomes less than  $O(1)$ . Instead, a streaming-induced scour-and-deposition pattern forms around the breakwater head, in the way as described in the preceding paragraph. The disappearance of the scour hole at the tip of the breakwater is due partly to the unseparated flow regime and partly to the large reduction in the bed shear stress (cf. Figs. 9 and 10).

The scale effects in connection with both the flow-description experiments and the scour tests have been discussed elsewhere (in Sumer et al. (1992 and 1993) in conjunction with scour around vertical piles and in Gökçe et al. (1994) in conjunction with scour around the head of a breakwater).

#### 4. Conclusions

- 1) The bed shear stress around a vertical, circular cylinder is increased considerably (by a factor of 10) with respect to its undisturbed value when the cylinder is exposed to a steady current, while this increase is by a factor of 3-4 when it is exposed to waves.
- 2) For a cone-shaped structure, the increase in the bed shear stress near the structure is small, a factor of 2-4, regardless of the flow type (steady current or waves).
- 3) The increase in the bed shear stress around the head of a vertical-wall breakwater (which is exposed to waves) is a factor of 10 or so. When the breakwater is encircled at the bottom with a sloping side wall with a slope of 1:1, the increase in the bed shear stress is only a factor 2.
- 4) The scour depth around a cone-shaped structure is an order of magnitude smaller than in the case of cylinder struc-

ture in steady currents. In the case of waves, however, the scour depth appears to be smaller than that measured in the case of cylinder when  $KC > O(5)$ . For  $KC = O(5)$ , however, the cone scour is in the same order of magnitude as the cylinder scour.

- 5) Although the scour hole at the tip of the breakwater disappears in the case of rubble-mound breakwater (apparently due to the effect of the side slope), another mechanism, namely the steady streaming, may induce a scour-and-deposition pattern around the breakwater head.

#### Acknowledgement

This work was undertaken as part of MAST II "Monolithic (Vertical) Coastal Structures" and "Rubble Mound Breakwater Failure Modes" research programmes. It was funded jointly by the Danish Technical Research Council (STVF) under the programme "Marin Technique" and by the Commission of the European Communities, Directorate General for Science, Research and Development under MAST contracts No. MAS2-CT92-0042 and MAS2-CT92-0047.

## CHAPTER 116

# LABORATORY MEASUREMENT OF OBLIQUE IRREGULAR WAVE REFLECTION ON RUBBLE-MOUND BREAKWATERS

Charles TEISSON<sup>1</sup> and Michel BENOIT<sup>2</sup>

### Abstract

The present work aims to improve our knowledge of reflection coefficient of waves on a breakwater through a programme of laboratory tests. The experiments are conducted on a linear rubble-mound breakwater under random long-crested wave conditions. The wave signals are recorded through an array of 8 wave probes. Three wave reflection analysis approaches are applied and compared on the laboratory recorded data : Least-Squares Methods, Directional Analysis Methods, Modified Directional Analysis Methods. These methods are briefly presented, their assumptions are highlighted and their characteristics are discussed on numerical tests. The Directional Analysis Methods appear to be unable to properly model the superimposition of incident and reflected wave fields. When applied to laboratory experiments, the Least-Squares Methods and the Modified Directional Methods show concordant results, but nevertheless exhibit some differences. The effect of oblique incidence on reflection coefficient is then tentatively analysed.

### 1. INTRODUCTION

The reflection of waves on a marine or coastal structure is a rather complicated physical process to analyse, depending both from hydrodynamical conditions (wave steepness, wave period, wave obliquity,...) and characteristics of the structure (type of breakwater, slope of the reflective face, permeabilities of the various layers,...). The wave field in front of the reflective structure results from the superimposition of incident and reflected wave field and one has to use special analysis techniques in order to achieve the decomposition. The scope of the present work is to compare various such reflection analysis techniques on laboratory data.

In order to study the reflection coefficient of waves on a linear rubble-mound breakwater, a programme of laboratory tests in a long-crested random wave basin has been performed at Laboratoire National d'Hydraulique (LNH). These tests aimed to study the effects of the three following parameters on the reflection process : wave steepness, wave obliquity and mound slope. In order to determine the reflection coefficient of waves on the breakwater two problems have to be successively addressed and are briefly summarized hereafter.

1 Head of Maritime Group

2 Research Engineer — Maritime Group

EDF - Laboratoire National d'Hydraulique, 6, quai Watier 78400 CHATOU, FRANCE

- a. firstly a wave measurement system must be set up to record simultaneously several wave properties (elevation, pressure, velocities,..) at one or more locations. Such measuring devices may be co-located probes (e.g. Hughes, 1994) or wave probe arrays (e.g. Goda and Suzuki, 1976 ; Isaacson, 1991 ; Bird *et. al.*, 1994). In the present experiments we have only made use of an array of 8 wave gauges, recording the free-surface elevations.
- b. secondly a reflection analysis method must be used to proceed to the separation of incident and reflected components and determine the reflection coefficient. This problem has been addressed by several authors both for laboratory and field experiments (e.g. Mansard and Funke, 1980 ; Isobe and Kondo, 1984 ; Hashimoto and Kobune, 1987). There is however up to now no unique approach for the analysis of obliquely incident waves. The core of the present study is thus to compare three different approaches to model and analyse the wave field in front of the structure, namely :
  - \* Least-Squares Methods (section 2)
  - \* Directional Analysis Methods (section 3)
  - \* Modified Directional Analysis Methods (section 4)

All these methods are applied to the laboratory data (sections 6 and 7) recorded during the experiments described in section 5.

The present experiments have been conducted in the continuation of LNH tests on the effect of wave obliquity on breakwater stability (Galland, 1994).

## 2. THE LEAST-SQUARES METHOD (LSM)

This type of methods has been initially proposed by Goda and Suzuki (1976) for reflection analysis in a wave flume through two wave probes set up on the axis of the flume. The technique has been improved by Mansard and Funke (1980) for a linear array of three gauges. They provided spacing rules for the gauges and their method is now widely used for reflection analysis in random wave flumes. Recently Isaacson (1991) generalized the method to two-dimensional gauge arrays for basin experiments. Hughes (1994) also used this technique with a co-located gauge for oblique wave reflection measurement.

**Figure 1 :** Definition sketch for reflection analysis.

The main assumptions of this analysis approach are listed hereafter :

- > Both incident and reflected waves are long-crested and linear. The random wave fields are expressed using a linear superposition of numerous long-crested monochromatic components. For instance the incident wave field (referred by subscript i) reads (see figure 1 for definition sketch) :

$$\eta_i(M,t) = \sum_{j=1}^J A_j \exp(i.\omega_j.t) \exp(i.(-\vec{k}_j.\vec{OM} + \psi_j))$$

$A_j$  is the amplitude of the  $j$  component,  $\omega_j$  is the cyclic frequency,  $k_j$  is the wave-number given by the dispersion relation and  $\psi_j$  is the phase, which is generally assumed to be uniformly and randomly distributed over  $[0 ; 2\pi]$ .

- > Each component is assumed to reflect independently. In the following we thus focus on a particular component and drop the  $j$  subscript.
- > Frequency and wave-number remain unchanged during reflection.
- > The incident wave direction is assumed to be known and must be given as input to the method.
- > The incident and reflected wave directions are symmetrical :  $\theta_r = \pi - \theta_i$
- > The reflection coefficient is taken to be complex :  $R_j = C_{rj} \exp(i.\phi_j)$

The modulus  $C_{rj}$  is equal to the ratio of reflected and incident wave amplitudes and  $\phi_j$  is the phase lag during reflection.

By using these assumptions the resulting contribution of the component reads :

$$\eta(M,t) = A.\exp(i.\omega.t) . \left\{ \exp(i.(-\vec{k}.\vec{OM} + \psi)) + C_r.\exp(i.(-\vec{k}'.\vec{OM} + \psi - 2.k.D.\cos(\theta_i) + \phi)) \right\}$$

Through this approach we have only three unknown quantities at each frequency of analysis :

- the incident wave amplitude  $A$ .
- the modulus of reflection coefficient  $C_r$ .
- the phase lag during reflection  $\phi$ .

The analysis may thus be carried out from the measurements of only two wave gauges as in the wave flume, but it is preferable to increase the number of gauges (3 or more) and to perform a least-squares resolution of the system in order to improve the stability of results.

In order to study the effect of deviating from some of the above assumptions, several numerical tests have been performed prior to the experiments. For these numerical simulations we used the 3-gauges linear array presented on figure 2.

**Figure 2 :** Linear gauge array used for numerical simulations with LSM.

The numerical simulation characteristics (simulation method, wave period, water depth, time step, record duration,...) are identical to the ones used for the random wave laboratory experiments and presented in section 5.

We only report here some results related to the violation of the assumptions on incident and reflected directions to illustrate the sensitivity of the method :

— effect of wrong estimation of incident wave direction : Several simulations are performed with an actual incident wave direction varying from 0 to 60 degrees. For all these simulations the reflected wave direction is symmetrical of the incident direction. The direction given as input to the analysis method is however taken to be constant at a value of 0 degrees (figure 3-a), 30 degrees (figure 3-b) and 60 degrees (figure 3-c). Examination of results shows that the effect of a difference between actual and assumed incident directions is quite slight if both these directions are close to be normal to the reflection line (figure 3-a). In other words, one can assume an incident direction of 0 degrees for the analysis of wave fields with actual incidence up to 30 degrees : the resulting error is feeble. If the assumed direction is 30 degrees (figure 3-b) the actual incident direction must remain in the range  $[20^\circ ; 40^\circ]$  to keep reliable results. On the other hand, figure 3-c shows that almost no estimation error is allowed for the incident direction when working at large angles of incidence. These observations are largely explained by the fact that only the cosine of incident direction is used by the analysis method.

— effect of angular deviation during reflection : Several simulations are performed with an actual incident wave direction of 40 degrees. For all these simulations the incident direction taken for the analysis is equal to this value of 40 degrees (figure 3-d). The reflected wave direction is however no more symmetrical of the incident direction and there is an angular deviation during reflection. Figure 3-d shows the effect in the estimation of reflection coefficient and incident wave height of an angular deviation varying from -10 to +10 degrees. It appears that the sensitivity of estimated parameters is rather slight, at least at this value of incident direction.

These numerical tests (and additional ones, not reported here) lead to the conclusion that the method is quite stable, even if its basic assumptions are slightly violated. The effect of slightly misjudging the incident wave reflection for instance (say  $\pm 5$  to 10 degrees) is quite acceptable as long as the actual incident direction is lower than 45 degrees. At large angles of incidence however, great attention should be paid to the precise estimation of incident wave direction. The hypothesis that the incident and reflected wave directions are symmetrical is not very sensitive as long as angular deviations are lower than  $\pm 10$  degrees.

### 3. DIRECTIONAL WAVE ANALYSIS METHODS

In order to invoke less restrictive assumptions than the former approach, one may think to use (multi-)directional wave analysis methods. The LNH has acquired a good experience in this field, by implementing most of the available methods currently used in the world (Benoit, 1993). Very recently, these methods have been applied on laboratory simulated data for various types of recording systems : co-located or "single-point" gauges as well as probe array (Benoit and Teisson, 1994b). These tests have in particular shown that the gauge array has a unique resolving capability when associated with sophisticated methods (such as Maximum Entropy Method or Bayesian Directional Method) for severe bimodal test-cases.

**Figure 3 : Results of numerical simulations with LSM.**

The theoretical background of the directional wave analysis is based on the following pseudo-integral relationship between the free-surface elevation field  $\eta(x,y,t)$  and the directional spectrum  $S(f,\theta)$  :

$$\eta(x,y,t) = \int_0^\infty \int_0^{2\pi} \sqrt{2.S(f,\theta).df.d\theta} \cdot \cos[2\pi ft - k.(x.\cos\theta+y.\sin\theta) + \varphi]$$

- The directional wave spectrum  $S(f,\theta)$  is a function of wave frequency  $f$  and direction of propagation  $\theta$  and is decomposed as :  $S(f,\theta) = E(f).D(f,\theta)$
- $E(f)$  is the 1D-variance spectrum and  $D(f,\theta)$  is the Directional Spreading Function (DSF) satisfying two important properties :

$$D(f,\theta) \geq 0 \text{ over } [0, 2\pi] \quad \text{and} \quad \int_0^{2\pi} D(f,\theta) d\theta = 1$$

- $\varphi$  is the phase, which is here assumed to be uniformly and randomly distributed over  $[0 ; 2\pi]$ .

By using an array of  $N$  wave probes, it is possible to record the sea-surface elevation at  $N$  different locations simultaneously (see figure 4).

**Figure 4 :** Definition sketch for probe array configuration.

The computation of the cross-spectra  $G_{ij}(f)$  between each couple  $[\eta_i(t), \eta_j(t)]$  is performed by spectral analysis. The following relation yields between the measured complex cross-spectra  $G_{ij}(f)$  and the unknown directional spectrum  $S(f,\theta)$  :

$$G_{ij}(f) = C_{ij}(f) - i.Q_{ij}(f) = \int_0^{2\pi} S(f,\theta).exp(-i.\vec{k}.\vec{x}_{ij}) d\theta \quad i = 1, \dots, N \text{ and } j \geq i$$

The purpose of directional analysis is to solve the above inverse problem by considering the  $N.(N+1)$  real equations obtained from the cross-spectra  $G_{ij}(f)$  ( $j \geq i$ ). There is no unique way to deal with this awkward inverse problem and plenty of methods have been proposed (e.g. Benoit, 1993 ; Benoit and Teisson, 1994-b). Among them, the Maximum Entropy Method (MEM2) and the Bayesian Directional Method (BDM) are retained for this study as they have shown the highest resolving capabilities. They are only briefly presented hereafter. The reader is invited to consult the given references for more details.

— Maximum Entropy Method - version 2 (MEM2) (e.g. Kobune and Hashimoto, 1986 or Nwogu, 1989). This version is based on the definition of Shannon for the entropy function :

$$\chi = - \int_0^{2\pi} D(f,\theta).ln(D(f,\theta)) d\theta$$

This entropy has to be maximized under the constraints given by the cross-spectra. This results in a non-linear system of equations whose solutions are Lagrange multipliers  $\mu_I$  ( $I=1, \dots, N(N-1)+1$ ) and the estimate of DSF then reads :

$$D(f,\theta) = \exp \left\{ -1 + \sum_{I=1}^{N(N-1)+1} \mu_I \cdot q_I(\theta) \right\} \begin{cases} q_I(\theta) = \cos[\vec{k} \cdot \vec{x}_{ij}] & I = 1, \dots, N(N-1)/2 \\ q_I(\theta) = \sin[\vec{k} \cdot \vec{x}_{ij}] & I = N(N-1)/2+1, \dots, N(N-1) \\ q_I(\theta) = 1 & I = N(N-1)+1 \end{cases}$$

— Bayesian Directional Method (BDM) : (Hashimoto *et al.*, 1987). No *a priori* assumption is made about the spreading function which is considered as a piecewise-constant function over  $[0, 2\pi]$ . The unknown values of  $D(f,\theta)$  on each of the  $K$  segments dividing  $[0, 2\pi]$  are obtained by considering on one side the constraints of the cross-spectra and on the other side additional conditions on the smoothness of  $D(f,\theta)$ . Both these constraints are combined using an "hyperparameter" whose value may be computed by minimizing the ABIC (Akaike Bayesian Information Criterion). This method is quite difficult to implement, but its main features are to be model independent, data-adaptive and to consider the possibility that the recorded data may be contaminated by some noise.

In order to compute a reflection coefficient at each frequency of analysis with the directional analysis methods, one has first to integrate the computed DSF function over the range of incident directions on one hand and over the range of reflected directions on the other hand and then to compute the ratio of these values.

The application of directional analysis methods in the above described procedure is not fully well-founded in the sense that these methods are based on the assumption that the phases  $\phi$  are uniformly and randomly distributed over  $[0 ; 2\pi]$ , and thus that the directional spectrum  $S(f,\theta)$  is an homogeneous function. This assumption is however clearly violated close to a reflective structure because of the phase relationship between the incident and reflected components at each frequency. Isobe and Kondo (1984) provide a deeper discussion of this problem. Figure 8 shows an example of recorded 1D-variance spectra  $E(f)$  at various gauges of the array used for laboratory experiments. It is clearly noticeable that the sea-state can not be regarded as homogeneous and thus that the directional analysis methods may fail in the estimation of the DSF. Both MEM2 and BDM will however be tentatively considered when analysing laboratory data.

**4. MODIFIED DIRECTIONAL WAVE ANALYSIS METHODS**

In order to take into account the above remark on the phase relationship between incident and reflected components, Isobe and Kondo (1984) proposed to limit the determination of the directional spectrum to the range  $[0, \pi]$  and to modify the basic expression of the wave field in the following way :

$$\eta(x,y,t) = \int_0^\infty \int_0^\pi \sqrt{2 \cdot S(f,\theta)} \cdot df \cdot d\theta \cdot \{ \cos[2\pi ft - k \cdot (x \cdot \cos\theta + y \cdot \sin\theta) + \phi] + r(f,\theta) \cdot \cos[2\pi ft - k \cdot (x \cdot \cos\theta - y \cdot \sin\theta) + \phi] \}$$

In this expression the directional spectrum is an incident directional spectrum only, defined on  $[0, \pi]$  by using the definition sketch of figure 5. The directional reflection coefficient  $r(f, \theta)$  is an additional unknown, also defined on  $[0, \pi]$ . The main other assumptions of the above relationship are the following ones :

- the phase  $\varphi$  is assumed to be uniformly and randomly distributed over  $[0; 2\pi]$  for the incident spectrum only.
- the incident and reflected directions at each frequency are taken to be symmetrical, as for the LSM methods.
- the phase lag during reflection is assumed to be negligible.

**Figure 5 :** Definition sketch for directional wave reflection.

By using the above expression and the definition sketch of figure 5, the inverse problem to be solved now reads :

$$G_{ij}(f) = \int_0^\pi S(f, \theta) \cdot \left\{ \exp(-i \cdot \vec{k} \cdot \vec{x}_{ij}) + r^2(f, \theta) \cdot \exp(-i \cdot \vec{k} \cdot \vec{x}_{ij}') \right. \\ \left. + r(f, \theta) \cdot \left[ \exp(-i \cdot \vec{k} \cdot \vec{x}_{i}') + \exp(-i \cdot \vec{k} \cdot \vec{x}_{j}') \right] \right\} d\theta \quad i = 1, \dots, N \text{ and } j \geq i$$

In order to solve this problem, two methods have been implemented at LNH and validated on numerical simulations :

- Modified Maximum Likelihood Method (Isobe and Kondo, 1984)
- Modified Bayesian Directional Method (Hashimoto and Kobune, 1987)

Numerical tests have shown that the MBDM is more powerful than MMLM, but it is also more difficult to implement and to operate (tuning, stability,...). Moreover both these methods assume that the distance from the gauge array to the reflection line is known, which is not always easy to insure (in particular in the case of a permeable slope). In this case, additional developments, such as the ones reported par Bird *et. al.* (1994), would be necessary.

**5. EXPERIMENTAL LAY-OUT AND TEST CONDITIONS**

We only report here for clarity a brief description of experimental conditions and test parameters (see Teisson and Benoit (1994-a) for more details).

- Wave tank and wavemaker :

The experiments are performed in a semi-circular wave tank equipped with a 17 m long flap-type wavemaker. The wavemaker is able to rotate around the center of the breakwater in a range of  $[-90^\circ; +90^\circ]$  (see figure 6-a). It is computer monitored in order to produce regular or random waves according to a given energy spectrum. All tests have been conducted with a constant water depth of 0.40 m.

**6-a. Experimental set-up - Definition sketch**

**6-b. Breakwater cross-section**

**6-c. Probe array lay-out.**  
(All dimensions in centimeters)

**Figure 6 : General description of experimental conditions.**

— Breakwater description :

The breakwater is a 8 m long linear breakwater armoured with cubic blocs and terminated at each side by roundheads of quarry stones. The blocs are grooved Antifer-type cubes, laid on two layers (weight : 61 g ; density : 2.4). The core and filter-layers are reproduced following scaling rules used for this type of breakwater. The breakwater is designed to face without any damage all the test conditions of this study. In addition, the breakwater is almost never overtopped, so that no energy loss should occur through transmission by overtopping. An example of cross-section is presented on figure 6-b. In the present study we only report results of the 3/4 mound slope, but two other slope values have been tested (2/3 and 1/2) in order to study the effect of mound slope on wave reflection (Teisson and Benoit, 1994-a).

— Simulated wave characteristics :

During the various tests of this study a JONSWAP-type spectrum is used, with a peak enhancement factor of 3.3. Random waves sequences composed of about 1000 waves are generated. Five tests are considered with the following characteristics :

- \* The peak period used for the five tests is  $T_p=1.3$  s. The corresponding wavelengths are :  $L_p = 2.17$  m for the water depth of 0.40 m.  
 $L_{op} = 2.64$  m for infinite water depth.
- \* The significant wave height used for the five tests is  $H_s=0.06$  m. The corresponding value of steepness, defined as  $s_{op} = H_s/L_{op}$ , is 2.3 % and The surf-similarity parameter, defined as  $Ir_p = \tan \alpha / \sqrt{s_{op}}$ , is equal to 5.
- \* The incident wave direction is changed from one test to another and takes the values :  $0^\circ$ ,  $15^\circ$ ,  $30^\circ$ ,  $45^\circ$  and  $60^\circ$  successively.

— Wave probe arrangement and sampling characteristics:

An array of 8 resistive-type wave probes is used for each experiment. The probes lay-out is reported on figure 6-c. Several different probes combinations may be extracted from the whole array. The time series of free-surface elevation are recorded simultaneously with a sampling rate of 12.5 Hz and a duration of 819.2 s.

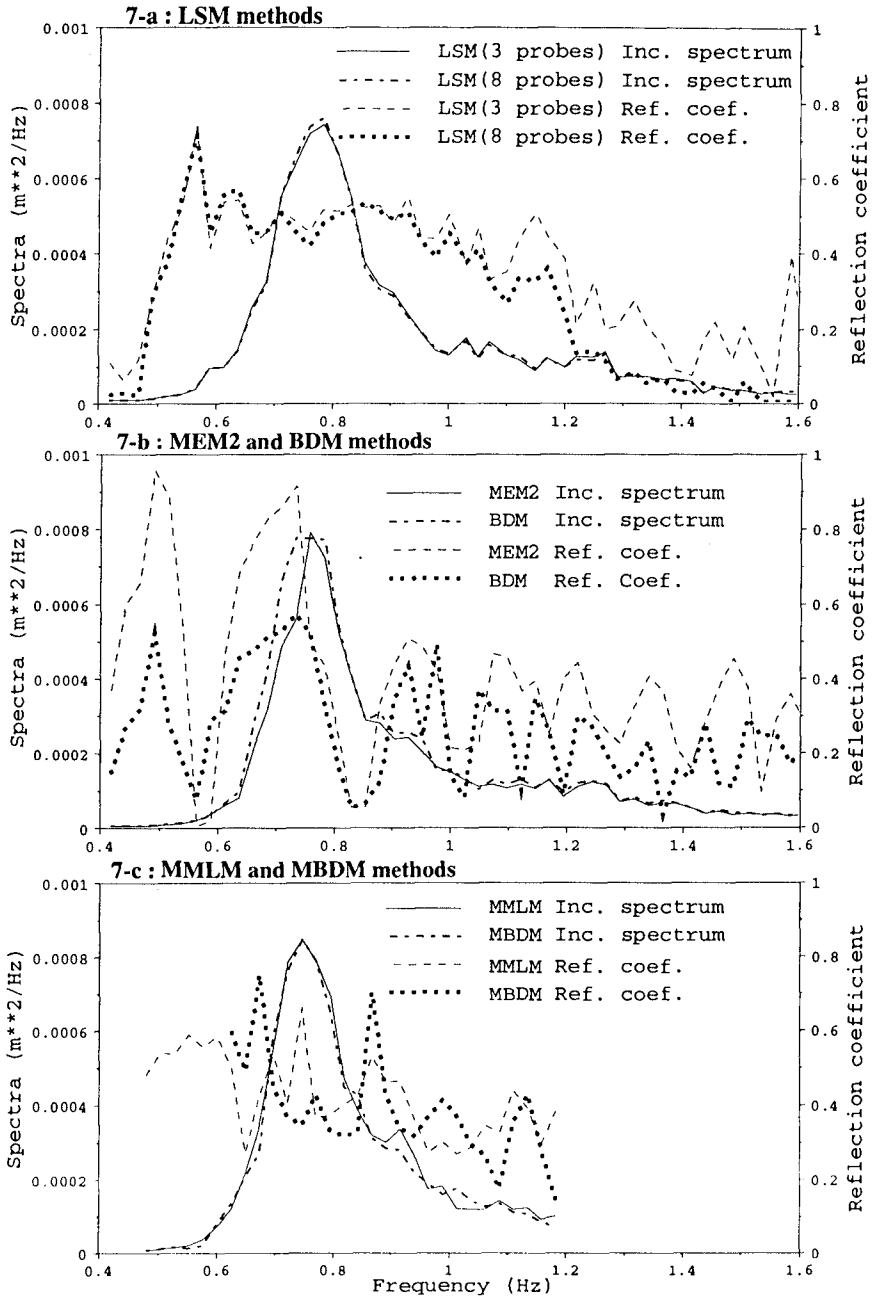

## 6. DETAILED ANALYSIS OF A PARTICULAR TEST (INCIDENT DIRECTION : $45^\circ$ )

In this section, the application of the various proposed reflection analysis methods on a particular test corresponding to an incident direction of  $45^\circ$  is presented and discussed in order to highlight the characteristics of the methods. Figure 7 shows both the incident spectrum and the significant reflection coefficient analysed by the various methods on this particular test.

— Least-Squares Methods (LSM) — figure 7-a :

Figure 7-a illustrates the results obtained with LSM by using on one hand only 3 wave probes (probes 1, 2 and 3) and on the other hand all the 8 probes of the array.

It is first noticeable that there is no great difference in the estimated incident spectra and reflection coefficients between the 3-probes array and the 8-probes array. Only at higher frequencies, the reflection coefficient computed from the 3-probes array appears to be somewhat higher than the one computed from the 8-probes array. In fact the 3-probes array is mainly designed for the peak frequency region of the spectrum and it is quite normal that its efficiency becomes somewhat lower as one moves away from this region. In addition, the reflection coefficient obtained from the 8-probes array is a little bit smoother than the one obtained from the 3-probes array, what may also indicate some more physical reliability. An important comment is thus that there is no need to use complex measuring devices

**Figure 7 :** Reflection analysis on a particular laboratory experiment (direction 45 deg).

with a lot of gauges for the LSM method and that stable estimates may be obtained from 3 probes. The explanation is clearly related to the fact that there are only few unknown parameters by using LSM, as discussed in section 2. On the other hand an important drawback of this method is the rather strong assumptions it requires in order to set this quite simple problem.

The value of the reflection coefficient is quite stable in the peak frequency region (between 45 and 50 %). This value seems in agreement with results of previous experiments performed in wave flumes (e.g. Seelig, 1983 ; Allsop and Hettiarachchi, 1988).

— Directional analysis methods (figure 7-b) :

The incident spectra obtained by MEM2 and BDM (figure 7-b) are in good agreement between each other and also compare quite well to the one obtained with LSM. Major discrepancies however appear when considering the reflection coefficients. Compared to the LSM estimates, the reflection coefficients computed both from MEM2 and BDM exhibit strong variations with frequency. These variations are quite similar for MEM2 and BDM estimates, except that their amplitudes are higher for the MEM2 method. Even if the mean value seems to keep a physical sense, the frequency dependency is definitely meaningless. This spurious behaviour of reflection coefficient is clearly related to the main shortcoming of this analysis approach that does not take into account the phase relationship between incident and reflected components, as discussed in section 3.

To illustrate that point, figure 8 shows the 1D-variance spectra recorded by various probes of the measuring array (see figure 6-c for the array geometry). It is clearly noticeable that the hypothesis of spatial homogeneity of energy is no more applicable and thus the directional analysis methods in their standard form do not seem to offer an obvious modelling approach for that kind of problems where reflection is quite important.

**Figure 8 :** 1D-variance spectra recorded at various gauges (direction 45°).

— Modified directional analysis methods (figure 7-c) :

The incident spectra obtained both from MMLM and MBDM are quite similar with each other and also compare quite well with the ones obtained from the previous methods. The reflection coefficients computed both from MMLM and MBDM show some oscillating behaviour, but clearly not as much as for the previous standard directional analysis methods. Their mean values are quite concordant, but appear to be a little bit lower than the ones obtained from the LSM methods (about 40 % here versus 45 % for LSM methods).

Even if they exhibit some deviation in absolute value of reflection coefficient, these methods seem to give converging results with the LSM methods. It must however be emphasized that the results obtained with the modified directional analysis methods might undoubtedly be improved by additional tests and developments. First of all, there are still work to be done on numerics (in particular with MBDM) in order to insure a more stable convergence towards the solution. Secondly, the effect of misjudging the distance from the array of gauges to the reflection line should received some attention (through numerical sensitivity tests for instance). It would be worthwhile to consider this distance as an additional unknown parameter of the problem. Finally, but this remark also holds for the standard directional methods, one may discuss the fact that we tried to apply directional approaches (and assume a continuous directional distribution of energy) to analyse long-crested waves (whose energy should be concentrated over one direction). This latter point could also be studied by additional numerical tests.

## 7. ANALYSIS OF A SERIES OF TESTS — EFFECT OF INCOMING DIRECTION

In this section, the results of the five tests described in section 5 are presented for the various analysis methods. We recall that only the incident direction changes from one test to another, in the range [0 ; 60 deg]. The reflection coefficients computed by all the methods are plotted as function of frequency on figure 9.

**Figure 9 :** Effect on incident wave direction on reflection coefficient.  
(Laboratory tests — Mound slope 3/4 — Wave steepness 2.3 %)

All methods indicate quite the same variations of reflection coefficient with incident wave direction, even if the range of variation of the reflection coefficient is quite feeble. Starting from normal incidence, the reflection coefficient decreases to become minimum at an incidence of about 15 degrees and then increases again to become maximum at an incidence of 45 degrees. For most of methods, the maximum value at 45 degrees is greater than the value obtained at normal incidence. For the incidence of 60 degrees, the reflection coefficient starts decreasing, but the results obtained at such large incidence have to be handled carefully because of the possible occurrence of Mach reflection which is not taken into account in the present analysis methods. This typical behaviour has been observed on the other tests, performed at different values of wave steepness and different mound slopes (Teisson and Benoit, 1994-a). Recent experiments performed by Juhl and Sloth (1994) in order to examine the effect of incoming direction on the amount of overtopping seem to confirm this trend, as the amount of overtopping appears to be maximum for an incidence of about 10 degrees.

## 8. CONCLUSIONS - FUTURE WORK

The main comments arising from this study are expressed hereafter :

- the Least-Squares Methods (LSM) seem to produce reliable results. This modelling approach requires rather strong assumptions, but it has been shown through numerical tests that this method is quite stable in its results even if one slightly departs from its assumptions.
- these Least-Squares Methods are quite easy to implement and to run. Furthermore, as there are only few unknown parameters in the problem, there is no need to use sophisticated arrays for wave measurement. A linear array of three wave probes or a co-located gauge recording 3 wave signals at the same location (Hughes, 1994) is sufficient for the analysis.
- the directional analysis methods MEM2 (Maximum Entropy Method - version 2) and BDM (Bayesian Directional Method) are not advised for this kind of problem where reflection is important. The relationship that exists between incident and reflected components violates the basic assumption of random phases needed by the methods and results in spurious variations of reflection coefficient with frequency. The mean value of reflection coefficient seems however to keep some physical sense.
- the modified directional analysis methods MMLM (Modified Maximum Likelihood Method) and MBDM (Modified Bayesian Directional Method) take into account the above mentioned phase relationship. Although they assume a continuous directional distribution of energy, these methods have been applied to the present tests performed with long-crested waves. The results seem concordant with the ones obtained from LSM methods, but these methods still need some developments to be fully efficient.

Based on these experiments, the LSM approach appears to be the obvious operational solution for laboratory experiments. The tests of the whole programme have been analysed with this method (Teisson and Benoit, 1994-a) and a typical variation of reflection coefficient with incoming direction has been highlighted. Future research interests will address the optimization of Modified Directional Analysis Methods, in order to study the sensitivity of the distance from the gauge array to the reflection line and possibly to incorporate this distance as an additional unknown parameter to the problem.

## 9. ACKNOWLEDGEMENTS

This study is a joint research program between EDF-Laboratoire National d'Hydraulique and the French Ministry of the Sea (Service Technique Central des Ports Maritimes et Voies Navigables — STCPMVN).

### Abstract

Physical model tests were carried out aiming to provide information on armor stone movements in a berm breakwaters. The following items were examined: displacement threshold, frequency and length of stone displacements. Data were obtained from the observation of cumulative displacements at the end of each wave attack and from video records during the attacks; basic statistical analysis was performed. Threshold conditions, moving frequency and cumulative displacements are expressed as function of a modified mobility number, as stone mobility increases with both wave height and wave period.

Information on mobility and displacement is eventually used to estimate longshore transport and abrasion. The longshore model is based on the assumption that stones move during up- and down-rush in the direction of incident and reflected waves; the model compares favourably with experimental existing results. The abrasion model is based on a proportionality assumption between abrasion volume and abrasion work; the proportionality coefficient characterizing the stone material resistance to abrasion is derived from Latham and Poole mill abrasion tests.

### 1. Introduction

The berm breakwater concept, i.e. the conscious design of a rubble mound breakwater for dynamically stable conditions, is relatively new. The central idea is to maintain the profile stable in presence of extreme waves accepting some displacements, whose effect on the reshaped profile is irrelevant, and using rock armor of smaller size than required for a traditional (no movement) design criterium. In such a way available rock may be used in some cases where, according to the traditional design, this would not have been possible. Aiming to use available rock, even stones of poor quality may sometimes be used and were actually used (Sigurdarson & Viggosson, 1994) with satisfaction.

Berm breakwaters introduce some new shapes and variants to well known phenomena but also some completely new topics in breakwaters analysis.

In the first class we may include the strongly convex profile where breakers hit the armor layer and its high permeability caused by its greater thickness; these new

shapes require at least a verification of formulae and equivalence criteria used in the case of traditional breakwaters to estimate armor stability, reflection, wave run-up, overtopping and transmission.

In the second class we should include the reshaping process under eventually static or truly dynamic conditions, the abrasion or breakdown of sliding or colliding rock units and the longitudinal transport of mobile stones.

Run-up on a plane (uniform slope) impermeable surface or on a permeable rubble mound is experimentally well documented. Engineers, needing for an estimate of the behavior of more complex profiles, refer normally to the composite slope method proposed by Saville (1958). Herbich & al. (1963) pointed out the need for some correction for very wide berms; when the berm width is greater than 15% of the wave length its relative effectiveness in reducing wave run-up is strongly reduced. Pilarczyk (1990) describes similar results showing that the critical width is dependent on the breaker type. Van der Meer & Stam (1992) propose formulae describing wave run-up on rock slopes where run-up depends on the probability level (frequency of greater values), on the surf similarity parameter and on mound permeability. Ahrens & Ward (1991) express the reduction in run-up due to the berm as function of the berm geometry and observe that, while the reduction in run-up is modest, the improvement in stability of the revetments is substantial.

We have quoted just some of the information about run-up that can be found in the literature, as an example of how the knowledge of traditional breakwater behavior has been transferred to breakwaters with a relevant berm.

Among the other class of problems, the development of the dynamically stable seaward profile of a reshaping breakwater can be predicted by mathematical models based on extensive physical tests, cf. van der Meer (1988).

The movement of stones along the active profile is a peculiar characteristics of dynamic stability and this causes inherently some abrasion of stones and, when wave attack is oblique, some along-structure transport.

The effect of abrasion can nowadays be evaluated in a semi quantitative manner by the method proposed by Latham (1991) and included in CIRIA-CUR (1991) manual. The method is based on the similarity of armor units weight degradation in nature and in a standardized mill abrasion test (Latham & Poole, 1987); the scale factor for the conversion from milling time (measured as thousands of revolutions) to prototype time (measured as years) is given as the product of 9 factors accounting for: incident wave energy ( $\sim 10$ ), zone in the structure ( $\sim 10$ ), waterborne attrition agents ( $\sim 7$ ), mobility of armor in design condition ( $\sim 4-10$ ), size of the armor stones ( $\sim 2-10$ ), meteorological climate ( $\sim 5$ ), stone grading ( $\sim 2$ ), stone initial shape ( $\sim 2$ ), concentration of wave attack ( $\sim 2$ ); the numbers within parentheses are the measures of the ranges of possible factor values and therefore of the relative influence of the factor.

The along-structure transport  $S$  can nowadays be evaluated with the formula proposed by Van Hijum & Pilarczyk (1982) which may be written as:

$$\frac{S}{g \cdot D_{n50}^2 \cdot T_p} = 0.0012 \cdot \Delta^2 \cdot \frac{H_s \sqrt{\cos\beta}}{\Delta D_{n50}} \cdot \left( \frac{H_s \sqrt{\cos\beta}}{\Delta D_{n50}} - 7 \right) \cdot \sin\beta \quad (1)$$

The above equation was established in the range  $N_s := H_s/\Delta D_{n50} \simeq 12-27$  and is supposed to be usable in the range  $10 \div \infty$ , since when the mobility index is greater than 50 the formula becomes

$$S \simeq 0.0012 \cdot \pi \cdot H_s^2 \cdot c_{op} \cdot \sin 2\beta$$

i.e. similar to CERC formula.

The formula returns the volume transport rate; it gives anyways results of poor utility for actual berm breakwaters, since in almost every case  $N_s < 7$  and the formula returns no transport at all.

A second formula was proposed by Vrijling & al. (1991):

$$S = 4.8 \cdot 10^{-5} (H_0 T_0 - 100)^2 \quad (2)$$

The formula gives the along-structure transport measured as number of stones per wave and was verified in the range 100–400 of the mobility index used, i.e. in a range of mobility more representative of actual berm breakwaters. The absence of obliquity, for which the formula was criticized, may be interpreted as the effect of the range of the tested obliquity  $-25^\circ$  and  $50^\circ$ - wide but in the range of values where the sensitivity is irrelevant because the effect is maximum. The formula may be however easily adjusted including a factor  $\sin 2\beta$ .

The mobility index used in the formula  $-H_0 T_0$ , where  $H_0 := N_s$  and  $T_0 := T_p \sqrt{g/D_{n50}}$  is related to the more usual mobility number  $N_s$  by the trivial relation

$$H_0 T_0 = N_s \sqrt{2\pi N_s / (\Delta s_p)} \quad (3)$$

and, for the usual range of wave steepness ( $s_p \simeq 0.03$ ), the range of mobility where the formula was tested corresponds to  $N_s = 4-10$ .

If berm breakwaters are designed according to Burcharth & Frigaard (1987) recommendations ( $N_s \leq 3.5$  or  $4.5$  in the trunk under oblique and long or respectively steep waves;  $N_s \leq 3$  in the roundhead) the formula returns no transport at all and, as the one mentioned before, doesn't provide any information about the accepted "damage".

The present study:

- synthesizes physical model tests performed, cf. Tomasicchio & al. (1992) and Lamberti & al. (1994), aiming:
  - to determine conditions characterizing the incipient movement of stones along the dynamically stable profile,
  - to quantify stone movement frequency and amplitude for a sufficiently wide set of conditions and
  - to establish a relationship between movement characteristics and wave conditions in the range of mobility typical of a berm breakwater;
- shows how this information may be used in order to provide a longshore transport model calibrated in the mobility range typical of berm breakwaters, and to rationalize Latham method for the estimate of armor stone degradation.

## 2. Model tests

Physical model tests were performed using two different wave flumes, one at Danish Hydraulic Institute (DHI) and the others at ESTRAMED Pomezia Italy in 1993. The test set-up is described in more detail in Lamberti & al. (1994). The tests consisted in a reshaping phase carried out with the design wave attack, followed by stone movement measurements carried out with lower wave intensity. Profile surveys and video records were performed during the investigation. The offshore significant wave height used during reshaping was fixed at  $H_{so} = 0.18$  m; due to shoaling and breaking wave height incident on the structure differs somewhat from the offshore one; the significant height of waves incident on the structure  $H_s$  was systematically used as the wave intensity parameter. Armour stone size was chosen in order to give a mobility number  $N_s = H_s / \Delta D_{n50} \approx 3$  under the reshaping (design) conditions.

For all tests at DHI a fixed initial profile was used (fig. 1); the channel had a constant depth ( $h = 0.60$  m), the relative wave height was low ( $H_{so}/h < 0.3$ ) and waves broke essentially on the structure.

In the tests performed at ESTRAMED the channel presented a foreshore slope 1:20 from 0.60 m depth in the generating area to 0.34 m depth, followed by a more gentle 1:100 slope reaching  $h = 0.30$  m water depth at the structure toe; the range of offshore significant wave height is the same. Waves were moderately limited by water depth.

Fig. 1 As built structure in deep water

Each test series started with an initial reshaping phase of the berm-breakwater, composed by 6 wave attacks of 1000 waves each and reaching an almost equilibrium seaward profile of the breakwater. The phase was followed by further 1000 wave attacks of increasing intensity, starting at  $N_s \approx 2$  and increasing up to the reshaping wave conditions, aiming to analyze stone movements. During both phases irregular waves were used derived from a Pierson-Moskowitz spectrum with different significant wave steepness.

During the tests the offshore and the incident wave characteristics were measured and the reshaped profiles surveyed, as shown in fig. 2.

Data about displacements were obtained from two sources: video-records of individual stone movements during the wave attacks and observations of the cumulative displacements at the end of each wave attack.

The intensity of stone movements was experimentally defined through the number of stones displaced from the active profile: the convex part of the reshaped profile from the *step* to the *crest* (van der Meer, 1988).

Two non dimensional indexes are used because they naturally appear in the longshore transport and in the abrasion models: the traditional damage index  $N_{od}$ , defined as the ratio of the number of displaced stones to the number of the stones in a longitudinal line of the observation area, and the *surface damage level*  $S_s$ , defined similarly as the ratio of the number of displaced stones to the number of stones in the upper one grain layer in the active profile portion of the observation area.

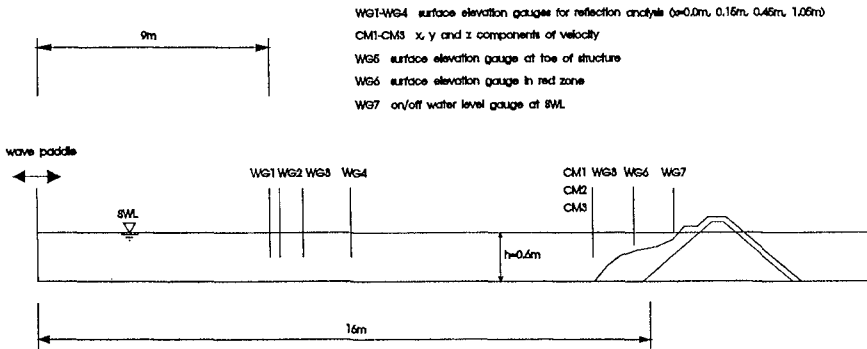

Fig. 2 Model test set-up in deep water

### 3. Threshold of movement

The threshold of stone movement along the reshaped profile was analyzed in deep and shallow water conditions. Movement on the profile is measured by the damage index:

$$N_{od} := N_d \cdot D_{n50} / B \quad , \quad (4)$$

or by the surface damage level:

$$S_s := N_d \cdot D_{n50}^2 / A \quad , \quad (5)$$

where  $N_d$ ,  $B$  and  $A$  are respectively: the number of stones displaced from the active profile at the end of the 1000 waves attack, the width of the observed area and the area itself.

Referring only to DHI model tests, small values of the damage, i.e.  $S_s < 0.05$  roughly corresponding to *zero damage* conditions of SPM (1984), were observed to depend mainly on the *stability number*  $N_s := H_s / \Delta D_{n50}$  with a minor but clearly observable influence of wave steepness. A good correlation was observed between damage and a modified stability number:

$$N_s^{**} \propto N_s \cdot s_m^{-1/5} \quad .$$

This relation suggests that the relevant wave intensity parameter obtained combining wave height and wave period is the onshore energy flux or the breaker height, cf. Lamberti & al. (1994) and Komar & Gaughan (1972).

The following tests showed that the same relation is satisfied for a berm breakwater also in shallow water conditions (see fig. 3) if as wave intensity parameter the incident wave height is considered, which has exceedence frequency almost equal to the frequency of stone movements, i.e. for practical purposes  $H_{1/50}$ .

In order to obtain a mobility index that accounts for the above mentioned observed phenomena and exhibits on average conditions the same values of the traditional stability number  $N_s$ , the following definition of the modified stability number is introduced.

$$N_s^{**} := \frac{H_{k0}}{C_k \Delta D_{n50}} \cdot \left( \frac{s_{m0}}{s_{mk}} \right)^{-1/5} \cdot (\cos \beta_0)^{2/5} \simeq \frac{0.89 \cdot H_{kb}}{C_k \Delta D_{n50}} \quad (6)$$

where  $H_k = H_{1/50}$ ,  $C_k = 1.55$ , i.e. the ratio  $H_{1/50}/H_s$  according to Rayleigh distribution of wave heights, and  $s_{mk} = 0.03$ . The last term includes the effect of wave obliquity according to the hypothesis that the onshore energy flux is the relevant wave intensity parameter.

Fig. 3 The empirical relation between the damage in 1000 waves  $N_{od}$  and the modified stability number  $N_s^{**}$ . +, x : deep water; o, \* : shallow water.

Fig. 4 The empirical relation between frequency of stone movement in 1000 waves  $S_s$  and the modified stability number  $N_s^{**}$ . +, x : deep water; o, \* : shallow water.

Strict threshold conditions correspond to  $N_s^{**} \simeq 2$ , or approximately to  $H_0T_0 \simeq 33$ . There is therefore a rather wide range of conditions where some stone movements occur below the threshold conditions of formulae (1) and (2).

#### 4. Stone mobility

An estimate of the frequency of stone movement can be obtained dividing the damage level by the length of the observation period ( $\simeq 1000$  waves).

The analysis of video records provided some simple statistical description of stone displacements; the mean and standard deviation of the interdisplacement period and of the displacement length were evaluated. The mean interdisplacement period resulted in good agreement with the global frequency derived before (frequency equal to the reciprocal of mean interdisplacement period).

Figure 5 shows the relation between the nondimensional mean displacement  $D_s^{**}$  and the modified mobility number  $N_s^{**}$  for deep water tests. In order to obtain a unique relation between the average displacement  $l_d$  scaled with the nominal stone

size and mobility the former should be multiplied by the square of the wave aspect ratio at structure toe (ratio between the vertical and the horizontal dimensions of the particle horbits). This factor includes the effect of both the water depth and the wave period. If the exponent was 1, the displacements would increase respect to wave height as the horizontal dimension of the horbits. The greater exponent was required for a complete compensation of shallow water effects.

The equations representing the average empirical correlation for mean damage level (frequency) and mean displacement length are:

$$N_{od} = 1.8 \cdot N_s^{**} \cdot (N_s^{**} - 2.0)^{2.2}, \text{ for } N_s^{**} > 2.0 \tag{7.1}$$

$$S_s = 0.14 \cdot (N_s^{**} - 2.0)^{2.2}, \text{ for } N_s^{**} > 2.0 \tag{7.2}$$

$$D_s^{**} := l_d t g h^2 (kh) / D_{n50} = 1.4 \cdot N_s^{**} - 1.3 \tag{8}$$

They represent a refinement of those published in Lamberti & Tomasicchio (1994), including more data on shallow water conditions.

Fig. 5 The empirical relation between mean displacement length and the modified stability number  $N_s^{**}$ . +, x : deep water; o, \* : shallow water.

**5. The longshore transport model**

The two equations (7.1) and (8), or other similar ones giving the frequency and mean length of displacements, combined with the hypothesis that under oblique wave attack the displacement takes place in the direction of wave propagation, or an equivalent one, can be reworked in a long-structure transport formula for very low mobility levels, for which eq. (1) and (2) are not accurate.

A particle will pass through a certain control section in a small time interval  $\Delta t$ , if and only if it is removed from the updrift area of extension equal to the longitudinal displacement length  $l_d$  (if the intervall is small the probability of multiple movements is small of 2nd order, and the corresponding event may be treated as having 0 probability). The number of particle removed from this area is  $N_{od}$  in 1000 waves per one diameter long strip, i.e. the number of particles traversing the control section

$$S \cdot \frac{\Delta t}{T_m} = \frac{l_d \cdot \sin \beta_{kb}}{D_{n50}} \cdot \frac{N_{od} \Delta t}{1000 T_m}$$

i.e.:

$$S = \frac{l_d}{D_{n50}} \cdot \frac{N_{od}}{1000} \cdot \sin \beta_{kb} \tag{9}$$

where the characteristic wave obliquity at breaking point is evaluated from the wave characteristics at the measure point according to the procedure (the breaker index  $\gamma$  is set equal to 1.42 according to Komar & Gaughan, 1972):

$$H_{kb} = (H_k^2 \cdot c_g \cdot \cos \beta \cdot \sqrt{\gamma/g})^{2/5}$$

$$c_{kb} = \sqrt{g H_{kb} / \gamma}$$

$$\sin \beta_{kb} = \sin \beta \cdot c_{kb} / c$$

For the sake of simplicity we have assumed in the presentation that the length of displacements and the time between displacements are deterministic, but the result is asymptotically exact whichever are the distributions of the displacement length  $L_d$  and of the residence (between movements) time  $T_r$ , provided they are independent: the mean velocity of each mobile particle (time derivative of the mean particle position) is asymptotically  $E(L_d)/E(T_r)$ . The same relation is exact at any time if the event process of movements is Poissonian.

Fig. 6 shows the experimental data of Burcharth & Frigaard (1987) and van der Meer & Veldman (1992), interpreted according to the structure of formula (9). Fig. 7 shows the comparison between formula (9), which the substitutions corresponding to (7.1) and (8), and the experimental results. No calibration was necessary and the comparison is a verification of the approach. The four point which do not conform to the general trend refer to van der Meer data with 50° obliquity, for which no offshore equivalent conditions exist due to the great inshore obliquity.

Fig. 6 Relation between the measured longshore transport at berm breakwaters and mobility.

## 6. The abrasion model

Information on mobility and displacement is eventually used to estimate armor stone abrasion for a given wave climate. The model is based on a proportionality assumption between abrasion volume and abrasion work, which is an ancient hypothesis due to Reye (1848) widely used in tribology; the proportionality coefficient, characterizing the stone material resistance to abrasion, may be easily derived from Latham and Poole mill abrasion tests.

The essence of Reye hypothesis is that between the two factors of the abrasion work, friction stress and sliding distance, a perfect compensation is possible: i.e. if both are altered but the product does not change so does erosion. Or when the energy is dissipated in the impacts, the hypothesis assumes that all the dissipated energy is spent for the disgregation of small volumes of material near the contact. In both cases it is evident that if the material resistance is greater than the applied local stress, part of the work may be converted into heat and not into abrasion. Some scale effects are therefore to be expected, since stress increase considerably with the size of the units while the material resistance remains unchanged.

Fig. 7 Comparison between formula (9) and measured longshore transport in berm breakwaters

In the original Latham & Poole (1987) mill a  $\Phi$  176 mm cylinder is half-full with rock grains of size 25-32 mm submerged in water and is kept turning at 26-27 rpm speed (a second version of the mill -Latham, 1991- has  $\Phi$  195 mm and rotates at 33 rpm giving 1.5 higher abrasion per rotation); due to the internal friction the surface of the granular forms an angle with the horizontal equal to dynamic internal friction angle  $\varphi_d$ ; the gravity center results eccentric and the resisting moment, the work dissipated by abrasion per revolution  $\mathcal{L}_u$ , and the relative volume loss can be easily expressed

$$\begin{aligned}
 b &\simeq 4R/3\pi \cdot \sin\varphi_d \\
 \mathcal{L}_u &= W \cdot b \cdot 2\pi \simeq 8/3 \cdot (\rho_a - \rho_w)g \cdot V \cdot R \cdot \sin\varphi_d \\
 -\Delta V &= k \cdot \mathcal{L}_u \cdot N
 \end{aligned}
 \tag{10}$$

where  $b$  is the eccentricity of rock gravity center,  $W$  and  $V$  are respectively the submerged weight of the grains and their volume,  $\Delta V$  is the volume lost by abrasion and  $k$  is the proportionality constant characterizing rock material;  $1/k$  is homogeneous to a stress and is presumably proportional to material resistance. Combining the equations and assuming that during the test  $N = 1000$  revolutions are

carried out, since by definition  $k_s$  in this case is equal to the relative volume reduction, one obtains

$$l_{test} = 8/3 \cdot R \cdot N = 235 \text{ m (260 m in the 2nd version)}$$

$$-\Delta V/V \approx \ln \frac{V_0}{V} = k_s = k \cdot l_{test} \cdot (\rho_a - \rho_w)g \cdot \sin\varphi_d \tag{11}$$

Fig. 8 Geometric scheme of Latham & Poole mill abrasion test

In prototype, a stone sliding for a length  $l$  over the profile having slope  $\alpha$  is accompanied by the dissipation work

$$\mathcal{L} = l \cdot (\rho_a - \rho_w)g \cdot V \cdot \cos\alpha \cdot \tan\varphi_d \approx l \cdot (\rho_a - \rho_w)g \cdot V \cdot \sin\varphi_d$$

since  $\cos\alpha/\cos\varphi_d \approx 1$ . According to Reye hypothesis and to relation (11) the relative loss of volume is

$$-\Delta V/V = k_s \cdot l/l_{test} \tag{12}$$

In the lifetime of the breakwater  $-L-$  the total displacement length of a stone on the active profile  $-l_L-$ , reminding that the damage level  $-S_s-$  was evaluated over 1000 wave periods, is

$$l_L = \int_0^L l_{avg}(t) \cdot S_s(t) \cdot \frac{dt}{1000T}$$

or, since no movement occurs if wave intensity is below threshold,

$$l_L = \sum_{\text{storms exceeding threshold}} l_{avg} \cdot S_s \cdot \frac{N_w}{1000} .$$

The number of storm exceeding threshold is in the case of practical interest great enough to assume the number of storms  $N_{st}$  deterministic and to approximate the sum by its expected value, and therefore

$$l_L = N_{st} \cdot E\left(l_{avg} \cdot S_s \cdot \frac{N_w}{1000} \mid \text{threshold is exceeded}\right)$$

Let  $\lambda$  be the mean frequency of storms and  $P_*$  the probability that a generic storm intensity  $h$  exceed threshold  $h_*$ , the expected number of storm is

$$N_{st} = \lambda_* \cdot L := \lambda \cdot L \cdot P_*$$

Let  $F_{H_s}(h)$  be the climatic distribution of storm wave height and let assume that the distribution has exponential behavior provided the threshold is exceeded:

$$F_{H_s}(h) \simeq 1 - \exp\left(-\frac{h-h_0}{h_1}\right) \quad \text{and} \quad P_* = \exp\left(-\frac{h_*-h_0}{h_1}\right)$$

The conditioned distribution, provided that the threshold is exceeded, has similar distribution with the parameter  $h_0 = h_*$ . Assuming finally for the sake of simplicity that both the number of waves per storm and the wave steepness are constant, that water is deep so that  $H_k/C_k = H_s$ , letting  $\xi$  be the running value of the modified mobility parameter and

$$\xi_1 := \frac{h_1(s_m/s_{mk})^{-1/5}}{\Delta D_{n50}} \quad (13)$$

the total displacement length in lifetime is

$$l_L = N_{st} \cdot N_w \cdot D_{n50} \cdot f_1(\xi_1) \quad (14)$$

where

$$f_1(\xi_1) := \int_{2.0}^{\infty} (1.4\xi - 1.3) \cdot 0.14\xi(\xi - 2.0)^{2.2} \cdot \exp\left(-\frac{\xi-2.0}{\xi_1}\right) \cdot \frac{d\xi}{1000\xi_1}$$

$$- \Delta V_L/V \simeq \ln \frac{V_0}{V} = k_s \cdot L \cdot \left[ \frac{\lambda_* \cdot D_{n50}}{l_{test}} \cdot N_w \cdot f_1(\xi_1) \right] \quad (15)$$

The function  $f_1$  may be approximated without any practical loss of accuracy as:

$$f_1(\xi_1) \simeq 0.0020 \cdot \xi_1^{3.0} \quad (16)$$

The factor in brackets in eq. (15) represents the conversion factor of lifetime into equivalent number of thousands of revolutions and should be equal to the reciprocal of Latham (1991) conversion factor  $X$ . Actually only some of the factors influencing stone degradation appear in our model; these are: 1-size, 4-incident wave energy, 9-mobility of armor in design concept.

Factor  $X_1$  is according to Latham (1991) directly proportional to the nominal diameter, whereas in our formula stone size acts as inversely proportional.

Factor  $X_4$  is also a scale factor as it is inversely proportional to wave height; it also represents the integrity of blocks.

Factor  $X_9$  depends on the ratio of the two mentioned scale parameters.

Actually the are at least two different scale effects: one for the external abrasion agents, such as chemical attack or waterborne attrition agents, and one for abrasion due to armor stone movement. The first type of abrasion acts on the surface of the stone and erodes a layer of thickness independent from stone size, and hence the scale effect on the relative lost volume is inversely proportional to its size; the factor representing the associated scale effect is  $X_1$ . In the second type, stresses on the contact among stones increase proportionally to stone or wave size, whereas the material resistance remains constant; this produces an effect on relative volume loss proportional to size and  $X_4$  is the factor representing this scale effect.

In any case since the two types of abrasion have different scaling factors and the effects are naturally added on stones, the effects should preferably be evaluated separately in the prototype and in the model. The model we propose can be used to evaluate one of the types of abrasion, provided the  $k_s$  values derived from small scale tests may be significant. For the other type existing statically stable breakwaters can provide useful information.

Example applications (Lamberti & Tomasicchio, 1994) show that Latham's method, including abrasion due to external agents, returns greater degradation of stones (one order of magnitude greater  $\Delta V_L/V$ ) but is less sensitive to mobility (half order of magnitude). Latham method is calibrated with the aid of several real world cases.

Some scale effects relative to Reye hypothesis are evident from the comparison between the 1st and the 2nd Latham mill: a factor 1.1 in the mill size or sliding length and 1.4 in peripheral velocity produces a factor 1.5 in abrasion intensity for the same material. This indication could suggest to scale up the degradation proportionally to the impact velocity scale, i.e. for a stone rolling on a mound, proportionally to the square root of the length scale. Since the length scale from the mill to reality is almost 100, the scaling would compensate approximately for the pointed out difference. More definite information is anyway required about the scale effects due to impact velocity and stress.

## 7. Conclusions

A careful analysis of stone mobility shows that:

- the wave height and wave period combination which describes properly stone mobility is the combination proportional to onshore energy flux ( $\propto H^2T$ ); according to the same concept also the effect of wave obliquity can be easily included in the wave intensity parameter; as a consequence a stability number modified respect to the traditional  $N_s$  is introduced.
- a wave height greater than the significant one should be used as wave height parameter in order to have comparable stability results in deep and shallow water conditions;
- the true threshold of stone movement corresponds to mobility conditions significantly lower than defined by previous researchers: in the range of mobility conditions typical of berm breakwater operation ( $N_s = 2 - 3$ ) the mobility is low but appreciable;
- relations are provided giving the non dimensional frequency of stone movements and their average length as function of the modified stability number.

The proposed longshore transport model, derived without any special calibration from frequency and length of displacements, gives results in good agreement with measurements performed on berm breakwater models.

The proposed conceptual method for the evaluation of armor stones abrasion on berm breakwater due to stone movement gives only reasonable results and requires some adjustment in order to account for the scale effects relative to impact velocities and stresses.

## Notations

The following symbols and notations are used in the paper:

- $c$  = wave celerity, [ $m \cdot s^{-1}$ ];
- $c_g$  = group velocity, [ $m \cdot s^{-1}$ ];
- $C_k$  = ratio between the characteristic and significant wave height;
- $D_{nxx}$  = nominal diameter of armor stones corresponding to fractile  $xx\%$ :  
 $(W_{xx}/g\rho_a)^{1/3}$ , [m];
- $E()$  = expected value;
- $H$  = wave height, [m];
- $H_s$  = significant wave height, [m];
- $H_{1/n}$  = mean wave height of the  $1/n$  fraction of the highest waves;
- $L$  = wave length, [m];
- $L_d, l_d$  = length of displacement, stochastic variable and mean value, [m];
- $N_s$  = armor stone mobility (stability) number:  $H_s/\Delta D_{n50}$ , [];
- $N_s^{**}$  = modified stability number, [];
- $S$  = along-structure transport measured as bulk volume, [ $m^3 \cdot s^{-1}$ ], or as number of stones per wave, [];
- $s$  = wave steepness:  $H_s/L_o$ , [];
- $T$  = wave period, [s];
- $W_{xx}$  = weight of which  $xx\%$  by weight of the armor stones are smaller, [kg];
- $\beta$  = angle of wave attack (between wave front and shoreline), [];
- $\gamma$  = breaking index: ratio between breaking wave height and water depth, [];
- $\Delta$  = relative density of armor stones =  $(\rho_a - \rho_w)/\rho_w$ , [];
- $\rho_a$  = mass density of armor stones, [ $kg \cdot m^{-3}$ ];
- $\rho_w$  = mass density of water, [ $kg \cdot m^{-3}$ ];
- $\cdot_b$  = at wave breaking point;
- $\cdot_k$  = characteristic or effective value;
- $\cdot_m$  = relative to spectrum mean frequency;
- $\cdot_o$  = in offshore conditions;
- $\cdot_p$  = relative to spectrum peak frequency.

## CHAPTER 118

### THE LARGE SCALE DOLOS FLUME STUDY

George F. Turk and Jeffrey A. Melby<sup>1</sup>

**ABSTRACT:** In 1993, the U.S. Army Corps of Engineers, Waterways Experiment Station, Coastal Engineer Research Center conducted the Large Scale Dolos Flume Study (LSDFS) in order to investigate the structural response of concrete armor units. The study was primarily carried out in the large wave flume at the O.H. Hinsdale Wave Research Laboratory, Oregon State University. Over 300 model dolos units with a mass of 26 kg and a waist ratio of 0.32 were used. The units were cast from concrete. The instrumented dolosse were fitted with surface-mounted strain gages then subjected to a wide range of wave loading conditions. This strain gaging and the state-of-the-art data acquisition system increased the signal-to-noise ratio so that accurate measurements of static, quasi-static, wave-induced hydrodynamic, and unit-to-unit impact loading could be recorded. The LSDFS included a standard calibration series, static ramp tests, dry-land impact tests, and regular and irregular wave flume tests. Hydrodynamic instrumentation in the flume tests consisted of a very dense array of wave gages, current meters, runup-rundown gages, pore pressure transducers, hydrophones, digital video, and still photography in the nearshore zone. This paper presents previously unpublished details of the LSDFS specifically pertaining to instrumentation, calibration, dry-land impact tests, and some preliminary results of impact response captured in the flume tests.

### INTRODUCTION

Dolosse are the dominant concrete armor units used on U.S. rubble-mound structures. They continue to be specified for new breakwater construction and for rehabilitation. Recent surveys by Corps researchers of concrete-armored breakwaters indicate an urgent need for concrete armor repair and rehabilitation design guidance (Melby and Turk 1994a). But, despite many concrete armor structural investigations during the last 20 years, there is still a general lack of knowledge of dolos structural

---

1) Research Hydraulic Engineers, Coastal Engineering Research Center, USAE Waterways Experiment Station, Vicksburg, MS, 39180

response. This is partly because of the complexity of the response with both the loading and boundary conditions being stochastic and highly variable and the wave loads not being currently analytically solvable. The inadequate knowledge is also due to the lack of a high accuracy strain measurement system for concrete armor.

Past efforts to measure the structural response of dolosse have included the Crescent City Prototype Study (Howell 1986), where 38-tonne dolosse were internally structurally instrumented. The Crescent City study provided a valuable data set of wave-induced hydrodynamic loadings at prototype scale which was used to calibrate a strain amplifying load cell for measuring dolos structural response at small scale (Markle 1989). But no impacts were recorded during this study and the static data set was limited to the 15 dolosse that were sampled. Also, the static data may have drifted over the course of the measurement period due to long term differential curing of the concrete.

Numerous dolosse small scale model experiments have been conducted by Scott et al. (1986), Anglin et al. (1989), Markle (1989), Melby et al. (1989), and Burcharth et al. (1991). Most of these studies used a load cell developed by or similar to that of the Canadians. While these efforts have contributed to the understanding of dolos structural response, all have proven less than satisfactory in determining the maximum stresses in dolosse. The load cell was calibrated for response to hydrodynamic loading by Markle (1989). But small scale load cell structural investigations are subject to scale and modeling effects, as discussed by Melby and Turk (1994b). For instance, calibration for static response is difficult because the small scale units have different surface friction than prototype units and static strains in load cell instrumented units are so small that they are very unreliable. Also, calibration for impact stresses has been done using uninstrumented drop test results (Burcharth 1991). These tests define failure as a specific crack width and relate the height dropped that produced this crack width to concrete cylinder compressive test strength. There are a large number of factors contributing to the uncertainty in these tests including fatigue effects from ever increasing drop heights, failure occurring at different locations on the units, armor unit strength being very different than the cylinder strength, incorrect estimation of cylinder tensile strength, and the load cell unit responding dynamically entirely differently than an uncut unit.

The Coastal Engineering Research Center's Large Scale Dolos Flume Study (LSDFS) provided an effective solution for quantifying the maximum stresses in dolosse. By using large scale concrete models instrumented with surface-mounted strain gages, direct strain measurements were made. This limited the required assumptions concerning the concrete response and added a degree of control not possible in prototype investigations.

## **LARGE SCALE DOLOS FLUME STUDY OVERVIEW**

The purpose, goals, and experimental plan of the LSDFS, which began in 1991, are discussed in detail by Melby and Turk (1994b, 1994c) and will only be outlined herein. The large scale used was intended to minimize scale effects associated with flow forces, surface friction, materials, modeling, and instrumentation. The purpose of the study was to accurately and simultaneously measure dolos structural and hydrodynamic stability response. These data have been useful for verifying structural scaling criterion, developing design methods, and calibrating small scale model instrumentation. In addition, the results led to the development of a new concrete armor unit shape, the CORE-LOC™ (Melby and Turk 1995). The technology developed during this study for

constructing, instrumenting, and collecting data will hopefully be helpful in future physical structural modeling. Finally, the data set will provide calibration for several numerical models under development at the CERC.

Besides accurate structural measurements of dolos response, measurements of real-time dolos movement, incident and reflected waves, and water particle velocities in front of the slope were also sought from the study. Dynamic dry-land tests were conducted to quantify impact response, and validate scaling using impact drop tests under idealized conditions. Dry-land static ramp tests were conducted to measure static stresses found in the dolos for a wide range of boundary conditions and several positions in the armor layer.

### Model and Instrumentation Development

Approximately 300 concrete dolosse with a mass of 26 kg and a waist ratio of 0.325 were cast for the LSDFS (Figure 1). The most critical aspect of the LSDFS was the development of the Large Scale Instrumented Dolos (LSID). The LSID needed to be capable of detecting minute strains at a variety of locations on a dolos surface while maintaining integrity under the rigors of long-term underwater testing. Much discussion went into the planning of these units. Doubts were expressed that the strains produced, much of which would be below  $20 \mu\epsilon$ , would even be measurable. Noise levels of less than  $100 \mu\epsilon$  were at one time considered good. The option of using a cut section and strain amplifying instrumentation was discussed but ultimately rejected. A cut dolos with a metal pipe inserted between the sections does not respond dynamically like an uncut dolos. As discussed above, identification of an apparent elasticity is very difficult.

#### Dolos Concrete.

Concrete Type:	Type I Portland Cement
Aggregate:	Coarse Sand
Density:	$\rho = 2180 \text{ kg/m}^3$
Youngs Modulus:	$E = 29 \text{ GPa}$
Poisson Ratio:	$\nu = 0.46$

Armor Unit Volume:	$V = 0.012 \text{ m}^3$

Figure 1. 26 kg instrumented dolos (LSID)

It was decided that surface-mounted strain gages, placed at up to 18 critical locations on the dolos shank and flukes (Figure 1), would be the the most successful instrumentation scheme. This scheme provided measurement of the exact surface strain

at the extreme fiber. Young's Modulus was determined from concrete cylinder sample tests, and Hooke's law applied to get a precise surface stress. Load cells generally measure two moments and a torque. Using these load-cells in small-scale dolosse, two moments and torque are determined as a function of voltage output by hanging weights off the end of the dolos. These gross responses are based on differencing the voltage across the wheatstone bridge circuit. For load cell instrumented units, a linear stress distribution must be assumed, with equal magnitudes of compressive and tensile strains at the extreme fibers. But Melby et. al. (1989) showed highly non-linear stress distributions in dolos shank sections under static loading, even for low stress levels, due to the abrupt changes in sectional shape. Therefore, the linear cross-sectional stress distribution assumption will always produce an unquantifiable error. In the LSDFS, by measuring the individual strains on opposite sides of a section, we can directly measure the compressive and tensile extreme fiber strains and use Hooke's Law to compute stress.

By casting the LSIDs out of sand aggregate concrete, the strain gages could be placed directly on the prepared concrete surface without concern that a gage would be placed on an undetected aggregate stone. But one of the compromises that had to be made was the need for extensive waterproofing and impact protection (Figure 2a) for the surface-mounted gages (Figure 2b). Dry-land tests showed that, if a LSID impacted another LSID on the waterproof covering, the impact strain amplitude could be attenuated by up to 40%. This was a great concern during the flume tests. Fortunately, rarely

Figure 2. (a) Waterproofing and protection for (b) surface mounted strain gages

during the testing were impacts directly on the waterproofing evident. This was because the units generally impacted on the fluke ends, falling like a hammer. The waterproofing procedure was tedious and time consuming; but it was important because water intrusion into the instrumentation could cause gage drift and gage failure. Waterproofing integrity tests were done over the period of several weeks by soaking the LSIDs in tubs filled with water. During the waterproofing testing, the instrumentation showed minute and acceptable degrees of gage drift as shown in Figure 3.

The final strain gage layout consisted of 350  $\Omega$ , 1.25 cm foil gages set in a Wheatstone half bridge configuration (Figure 2b). By using a Poisson gage, signals were temperature compensated and amplified 10% to 30%. The waterproofed gages were capable of detecting strains on the surface of the concrete dolosse with a resolution of one

micro-strain ( $\mu\epsilon$ ) peak-to-peak and a variable range of around 1000  $\mu\epsilon$ . The high resolution was required for accurate measurement of strains due to static and hydrodynamic loads and the large ranges for measurement of static, quasi-static, and impact strains simultaneously. A total of seven dolosse were instrumented with up to 18 of these strain gages.

Other aspects of the model dolosse, instrumentation, and data acquisition system, including the details of molding the dolosse, the strain gaging development, and the data acquisition hardware specifications are given in Melby and Turk (1994c).

Figure 3. Typical waterproofing test results

### Dolos Calibration

The purpose of conducting an extensive bench test program for the instrumented dolosse was to check the strain gages and bridge circuitry and to quantify the amplification of the Poisson gages. By applying known torsion and bending moment loads to the dolos units and knowing the Young's Modulus, strain readings obtained from each of the bridge circuits were compared against theoretical values derived by combining simple beam theory and Hooke's Law. The strain was analytically calculated for bending as

$$\epsilon = \frac{FL}{0.0956d^3 E} \quad (1)$$

and for torsion as

$$\epsilon = \frac{16FL(1 + \mu)}{\pi d^3 E} \quad (2)$$

Here  $\epsilon$  is strain,  $F$  is the applied load,  $L$  is the moment arm,  $d$  is the distance between opposing faces of the dolos section,  $E$  is Young's Modulus, and  $\mu$  is the Poisson Ratio. Table 1 shows typical results of the static calibration, where measured strains were compared to analytically-calculated strains. The LSID measurements were at a maximum within 10% of the theoretical values.

Table 1. Typical results of dolos bench test

Load (N)	Bending Gage			Torsion Gage		
	Estimated Strain ( $\mu\epsilon$ )	Actual Strain ( $\mu\epsilon$ )	Percent Error (%)	Estimated Strain ( $\mu\epsilon$ )	Actual Strain ( $\mu\epsilon$ )	Percent Error (%)

E = 29 Gpa , Moment Arm = 61 cm, Width of Shank = 13.8 cm

## Flume Setup

The OSU flume used for the LSDFS measured 104 m x 3.7 m and is 3.7 m deep (Figure 4a). The waves were generated by a flap-type wavemaker with active reflected wave suppression. The flume was fitted with an instrumentation carriage and had a configurable foreshore slope.

The flume instrumentation (Figure 4b) and data acquisition system included:

- 1) VAX-based 64-channel DAS
- 2) Time code generator linking all data acquisition devices with atomic clock
- 3) 4-three-axis current meters
- 4) 4-electro-resistive wave gages
- 5) 2-electro-resistive runup/rundown gages
- 6) 8- pore pressure transducers
- 7) 2-surface video cameras
- 8) 2-underwater video cameras
- 9) 2-underwater microphones
- 10) 2-35mm still cameras

Figure 4. (a) Flume Layout. (b) Instrumentation. (c) Cross-section

Approximately 300 uninstrumented dolosse and up to seven LSIDs were placed on a 1V:1.5H structure slope (Figure 4c). The units were placed with a packing density of  $\phi = 0.83$ , a layer coefficient of  $K_{\Delta} = 0.94$ , and a porosity of  $P = 56\%$ . Using these parameters, 15 dolosses were placed per square meter of surface area.

## PRELIMINARY RESULTS

### Static Ramp and Dynamic Drop Tests

Results of the static ramp tests have been previously discussed in detail by Melby and Turk (1994b, 1994c). The ramp tests included 84 rebuilds on a 1V:1.5H slope. Strain measurements were taken with the slope flat, sloped, sloped and nested (vibrated), and flat again. The static ramp tests produced an overall non-dimensional static mean tensile stress,  $\sigma/\rho g C$ , of 15.2 with a standard deviation of 9.0, where  $g$  is the acceleration of gravity,  $\rho$  is the concrete density of  $2180 \text{ kg/m}^3$ , and  $C$  is the dolos fluke length of 43 cm.

The dynamic drop tests were conducted in the usual manner (Figure 5) with nine incremental centroidal drop heights from 0.035 to 1.98 cm. The dolosse were dropped on a structural concrete base over 1 meter thick. It was assumed that this base did not absorb an appreciable amount of energy.

Figure 5. Standard drop test configuration

Two LSIDs were used (Figure 1) and 5 drops were performed at each of the nine heights on each end of the instrumented fluke. Figure 6 shows a typical impact signal recorded from the four gages located about the dolos shank. Figure 6(a) shows signals from gages A and D, located on the top and bottom of the shank. Here most of the vibrational energy is in the fundamental flexural vibration mode. Figure 6(b) shows signals from gages B and E, located on the sides of the shank where little straining occurs. These signals show that the dolos is in almost pure in-plane bending, with no out-of-plane bending or torsion introduced from the test procedures.

Figure 7a shows the maximum strains recorded during each drop from the four shank gages (gages A,B,D,E). In Figure 7, the abscissa is the ratio of the centroidal

drop height,  $h$ , to the dolos fluke length,  $c$ . Figure 7b shows maximum strains recorded from eight of the fluke gages (gages AF1,BF1,EF1,GF1,BF2,DF2,EF2,GF2). The raw data show consistent amounts of scatter between different drop heights. However, when observing the coefficient of variation (standard deviation divided by the mean), as plotted against the non-dimensional drop height (Figure 8), a greater degree of scatter becomes apparent at the lower drop heights. This is expected, as imperfections in the impacting face made accurate repeatability almost impossible for the smallest five drop heights

Figure 6. Typical impact signal. (a) signal from top and bottom gages. (b) signal from side gages

( $h/c = 0.0008$  to  $0.005$ ). But the region of interest in the drop tests is over those drop heights in the fully elastic range; in this case, the upper four drops. Figure 9 shows the results of a linear regression through these non-dimensional stresses as a function of the square root of the non-dimensional centroidal drop heights for both the shank and fluke. Theory indicates that the magnitude of impact stress is proportional to the square root of the drop height (Burcharth 1981, Melby and Turk 1994b), and these results support this impact scaling law reasonably well. The impact stresses found in the flukes also follow this scaling but are approximately 80% of those found in the shank.

The results indicate that impact stress scaling is proportional to the square root of the characteristic length scale, but the magnitudes of the impact stresses are significantly larger than those reported from prototype failure tests (Burcharth 1991). As discussed in Melby and Turk (1994b), this difference is very likely due to the weaknesses in uninstrumented prototype destructive dolos field tests, as discussed above. The prototype dolosse were dropped several times before cracks could be seen. Initial cracking and cylinder strength were used to define impact stress. Uncertainty in these tests can be due to scatter in levels and types of failure stresses, differences in the stiffness of the impacted bases for the various tests, failure stresses being not necessarily similar to test cylinder failure stresses, and assumptions about the actual strength and elasticity of the concrete at the time of the drop test.

Figure 7. Record of all strains measurements from 9 drop heights. (a) Shank. (b) Fluke

Figure 8. Coefficient of Variation for impact stresses in shank and fluke

Figure 9. Nondimensional impact stress vs. Nondimensional centroidal drop height. (a) Shank. (b) Fluke

Figure 10. Comparison between impact duration recorded by trigger and flexural vibration recorded by top mounted strain gage (Gage D)

Melby and Turk (1994b) stated that the impact duration is governed predominately by the by the flexural response of the dolos. The impact duration was measured directly from a tip mounted strain gage. Figure 10 shows a raw data plot of an impact single from a drop height of 0.23 cm. The figure shows the duration of impact from the trigger to be nearly identical to the period of vibration recorded from a shank-mounted strain gage. This validates that the impact duration is governed by the flexural bending response of the unit and is equal to the inverse of the fundamental frequency of flexural vibration of the unit.

### Preliminary Flume Test Results

The intent of the flume tests was to quantify the maximum stresses in dolosse under wave loading. The model dolosse were sized based on small-scale model hydraulic stability tests results and the limitations of the wavemaker. The range of wave heights for the flume tests was chosen to produce a range of Hudson stability numbers,  $N_s$ , up to 4.6 ( $K_D$ 's up to 64). From the small-scale model testing, it was expected that dolos movement would achieve an upper limit of 4% rocking. In the small scale-tests, it was found that, at wave heights corresponding to  $N_s < 2.3$  ( $K_D < 8$ ), the dolosse generally do not move. At wave heights between  $N_s = 2.3$  and  $N_s = 2.9$ , dolosse that are not interlocked start to rock about on the slope. For  $N_s > 2.9$ , the movement of dolosse on slope becomes more unpredictable. Increasing the wave height may cause dolos to rock more violently, to move out of their original positions, groups of dolosse may become mobile, or the whole slope may slump.

The LSDFS dolosse, made from concrete, proved to be surprisingly more stable than their small-scale counterpart. Although it was previously felt that small scale models had little scale effects, the LSDFS tests showed dolosse stable up to  $N_s = 4.6$ . It was a rare case that 2% of the dolosse were rocking, and in general, for the more severe wave cases, only 1% rocking was observed. It was felt at the time that the higher surface friction on the large scale units caused the higher stability.

At present, a preliminary analysis of select records from the large volumes of impact data generated by the LSDFS (over 4 GB) has been accomplished. Impact response was recorded during 136 flume tests, and 10% of the impact records have been analyzed to-date. The records analyzed were from tests performed with monochromatic waves with periods ranging from 3 to 5 sec and wave heights to 1.4 m. The water depth for these tests was 1.5 meters.

Several plots are presented to show correlation, or the lack thereof, between impact stress and several typical wave parameters. In Figure 11a, the nondimensional impact stress,  $\sigma/(E\gamma C)^{1/2}$ , has been plotted against relative wave height,  $H/d$ , where  $H$  is incident wave height and  $d$  is depth. In general, one would expect the magnitudes of the impact stresses to increase with wave height; but little correlation has been found. Observing the tests, the authors noted that, for units with unstable boundary conditions, impacts occur at given wave particle velocities, regardless of the amount of incident wave energy. So, while it is certainly true that larger waves have more capacity for loosening stable armor units, waves below a given threshold have little capacity for loosening stable units and impact stresses will not, in general be a function of wave height. The data indicate that the stresses are related to the threshold of movement.

Figure 11b shows impact stress as a function of wave steepness,  $H/L_o$ , where  $L_o$  is the deep water wavelength. Stresses do not appear to be a function of the wave length.

Figure 11c shows impact stress as a function of Stability Number,  $N_s$ . This plot is similar to Figure 11a. The maximum stresses recorded were higher for the larger wave heights and higher stability numbers; but, in general, the mean stress and the mean stress plus one standard deviation was approximately the same for  $N_s$  between 3.0 and 5.0. Finally, the impact stresses are plotted as a function of the surf similarity parameter,  $\tan\alpha/(HL_o)^{1/2}$ , (Figure 11d), where  $\alpha$  is the structure slope angle. The effects of breaker

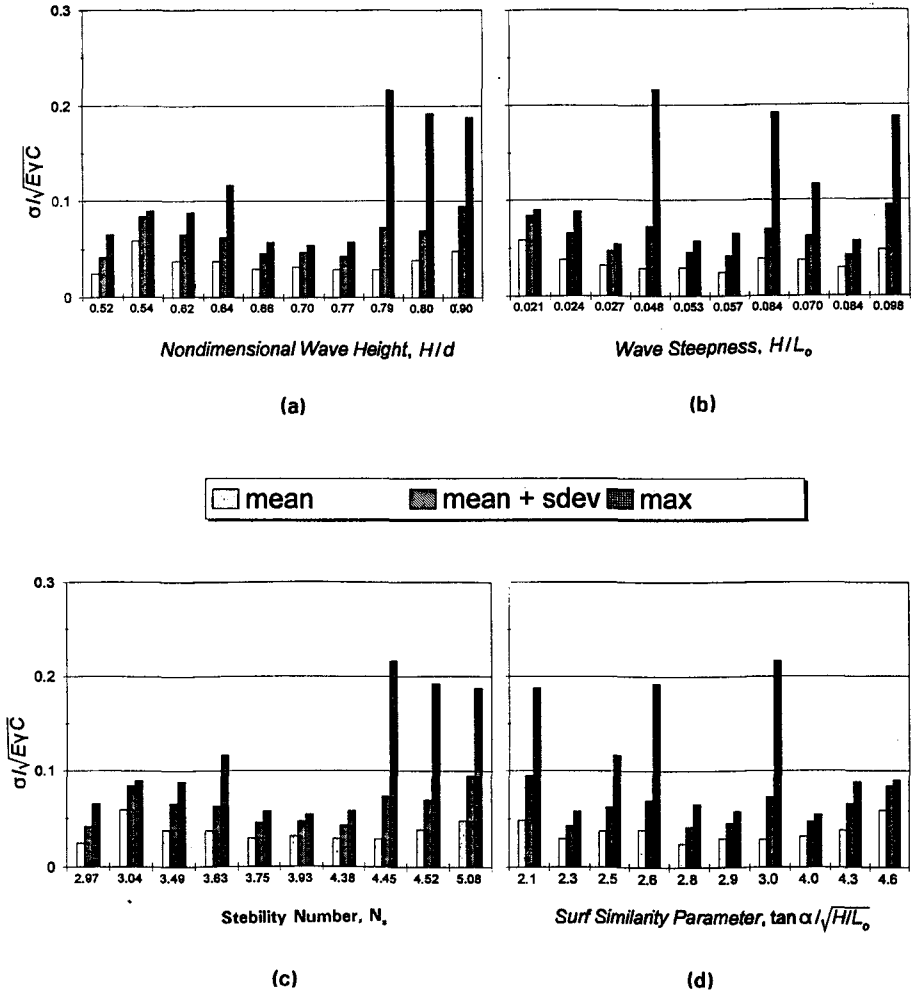

Figure 11. Nondimensional impact stress vs. (a) nondimensional wave height. (b) wave steepness. (c) Stability Number. (d) Surf Similarity Parameter.

type do not seem to effect the magnitudes of the impacts, with stress values approximately the same for both plunging and collapsing breakers.

At this point in the data analysis, trends are difficult to ascertain. It would be expected that large wave heights, plunging waves, and high energy content would all contribute to producing the largest impact stresses; but initial observations of the data do not show this to be the case. It seems that the magnitudes of the stresses are more predicated on the boundary conditions. The less stable the boundary conditions the more likely high impact stresses will occur, even in moderate wave conditions. This seems to allude to the fact that the integrity of a dolos armor slope is largely based on proper construction techniques, where no units are placed on slope without adjacent interlocking, as discussed by Melby and Turk (1994a).

This is made more significant by the magnitude of the impact stress over the broad range of wave conditions. While the tensile strength of concrete dolosse used in the LSDFS was approximately  $f't = 5.5$  MPa (or a nondimensional strength  $f't/(E\gamma C)^{1/2} = 0.34$ ), 12 dolosse were broken by wave action during the course of the experiment. Many dolos prototype structures have used concrete with tensile strengths around  $f't = 3.5$  MPa and have length scales of 5:1 to 8:1 relative to the LSDFS dolos. If the concrete strength for LSDFS has been scaled by these criteria and the impact scaling law, the reduced tensile strength for the LSDFS dolos would have been  $f't = 1.2$  to  $1.6$  MPa or  $f't/(E\gamma C)^{1/2} = 0.07$  to  $0.1$ . And in many cases, the mean impact stress plus standard deviation approaches or exceeds these values over the range of wave conditions. Also, in many of the records analyzed, the maximum stresses recorded are double this reduced tensile strength. The main point is, for unreinforced dolosse, unit-to-unit impact loading should not be permitted unless the resultant damage is deemed acceptable.

## SUMMARY AND CONCLUSIONS

The LSDFS allowed accurate measurement of structural response and quantification of the maximum stresses in dolosse for a wide range of boundary and loading conditions. The tests indicated that when a dolos nears its hydraulic stability threshold, at least 1%-2% of the units are rocking on slope. This rocking, and the associated unit-to-unit impact, produces impact stresses that, when combined with static and wave induced hydrodynamic stresses, can often be high enough to exceed the concrete strengths typically found in prototype dolosse. This can result in higher breakage levels than anticipated by conventional design. For even modest waves produced in the LSDFS, maximum tensile strains often exceeded  $80 \mu\epsilon$ . Scaled to prototype and converted to stress using Hookes Law and a dynamic modulus, these stresses would far exceed prototype concrete strength.

While data reduction and analysis of the substantial data set is ongoing, it is anticipated that these data will be incorporated into the Corps' probabilistic, reliability-based design program for concrete armor units, *PCARMOR*.

## ACKNOWLEDGEMENT

The work described in this paper was conducted as part of the Repair, Evaluation, Maintenance and Rehabilitation Research Program of the U.S. Army Engineer Waterways Experiment Station, US Army Corps of Engineers. The authors would like to express their gratitude to the following individuals for their contributions, comments,

and review of the LSDFS: Prof. Charles Sollitt, Oregon State University, Prof. Joseph Tedesco, Auburn University, Prof. Hans Burcharth of Aalborg University, Denmark, Mr. Joop Zwamborn from South Africa, and Prof. Fred Raichlen of the California Institute of Technology, Mr. Thomas Kendall, USAE San Francisco District, and Prof. Nobu Kobayashi of the University of Delaware. Permission to publish this paper was granted by the Chief of Engineers.

## CHAPTER 119

### **H<sub>o</sub> Parameter for Preliminary Design of Conventional Breakwater Structural Head. Data Analysis of Spanish North Coast Harbours**

\* Vicente Negro Valdecantos  
\*\* Ovidio Varela Carnero

\* Civil Engineer, Ph. D. Associate Professor. University of Madrid  
\*\* Civil Engineer, Ph. D. Head of Harbour Dpt. DRAGADOS.

### **SUMMARY**

The determination of the response of a Coastal Structures to waves is almost determined by model tests of using formulae fitted to model data. Using results of Aalborg University, 1987-88, and Collecting Spanish data from the North Coast, 1988, we approach for preliminary design the dimensionless wave height parameter,  $H_o$ , Van der Meer, 1988 for conventional breakwater, structural head, and start of damage and collapse of the structure.

The effect of wave length, storm duration, and the influence of the breakwater geometry, interlocking blocks and water depth will be include in the future for better calibration of Van der Meer parameter

### **1. INTRODUCTION**

The determination of the response of a Coastal Structure or a breakwater, trunk or head, to waves is almost always determined by model tests. Sometimes, Hydraulics Engineers use formulae fitted to model tests. The main problem depends on the stochastic nature of loads and random placement of the armour units in breakwater.

Brosen et al, 1974, demonstrated that the Hudson formula is not valid for complex interlocking types of armour blocks with respect the slope angle. Van der Meer, 1988, proposes the dimensionless wave height parameter,  $H_o$ ,  $H_s/\Delta D$ , to give the relationship between different structures and represents an important variable in a stability formula.

The agreement will be conclude:

$$\frac{u^2}{\Delta g D} \approx \frac{H_s}{\Delta D} = (\cotg \alpha \cdot K_D)^{1/3} = N_s$$

Shield parameter Van der Meer Hudson Brebner and Donelly

Using model tests of Aalborg University and collecting the Spanish Data, we approach for preliminary design the  $H_o$  parameter and

$$\frac{H^{2/3} \cdot L^{1/3}}{\Delta D}$$

for conventional breakwater, structural head, start of damage and collapse of the structure.

## 2. CLASSIFICATION OF RUBBLE MOUND STRUCTURES

Rubble mound structures can be classified by use of the static parameter,  $H_o$ ,

$$H_o = \frac{H_s}{\Delta D_{n50}}$$

where:

$H_s$  Significant wave height (m)

$\Delta$  Relative mass density (-)

$$\frac{\gamma}{\gamma_w} - 1 \quad \begin{array}{l} \gamma \text{ Specific weight of an individual unit (t/m}^3\text{)} \\ \gamma_w \text{ Specific weight of seawater (t/m}^3\text{)} \end{array}$$

$D_{n50}$  Nominal diameter (m)

Dynamically stable structures are characterized by the forming of a profile under wave attack. In this case, conventional breakwater can be classified with the combined wave height-wave period parameter  $H_o \cdot T_o$ , defined by,

$$H_o = \frac{H_s}{\Delta D_{n50}}, \text{ dimensionless wave height parameter}$$

$$T_o = T_m \cdot \sqrt{\frac{g}{D_{n50}}}, \text{ dimensionless wave period parameter}$$

As a simple remark, rubble mound structures can be classified (Fig. 1).

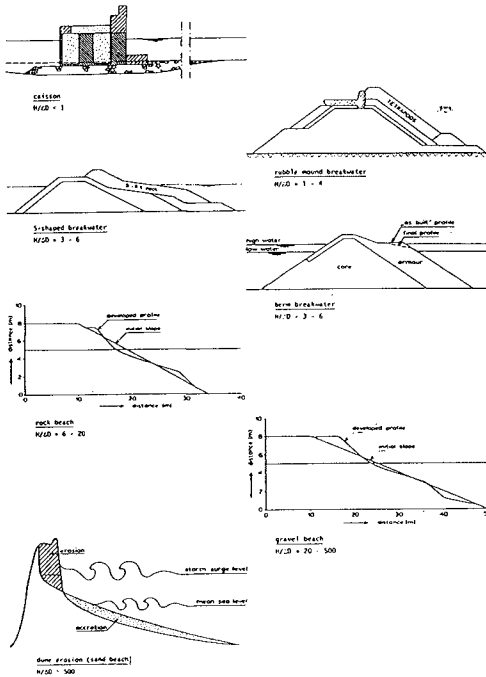

Fig. 1. Type of structure as a function of  $\frac{H}{\Delta D}$ , Van der Meer, 1988

- $H_o < 1$       Caissons, seawall, vertical breakwater. Instantaneous Failure.
- $1 < H_o < 4$       Conventional breakwater. Gradual Failure.
- $3 < H_o < 6$       Special breakwater, S shaped, berm

- $6 < H_o < 20$     Rock slopes. Nominal diameter relatively small.
- $15 < H_o < 500$     Gravel beaches.
- $H_o > 500$     Sand beaches.

The hydraulic stability can be classified including static and dynamic profiles,

- $H_o \cdot T_o < 100$     Static criteria
- $H_o \cdot T_o > 100$     Dynamic criteria

This classification is a great contribution to the total uncertainty of the coastal structures response and follows single estimation like Professor Suarez Bores 1968-74-78 and the evolution of breakwater structures, Goda and Tanimoto, 1991 (fig. 2).

Fig. 2. Evolution of breakwater structures, Goda-Tanimoto, 1991

Burcharth and Frigaard, Aalborg University, studied the front profile development, erosion and deformation of slopes, when exposed to oblique waves. Their range of tests correspond:

$$3,50 < H_0 < 7,10$$

the following stability factor values were proposed by Burcharth et al, 1988, for the start of significant transport of stones along the structures (angle of wave incidence  $\leq 30^\circ$ ).

	$\frac{H_s}{\Delta D_{n50}}$
. Trunks exposed to steep oblique waves	4,50
. Trunks exposed to long oblique waves	3,50
. Round heads	3

This research and study have been the basis to preliminary design of conventional breakwaters, structural head,  $1 < H_0 < 4$ , with a theoretical approach and using the long series of

Spanish Data from the North Atlantic Sea, the North Coast, and collecting model tests results.

### 3. DATA ANALYSIS AND ENGINEERING METHODS FOR PREDICTING THE DESIGN OF STRUCTURAL HEAD. START OF DAMAGE AND COLLAPSE OF THE STRUCTURE. SPANISH NORTH COAST EXAMPLES.

The waves reaching the Cantabrian Sea Coast, Spanish North Coast, are generated in the North Atlantic by the action of extratropical storm. The polar mass oscillations through the year define the path of the storms through the Bay of Biscay. Under such conditions, the winds are from West to North, including North West and NNW with the dominant gradient wind speed of 40 m/sg.

In that case, there are maximum frequency and intensities of waves, reaching values of significant wave height over ten meters with peak period of eighteen seconds. This is representative of the rough conditions in deepwater.

The studies reported here were done using the Spanish Data of conventional breakwaters, more than 100 ports and harbours, in the Cantabrian Sea Coast, and with a theoretical approach, obtained the following results,

Burela	72 t	3,10 m	7,45 m	1,79
San Ciprián	90 t	3,35 m	8,90 m	1,98
Cillero	28 t	2,25 m	6,25 m	2,06
Cariño, quarystone	12 t	2,05 m	5,00 m	1,96
Malpica	120 t	3,68 m	10,70 m	2,16
Lage	20 t	2,05 m	5,00 m	1,96
Finisterre	15 t	1,85 m	5,00 m	2,09
Panjón	5 t	1,28 m	3,18 m	1,85

Another conventional breakwaters were designed after this preliminary analysis in the Spanish North Coast. The results were:

Type of Breakwater	Weight of the main armour layer (t)	Nominal Diameter (m)	Significant wave height (m)	H <sub>o</sub> (-)
Zurriola, blocks	45 t	2,55 m	8,20 m	1,96
Cala Bens, La Coruña	125 t	3,75 m	10,00 m	1,98

The relative mass density coefficient ( $\Delta$ ) oscillate between 1,63 for quarrystone, 1,34 for concrete blocks, tetrapod, acropod ... etc, and 1.731 for high density natural blocks.

This analysis reported before is relation with the classic point of view for calculating head in conventional breakwater,

$$W_{\text{head}} = \text{Coefficient } (> 1,00) \times W_{\text{Hudson}}$$

The dimensionless coefficient accounts for all variables like (Fig. 3)

- Shape of the armour layer
- Number of units of the main armour layer
- Manner of placing armour layer
- Type of wave attacking structure (breaking or nonbreaking)
- Slope

Looking at the statistics of the present analysis and "only" for preliminary design in conventional breakwater head, start of damage, we can conclude in first step, fitting the model with nature test (Fig. 4-9),

$$H_o = \frac{H_s}{\Delta D_{Dn50}} \approx 2,00$$

Iribarren's model tests, 1965, presented in PIANC Congress Stockolm, demonstrated the evolution of a slope affected with groups of waves, obtaining the complete results of the evolution of damage in the armour layer of a conventional breakwater. The three phases are:

- Total stability
- Partial stability, start of damage
- Inestability, moderate damage to collapse of the structure

Stablishing the state of damage under the action of a monochromatic wave train, the slope is indefinite and the units of the main armour layer are quarrystone, concrete blocks and tetrapod (Fig. 10).

The results of damage levels with two diameter thick armour layer, Van der Meer, 1988, show the limits of the adimensional parameter  $S = A/D^2$ , a cross sectional eroded area, D nominal diameter of the armour layer (Fig. 11).

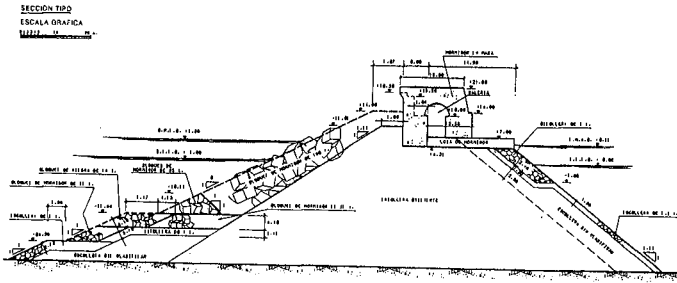

Fig. 4. Cross section Bilbao breakwater

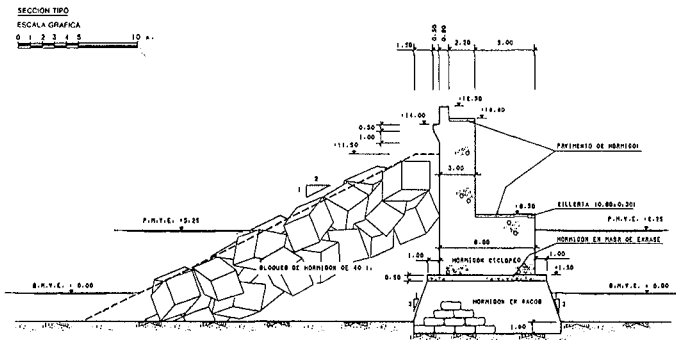

Fig. 5. Cross section Lastres breakwater

Fig. 6. Cross section principe de Asturias, Gijón breakwater

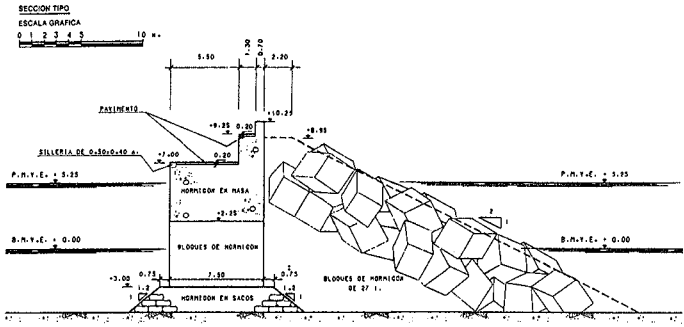

Fig. 7. Cross section Caudas breakwater

Fig. 9. Cross section San Ciprian breakwater

Type of armour layer	Slope	Damage Levels		
		Start of damage	Moderate damage	Filter visible
Stone armour layer	1,5/3,0	S = 2	S = 4/8	S $\geq$ 8/12
Block	1,5/2,0	Nod = 0	Nod=0,50/1,50	Nod = 2
Tetrapod	1,50/1	Nod = 0	Nod=0,50/1,00	Nod=1,50
Acropod	1,33/1,50	Nod = 0	---	Nod=0,50

Losada et al (1986) defined three hydrodynamic damage criteria,

1. Incipient damage
2. Iribarren's damage
3. Destruction

In order to be more precise, another stage of damage is included as a visual response, it is called incipient destruction, Vidal et al (1991). For a mound breakwater consisting of a main layer, secondary layer and core,  $P \approx 0,40$ , the definitions of the four damage criteria are as follows:

1. Initiation of damage. This level of damages defines the condition attained when a certain number of armour units are displaced from their original position to a new one at a distance equal to or larger than a unit length. Holes larger than average porous size are clearly appreciable.
2. Iribarren's damage. This damage occurs when the extension of the failure area on the main layer is so large that the wave action may extract armour units placed on the lower layer of the main armour layer.
3. Initiation of destruction. A small number of units, two or three, in the lower armour layer are forced out and the waves work directly on pieces of the secondary layer.
4. Destruction. Pieces of the secondary layer are removed. If the wave height does not change the mound will definitely be destroyed and it will cease to give the level of service defined in the design. It is called Filter visible.

As a consequence, for a preliminary design of mound breakwaters, and start of damage, we propose,

$$H_o = \frac{H_s}{\Delta D_{n50}} = 2,00$$

After the model tests performed by Iribarren, 1965, the medium relationship between the wave height of start of damage and the wave height of destruction or filter visible, is equal for stone armour layer, blocks and tetrapods and the value is 0,62.

Using the adimensional parameter for preliminary design and start of damage,  $H_o \approx 2,00$  and with the relation between the wave height start of damage and filter visible-destruction, the value of  $H_o$  will be,

$$\frac{H_{start\ of\ damage}}{H_{filter\ visible,\ destruction}} = 0,62$$

$H_o \approx 1,25$  Filter visible, collapse of structure thus, the following point will emphasized, with the concept of weight of the main armour layer,

$$W_{destruction} = \left(\frac{1}{0,62}\right)^3 W_{start\ of\ damage}$$

$$W_{destruction} = 4,10 W_{start\ of\ damage}$$

The results with oblique incidence do not show the same value for every Kind of armour piece, obtaining relation of 0,69 in rip-rap, armour layer with stone, and 0,73 with blocks and tetrapods.

However, the first analysis for a preliminary design can be consider stable.

The effect of wave length, storm duration, and the influence of the breakwater geometry, interlocking blocks, and water depth,

$$H_o = \frac{H_s}{\Delta D_{n50}} = 2,00 \quad \text{Start of damage}$$

$$H_o = \frac{H_s}{\Delta D_{n50}} = 1,25 \quad \text{Filter visible, destruction}$$

The effect of wave length, storm duration, and the influence of the breakwater geometry, interlocking blocks, and water depth, slope and other factors will be search in a future. Model test will provide the following conclusions,

$$H_o = \frac{H_s}{\Delta D_{n50}} = \frac{H_s^{2/3} \cdot L^{1/3}}{\Delta D_{n50}} = (\cot \alpha \cdot K_D)^{1/3} = N_s$$

$$\frac{H_s^{2/3} \cdot L^{1/3}}{\Delta D_{n50}} \cdot f(N)$$

where,

- L Wave length,  $\frac{1}{25} < \frac{d}{L} < \frac{1}{2}$  (m)
- N Number of active waves (-)
- $\alpha$  Slope of the breakwater ( $^\circ$ )
- $K_D$  Stability coefficient, Hudson (-)
- $N_s$  Stability coefficient, Brebner and Donelly (-)
- $H_o$  Van der Meer's parameter (-)
- $H_s$  Significant wave height (m)
- $D_n$  Nominal diameter (m)

$$Dn = \sqrt[3]{\left(\frac{W}{\gamma}\right)},$$

W Weight of an individual unit of the main armour layer (t)

$\gamma$  Specific weight of an individual unit (t/m<sup>3</sup>)

Fig. 10. Stability curve, Iribarren, 1965

Fig. 11. Value of parameter "S", A cross sectional eroded area; D, nominal diameter of the armour layer

4. CONCLUDING REMARKS

According the model tests of Burcharth and Frigaard, and the data analysis and only for preliminary design and of no other more qualified information is available, the Spanish experience in the Cantabrian Sea Coast recommends for conventional breakwater, structural head, the value of the dimensionless wave height parameter  $H_o = H_s/\Delta D$ .

$$H_o = \frac{H_s}{\Delta D_{n50}} \approx 2,00 \quad \text{Start of damage}$$

$$H_o = \frac{H_s}{\Delta D_{n50}} \approx 1,25 \quad \text{Destruction, collapse}$$

The effect of wave length, storm duration, and the influence of the breakwater geometry, interlocking blocks and water depth are now in study and they will be include in the future as a function of L, N, D, H<sub>s</sub>, D, d and α.

## CHAPTER 120

# Numerical Modelling of Breaking Wave Impacts on a Vertical Wall

N. T. Wu \*      H. Oumeraci †      H.-W. Partensky ‡

### Abstract

The impact processes on a vertical wall resulting from breaking waves are numerical simulated. Two dimensional incompressible viscous flow which is governed by the Navier-Stokes Equations and the continuity equation is solved by a finite difference scheme based on the Volume of Fluid (VOF) concept. Some comparisons with experimental results reveal that the present model is able to simulate the impact process with negligible air entrainment not only qualitatively but also quantitatively well. Although the impact pressure of a plunging breaker with non-negligible air entrainment can not be quantitatively well simulated by this model due to the restriction of the incompressible flow, the wave kinematics is still well simulated.

## 1 Introduction

Breaking waves represent the major cause for the damage of vertical face breakwaters. The stability of such structures is in fact a dynamic problem. The solution of this problem requires among others a detailed knowledge of the impact loading; i.e. the spatial and temporal distribution of the pressure induced by the breaking waves on the structure must be determined. To date, no theoretical approach for this problem is available. On the other hand, small-scale model investigations suffer from scale effects, so that no definite quantitative conclusions can be drawn. Even results from large-scale model tests recently conducted in super-wave tanks seem to be affected to some extent by scale effects. In addition, the use of such large facilities is so expensive and so time consuming that a reasonable parameter study cannot be effectively performed. Therefore, more attention has been paid within the last 15 years to numerical methods.

Most of the existing numerical model for the simulation of breaking wave impact loads are based on potential flow theory. These methods are however unable to describe the

†Prof. Dr. -Ing., Univ. Professor, Techn. Univ. Braunschweig, Beethovenstr. 51a, 38106 Braunschweig, Germany

‡Prof. Dr. -Ing., Dr. phys., Prof. em. formerly Director of Franzius-Institut, Univ. Hannover, Germany

whole breaking and impact process due to the great distortion of the flow around the free surface interfaces which will not remain irrotational.

Therefore, the Volume of Fluid (VOF) (Nichols, et al., 1980) concept has been adopted here to develop a numerical model which can describe the complex free surface associated with breaking waves and the integral history of the impact pressures and forces on a vertical wall with a foreshore slope. The present paper is principally intended to present some of the results of the Ph.D. work of the first author. It will give a brief description of the developed viscous incompressible fluid model, but will particularly focus on the discussion of the results, as compared to experimental data and observations. Further developments of the model which are planned for the next years are finally outlined (air entrainment/ entrapment).

## 2 Governing Equations

A viscous incompressible 2D-flow is considered and the governing equations are the continuity equation:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (1)$$

and the Navier-Stokes Equations:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \nu \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) + g_x \quad (2)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial y} + \nu \left( \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} \right) + g_y \quad (3)$$

where:

$\rho, \nu$  are the density and the kinematic viscosity of the fluid, respectively.

$u, v$  are the velocity components in x and y direction, respectively.

$g_x, g_y$  are the x and y components of the gravitational acceleration.

p is for pressure and t is for time.

The computational domain and the boundary conditions are shown in Fig. 1. At the free surface, the pressure p should be continuous and p is therefore equal to the atmospheric pressure  $p_a$ . At the impermeable vertical wall, the free-slip condition ( $\frac{\partial v}{\partial x} = 0$ ) and the no-flux condition ( $u=0$ ) must be fulfilled.

For the inflow boundary conditions, any wave theory can be used to prescribe the surface elevation  $\eta(t)$  and the velocity components  $u(t)$  and  $v(t)$ . In this study, the linear wave theory, the second order solitary wave theory and the cnoidal wave theory of Keulegan and Patterson (Wiegel, 1960) are used. On the other hand, in order to keep the computational domain as small as possible, the weakly reflecting boundary condition (Delft Hydraulics, 1991) will be implemented. This allows the reflected wave to flow out the computational domain without inducing undesirable disturbance to the incident wave. The following free-slip condition for a slope is derived and considered in the model for the impermeable foreshore slope:

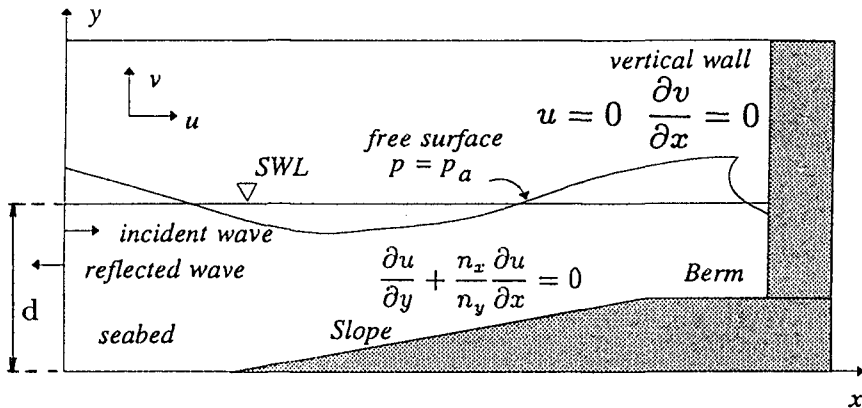

Figure 1: Computational Domain and Boundary Conditions

$$\frac{\partial u}{\partial y} + \frac{n_x}{n_y} \frac{\partial u}{\partial x} = 0 \tag{4}$$

where  $n_x$  and  $n_y$  are the components of the normal vector  $\vec{n}$  in  $x$  and  $y$  direction, respectively.

The governing equations are numerically solved by using a finite difference scheme incorporated with the Volume of Fluid (VOF) concept developed by Nichols et al. (1980) which deals with the free surface description. In this technique a function  $F(x,y,t)$  which describes the fractional volume of fluid in the mesh cells is included. The free surface can therefore be described according to the value of  $F$  in the mesh cells. Besides, the kinematic free surface boundary condition can be satisfied approximately by including the following transport equation of  $F$ :

$$\frac{\partial F}{\partial t} + \frac{\partial Fu}{\partial x} + \frac{\partial Fv}{\partial y} = 0 \tag{5}$$

Physically, this means that the  $F$  function moves with the flow motion.

### 3 Computational Results

#### Nonbreaking Waves

First of all, nonbreaking waves are numerically simulated in order to verify that the present model is able to simulate correctly nonbreaking waves not only qualitatively but also quantitatively. This will then offer a reasonable working platform for simulating the more complicated breaking waves. Two cases are considered for achieving this goal, namely, solitary wave run up on a vertical wall and the formation of standing waves.

Figure 2: Comparison of Experimental and Computed Run-up Heights of Solitary Waves at a Vertical Wall

**Solitary Wave Run Up on a Vertical Wall**

Solitary waves propagating on a horizontal bed toward a vertical wall are first taken into account in order to verify that the free surface boundary condition is well handled in the present model. The second order solitary wave theory of Laitone(1960) is considered for incident waves. Solitary waves with relative wave heights  $H/d = 0.2, 0.3, 0.4$  and  $0.5$  are considered.  $H$  is the wave height and  $d$  the water depth.

The computed results for the relative run up height  $R/d$  of solitary waves for different wave heights are compared with the experimental results from Street and Camfield(1966) A very good agreement between the computational and experimental results is shown in Fig. 2.

**Standing Waves**

In order to verify that the weakly reflecting boundary condition is well implemented in the present model, incident waves propagating toward a vertical wall with and without a foreshore slope are therefore taken into account. Due to the impermeable vertical

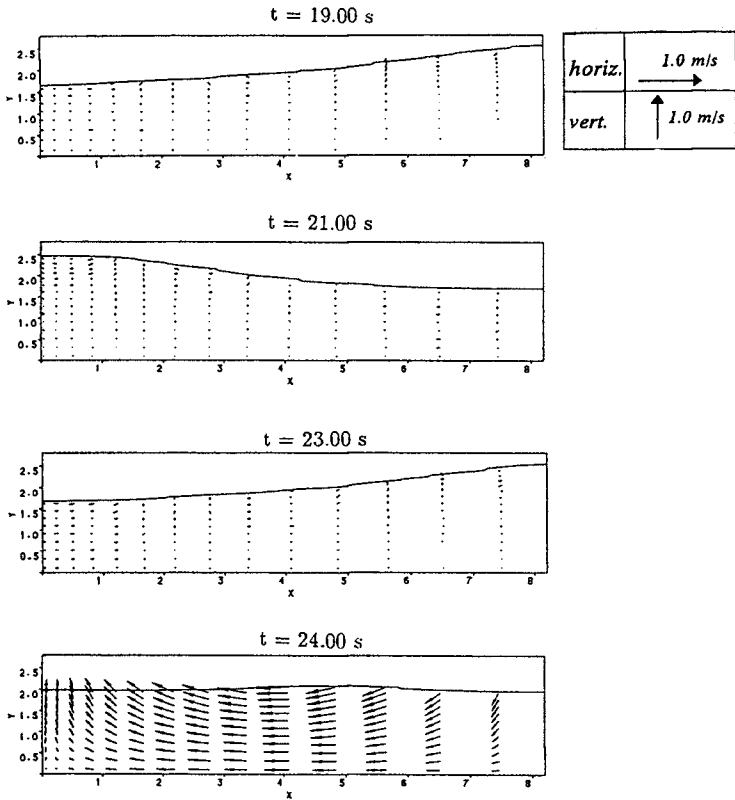

Figure 3: Numerical Simulated Standing Waves( $H=0.4 \text{ m}$ ,  $T=4.0 \text{ sec}$ ,  $d=2.0 \text{ m}$ )

wall, standing waves are expected to appear once the implemented weakly reflecting boundary condition can successfully let the reflected wave flow out the computational domain without inducing any unexpected re-reflection. The wave parameters used for this numerical test are:

- Incident Wave Height  $H = 0.4 \text{ m}$ ; Wave Period  $T = 4.0 \text{ sec}$ ; Water Depth  $d = 2.0 \text{ m}$

Airy wave theory is used for the incident waves. The wave length can be calculated as about  $16.2 \text{ m}$ . The computational domain is  $8.2 \text{ m} \times 2.8 \text{ m}$  and consists of a non-uniform grid with  $40 \times 20$  cells. The antinode is located at a distance  $nL/2$  ( $n=0,1,2, \dots$ ) from the vertical wall. Therefore, the second antinode should be located near the other side of the computational domain. The numerical simulated standing wave at times  $t=19.0$ ,  $21.0$ ,  $23.0$  and  $24.0$  second are shown in Fig. 3. It is seen that a standing wave with also 4 second of period appeared. On the other hand, the numerically simulated pressure distribution of a standing wave on a vertical wall is compared with the theoretical

Figure 4: Pressure Distribution of Standing Wave on a Vertical Wall

results developed by Sainflou (Horikawa, 1978), and a very good agreement is shown as in Fig. 4.

### Breaking Waves

Four types of breaking waves impacting on a vertical wall are distinguished by Hattori et al. (1994):

- Flip-Through type breaker
- Impact of an almost vertical breaker front on the wall with a thin air layer
- Impact of a plunging breaker on the wall with a small air pocket
- Impact of a plunging breaker on the wall with a large air pocket

The four breaker types are shown as in Fig. 5 schematically. The term "Flip-Through" was first introduced by Cooker and Peregrine (1990). This kind of impact process contains either very few or no entrapped air and the impact pressure originates from the large flow acceleration due to the concentration of flow adjacent to the vertical wall. The impact process from (b) to (d) indicates an increasing air content.

These four types of breaking waves and the resulting pressure distribution on the vertical wall are numerically simulated. The experiments by Takahashi et al. (1983) are considered for comparison, since pictures of breaking processes at different stages were recorded which can be well compared with the numerical simulated breaking processes.

Figure 5: Schematized Breaker Types Simulated by the Numerical Model

Besides, different breaking wave impact can be systematically obtained in these experiments by simply changing the berm length in front of the vertical wall.

The wave parameters of the series of experiments which are also used for numerical simulation are

- Wave height  $H$  in front of the berm = 0.351 m
- Wave period  $T = 3$  sec
- Water depth  $d = 0.8$  m

The berm lengths considered in the numerical simulation are  $B = 0.25$  m, 0.50 m, 0.75 m and 1.25 m, respectively. The berm height is 0.5 m and the slope is 1:10. The computational domain is 7.0 m  $\times$  1.5 m and consists of a nonuniform grid with 150  $\times$  40 cells. The smallest cell width is 0.02 m and is located on the wall side and the smallest cell height is 0.02 m and is located on the mean water level.

The wave theory to be used in the numerical simulation corresponding to the wave parameters is the cnoidal wave theory. Among various existing mathematical description of cnoidal wave theories, the theory developed by Keulegan and Patterson (1940) is finally taken as the most appropriate, as recommended by Le Méhauté et al. (1968). The detailed mathematical description of the related components like the surface elevation  $\eta$ , the velocity components  $u$  and  $v$  etc. can be found in Wiegel(1960).

The first case to be considered is the "flip-through" type of breaking waves. The photographs recorded by Takahashi et al. (1983) refer to Photo 1(2) of the original paper. The numerical simulated breaking processes of flip-through with both of the free surface profile and velocity vector field are shown as in Fig. 6. Only a part of the computational domain is presented in this figure,  $x$  coordinate ranges from 3.5 m to 7.0 m and

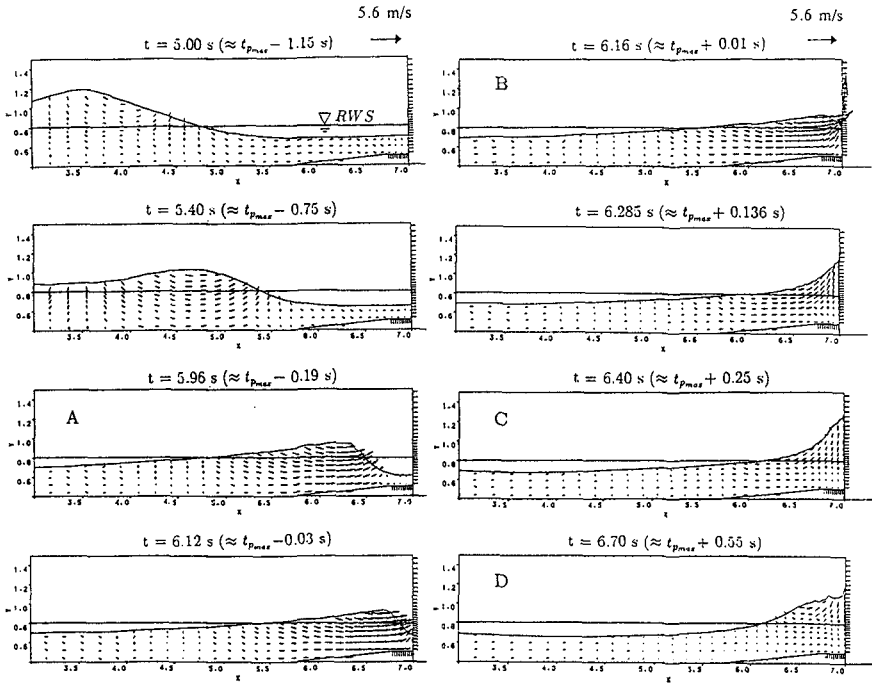

Figure 6: Computed Wave Profiles and Velocity Fields for the Flip-Through Breaker Type

the y coordinate ranges from 0.4 m to 1.5 m. After the comparison is made with the photographs taken by Takahashi et al. (1983), it is found that the numerical simulated flip through impact process agree qualitatively with the experiment.

The time history of the numerical simulated impact pressure is given in Fig. 7. The numerical simulated results agree not only qualitatively but also quantitatively well with the experimental results refer to Takahashi et al.(1983). The time history of the total force obtained by integrating the pressure distribution is shown as in Fig. 8. The characters A, B, C and D in Fig. 7 and 8 correspond to the A, B, C and D of the breaking wave processes shown in Fig. 6. It is worthwhile to mention that the point C in Fig. 8 which is the trough of the force history corresponds to the maximum run-up height of the impact process shown in Fig. 6. This phenomenon has already been pointed out experimentally by Mitsuyasu (1962) which also support the numerical simulated results.

For the other three breaker types, the numerically simulated free surface evolution of the other three breaking processes still agree qualitatively well with the photographs of the experiments. Fig. 9 is the numerical simulated breaking processes of the impact process-almost vertical breaker front with a thin air layer. The photographs of this

Figure 7: Computed Time History of Flip-Through Type Impact Pressure

impact process refer to Photo 1(3) of Takahashi et al. (1983). However, because the damping effect of the entrapped air can not yet be studied using the present model for incompressible flow, the resulting impact pressures of these three breaker types appear to be much larger than the experimental results and are not presented here. On the other hand, it is also found that the numerically simulated peak pressure can still be adjusted to the same order of magnitude with the experimental results once the impact velocity and breaker profiles obtained from the numerical simulation are used as the input data of Bagnold's formula which accounts for the damping effect of entrapped air. Fig. 10 are the numerical simulated free surface evolution of the plunging breaker type with small amount of air entrainment. The photographs of this impact process refer to the Photo 1(4) of Takahashi et al. (1983). Fig. 11 are the numerical simulated free surface evolution of the plunging breaker type with larger amount of air entrainment. The photographs of this impact process refer to Photo 1(5) of Takahashi et al. (1983).

Figure 8: Computed Time History of Flip-Through Type Impact Force

On the other hand, in order to gain more insight of the computed wave kinematics of breaking waves, a comparison is made of the velocity distributions under wave crest around the breaking point. Besides, it is very difficult to define the exact breaking point during the breaking process since the free surface and velocity distribution rapidly change. It is therefore necessary to perform the comparison of experimental and numerical results under the consideration of both free surface and velocity distribution. However, this kind of measurement is rare due to the difficulty of getting an accurate velocity measurement and surface profile simultaneously. The experiment run by Iversen(1952) is still one of the most well known experiments which have considered both the surface profile and the velocity distribution. Fig. 12 shows the surface profile around the breaking point with the simultaneously observed velocity distribution. Fig. 13 shows the computed free surface around the breaking point and agrees also qualitatively well with Fig. 12. The quantitative comparison of the velocity distribution under a wave crest around breaking point is given in Fig. 14, also showing a good agreement. The X-coordinate represent the dimensionless velocity which is normalized by  $\sqrt{g\eta_b}$ ,  $\eta_b$  is the water depth under the wave crest. The Y-coordinate represent the relative depth  $Y/\eta_b$ ,  $Y=1.0$  indicates the wave crest,  $Y=0$  is on the bottom under the wave crest.

## 4 Discussion

The comparative analysis of the results of the computations may be summarized as follows:

- The basic tests of simulating non-breaking waves phenomena like the run up height of solitary waves on a vertical wall and the formation of standing waves have already proven that the present numerical model is able to correctly handling nonlinear waves and the weakly reflecting boundary.
- For flip-through breaker type (negligible air entrapment), the numerical results are qualitatively and quantitatively reliable with respect to the description of the breaker kinematics and to the subsequent impact loading on the vertical wall.

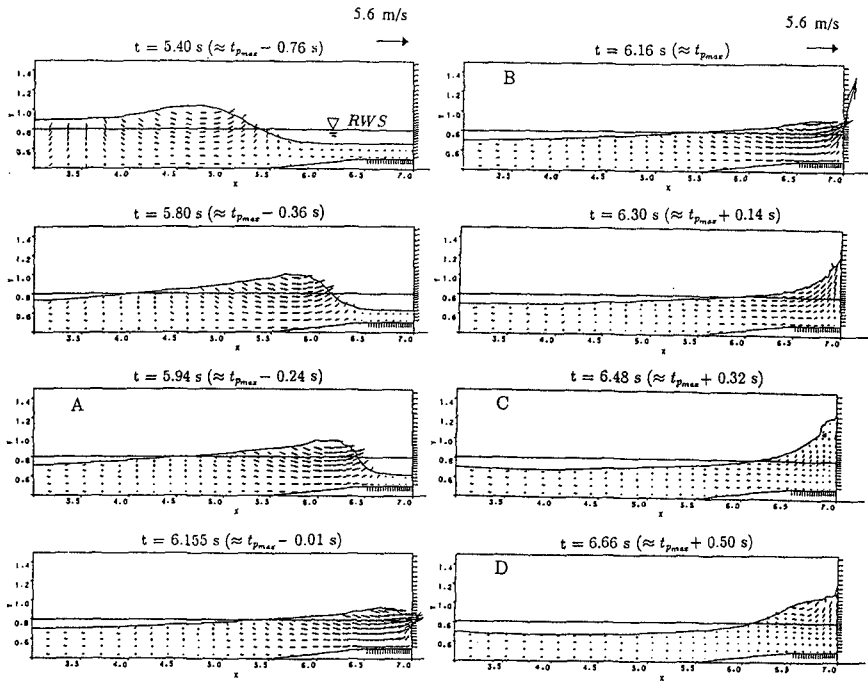

Figure 9: Computed Wave Profiles and Velocity Fields of Breaker Type- Almost Vertical Breaker Front with a Thin Air Layer

- For the last three breaker types with air entrapment in Fig. 5, the wave kinematics of the breakers is well simulated. However, the computed impact loading is much higher than the loading obtained from experiment. This result was expected since the numerical model cannot yet account for air entrapment (incompressible flow). However, by using the impact velocities and breaker profiles obtained from the numerical computation as input data into Bagnold's formula (Bagnold, 1939) which accounts for the damping effect of entrapped air, reasonable results are obtained for the magnitude of the peak impact loading.
- The last comparison is performed between the numerical simulation and the experiment done by Iversen(1952) for the velocity distribution under the wave crest around the breaking point; a quantitatively good agreement is also achieved.

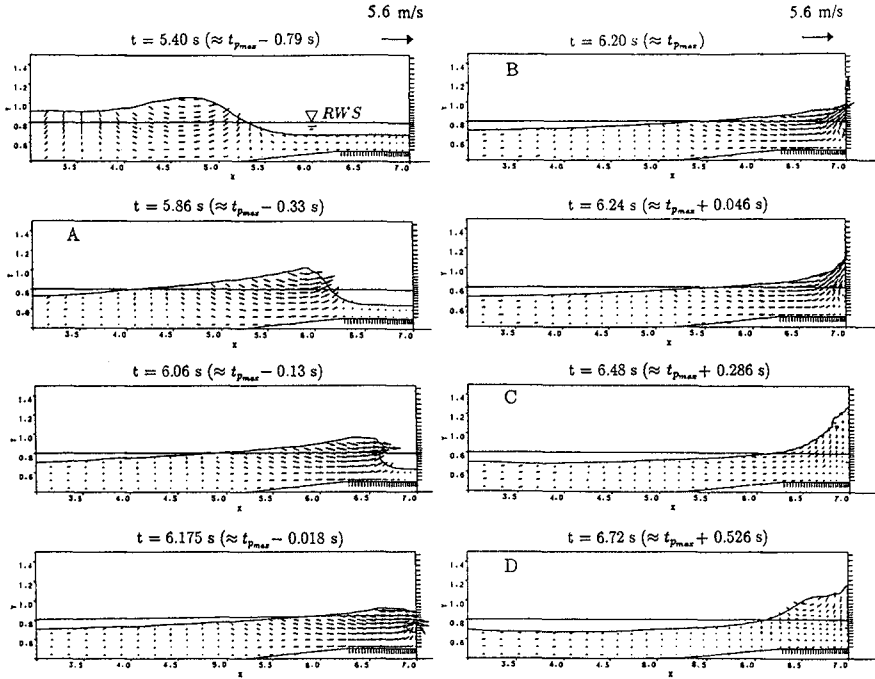

Figure 10: Computed Wave Profiles and Velocity Fields for Plunging Breaker with medium Entrapped Air Pocket

### 5 Concluding Remarks

The application of the VOF concept for the numerical solution of the governing equations and the development of further numerical schemes for the treatment of the boundary conditions have led to a powerful tool for the simulation of breaking and nonbreaking wave kinematics at and on a vertical structure with various foreshore geometries. The complete impact pressure and the resulting loading (impact) are also well simulated as far as the entrapped air is negligible. Corrective coefficients for the magnitude of the impact loading for the cases where air is entrapped in the breaker can be obtained from Bagnold's formula in which the impact velocity and the breaker profile during impact obtained from the numerical model are used as input data.

Further development of the model is directed towards accounting for the compressibility of air in order to obtain directly the proper magnitude of the impact loading in the case of plunging breakers with entrapped air.

## CHAPTER 121

### WIND EFFECTS ON RUNUP AND OVERTOPPING

by Donald L. Ward,<sup>1</sup> Christopher G. Wibner,<sup>2</sup> Jun Zhang,<sup>3</sup> and Billy Edge<sup>4</sup>

#### ABSTRACT

The maximum distance a wave may travel up the face of a coastal structure, or rate of overtopping if runup exceeds structure crest elevation, are critical parameters in planning and design of a coastal structure. Runup and overtopping are usually estimated by empirical equations based on physical model studies that do not include the effects of strong onshore winds that are typically present during design storm conditions. While it is generally assumed that onshore winds will increase runup and overtopping over no-wind conditions, there is currently no means of accurately calculating effects of these winds on runup and overtopping.

A joint research project by US Army Corps of Engineers and Texas A&M University (TAMU) is currently investigating wind effects on runup and overtopping of revetments and vertical walls through a series of physical model studies conducted in a combined wind/wave flume at TAMU. Initial tests measured runup and overtopping rates on a 1:3 smooth revetment for a range of incident monochromatic wave conditions, with wind speeds varying from no wind to maximum blower output. With the addition of wind, large increases in runup and overtopping were recorded over the no wind condition. The combined wind/wave spectrum recorded during tests with wind was then reproduced mechanically. Runup and overtopping were significantly higher during tests with

<sup>4</sup>Head, Ocean Engineering Program, Texas A&M University, College Station, Texas

wind than during no-wind tests that reproduced the combined wind/wave spectrum.

The tests indicate that runup and overtopping estimates that do not include wind effects are underpredicting runup and overtopping on coastal structures. Continuing efforts in this study are aimed at quantifying prototype wind effects on runup and overtopping based on physical model results.

## BACKGROUND

The ability to accurately estimate potential runup and overtopping on a coastal structure is essential to structural and economic design of the structure. Although it may be desirable to construct shore-protecting structures with sufficient crest elevation to prevent overtopping, this is generally not economically feasible and overtopping rates must be considered. An analysis of runup heights and overtopping rates is necessary to determine structure crest elevations, design drainage systems, and estimate overtopping-induced damage levels for determining benefit/cost ratios. Typically, runup and overtopping are estimated from empirical equations that were developed from physical model studies (e.g., Weggel 1976, Ahrens and Martin 1985, Ahrens and Heimbaugh 1988, van der Meer 1988, van der Meer and Stam 1991, de Waal and van der Meer 1992, Schulz and Fuhrboter 1992, Ward 1992, Ward and Ahrens 1992, Yamamoto and Horikawa 1992), or determined directly from physical model studies. Numerical models have also been developed to estimate runup and overtopping (e.g., Kobayashi and Wurjanto 1989, Wurjanto and Kobayashi 1991, Kobayashi and Poff 1994); these numerical models are generally calibrated with physical model test results.

The typical design condition for a coastal structure is a severe storm accompanied by strong onshore winds, yet physical model tests on which runup and overtopping rates are based do not include wind effects. The Shore Protection Manual (1984) includes an equation for a wind correction factor that increases wave overtopping rates by up to 55%, but there is no data to support this equation. It is generally agreed that wind speeds greater than 50 km/hr may have a significant effect on runup and overtopping, but little research has been conducted to quantify wind effects (Sibul and Tickner 1956, Weggel 1976).

Resio (1987) divided action of winds on overtopping into two distinct physical processes: (1) increase of runup and overtopping due to wind energy input during the wave runup interval, and (2) advection by wind of water spray and splashing resulting from wave impact on coastal structures. The first process is the major cause for increase in runup and overtopping of mild-slope structures and the second is more important to vertical or steep-slope structures. A third process ignored in the previous studies is that onshore wind may generate onshore surface currents through the work of wind shear stresses and wind-induced wave breaking in the surf zone. This onshore surface current may greatly increase initial runup bore speed on the surface of revetments and consequently may increase runup heights and overtopping rates.

The influence of wind speed on runup and overtopping needs to be

determined. Because of very few laboratory and field measurements concerning wind effects on runup and overtopping, our knowledge of how wind may increase runup heights and overtopping rates is far from sufficient. If design wind conditions are found to have a significant effect on runup and overtopping rates, then a method of calculating runup and overtopping that accounts for wind is clearly needed. Funded by U.S. Army Corps of Engineers (USAE), a joint research program is being conducted by USAE Waterways Experiment Station's Coastal Engineering Research Center (CERC) and the Ocean Engineering Program of the Civil Engineering Department at Texas A&M University (TAMU). This paper presents some initial findings from this on-going study.

### OBJECTIVES

This study is evaluating effects of wind on runup and overtopping of coastal structures through physical model studies conducted in a combined wind/wave flume at TAMU.

Analysis of the data should lead to a better understanding of the physics of wind effects on coastal structures. Although it is not possible to fully describe mathematically the processes involved, such as wave breaking or flow through a porous media of randomly shaped, randomly placed armor units, a better understanding is sought of the energy transfers and physical processes involved.

Because of the difficulty of fully describing mathematically the processes involved, empirical equations will be developed to estimate runup and overtopping on coastal structures, including wind effects. This study hopes to provide design guidance for the range of conditions typically encountered in coastal structures design work, within the limitations of the test facility and test conditions.

### TEST FACILITY

Physical model tests are being conducted in a 36-m-long by 0.61-m-wide by 0.91-m-deep glass-walled wave flume equipped with a flap-type mechanical wave generator (Figure 1). The electrically-activated wave generator is capable of producing monochromatic wave trains as well as spectral wave trains through a computer-generated signal.

A blower is mounted above and at the far end of the wave flume, away from the wave generator. An intake manifold is located in front of the wave generator, therefore wind is pulled along the length of the flume and exhausts away from the wave generator. The entire flume is covered with removable panels to contain the wind. The blower is capable of producing an average wind velocity in the flume of 16 m/s over a water depth of 50 cm.

A plywood slope followed by a 2-m-long sealed overtopping basin are installed in the end of the flume away from the wave generator. Various extensions allow crest elevation of the slope to be varied. The current slope is set

**Figure 1.** Wave flume test facility at Texas A&M University.

at 1:3 (V:H); other slopes will be installed at the conclusion of testing with the 1:3 slope. Runup on the slope is measured by two resistance gages mounted on the slope face, and by visual observation.

Three resistance wave gages are set in an array approximately mid-way between the wave generator and test slope, and a fourth gage is positioned at the toe of the slope. Gage spacing in the three-gage array is adjusted for different test periods to allow separation of incident and reflected wave trains using the method of Goda and Suzuki (1976).

#### TEST PARAMETERS

Table 1 lists parameters that will be varied in this study to provide design information covering a range of typical design conditions and to study separately the various effects of wind on runup and overtopping. The current test schedule includes revetment slopes of 1:1.5, 1:3, and 1:5, and of varying crest elevations to study both runup and overtopping rates. Overtopping of a vertical wall will also be studied. Two water depths are being tested, and two or three monochromatic wave heights at each of three wave periods. Greater wave height would have been preferred for the longer wave periods, but were limited by wave generator capability. Each combination of water depth and incident wave conditions will be tested without wind, then at 50%, 75%, and 100% of maximum blower output. Both smooth and rough revetments slopes will be tested, with rough slopes covered with armor stone in accordance with design guidance in the Shore Protection Manual (1984) and Engineering Manual 1110-2-1614, Design of Coastal Revetments, Seawalls, and Bulkheads (1985). At the completion of tests with monochromatic wave conditions, a series of tests will be conducted with irregular waves covering a range of wave heights and periods.

It should be emphasized that the testing program is still in its early phases. This paper presents results obtained only from the 1:3 smooth slope revetment with monochromatic wave conditions and a water depth of 50 cm. Each test was conducted twice; data shown in this paper is the average of the two tests.

Table 1. Ranges of test parameters planned for this study.

Wave Periods(s)	Wave Height(cm)	Revetment Slopes	Structures
1.0	5.0, 7.0, 10.0	1 : 1.5	* Smooth Slope Revetment

## RESULTS AND DISCUSSION

### Causes of wind effects on runup and overtopping

Wind affects runup and overtopping of coastal structures in several ways that are not reproduced in a typical wave flume (without wind generating capabilities). Beginning seaward of the structure, local winds may modify incident wave spectra through changes in direction or intensity and affect shoaling of wave trains as they approach shallow water. Wind-induced setup by onshore winds is also observed due to pressure gradients and wind shear at the air/water interface. Higher water levels due to setup result in higher runup both by raising the elevation at which runup begins and by allowing larger waves to reach the structure without breaking. As waves reach shallower water, onshore winds may cause a transfer of potential energy (wave height) to kinetic energy (surface current) through wind-induced wave breaking and through shear effects. Increased kinetic energy may cause higher initial velocities of the runup bore, which would result in greater runup heights. On the structure itself, onshore winds may create a favorable pressure gradient around the wave, and produce shear forces on the wave and runup bore. Finally, waves breaking on a coastal structure create large quantities of spray and on vertical structures may produce large vertical sheets of spray. On prototype structures the onshore winds carry spray over the structure, contributing to overtopping, but in most wave flumes the spray falls back into the flume seaward of the structure and is not measured as overtopping.

### Wave runup and overtopping results

A series of tests with monochromatic wave conditions was conducted to compare runup and overtopping rates without wind to runup and overtopping rates when wind of different intensities is added to monochromatic wave conditions. Mechanically-generated waves used in these tests had frequencies of 1.0 Hz, 0.57 Hz, and 0.40 Hz. Waves generated by wind had a frequency of about 2.0 Hz at the toe of the test revetment. Because the mechanically generated waves had a different frequency than waves generated by wind, the result was a bi-modal spectrum comprised of a sharp, low-frequency monochromatic peak for the mechanically generated wave and a broader, high-frequency peak for wind generated waves. In an exaggerated fashion, this is somewhat analogous to ocean swell nearing the coast and being acted upon by local winds.

The figures that follow in this text plot data collected from the wave flume study. The abscissa in all but one of the following figures is wave steepness defined as wave number,  $k$ , times wave amplitude,  $a$ . Wave number is defined as  $2\pi/L$ , where  $L$  is Airy wavelength determined from flume depth and wave period of the mechanically generated wave. Wave amplitude was determined as one-half the wave height of the mechanically generated wave. To simplify understanding the data these figures, wave steepnesses ( $ka$ ) used in these tests are given in ascending order in Table 2 along with wave period and wave height. All tests were conducted at a water depth of 50 cm.

Table 2. Wave steepness, period, and height for each set of test conditions presented in this paper.

$ka$	Wave Period (sec)	Wave Height (cm)
0.013	2.50	2.2
0.023	2.50	3.8
0.029	1.75	3.2
0.049	1.75	5.4
0.104	1.00	5.0
0.146	1.00	7.0
0.208	1.00	10.0

**Figure 2.** Maximum wave runup for various wind speeds tested.

Figure 2 plots maximum runup versus wave steepness for a range of wind

conditions. Because different revetment crest elevations were tested for the overtopping portion of this study, much of the runup data was collected from revetments with more than one crest elevations, which accounts for the paired data points shown in the figure. The ordinate in Figure 2 is maximum runup divided by wave height of the mechanically generated wave without wind effects. Maximum runup was determined visually by observing the runup bore. Small, narrow streams of runup that progressed considerably higher up the test revetment than the bulk of the runup bore were ignored, and an average maximum runup across the middle one-third of the flume was estimated. Wind speeds are presented as a fraction of the maximum blower speed. Average wind speeds for the two depths tested are shown in Table 1.

Figure 2 shows a dramatic increase in runup for tests with wind over tests without wind. This is hardly surprising because wind is introducing more energy into the system. Maximum wave heights occur when crests of a wave from each of the two wave trains coincide, producing a wave amplitude slightly greater than the sum of the individual wave heights (Zhang *et al.* 1992). Because maximum runup elevation is proportional to maximum wave height, increases in maximum runup elevation with addition of wind is expected.

Although crests of a wave from each wave train may coincide to produce a maximum wave height, it is just as likely that a wave trough from one wave train will coincide with a crest from the other wave train. The effect of the wind-generated wave train on overtopping rate, which is time-averaged, is therefore

**Figure 3.** Overtopping rate for different wind speeds tested (revetment height 10 cm above swl).

expected to be less significant than effect of wind on maximum runup. This is illustrated in Figure 3, which shows overtopping rates for a fixed revetment crest elevation of 60 cm (10 cm above swl). The 50% wind speed had little effect on overtopping rate, although larger increases were observed at 75% and 100% wind speeds. The sharp decrease in overtopping rate for maximum wind speed and wave steepness between 0.146 and 0.208 is noteworthy. The mechanically generated wave for  $ka = 0.208$  was a 1.0-sec, 10-cm wave (Table 2). At 100% wind speed, the 10-cm waves broke before reaching the revetment.

It is seen in Figure 3 that the increase in overtopping rate with wind is much greater for waves tested with a period of 1.0 sec ( $0.10 \leq ka \leq 0.20$ ) than for tests with wave periods of 1.75 sec or 2.5 sec. An explanation for this may be found in Figure 4.

Figure 4 shows the change in  $H_{m0}$  of the mechanically generated wave under the influence of wind. Because the frequency of wind waves ( $\approx 2$  Hz) differs significantly from frequencies of the 1.75-sec or 2.5-sec waves, wind is seen to have little effect on  $H_{m0}$ 's of the longer waves. However, the frequency of the wind waves is relatively close to the frequency of 1.0-sec waves, and wind energy is seen to have a significant effect on the  $H_{m0}$  of the 1.0-sec waves.

#### Mechanically reproducing a wind/wave spectrum

Assuming constant wind conditions, effects of wind on incident waves prior to shoaling may be accounted for by mechanically reproducing a fully developed

**Figure 4.** Wind effect on  $H_{mo}$  of mechanically-generated wave.

wind spectrum. This is the typical test condition for runup and overtopping in most wave flumes, but fails to account for wind effects during shoaling or wind effects at or near the structure.

To determine effects of wind on runup and overtopping at the structure, an attempt was made to mechanically reproduce the combined wind/wave spectrum. The wave record from the wave gage at the revetment toe (gage 4) taken during tests which included wind blowing over a mechanically-generated wave train was analyzed and the combined spectrum determined. The combined spectrum included a low-frequency wave from the mechanically-generated wave train, and a high-frequency wave generated by wind. Because high-frequency waves travel slower than low-frequency waves, the combined spectrum could be reproduced mechanically by generating a series of high-frequency waves and following with a series of low-frequency waves. When the low-frequency waves catch up with high-frequency waves, the combined spectrum is obtained. Trial and error was used to adjust the  $H_{mo}$ 's of the high- and low-frequency mechanically generated waves to match the combined wind/wave spectrum.

The wave generator was unable to reproduce the high frequency of wind waves ( $\approx 2$  Hz), therefore the frequency used was the highest frequency at which  $H_{mo}$  of the 50% wind could be reproduced. The 50% wind was chosen because the wave generator was capable of reproducing the wind wave at a higher frequency than it could reproduce larger wave heights generated by higher wind speeds. Figure 5 shows a mechanically-produced spectrum compared to the wind/wave spectrum. Except for the slightly higher frequency of wind waves, the two spectra are very similar.

**Figure 5.** Comparison of energy spectra of wind/wave spectrum and mechanical reproduction of wind/wave spectrum.

**Figure 6.** Maximum wave runup for no-wind condition, wind/wave condition, and mechanical reproduction of wind/wave condition (wind speed 50% of maximum).

Figure 6 shows runup information for the four tests reproduced mechanically. Runup data for mechanically-generated, low-frequency wave and for the combined wind/wave spectrum is the same as seen in Figure 2, but Figure 6 also plots runup from mechanically reproduced dual-peaked spectrum. Additional runup observed with wind is attributed to higher surface velocities due to wind-induced breaking and to wind effects on the runup bore.

Figure 6 clearly demonstrates that mechanically simulating wind waves fails to reproduce runup that will occur on prototype structures in the presence of onshore winds, and suggests that current formulae for estimating runup and overtopping of coastal structures therefore underestimate prototype runup and overtopping. However, until scaling relationships for a combined wind/wave experiment have been determined, and until relative effects of wind-induced setup in a wave flume and the prototype have been examined, it is not possible to quantify additional runup and overtopping that will occur on prototype structures.

#### Final comments

It is clear that wind affects runup and overtopping through a variety of processes and that mechanically reproducing a wind/wave spectrum will only account for some of the wind effects. Additional study is required to separate and quantify effects of wind due to the various processes involved.

In these tests, two key questions need to be answered before a relationship can be determined between model test results and real-world situations. First, the relationship between wind-induced setup in a wave flume and prototype wind-induced setup needs to be determined. Significant setup was observed during physical model tests with wind, which was seen to have an important effect on runup and overtopping. Second, a scaling relationship for runup and overtopping in a combined wind/wave environment needs to be determined. Waves, with gravity as the main restoring force to the inertial forces, are scaled by Froude's law. Wind effects, on the other hand, transfer energy to fluid through shear forces and are scaled by Reynold's law. To satisfy both Froude's law and Reynold's law in a single model requires either a centrifuge to increase gravitational effects in the model, or use of a "super fluid" to change viscous effects in the model. Neither of these options is practical for tests of this size.<sup>5</sup> Scaling relationships need to be explored to allow effects of wind and waves on runup and overtopping to be

---

<sup>5</sup>A large centrifuge is currently being constructed at WES to be completed in 1995. Test beds for the centrifuge will include a miniature wave flume approximately 2 m long equipped with a flap-type wave generator with spectral capabilities and a water-based fluid that can be mixed to obtain a range of kinematic viscosities. Although the centrifuge will be able to create up to 350 g's, the wave flume will be designed only for loads up to about 35 g's. A combined wind/wave environment in the flume could be obtained by redirecting wind created by movement of the wave flume through the air by the centrifuge.

considered separately and then hopefully they may be applied to prototype prototype coastal structures.

#### ACKNOWLEDGEMENT

The testing program reported herein is funded by the U.S. Army Corps of Engineers, and the authors gratefully acknowledge this support. Permission to publish this paper was granted by the Office, Chief of Engineers.

## CHAPTER 122

# Modelling of Wave Overtopping over Breakwater

F. Zhuang<sup>1</sup>, C. Chang<sup>2</sup>, J.J. Lee<sup>3</sup>

### Abstract

From a recent experimental study on the kinematics of wave overtopping on marine structure by Lee, Zhuang and Chang (1993) it was found that the overtopping wave generates a strong rotational velocity field in the shoreward region of the breakwater. The present study focuses on the development and the implementation of a numerical model for the generated velocity field in the vicinity of the shoreward face of the breakwater. The numerical model consists of two basic elements: The velocity field generated by using the potential flow theory utilizing boundary element method and the rotational velocity field generated by the separated flow of the overtopping waves as they leave the breakwater site using vorticity stream function formulation. The computational results at a region far away from the separation zone based on the potential flow theory (boundary element method) are used as specified boundary conditions for simulation in the vorticity stream function model. The numerical results have been compared with the experimental data revealing the rotational feature of the velocity field in the separated zone (shoreward region of the breakwater). The generated vortical motion remains in the separation region even when the wave has travelled to the region far away from the breakwater.

## 1. Introduction

Interaction of nonlinear waves with marine structure such as the breakwater has been an important problem for coastal and ocean engineers. Among the many aspects of the interaction problem, wave overtopping may require more attention due to the complexity of the physical process and the lack of available predictive models. When the water depth at the breakwater site is quite close to the breakwater height, and the incident wave amplitude is large, a substantial wave overtopping can be expected.

In a recent experimental study on the kinematics of wave overtopping on marine structure by Lee, Zhuang and Chang (1993) some very fascinating results have been found. It was found that the overtopping wave constitutes a jet-like water mass impacting the shoreward region of the breakwater. This jet-like water mass induces strong vortices and large water particle velocities in both the horizontal and vertical direction. Moreover, the overtopping wave also generates waves in the shoreward region possessing significant wave energy with oscillatory wave trains. These two major conclusions have significant practical implications: The large rotational velocity field can remove the armor units of the breakwater and scour the bed. The generated waves could induce significant basin oscillations in the shoreward basin with resonant frequencies which are different from the incident wave frequencies. The present study focuses on the development and the implementation of a numerical model capable of generating the rotational velocity field in the vicinity of the shoreward face of the breakwater.

## 2. Experiments

Experiments involving propagation of solitary waves over various submerged breakwater configurations are conducted in a wave tank 15.2 meter long, 39.4 centimeter wide, and 61 centimeter deep. A programmable piston type wave generator is installed at one end of the tank and a sloping beach is installed at the other end of the tank to aid the wave dissipation for the purpose of reducing the waiting time between experimental runs. Two different breakwater configurations are used in the experiment. Three resistance type wave gauges are installed at desired locations to make simultaneous wave profile measurements.

The water particle velocities are measured using a portable four-beam, two-component, fiber optic Laser Doppler Velocimeter (LDV) manufactured

by TSI Inc.. Titanium Dioxide powder ( $\text{TiO}_2$ ) is used in the experiments as a seeding agent.

### 3. Numerical Models

Motivated by the findings in the experiment, the present paper will focus on the development and the implementation of a numerical model for modeling the generated velocity field in the vicinity of the breakwater as well as the wave field generated by the overtopping waves. The numerical model consists of two basic elements: The velocity field generated by using the potential flow theory and the rotational velocity field generated by the separated flow (vortices) of the overtopping waves as they leave the breakwater site. For the potential flow theory, the Boundary Element Method has been used. The nonlinear boundary condition at the free surface is satisfied in the numerical model to allow simulation of large amplitude waves. The transient non-rotational flow field obtained by the potential flow theory is combined with the time dependent rotational flow field due to vortices generated in the separation zone.

The potential flow theory formulation using boundary element method has been presented in Lee, Chang and Zhuang (1992). The rotational flow field in the vicinity of the shoreward breakwater is simulated with the governing equations for the vorticity stream function formulation of incompressible laminar flow. Figure 1 shows the computational domain for this rotational flow field (ABCDE). The governing equations are:

$$\frac{\partial \omega}{\partial t} + u \frac{\partial \omega}{\partial x} + v \frac{\partial \omega}{\partial y} = \nu \left( \frac{\partial^2 \omega}{\partial x^2} + \frac{\partial^2 \omega}{\partial y^2} \right) \quad (1)$$

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = \omega \quad (2)$$

where  $\omega$  is the vorticity vector;  $u, v$  are the horizontal and vertical components of the velocity vector, and  $\nu$  is the kinematic viscosity of the fluid. The boundary conditions in conjunction with the governing equations (1) and (2) are listed as follows:

A-B and A-E:

$$u = 0, \quad v = 0, \quad \psi = 0$$

B-C:

$$\frac{\partial \psi}{\partial y} = u, \quad \omega = \frac{\partial u}{\partial y} - \frac{\partial v}{\partial x}$$

C-D:

$$\frac{\partial \psi}{\partial x} = -v, \quad \omega = \frac{\partial u}{\partial y} - \frac{\partial v}{\partial x}$$

D-E:

$$\frac{\partial \omega}{\partial x} = 0, \quad \frac{\partial^2 \psi}{\partial x^2} = 0$$

For each time step, the particle velocity solution is collected along B-C and C-D from the computational results based on the boundary element method (potential flow theory). These are used as the boundary conditions for the vorticity stream function formulation, hereafter we refer it as combined rotational model. Equation (2) is solved using Successive Over Relaxation method. Equation (1) is then solved using Alternating Direction Implicit method. The same computational procedure is repeated over the successive time steps.

#### 4. Results and Discussion

The wave profile and the velocity vector field induced by an incoming solitary wave with various wave amplitude to water depth ratio over a submerged breakwater has been computed using the boundary element method presented by Lee, Chang and Zhuang (1992). Figure 2 presents computational results for the case of  $H/d=0.2$  for different time steps. The incident solitary wave is propagating from left to right. From Figure 2 it is seen that the transmitted waves contains oscillatory tails and the velocity field in the shoreward side of the breakwater does not show any rotational flow field based on this potential flow computation. As mentioned in Lee, Chang and Zhuang (1992) however, the experimental data agree well with the theory on the computed wave profiles and accompanying kinematics of the water particle in the region close to the free surface as well as in the region far away from the separation zone. However, the agreement between the experimental data and the results of the potential flow theory breaks down in the region near the separated zone. In fact, experimental evidence shows that as soon as the incident solitary wave passes over the breakwater, vortices are generated in the separation zone. These vortices are then formed to create a rotational flow field with both the horizontal and vertical components of the water particle velocity changing directions rapidly.

Figure 3 is a photograph taken in the experiment. It shows the generation of a vortex at the vicinity of the shoreward step of the breakwater, after the passage of the solitary wave over the breakwater. It is observed that a strong rotational flow field has been generated and the flow direction close to the shoreward breakwater surface is upward and seaward.

It is reasonable to expect that the computational results from the boundary element method based on the potential flow theory would fail at the separation zone due to its imposed assumption of inviscid fluid and irrotational condition. However, the computational results should be reasonably valid in the region far away from the separation zone. Therefore, our modelling strategy for the region near the separation zone is adopted as follows: As the incident wave propagates over the breakwater, the computed velocity field from the boundary element method in the regions BC and CD are used as input boundary condition for the rotational flow simulations based on equations (1) and (2). In this approach, the domain of computation is fixed thus the computational effort is greatly simplified.

Figure 4 presents the computed streamlines showing the process of the vortex generation at different time steps. As mentioned earlier the specific condition simulated is such that the crest of the breakwater is at one-half of the water depth. The wave height/water depth ratio is 0.3. The breakwater width is ten times the breakwater height. The domain of simulation for rotational flow computation is  $AC=DE=0.8d$ , and  $AE=CD=4d$ , where  $d$  is the still water depth. Figure 5 is the velocity vector field plot corresponding to the streamline plot presented in Figure 4. The results show that the vortex motion will remain eventhough the wave peak has travelled away from the breakwater. These aspects of the simulated results are in agreement with the experimental observation. A practical point to remember is that the rotational field so generated will induce more scouring capability in the shoreward region of the breakwater.

Figures 6 and 7 show the velocity time history at a location P (as indicated in the definition sketch included in Figure 1). The location P is at the vertical position one-half of the breakwater height and one-tenth of the depth from the breakwater shoreward surface. Included in the figure are the results of the potential flow theory (solution from boundary element method) shown in solid line. The results from the combined rotational model are shown in dotted line. The velocity time history obtained by using the Laser Doppler Velocimeter measurement are plotted using the star symbols. The ordinates in both figures are the velocity components normalized with

respect to  $\sqrt{gd}$  (the wave celerity in water depth  $d$ ). The abscissa is the real time normalized as  $t\sqrt{g/d}$ . Examining both Figure 6 and 7, it is seen that, at location P, both the combined rotational model and experimental data reveal that the horizontal velocity changes direction from positive to negative and vertical velocity changes the direction from negative to positive. That means the flow direction at that point changes from forward and downward to backward (seaward) and upward. It clearly shows that a vortical motion has been generated during the wave overtopping process. The present combined rotational model predicts this feature of particle movement and agree qualitatively well with the experimental data. As expected, the potential theory predicts only positive horizontal velocity and negative vertical velocity. Thus, according to the potential flow theory, the particles are always going forward and downward directions during the overtopping process, representing no rotational motion. The magnitude differences between the present model and the experimental data in the early stages of flow could be caused by the minor geometry differences of the breakwater (the experimental model breakwater has a slight slope at both seaward and shoreward side). Since the absolute value of the present model is smaller than the experimental data at the early stages of flow, it might be that the model computation was still warming up at the time. We plan to conduct more experimental measurements using the physical model breakwater with the exact geometry as the computation model. Another noticeable feature from the time history graph is the magnitude of the positive velocity and negative horizontal velocity, both are much greater than the particle velocities associated with an unmodified solitary wave. This feature of increased particle motion could contribute to the destabilization of the breakwater armor units in the shoreward face.

## 5. Conclusions

The major conclusions drawn from this study can be summarized as follows:

1. The combined potential flow theory and vorticity stream function formulation model describes the flow field quite well based on the comparison with the experimental data. It offers a tool for modelling the flow field in the vicinity of the shoreward region of the breakwater.
2. There is a vortex generated by the overtopping of solitary wave in the vicinity of the shoreward breakwater. The vortical motion remains

there even when the wave has travelled to the region far away from the breakwater. This vortical motion produces a velocity field which could cause significant scouring in the region close to the breakwater.

3. Because of the vortex motion, there is a relatively large velocity component in the upward and seaward direction. This velocity could produce a lifting force which could destabilize the armor units in the shoreward face of the breakwater.
4. The present combined rotational model can be easily implemented because of its time-saving feature. It only computes rotational flow field in a relatively small local domain, while the efficient potential theory using boundary element method offers the information away from the separation zone, where the irrotationality assumption is valid. Furthermore, this model can be extended to solve other wave-structure interaction problems.

## CHAPTER 123

# STRESSES IN TETRAPOD ARMOUR UNITS INDUCED BY WAVE ACTION

by

K. d'Angremond<sup>1</sup>, J.W. van der Meer<sup>2</sup> and C.P. van Nes<sup>1</sup>

### ABSTRACT

An extensive research program has been set up under the name of "*Rubble mound breakwater failure modes*". This research is part of the European MAST II project, (MARine Science and Technology) in which a number of universities and hydraulic institutes, from various countries in Europe, are participating.

In this study an analysis concerning the pulsating and impact portion of the tensile stresses inside tetrapod armour units is presented. The data has been obtained from a series of small scale model tests performed at Delft Hydraulics. Stresses have been measured using a load-cell technique developed and made available by Coastal Engineering Research Centre in association with Aalborg University Center.

For the tested area of the breakwater the following parameters only appeared to have influence on the stress distribution inside a leg of a tetrapod :

- significant wave height :  $H_s$
- water depth in front of the breakwater :  $h_{10c}$

Other parameters investigated which appeared to have no or a negligible influence on the stress distributions were:

- the fictitious wave steepness,  $s_{op}$
- the *location* of the tetrapod
- the *orientation* of the instrumented leg of the tetrapod.

## INTRODUCTION

In the late seventies, begin eighties a number of large breakwaters was severely damaged. The armour layer of these breakwaters consisted of slender concrete armour units, like dolosse or tetrapods.

It appeared that one of the main reasons of failure of these breakwaters was breakage of the armour units. Obviously, the mechanical strength of the armour units had been exceeded. The design of these breakwaters was actually based on extrapolation of experience from smaller or less exposed breakwaters.

New design methods, which not only take into account the hydraulic stability but the structural stability as well, are therefore needed. Especially for the slender armour unit types which are more vulnerable to breakage than the massive armour units.

## EARLIER RESEARCH

Two lines of research are identified on the determination of stresses in armour units. The first one, the CUR C70 investigation (1989, 1990), concentrated on movements or rocking of the armour units and the actual stresses in prototype armour units caused by those impacts.

The second line concentrated on describing the internal stresses of armour units by measuring the stresses directly inside the armour units. (Burcharth et al, 1993)

### *Rocking*

The impact momentum originating from collisions of rocking units can be described using the following parameters : (CUR C70, 1989)

- acceleration	a	[m/s <sup>2</sup> ]
- duration of impact	$\Delta t$	[s]
- development of acceleration in time	$\psi$	[-] (shape factor)
- mass	M	[kg]

The *integrated* signal of the accelerations,  $\int a \, dt$ , i.e. the impact *velocity*, can be scaled to prototype, using Froude, i.e.,  $\lambda_v = \lambda_L^{0.5}$ . (CUR C70, 1990) From this velocity, together with the mass of a prototype armour unit, the prototype impact momentum can be calculated. Further research was focused on the elasto-plastic behaviour of prototype colliding concrete units.

A design procedure based on the CUR C70 study results has been incorporated in the computer program, "ROCKING", using a full probabilistic approach. This takes into account the following elements:

- displacements, movements and impacts of armour units;
- impact velocities;
- impact behaviour;
- strength model.

For this probabilistic approach a Monte Carlo simulation has been used. The program calculates the number of broken units for a given combination of environmental conditions, armour unit characteristics and material properties. (Van der Meer and Heydra, 1990)

### *Direct method*

Whereas the CUR C70 approach concentrated on impact stresses due to rocking, Aalborg University Center investigated the behaviour of concrete armour units by directly measuring stresses in small scale models, not only measuring the loads or stresses caused by impacts but measuring the static and pulsating stresses as well.

Aalborg University Center has inserted a load cell in one of the two shank-fluke sections of a number of dolosse to investigate the stress distribution of dolosse. The dolos has been chosen because it was one of the types of armour units which caused the most problems when hydraulic stability and structural integrity were concerned.

Due to its slender form the dolos is vulnerable to breakage. Of all the component forces and moments, the two orthogonal bending moments,  $M_y$  and  $M_z$ , and torque,  $T$ , around the axial axis appear to be dominant. (Burcharth, 1991)

Beam theory has been used to calculate the maximum principal tensile stress at the surface,  $\sigma_T$ , using the cross sectional components moments as follows :

$$\sigma_T = \frac{\sigma}{2} + \sqrt{\left(\frac{\sigma}{2}\right)^2 + \tau^2} \quad (1)$$

where  $\sigma_T$  = maximum principal tensile stress [N/mm<sup>2</sup>]  
 $\sigma$  = normal stress [N/mm<sup>2</sup>]  
 $\tau$  = shear stress [N/mm<sup>2</sup>]

$$\sigma = \frac{\sqrt{M_y^2 + M_z^2}}{W_b} \quad \tau = \frac{T}{W_b/2} \quad (2)$$

where  $M_y$  = orthogonal bending moment [Nmm]  
 $M_z$  = orthogonal bending moment [Nmm]  
 $T$  = torque [Nmm]  
 $W_b$  = modulus of strain gauged cross section [mm<sup>3</sup>]

Failure is taken as the appearance of the first crack at the surface, i.e.

$$\sigma_T \geq S_T \quad (3)$$

where  $S_T$  = maximum tensile strength [N/mm<sup>2</sup>]

### PRESENT RESEARCH

In the present research, the method of measuring stresses in small scale units directly is used for the determination of stresses in tetrapod armour units induced by wave action. Model tests have been conducted in the 'Schedt' flume of Delft Hydraulics. This flume is 50 m. long, 1.0 m. wide and 1.2 m. deep.

#### Structural parameters

A 'standard' rubble mound cross section has been used, with a sloping foreshore of 1:50, Figure 1. The mass of the model tetrapods that have been used was 0.290 kg. The armour units were made of mortar with a mass density of  $\rho_a = 2307 \text{ kg/m}^3$ .

Figure 1 Cross section of model breakwater

#### Hydraulic parameters

Four different test series have been used, each consisting of 4 steps in which the significant wave height was increased. The spectrum used was a JONSWAP spectrum with a peak enhancement factor  $\gamma=4$ . For each repetition the same wave spectrum was used. In Table 1 an overview of the parameters is given.

The significant wave height,  $H_s$  and the wave steepness,  $s_{op}$ , given in Table 1 are the values near the wave board. The wave steepness is defined with the deep water wave length, i.e.

$$s_{op} = \frac{2\pi H_s}{gT_p^2} \quad (4)$$

- where  $H_s$  = significant wave height [m]  
 $g$  = gravitational acceleration [ $\text{m/s}^2$ ]  
 $T_p$  = peak period [s]

The relation between the 'deep' water significant wave height and the significant wave height at the toe of the structure has been determined before the actual model tests, without the structure present.

<i>variable</i>	<i>notation</i>		<i>range/value</i>	<i>remarks</i>

### Measurement of stresses

Five model tetrapods have been instrumented and calibrated by Aalborg University Center (Report 2<sup>nd</sup> workshop MAST 2, 1994) applying the same load-cell technique that was used for the dolos research. The instrumented tetrapods were able to record the bending moments in the critical cross section, i.e.,  $M_y$  and  $M_z$ . (Figure 2)

**Figure 2** Instrumented critical section of a tetrapod

Both the static and pulsating stresses as well as the impact stresses have been measured. In order to do so, the sample frequency of the instrumented tetrapods was set at 6000 Hz keeping well above the natural frequency of the instrumented leg of the tetrapod, which was approximately 800 Hz both in air and in water.

With 5 instrumented tetrapods on the model breakwater it was only possible to run 200 waves per significant wave height, i.e., 800 waves per test series, due to the enormous amount of data storage required (approx. 250 Mb/test)

### THE STRESS SIGNAL

Before starting with the analysis of the stresses, the stress signal itself will be discussed. Looking at a few examples of the stress signal, Figure 3, a number of conclusions can be drawn :

- the signal shows some noise; the instruments were sensitive for the influences from the mains.
- the base level or static stress is not constant. Obviously, the armour units sometimes move which causes a change in static stress. ( $\sigma_{static}$ )
- on top of this static stress a gradually fluctuating stress component can be identified, i.e. the pulsating stress. ( $\sigma_{puls}$ )
- the impacts are clearly recognizable. ( $\sigma_{impact}$ )
- within one wave period more than 1 impact may occur.

Figure 3 Examples of measured stress signals

Firstly, the noise was removed using a low-pass filtering technique. Together with the noise, the impacts are filtered as well.

Secondly, because of the fluctuations of the static stress, a moving average is needed in order to identify the local maximum value of the pulsating signal,  $\sigma_{puls,max}$ . This moving average was also determined using a low-pass filtering technique. Using the moving average as a reference, the treatment of the stress signal becomes more or less analogous to the analysis of a simple surface water wave.

Finally, the identification of the impacts was done by applying a high-pass filter technique on the raw stress signal which removed the lower frequencies, leaving the higher frequencies undisturbed.

### ANALYSIS OF STATIC AND PULSATING STRESSES

It appeared that only the wave height,  $H_s$ , the wave steepness,  $s_{op}$ , and the water depth,  $h_{toe}$  had influence on the combined maximum of the static and pulsating stress values, reducing the number of variables involved. In table 2 an overview of the found number of stress maxima is given.

<i>test series</i>	$H_{s,deep}$ [m]	$h_{toe}$ [m]	$s_{op}$ [-]	<i>Number of repetitions</i>	<i>Number of <math>\sigma_{puls,max}</math></i>	<i>Number of <math>\sigma_{impact}</math></i>	<i>N</i> [-]
1a	0.10	0.30	0.02	16	3474	615	3200
1b	0.15			16	3978	2157	3200
1c	0.20			19	4981	6010	3800
1d	0.25			22	5613	9340	4400
2a	0.10	0.30	0.04	21	4587	654	4200

4b	0.15			10	1988	203	2000
4c	0.20			13	2767	641	2600
4d	0.25			10	2393	1181	2000

**Table 2** *Number of found  $\sigma_{puls,max}$  and  $\sigma_{impact}$  for each combination of parameters*

On these 16 data-sets of stress values a Log Normal distribution has been fitted, giving typical plots like Figure 4. The Log Normal fit is described as follows :

$$f\left(\ln \frac{\sigma_{puls,max}}{\rho_a g D_n}\right) = \frac{1}{\sqrt{2\pi} \sigma_{LN}} \cdot e^{-\frac{1}{2} \cdot \left[ \frac{\ln\left(\frac{\sigma_{puls,max}}{\rho_a g D_n}\right) - \mu_{LN}}{\sigma_{LN}} \right]^2} \tag{5}$$

- where  $\sigma_{puls,max}$  = value of the maximum stress within a stress wave [MPa]
- $\rho_a$  = mass density of the armour units [kg/m<sup>3</sup>]
- $g$  = gravitational acceleration [m/s<sup>2</sup>]
- $D_n$  = nominal diameter of a tetrapod [m]
- $\mu_{LN}$  = average of Log Normal distribution [-]
- $\sigma_{LN}$  = standard deviation of Log Normal distribution [-]

Figure 4 Two examples of fitted Log Normal distributions on data

The averages,  $\mu_{LN}$ , and the standard deviations,  $\sigma_{LN}$ , of the Log Normal distributions have been plotted as a function of the significant wave height and are given in Figure 5.

Although, the averages increases with increasing wave height, this increment is rather small. Therefore, the influence of the wave height is neglected and a horizontal line is assumed :

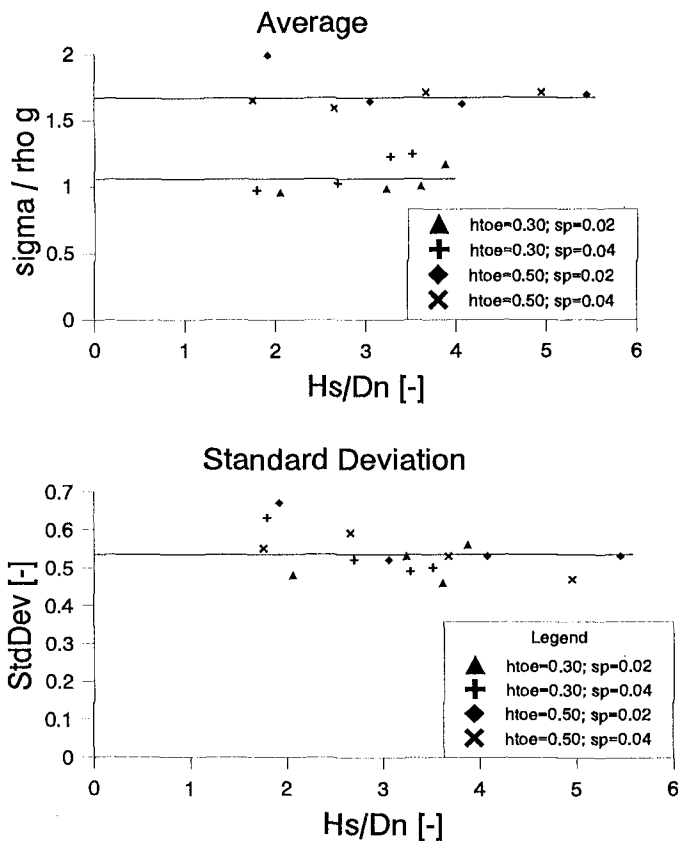

$$h_m = 0.30 \text{ m.} \quad \mu_{LN} = 1.10 \tag{5a}$$

$$h_m = 0.50 \text{ m.} \quad \mu_{LN} = 1.65 \tag{5b}$$

The standard deviation,  $\sigma_{LN}$ , seems to decrease somewhat with increasing wave height.

Again, a horizontal line is assumed, analogous to the research at Aalborg University Center. (Burcharth, 1993)

$$\sigma_{LN} = 0.53 \quad (6)$$

**Figure 5** The average and the standard deviation of the Log Normal fit as function of the wave height and the water depth

From these Figures, a number of conclusions can be drawn :

- the average,  $\mu_{LN}$ , of the Log Normal fit does not depend on the significant wave height. the water depth at the toe, however, does have influence on the combined static and pulsating stresses.
- the larger the water depth, the larger the combined static and pulsating stresses.
- the standard deviation,  $\sigma_{LN}$ , does not depend on both the significant wave height and the water depth at the toe.

## ANALYSIS OF IMPACT STRESSES

Before any statistical approach was applied to the impact stresses, a more detailed description of the physics was desired. Therefore, an effort has been made to answer the following questions :

- how many impacts can we expect within a test run?
- what are the orientations of these impacts?

Finally, the stress values itself, resulting from the concrete to concrete collisions have been described. This can be done in three different ways, i.e. :

- using all impact stress values and relate them to the number of impacts
- using the highest N impact stresses in a test run of N waves
- using the highest impacts stress value per wave and relate them to N waves

### Number of impacts

In Figure 6 the development of the number of impacts with increasing wave height is plotted for each tetrapod separately. Looking at Figure 6, it can be concluded that, firstly, the number of impacts increase with increasing wave height and, secondly, the number of impacts can vary substantially between two identical test series. Not only for the different locations investigated, but even for tetrapods at the same locations the number of impacts is quite different during subsequent tests.

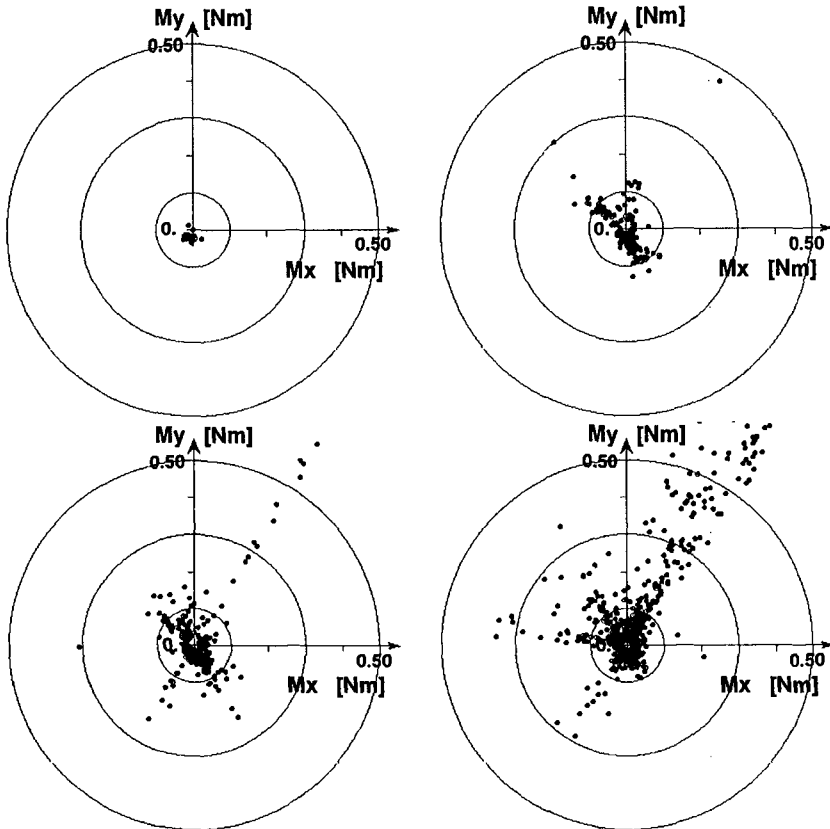

**Figure 6** Number of impacts as function of the significant wave height for two identical test series

Furthermore, it can be seen that for the larger values of the significant wave height, the number of impacts may exceed the number of waves. In the right plot of Figure 6, the tetrapod at location 5 received nearly up to 1000 impacts in 200 waves. This is clearly of importance when looking at fatigue of tetrapod armour units.

### Location of impacts

The next question concerned the location of the maximum tensile impact stress around the critical cross section. Taking the raw data signal which contains both the bending moments in X and Y direction, it is possible to obtain plots as presented in Figure 7.

From the plots it can again be seen that the number of impacts increases with increasing wave height. Secondly, the stress values become larger with increasing wave height. Finally, the scatter becomes larger.

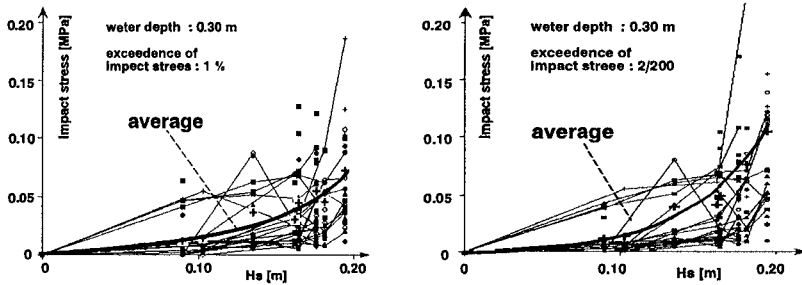

**Figure 7** Typical plots of development of orientation and size of the X and Y moment in a critical cross section of one tetrapod throughout a test series

Obviously, the armour unit was 'thrown around' the breakwater slope, hitting other tetrapods or being hit by others, resulting in a larger number of impacts from various directions. However, a number of main axes (1 to 3) are present. Again, this is important when looking at fatigue of the elements.

#### *Impact stresses*

Finally, a description of the actual impact stresses is needed. In Figure 8, two of the three earlier mentioned possible ways of presenting the impact stresses are given.

Firstly, in the left plot the stress levels of each test run are plotted that are exceeded by 1% of the total number of impacts in that test run. Secondly, in the right plot the 2nd highest stress value of each test run, i.e. 200 waves, is used. This stress value is given an exceedance value of 2/200.

**Figure 8** Impact stresses related to number of impacts (left) and to number of waves (right)

Figure 8 clearly, shows the difference in stress level when plotting either the 1% exceeded stress level, which is related to the number of impacts, i.e. the length of the data-set, or plotting the 2/200 exceeded stress level, which is related to the length of the test run.

The solid line in both plots is calculated using a weighted average of these stress values using the number of points per test run over the total number of points in the vertical as the weight factor.

Conclusions, based on the obtained data-sets, that can be drawn on the impact stresses, are :

- with increasing wave height, the number of impacts, the scatter in the orientation of the impacts and the impact stress values increase as well.
- for the larger water depth, i.e.  $h_{loe} = 0.50$  m the impact stresses are larger than compared to the depth limited case. This is according to the combined static and pulsating stresses.

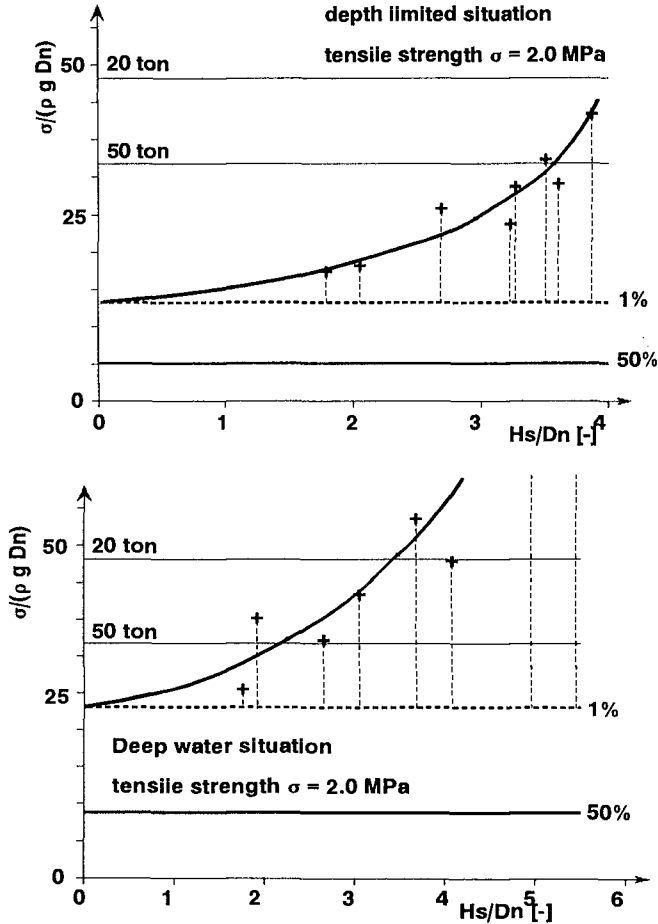

### PRELIMINARY DESIGN DIAGRAMS

Finally, combining the two descriptions, i.e., firstly, the Log Normal fit for the combined static and pulsating stresses and, secondly, the weighted average for the 1% exceeded impact stress level, it is possible to present very preliminary design diagrams for the stresses in tetrapod armour units exposed to wave action.

In Figure 9 the preliminary design diagrams are given for both the depth limited case as well as the deep water case, using the impacts stress levels related to the

number of impacts, i.e the solid line presented in the left plot of Figure 8.

The curved solid lines are the 1% exceeded impact stress levels for the prototype case of  $M = 20$  ton. From these Figures the more general conclusions can be drawn that the utmost care is recommended when applying tetrapods with a mass over 25 tons. For larger units it is advisable to reduce the permitted  $H_s/D_n$  values.

**Figure 9** Preliminary design chart for both the depth limited situation (top) and the not depth limited situation (bottom). 50% and 1% lines are stress level exceeded by the combined static and pulsating stress

However, because large differences between subsequent test runs have been observed under identical conditions, the randomness of the construction process of the breakwater must have large influence on the variation in stress level.

As the number of repetitions for each of the combinations of the parameters involved, i.e.  $H_s$ ,  $h_{toe}$ ,  $s_{op}$ , location and orientation, was rather small, it was not possible to derive trends between all individual variables and the accompanying stress distributions.

This means that further conclusions, concerning the influence of the individual parameters on the stress distributions, can only be drawn after performing a large number of tests, each test including a full reconstruction of the slope. However, before setting up such an extensive test program, it is recommended that a comparison is made between the method of measuring stresses in small scale armour units and the CUR C70 "Rocking" method.

## CHAPTER 124

# PORE PRESSURES IN RUBBLE MOUND BREAKWATERS

M.B. de Groot<sup>1</sup>, H. Yamazaki<sup>2</sup>, M.R.A. van Gent<sup>3</sup> and Z. Kheyri<sup>4</sup>

## ABSTRACT

Economic breakwater design requires knowledge of the wave induced pore pressures in the rockfill in view of sliding stability, filter requirements, wave transmission, wave overtopping and internal set-up. A mathematical model for the prediction of these pressures and the associated pore water flow has been developed. The model gives an integrated description of both external flow and internal flow. The sensitivity of the output to several input parameters and the validation of the external flow to model tests is discussed.

## 1. INTRODUCTION

Wave induced pore pressures influence the behaviour of rubble mound breakwaters in several ways. This may be relevant for the design. A numerical model, MBREAK/ODIFLOCS, has been developed for the prediction of pore water flow and pore pressures in the mound. Use is made of the progress made in the description of the external flow by Kobayashi and others (1987) and that made in the description of the internal flow by Barends and Hölischer (1988). The new model, however, gives an integrated description of both flow types. See Figure 1.

The paper will describe the relevancy of the pore pressures for the design, the basic features of the model, its potentials and its limitations. The results of a systematic series of calculations will be presented and the validation of the model with the help of measurements performed in flume tests, will be discussed.

## 2 PORE PRESSURES AND DESIGN

Economic breakwater design requires knowledge of the wave induced pore pressures in the rockfill. Figure 2 illustrates five design features that may be influenced by the pore pressures and pore water flow:

- A) Sliding stability may be seriously affected by the combination of a high pressure head in the rock fill mass and the low pressure head at the slope during run-down.
- B) A three layer thick geometric filter is often needed underneath a rubble mound breakwater constructed at a sandy seabed, according to traditional filter design. More economic "hydraulic" filter design enables a reduction of the number of filterlayers where the pore pressure gradients are low (de Groot et al 1993).
- C) The wave climate inside any harbour basin partly depends on the wave transmission through the rubble mound, which mainly depends on the absorption of wave energy due to pore water flow.
- D) Wave overtopping also influences the wave climate in the harbour. It is greatly influenced by the discharge of water seeping into the mound during run-up, which discharge is an important feature of the pore water flow.
- E) The water table in any sandy back-fill may rise one or two meters due to wave induced internal set-up, depending on the flow characteristics inside the mound.

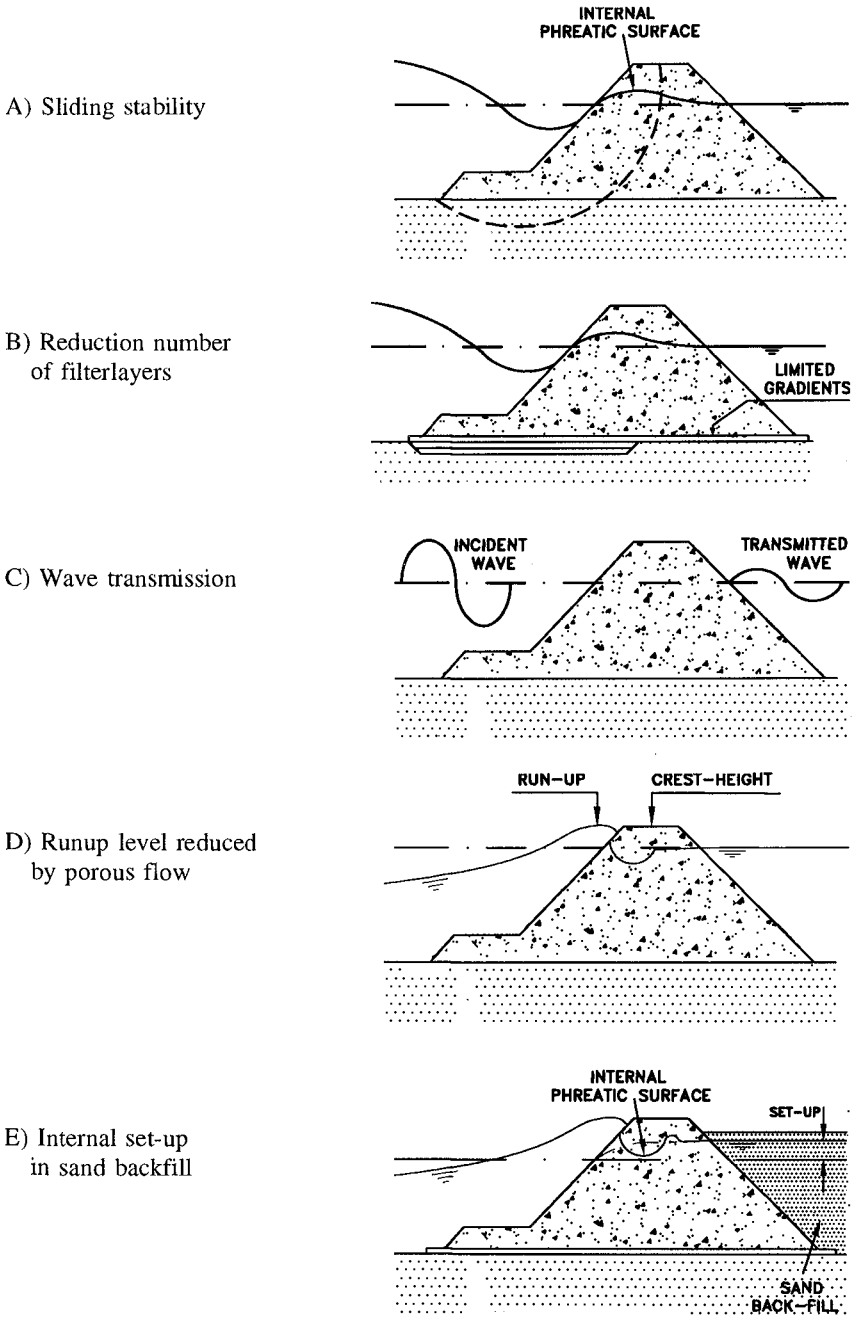

Figure 2 Breakwater design influenced by pore pressures

### 3. EXTERNAL AND INTERNAL FLOW

External and internal flow have much in common. Water level variations dominate both flow types. The pressure variations in vertical direction are roughly hydrostatic in most regions. The momentum in horizontal direction is determined in both flow types by inertia (including momentum convection), gravity (including pressure gradient) and friction.

There are, however, some important differences. Friction in the porous flow is much larger than friction in the external flow. Thus, the internal flow is dominated by friction and gravity; the external flow by inertia and gravity. The large friction limits the internal water velocities much more than the external velocities. As the water surface cannot move quicker than the water, also the motion of the internal phreatic surface is more limited than the motion of the external free surface. Thus, the friction causes a limited upward speed of the internal phreatic surface during uprush (Figure 3) and a limited downward speed during downrush. This yields the phenomenon of "disconnection" of the water surfaces: the point E where the external water surface meets the slope, is higher than the point I where the internal phreatic surface meets the slope during wave uprush (Fig.4A) and the other way around during downrush (Fig.4B)

Figure 3 Speed difference between external and internal watersurfaces

Figure 4A Water surfaces during maximum run-up

Figure 4B Water surfaces during maximum run-down

#### 4. MODEL DESCRIPTION

The above given flow characteristics enable both flow types to be largely described with long wave equations: for each flow type one storage equation and one equation for the momentum in horizontal direction. The coupling between both flow types requires a term to be added to the usual terms in each equation (Figure 5): an additional term in each of both storage equations for the infiltration discharge through the slope,  $q$ , and one in each of both momentum equations for the product of  $q$  with its horizontal component,  $q_h$ . Last term, however, can be neglected in many cases.

Figure 5 Coupling terms to be added to storage and momentum equations

At the seaward boundary of the external flow an incident wave is computed either with the Stokes second-order wave theory or the Cnoidal wave theory (Figure 6). The seaward boundary allows a reflected wave to leave the computational domain. This is calculated with the method of characteristics. This method allows water and momentum to leave the computational domain.

The modelling of the harbourside boundary of the external flow is based on work by Kobayashi et al. (1987). It uses a minimum waterdepth ("waterfilm") at the wave front above which level the slope is set dry.

The discharge through the slope,  $q$ , is a given boundary condition for the external flow, derived from the calculation of the internal flow. However, when point E is higher than point I (Fig. 4A),  $q$  between those points is the discharge of water freely falling through the partly saturated area. It is taken equal to the discharge which occurs when the downward head gradient equals unity. The water is supposed to reach the phreatic surface of the internal flow immediately.

Figure 6 Modelling of the external flow

The slope between the toe, T, and point I makes up the seaward boundary of the internal flow. There the pressurehead is a given boundary condition, derived from the calculation of the external flow. When point E is lower than point I (Fig. 4B), then the head between those points is taken equal to the slope surface.

The harbourside boundary can be either an open boundary, allowing a wave to leave the calculation domain (Figure 7A) or a closed boundary at which a wave reflects completely (Figure 7B). A breakwater with a sand backfill can be modelled with last option.

Two or more layers with different stone sizes can be modelled. At the boundary between two layers disconnection can take place, just like at the external slope.

The water movement in and over a breakwater with limited crest height can be described with a special model option, allowing for the prediction of the wave radiating into the harbour by a combination of overtopping and penetration through the porous mound (Figure 7C).

Three different versions of the model have been made: 1) ODIFLOCS, 2) a one dimensional version of MBREAK and 3) a semi two-dimensional version of MBREAK. The numerical schemes of ODIFLOCS and MBREAK differ, as do certain minor assumptions about the flow properties. Version 3) is realised by alternately calculating the two-dimensional internal velocities with a stationary model with given phreatic surface, calculating the corresponding horizontal discharge and calculating the phreatic surface change with the one-dimensional model. Application of the different versions for the same situation yields a helpful tool to study the influence of numerical effects and particular assumptions.

A more extensive description of the different versions of the model can be found in (van Gent and Engering 1992); more about ODIFLOCS in (van Gent 1994).

Figure 7 Different options for breakwater modelling

## 5 VALIDATION

The validation of the model started with an extensive sensitivity analysis for both model parameters and physical parameters. Application of the model requires assumptions concerning several model parameters, like the mesh size, the water film thickness, the maximum variation speed of the internal water level, the friction coefficients for the external and internal flow, the coefficient for added mass. Many calculations have been done in which these parameters have been varied to find out which parameter values would yield reasonable values.

The waterfilm thickness has a very large influence on many output parameters. An example is presented in Figure 8. It is seen that small values of the waterfilm thickness yield unreliable values of the run-down. An advise about the waterfilm thickness in proportion to the waveheight is formulated based on these results and a comparison with measurements of the run-down.

Figure 8 Influence of waterfilm thickness on run-up and run-down

Another important model parameter is related to the disconnection of the external and internal watersurface. A realistic limit to the speed of the internal watersurface must be selected. It can be shown that the maximum value of the downward speed equals the "free fall velocity" of the water, i.e. the downward water discharge per unit area occurring with a downward head gradient of unity, which means a pressure constant with depth. The upward watersurface speed may be more, because the effective upward gradient may reach higher values than unity during uprush (Hölscher et al 1988). Values up to 3 times the free fall velocity seem possible. A much higher limit yields the same results as no limit at all.

The external run-up and run-down, i.e. the highest level and the lowest

level of the points E of Figure 4, are hardly influenced by the limit to the internal watersurface speed. However, the internal run-up and run-down, i.e. the highest level and the lowest level of the points I of Figure 4, do depend a lot on this limit (Figure 9). It is of great interest to study this limit more in detail.

Figure 9 Influence of limit to internal water surface speed

Not only model input parameters have been varied during the sensitivity analysis, but also physical input parameters: the surf similarity parameter  $\xi$ , slope roughness, stone size, porosity, number of stone layers. Stone size and porosity determine the permeability of the rock fill. Its large influence on the external flow is illustrated in Figure 10 for a breakwater with impermeable core and permeable berm and for a completely impermeable berm breakwater (scaled to prototype dimensions). The thin lines show the water levels for the permeable breakwater at different moments during one wave. The thick lines represent their envelop. The envelop for the impermeable breakwater is indicated with interrupted lines. It is seen that the permeability of the breakwater has a large influence on the external head distribution, including run-up and run-down.

The relative influence of the different input parameters to one output parameter has been presented in Figure 11 as a kind of summary of the sensitivity analysis. The choice of the waterfilm thickness has the largest influence on output parameters like run-up level and discharge through the slope. Other important input parameters are the friction factors, the porosity the armour stone size and the wave period.

**WATER SURFACE LEVELS (m)**

Figure 10 Influence of permeability on external water surfaces

Figure 11 Relative influence of different input parameters to one output parameter

The effects of the parameter variation on the internal pore pressures and the external water movement, observed in these and other calculations, were qualitatively reliable. Whether they are quantitatively correct, however, can only be judged by comparison with model tests.

Many model test results are available on run-up values. Calculations made with MBREAK/ODIFLOCS for impermeable slopes for different values of the surf similarity parameter  $\xi$ , yield external run-up and run-down values which agree very well with model results. The same holds for the run-up values calculated for the breakwaters with permeable coverlayers tested by Ahrens (1975), as illustrated in Figure 12.

Figure 12 Run-up levels for breakwaters with permeable coverlayer

## 6 CONCLUSIONS

With MBREAK/ODIFLOCS a successful integration is realised of the mathematical modelling of the external flow on the slope of a rubble mound breakwater and the induced internal flow in the breakwater. Part of the success is due to the modelling of the disconnection between external and internal water surfaces. The sensitivity analysis made clear that many phenomena can be predicted qualitatively well. Run-up values can also be predicted fairly well. The further quantitative validation, however, is limited and requires more hindcasts to be made with the model for flume tests in which pore pressures have been measured.

## ACKNOWLEDGEMENTS

The model has been developed in the frame-work of the European MAST-G6-Coastal Structures project, co-sponsored by the Commission of the European Communities Directorate General XII (contract 0032-C). The sensitivity analysis is performed by close cooperation between the International Institute for Infrastructural, Hydraulic and Environmental Engineering (IHE) and Delft Geotechnics.

## CHAPTER 125

### WAVE ACTION ON AND IN PERMEABLE STRUCTURES

M.R.A. van Gent<sup>1</sup>, P. Tönjes<sup>2</sup>, H.A.H. Petit<sup>3</sup> and P. van den Bosch<sup>3</sup>

**ABSTRACT:** A numerical model that can simulate plunging waves on permeable structures is described. The 'Volume Of Fluid' method is used to solve the two-dimensional (2D-V) incompressible Navier-Stokes equations. After implementation of porous media flow for applications with permeable structures, the model has been verified by using several analytical solutions and by comparisons with physical model tests to study breaking waves on and inside permeable structures.

#### INTRODUCTION

Wave motion on permeable structures has often been studied using physical models. Small-scale physical modelling is influenced by scale effects while large-scale modelling is relatively expensive. Apart from this, measurements within breaking waves can be very complex. Therefore, numerical models simulating individual breaking waves are valuable design and research tools for studying wave motion on and inside coastal structures.

The description of breaking waves, the interaction with the porous part of permeable structures and the verification of the implementation of the most important phenomena involved, require a considerable amount of research of which some aspects are treated here. The numerical model described here (SKYLLA) was verified for breaking waves over a submerged bar, described in Van Gent *et al.* (1994-a). Other research concerning this numerical model, including the in- and outflow boundaries as well as the description of impermeable slopes were presented by Van der Meer *et al.* (1992) and Petit *et al.* (1994-b).

After a description of the numerical model and the method to solve the Navier-Stokes equations, adapted Navier-Stokes equations for porous media flow will be

given. The implementation of these are validated using both analytical solutions and physical model tests. The physical model tests are performed with a Berm breakwater where surface elevations, velocities and pore-pressures are measured.

## NUMERICAL MODEL

Several models to simulate breaking waves have been made. For instance Vinje and Brevig (1981) used a potential flow model and modelled a plunging wave until the overturning wave hits the trough water. Sakai *et al.* (1986) applied the MAC-method to simulate breaking waves. Here, the 'Volume of Fluid' (VOF) method by Hirt and Nichols (1981) is used to solve the Navier-Stokes equations in two dimensions. This powerful method enables simulation of complex flow patterns including those where the free surface can become multiply connected. To achieve this, the treatment at the surface based on the adapted flux-method known as FLAIR by Ashgriz and Poo (1991), has been improved. Figure 1 shows that an overturning wave on an impermeable slope can be simulated by applying the Navier-Stokes equations solved using the VOF-method.

*Fig.1 Simulation of a breaking wave on an impermeable dike with a berm.*

The VOF-method is a method where for each cell the fluid fraction can vary between zero (empty) and one (full). Fluid fractions are transported between each cell and its surrounding cells. In Figure 2 the principle of the method is shown for the transport between two neighbouring cells. Based on the two fluid fractions of two neighbouring cells, a 'local surface' can be constructed. By using the velocity

and the time-step (varied based on the instantaneous stability and accuracy criteria), a part of the fluid is transported between these two cells. In the numerical model this is done using a non-equidistant staggered grid.

**Fig.2** Transport of fluid based on the VOF-method.

The velocity as used in the VOF-method is obtained from the discretisation of the Navier-Stokes equations. At impermeable slopes and at the free surface not all velocities necessary to discretise the equations are within the fluid domain. Figure 3 shows the required velocities for discretisation inside the fluid (A) and near the free surface (B). Boundary conditions are required to fill the lack of information at the free surface. For instance one can assume no gradient in the velocities at the surface or that the flow is irrotational at the surface.

**Fig.3** Required information for discretisation of horizontal velocities.

Two open weakly-reflecting boundaries can be used at which regular wave trains can both be generated and absorbed. The incoming non-linear waves are based on the theory by Rienecker and Fenton (1981). The boundary for impermeable slopes are defined on sub-grid level which means that the slope can intersect cells (no 'stair-case' slope). At impermeable slopes no-slip or free-slip boundaries can be applied. In Van Gent *et al.* (1994-a) two weakly-reflecting boundaries were applied for wave breaking over a submerged bar schematised with a free-slip boundary. The comparison of these computed breaking waves with video images showed that plunging occurs at the same position as in the physical model tests. Although the decrease in wave height occurs somewhat quicker in the numerical model than in reality, the height of the transmitted wave is accurate. Here, after implementation of porous media flow, breaking waves on permeable structures will be verified.

## IMPLEMENTATION OF POROUS MEDIA FLOW

The VOF-method can also be applied for solving the wave motion inside permeable structures. The momentum equations, however, are different from those for the external wave motion. The Navier-Stokes/Reynolds equations for the external wave motion read:

$$\frac{\partial u}{\partial t} + \frac{\partial u^2}{\partial x} + \frac{\partial u w}{\partial z} + \frac{1}{\rho_w} \frac{\partial p}{\partial x} - \nu_t \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial z^2} \right) + g_x = 0 \quad (1)$$

$$\frac{\partial w}{\partial t} + \frac{\partial u w}{\partial x} + \frac{\partial w^2}{\partial z} + \frac{1}{\rho_w} \frac{\partial p}{\partial z} - \nu_t \left( \frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial z^2} \right) + g_z = 0 \quad (2)$$

where  $u$  and  $w$  are the velocities in the  $x$  and  $z$  direction respectively and  $\nu_t$  the eddy-viscosity for which a constant value will be used. Together with conservation of mass ( $\partial u/\partial x + \partial w/\partial z = 0$ ), which is satisfied by solving the Poisson equation, and boundary conditions, the VOF-method can then be applied yielding the external wave motion. For the internal wave motion adapted Navier-Stokes equations were derived (see Van Gent, 1991):

$$\frac{1+c_A}{n} \frac{\partial u}{\partial t} + \frac{1}{n^2} \left( \frac{\partial u^2}{\partial x} + \frac{\partial u w}{\partial z} \right) + \frac{1}{\rho_w} \frac{\partial p}{\partial x} + g_a u + g_b u \sqrt{(u^2+w^2)} + g_x = 0 \quad (3)$$

$$\frac{1+c_A}{n} \frac{\partial w}{\partial t} + \frac{1}{n^2} \left( \frac{\partial u w}{\partial x} + \frac{\partial w^2}{\partial z} \right) + \frac{1}{\rho_w} \frac{\partial p}{\partial z} + g_a w + g_b w \sqrt{(u^2+w^2)} + g_z = 0 \quad (4)$$

where  $u$  and  $w$  are both filter-velocities,  $a$  and  $b$  are dimensional friction coefficients and  $c_A$  is a coefficient to take the phenomenon *added mass* into account. Because filter/discharge velocities are used, the procedure to transport mass between the

cells, the VOF-method, does not require any adaptation. The discretisation (partial upwind scheme) and stability criteria are described in Van Gent *et al.* (1994-b). In the computational domain numerous regions with different properties can be selected and awarded a certain porosity and stone diameter. The permeable slopes are not, like for impermeable slopes, defined on sub-grid level which means that the properties cannot be varied within one cell. Permeable slopes can also be combined with impermeable regions. This implementation of permeable parts in this two-dimensional model, therefore, enables applications with breaking waves and other complex flow patterns for a very wide range of structure types. Here, some validation tests will be discussed. For some other applications see for instance Van Gent and Petit (1994).

## VALIDATION WITH ANALYTICAL SOLUTIONS

Several verifications of the implementation of porous media flow have been performed. Before the wave motion on and inside a permeable structure is verified using physical model tests, three comparisons with analytical solutions are carried out. The first case concerns a layer of water with a thickness  $L$  that is initially positioned above a dry permeable part, see Figure 4. At  $t=0$ , the layer of water starts entering the permeable part. For this simplified case of uniform flow entering a permeable part ( $-L < x_0 < 0$ ), the Navier-Stokes equations reduce to a set of one dimensional differential equations (Van Gent *et al.*, 1994-b) where  $u$  is the filter-velocity,  $n$  the porosity and  $x_0$  the position of the free surface, at  $t=0$ ,  $x_0=-L$ :

$$\frac{du}{dt} = \frac{-\frac{g}{n} (L + x_0) (a u + b u^2 - 1) - \left(\frac{1}{n^2} - 1\right) u^2 - g x_0}{\frac{L + x_0}{n^2} - x_0} \quad (5)$$

With  $dx_0/dt=u$ , this set of differential equations was solved using a fourth-order Runge-Kutta method with  $\Delta t=0.005$  s and  $\Delta x=0.05$  m while for the constants  $L$ ,  $n$ ,  $g$ ,  $a$ ,  $b$  the values 0.5 m, 0.5, 4 m/s<sup>2</sup>, 0 s/m and 16.9 s<sup>2</sup>/m<sup>2</sup> were used respectively (for  $g$ , 4 m/s<sup>2</sup> is taken instead of 9.81 m/s<sup>2</sup> to exaggerate the local maximum in Figure 4). After the layer has entered the permeable part, the differential equation reduces to:  $du/dt=ng(1-au-bu^2)$  for which an analytical solution was found:

$$u(t) = \left( u_1 - u_2 \frac{u(t_0) - u_1}{u(t_0) - u_2} e^{-bng(u_1 - u_2)(t - t_0)} \right) / \left( 1 - \frac{u(t_0) - u_1}{u(t_0) - u_2} e^{-bng(u_1 - u_2)(t - t_0)} \right) \quad (6)$$

where  $u_1=-a/2b + \sqrt{(a^2+4b)/2b}$ ,  $u_2=-a/2b - \sqrt{(a^2+4b)/2b}$  and  $u(t_0)$  is the initial velocity at  $t=t_0$  where  $t_0$  is the moment at which the whole layer of water has

**Fig. 4** Comparison of numerical model results with solutions of simplified differential equations for the velocity of a layer of water entering a porous block.

**Fig. 5** Calculated pressure jumps at the interfaces of a porous block with a steady flow.

entered the permeable part. Figure 4 shows the comparison of the numerical results and these solutions. At  $t=0$ , the velocity is zero, at  $t=0.435$  s a local maximum of  $u=0.6848$  m/s occurs and at  $t=0.850$  s ( $t_0$ ) the layer has entered the permeable part after which the velocity rapidly converges to the velocity 0.75 m/s. The difference between the numerical model results and the solutions of the set of simplified differential equations reaches a maximum of 0.0129 m/s at  $t=0.4$  s. As shown in Figure 4, the phenomenon is reproduced with good result.

A second verification concerns the flow through a saturated permeable block, see Figure 5. At  $x=0$  a constant inflow with a velocity of  $1\text{ m/s}$  is produced, between  $x=1\text{ m}$  and  $x=2\text{ m}$  a saturated permeable block is positioned. The pressure jumps at the porous interfaces ( $x=1\text{ m}$  and  $x=2\text{ m}$ ) can be determined analytically. Integrating the momentum equation for a uniform flow in the  $x$ -direction yields:

$$P(x_2 + \delta x) - P(x_2 - \delta x) = \left( \frac{1}{n^2} - 1 \right) u^2 - \delta x \left( g(au + bu^2 + 2) + \left( 1 + \frac{1 + c_A}{n} \right) \frac{\partial u}{\partial t} \right) \quad (7)$$

where  $x_2$  is the position of the outflow boundary ( $x=2\text{ m}$ ). The same procedure can be used at the inflow boundary ( $x=1\text{ m}$ ). The pressure jump is then equal to the one at the inflow boundary, except for the sign. Outside the stone the pressure is determined by  $\partial P/\partial x = -g$  while inside the stone the pressure gradient can be assessed through  $\partial P/\partial x = -g(au + bu^2 + 1)$ . In Figure 5 the comparison between the analytical solution and the numerical results is shown. Some arbitrary values for the constants  $n$ ,  $a$ ,  $b$  and  $g$  were used ( $0.5$ ,  $1\text{ s/m}$ ,  $0.75\text{ s}^2/\text{m}^2$  and  $2\text{ m/s}^2$  respectively). Because in the numerical model the pressure jumps are simulated in steps of  $3\Delta x$ ,  $\delta x = 3/2\Delta x$  is used in the analytical solution (Equation 7) for comparison with the numerical model results. The pressure jumps by the analytical solution and the numerical model results were  $2.4375\text{ m}^2/\text{s}^2$  and  $2.5065\text{ m}^2/\text{s}^2$  respectively. This comparison is again rather good. For  $\delta x \downarrow 0$ , the real analytical solution gives  $3\text{ m}^2/\text{s}^2$  to which the numerical model results will come close for smaller values of  $\Delta x$ .

**Fig.6** Comparison of numerically computed phreatic surface and an analytical solution.

A third analytical solution has been compared with numerical model results. Now, a stationary flow through a rectangular block with only linear porous friction

( $b=0$ ) has been examined. Neglecting convection and assuming hydrostatic pressures and uniform flow over the depth, the solution for the phreatic surface is determined by  $h(x') = \sqrt{(H_1^2 - x'/L(H_1^2 - H_2^2))}$  where  $H_1$  is the free surface level at the inflow boundary (left in Figure 6),  $H_2$  is the free surface level at the outflow boundary and  $L$  the length of the permeable block (for Figure 6:  $x'=x-2$ ). Some arbitrary values for the constants  $n$ ,  $a$ ,  $L$  and  $g$  were used ( $0.2$ ,  $4.0$  s/m,  $6.0$  m and  $10$  m/s<sup>2</sup> respectively). The levels  $H_1$  and  $H_2$  were  $2.0$  m and  $1.0$  m respectively. In the numerical computation,  $\Delta x=0.1$  m has been used. The phreatic level was defined as the level where in the computation 50% of the cell was filled with water ( $F=0.5$ ). Differences between both phreatic surfaces at  $x=2, 4, 6$  and  $8$  m in Figure 6 were  $0.0233, 0.0206, 0.0105$  and  $0.0234$  m, respectively.

## VALIDATION WITH PHYSICAL MODEL TESTS

By means of the numerical model complex phenomena such as scale effects, wave transmission, the effects of non-stationary porous media flow, added mass and forces on stones can be studied. However, a verification with physical models must be performed first.

Non-stationary porous media flow tests have been performed in a U-tube tunnel. These measurements resulted in expressions for the porous media flow friction-coefficients  $a$ ,  $b$  and  $c_A$  in Equations 3 and 4, see Van Gent (1994). For the dimensional coefficients  $a$  and  $b$ , theoretically derived expressions are used:  $a = \alpha \cdot (1-n)^2/n^3 \cdot \nu/gD_{n50}^2$ ,  $b = \beta \cdot (1-n)/n^3 \cdot \nu/gD_{n50}$  and  $c_A = \gamma \cdot (1-n)/n$ . The physical model tests showed a dependency of  $\beta$  on the flow field, accounted for by including a dependency of  $\beta$  on the  $KC$ -number,  $\beta = \beta_c (1 + 7.5/KC)$ , where  $KC = \hat{U}T/nD_{n50}$  and  $\beta_c = 1.1$ . In the computations with the numerical model this has been included by estimating a representative filter-velocity  $\hat{U}$  beforehand and using the wave period for  $T$ .

Fig. 7 Cross-section of the Berm breakwater in experimental set-up.

A second series of physical model tests was performed to verify the numerical model. A small-scale model of a Berm breakwater was used for this purpose. Figure 7 shows a sketch of the experimental set-up with the initially horizontal berm at a level of  $0.80\text{ m}$ , the still water level being  $0.75\text{ m}$ . All slopes were  $1:1.5$  except for the submerged seaward slope which was  $1:1.25$ . The size of the stone material was  $D_{n50}=0.0266\text{ m}$  in the cover layer and  $D_{n50}=0.0175\text{ m}$  in the core. The porosity of the two permeable parts were measured *in situ*, both giving  $n=0.417$ . Reshaping the seaward profile was achieved by four series of  $1000$  regular waves. After the last series, with the largest waves, the seaward profile was reshaped while the crest was heightened from  $0.95\text{ m}$  to  $1.00\text{ m}$ . Several series of regular waves were used to study the flow field. No reshaping took place during these tests. The flow field was recorded using a video, electro-magnetic flow meters (EMF), wave gauges and pressure transducers. The positions of the pressure transducers are indicated in Figure 7.

Surface elevations above the seaward slope were determined at ten points of time within a wave cycle for four series of regular waves:  $H=0.119\text{ m}$ ,  $T=1.5\text{ s}$ ;  $H=0.230\text{ m}$ ,  $T=1.5\text{ s}$ ;  $H=0.112\text{ m}$ ,  $T=2.1\text{ s}$  and  $H=0.217\text{ m}$ ,  $T=2.1\text{ s}$ . The computational domain in the numerical model started at  $4\text{ m}$  in front of the toe of the reshaped structure where the waves were generated at this weakly reflecting boundary by applying the method by Rienecker and Fenton (1981) using 16 Fourier-components. This method was adapted to deal with reflected waves as described in Petit *et al.* (1994-a). No net transport was allowed through this boundary. At the landward boundary again a weakly reflecting boundary was positioned at  $1.5\text{ m}$  behind the crest of the structure. In  $x$  and  $z$ -direction,  $270$  and  $80$  computational cells were used respectively. The computations were performed with a constant viscosity  $\nu_t=0.005\text{ m}^2/\text{s}$ . In the discretisation of the equations an up-wind fraction of  $0.2$  was used. Surface elevations were defined at positions of cells which were filled with fluid for  $50\%$ . After an adjustment time of six to eight waves to obtain a periodic computation, data was used for comparison with the measured properties.

Figure 8 shows comparisons of surface elevations for ten points of time for two wave conditions with a wave period of  $1.5\text{ s}$  (five surface profiles per graph with  $0.15\text{ s}$  in between two profiles). Only the surface elevations above the berm, where the waves are breaking, are shown since in the section in front of the structure only minor differences in wave height occur. Also for the two wave conditions with a wave period of  $2.1\text{ s}$ , as shown in Figure 9 ( $0.21\text{ s}$  in between two profiles), the comparisons for the five profiles in the first half of each wave cycle show good agreement (upper graph for each wave condition). In the second half of each wave cycle (lower graph for each wave condition) considerable air-entrapment occurs for the two highest waves. In the figures with measured surface elevations the position of entrapped air is indicated by the area in between the two lines of each surface profile. The comparisons with the computed results become rather complex in this part since the exact position of the free surface is not clear. However, the comparisons indicate that the decrease in wave height above the berm faster occurs

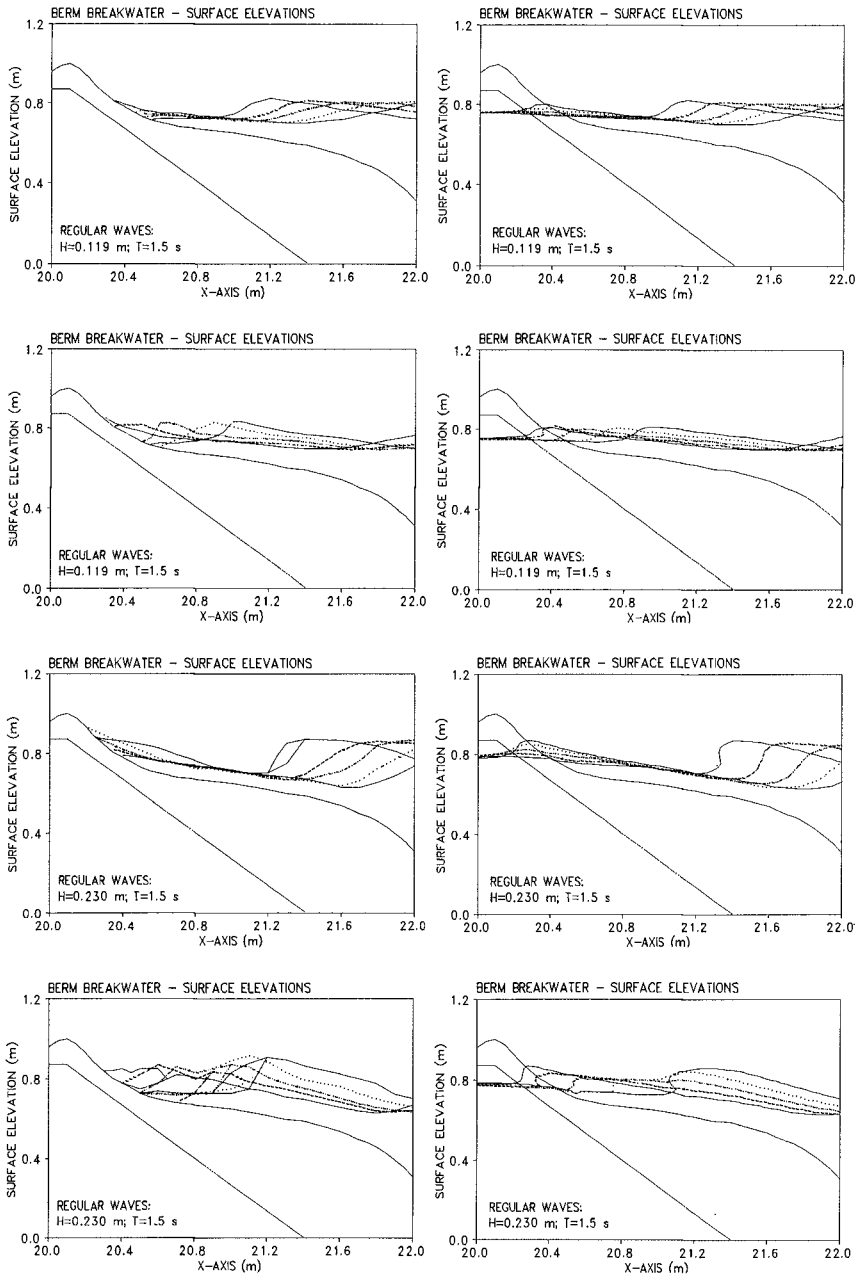

Fig.8 Comparison of measured (left) and computed (right) surface elevations.

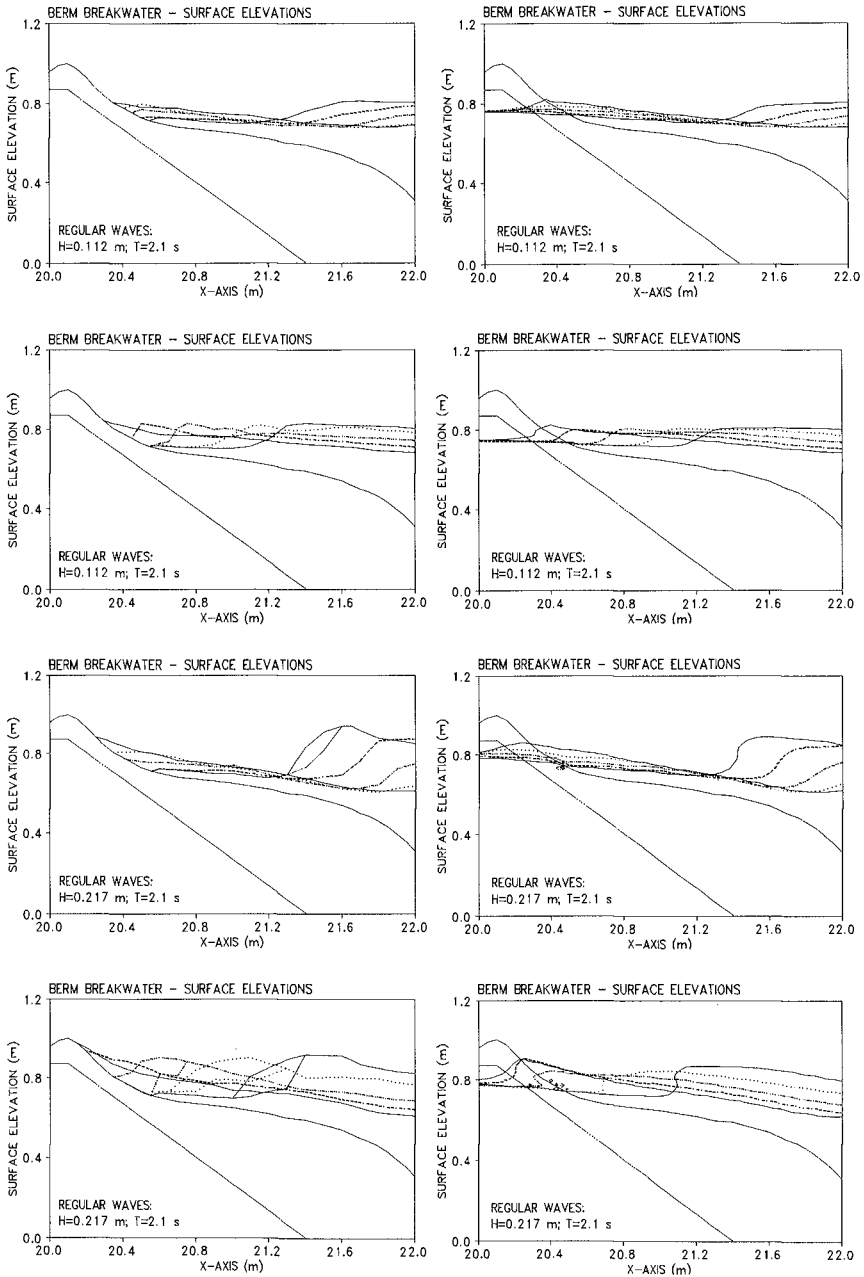

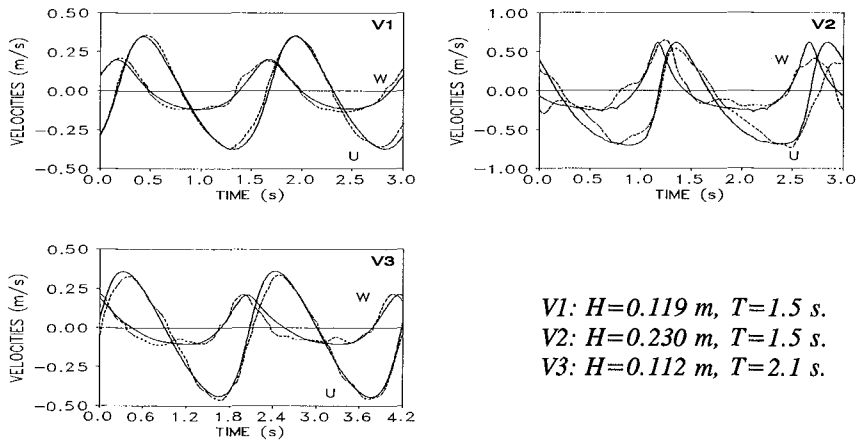

Fig.9 Comparison of measured (left) and computed (right) surface elevations.

in the computation than observed from the measurements. It seems as if this overestimated reduction in wave height, possibly due to a too large dissipation, leads to an underestimation of the run-up levels. For the two wave conditions with smaller waves, the comparisons are also rather good in the second half of the wave cycle.

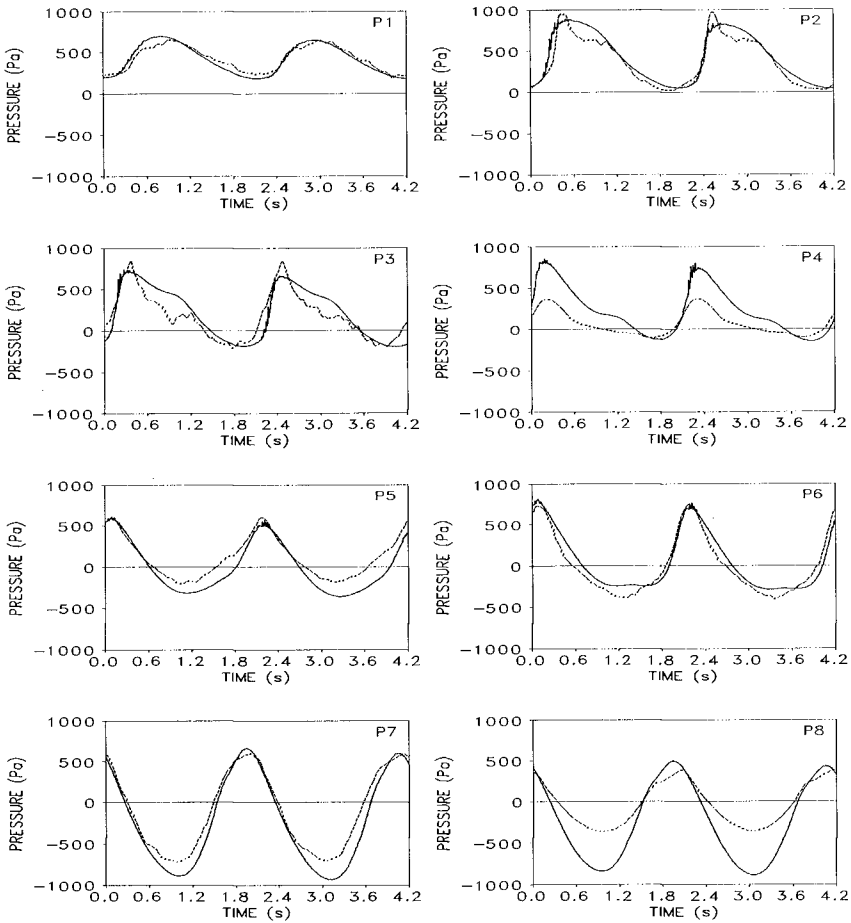

For all four wave conditions  $H=0.119\text{ m}$ ,  $T=1.5\text{ s}$ ;  $H=0.230\text{ m}$ ,  $T=1.5\text{ s}$ ;  $H=0.112\text{ m}$ ,  $T=2.1\text{ s}$ ;  $H=0.217\text{ m}$ ,  $T=2.1\text{ s}$ , the computed run-up levels are too low compared with the measured run-up levels:  $0.07\text{ vs. }0.10$ ;  $0.14\text{ vs. }0.21$ ;  $0.08\text{ vs. }0.11$  and  $0.18\text{ vs. }0.27\text{ m}$ , respectively. All these values are relative to the average water levels in front of the structure during testing. The choice to define the surface elevations at the positions of cells that are filled with water for 50% instead of another percentage, might influence the computed run-up levels slightly. If for this definition positions of cells that are filled with water for 10% are regarded as surface elevations, the computed run-up levels might increase but not so much that they would fit to the measured run-up levels. The dissipation in the computed breaking process, by the description of the physical processes or by numerical dissipation, is assumed to cause these underestimated run-up levels.

Comparisons between measured and computed velocities were made. Because of air-entrainment the position closest to the crest without this difficulty was at  $x=21.6\text{ m}$ ,  $z=0.65\text{ m}$ . For three waves the comparisons for both the horizontal ( $u$ ) and the vertical ( $w$ ) velocities are shown in Figure 10. The comparison for the fourth wave ( $H=0.217\text{ m}$  and  $T=2.1\text{ s}$ ) was not possible because in the physical model this position was dry for some period within a wave cycle causing severe disturbance of the measured signal. The comparisons for the other three waves show accurate results for both the horizontal and vertical velocities.

**Fig.10** Comparison of velocities at  $x=21.6\text{ m}$  and  $z=0.65\text{ m}$ ; measured (dashed) and computed (lines).

**Fig.11** Comparison of pressures; measured (dashed) and computed (lines),  $H=0.217$  m,  $T=2.1$  s.

Also comparisons between measured and computed pressures were made. Figure 11 shows the signals from the eight transducers and the computed pressures at the same positions. The positions of these transducers are shown in Figure 7. Transducer *P4* is positioned in between the transducers *P3* and *P6*. The recorded pressures by transducer *P4*, however, clearly deviate from those recorded by *P3* and *P6*. Because no decisive physical explanation can be given for these low pressures, estimated to be roughly 50% of the expected pressures for all analysed wave conditions, the signals of transducer *P4* are highly questionable. The comparisons with the other transducers are fairly accurate except for those with transducer *P8*.

Both the internal set-up as recorded by transducer *P1* (average level) and the internal wave height are reproduced with a high accuracy. The computed signals at positions just below the breaking waves, transducers *P2*, *P3* and *P6*, also show good correspondence with the measured signals although these measured signals show more higher-order fluctuations.

## CONCLUDING REMARKS

A numerical model solving the two-dimensional Navier-Stokes equations for simulating normally incident waves, including breaking waves, has been extended with porous media flow. The implementation of the combined external and internal wave motion on and inside permeable structures was successful as shown by comparisons with both analytical solutions and physical model tests. The model, now capable of providing a detailed flow description of breaking waves on permeable structures, will, however, be improved by including more sophisticated modelling of air-extrusion and turbulence. Furthermore, irregular waves will be implemented.

## ACKNOWLEDGEMENTS

The financial support by Rijkswaterstaat (Ministry of Transport, Public Works and Water Management, Road and Hydraulic Engineering Division) and by the Commission of the European Communities by way of the MAST-Berm Breakwater project (contract MAS2-CT94-0087) is gratefully acknowledged.

## CHAPTER 126

### PROBABILISTIC CALCULATIONS OF WAVE FORCES ON VERTICAL STRUCTURES

J.W. van der Meer<sup>1)</sup>, K. d'Angremond<sup>2)</sup> and J. Juhl<sup>3)</sup>

#### ABSTRACT

In the past wave forces on vertical structures have been measured in a number of site specific projects at the Danish Hydraulic Institute and Delft Hydraulics. For nine selected cases, the data on forces and moments were re-analyzed, leading to an expression for reliability of Goda's formula for calculation of forces and moments on vertical breakwaters. Secondly, probabilistic level II design calculations were made using Goda's formula with the found reliability. It appears that the reliability of this formula has by far the largest influence on the probability of failure. Finally the influence of model tests on the probability of failure was studied. In that case the wave height has the largest influence on stability, which is usual for most coastal structures designs.

#### INTRODUCTION

Design of vertical breakwaters has for instance to take into account hydraulic, geotechnical and structural aspects. The wave forces exerted on a vertical structure depend on characteristics of the incident waves, type of structure, elasticity of the structure, air enclosure and the entrainment of dissolved air and foreshore characteristics

In a deterministic design approach, vertical breakwaters are designed based upon characteristic values of the load determining parameters. A safety factor is then introduced to allow for uncertainties. However, all parameters which are important

  - 2) Delft University of technology, P.O. Box 5048, 2600 GA Delft, The Netherlands
  - 3) Danish Hydraulic Institute, Agern Allé 5, 2970 Hørsholm, Denmark

for the wave loads on and the strength of a hydraulic structure are of a stochastic nature, ie a probability distribution can be assigned to each value of these parameters. Since the last decades methods for probabilistic design of hydraulic structures have been developed, taking into account the stochastic nature of the load determining parameters.

The formulae of Goda (1985) for wave forces on vertical structures is used worldwide. The distribution of wave pressures on a vertical structure can be calculated based on knowledge of structure geometry, seabed characteristics and wave parameters in front of the structure, see Figure 1, taken from Goda (1985).

Figure 1 Distribution of wave pressures on a vertical structure, Goda (1985)

The design wave parameters are the maximum wave height in front of the structure,  $H_{\max}$ , and the corresponding wave period taken as the significant wave period,  $T_s$  (which is close to the peak wave period,  $T_p$ ). Goda (1985) states that: " $H_{\max}$  is the mean of the heights of the waves included in 1/250 of the total number of waves, counted in descending order of height from the highest wave. This definition yields the approximate relation  $H_{\max} = 1.8 H_{1/3}$  outside the surfzone". The formulae for pressures, total forces and moments, and definitions of symbols given in Fig. 1 can be found in Goda (1985) pp 115-119.

The present paper describes a re-analysis of model tests on various vertical structures carried out at the Danish Hydraulic Institute and Delft Hydraulics. Later two cases were added from CEDEX-CEPYC, Spain, and ENEL-CRIS, Italy. The reliability of Goda's formulae has been established by use of these practical cases by making comparisons of calculations and measurements. In a second stage, these data have been used for probabilistic level II calculations.

## RE-ANALYSIS

A total of eleven cases has been re-analyzed with respect to wave forces and moments on vertical structures. Details on caisson geometry, foreshore slopes, wave conditions and horizontal forces were stored in a database as presented in Juhl and Van der Meer (1992). The analysis of horizontal forces is also described in Juhl and Van der Meer (1992) with a summary in Van der Meer et al. (1992). Vertical forces and overturning moments were treated later by Bruining (1994).

The analyzed cases have been divided in three categories: vertical superstructure, inclined superstructure, and curved superstructure. In Figure 2, an example of each of these three categories is shown.

Figure 2 Examples of different superstructures

The significant and maximum wave heights in front of the vertical structure were calculated by Goda's formulae for transformation and deformation of random sea waves, Goda (1985) pp 71-87. Only total wave forces, measured by means of strain gauge based measuring equipment (eg a measuring frame or a dynamometer), are considered. This means that local wave impacts are not treated, as they cannot be measured by this measuring technique. It was assumed, however, that very fast local impacts would not influence the stability of a caisson and were therefore not interesting.

In all cases, wave trains with lengths of 1000-3000 waves were considered. Based on the recordings the horizontal and vertical forces and horizontal and vertical overturning moments at the heel of the caisson were tabulated, with exceedance frequencies of 0.1%, 0.4%, 1%, 2% and 5% respectively. In Figures 3-5 the measured horizontal forces,  $F_{0.4\%}$ , are compared with the horizontal forces calculated by Goda's formula,  $F_{Goda}$ . The cases with a vertical superstructure have been plotted in Figure 3, and the cases with an inclined or curved superstructure have been plotted in Figure 4. Due to the various structure geometries, foreshore slopes, wave characteristics, etc., a significant scatter in the measured wave forces was found.

Figure 3 Measured and calculated horizontal wave forces; vertical superstructures

Figure 4 Measured and calculated horizontal wave forces; inclined and curved superstructures

From Figure 4, it is clear that for inclined and curved superstructures, the wave forces calculated by Goda’s formula are much higher than the measured forces. In the major part of those cases, the ratio between the calculated and measured force is in the order of 1.4-1.6. For inclined and curved superstructures, the maximum force on the superstructure occurs later than the maximum horizontal force on the vertical front. This phase difference in the forces led to the following modification of Goda’s formula for inclined and curved superstructures:

*The crest height should be determined at the transition from the vertical front to the inclined or curved superstructure.*

The horizontal forces,  $F_{Goda}$ , were re-calculated with a reduced crest height in accordance with the above-mentioned modification to Goda’s formula. The results are presented in Figure 5 and it is found that the ratio’s between calculated and measured forces are in the same order as found for the cases with a vertical superstructure.

Figure 5 Measured and calculated horizontal wave forces; inclined and curved superstructures, ignoring the inclined or curved superstructure in the Goda force calculations

The average ratio between measured ( $F_{0.4\%}$ ) and calculated ( $F_{Goda}$ ) forces and moments was based on 134 data sets for horizontal forces and moments; 31 data sets were used for the uplift forces and moments and were treated in the same way as the horizontal forces. The average values of these ratios and the standard deviations, assuming a normal distribution, are given in Table 1.

		Ratio measured/calculated	Average	Standard deviation
Horizontal force	$F_h$	$r_{Fh}$	$\mu = 0.83$	$\sigma = 0.25$
Horizontal moment	$M_h$	$r_{Mh}$	$\mu = 0.75$	$\sigma = 0.40$
Vertical force	$F_b$	$r_{Fb}$	$\mu = 0.71$	$\sigma = 0.25$
Vertical moment	$M_b$	$r_{Mb}$	$\mu = 0.67$	$\sigma = 0.37$

Table 1 Comparison between measured and calculated forces and moments  
Measured = 0.4% exceedance; calculated = Goda

In all cases the ratio is smaller than one, which means an overprediction by the Goda formulae. The most important conclusion is that the standard deviations are large. The variation coefficients,  $\sigma/\mu$ , amount to 30-50%! It can be concluded that the Goda method gives only a rough estimation of the forces and moments.

Through a more in depth description of each of the cases, the following observations were made:

- Goda's formula is valid for caissons founded on a rubble mound berm well above the seabed. In a number of the tested cases, the caisson was founded at the seabed level. The results of some of these cases give the impression

that Goda's formula over-predicts the horizontal forces when the caisson is founded at the same level as the seabed;

- no general conclusions could be made on the influence of wave breaking on the foreshore or on the wave period (or wave steepness).

**EXCEEDANCE CURVE FOR THE HIGHEST FORCES**

Figure 6 shows an example of measured exceedance curves for the horizontal force. Through the five tabulated measured horizontal, but also vertical forces, with exceedance values of 5%, 2%, 1%, 0.4% and 0.1%, a two-parameter Weibull distribution was fitted for each test run (95 in total). This analysis resulted in an average shape parameter of 2.1 which corresponds closely to a Rayleigh distribution for the higher wave forces. The reliability of this factor 2.1 could be described by a standard deviation of 0.72. The average value for the vertical forces amounted to 2.35 with a standard deviation of 0.77. The conclusion was that, considering the large scatter, the distribution of the highest wave forces can be described by a Rayleigh distribution with a shape parameter of 2:

$$R(F) = e^{-\left(\frac{F}{a}\right)^2} \tag{1}$$

where R(F) is the exceedance probability and a the scale parameter. Results from using the Goda method were compared with measured 0.4% exceedance values. These ratio's have been given in Table 1. The Goda force is not equal to 1/250 = 0.4%, but equal to the average of the highest 1/250-th part of the forces. Now the shape of the force distributions has been found to be a Rayleigh distribution one can calculate the ratio between the average of the highest 1/250-part and the 0.4%. This ratio amounts to 1.084. With this factor the actual comparison between Goda and measured forces can be given as the average ratio's presented in Table 1, multiplied by 1.084. Table 2 gives the result.

		Ratio measured/calculated	Average	Standard deviation
Horizontal force	F <sub>h</sub>	Γ <sub>Fh</sub>	μ = 0.90	σ = 0.25
Horizontal moment	M <sub>h</sub>	Γ <sub>Mh</sub>	μ = 0.81	σ = 0.40
Vertical force	F <sub>b</sub>	Γ <sub>Fb</sub>	μ = 0.77	σ = 0.25
Vertical moment	M <sub>b</sub>	Γ <sub>Mb</sub>	μ = 0.72	σ = 0.37

Table 2 Comparison between the Goda method and measured values, both based on the average of the highest 1/250-th values

Figure 6 Example of measured distributions of horizontal forces

The most important force for stability is normally the horizontal force  $F_h$ . Based on the selected cases Goda overestimates this force by 10%. During a lecture Takayama (1994) gave the Japanese experience: based on 66 cases the average ratio amounted to  $\mu = 0.91$  with a standard deviation of 0.19. These values are in good agreement with those found for the horizontal force  $F_h$ , see Table 2.

The scale parameter in Equation 1 can be based on the Goda formula and on the found bias and reliability, given in Tables 1 or 2. With  $R(F_{0.4\%}) = 0.004$  substituted in Equation 1 the scale parameter  $a$  can be replaced using  $F_{0.4\%}$ :

$$R(F) = e^{-\left(\frac{2.35 F}{F_{0.4\%}}\right)^2} \tag{2}$$

With the factors  $r$  ( $r_{Fh}$ ;  $r_{Fb}$ ;  $r_{Mh}$ ;  $r_{Mb}$ , given in Table 1), which includes  $F_{0.4\%}$ , the formula becomes:

$$R(F) = e^{-\left(\frac{2.35 F}{r F_{Goda}}\right)^2} \tag{3}$$

Equation 3 can be seen as a design formula for the exceedance curve of the highest forces, based on Goda's method.

In reality the maximum wave force is related to the maximum number of waves during the sea state considered and not to the 0.4% or 1/250 wave only. Taking into account the actual maximum wave force based on the actual storm duration, a second factor,  $r_N$ , can be introduced:

$$r_N = \frac{F_{max}}{F_{0.4\%}} = \sqrt{\frac{\ln(1/N)}{\ln(0.004)}} \tag{4}$$

where  $N$  is the number of waves in the sea state. The design formula for the maximum wave force becomes then:

$$F_{max} = r \ r_N \ F_{Goda} \tag{5}$$

Figure 7 gives a graphical overall view of the above equations. It shows an example of a wave force exceedance curve. The horizontal axis has been plotted on a Rayleigh scale which means that a Rayleigh distribution becomes a straight line in this graph. Equation 3 gives the exceedance curve of the highest 5% of the wave forces. The calculated value for  $F_{Goda}$  has been drawn at 0.152%, which is equal to  $F_{1/250}$ , assuming a Rayleigh distribution. The difference between  $F_{Goda}$  and  $F_{0.4\%}$  is given by the ratio  $r$  from Table 1. The actual difference between  $F_{Goda}$  and the exceedance curve is given in Table 2. The 90% confidence levels can be calculated by taking into account the standard deviations given in Tables 1 or 2.

Figure 7 Distribution of horizontal forces (Weibull), including  $F_{Goda}$  and  $F_{max}$

The most right point on the curve in Figure 7 gives the maximum wave force  $F_{max}$  for an exceedance probability of  $1/N$ . The general conclusion is that the Goda formula gives, on average, a very good prediction of the maximum horizontal wave force for a storm duration of a few hours ( $N = 2000$  to  $3000$  waves).

## REFERENCE CASE FOR PROBABILISTIC CALCULATIONS

One test in one of the nine cases described in Juhl and Van der Meer (1992) will be taken as a reference (case 1, test 4F). Figure 8 gives a cross-section of the caisson. The parameters that are required for a calculation with the Goda formula are:

$$\begin{aligned} H'_0 &= 8.0 \text{ m (once per 50 years storm)} \\ T_p &= 15.4 \text{ s} \\ \text{Storm duration: } &8 \text{ hours (} N = 2550 \text{)} \\ h_{\text{sea}} &= 30.5 \text{ m} \\ h &= 19 \text{ m} \\ h_c &= 8 \text{ m, but inclined superstructure: } h_c = 1 \text{ m} \\ d &= 19 \text{ m} \\ \tan m &= 0.002 \end{aligned}$$

Furthermore a weight,  $W$ , of 5500 kN/m length and a friction coefficient,  $f$ , of 0.7 are assumed. Based on later communications with Takayama (1994) the Japanese experience on the friction coefficient can be summarized as follows. The design value is  $f = 0.6$ . Based on 42 cases on nearly prototype scale the average friction factor amounted to  $\mu = 0.64$  with a standard deviation of  $\sigma = 0.16$ .

Figure 8 Cross-section of the caisson used for calculations

## PROBABILISTIC CALCULATIONS

In a probabilistic approach a reliability function,  $Z$ , should be given, which is in fact a design formula or design process. The two main failure mechanisms for a caisson are sliding and overturning. The reliability function for sliding becomes:

$$Z = (W - r_{Fb} r_N F_{b(Goda)}) f - r_{Fh} r_N F_{h(Goda)} \quad (6)$$

The first term describes the weight minus uplift force, multiplied by the friction coefficient. This gives the total friction resistance. The second term gives the maximum horizontal force.  $F_{b(Goda)}$  is the vertical force on the base of the caisson and  $F_{h(Goda)}$  is the horizontal force on the front side, both calculated by the Goda method described in Goda (1985) and depending on a large number of parameters.

A probabilistic approach with Equation 6 gives the probability that the caisson will slide during a (design) sea state. All calculations were made with a level II first-order second-moment (FOSM) with approximate full distribution approach (AFDA) method. General references on this aspect are Thoft-Christensen and Baker (1982), Hallam et al. (1977) and PIANC (1993). Calculations have been made for three cases: one for the design event, one for the life time of the structure and one including the results of physical model tests.

### Case 1: Calculations for the Design Event

In order to show the influence of the uncertainty of the Goda formula on the probability of failure a few different calculations have been made. One calculation has been made with only  $r$  and  $r_N$  as stochastic variables, another with  $f$  and  $W$  also as stochastic variables and finally one also including all the parameters in  $F_{Goda}$  as stochastic variables. The mean values and standard deviations of the normal distributions used in the calculations are shown in Table 3. The factor  $r_N$  is described by the number of waves,  $N$ , see Equation 4.

The probabilities of failure,  $P(f)$ , for the three calculations were 0.062, 0.086 and 0.097, respectively. These are the probabilities of failure during the (design) sea state of 1/50 years. All three probabilities are close, which means that the reliability of the Goda formula, by means of  $r_{Fb}$  and  $r_{Fh}$ , have by far the largest influence. In fact the influence of  $r_{Fh}$ , the reliability of the horizontal force, on the probability of failure amounted to 99%, 73% and 65% in the three calculations, respectively.

Parameter	Mean	Standard deviation	
$r_{Fh}$	0.83	0.25	calculation 1
$r_{Fb}$	0.71	0.25	
N	2550	127 (5%)	
f	0.7	0.1	calculation 2
W (kN/m)	5500	165 (3%)	
$H_0'$ (m)	8.0	0.4 (5%)	calculation 3
$T_p$ (s)	15.4	1.54 (10%)	
$h'$ (m)	19	0.57 (3%)	
$h_c$ (m)	1	0.03 (3%)

Table 3 Parameters and values used for calculations.

### Case 2: Calculations for the Life Time of the Structure

More design information is obtained when not one (design) sea state is considered, but the whole wave climate by means of an extreme distribution for the wave heights. Taking the 1/50 years wave height as a reference (which was used for testing), such an extreme distribution can be established by means of an exponential distribution:

$$R(H_s) = e^{\frac{-(H_s - 5.1)}{0.51}} \quad (7)$$

In this case the once per year wave height is 5.1 m ( $R(H_s) = 1$ ) and the 1/50 years wave height becomes 8.0 m ( $R(H_s) = 0.02$ ).

With Equation 7 a probabilistic calculation gives the probability of failure per year instead of during the (design) sea state. Calculation 3 of case 1 above, where all parameters were treated stochastically, has been performed again, but now with the exponential distribution of the wave height (Equation 7) instead of the normal distribution for the 1/50 years wave height. This results in a probability of failure of 0.018 per year. The influence of  $r_{Fh}$  on the probability of failure amounted to 55% and of the wave height  $H_s$  to 17%.

The probability of exceedance for an X-year period can be obtained using:

$$P[Z < 0; X \text{ yr}] = 1 - (1 - P[Z < 0; 1 \text{ yr}])^X \quad (8)$$

With the above result of a probability of failure per year of 0.018 a graph can be drawn with the probability of failure as a function of the life time of the structure. The upper solid line in Figure 9 gives the result of above calculations. The proba-

bility of failure for a life time of 50 years is 0.60, considerably higher than for the 1/50 years sea state only (0.097). This is probably due to the fact that wave heights lower than the 1/50 years wave height increase the probability, but that also higher wave heights (with a lower probability of occurrence) increase the total probability.

Figure 9 Probability of failure as a function of the life time of the structure

**Case 3: Use of Results of Physical Model Tests**

Until now the calculations were done for the Goda formula only, including the uncertainties of all the parameters. The large variation of the Goda formula by means of  $\sigma(r)$  has the largest influence on the failure probability. This variation is due to the large variety of structure geometries and foreshores that were present in the nine selected cases (see Juhl and Van der Meer (1992) and Bruining (1994)). This large variation can be eliminated by performance of physical model tests. In that case forces are measured for the specific structure geometry including all effects of the foreshore.

With respect to Equation 6 it means that the exact values of  $r_{Fh}$  and  $r_{Fb}$  are known (the bias) and the scatter of  $r_{Fh}$  and  $r_{Fb}$  is much smaller than  $\sigma(r) = 0.25$ . Further the ratio  $r_N$  (Rayleigh distribution or not) is also known. The same calculations can be done as in case 2, but now with  $r_{Fh}$  and  $r_{Fb} =$  measured value,  $\sigma(r) = 0.05$  (assumed) and  $r_N =$  measured value.

The following factors were determined by model tests. Between brackets the previous values, based on the Goda method only, are also given.

$$\begin{aligned}
 r_{Fh} &= 0.88 & \sigma &= 0.05 & (0.83; \sigma &= 0.25) \\
 r_{Fb} &= 0.67 & \sigma &= 0.05 & (0.71; \sigma &= 0.25) \\
 r_N (F_h) &= 1.21 & \sigma &= 0.05 & (1.19; \sigma &= 0.05) \\
 r_N (F_b) &= 1.11 & \sigma &= 0.05 & (1.19; \sigma &= 0.05)
 \end{aligned}$$

The calculations of case 2 were repeated with the new factors given above. The probability of failure per year amounted now to 0.006, a factor three lower than for case 2. The influence of the most important parameters for both cases (with and without model tests) on the probability of failure is given in Table 4.

With model tests	Without model tests
Probability of failure $p = 0.006$	Probability of failure $p = 0.018$
Influence of	
$r_{Fh}$ : 2%	$r_{Fh}$ : 55%
$f$ : 33%	$f$ : 15%
$H_s$ : 45%	$H_s$ : 17%
$T_p$ : 16%	$T_p$ : 10%

Table 4 Influence of main parameters on the probability of failure, with and without model tests

The influence of the wave height amounted now to 45% (this was 17% in case 2) and becomes the most important parameter, which is usual, see PIANC (1993).

With Equation 8 and the probability of failure per year of 0.006 the lower dashed line in Figure 9 was calculated. The probability of failure for a life time of 50 years becomes now 0.26 (this was 0.60 in case 2). Figures like Figure 9 can be used by designers. They have to decide which probabilities of failure to accept.

## CONCLUSIONS

The performed re-analysis of the data on wave forces on vertical structures for eleven selected cases gave the following results and conclusions:

- An inclined or curved superstructure results in much lower wave forces than a vertical superstructure. It was found that by ignoring the inclined/ curved superstructure in Goda's formula for horizontal forces (i.e. the crest height is determined as the transition from the vertical front to the inclined/curved superstructure) the force ratio's (calculated/measured) were in the same order of magnitude as for completely vertical structures
- In general, the horizontal forces calculated by Goda's formula are about 10% higher than the corresponding measured forces. This is in agreement with Japanese experience. However, a considerable scatter (standard deviation 0.25 on a ratio between measured and calculated force) is present due to the site specific differences, eg caisson geometry and foreshore slopes.
- The results indicate that Goda's formula over-estimates the horizontal wave forces on a caisson founded at the same level as the bottom of the foreshore, i.e. in the absence of a traditional rubble mound foundation.

Probabilistic calculations gave the following main results and conclusions:

- The Goda formula gives in fact a good (average) estimate of the maximum horizontal wave force when the sea state has a duration of some hours, including about 2000 - 3000 waves.
- Probabilistic calculations show that the reliability of (scatter around) the Goda formula by means of the factor  $r_{Fh}$  has by far the largest influence of all parameters on the probability of failure. Model tests are therefore advised in all cases and these will decrease this scatter and the influence on the failure probability.
- Design graphs of failure probability (of sliding or overturning) versus desired life time of the structure can be given as a result of probabilistic calculations.

## ACKNOWLEDGEMENTS

The work has been performed under a project of the Commission of the European Communities, called MAST-G6 Coastal Structures, project 0032 and was further funded by the Dutch Public Works Department. Acknowledged are CEDEX-CEPYC, Spain and ENEL-CRIS, Italy for providing data on cases 10 and 11.

## Coastal Processes and Sediment Transport

## CHAPTER 127

### Velocity and Pressure Boundary Conditions for Flow Over the Permeable Boundary of a Porous Medium

İsmail Aydın<sup>1</sup>

#### Abstract

Effect of permeability on pressure distribution over the permeable surface of a porous medium is investigated. Measured pressure distributions comparing impervious and permeable cases are presented. Flow of the free fluid over the permeable boundary and flow of the fluid in the porous medium are computed numerically, maintaining the interaction of the two flow fields through the boundary conditions at the permeable surface. Turbulence is modeled by a low Reynolds number  $k-\varepsilon$  model including a novel technique to model surface roughness effect eliminating the need for wall functions.

#### Introduction

The interaction between waves, currents and the loose boundary at the sea bottom is a basic question in the study of sediment transport mechanism. In most cases the loose boundary takes an undulated shape with a separating complex flow field on it. The direction and the rate of sediment transport is strongly related to the resulting geometry of the loose boundary and to the dynamics of the flow over the boundary.

Sand particles are removed from the loose boundary by the tangential and the pressure forces, then hold suspended by the vortex structures and carried forward or backward depending on overall flow pattern. In order to define the incipient motion of the sand particles and explain the sediment transport mechanism, a numerical solution of the flow field over the loose boundary is required. However, in such a numerical

---

<sup>1</sup> Assoc. Professor, Civil Engineering Department, METU, 06531 Ankara, Turkey

solution the boundary conditions for velocity and pressure on a permeable surface should be defined correctly.

Two different flow regions can be defined; flow of the free fluid over the permeable boundary and flow of the fluid within the porous medium of the loose boundary. These two flow fields are strongly interacting. The flow of the free fluid over the undulated surface induces a pressure variation along the common boundary of the two flow regions. This pressure variation and the traction forces acting on the common boundary excite the flow in the porous medium. The velocity, pressure and turbulence along the common boundary are affected by both flow regions.

In flows over a porous medium it is necessary to specify boundary conditions on the tangential and normal components of velocity of the free fluid at the permeable boundary. There exists an extensive analytical literature which describes coupled fluid motions satisfying the Navier-Stokes equations in the free fluid flow and some empirical set of equations in the porous medium with common boundary conditions at the permeable interface of the two flow regions.

Obviously, some uncertainty exists in definition of a true boundary for a permeable material. Therefore, it is useful to define a nominal boundary. In mathematical formulation, a smooth geometric surface is considered to represent the nominal boundary along the surface of the porous medium. The nominal boundary is located at a distance such that the volumetric flowrate between the impervious rough surface and a fictitious surface placed at the tip of roughness elements is equal to the volumetric flowrate between the fictitious surface and the nominal boundary. In numerical computations, hydrodynamic consequences of roughness and permeability are simulated on the nominal boundary.

## **Experiments**

The experiment reported here is designed to examine the nature of the pressure distribution on the nominal boundary of a permeable surface. Briefly, there is a two-dimensional steady flow between an impermeable rippled surface and a flat test surface opposite to the ripple (Fig.1). The ripple geometry is selected to induce a pressure variation on the test surface. Description of the ripple geometry is given in numerical model section. The test surface is either an impermeable flat plate or the permeable boundary of a saturated porous volume.

Three experimental cases are considered. In the first case the test surface is fitted by a smooth solid flat plate. Pressure measurements for this case are indicated as "Impervious" on the figures. In the second case the

Fig.1 Experimental setup

test surface is fitted by a sieve screen and sand material is placed in the box indicated as "porous volume" in Fig.1. Hydraulic conductivity of the sand is measured to be 1.02 cm/s. Pressure measurements for this case are indicated as "Porous I". In the third case the sand material is replaced with another sample obtained from a different source. Hydraulic conductivity of this material is 1.07 cm/s, almost the same as in the second case. However, particle size distributions of the two sand materials are quite different. Pressure measurements for this case are indicated as "Porous II". The purpose of repeating the experiments with two different sand materials of approximately the same permeability is simply to verify experimental accuracy. Pressure distributions are measured for each case at about 25 different flowrates in the conduit. The maximum (centerline) velocity,  $U_m$ , in the conduit is varied between 50 ~ 250 cm/sec.

The measured pressure distributions at the test surface for the impervious and porous cases are shown in Fig.2 for three different flowrates. For  $U_m = 95$  cm/s, the difference between the pressures of the three test cases is negligible. Since the velocity is low, neither surface roughness nor permeability can affect the pressure distribution significantly. For  $U_m = 159$  cm/s, the pressures for the porous cases are less than the pressure for the impervious case at locations  $X \geq 16$  cm along the test surface. This pressure drop is due to the surface roughness effect of the sand material. When the flowrate is increased to  $U_m = 248$  cm/s the effect of surface roughness and permeability cancel each other and the resultant pressure distributions for the permeable cases are almost the same as the impervious case pressure distribution. At this high flowrate there is a larger pressure drop due to surface roughness effect of the permeable test surface but, permeability allowing flow into the porous medium from high pressure points and flow out of the porous medium from low pressure points, creates a counter effect to the contraction of flow section by the ripple on the

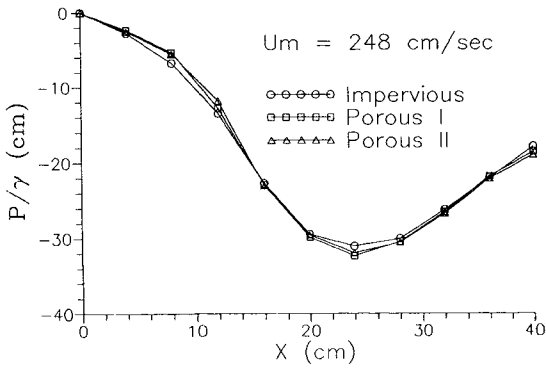

Fig.2 Comparison of pressure distributions along the test surface for flowrates  $U_m=95$ ,  $U_m=159$ , and  $U_m=248$  cm/s.

Fig.3 Comparison of pressures at fixed points  $X=28$  and  $X=36$  cm on the test surface as a function of flowrate in the conduit.

opposite side. In this way the pressure drop due to roughness effect is compensated by the relaxation introduced by permeability of the test surface.

This behavior can better be observed in Fig.3 where pressures at fixed points ( $x = 28$ ,  $x = 36$  cm) are compared as a function of flowrate. Pressure drop due to surface roughness can be recognized for  $U_m \geq 95$  cm/s and it is compensated by relaxation due to permeability for  $U_m \geq 190$  cm/s.

### Numerical Model

The flow of free fluid over the permeable boundary and the flow within the porous medium are solved simultaneously allowing interaction of the flow regions through the boundary conditions at the common boundary. Darcy law is assumed to govern the flow in the porous medium. The full

Navier-Stokes equations are solved in the region of free fluid flow and Laplace equation for pressure is solved in the porous medium.

A useful computational grid for the free fluid region is obtained from a conformal mapping between the physical plane ( $x, y$ ) and the computational plane ( $\xi, \eta$ ) defined by Eqns. (1) and (2)

$$x = \xi + c_m \frac{H}{2} \left[ \sin \alpha (\xi - \xi_1) e^{\alpha(\eta - \eta_1)} - \sin \alpha (\xi - \xi_2) e^{-\alpha(\eta - \eta_2)} \right] \quad (1)$$

$$y = \eta - \eta_1 - \eta_2 + c_m \frac{H}{2} \left[ \cos \alpha (\xi - \xi_1) e^{\alpha(\eta - \eta_1)} + \cos \alpha (\xi - \xi_2) e^{-\alpha(\eta - \eta_2)} \right] \quad (2)$$

$$\text{for } 0 \leq \xi \leq L, \quad 0 \leq \eta \leq \eta_1$$

where  $\alpha = 2\pi/L$ ,  $L = 40$  cm,  $H = 6$  cm,  $\eta_1 = -\eta_2 = 12$  cm,  $\xi_1 = 0$ ,  $\xi_2 = L/2$  and  $c_m = 1.023598$ . For  $\eta = \eta_1$  in Eqns. (1) and (2) the ripple geometry used in the experimental setup is obtained. The complete set of governing equations for the free fluid region in the computational plane are written as

$$\begin{aligned} \frac{1}{J} \frac{\partial u}{\partial t} + u_c \frac{\partial u}{\partial \xi} + v_c \frac{\partial u}{\partial \eta} &= \frac{\partial y}{\partial \xi} \frac{\partial \bar{P}}{\partial \eta} - \frac{\partial y}{\partial \eta} \frac{\partial \bar{P}}{\partial \xi} + \frac{\partial}{\partial \xi} \left( v_c \frac{\partial u}{\partial \xi} \right) + \frac{\partial}{\partial \eta} \left( v_c \frac{\partial u}{\partial \eta} \right) \\ &+ \frac{\partial v_t}{\partial \eta} \frac{\partial v}{\partial \xi} - \frac{\partial v_t}{\partial \xi} \frac{\partial v}{\partial \eta} \end{aligned} \quad (3)$$

$$\begin{aligned} \frac{1}{J} \frac{\partial v}{\partial t} + u_c \frac{\partial v}{\partial \xi} + v_c \frac{\partial v}{\partial \eta} &= \frac{\partial x}{\partial \eta} \frac{\partial \bar{P}}{\partial \xi} - \frac{\partial x}{\partial \xi} \frac{\partial \bar{P}}{\partial \eta} + \frac{\partial}{\partial \xi} \left( v_c \frac{\partial v}{\partial \xi} \right) + \frac{\partial}{\partial \eta} \left( v_c \frac{\partial v}{\partial \eta} \right) \\ &+ \frac{\partial v_t}{\partial \xi} \frac{\partial u}{\partial \eta} - \frac{\partial v_t}{\partial \eta} \frac{\partial u}{\partial \xi} \end{aligned} \quad (4)$$

$$\frac{\partial^2 \psi}{\partial \xi^2} + \frac{\partial^2 \psi}{\partial \eta^2} = - \left[ \left( \frac{\partial y}{\partial \eta} \frac{\partial v}{\partial \xi} - \frac{\partial y}{\partial \xi} \frac{\partial v}{\partial \eta} \right) - \left( \frac{\partial x}{\partial \xi} \frac{\partial u}{\partial \eta} - \frac{\partial x}{\partial \eta} \frac{\partial u}{\partial \xi} \right) \right] \quad (5)$$

$$\frac{\partial^2 \mathbf{P}}{\partial \xi^2} + \frac{\partial^2 \mathbf{P}}{\partial \eta^2} = -2\rho \mathbf{J} \left[ \left( \frac{\partial v}{\partial \xi} \frac{\partial y}{\partial \eta} - \frac{\partial v}{\partial \eta} \frac{\partial y}{\partial \xi} \right) \left( \frac{\partial u}{\partial \eta} \frac{\partial x}{\partial \xi} - \frac{\partial u}{\partial \xi} \frac{\partial x}{\partial \eta} \right) + \left( \frac{\partial u}{\partial \xi} \frac{\partial y}{\partial \eta} - \frac{\partial u}{\partial \eta} \frac{\partial y}{\partial \xi} \right)^2 \right] \quad (6)$$

where

$$\bar{\mathbf{P}} = \frac{\mathbf{P}}{\rho} + \frac{2}{3} \mathbf{k}, \quad \mathbf{u}_e = \mathbf{u} \frac{\partial y}{\partial \eta} - \mathbf{v} \frac{\partial x}{\partial \eta}, \quad \mathbf{v}_e = \mathbf{v} \frac{\partial x}{\partial \xi} - \mathbf{u} \frac{\partial y}{\partial \xi}, \quad \mathbf{v}_t = \mathbf{v} + \mathbf{v}_t,$$

$$\mathbf{u} = \mathbf{J} \left( \frac{\partial x}{\partial \xi} \frac{\partial \psi}{\partial \eta} - \frac{\partial x}{\partial \eta} \frac{\partial \psi}{\partial \xi} \right), \quad \mathbf{v} = \mathbf{J} \left( \frac{\partial y}{\partial \xi} \frac{\partial \psi}{\partial \eta} - \frac{\partial y}{\partial \eta} \frac{\partial \psi}{\partial \xi} \right),$$

$\mathbf{J}$  is Jacobian of coordinate transformation,  $\mathbf{v}_t$  is turbulent viscosity and  $\mathbf{k}$  is turbulent kinetic energy. In the porous medium the Laplace equation for pressure is written as

$$\frac{\partial^2 (\mathbf{P}/\gamma)}{\partial x^2} + \frac{\partial^2 (\mathbf{P}/\gamma)}{\partial y^2} = 0 \quad (7)$$

Pressures along the permeable boundary are obtained by integration of the momentum equations on the free fluid side and are supplied as boundary conditions of equation (7) for the potential flow in the porous medium. After solution of the Laplace equation for pressure, the velocity components due to porous media flow are computed. Tangential velocity on the permeable boundary is assumed to have two components. First component is the velocity induced due to the external tangential stress by the free fluid (Beavers and Joseph 1967, Saffman 1971, Taylor 1971) and the second is the velocity of porous media flow due to tangential pressure gradient. These two velocity components are combined to give the "slip velocity" at the permeable boundary.

$$\mathbf{u}_s = -\mathbf{K} \frac{\partial (\mathbf{P}/\gamma)}{\partial x} + \mathbf{c}_s \sqrt{\mathbf{K}\mu/\gamma} \left( \frac{\partial \mathbf{u}}{\partial y} \right)_{y=0} \quad (8)$$

where  $\mathbf{K}$  is hydraulic conductivity and  $\mathbf{c}_s$  is the slip velocity coefficient. In the literature slip velocity coefficient may take values between 0.1 ~ 4. In this study it is fixed as unity since the slip velocity has showed no control on the pressure distribution over the permeable boundary for the complete range of

values reported in the literature. The normal component of velocity is simply due to porous media flow and is named as the "seepage velocity" given by.

$$v_s = -K \frac{\partial(P/\gamma)}{\partial y} \quad (9)$$

The slip and seepage velocities are used as the boundary conditions for the momentum equations governing the free fluid flow.

In numerical computation of the free fluid flow a different technique is adopted. In Poisson equation for pressure (Eqn.6) divergence of velocity is not included, instead, the Poisson equation for the stream function (Eqn.5) is solved and velocities are recomputed from the stream function to enforce the continuity after solution of the momentum equations. Otherwise computations were not converging because of the added degree of freedom by the slip and seepage velocities at the permeable boundary.

Turbulent viscosity is obtained from a low Reynolds number  $k-\varepsilon$  model as described in (Aydın and Shuto 1988). This model allows a complete numerical solution starting from the boundary, eliminating the need for wall functions. When the wall functions are removed, a new model for the surface roughness is required. This is accomplished by introducing and additional viscosity due to surface roughness (Aydın, 1993). Roughness viscosity is defined in terms of a roughness length scale and the velocity gradient at the wall,

$$\nu_r = l_r^2 \left| \left( \frac{\partial u}{\partial y} \right)_{y=0} \right| \quad (10)$$

and the roughness length scale is given as

$$l_r = 0.4k_s f_r \quad (11)$$

where  $k_s$  is the equivalent sand roughness height and  $f_r$  is a function to express the turbulence level in terms of the roughness Reynolds number.

$$f_r = \frac{0.1}{\left[ 1 - \exp(-0.09R_k^{0.6}) \right]} \quad (12)$$

and

$$R_k = \frac{k_s u_*}{\nu} \quad (13)$$

In computations, turbulent viscosity at a point next to a boundary is equated to the roughness viscosity if  $\nu_t < \nu_r$ .

### Computations and Results

Pressure distributions for the first experimental case, the impervious boundary, are computed by the numerical model described above. Computed pressures are compared to experimental data at four different flowrates in Fig.4. In general computation and experiment agrees well, except the end points ( $X = 40$  cm). This is due to the uniform flow conditions imposed at the end of the computational domain which may be achieved at further downstream locations. Before computing the permeable cases, effects of surface roughness and permeability are studied separately. Pressure distributions on the test surface for  $U_m = 248$  cm/s using different  $k_s$  values are shown in Fig. 5. This figure indicates that the pressure drop along the test surface increases with the surface roughness. Fig. 6 shows pressure distributions for the same flowrate using different hydraulic conductivity values keeping  $k_s = 0$ . It is clearly observed that the increase in permeability reduces the pressure drop on the test surface.

Fig.4 Comparison of computed and measured pressures along the test surface for impervious boundary.

Fig.5 Pressure distributions along the test surface for different surface roughness values.

Fig.6 Pressure distributions along the test surface for different hydraulic conductivity values.

Fig.7 Comparison of computed and measured pressures along the test surface for permeable cases

Fig.8 Hydraulic conductivity as a function of roughness Reynolds number along the test surface

The roughness model used in this study, as well as other models, represents the roughness effect due to surface irregularities. When the surface is permeable, the roughness effect will be increased by permeability since it allows turbulent fluctuations to enter into pores of the medium. On the other hand high turbulence due to free fluid flow near the boundary reduces permeability of the surface.

In this study the effect of permeability on roughness effect is ignored and dependence of permeability of a porous boundary to the turbulence level is investigated. Numerical model is forced to satisfy the experimentally measured pressures along the test surface for variable hydraulic conductivity at each computational node. Fig.7 shows a comparison of the measured and computed pressures for permeable test surface with variable hydraulic conductivity. Hydraulic conductivity values used to fit the measured pressures are shown in Fig.8 as a function of roughness Reynolds number. In this figure  $K_0$  represents the hydraulic conductivity for laminar flow conditions. As seen from the figure, hydraulic conductivity is reduced by turbulence when the hydrodynamically rough condition is reached and the reduction is about 50 % at a roughness Reynolds number of 400. However, in order to be able to give an expression of the relation between hydraulic conductivity and roughness Reynolds number, the effect of permeability on surface roughness should be clarified.

## CHAPTER 128

# Physical Experiments on the Effects of Groins on Shore Morphology

Peyman Badiei<sup>1</sup>, J. William Kamphuis<sup>1</sup>, David G. Hamilton<sup>1</sup>

### Abstract

Physical mobile bed models were used to study the morphological effects of groins on an initially straight beach that was exposed to obliquely incident irregular waves. The tests were carried out at two different wave basins with the beach length of 8 and 28 m. A straight beach in the absence of groins was tested for each set of variables, then one or two impermeable surface piercing groins with different lengths were installed and tested. A detailed morphological and hydrodynamic data base was acquired which can be used for calibration and verification of numerical morphology models. Testing procedure and conditions are explained and typical results are presented along with a preliminary analysis which reveals the significant features of the evolution of beach bathymetry.

## 1. Introduction

Mobile bed models are widely used to study the problems dealing with morphological changes of coastal zones. The rapid growth in instrumentation technology has strengthened these models to provide more accurate and reliable results. The application of these models, however, is accompanied by problems associated with scale effects, boundary effects and operational errors discussed among others by Kamphuis (1991) and Hughes (1993). Kraus and Larson (1988) and Larson (1988) discuss examples of the application of large flumes in 2D morphology models to reduce the scale effects. The reduction of scale effects by using large basins, however, is not yet accomplished for a 3D model where wave induced longshore currents play a major role. In spite of these problems, mobile bed models are a unique way of providing a controllable environment for acquiring reliable data and insight into the physical processes.

---

<sup>1</sup> Department of Civil Engineering, Queen's University, Kingston, Ontario, Canada, K7L 3N6

In the present study a series of mobile bed *process models* (Kamphuis (1991)) were employed to investigate the effects of groins on the evolution of shore morphology under the attack of waves approaching with an angle towards the shoreline. These tests were carried out at the Queen's University Coastal Engineering Research Laboratory (QUCERL) and the Hydraulic Laboratory of the National Research Council of Canada (NRCC).

## 2. Objectives

This study attempts to understand the hydrodynamic and sediment processes near groins through the use of both physical and numerical models. The hydraulic model results provide a data base for the calibration and verification of a detailed numerical morphology model. The numerical model in turn will be used first to simulate the hydraulic model results and then to scale up to prototype, thus circumventing some of the shortcomings of the physical model. This paper presents the results of physical experiments.

A review of the very few mobile bed tests on groins reported in the literature (Barcelo (1968) and (1970), Price and Tomlinson (1968) and Hulsbergen et al (1978)) shows that no such comprehensive data base is at hand which can be used for the purpose of this study. The results of the available experiments have some common features; (1) tests were performed with regular waves, (2) they were restricted to one or two aspects and the overall impact of the groins was not investigated and (3) the data collection was limited to recording some parts of the overall process and many important details are lost.

Regular waves have concentrated energy around a single frequency, so they produce exaggerated offshore bar and strong currents (described by Hulsbergen et al (1978) as 'chaotic current patterns'). These effects which distort the test results and make the testing operation unmanageable were avoided in the present study by using irregular long crested waves. Moreover irregular waves have a closer resemblance to the waves in prototype. Detailed morphological data were collected along with measurements of hydrodynamic conditions (waves and currents). Because the changes in morphology made it difficult to perform sufficient steady state current measurements, a separate series of fixed bed tests were carried out at QUCERL basin to provide a more detailed hydrodynamic data base. The results of these tests will be discussed in a later paper. Finally, instead of looking at some specific features of morphological changes, within the framework of the variables of these tests (discussed in Section 3), all the important aspects of the groin impact on an initially straight beach were considered. During the tests and in the analysis of the results, special attention was given to the following morphological features:

1. The bar-groin interaction which affects the position of the breaker, the width of the surfzone, the reformation of the longshore current and the sediment transport distribution.

2. The extent and geometry of the accretion and erosion zones on either side of groin(s) which shows the length of the beach affected by the groin. In this regard the accretion and erosion pattern inside the groin bays are also very important.
3. The local scour holes or channels around the groin created by strong currents that are vital to the design of the groin structure.

### 3. Testing Procedure

Among the large number of parameters which could be varied in such tests, it was decided, due to practical limitations, to keep the following parameters constant. Based on a JONSWAP spectrum, irregular wave trains composed of 200 waves with a peak period of  $T_p = 1.15$  s and groupiness factor of  $G = 0.8$  were used. The mean diameter of the sand ( $D_{50}$ ) was 0.12 mm and the initial slope of the beach (m) was 0.1. The deep water wave angle  $\alpha$  and the ratio of  $S_g/L_g$  where  $S_g$  is the distance between the groins and  $L_g$  is the groin length measured from the still water line, were also constants. The variable quantities were the incident wave height  $H_s$ , the position and the number of groins and the ratio of  $L_g/L_b$  where  $L_b$  is the distance of the offshore bar (prior to the installation of any groin) measured from the still water line.

Table 1: QUCERL mobile bed tests summary

Test No.	Test Description	Target $H_s$ (cm)	Duration (hrs)	Estimate $L_g/L_b$	Groin Position (m)
QT1	Single Groin	Variable	---	----	----
QT2	Single Groin	6.0	25.2	1.0	Y = 4.50
QT3	Single Groin	6.0	22.0	0.9	Y = 4.50

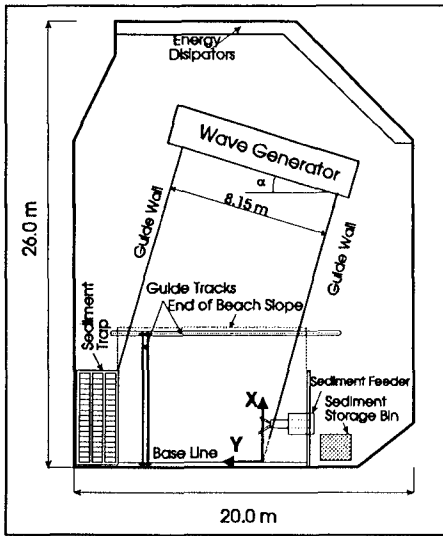

Figure 1: QUCERL Basin

Figure 2: NRCC Basin

Tables (1) and (2) summarize the tests carried out at QUCERL and NRCC respectively. Here  $Y$  is the distance from the updrift wave guide shown in Figures 1 and 2.

At the beginning of each test the sandy beach was reshaped to a plane 1:10 slope. Then the beach was exposed to waves for four hours. At that time a clear offshore bar-trough/step formation (as defined by point 2 in Figure (23)) had developed. When groins were tested they were installed at this stage. The tests were continued thereafter in 2 hour cycles.

Figures 1 and 2 show the layout of the basins at QUCERL and NRCC respectively. Both basins had a closed updrift and an open downdrift boundary and the wave generators were raised above the floor so that water could flow underneath them. This measure according to Kamphuis (1977) would reduce circulation in the testing zone.

For an easier comparison with QUCERL, the NRCC results were transformed into their mirror image so that in all the test results the longshore current flows from right to left.

At QUCERL the angle  $\alpha$  of the wave generator was  $10^\circ$  in a water depth of 0.55 to 0.58 m and at NRCC this angle was  $11.6^\circ$  in a depth of 0.65 m

Wet sediment was fed to the updrift boundary at a rate calculated by the expression developed by Kamphuis (1991a) which yields 27.5, 48 and 74.4 kg/hr of submerged sand for 6, 8 and 10 cm wave heights respectively. This amount was divided into two parts fed separately to the swash zone and near the offshore bar/step. The sediment was trapped at the downdrift boundary and its submerged weight was measured by the loadcells connected to the traps. When the accumulated sand filled the traps it was recirculated into the storage bin near the feeder.

The Generalized Data Analysis Package (GEDAP) developed by NRCC was used for data acquisition. Waves and wave induced currents, submerged weight of the sand in the traps and bottom topography were measured during each two hour testing cycle. Sampling frequency in all these measurements was 20 Hz and sampling duration for waves and currents was 230 s which covered all the 200 waves with an average period of 1.15 s.

Fifteen capacitance type wave probes with 0.20 m spacing measured the wave height profile perpendicular to the shore line from offshore of the breaker up to a point near the still water line. Deep water wave probes (one at QUCERL and three at NRCC) measured the deep water waves.

Figure 3: QUCERL Profiler

bed profiler manufactured by Delft Hydraulic Laboratory (Villaneuva(1989)) was used to survey the beach topography. In the other tests another bed profiler, designed and manufactured at QUCERL was used, shown in Figure 3. Here a roller (8) which was connected to the end of a pointing rod (7) followed the beach profile by simply resting on the sand. Knowing the length  $L$  and the angle  $\alpha$  which was measured by the reading of a potentiometer (6), the depth at each point was calculated. The distance in the  $X$  direction from the base line in (shown in Figure 1) was calculated from the readings of another potentiometer (3).

#### 4. Analysis of Morphological Data

The collected data along with the observations while performing the experiments are the basis of this first step of analysis. It should be mentioned that in the contour plots of the bathymetry and wave heights and the velocity vector plots of NRCC test results, the plotted distances in the  $X$  direction appear twice as large as the  $Y$  distances to make the plots clearer. Thus the angles of the velocity vectors are distorted.

##### 4.1. Straight Beach Tests

Four straight beach tests without any groins were performed as summarized in Tables 1 and 2. Comparing the results of these tests with the ones performed with

Electromagnetic (EM) bi-directional, sphere-headed current meters were used in both series of tests. Two current meters were used at QUCERL and maximum of four were used at NRCC. They were spaced at a distance greater than 0.25 m to avoid electrical interference. The time averaged velocities in  $X$  and  $Y$  directions were calculated from the measured time series and recorded.

In the first six tests at QUCERL and in all the NRCC tests the PV-07

groins allows the determination of the net effects of the groins. The contour plots of the beach bathymetry for tests QT7 after 14 hours and NT1 after 12 hours of testing are shown in Figures 4 and 5. The straight and parallel contour lines indicate that a straight and long beach was correctly modelled. The averages of three middle profiles (X = 3, 4 and 5 m) in QT7 and five middle profiles (X = 13.5, 15.5, 17.5, 19.5 and 21.5 m) in NT1 at different times are shown in Figures 6 and 7. These two Figures suggest that an equilibrium beach profile was not formed even after long hours of testing at QUCERL. They also show that smoother offshore bars were formed compared to the tests with regular waves reported by Larson(1988) and Kamphuis (1994). No build up of the offshore bar was observed after the first four hours of testing as opposed to Larson(1988). The smoother profile of the offshore bar formed by irregular waves is caused by the breaking of individual waves at different locations.

#### 4.2. Single Groin Near the Trap

Five tests were performed in this group to monitor the changes in the cross shore distribution of sediment transport rate downdrift of the groin and to evaluate the updrift length of the beach affected by the groin. The details of measuring the

(a)

(b)

(c)

(d)

Figure 9: Cross shore sediment transport distribution at 4 and 16 hrs in QT10 with  $L_g/L_b = 1.5$

distribution of sediment transport rate at the sediment trap are explained in Kamphuis and Kooistra (1990). Figures 8 and 9 show typical examples of these distributions for

two extreme cases of  $L_g/L_b = 0.5$  and  $1.5$  (Tests QT8 and QT10 respectively). These Figures show the distributions at 4 hours with no groin and sometime after the groin was installed. In QT8 a considerable portion of the sand was bypassed into the trap. On the contrary in QT10, after 16 hours, practically no sediment was caught by the trap and all of the sediments were either accreted updrift of the groin or diverted offshore and created a shoal. Figure 8 shows an offshore shift of the peak of the longshore sediment transport rate, indicating that even a short groin deflects the longshore sediment flow.

Figure 10 presents the contours of QT10 at 4 and 16 hours. The still water line called  $L_0$  and the contour line with the closest depth to the breaker depth (here  $-8$  cm) called  $L_{br}$ , are highlighted. These lines are used to trace the evolution of beach bathymetry.  $L_{br}$  and  $L_0$  run almost parallel to each other during this test and both of

Figure 10:  $H_s = 6$  cm, groin at the sediment trap,  $L_g/L_b = 1.5$ .

Figure 11: QT10 profiles at  $X=4$  m

them were deflected seaward by the groin.  $L_{br}$ , as shown in Figure 10 almost reached the head of the groin after 16 hrs.

Figure 11 shows that in QT10 the still water line at  $X=4$  m did not recede shoreward. The accretion caused by the groin at this location compensated the recession of the still water line,  $L_0$ , that was observed in the straight beach tests (discussed in Section 4.1). The distance of this point from the groin is almost equal to

that of the updrift boundary from the groin in QUCERL test with a groin in the middle of the basin. Evidently in these tests the groin affects the updrift boundary and the long beach condition updrift of the groin is not valid.

### 4.3. Groin(s) in the Middle of the Basin

#### 4.3.1. Single Groin in the Middle of the Basin

The contour plots of QT3 and NT2 shown in Figures 12 and 13 will be discussed as two examples in this group. Because the boundaries are affected by the groin, the contour pattern on either side of the groin in QT3 does not show the expected shape. Local effects near the groin such as the shift in  $L_0$  on either side of the groin, the deflection of  $L_{br}$  (depth 8 cm) to the offshore direction and the formation of a scour hole near the head of the groin are all well presented by this model, thus the results of this model are still useful as input to a numerical model. Nevertheless, to reduce the boundary effects, similar tests were carried out at NRCC and the result of the test with a single groin is shown in Figure 13 which shows a significant improvement. Here on the updrift side,  $L_0$  remained parallel to its original position far from the groin and advanced seaward close to the groin. Downdrift of the groin  $L_0$  receded shoreward except in the close vicinity of the groin and its direction was similar to that of  $L_0$  on the updrift side. The formation of a scour hole near the head of the groin was also quite obvious. In addition, a shoal was created in front of the groin which was due to the deposition of the deflected longshore sediment flow. Line  $L_{br}$  (depth -10 cm) runs parallel to  $L_0$  on the updrift side and remains parallel to its original alignment downdrift of the groin.

Figure 12:  $H_s = 6$  cm,  $L_g/L_b = 0.9$

Figure 13:  $H_s = 8$  cm,  $L_g/L_b = 1$ .

#### 4.3.2. Double Groins in the Middle of the Basin

Figures 14-16 show the bathymetry of the tests with double groins with  $L_g/L_b = 0.8$  to 1.4 and  $H_s = 8$  cm at 12 hrs. Note that the updrift sides of Figures 13 and 14 are quite similar which is an indication of the repeatability of the tests. Two distinct shoals were formed offshore of the heads of the groins. These shoals were absent with short groins ( $L_g/L_b = 0.8$ , in test NT5).

Figure 14:  $H_s = 8$  cm,  $L_g/L_b = 1$ .

Figure 15:  $H_s = 8$  cm,  $L_g/L_b = 1.4$ .

Figure 16:  $H_s = 8$  cm,  $L_g/L_b = 0.8$ .

The bypassed sediments collected downdrift near the groin and partly filled the zone eroded by the sediment transport rate deficit. This formed a depression zone (a ditch) at a distance downdrift of the groin. The ditch was closer to the groin with the longest groin (Figure 15) because the bypassing was small and was almost absent with shortest groin (Figure 16) due to increased bypassing. The contour line pattern on both sides of groins were similar with NT2.

The contour lines in the bay between the groins were more inclined and parallel to the incoming wave crests in NT4 where  $S_g$  was longer and little bypassing into the bay was allowed by the long groin.

Test NT6 with  $H_s = 10$  cm at 12 hrs is shown in Figure 17. The diversion of the more powerful longshore sediment flow caused a distinct offshore shoal, and more offshore contour lines were affected. Finally the topography of the low energy test NT7 at 12 hrs is presented in Figure 18.

Figure 17:  $H_s = 10$  cm,  $L_g/L_b = 1$ .

Figure 18:  $H_s = 6$  cm,  $L_g/L_b = 1$ .

In Figures 14-16  $L_{br}$  is the -10 cm contour line. With the short groin shown in Figure 16,  $L_{br}$  is almost unaffected by the groin.  $L_0$  in this case matches the expected pattern. In Figure 14 where  $L_g/L_b=1$ , the groin deflects  $L_{br}$  to some extent and for the case of the long groin shown in Figure 15,  $L_{br}$  is deflected considerably and runs almost parallel to  $L_0$  both updrift and downdrift of the groins. It is seen that the behaviour of  $L_{br}$  depends to a great extent, on the length of the groin.

#### 4.4. Net Morphological Changes Caused by Groins

As shown in Section 4.1 the bottom topographies in all the straight beach tests were continuously evolving and no equilibrium condition was reached. To differentiate between the bottom changes in a straight beach and that caused by the groin(s) the topographies of these two after the same duration of testing were subtracted from each other. Examples are shown in Figures 19-22. Here the dashed contour lines show the eroded zones and the solid lines represent the accreted areas. In all these figures it

Figure 19: Net groin effect in NT2 at 12 hrs

Figure 20: Net groin effect in NT3 at 12 hrs

Figure 21: Net groin effect in NT4 at 12 hrs

Figure 22: Net groin effect in NT5 at 12 hrs

is seen that the amount of net accretion caused by the groins is considerably more than the net erosion. This is possibly caused by the closeness of the downdrift boundary. It is not far enough from the groin to allow the erosion to compensate the accreted

volume updrift of the groin. The nonuniformity of the longshore current due to the circulation inside the basin could be another reason for this imbalance. The presence of offshore shoal is quite clear in Figures 20 and 21.

#### 4.5. Analysis of Characteristic Lines

The behaviour and evolution of the beach bathymetry can be studied by monitoring the changes in the positions of some *characteristic points* which define the geometry of the active zone of the beach profile. These points are defined in Figure 23. The offshore bar/step position is closely related to the breaker point and the beach head is located at the end of the wave uprush. The beach head and the offshore bar/step also define the boundaries of a *channel* in which most of the longshore sediment flow occurs. A FORTRAN code was written to detect the positions of these points based on the measured profiles.

The results of this analysis on the straight beach in test NT1 is shown in Figure 24. The process of beach profile lengthening in which beach head recedes and bar crest (offshore step) advances offshore is quite apparent if the characteristic lines of this test at different times are compared. It is also seen that the position of the bar crest (or the offshore step) and trough varied along the shore with a maximum difference of about 0.50 m in the X direction. A rip current which pushed the breaker and consequently the offshore bar/step away from the shore line is considered to be the cause of this behaviour. The formation of the rip currents in an experimental wave basin will be presented in more

Figure 23: Definition of characteristic points

Figure 24: Characteristic lines for NT1 at 12 hrs

Figure 25: Characteristic lines for NT4 at 12 hrs

detail in a later paper. The comparison of  $L_0$  and  $L_{br}$  in Figure 15 and the bar/step and beach head characteristic lines in Figure 25 shows a similar pattern for the *channel* of longshore current in this test.

## 5. Wave and Current Data

To conduct these tests properly a large number of wave and current measurements within a short period of time were necessary to have a clear impression of waves and current patterns inside the testing zone which is unaffected by the changes in the movable bed. It was decided for practical reasons to perform limited measurements on waves and currents in these series of tests and use a fixed bed model later to acquire more detailed data on waves and currents. At NRCC more data acquisition channels were available, which provided a large number of simultaneous wave measurements. Thus the intensity of wave data within each test cycle was high enough as shown in Figure 26 to give a clear view of the wave pattern around the groins.

Typical results of wave and current measurements are presented in Figure 26 and 27.

Figure 26:  $H_{ms}$  contours in NT4 at 12 hrs

Figure 27: Velocities in NT4 at 6 hrs

## 6. Conclusions:

- Detailed morphological and hydrodynamic data were acquired in a set of mobile bed hydraulic model tests with and without groins
- At QUCERL the short distance of the boundaries from the groin prevented the simulation of a long beach on either side of a groin. The effects of the groin(s) on the boundaries were smaller in the tests at NRCC but not totally eliminated. However the boundary conditions in both series of these tests were measured and knowing these boundary conditions will permit the use of the collected data in a numerical model.

- Straight and parallel contour lines in straight beach tests both at QUCERL and NRCC indicate that a long straight beach was successfully modeled. Equilibrium beach profiles were not observed even after long hours of testing (maximum of 28 hours at QUCERL). In contrast to the tests with regular waves no pronounced offshore bar was formed and in most of the cases an offshore step was created instead of an offshore bar. No build-up of the offshore bar was observed after the first four hours of testing.
- The QUCERL tests with a groin at the trap showed that with a long groin, practically no sand was bypassed into the trap; the sediments were either accreted updrift of the groin or diverted offshore. A short groin on the other hand permitted some bypassing and simply deflected the peak of the longshore sediment transport rate offshore.
- The updrift accretion and downdrift erosion in the NRCC tests were quite similar to the expected pattern formed by groins on a straight and long beach. However, in these tests, the net erosion caused by the groin(s) was less than the net accretion which indicates that the downdrift boundary was not far enough from the groin.
- In the test with two long groins (NT4 ) the span of the bay was long enough and little bypassing was permitted so the contour lines inside the groin bay became parallel with the crests of the incoming waves. For the rest of the tests with double groins, the alignment of the contour lines ( $L_0$  in particular) did not change significantly inside the groin bay.
- The bypassing of sand created a shoal offshore of the head of the groin. The size of the shoal was proportional to the length of the groin. Longer groins diverted more sand offshore and created a more distinct shoal.
- The formation of a depression zone downdrift of the groin was also caused by sand bypassing. The depression zone which had the form of a ditch or a channel, was aligned with an angle to the groin and its location was farther from the groin when the groin was shorter. In prototype such a ditch will not be formed because of the variations in the wave condition. But its presence in these experiments with a persistent wave condition is essential to test the ability of a detailed numerical model to correctly simulate this process.
- The formation of a scour hole near the head of the groin is quite evident in all the tests both at QUCERL and at NRCC. The scouring channels however are not shown in the bathymetry plots because of the resolution of the surveying.
- The presence of rip currents in the NRCC basin was shown by the analysis of characteristic lines. Rip currents pushed the location of the breaker point and consequently the offshore bar/step away from the shore and caused changes in the position of characteristic points i.e. offshore bar/step, along the shore of a beach without groins.

## CHAPTER 129

### Line-Modeling of Shoreface Nourishment.

by  
Willem T. Bakker<sup>1</sup>, Nico F. Kersting<sup>2</sup> and Hanz D. Niemeyer<sup>3</sup>

#### Abstract

Using line modeling, in the scope of the NOURTEC project a prediction is made concerning the behavior of the shoreface nourishment of Terschelling and an evaluation concerning the behavior of the combined supply on beach and shoreface at Norderney. Computations suggest smaller long-shore diffusivity on the upper beach than on the zone between NAP-1 m to -3 m for Terschelling and the inverse for Norderney (groynes!). Cross-shore diffusivity at Norderney appears to be much larger than at Terschelling. If further investigations substantiate those results, these lead to the conclusion, that shoreface nourishment at Norderney is still more preferable than at Terschelling.

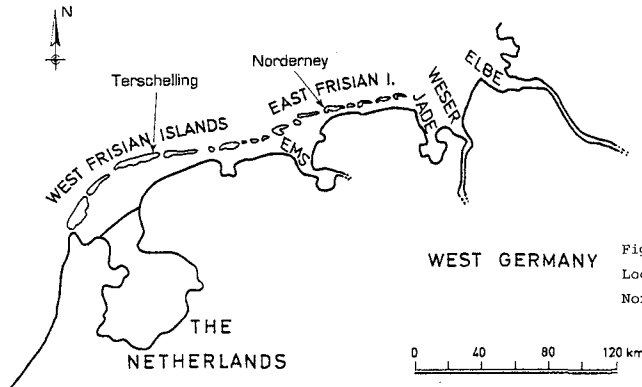

Fig. 1.  
Location Terschelling and  
Norderney

#### 1 Introduction

In the scope of the NOURTEC project (cf. Mulder et al., 1994) national coastal authorities in three different countries around the North Sea (Germany, the Netherlands

1 Netherlands Centre for Coastal Research (on secondment from Rijkswaterstaat, The Hague); Delft Univ. of Techn., Stevinweg 1, 2628 CN Delft, The Netherlands

2 Delft Univ. of Techn., Stevinweg 1, 2628 CN Delft, The Netherlands

3 Coastal Research Station Norderney, An der Mühle 5, D2982 Norderney, Germany

and Denmark) have carried out full-scale experiments with alternative coastal nourishment techniques: shoreface nourishment and combinations of shoreface and beach nourishment. These experiments are implemented under a range of environmental conditions. Extensive modelling and monitoring programmes form an essential part of the projects. The present paper deals with the prediction of the coastal behaviour with the aid of line models and comparison with prototype data for the Dutch and German supply: at Terschelling and Norderney (fig.1) respectively. In the future, also an analysis of the Danish supply will be given. A more detailed description of the investigations is given by Bakker & Kersting (1994) and by Kersting, Bakker & Niemeyer (1995) respectively.

## 2 Terschelling

### 2.1 Situation

Fig.2 Location study area Terschelling

An underwater supply of ca. 2 Mm<sup>3</sup> has been carried out in spring and summer of 1993 on the Dutch Wadden isle of Terschelling. Fig. 2 shows the site. Three breaker bars are gradually moving seaward along the whole stretch; the motion is periodic.

Mutual distance between the breaker bars is 500 m; seaward propagation velocity is 50 m/year and period 10 years. Depth-averaged (between NAP + 3 m and NAP - 6 m; "NAP" denotes a level, which is about mean sea level) the area under consideration shows a coastal retreat of about 2.75 m/year.

### 2.2 Three-line model

Fig.3. Schematization 3-line theory

Concerning the principles of line modeling is referred to the literature (Bakker, 1968a etc.). In the three-line model used the coastal zone is schematized in three zones (fig.3), which will be called: "beach", "inshore" and "deeper part".

In each zone it is assumed that all contour lines remain parallel and that the profile in this zone only moves horizontally. It is sufficient to compute only an average line in each zone, because it characterizes this zone. There is assumed to be a horizontal separation plane

between the zones. The sediment transport between the lines is assumed to be proportional to the difference between the equilibrium distance and the actual distance between the characterizing lines.

In the present application an initial equilibrium position (before any supply takes place) is assumed, where the three lines are straight and parallel (fig.4).

Distances  $y_{1,2,3}$ , are the deviations of the lines of the beach, inshore and deeper part, compared with this initial position. The y-value is computed by dividing the surplus volume in a zone (with respect to the initial position) by its height. In case  $y_1 = y_2 = y_3$ , the profile again is an equilibrium slope. If longshore transport could be neglected (see Appendix) the coast would tend to this equilibrium, if for instance originally sand on the inshore would have been supplied (fig.4).

Fig.4. Definition  $y_1, y_2, y_3$

The process, sketched above results in cross-shore diffusion of sand. Adding longshore diffusion to the cross-shore diffusion, according to the approach of Pelnard-Considere (1954) and Bakker (1968a), the following dynamic equations can be derived:

$$\frac{dy_1}{dt} = \frac{s_1}{h_1} * \frac{\partial^2 y_1}{\partial x_1^2} - \frac{s_{y1}}{h_1} * (y_1 - y_2) \tag{1a}$$

$$\frac{dy_2}{dt} = \frac{s_2}{h_2} * \frac{\partial^2 y_2}{\partial x_1^2} + \frac{s_{y1}}{h_2} * (y_1 - y_2) - \frac{s_{y2}}{h_2} * (y_2 - y_3) \tag{1b}$$

$$\frac{dy_3}{dt} = \frac{s_3}{h_3} * \frac{\partial^2 y_3}{\partial x_1^2} - \frac{s_{y2}}{h_3} * (y_2 - y_3) \tag{1c}$$

On the lefthand side is the accretion of line of beach, inshore and deeper part respectively. On the righthand side the gradient of the longshore transport is determined by the constants  $s_1, s_2$  and  $s_3$  respectively; the cross-shore transport ("beach to inshore" and "inshore to deeper part") by  $s_{y1}$  and  $s_{y2}$  respectively.  $h_{1,2,3}$  denotes the depth allotted to the three zones. Fig 5 shows the diffusion of the (originally rectangular) supply shape in longshore direction in the course of time.

Fig. 5 Diffusion of supply

### 2.3 Coastal constants

**Cross-shore constants:** by the supply (between two breaker bars; fig.3) the breaker bars get an "antropogenic distortion". It is assumed, that by a diffusion process the sand, involved in this distortion will diffuse to the neighbouring breaker bars. Furthermore, it is assumed, that the velocity of diffusion is related to the time laps between the replacement of one bar by the next-landward bar. Per cycle, a certain percentage (determined by "engineering judgement") is retained; the rest of the sand is transported to the two adjacent breaker bars. The engineering judgement is based upon the solution of Smit (1987) for the cross-shore diffusion, reproduced in the Appendix. From his equations it can be derived, that in a period  $T_{01}$  (defined in the Appendix) the process of spreading the supply evenly over the profile is completed for almost 80 %. It does not seem illogical to assume, that the diffusion process to a similar rate is accomplished during the propagation period of the bars. The periods  $T_{01}$  and  $T_{02}$  are therefore chosen both equal to 10 years. With values for  $h_{1,2,3}$  (6 m, 3 m, 3 m; see fig.3), values of  $s_{y1}$  and  $s_{y2}$  of respectively .2 and .15 m/year are found. A higher cross-shore diffusivity at the upper part is found than at the lower part, which seems reasonable.

It is assumed, that processes, dominated by the diffusion of the supply can be linearly superponed to the natural longshore and cross-shore coastal processes. The latter processes are implemented by assuming an autonomous erosion of 2.75 m/yr for the zone between NAP -6 m and NAP + 3 m (derived from Van Vessem, 1992)

In the mathematical model it is assumed, that cross-shore transport of supply below a level of NAP -9m is negligible (during the time of consideration) compared to the transport above this level. Thus, in the model no period-averaged cross-shore transport is assumed by the periodical motion of the breaker bars as such.

To determine the **longshore constants** for the line-model use is made of the CERC-formula and the assumptions of Svasek (1968): the local sediment transport between two contour lines is proportional to the longshore component of the decrease of the energy flux between those two lines. For detailed description is referred to Svasek & Bijker (1969), Bakker et al. (1971), Ten Hoopen & Bakker (1974) and to Bakker et al. (1988).

Sloping shores (fig.6) have been assumed between terraces, separating beach, inshore and deeper zone; local height of the spilling breaker is taken proportional to local depth. Total wave climate has been taken into account, taking discrete wave classes, each defined by a certain wave height H, period T and direction  $\phi$  and a probability of occurrence:

Fig.6 Schematization used for transport computations

$$S_{\phi} = S_{H,T,\phi} * P_r(H,T,\phi) \tag{2}$$

Fig. 7 shows the various classes of wave direction, translated into angles of incidence.

Fig.7. Directions of wave approach.

Vertical tide has been taken into account by schematizing it by a number of levels, combined with its probability of occurrence; furthermore it has been taken into account, that high waves from certain directions are

linked with water level rise (storm surge height).

The black arrows in fig.8 give the transport rates when all contour lines are parallel. Under those circumstances the method results in a total depth-integrated longshore transport for a certain H,T, $\phi$  as given by the

CERC-formula: 
$$S_{H,T,\phi} = .040 H_{b, sig}^2 n_b C_b \sin \phi_b * \cos \phi_b \tag{3}$$

Fig.8 Transport rates along the three zones as function of angle of approach of the waves at deep water and the effect of  $\delta = 2^\circ$ .

Table 1. Transport rates ( $10^3 \text{ m}^3/\text{yr}$ ) Volumes of the arrows in fig.8 are proportional to numbers in table 1.

The columns in fig.8 denote the various angles of wave incidence; the 3 sets of 3 rows the 3 zones. The size of the arrows is proportional to the transport (weighted with its probability of occurrence) integrated over all classes of H and T. Probability of occurrence has been derived from SON, a measurement station in the vicinity of Schiermonnikoog. Wave data have been made available by Rijkswaterstaat (Roskam 1988). Calculated numerical values of transport rates (in thousands  $m^3/year$ ) are depicted in table 1 (the lines "0 degree "; for beach, inshore and deeper zone respectively).

For both upper zones the longshore transport has been computed three times for each wave direction: apart from assuming parallel depth contours also the angle of the beach (inshore) has been turned over an angle  $\delta$  with respect to the other contour lines. For instance: in fig 6 the angle of the beach is turned. The gray arrows in fig 8a show the effect, where  $\delta$  has been chosen  $\pm 2^\circ$ . Table 1 shows the numerical results.

The constants  $s_1$  and  $s_2$ , which can be shown theoretically (Pelnard Considere, 1954) to be the derivative of the longshore transport to the coastal direction (atan  $\partial y/\partial x$ ), are calculated from:

$$s_i = \frac{\sum_{+82.5^\circ}^{-82.5^\circ} S_i(\phi_i + \delta) - \sum_{+82.5^\circ}^{-82.5^\circ} S_i(\phi_i - \delta)}{2\delta} \quad (4)$$

## 2.4 Results

From the last column of table 1  $s_1$  is found by substitution of the total transport of  $804.2 \cdot 10^3$ , resp.  $551 \cdot 10^3$   $m^3/year$  for the terms in the numerator of (4) ( $\delta$  equals  $\pi/90$ ). A similar computation gives  $s_2$ ; then for  $s_1$ , resp.  $s_2$  values of  $3.63 \cdot 10^6$ , resp.  $0.964 \cdot 10^6$   $m^3/year/rad$  are found. A total transport of  $(697.3 + 165.3 + 4.09) \cdot 10^3 = .85 \cdot 10^6$   $m^3/year$  results.

It was found, that diffusivity in longshore direction along the deeper part could be neglected. Effect of curvature of the inshore on the coastal constant for the beach (the inshore turns more or less in the same way at the same time as the beach) has not been taken into account. Neglecting this effect can give a rather important over-estimate of the coastal constant of the beach (Bakker & Delver, 1986; Bakker et al., 1988). Another extreme (no longshore diffusion) is given by the formulae of Smit (1987) (Appendix)

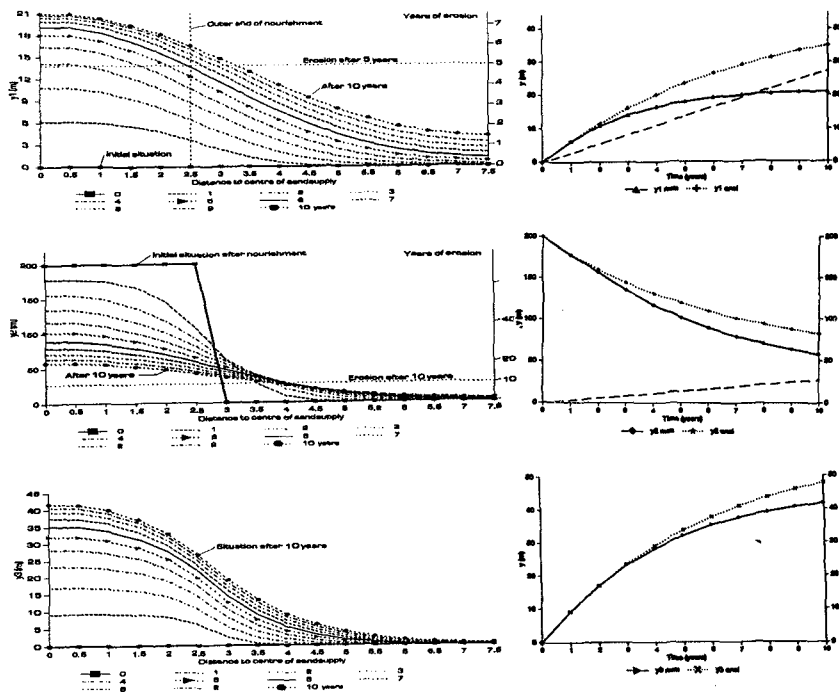

Fig 9a,b,c.Lines of beach, inshore and deeper part  $y_{1,2,3}$

Fig.10a,b,c Site of beach, inshore, deeper part in the course of time (in center of supply).

Fig 9 a,b,c shows (extreme high diffusivity) a plan view of the expected development of beach, inshore and deeper part (mind the different vertical scales). The autonomous erosion of the coast is depicted on the righthand side of the figure.

Fig.10a,b,c show the expected position (in the course of time) of the line of the beach, inshore and deeper part, in the center of the supply area.

Both extremes (no c.q. extreme longshore diffusivity) are shown, where autonomous erosion is not taken into account.

The positive direction denotes a more seaward position. The drawn lines show the development, if one ignores the autonomous coastal erosion. The beach would increase, the inshore (where the supply was applied at  $t=0$ ) would retreat from its exposed position. Finally, supply sand would spread evenly over the profile.

The interrupted lines in fig. 10 a,b,c show the rate of autonomous coastal erosion at the same scale, more exactly: the amount of cumulative supply, necessary to balance this kind of erosion.

During the time the drawn line lies above (c.q. below) the interrupted line, the beach, c.q. inshore has a more seaward (c.q. landward) position than just before the application of the supply.

It shows, that according to the computations the supply will stop the erosion of the beach during the order of a decennium, without causing considerable accretion.

### 3 Norderney

#### 3.1 Conditions at the site of supply.

Fig.11 Combined beach and shoreface nourishment. Coastal protection.

Near the west point of the German Wadden island of Norderney, 450.000 m<sup>3</sup> of sand has been supplied in 1992 to the beach and the shoreface (fig. 11).

The seaward limit of the nourishment coincides with the 5 m depth contour. The coastline is protected by groynes, revetments and seawalls. For the largest part the area is inside the "Riffbogen" (bars formed by the outer delta).

Wave attack is important on the North West side.

At the South West side (Norderneyer Seegat) current dominates (cf. Thilo & Kurzak (1952), Luck (1977) and Niemeier (1986 a,b,c, 1990 and 1992)).

Since the first artificial nourishment (1.25 Mm<sup>3</sup> in 1951/52) (major) sand supply in this area and its vicinity was repeated 6 times (incl.1992). Fig. 12 shows the area of coastal nourishment in 1992: an amount of .5 Mm<sup>3</sup>, of which 50 % supplied above NN-1m (as NAP the level NN is about mean water level). Ca. 20% was supplied between NN-3m and NN-5m.

#### 3.2 Wave climate and wind set-up

The outer delta largely shelters the considered area from the deep water wave field. However, even more than at Terschelling, high waves and high surge levels are often linked together. Kersting et al.(1995) compute the sand transport using the SON deep water wave climate as well for Terschelling as for Norderney. However, storm surge

levels at Norderney are higher than at Terschelling. Thus, if Norderney would have been located near Terschelling, its (present) outer delta would give better protection; it would reduce wave height at the Westpoint shore more than in the present situation. Kersting et al. estimate that the effect of location on the surf height results (for the same wind, i.e. offshore wave height) in surge top water level rises, being 22% higher at Norderney than at Terschelling. They use as well theoretical considerations (Schalkwijk (1947) and Weenink (1958)) as well as analysis of the SON wind and wave data.

### 3.3 Sand transport computations

#### 3.3.1 Schematization

Fig.12a Refraction pattern

Fig.12b Schematization and points I to IV

Fig 12c Schematization (3D)

Investigations concern the coastal area with a length of ca 5 km between the tidal inlet and the site where the outer delta merges with the island (between point I to IV; fig 12b).

The wave climate on the inshore and the beaches in this area is strongly influenced by the bars of this outer delta. These bars reduce the energy of the incoming waves and also influence the propagation direction of the waves by refraction.

Fig 12b,c shows the schematization chosen; contour lines are schematized to sets of parallel straight lines. Furthermore, fig. 12a displays the real contour lines and a refraction diagram, from Niemeyer (1986), which indicates analogy in similarity of hydraulic response between schematization and prototype. Further research with respect to this aspect is proceeding. Convergence and divergence of wave rays are, in the schematization, partially taken into account: difference in direction of beach and inshore is implemented. However, the effect of the curvature of beach and inshore on the refraction coefficient is not taken into account. By the chosen schematization, the three parts of the outer delta together act as a convex lens, focussing the wave rays. From the refraction diagram of fig.12a the same picture arises. Because of this, a convex beach, making everywhere (about) the same angle with the wave crests will be stable, where for an offshore topography with totally

straight contour lines, parallel to the beach, a straight beach would have been stable. This explains the convex character of the Westend of the island.

Up to now, only the transport along the shore (beach and inshore) of the island has been calculated. The transport along the seaward shoreface of the outer delta will be calculated in the future. Again, the Svasek method of computation has been used (cf. ch.2 for literature). Effects of current are not taken into account.

Preliminary computations concerning diffusivity constants  $s_{1,2}$  have been carried out (for point IV; fig.12b) by varying the direction of beach or inshore as done in ch.2. Apart from this, diffusivity constants for Norderney will be calculated from measured data (sect.3.4)

### 3.3.2 Results

Fig.13 Transport capacity (without groynes) if the coast would be straight

Fig. 13 shows the calculated transport capacities in the points I to IV, which would occur, if the coastline would be straight. It shows, that accretion in the coastal area between points I and IV would result (according to the computations). Longshore diffusivity constants  $s_1$  and  $s_2$  in point IV are found of

$.6 \cdot 10^6$  and  $2.8 \cdot 10^6$   $m^3/year/rad$  for beach and inshore respectively. From the values calculated one would find, that a convex coast with a difference in coastal direction of ca.  $9^\circ$  to  $12^\circ$  between point I and point IV (fig.12b) would give a stable coast. The present difference in coastal direction is ca  $15^\circ$  which is more; thus erosion (as occurs) can be expected. For the computations is referred to Kersting et al. (1995). As accuracy is low, the result has only qualitative importance.

Because of the existing groynes the real transport, along the inshore, will be much less than the transport capacity. Bakker & Joustra (1970), comparing coastal erosion along the dutch coast before and after the construction of groynes, indicate, that groynes might reduce coastal transport with a factor of 4. This would reduce the value of  $s_2$  (in case of erosion) in the same way.

### 3.4 Line modeling

#### 3.4.1 Coastal constants; relation between curvature and erosion

Bakker (1968b) describes another way to find the coastal constants: from coastal measurements. Related are the data of volumetric change and curvature; the latter taken as difference of coastal direction  $\Delta\phi$  between left side and right side of the stretch. In order to obtain uniformity of data, a stretch of (only) 890 m (between groynes "A" and "H1") near the Western end of Norderney has been analyzed. Fig. 14 displays this relationship; from this figure Kersting et al. (1995) derive values of  $s_1=1.1*10^6$  and  $s_2=.9*10^6$  m<sup>3</sup>/year/rad. As for the first observation (encircled in fig.14b) leading to  $s_2$  the groynes will have been less effective (the supply extended further seaward than the groynes), this observation has been discarded, leading to  $s_2=.2*10^6$  m<sup>3</sup>/year/rad. Based upon fig. 14d,  $s_3$  has been taken zero. The constants  $s_{y1,2}$  (both assumed as 4 m/year) have been found by estimating  $T_{01}$  from the measurements and by iterative approximation, using the numerical three-line model (ch.2.2). Initial- and boundary conditions are imposed by prototype data.

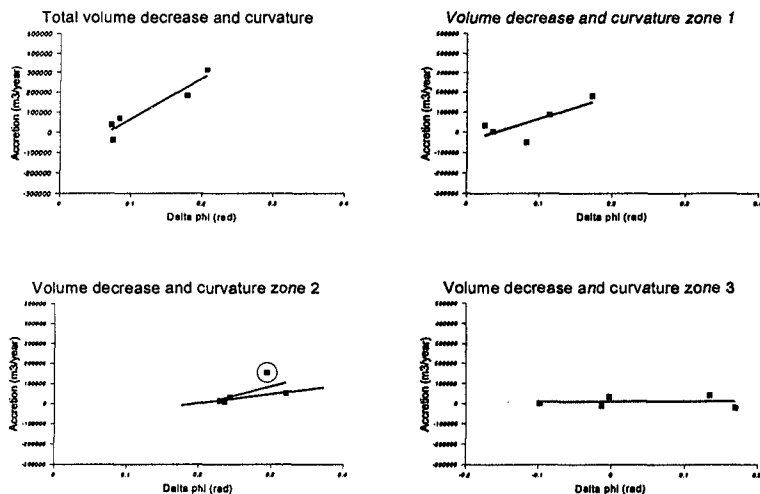

Fig.14a,b,c,d Volume decrease & curvature

#### 3.4.2 Results

In the Norderney case, " $y_{1,2,3}$ " will be defined as the surplus volume since the supply, (expressed in m<sup>3</sup>/m'/m

depth) between 2 successive separation planes (see fig.13). Comparison between measurement and computation show fig.15 ( $y_{1,2,3} = f(x); t$  as parameter) and 16 ( $y_{1,2,3} = f(t); x$  in the center of the field). For  $y_1$  and  $y_2$  good agreement is found;  $y_3$ , which in the model can only change because of cross-shore transport, appears to remain too large in the model. This suggests scour by current in the area below the groynes.

#### 4 Discussion and conclusions.

##### 4.1 Terschelling

- Depending on the assumptions (of which the extremes are: "only cross-shore diffusivity" and "cross-shore plus unfavorable high value of longshore diffusion", a "life time" of the supply can be estimated, which varies respectively between 13 and 7 years (estimating the autonomous erosion as 2.75 m/year).

#### 4.2 Norderney

- Concerning Norderney only preliminary conclusions and some indications can be given. Comparing longshore coastal constants derived from transport formulae (sect.3.3) and from evaluation of topographic field data the  $s_2$ -value, found from those field data is lower than expected (even considering the effect of the groynes), where the  $s_1$ - value is considerably larger. The total of  $s_1+s_2$  is in the expected range.
- The coastal measurements indicate much larger longshore diffusivity on the beach (above NN - 1 m) than on the inshore (NN-3 m<h<NN-1 m).
- In the future effects of currents should be carefully examined, especially concerning the zone seaward of the groynes. For the three-line model (which is able to reproduce the development of beach and inshore rather well) underestimates (without current effects) the erosion of the deeper zone.

#### 4.3 General

- Comparison of coastal constants in general for various stretches of coast is given by Bakker et al. (1988). In that scope, the maximum values of the longshore diffusivity assumed for Terschelling are rather high: values of 1 to  $2 \cdot 10^6$  are more common. The cross-shore transport constants  $s_{y1,2}$  are (physically) strongly dependent upon the depth of the separation plane, as well on the schematization. Compared to the values, mentioned by Bakker et al. (1988), the cross-shore transport constants assumed for Terschelling are somewhat low. For instance, using Kalman filtering, de Vroeg (1987) finds  $s_y \approx 0.7$  m/year at NAP - .72m ( $T_{01} \approx 7$  years) for the Dutch Rijnland-coast. Compared to this, the value of  $s_{y1,2}$  of 4 m/year at NAP -3m ( $T_{01} = 0.4$  year and  $T_{02} = 0.25$  year) seems extremely high. Up to now,  $T_0$ -values of the order of 1 year were the smallest ever found (in Cadzand, CUR et al., 1986;  $s_y = 3$  m/year at NAP -2m). As in Norderney, in Cadzand a tidal channel is near to the coastal area. In the Norderney case, the wave attack is probably larger than in Cadzand.

Remarkable is the difference in character between the supplies of Terschelling and Norderney:.

- Supplying high on the beach instead of on the inshore would have been favorable for the Terschelling case if the costs of supplying on beach or inshore would have been equal. In Norderney however this is different because (most probably) the groynes largely reduce the longshore diffusivity of the inshore (compared to the beach).
- Probably the role of the deeper zone in Norderney will show to be more active (current effects near to the Norderneyer Seegatt) than at Terschelling.
- Different as well is the goal of both supplies, which emphasizes the importance of the offshore nourishment in Norderney: here the supply forms an essential part as a maintenance measure for the coastal protection by reducing the damage to the coastal defence works (sea-walls and groynes). This goal was formulated already in 1952 (Arbeitsgruppe Norderney); it has been shown to be very cost effective since then.

**Appendix. Smit's solution of the two-dimensional three-line problem.**

The dynamic equations for the cross-shore transport  $S_{y_i}$  between the layers (with  $i=1,2$ ) read:

$$S_{y_i} = s_{y_i}(y_i - y_{i+1}) \tag{A1}$$

Continuity ( $\Sigma(h_i \cdot y_i) = 0$ ) with  $i=1,3$  shows, that  $y_2$  is implicitly determined by  $y_1$  and  $y_3$ .

Continuity also yields:  $S_{y_1} = -h_1 \cdot dy_1/dt$        $S_{y_2} = +h_3 \cdot dy_3/dt$  (A2a,b)

Combination of (A1) and (A2a,b) leads to the vectorial equation:  $d\vec{y}/dt = \vec{A} \cdot \vec{y}$  (A3)

where  $\vec{y}$  is  $y_{1,3}$  and the matrix  $\vec{A}$  is  $(\alpha_{11} \dots \alpha_{22})$ , where:

$$\alpha_{11} = -\frac{s_{y_1} \cdot (h_1 + h_2)}{h_1 \cdot h_2} \quad \alpha_{12} = -\frac{s_{y_1} \cdot h_3}{h_1 \cdot h_2} \quad \alpha_{21} = -\frac{s_{y_2} \cdot h_1}{h_2 \cdot h_3} \quad \alpha_{22} = -\frac{s_{y_2} \cdot (h_2 + h_3)}{h_2 \cdot h_3} \tag{A4}$$

Displaying the solution gives a reason to define 5 timescales. Two of those are the time scales  $T_{01}$  and  $T_{02}$  of the two two-line systems: "beach + inshore" and "inshore + deeper part" (Bakker, 1968), equal to  $-1/\alpha_{11}$  and  $-1/\alpha_{22}$  respectively. The third one,  $T$ , is related to the other

diagonal of the matrix  $\vec{A}$ :  $T^2 = \frac{1}{\alpha_{12} \cdot \alpha_{21}} = \frac{h_2^2}{s_{y_1} \cdot s_{y_2}}$  (A5)

The last ones are  $1/\lambda_{1,2r}$  as occur in the solution of (A3):  $\vec{y} = \vec{K} e^{\lambda_1 t} + \vec{M} e^{\lambda_2 t}$  (A6)

where  $\vec{K} = (K_1, K_2)$  and  $\vec{M} = (M_1, M_2)$ , in which:

$$K_1 = -\frac{\alpha_{21}}{\lambda_2 - \lambda_1} y_{3b} + \frac{\lambda_2 + \frac{1}{T_{01}}}{\lambda_2 - \lambda_1} y_{1b} \quad M_1 = +\frac{\alpha_{21}}{\lambda_2 - \lambda_1} y_{3b} - \frac{\lambda_1 + \frac{1}{T_{01}}}{\lambda_2 - \lambda_1} y_{1b} \tag{A7a,b}$$

$$K_2 = \frac{1}{\alpha_{12}} \left( \lambda_1 + \frac{1}{T_{01}} \right) K_1 \quad M_2 = \frac{1}{\alpha_{12}} \left( \lambda_2 + \frac{1}{T_{01}} \right) M_1 \tag{A7c,d}$$

where  $y_{1b}$  and  $y_{3b}$  are the initial values of  $y_1$  and  $y_3$ .

## CHAPTER 130

### Statistical Variations in Beach Parameter Change Rates for Walled and Non-Walled Profiles at Sandbridge, VA

John M. Hazelton<sup>1</sup>, David R. Basco<sup>2</sup>, Doug Bellomo<sup>3</sup>, Greg Williams<sup>4</sup>

#### Abstract

It has been argued that seawalls have a detrimental effect on the adjacent beach. These effects may only be noticeable over a period of years or may be short-term effects associated with storms or with seasonal transitions of the beach. Many theories on beach and seawall interaction have been speculative and have lacked actual field or laboratory evidence for their basis. This study uses four years of monthly and post-storm beach profile data to examine what influences the seawalls at Sandbridge, Virginia (USA) have on the adjacent beaches. Long-term effects of the seawalls are analyzed using fourteen years of profile data. Five parameters are defined to describe the subaerial beach profiles. Changes in the profile parameters in time are quantified using three methods of analysis.

#### 1. Introduction

Sandbridge, Virginia is the site for an ongoing investigation of seawall and beach interaction. The study area lies on the east coast of the United States. Sandbridge is located south of the Chesapeake Bay and north of the Virginia-North Carolina border, as depicted in Figure 1. The beach is used by local property owners, residents and tourists as a recreational area.

In August 1990 the Civil and Environmental Engineering Department at Old Dominion University (ODU) began a beach monitoring program at Sandbridge, Virginia. The purpose of the monitoring program was to examine the effects of seawalls on the adjacent beach. The monitoring program involves surveying 28 beach profiles at seawalls and dunes out to mean low water. Surveys are conducted once a month and after significant coastal storms. Results of the two year study may be found in Basco et al. (1992) and Bellomo (1993).

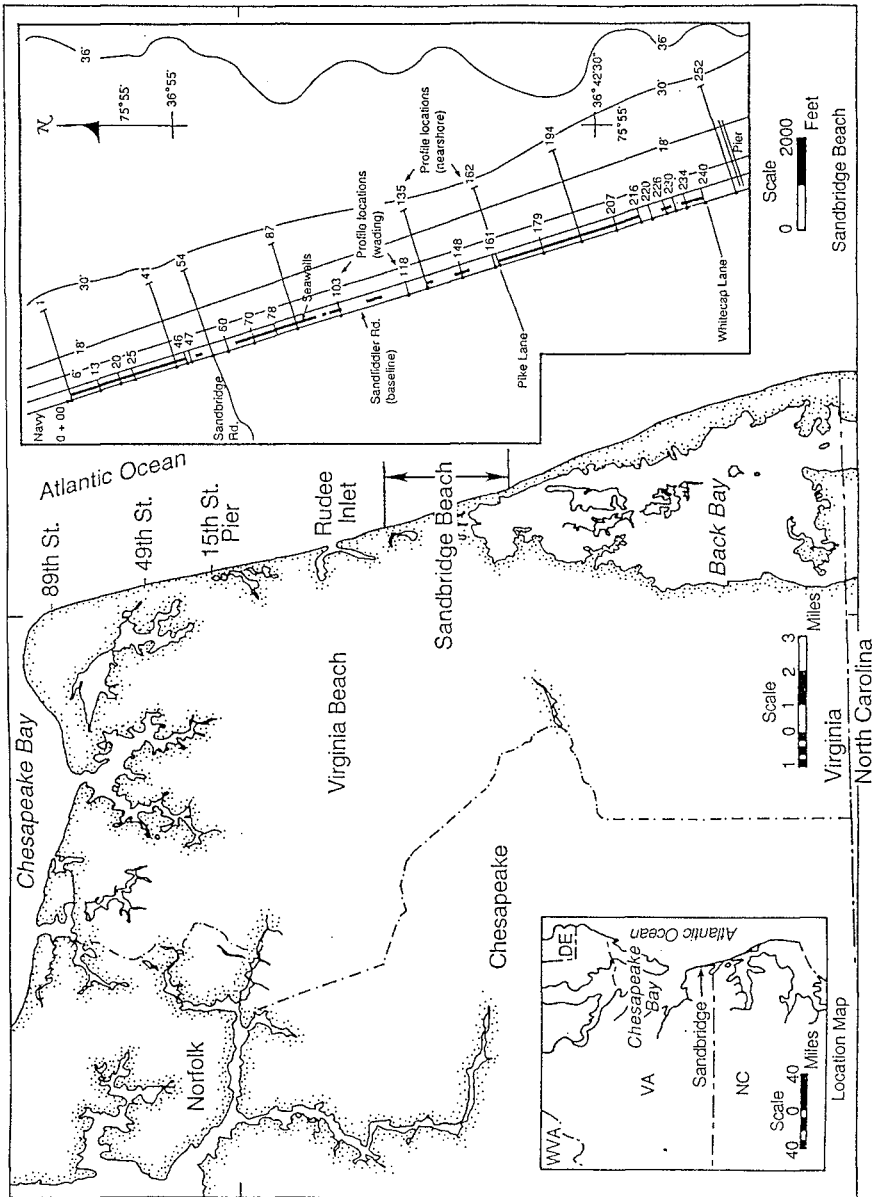

Figure 1. Location Map

The City of Virginia Beach began survey work at Sandbridge in 1980 with profiles at roughly 305 m intervals. Most profiles extend only out to wading depths, however some nearshore profiles (i.e. to depths of -8.0 meters) have been taken. The time between City surveys varies over the past 14 years. The Virginia Institute of Marine Science has also sponsored survey work at Sandbridge.

There are currently 2,350 profile-surveys at 53 locations collected during the last 14 years in the data base. Four of the profiles have had a seawall built during the period they were surveyed. Seven non-wall profiles have been surveyed before the boom in seawall construction in 1989.

The U.S. Army Engineer Waterways Experiment Station's Coastal Engineering Research Center (CERC) is sponsoring this study. This paper presents the preliminary results of what will be a five year study. They are also supporting two other beach and seawall interaction studies on United States beaches with one on the California coast and the second located at the eastern shore of Lake Michigan. It is anticipated that from the results of long-term field monitoring at three different locations, some facts will become clear regarding seawall and beach interaction.

## 2. Literature Survey

The Journal of Coastal Research (1988) Special Issue Number 4 entitled, "The Effects of Seawalls on the Beach", was specifically devoted to this topic. Included was a literature review by Kraus (1988) of beach and seawall interactions. Kraus concluded that there were no adverse effects of a seawall on the adjacent beach if a sediment supply exists.

Griggs et al. (1994) have described the results of seven years of monitoring beach and seawall interactions at Monterey Bay, California. They concluded that there were no significant long-term effects of the seawalls on the adjacent beach and the summer rebuilding of the beach was not influenced by the seawall. They found no difference between the winter profiles of the walled and non-walled beaches. At Monterey Bay the shoreline is stable and a steady sediment supply exists. This is different than at Sandbridge where a long-term, erosional trend exists.

### 3.0 Study Area Characteristics

Sandbridge, Virginia is quite literally a 'sand bridge' that is 7.7 km long and about 250 m wide at its narrowest point. Sandbridge separates the Atlantic Ocean to the east and the freshwater estuary Back Bay to the west. The long-term shoreline recession rate has been shown to vary linearly at Sandbridge from 1.1 m/yr at the north end, to 2.9 m/yr at the south end (Everts et al., 1983).

There are 4738 m of seawalls in 15 different sections along the Sandbridge shoreline. This is 62% of the oceanfront. The seawalls were built to protect septic tanks, driveway concrete slabs, and other property at ground level. The majority of the homes in the area are on piles above the one percent chance storm surge

elevation. Most of the walls are made of steel sheet-piles with others being constructed of timber. Short stretches of concrete and asphalt rubble revetments also exists along the Sandbridge shoreline.

Seawalls along the southern portion of Sandbridge have their base located within the tidal range during the summer months and below mean low water during the winter months. Seawalls along the middle and northern portion have their base above mean high water during the summer and within the tidal range during the winter months. The mean tidal range is 1.04 meters.

4.0 Parameter Definitions

To quantify profile "change" we have adopted five parameters as depicted in Figure 2. There are three section volume parameters, namely: landward volume ( $V_L$ ), seaward volume ( $V_S$ ), and total volume ( $V_T$ ), each carrying units of  $m^3/m$ . The area between the profile and the MLW line is calculated using the trapezoidal rule. To obtain a volume, this area is then multiplied by a unit length parallel to the beach. The different volumes (landward, seaward, and total) are calculated using different right and left hand boundaries. Landward volume is bounded on the left by the survey baseline. For a walled profile, the right hand boundary for landward volume is the wall itself. However, for a dune/beach profile, an imaginary partition is used as the landward right hand boundary. This imaginary partition is located at the same distance from the baseline as the nearby seawalls. Seaward volume is bounded on the left by the imaginary partition or seawall, and on the right by the intersection of the profile and the MLW line. The total volume is simply the sum of the landward and seaward volumes.

The berm elevation ( $E_B$ ) is measured in meters above the vertical datum. It is simply defined as the elevation of the profile at the seawall or imaginary partition, as shown in Figure 2. The shoreline position (P) is also shown in Figure 2. It is defined as the distance from the baseline, to where the profile intersects the MHW line.

Figure 2 Definition Sketch

### 5.0 Methods of Analysis

Three basic methods have been devised to analyze changes in the profile parameters: (1) Individual Profile Method, (2) Simple Average Method and (3) Weighted Average Method. Each method uses an increasing number of profiles in their procedures and is useful in studying different topics of beach and seawall interaction. Linear regression was used to find the parameter rate of change for each method.

The weighted average method (WAM) used only 28 profile locations surveyed by ODU since August of 1990. The 28 profiles were separated into two categories, wall and non-wall profiles. Each wall profile was assigned a representative length of seawall along the beach. One wall profile is said to represent the conditions along this particular length of shore. The wall profile parameter is multiplied by the representative length. This is done for each wall profile. The sum of the representative lengths equals the total length of seawalls at Sandbridge, 4738 m. All of the weighted profile parameters were added together and then divided by 4738 m. The result is a single set of five weighted parameters ( $V_s, V_L, V_T, P$ , and  $E_B$ ) that represent all the wall profiles at Sandbridge. The same scheme was used with the dune profiles but with different representative lengths totaling 2953 m of non-walled beach.

For the simple average method (SAM) Sandbridge was divided into three reaches. The reasons for the division were due to differences in the baseline elevation and erosion rates along the Sandbridge shoreline. ODU profiles 1 to 54 were placed into the northern section, profiles 60 to 161 into the middle section and profiles 162 to 252 into the southern section. For each section the profiles were sorted again into wall and non-wall profiles. The data base has now been sorted into six categories. For each category, every profile had their parameters averaged together. The outcome is five parameters for a particular survey date representing either wall or dune profiles for each section.

For the individual profile method (IPM), the parameters were calculated for all surveys of a particular profile. This allows the profile history to be analyzed beyond the four years of ODU monitoring. The most significant benefit of the IPM was that parameter rates of change could be looked at before and after wall construction. An individual spreadsheet for each profile was created and contained the five parameters for every date that the profile was surveyed.

Seasonal variations of the profile parameters were studied using the results of the WAM. Seasonal trends can be mathematically modeled as a sinusoidal wave with a wave length of one year. The equation for the seasonal sine wave is given by:

$$Y = b + m(t) + (a)\sin(-2\pi(t-t_0)/365) \quad (1)$$

where:  $Y$  = parameter value ( $V_s, V_L, V_T, P$ , or  $E_B$ )  
 $b$  = parameter starting value, constant, at October 1990  
 $m$  = slope of best fit linear regression line  
 $t$  = time in number of days since January 1, 1900

$a$  = amplitude of sine wave

$t_0$  = start date October 1990

Linear regression was used to find the values of  $b$  and  $m$ . The amplitude,  $a$ , was found by using a value of the amplitude that gave the least variance between the measured WAM values and the predicted sine wave values,  $Y$ . Four years of WAM survey data were utilized in the analysis (October, 1990 to September, 1994). All values in the seasonal variation plots were subtracted by the parameter's linear regression intercept at October 1990. By using the "difference" values discrepancies between wall and dune profiles are more easily seen.

## 6. Beach and Seawall Interaction Hypotheses

To prove if the seawalls at Sandbridge are adversely affecting the adjacent beaches, three basic hypothesis were tested. The first hypothesis is that seawalls delay the recovery of the beach transition from winter to summer seasons. This hypothesis will be accepted or rejected by studying the weighted average volume seaward of the dune and wall profiles.

The second hypothesis is that the volume of sand in front of the walls erodes faster than the volumes in front of the partition for the dune profiles. This hypothesis will be accepted or rejected by comparing the rates of loss of volume seaward for the wall and dune profiles.

The third hypothesis is that the dune landward volumes are eroding at a faster rate because of sand being held back by adjacent seawalls. The volume of sand behind the wall is removed from the littoral system. This hypothesis will be tested by comparing the volume landward loss rates before and after seawall construction at the dune profile locations.

## 7.0 Results

### 7.1 Weighted Average Method

Results of the weighted average method are included in the plots of the seasonal variations in Figures 3 through 9. The solid dots represent the measured weighted average parameter difference. The heavy, solid line is the linear regression slope of the parameter rate of change using data from October, 1990 to September, 1994. The values of these four year, WAM slopes are summarized in Table 1. Also included in Table 1 are parameter rate of change using one, two and three years of data. There is some variability in the value of the parameter rate of change with an increasing number of years. The cause of this variability is that some winter seasons had more severe storms and some summers resulted in more beach recovery. By using the longest time span available, such inconsistencies are reduced. Parameter rate of change tends to decrease as the number of years used increased, except for the dune landward volume.

The null-hypothesis at the 95% confidence level was used to determine that the four year shoreline recession rate was statistically higher for the dune profiles. The volume seaward erosion rate was also statistically higher for the dune profiles. Berm elevation recession rates were found to be statistically the same for the wall and dune profiles.

### WAM Dune - Volume Seaward

Figure 3 Dune Volume Seaward Seasonal Variations

### WAM Wall - Volume Seaward

Figure 4 Wall Volume Seaward Seasonal Variations

The amplitude of the seasonal sine wave is larger for the wall profiles than for the dune profiles. This amplitude is one-half of the active volume of sand that builds in the summer and is removed in the winter. Active volumes for the dune and wall profiles are 6.2 m<sup>3</sup>/m in Figure 3 and 8.9 m<sup>3</sup>/m in Figure 4, respectively. The active seasonal volume of sand landward of the partition is 4.0 m<sup>3</sup>/m for the dune profiles as shown in Figure 5. Fluctuations in the seasonal berm elevation and shoreline position were found to be larger for the wall profiles than the dune profiles (see Figures 6, 7, 8 and 9).

These results suggest that the walls produce more seasonal variations causing lower winter profiles and more sand piled up in front of the walls in the summer than the duned sections. Dune and wall parameters reached their transition from winter to summer profiles in April and from summer to winter profiles in October. Volume seaward for the wall recovered before the dune in 1991 and simultaneously in 1993 and 1994. The dune recovered before the wall in 1992. Dune profiles achieved their winter profile before the wall in 1991 and simultaneously in 1990, 1992, 1993 and 1994. There is no evidence that walled sections recover at a later time than the duned sections.

### WAM Dune - Volume Landward

Figure 5 Dune Volume Landward Seasonal Variations

#### 7.2 Simple Average Method Results

Results from the simple average method are listed in Table 2. Column one is the section number and column two is the profiles used in that section. The third column is the percent of shoreline that is fronted with seawalls in that section. Column four is the profile parameter type. This table includes the parameter rate of change for each of the three sections in the last five columns.

			Dune	-4.6	-2.1	-2.5	-0.2	-1.5

Table 2 Simple Average Method Parameter Rate of Change  
from Oct. 1990 to Sep. 1994

The time span used in the regression analysis was from October 1990 to September 1994.

Section 3 experienced the largest total volume decrease of the three sections. Volume seaward loss and shoreline retreat were the highest for walled profiles in Section 3. The higher parameter change rates in Section 3 are due to the seawalls being located closer to the surf zone than the seawalls in Section 1 and 2.

### 7.3 Individual Profile Method Results

The parameter rates of change for each of the 28 profiles are provided in Table 3. Volume seaward and landward for profiles 1, 25, 161 and 252 have been plotted in time and are shown in Figures 10, 11, 12, and 13, respectively. Dune profile 1 is at the north end of Sandbridge and dune profile 252 is at the south end. These profiles have been regularly surveyed since October 1980 and have been the least affected by road maintenance, beach bulldozing and home construction. Both profiles show a significant increase in the loss rates of all parameters ( $V_T$ ,  $V_S$ ,  $V_L$ ,  $E_B$  and  $P$ ) after the construction of nearby seawalls in 1989. Profile 1 and 252 can be considered as control profiles in this study. The other dune profiles surveyed back to 1980 have seawalls to the north and south of them and have been modified by man. These other profiles have mixed results. The plot of dune profile 161 has a decrease in sand loss after a seawall was built 30 m to the south.

Profile 25 has been surveyed since 1980 and changed to a wall profile in the fall of 1988. Volume landward has a decreasing rate due to sand mechanically removed in the spring of 1994. The amount of sand decreased in front of the seawall after construction but has been increasing since then.

## 8.0 Conclusions

The hypothesis that erosion in front of the seawalls is greater than that on adjacent non-walled beaches was statistically found to be false. The hypothesis that seawalls inhibit the recovery of the beach after the winter storm season was also found to be false at Sandbridge. There is support for the hypothesis that the landward dune volume is eroding at a faster rate due to seawall construction on adjacent beaches. Complete details can be found in Hazelton (1994).

The seawalls at Sandbridge are performing exactly as they were intended to perform. They are protecting the infrastructure behind them from damage due to wave action. They were never intended to save the beach from erosion. The shoreline was receding well before the seawalls were constructed but now people have a reference point from which to judge the amount of retreat.

What is of concern in this study is the additional erosion caused by coastal armoring above the historic background erosion rates. The adverse effects of coastal armoring can be mitigated by nourishing the beach suffering from the increased erosion with sand so that the armoring has a neutral effect on the beach

Profile No.	Profile Type	Dates Used in Regression	No. of Years Used	No. of Survey Points	Volume Total (m <sup>3</sup> /m/yr)	Volume Seaward (m <sup>3</sup> /m/yr)	Volume Landward (m <sup>3</sup> /m/yr)	Berm Elevation (m/yr)	Shoreline Position (m/yr)

(Dean, 1986). Even with this mitigating nourishment, the historic background erosion will continue to erode the beach and the shoreline will eventually reach the seawall and no beach will exist.

Seawalls and beaches can only coexist with periodic beach nourishment for a beach experiencing high rates of historic erosion. A nourishment project has been planned for Sandbridge in the spring or summer of 1997. The seawalls can continue to provide protection to homes during periods of high waves and storm surges and tourist can also enjoy the wide summer beach. Subaerial beach monitoring at Sandbridge will continue until a nourishment project is completed after which full profile monitoring to closure depth will take place.

### Acknowledgments

This study has been supported by the U.S. Army Corps of Engineers, Coastal Engineering Research Center in Vicksburg, MS and was performed under the Work Unit entitled "Impacts of Coastal Armoring on Beaches". Permission was granted by the Chief of Engineers to publish this information. Some of the survey data used in the study was supplied by the City of Virginia Beach, VA and the Virginia Institute of Marine Science.

## CHAPTER 131

### A Bottom Boundary Layer Sediment Response to Wave Groups

J. Lee<sup>1</sup> , S. O'Neil<sup>1</sup>, K. Bedford<sup>2</sup>, and R. Van Evra<sup>3</sup>

#### Abstract

A field experiment measured *in situ* sediment resuspension in the bottom boundary layer. Spatially and temporally dense suspended sediment concentration profiles, three-dimensional velocities and pressures were obtained from a location with a flat, fine-sand bottom in Lake Erie in 1992. By use of a conceptual model, ten minute averaged near bottom sediment concentration is found to be proportional to significant wave orbital velocity and group wave parameters. The result attempts to clarify the ambiguity of using a monochromatic wave parameterization for bottom boundary layer model comparisons with measured data containing spectral wave conditions.

#### Introduction

Sediment transport models encompass many complex physical processes. Shear stresses exerted on the bottom, wave and current interactions and sediment concentration induced stratification are a few examples. Many bottom boundary layer models now have components which attempt to describe these processes. For certain flow regimes these models may accomplish the tasks of modeling natural phenomena.

Recently Bedford and Lee (1994) pointed out that

an external parameter in the Glenn and Grant (1987) model, the averaged wave orbital velocity,  $U_b$ , is one of the most sensitive input parameters required for calculating suspended sediment concentration profiles for a particular coastal bottom boundary layer in Mobile Bay, Gulf of Mexico. A monochromatic wave is used in this bottom boundary layer model for representing wave conditions. With reference to the spectral behavior of real waves, there has been a vigorous debate between researchers concerning the representative wave to be used for such sediment transport modeling. Obviously, a monochromatic wave formulation in the models makes it impossible to directly account for the randomness and nonlinearity of real waves.

It is believed that the nonsteady wave height variation in the surf zone generates the cross-shore component of radiation shear stress; any remnant wave height then contributes to group wave generation (Longuet-Higgins and Stewart, 1964). Grouping effects on near bottom sediment concentration were investigated by Hanes (1987), where he showed that longer period group waves (50 to 100 s) were more effective than shorter period group waves for enhancing sediment concentration. Sato (1992) performed laboratory experiments using bichromatic wave groups and showed enhanced suspended sediment concentrations due to an equivalent amount of monochromatic wave energy. But the question still remains as to how the wave grouping affects the amount of suspended sediment concentration, especially in the very near bottom.

In this paper, the authors will address the above question using a conceptual model of sediment entrainment by wave groups. First, a field experiment and data will be discussed. Then two methods of wave group analysis will follow, the run length method (Goda, 1985) and the envelope function method (List, 1991). Third, a conceptual model will be developed. Finally, group wave effects on the near bottom sediment concentration will be examined by the model and the validity of the monochromatic wave formulation will be tested.

### Field Experiment and Data

Fully automated sediment resuspension measurements were made near the southernmost part of Lake Erie from Oct. 20 to Oct. 28, 1992 (Figure 1). A galvanized steel tripod equipped with instruments and batteries (ARMS, the Acoustic Resuspension Measurement System) was situated on the flat fine sandy bottom in a water depth of 4.5m, 500m offshore. During the deployment, both

Figure 1. Map of *in situ* experiment site, Lake Erie, United States.

mild and weak storm events occurred and two 50 Mbytes data sets were collected. The suspended sediment concentration profiles are composed of 114 data points comprising a height of 132 cm above bottom (AB). Three-dimensional water particle velocities at the four heights ( 20, 50, 80, 110 cm AB) and the water pressure fluctuation at 212 cm AB were also obtained. The effective sampling rate of the acoustic concentration profiler was 1 Hz, the BASS (Benthic Acoustic Stress Sensor) current meters was 4 Hz and that of the pressure transducer was 4 Hz.

The flow characteristics of the two storms were extracted from the measured water surface fluctuations and velocity data. The first storm was mild, having a ten-minute averaged significant wave height of 56 cm. The second storm was very weak and not used in this analysis. The duration of the first storm spans almost 10 hours and is the data set analyzed in this paper. Figure 2 shows the significant wave orbital velocity,  $U_{bs}$ , calculated directly from the time trace of the orbital velocity,  $u_p(t)$ , at 20 cm AB, and the accompanying suspended sediment concentration at 5.2 cm AB.

Figure 2.  $U_{bs}$  and suspended sediment concentration at 5.2 cm AB.

For subsequent wave group analysis, the wave orbital velocity time series,  $u_b(t)$  was examined as opposed to the conventional choice of the surface water fluctuation time series. This is similar to the choice of Hanes(1991) who used  $u_b^2(t)$  to do spectral wave group analysis.

### Wave Group Analysis and Correlation

Real waves exhibit two distinct spectral energy distributions. One comes from the incident waves, the other comes from group waves. The former can be represented by a statistical or spectral wave estimate. The latter may be characterized by group wave parameters. As the incident wave parameters, the  $U_{bs}$ , at 20 cm, is selected for analysis because the  $U_{bs}$  shows a higher correlation with the near bottom sediment concentration than does the significant wave height does. In Figure 2 the value of the correlation coefficient between  $U_{bs}$  and sediment concentration at 5.2 cm AB is 0.96 and that using significant wave height data is 0.95.

### Wave Group Parameterization

Two approaches are taken in the study of wave groups. Mase(1987) emphasized the necessity of more than two group wave parameters to characterize wave groups. One is the statistical investigation of *run length* and the other is the *envelope function*. The former is a measure of height exceedance duration and the latter is a measure of overall amplitude variability. In this paper the run length method by Goda (1985) and the envelope function method of List (1991) are used to parameterize the wave groups.

#### *Run Length Method*

Wave groups can be quantitatively described by counting the number of consecutive waves exceeding a threshold value (Goda, 1985). A succession of such high waves is called a run of high waves, and the number of waves is termed the run length, denoted by  $j_1$ . Another statistic is the measure of separation between the two consecutive groups denoted by  $j_2$ . Figure 3 depicts statistics  $j_1$  and  $j_2$ . The crest and trough velocity difference,  $v_i$ , and wave order number are defined similar to Goda (1985).

#### *Envelope Function Method*

The envelope function method (List, 1991) is a

Figure 3. Schematic plot of the run lengths,  $j_1$  and,  $j_2$

method of obtaining the incident wave envelope,  $A(t)$  from the incident wave signal (Figure 4). The first procedure for determining  $A(t)$  is to high-pass filter the incident wave signal which removes the low-frequency or infra-gravity band waves. Then low-pass filtering of the envelope-related variance signal of  $A(t)$  gives the amplitude modulation of the incident waves. In this step the proper selection of a cutoff frequency for removing the incident waves is critical for obtaining a true envelope series. The final step is to multiply the envelope series by  $\pi/2$ . Using this final envelope function, the GF (Groupiness Factor) is defined as,  $GF=1.41S/A$  where  $S$  is the standard deviation of  $A(t)$  and  $A$  is the mean of  $A(t)$ .

Figure 4. Wave envelope function,  $A(t)$

A Conceptual Model

*Implication of Run Length ( $j_1$  and  $j_2$ ) Value*

Figure 5 conceptually examines the near bottom sediment response to four different combinations of run length,  $j_1$ , and  $j_2$ . In this model only three dominant processes are considered: The entrainment rate as

parameterized by  $v_i$ , delayed settling by the group waves and sediment settling itself. From the simulations, the high  $j_1$  and low  $j_2$  combination of the upper left box in Figure 5 shows the most enhanced concentration of near bottom sediments. The high value of  $j_1$  enables sediment entrainment and the low value of  $j_2$  allows for the sediment already in suspension to remain there. However, a theoretical analysis by Ewing (1973) reveals that this type of flow field does not occur frequently.

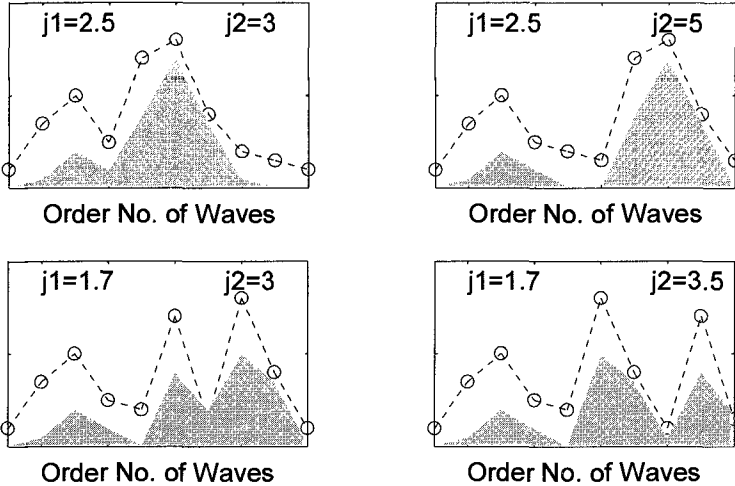

Figure 5. Sediment response due to the change of run length(-o-,  $v_i$  ; shadowed, sediment response)

*Implication of GF*

The groupiness factor defines the shape of the envelope function. High GF values indicate that the group wave envelope function possesses high temporal fluctuations. This high value of GF means a high value of the standard deviation when compared with the mean value of the envelope function  $A(t)$  (List, 1991). However, a high GF doesn't necessarily imply high sediment concentration because the probability of clustered high waves in time becomes rare. Figure 6 depicts this concept.

Results

The complete life cycle (10 hours) of a mild storm event in Lake Erie was measured. Consequently the

Figure 6. Sediment response due to the change of groupiness factor

evolution of wave groups and the resulting sediment response was completely recorded and analyzed. Run lengths  $j_1$  and  $j_2$  were estimated in 60, ten-minute blocks counted from the time of deployment. Figure 7 shows the changes in run length and the near bottom concentration at 5.2 cm AB.

Figure 7. Run lengths,  $j_1$  and  $j_2$  compared with suspended sediment concentration at 5.2 cm AB

In the figure, the run lengths  $j_1$  and  $j_2$  weakly follow the storm pattern, i.e. spin up and spin down, over the storm period. The correlation coefficients between concentration at 5.2 cm AB and  $j_1$  and  $j_2$  are  $r_{j_1} = 0.32$  and  $r_{j_2} = 0.33$ , respectively.  $j_1$  and  $j_2$  show fluctuations even during the middle or equilibrium period of the storm.

Figure 8 shows the GF variation during the storm period and near bottom concentration at 5.2 cm AB. Although it loosely follows the storm pattern, it is hard to extract any significant correlation ( $r_{GF}=0.36$ ) between the GF and the near bottom concentration at 5.2 cm AB.

As indicated by the conceptual model group waves

Figure 8. Groupiness factor(GF) compared with suspended sediment concentration at 5.2 cm AB

enhance the suspended sediment concentration by continuing entrainment of settling sediments which are already in suspension. To further see the effects of group waves we have to pick blocks with the same wave energy levels and compare only the suspended sediment concentration by group waves. In 10 hours of resuspension processes there are 5 pairs of comparable 10 minute blocks: 102 and 103; 107 and 108; 114 and 115; 119 and 120; and blocks 136 and 137. These pairs have very similar wave kinetic energy. Figure 9 summarizes the results.

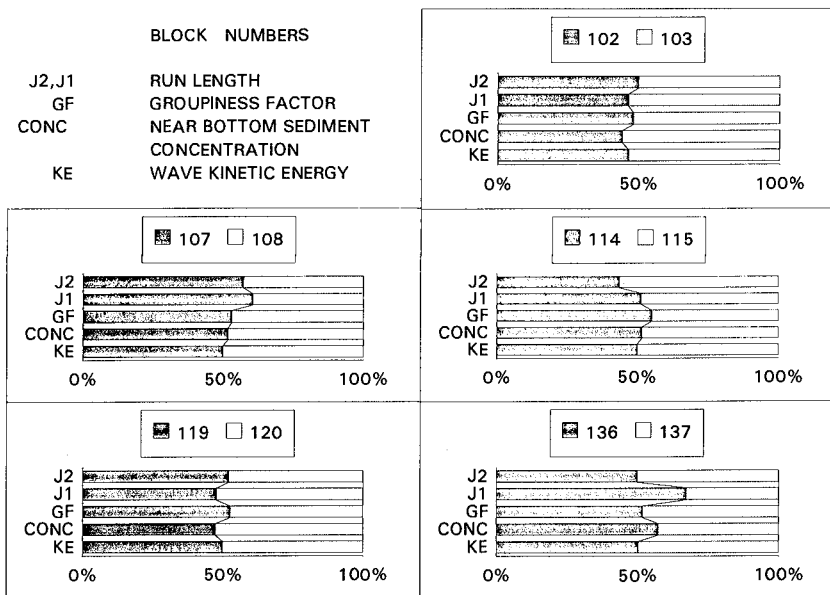

Figure 9. Test results of the conceptual model

From the first row of the upper right box, the combination of  $j_1(B102, \text{darker shadow bar}) < j_1(B103)$ ,  $j_2(B102) = j_2(B103)$ ,  $GF(B102) > GF(B103)$ . Thus the concentration of B102 is lower than that of B103. This case was also characterized by the conceptual model having lower concentration. In the second comparison, the group wave parameters of block 107 are bigger than those of block 108. Among them,  $j_1$  of block 107 shows the biggest difference. The result is higher concentration in block 107. It is noted that, even though the  $j_2$  of block 107 is bigger, the concentration of block 107 is higher. In other words, we can see the dominance of  $j_1$  in determining the amount of concentration. This idea is also suggested by the conceptual model. The third case examines how  $j_2$  can contribute to the enhancement of concentration.  $j_2$  of block 114 is far smaller than that of block 115, and results in a higher concentration. The fourth comparison in the bottom row, shows once again the dominance of  $j_1$  compared to GF.  $j_1$  of block 119 is smaller and results in a lower concentration. Also, a bigger  $j_2$  in block 110 helps to enhance the concentration. In the final comparison,  $j_1$  of block 136 is overwhelming. It leads to a much higher concentration. Again it shows the dominance of  $j_1$  in being the most effective group wave parameter in denoting enhanced concentration.

### Conclusions and Discussions

From the *in situ* measured data set we can verify the concepts of an enhanced near bottom suspended sediment concentration by group waves. Using the results obtained in this paper we can clarify some of the arguments in the study of sediment entrainment and resuspension due to both incident waves and group waves.

- i) Incident waves are the dominant forcing in determining the suspended sediment concentration at 5.2 cm AB.
- ii) Group waves may induce still higher concentration by delaying the suspended sediment settling.
- iii) The value of  $j_1$  governs the amount of enhanced sediment concentration and is the obvious indicator of group wave effects on the near bottom suspended sediment concentration.
- iv) The run lengths,  $j_1$  and  $j_2$ , are sufficient group wave parameters for describing enhanced sediment concentration. The GF(groupiness factor) is redundant.
- v) The monochromatic wave assumption in the bottom boundary layer models is correct to 96 percent

correlation coefficient when the significant wave orbital wave velocity is substituted for the monochromatic wave in a ten minute averaging period.

- vi) The remaining accuracy will be accounted for by group wave parameters particularly  $j_1$ .

## CHAPTER 132

### Geomorphological Analysis of a Beach and Sandbar System

Chen-Shan Kung<sup>1</sup>, Marcer Stive<sup>2</sup> and Geffery Toms<sup>3</sup>

#### Abstract

At Yunlin county a major development of over 10,000 ha of reclamation is being planned for port related industries. The development is taking place along a coast that bordered by Choshui river and the Wai-San-Ting sandbar. Detailed modeling using MIKE21 package with wave, flow and sediment transport modules were used to assess the morphological changes. Four such "relict" deltas were identified according to its ancient river courses. The decay of the sandbars was mostly independent due to the major discontinuities at sandbar headlands and tidal channels. The analysis of the complex morphological processes has provided an important insight into the probable impacts of coastal developments and guided the expensive and time-consuming model operations.

#### Introduction

At Yunlin county a major development of over 10,000 ha of reclamation is being planned for accommodating large scale port related industries and including a power plant and other developments. The reclamation, which covers shallow coastal areas along a 40 km length of coast, will be served by two new deep water ports.

The development is taking place along a stretch of coast that bordered in the North by Choshui river and in the South by the unique shoreline attached Wai-San-Ting sandbar. Wai-San-Ting, over 20 km long, is Taiwan's largest coast bar feature and morphologically is very active (Figure 1). Typhoons and a predominant NNE wind and wave climate approaching at very oblique angle to shore together with strong tidal currents are the main

<sup>2</sup>Delft Hydraulics, Emmeloord, The Netherlands

<sup>3</sup>Frederic R. Harris Inc., The Hague, The Netherlands

features shaping the existing coastline development.

During the six month winter period, the most frequently wave direction is NNE-N at offshore with 1.5-2 m in height, 5-6 second in period. In summer season, the most wave is coming from SSW direction with 0.5-1 m in height, 4.5-5.5 second in period. The tidal range is about 3-3.5 m in Yunlin coast with maximum current velocity of 1.5 m/s. Under these very rough sea conditions, a careful prediction is needed for the impacts' studies of the major reclamation project on the adjacent coast and sandbar systems for the Master plan study.

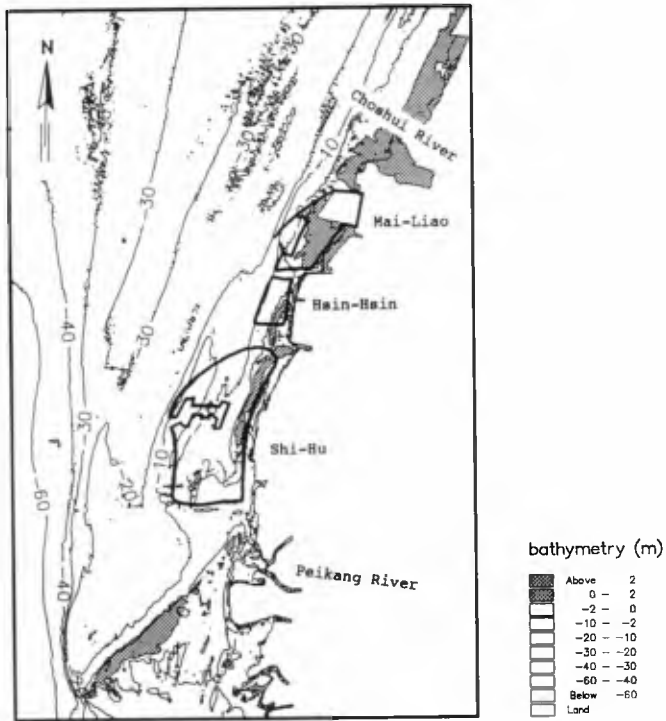

Figure 1 The Layout of Yunlin Offshore Industrial Estate in Yunlin Coast

Historical Development of Yunlin Coast

Most of the sediment between the shore and water depths of, say 20 to 30 m, originate from the various rivers and deposited in the last 100 to 300 years. At least four rivers have played an important role in the Yunlin coast, namely (from south to north) the Peikang river, the Old Huwei river, the New Huwei river and the Choshui

river. In the last 300 years, these four rivers were the tributary of the Choshui river system, the old river channel traces of these rivers are shown in figure 2. The first three mentioned rivers transported much more sediment in the last century than nowadays when they were the main channel of the Choshui river during the flood season.

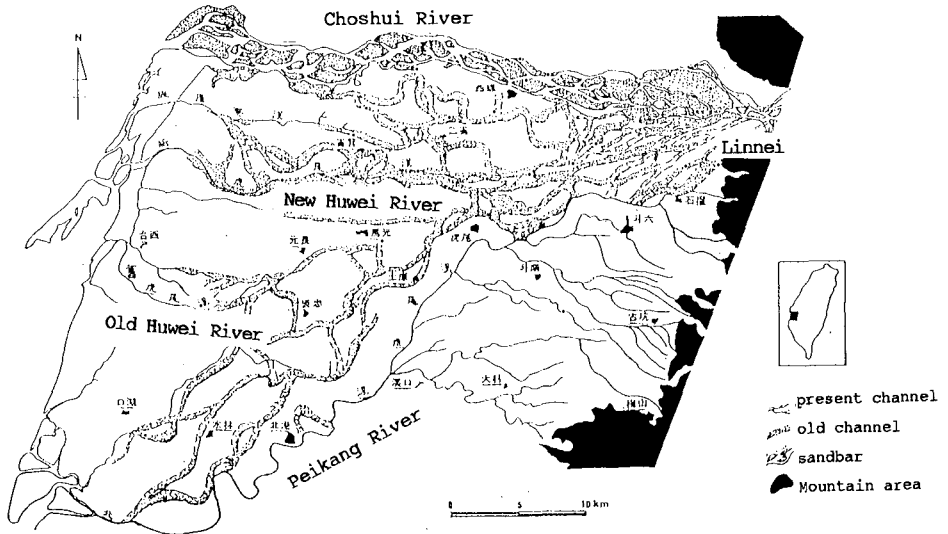

Figure 2 The old flow channel of Choshui river

In order to control the flood, several dikes and dams were constructed near the Linnei in 1911. The effect of these dikes was that the most of the drainage area of the Peikang river and the Old and New Huwei rivers were largely reduced. Their role as main sediment supplier to the coast stopped almost instantly. On the other hand, the Choshui rivers become the only sediment and water supplier to the coast. The consequence of this disturbance to the coast is the old river deltas are shrinking according to the reduction of the river sediment supply.

Figure 3 shows the historical development of the Wai-San-Ting coast line based on old map and remote sensing images. This historical movement of the sandbar system reflects this disturbance of the old Yunlin coast. The present-day coastal morphology still reflects the importance of the Peikang river and the Old Huwei river. The Wai-San-Ting and Pao-Zi-Liao sandbar are most likely the remnants of the deltas of these rivers. The disturbance of the old balance between river discharge and marine forces has results in significant morphological changes of these "relict" deltas. This is the more true for the wave dominated areas above, say, MSL -10 m. Due to the long morphological time scale at the sea bed below MSL -20 m, it still reflected the "old" situation of several decades ago. Wai-San-Ting has steadily moved southwards with

an average speed of 150 m/y. In the last two decades this southward movement took slowly rate of 75 m/y (Tsai and Huang, 1992). The orientation of depth contour of Wai-San-Ting has also undergone some changes. While the orientation of LW-line in 1932 was perpendicular to 305 degrees North, this is presently perpendicular to some 325 degrees North. This rotation took place mainly in the period among 1947 and 1972, the same period in which the largest southward movement occurred. The height of Wai-San-Ting has also undergone changes. In early time, Wai-San-Ting was a typical barrier coast, with heights above MSL along the entire coastline. Today, a lot of part of Wai-San-Ting is under the MSL.

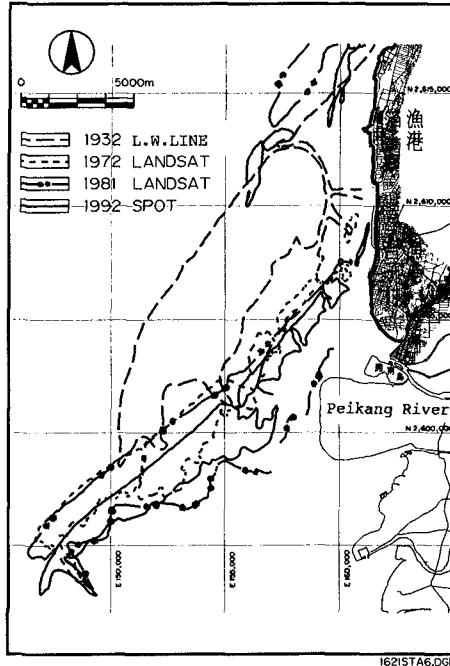

Figure 3 The historical changes of LW line of Wai-San-Ting

The Pao-Zi-Liao sandbar has undergone comparable changes in the last century like Wai-San-Ting: a steady southward movement (average above 100 m/y), its level being lowered in the last two decades, and a small westward rotation of 5 to 10 degrees. The general shape of the Pao-Zi-Liao has undergone significant changes. The sandbar has been broken up into separate bars that move southward and in a landward direction. The most southern sandbar has clearly become an isolated sand bar feature. The Pao-Zi-Liao sand bar system has degenerated more pronounced than Wai-San-Ting. Marine forces tend to disperse the sand bars and to smooth out the coast feature.

After the Linnei dike construction, the delta at Choshui river mouth becomes growing. The delta grows like a bow shape with strongly southward sediment transport. Due to the fish pond construction, the main stream of Choshui river changes toward to the north bank. The consequence of this disturbance is the sediment deposited at the north part of the delta during last two decades. After the construction of the Mailiao land reclamation (south of Choshui river mouth), the 10 meter's depth contour moved seawards. The MSL -20 m depth contour, on the other hand, did not follow this movement, which results in a steeping of the profile.

### Conceptual Model of Morphological Change

The above considerations reflect for a part the complexity of the area. A mix of physical processes determines the morphodynamic behavior of the sea bed, each with their own time and space scale. The complexity makes it virtually impossible to simply calculate the future development and the impact of reclamation. Uncertainty will always be part of such prediction, even with today's most advanced modeling tools, such as MIKE 21 (DHI, 1992) coastal hydrodynamic simulation system. Although state-of-the-art knowledge on the various physical processes has been incorporated in this model, this does not guarantee that the large-scale morphological developments are represented well. In order to assess the long term morphological changes in the Yunlin coast, a conceptual model is need. This conceptual model is based on good interpretation of historical data and information from recent measuring data. The conceptual model will indicates which questions have to be answered by the numerical model and the numerical model will aim at quantifying the conceptual model.

At Yunlin coast, the balance between river sediment transport and the onshore sediment transport is to a certain extent the dimension of a river delta. After the dike construction at Linnei, the Peikang river and Old Huwei river is lost its drainage function. Consequently, the sand bars and relict deltas start erosion under very rough wave climate. Since most of the wave energy comes from north to north-east directions, the direction of littoral transport will be southward. Although the coastline of Yunlin is straight, relatively large local gradients in the depth orientation occur. These local gradients in the orientation of the depth contour are caused by the presence of the old deltas along the coastline. These give rise to relatively large gradients in alongshore sediment transport, which results in morphological changes. The net southward littoral transport contributes to the net southward movement of sand bars and other morphological features.

Since the littoral transport is a function of incoming wave angle, the river delta will reach its equilibrium condition according its wave condition. Due to the prevailing north wave condition, the northern part of Wai-San-Ting delta coastline tends to erode, and the seaward part tends to accrete. Due to this erosion and accretion processes, the coastline of delta will be re-shaped, which causes the point of

maximum littoral transport to shift in downdrift direction. Hence, no limitation occurs to the seaward growth of the delta (Kung, 1993).

After the dike construction of Linnei, the erosion due to littoral transport is concentrated along the northern part of the coastline resulting in a steady rotating of Wai-San-Ting. Due to the sheltering effect of southward moving sand bars of Pao-Zi-Liao, the littoral transport at Wai-San-Ting as well as gradients in littoral transport, reduced and so the retreat of the coastline. Consequently, the rotation of Wai-San-Ting has remained more or less the same in the last two decades. The conceptual model of coast beach and sand bars morphological change in Yunlin coast is shown in figure 4.

Figure 4 The conceptual model of morphological changes of "relict" deltas

Quantitative Analysis

The quantitatively analysis of morphological changes in Yunlin coast is initially concentrated on the geostatistical analysis. Natural variables such as grain size,

shoreline change, land form, length of coast is all function of natural forces. Due to the stochastic nature of nature forces, the natural variables are also have stochastic characteristics in space and time domain. In a geostatistical model of shore line change or grain size distribution can represent its spatial structure of the natural forces and it's controlling physical processes.

A semi-variogram of shore line change among 1932 and 1992 based on Yunlin coast data is given in figure 5 as an example of the geostatistical analysis. The results show that the characteristic length is 7.5 km for the shore line changing rate. The characteristic lengths of the shore line change rates are similar to different periods - this reflects the similar processes within last century. The characteristic lengths also reflect the largest length scale of the coastline evolution process. The distance between Choshui river mouth and New Huwei river mouth is about 8 km and the distance between New Huwei river mouth and Old Huwei river mouth is 7 km. The length of the Santiaolun sand bar is 8 km. The length of north part of Wai-San-Ting is 7 km and the length of south part is 15 km. The geostatistic analysis shows that the shore line changes within the elic delta region are correlated and the shore lines' changes on different delta are more or less independent. The characteristic length of the grain size distribution is also 7.5 km along the main tidal direction. This length scale is very close to the tidal velocity length in Yunlin coast. The analysis shows that the morphological changes at deep water part, say MSL -20 m, is dominated by tidal movement.

Figure 5 The semi-variogram of shoreline changing rate along Yunlin coast

The UNIBEST model (DH, 1991) was used for evaluating the longshore sediment transport rate along the Yunlin coast. The offshore wave climate was simulated by

using MIKE21 NSW package based on the local wave measurement data. The typical tidal motion was simulated by using MIKE21 HD model. The current velocity and wave information are used in the long shore sediment transport by using UNIBEST model. The result of the longshore sediment transport calculation is shown in figure 6. Due to the large ground water subtraction along the coast, the possible land subsidence rate along the Yunlin coast is also shown in figure 6.

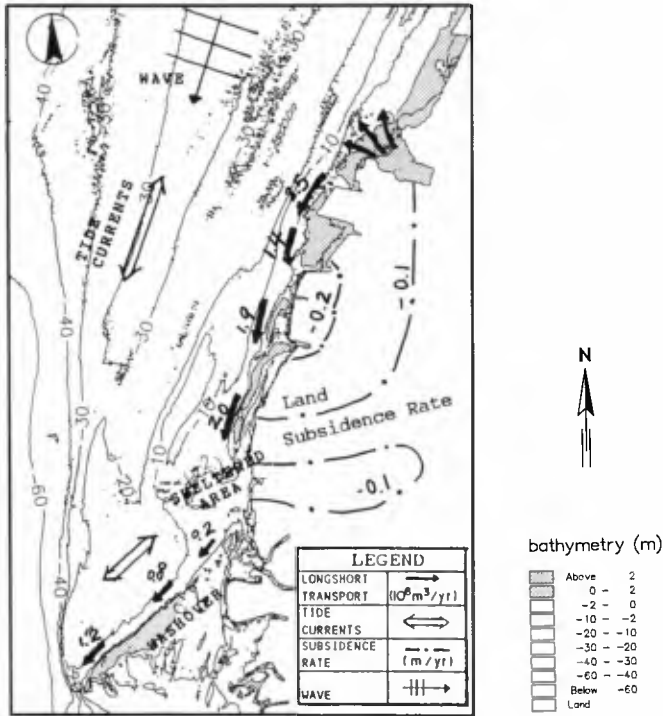

Figure 6 The longshore sediment transport rate of Yunlin coast

The longshore transport rate calculation shows that the local gradients of sediment transport exist at the tip of sand bar and along the Wai-San-Ting. The coast segment at south of Choshui river will be accretion due to the huge sediment supply from the river and south going littoral transport. The littoral transport rate is increased along the Santiaolun sand bar which imply the erosion of the sand bar. The littoral transport rate of the Wai-San-Ting is also gradually increasing along the southward direction. This local gradient implies the erosion of the Wai-San-Ting. The littoral transport rate is very minor at the north part of Wai-San-Ting due to the sheltering effect of

shelter by the Pao-Zi-Liao sand bar. The Pao-Zi-Liao sand bar its self has very huge littoral transport rate and gradient that means the significant morphological changes.

Does the Pao-Zi-Liao sand bar provide sediment transport to the Wai-San-Ting that is the main question on the impact assessment of the reclamation. If the Pao-Zi-Liao sand bar is the sediment supplier to the Wai-San-Ting, the reclamation will stop the sediment to the downstream area and causing more serious erosion. In order to answer this question, the more details two dimensional sediment transport simulation is need due to the complicated coast geometry and flow conditions. The well-known MIKE21 coastal hydrodynamic modeling system was used for analyzing the sediment transport capacity and initial movement of the coast sand near the Wai-San-Ting area. The 75 meter grid was used for balancing the computation time and the resolution. This gives around 4 grid point in the surf zone that provides reasonable accuracy for alongshore current simulation. Three different wave conditions was simulated by using NSW module which represents the wave climate of the area. The radiation stress field was used in the hydrodynamic simulation for calculation the velocity field under the tide and wave combination situation. The Engelund-Fredsoe formula (Engelund and Fredsoe, 1976) was used to calculated the sediment transport capacity at each grid point. The result of sediment transport capacity of Wai-San-Ting region is shown in figure 7.

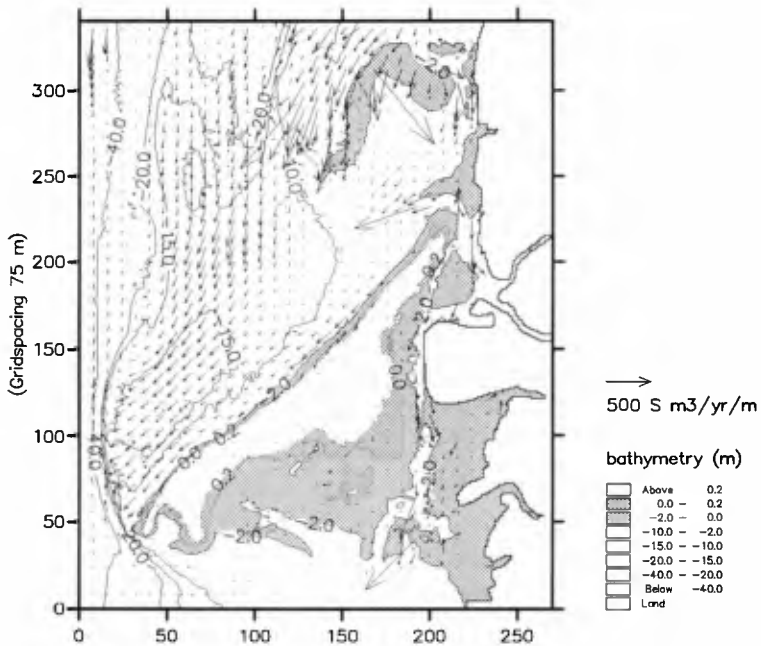

Figure 7 The sediment transport capacity near the Wai-San-Ting area

Results show that the sediment transport capacity is very small in the area between two sand bars due to the deeper water depth, stronger tidal current and the sheltering effect of Pao-Zi-Liao sand bar. Along the sand bars, the sediment transport capacity is much stronger that represent significant morphological changes along the sand bars. The sea bed initial movement of the sand bars is shown in figure 8. The result of simulation shows that two sand bars are evolution by itself. The migration of the Pao-Zi-Liao sand bar is toward to south-west and south. The sand bar does not provide sediment to the Wai-San-Ting that give quantitative explanation to the conceptual model.

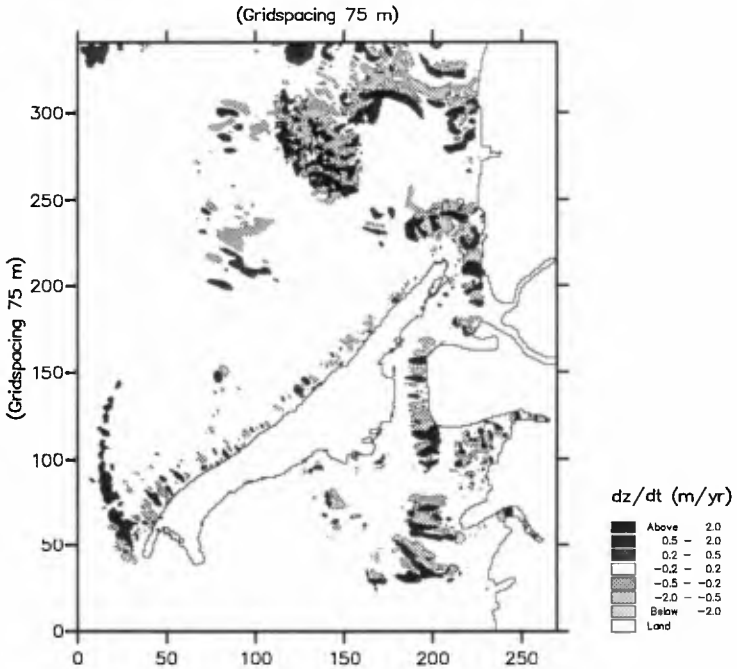

Figure 8 The sea bed initial moveemnt rate distribution of Wai-San-Ting area

Figure 9 shows the erosion and accretion area between the survey 1993 and 1994. The measurment bathymetry show similar erosion and accretion pattern among Pao-Zi-Liao and Wai-San-Ting sand bars. The maximum erosion rate is around 2m/year near the tips of the sand bars. The conceptual model and numerical model very well agree with the measurement data.

Figure 9 The erosion and accretion area among 1993 and 1994 bathymetry

### Discussion and Conclusion

A hypothesis concerning the historical morphological development of the coast and its present state in the ongoing coastal development process was formulated. Explanations to the questions concerning the origin and persistence of the main shoreline features were found in deeper water than the present surf zones. The -20 m contour marked the outer edge of very distinct historical features. The features were linked to the pathways of ancient river courses which deposited deltas over thousands of years. At the persistent and very oblique wave attack cut the original deltas to form the present day sandbars. Four such "relict" deltas were identified according to its river courses. Below -10 m the time scales of development and change were far larger

than those above -5 m, marking the difference between tide and wave dominated Zones. In the zone -5 to -10 m combined wave and tide effects dominate the processes.

Detailed modeling using MIKE21 package with wave, flow and sediment transport modules together with geostatistical analysis were used to assess key elements of the morphological hypothesis. Critical findings for the Yunlin coast morphological processes were:

(1) that the decay of the sandbars was mostly independent from the upstream coastal sediment supply due to the major discontinuities at sandbar headlands and tidal channels.

(2) That the deep water transport due to currents and waves outside the surf zone was not playing an important role in the development of the shoreline feature.

The analysis of the complex morphological processes has provided an important insight into the probable impacts of coastal developments and guided the expensive and time-consuming model operations. Many of the processes and investigations are common to other complex sandbar coasts worldwide.

## CHAPTER 133

# Suspended Sediment Transport in Inner Shelf Waters During Extreme Storms

O.S. Madsen<sup>1</sup> T.A. Chisholm<sup>2</sup> and L.D. Wright<sup>2</sup>

### Abstract

The paper presents a simple model for the prediction of longshore and crossshore suspended sediment transport rates outside the surf zone in water depths less than 20 m or so. The model consists of a depth-resolving hydrodynamic component, which considers wind-induced currents in the presence of waves and includes the Coriolis effect. The hydrodynamic model component is coupled with a model for the mean suspended sediment concentration to produce a prediction of the depth-varying mean suspended sediment flux vector. In addition to specification of environmental conditions, *i.e.* waves and sediment characteristics as well as current driving forces (wind velocity and pressure gradient), the model requires three parameters:  $C_a$ , the wind-drag coefficient;  $k_N$ , the movable bed bottom roughness; and  $\gamma_0$ , the resuspension parameter. These three model parameters were determined (Madsen et al., 1993) from a subset of field data obtained in 13 m depth off Duck, North Carolina, during the severe “Halloween Storm” of 1991 and are used to perform a limited comparison between predicted and observed current velocity vectors and mean suspended sediment concentrations. The agreement is very encouraging and model prediction of an offshore loss of 22 m<sup>3</sup> sediment per m beach compares favorably with the loss of 27 to 54 m<sup>3</sup> obtained from beach profile surveys.

## Introduction

The importance of storms to coastal change has been documented extensively. Storm-driven processes are also known to dominate sediment transport on the inner shelf, *i.e.* outside the surf zone in water depths up to 20 m or so. However, very little quantitative information is available on near-bottom currents, bed shear stresses and sediment fluxes for the reliable prediction of sediment transport processes on the inner shelf which forms an important link between the extensively studied processes within the surf zone and deeper continental shelf waters.

Across the inner shelf currents are induced by wind and pressure gradients more so than by wave-associated radiation stresses. This paper presents a depth-resolving model for the wind-induced and pressure gradient driven (tidal) current in inner shelf waters along fairly straight coastlines. The bottom boundary condition for the current is specified in terms of the apparent bottom roughness experienced by currents in the presence of waves and is calculated from the theory of Madsen (1994). Since the determination of the apparent bottom roughness requires the current to be specified, an iterative solution procedure is necessary to solve for the depth-varying current velocity vector. In addition to wave-current interaction in the bottom boundary layer the model includes Coriolis effects, since crossshore sediment transport is sensitive to even minor changes of the current velocity vector's direction.

The current shear velocities and eddy viscosities obtained from the hydrodynamic model are used to predict the profiles of mean suspended sediment concentration. For the suspended sediment concentration the effect of waves is again manifesting itself through the specification of a reference concentration at the bottom. Mean suspended sediment fluxes are obtained from the product of current velocity and mean concentration, and integration over depth produces the total mean suspended sediment transport rate in the alongshore and crossshore directions.

The unique data set obtained during the severe "Halloween Storm" of 1991 is used to perform a limited comparison between observations and predictions by the hydrodynamic and sediment transport model. Although a small subset of this available field data set was used (Madsen et al., 1993) to determine empirical values for important model parameters (wind-drag coefficient, movable bed roughness, and resuspension parameter) this comparison is quite encouraging, as is the model's prediction of a net loss of sediment per meter beach during the entire "Halloween Storm" which is within a factor of two from the loss determined by beach profile surveys.

### The Depth-Resolving Hydrodynamic Model

Under the assumptions of slowly varying forcing in space and time the equations governing the depth-dependent current velocities,  $u = u(z)$  and  $v = v(z)$  of a constant density,  $\rho$ , fluid in the horizontal  $xy$ -plane may be written

$$\frac{Du}{Dt} \simeq 0 = -\frac{1}{\rho} \frac{\partial p}{\partial x} + fv + \frac{\partial}{\partial z} \left( \nu_t \frac{\partial u}{\partial z} \right) \quad (1)$$

$$\frac{Dv}{Dt} \simeq 0 = -\frac{1}{\rho} \frac{\partial p}{\partial y} - fu + \frac{\partial}{\partial z} \left( \nu_t \frac{\partial v}{\partial z} \right) \quad (2)$$

in which  $f = 1.45 \cdot 10^{-4} \sin(\text{latitude}) s^{-1}$  is the Coriolis Parameter,  $z$  is the vertical coordinate ( $z = 0$  at the bottom), the pressure gradients,  $\partial p/\partial x$  and  $\partial p/\partial y$ , are assumed independent of  $z$  corresponding to hydrostatic pressure distribution and  $\nu_t$  is a turbulent eddy viscosity.

Introducing the geostrophic current defined by

$$f\{U_g, V_g\} = -\frac{1}{\rho} \left\{ \frac{\partial p}{\partial y}, -\frac{\partial p}{\partial x} \right\} \quad (3)$$

multiplication of (2) by  $i = \sqrt{-1}$  followed by addition of (1) leads to a single governing equation

$$\frac{\partial}{\partial z} \left( \nu_t \frac{\partial W}{\partial z} \right) - ifW = 0 \quad (4)$$

in the complex velocity

$$W = (u - U_g) + i(v - V_g) \quad (5)$$

The complete analogy of (4) to the equation governing oscillatory turbulent bottom boundary layer for simple periodic waves, *e.g.* Eq. (4) of Madsen (1994), is noted. Here the Coriolis Parameter,  $f$ , replaces the radian frequency,  $\omega$ , and the imaginary part of the solution of (4) represents the  $y$ -component of the velocity whereas it, in the wave boundary layer case, is without physical significance.

In order to solve (4) it is first necessary to specify the turbulent eddy viscosity,  $\nu_t$ . Here we follow the suggestion of Madsen (1977) as did Jenter and Madsen (1989) by adopting an eddy viscosity which increases linearly with distance from a sheared boundary and is scaled by this boundary's shear velocity,  $u_* = \sqrt{\tau/\rho}$ . In the present case wind stress,  $\tau_s$ , acts on the free

surface,  $z = h$ , and a bottom stress,  $\tau_c$ , acts on the bottom  $z = 0$ . The resulting model for  $\nu_t$  therefore becomes

$$\nu_t = \begin{cases} \kappa u_{*c} z & \text{for } 0 < z < z_m \\ \kappa u_{*s} (h - z) & \text{for } z_m < z < h \end{cases} \tag{6}$$

in which  $\kappa =$  von Karman's constant ( $\kappa = 0.4$ ), and  $z_m$  is the distance above the bottom at which the transition from bottom to surface shear dominated turbulence is made. This level is chosen, as suggested by Madsen (1977), to be scaled by the relative magnitude of the two shear velocities, *i.e.*

$$z_m = \frac{u_{*c}}{u_{*s} + u_{*c}} h \tag{7}$$

With  $\nu_t$  given by (6) and (7) the general solution of (4) is obtained (Jenter and Madsen, 1989) in terms of zeroth order Kelvin functions

$$W = W_b = A_b (ber 2\sqrt{\zeta_b} + ibei 2\sqrt{\zeta_b}) + B_b (ker 2\sqrt{\zeta_b} + ikei 2\sqrt{\zeta_b}) \quad \text{for } 0 < \zeta_b < \zeta_{bm} \tag{8}$$

and

$$W = W_s = A_s (ber 2\sqrt{\zeta_s} + ibei 2\sqrt{\zeta_s}) + B_s (ker 2\sqrt{\zeta_s} + ikei 2\sqrt{\zeta_s}) \quad \text{for } 0 < \zeta_s < \zeta_{sm} \tag{9}$$

in which  $A_b, B_b, A_s$  and  $B_s$  are arbitrary complex constants, and the nondimensional vertical coordinates are given by

$$\zeta_b = \frac{zf}{\kappa u_{*c}} \quad \text{and} \quad \zeta_s = \frac{(h-z)f}{\kappa u_{*s}} \tag{10}$$

and  $\zeta_{bm}$  and  $\zeta_{sm}$  are the matching coordinates given by (10) with  $z = z_m$ .

The arbitrary constants in (8) and (9) are determined by the boundary condition at the surface

$$\left( \kappa u_{*s} \sqrt{\zeta_s} \frac{dW_s}{d(2\sqrt{\zeta_s})} \right)_{\zeta_s \rightarrow 0} = -\frac{1}{\rho} (\tau_{sx} + i\tau_{sy}) \tag{11}$$

in which the wind shear stress at the free surface is given by

$$\tau_s e^{i\phi_a} = \rho_a C_a U_a^2 e^{i\phi_a} = \tau_{sx} + i\tau_{sy} \tag{12}$$

with  $\rho_a$  being the air density,  $U_a$  the wind speed,  $\phi_a$  the wind direction measured from the x-axis and  $C_a$  is the wind-drag coefficient; and the turbulent no-slip condition at the bottom

$$W_b = -(U_g + iV_g) \quad \text{at} \quad \zeta_b = \zeta_{bo} = \frac{z_{oa}f}{k u_{*c}} \tag{13}$$

in which  $z_{oa}$  denotes the apparent bottom roughness, *i.e.* the bottom roughness experienced by the current in the presence of waves (Madsen, 1994).

The additional conditions are supplied by the requirement of continuity of velocity and shear stress at the matching level, *i.e.*

$$W_b(\zeta_b = \zeta_{bm}) = W_s(\zeta_s = \zeta_{sm}) \tag{14}$$

and

$$u_{*c} \sqrt{\zeta_{bm}} \frac{dW_b}{d(2\sqrt{\zeta_b})} \Big|_{\zeta_b = \zeta_{bm}} = -u_{*s} \sqrt{\zeta_{sm}} \frac{dW_s}{d(2\sqrt{\zeta_s})} \Big|_{\zeta_s = \zeta_{sm}} \tag{15}$$

in which the minus signs in (11) and (15) are the result of  $\zeta_s$  being proportional to  $(h - z)$  rather than  $z$ .

Formally the arbitrary constants may be obtained by sloving (11) through (15). Series expansions for the zeroth order Kelvin functions and their derivatives found in Abramowitz and Stegun (1972; Chapter 9) greatly facilitate this task. However, the vertical coordinate used in the lower (bottom) layer depends on the bottom shear stress,  $u_{*c} = \sqrt{\tau_c/\rho}$ , which is *a priori* an unknown. The same is true for the apparent bottom roughness which depends on wave-current interaction within the wave bottom boundary layer and hence needs a specification of the current characteristics before it can be determined (see Madsen, 1994). Finally, the pressure gradients need to be determined (or known) in order to solve the problem.

#### The Bottom Shear Velocity, $u_{*c}$

To overcome the problem of an initially unknown value of the bottom shear stress, we proceed in an iterative manner by assuming a value of  $u_{*c}$  to obtain the solution for  $W_b$  and subsequently evaluate the bottom shear stress from

$$\tau_c e^{i\phi_c} = \rho \kappa u_{*c} \sqrt{\zeta_{bo}} \frac{dW_b}{d(2\sqrt{\zeta_b})} \Big|_{\zeta_b = \zeta_{bo}} \quad (16)$$

which, since  $\tau_c = \rho u_{*c}^2$ , yields a "new" value of  $u_{*c}$ . When convergence has been achieved the angle  $\phi_c$  denotes the direction of the bottom shear stress and hence the direction of the near-bottom current velocity.

The Apparent Bottom Roughness,  $z_{oa}$

The evaluation of the apparent bottom roughness depends on the wave characteristics, the physical (movable bed) bottom roughness,  $k_N$ , and the current specification. The details of a spectral wave-current interaction model are presented by Madsen (1994). Here it suffices to mention that the wave motion is specified by a representative periodic wave of near-bottom orbital velocity amplitude,  $u_{br}$ , radian frequency,  $\omega_r$ , and direction of propagation  $\phi_{wr}$  (Eqs. (22), (23) and (24) in Madsen, 1994). From this information, along with  $k_N$  and an assumed current specified by its shear stress  $\tau_c$  and direction  $\phi_c$ , the solution of the wave-current interaction problem is detailed by Madsen (1994) and leads to a solution for the apparent bottom roughness obtained from Eq. (11) of Madsen (1994)

$$z_{oa} = \left( \frac{k_N}{30\delta_{wc}} \right)^{u_{*c}/u_{*r}} \delta_{wc} \quad (17)$$

in which  $\delta_{wc}$  and  $u_{*r}$  denote the wave bottom boundary layer thickness and the shear velocity based on the maximum combined wave-current bottom shear stress, respectively, and are defined by Eqs. (36) and (26) of Madsen (1994).

Specifying the no-slip condition for the current in terms of the apparent roughness  $z_{oa}$ , avoids the determination of the current velocity profile within the wave boundary layer. This information is, however, needed for the evaluation of suspended sediment flux immediately above the bottom. With general reference to Madsen (1994) for details, we merely state the proper form for the current velocity profile within the wave bottom boundary layer as

$$u + iv = \frac{u_{*c} u_{*c}}{u_{*r} \kappa} \ell n \frac{30z}{k_N} e^{i\phi_c} \quad (18)$$

valid for  $z < \delta_{wc}$  with  $\phi_c$  obtained from (16).

The Pressure Gradients,  $\partial p/\partial x$  and  $\partial p/\partial y$ 

It is consistent with the assumption of slow spatial variability to assume an essentially straight coastline. We therefore choose a coordinate system with a shore-parallel x-axis. Furthermore, limiting the model's application to water depths less than 10 to 20 m, corresponding to distances from shore of the order of at most 1 km or so, suggests that any crossshore depth-averaged current should be negligible.

For wind-dominated storm events the uniformity in the shore-parallel x-direction justifies the neglect of an alongshore mean surface slope and results in a pressure gradient of  $\partial p/\partial x \simeq 0$ . If the longshore mean surface slope cannot safely be assumed negligible an approximate methodology for obtaining an estimate of  $\partial p/\partial x$  to be used in conjunction with the steady depth-resolving model is presented by Chisholm (1993) and is outlined in Appendix A.

Imposing the negligible crossshore mean current on the general solution yields the condition

$$\int_0^h v dz \simeq \int_0^h \Im \{W + iV_g\} dz = 0 \quad (19)$$

from which the crossshore pressure gradient,  $\partial p/\partial y$ , may be determined with  $W$  given by (8) and (9). For the simplest model application (3) shows that  $V_g = 0$  since  $\partial p/\partial x \simeq 0$ .

## Solution Strategy

To apply the depth-resolving hydrodynamic model it is assumed that the representative periodic wave characteristics,  $u_{br}$ ,  $\omega_r$  and  $\phi_{wr}$  as defined by Madsen (1994) are known. From the wave conditions and knowledge of the bottom sediment characteristics the physical (movable bed) bottom roughness,  $k_N$ , may be estimated from, *e.g.* Wiberg and Harris (1994) for rippled bed or Madsen et al. (1993) for flat movable bed. The surface wind shear stress, is obtained from (12) with  $C_a$  estimated from, *e.g.* Wu (1982) or Madsen et al. (1993).

Assuming the wind to have a substantial longshore component an initial estimate of the bottom shear stress is obtained by considering the alongshore flow to be approximately described by as a Couette flow, *i.e.*  $\tau_c = \rho u_{zc}^2 \simeq \tau_s \cos \phi_a$ . With this shore-parallel current bottom shear stress "known" the wave-current interaction model by Madsen (1994) may be used to obtain a first estimate of the apparent bottom roughness,  $z_{oa}$ , from (17).

The depth-resolving hydrodynamic model may now be formally solved. The "unknown" crossshore pressure gradient,  $\partial p/\partial y$  (or  $U_g$ ), is obtained from

(19) and the bottom shear stress vector and shear velocity are upgraded by use of (16). We may now re-evaluate the apparent bottom roughness from (17) and continue the iteration until convergence has been achieved.

### The Mean Suspended Sediment Transport Model

The concentration of suspended sediment is described by the diffusion equation. Limiting the model's applicability to slowly varying conditions in space and time, *i.e.* disregarding variations over the timescale of the wave motion, the equation governing the mean suspended sediment concentration,  $c(z)$ , reads

$$\frac{Dc}{Dt} \simeq 0 = \frac{\partial}{\partial z} \left( \nu_s \frac{\partial c}{\partial z} \right) + \frac{\partial}{\partial z} (w_f c) \quad (20)$$

in which  $w_f (> 0)$  denotes the fall velocity of the sediment and  $\nu_s$  is the eddy diffusivity.

The eddy diffusivity is taken equal to the eddy viscosity used in the depth-resolving hydrodynamic model, *i.e.*  $\nu_s = \nu_t$  with  $\nu_t$  given by (6). The hydrodynamic model, however, did not explicitly include the description of the current profile in the immediate vicinity of the bottom, *i.e.* within the wave bottom boundary layer of thickness  $\delta_{wc}$ . Within the wave boundary layer the eddy viscosity and hence the eddy diffusivity is given by the wave-current interaction model (see Madsen, 1994) and we therefore have

$$\nu_s = \begin{cases} \kappa u_* r z & 0 < z < \delta_{wc} \\ \kappa u_* c z & \delta_{wc} < z < z_m \\ \kappa u_* s (h - z) & z_m < z < h \end{cases} \quad (21)$$

Integration of (20) leads to an expression for the vertical flux of suspended sediment which, by virtue of the steady state assumption, must be zero and the resulting equation becomes

$$\frac{dc}{dz} = -\frac{w_f}{\nu_s} c \quad (22)$$

To solve this equation with  $\nu_s$  given by (21) one boundary condition is needed.

### The Reference Concentration

We adopt the reference concentration,  $c_R$ , specified at a given elevation,  $z = z_R$ , within the wave boundary layer, *i.e.*  $z_R < \delta_{wc}$ , as our boundary

condition. Following Smith and McLean (1977) we assume the functional form of the mean reference concentration to be

$$c_R = \gamma_0 c_b \left( \frac{|\tau'_b|}{\tau_{cr}} - 1 \right) \quad \text{at} \quad z = z_R = 7d \quad (23)$$

in which  $c_b$  is the volume concentration of sediment in the bed,  $\tau'_b$  is the skin friction bottom shear stress due to the combined wave-current flow,  $\tau_{cr}$  is critical shear stress for initiation of motion (Madsen and Grant, 1976), and  $\gamma_0$  is the resuspension parameter. The functional form of (23) is supported by the simple bedload formula for saltating grains derived by Madsen (1991). Regarding the transport that takes place within the saltation layer as bedload (and therefore not to be included in the suspended load transport) the level at which the reference concentration is specified is taken as the top of the saltation layer which is approximated as  $z_R = 7d$ , with  $d$  being the diameter of the bottom sediment.

The skinfriction shear stress,  $\tau'_b$ , in (23) includes the contribution from wave motion. In fact, it is to be expected that  $|\tau'_b|$  is dominated by wave action with currents playing only a secondary role in the suspension of bottom sediments. Since the intended application of the present model is for stormy conditions, we shall assume wave-dominance and take

$$\tau'_b \simeq \tau'_w = \tau'_{wm} \cos(\omega_r t + \phi'_{\tau r}) \quad (24)$$

where  $\phi'_{\tau r}$  is a phase angle which, in the present context, is of no importance, and

$$\tau'_{wm} = \frac{1}{2} \rho f'_w u_{br}^2 \quad (25)$$

is the maximum skinfriction bottom shear stress of the representative periodic wave defined by Madsen (1994) evaluated for a bottom roughness equal to the mean diameter of the bottom sediment. Given the functional form of (23) it follows logically that the representative periodic wave defined by Madsen (1994), *i.e.* not the "significant wave", is the proper choice for the determination of the mean reference concentration in combined wave-current boundary layer flows.

Introduction of (24) in (23) therefore results in a relatively simple expression for the mean reference concentration for wave-dominated flows

$$c_R = \gamma_0 c_b \left( \frac{2}{\pi} \frac{\tau'_{wm}}{\tau_{cr}} - 1 \right) \quad \text{at} \quad z = z_R = 7d \quad (26)$$

with  $\tau'_{wm}$  given by (25) which is readily evaluated using formulas given by Madsen (1994). It is important to emphasize at this point that the empirical value of the resuspension parameter,  $\gamma_0$ , is intimately tied to the level,  $z_R$ , at which it is specified and to the particular theoretical model used to extrapolate actual concentration measurements from their level, to the chosen reference level. Wikramanayake (1992), using the present reference level obtained values of  $\gamma_0 = 2 \cdot 10^{-3}$  and  $2 \cdot 10^{-4}$  for rippled beds and flat movable beds, respectively. These values may be used for preliminary considerations, but it should be recognized that a great deal of uncertainty is associated with the specification of  $\gamma_0$ .

### The Mean Suspended Sediment Concentration

With the mean concentration governed by (22), the eddy diffusivity given by (21) and the reference concentration specified by (26) the solution for the mean suspended sediment concentration is readily obtained.

*Within the wave boundary layer,  $z_R < z < \delta_{wc}$  we obtain*

$$c = c_R \left( \frac{z}{z_R} \right)^{-\frac{w_f}{\kappa u_* r}} \quad (27)$$

*In the bottom layer of the water column,  $\delta_{wc} < z < z_m$ , integration of (21) and matching the concentration with (26) at  $z = \delta_{wc}$  gives*

$$c = c_R \left( \frac{\delta_{wc}}{z_R} \right)^{-\frac{w_f}{\kappa u_* r}} \left( \frac{z}{\delta_{wc}} \right)^{-\frac{w_f}{\kappa u_* c}} \quad (28)$$

*In the surface layer of the water column,  $z_m < z < h$ , the mean concentration is given by*

$$c = c_R \left( \frac{\delta_{wc}}{z_R} \right)^{-\frac{w_f}{\kappa u_* r}} \left( \frac{z_m}{\delta_{wc}} \right)^{-\frac{w_f}{\kappa u_* c}} \left( \frac{h - z_m}{h - z} \right)^{-\frac{w_f}{\kappa u_* s}} \quad (29)$$

### Mean Suspended Sediment Transport

The complex current velocity profile

$$u + iv = W + U_g + iV_g \quad (30)$$

is obtained from (3), (8) and (9), with (8) replaced by (18) within the wave boundary layer, for the three depth-intervals for which the mean concentrations of suspended sediments are given by (27) through (29). The depth-integrated complex suspended sediment flux vector is evaluated from

$$q_{sx} + iq_{sy} = \int_{z_R}^h (u + iv)cdz \quad (31)$$

### Extension of Model to Sediment Mixtures

The preceding presentation of the mean suspended sediment transport model treated the sediment as uniform, *i.e.* represented by a single size-class of diameter  $d$ . The model is formally extended to sediment mixtures consisting of several size-classes represented by diameter  $d_n$  for the  $n$ 'th size-class.

For mixtures the current velocity profiles are obtained with the mean sediment diameter,  $d_{50}$ , used to represent the sediment mixture in the evaluation of the movable bed roughness,  $k_N$ , and the skinfriction bottom shear stress. The reference concentration is obtained from (26) for the individual size-class with  $c_b$  and  $\tau_{cr}$  replaced by the values corresponding to the particular size-class,  $d_n$ . Finally, the concentration of each size class is obtained from (27) through (29) with  $w_f$  replaced by  $w_{fn}$  and the total mean concentration of suspended sediment is obtained by summation of the contributions from the individual size classes.

It is emphasized that the extension of the model to sediment mixtures, as presented above, is purely formal and based on a number of essentially unsubstantiated generalizations as well as several omissions. Thus, the generalization of the reference concentration formulation to mixtures, which follows the suggestion of Wiberg et al. (1994) is unsubstantiated. In fact, Wilcock and Southard (1988) present data on the initiation of motion of individual size-classes in a mixture that suggest the critical shear stress to be the same for all size-classes, in direct conflict with the proposed generalization. The formal extension of the model to sediment mixtures omits any consideration of armouring effects which ought to be included in a physically realistic manner to produce a complete model. At present the weaknesses of the proposed extension to sediment mixtures become part of the model and are reflected in the empirical determination of model parameters such as the resuspension parameter  $\gamma_0$ , obtained from this model.

### Model Application

The hydrodynamic and suspended sediment transport model presented in the preceding sections contains two parameters that are model-specific: the movable bed roughness,  $k_N$ , and the resuspension parameter,  $\gamma_0$ . These parameters and the wind-drag coefficient  $C_a$  were determined for an extreme storm event, the "Halloween Storm" of 1991, from a selected subset of field data obtained at the U.S. Army Corps' Field Research Facility (FRF) in 13 m water depth off Duck, North Carolina. For details of field experiments

and the data analysis, which produced values of  $k_N = 0.144 \text{ cm} \simeq 15 d_{50}$ ,  $\gamma_0 = 4.0 \cdot 10^{-4}$  and  $C_a = 5.0 \cdot 10^{-3}$ , the reader is referred to Madsen et al. (1993). Here it suffices to point out that a subset of five bursts of twenty three available were used to obtain the hydrodynamic parameters,  $k_N$  and  $C_a$ , whereas  $\gamma_0$  was obtained from analysis of three bursts of twelve available.

Adopting these parameters for the entire storm period, October 27 through November 1, 1991, with wind records from the FRF and augmenting our wave information by use of data from FRF's 8 m pressure sensor array (our tripod surcame to the elements around 18:00 h (EST) on October 30, 1991, when the significant wave height reached  $H_s \simeq 4.5 \text{ m}$  with a peak period of  $T_p \simeq 20 \text{ s}$ ) the required input for application of the model is available.

Figure 1 shows a comparison of predicted and measured longshore (southerly directed when positive) and crossshore (offshore directed when positive) currents at 29 cm above the bottom. The predicted relatively rapid increase in longshore current around 35 h, associated with a rapid increase in wind speed from about 7 m/s to about 16 m/s, precedes and exceeds the measured currents. The reason for this is most likely the neglect of unsteady effects in the hydrodynamic model formulation. Overall agreement between predicted and observed longshore currents is, however, considered acceptable and quite encouraging given the simplicity of the model. The agreement between predicted and observed crossshore currents is far less striking. Given, however, the very low crossshore current velocities the measurements are expected to be extremely sensitive to experimental errors, making detailed point-by-point comparison less meaningful.

Figure 2 shows a comparison of predicted and observed suspended sediment concentrations at 27 cm and 87 cm above the bottom. Considering the fact that only two of the twelve experimental observations at these elevations were used to determine  $\gamma_0$  the overall agreement between predicted and observed suspended sediment concentrations is very encouraging.

The model results presented in Figures 1 and 2 were obtained without inclusion of a longshore pressure gradient, *i.e.* taking  $\partial p / \partial x = 0$ . It is of practical interest to point out that the first model run, which was based on the initial estimate of  $z_{oa}$  obtained in the manner proposed above, yielded results that were practically indistinguishable from the results obtained after two and three iterations. Also, model runs were performed in which the longshore pressure gradient was estimated from tide records at Virginia Beach and Kitty Hawk, North Carolina, following the procedure described in Chisholm (1993). The inclusion of longshore tidal forcing resulted in only minor modifications of the longshore current of at most 5 cm/s and a negligible (less than 0.2 cm/s) effect on the crossshore velocity. This apparent success of the sediment transport model in its simplest form is, of course, a

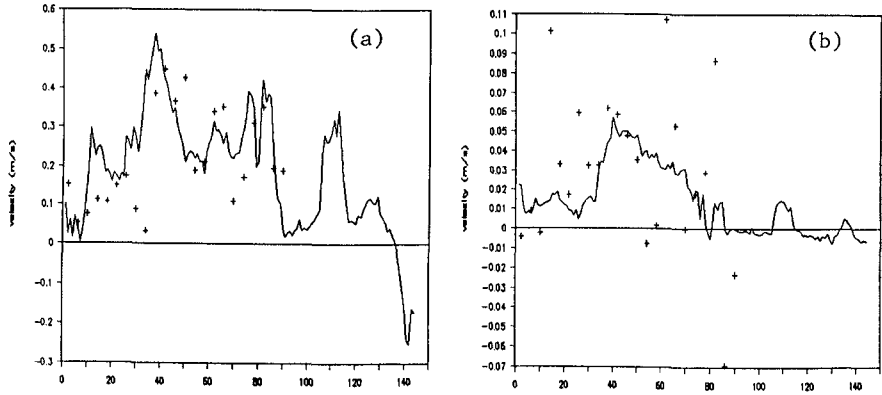

Figure 1: Comparison of measured (crosses) and predicted (full lines) long-shore, (a), and cross-shore, (b), velocities (m/s) 29 cm above the bottom as a function of time in hours from 0:00 on 27 October, 1991. Measurements at  $t = 58, 62, 66, 78$  and  $82$  hours used in model calibration to obtain  $k_N$  and  $C_a$ .

Figure 2: Comparison of measured (triangles) and predicted (full lines) mean suspended sediment concentration (volumetric) at 27 cm, (a), and 87 cm, (b), above the bottom as a function of time in hours from 0:00 on 27 October, 1991. Measurements at  $t = 58$  and  $66$  hours used in model calibration to obtain  $\gamma_0$ .

result of the specific nature of the extreme conditions encountered during the "Halloween Storm" and should not be interpreted to mean that longshore pressure gradients generally may be neglected.

### Conclusions

A relatively simple hydrodynamic model for currents induced in inner shelf waters extending from the surf zone to depths of 10 to 20 m along relatively straight coastlines was presented. The model includes Coriolis effect and wave-current interactions in the bottom boundary layer and predicts the current velocity profiles in both the longshore and crossshore directions.

The hydrodynamic model is coupled with a model for the prediction of the mean suspended sediment concentration to produce a mean suspended sediment transport model for inner shelf coastal waters.

The capabilities of the model were illustrated by its application to an extreme storm event, the "Halloween Storm", for which field data were available for comparison with model predictions. The limited comparison presented in this paper will be expanded upon in forthcoming publications. However, the comparison between predictions and observations presented here suggests an accuracy of within a factor of two to be achievable when the model is properly calibrated. This conclusion is further supported by computations of the net loss of sediment volume per meter of beach during the entire Halloween Storm. The model's predictions of a loss of about  $22 \text{ m}^3$  per meter compares favorably with losses of 27 and  $54 \text{ m}^3$  per meter beach obtained from profile surveys from before and after the "Halloween Storm" by the FRF along transects north of the FRF pier.

It is believed that the model presented here may serve the role of providing the important link between surf zone sediment transport processes and those in deeper waters of the continental shelf.

#### Appendix A: Approximate Determination of $\partial p/\partial x$

If evidence of pronounced variations in mean water level along the coastal section under consideration is available, *e.g.* from tide gauge records, it may not be safe to assume the alongshore pressure gradient to be zero. To estimate the effect of a nonzero longshore pressure gradient it is assumed that an estimate of the mean surface slope, as a function of time, is available for the location of interest, *i.e.* the pressure gradient driving a longshore flow is given by  $\rho g \partial \bar{\eta} / \partial x$ . In the absence of any Coriolis forcing in the x-direction ( $V = 0$ ) the equation governing the depth-averaged longshore velocity  $U$  induced by the pressure gradient in water depth  $h$  is

$$\frac{\partial U}{\partial t} = -g \frac{\partial \bar{\eta}}{\partial x} - (C_b/h) |\bar{u}| U \quad (\text{A.1})$$

in which  $|\bar{u}|$  is the depth-averaged longshore velocity obtained from the depth-resolving model solution, *i.e.*

$$|\bar{u}| = \frac{1}{h} \int_0^h \Re\{W_{Ug}\} dz \quad (\text{A.2})$$

with  $W$  given by (8) and (9). Since model application is limited to water depths of 10 to 20 m or less, it is reasonable to assume that the longshore velocity is closely described by the logarithmic profile up to half-depth, *i.e.* up to  $z = h/2$ , and that the velocity at  $z = h/2$  is a close approximation to the depth-averaged total longshore velocity (wind-induced as well as pressure gradient driven). It follows from these considerations that the bottom drag coefficient,  $C_b$ , is related to the apparent bottom roughness  $z_{oa}$ , which is known from (16) of the depth-resolving model, through

$$\sqrt{C_b} = \frac{\kappa}{\ell n \frac{h}{2z_{oa}}} \quad (\text{A.3})$$

With  $|\bar{u}|$  and  $C_b$  known as functions of time from the depth-resolving model, (A.1) may be solved numerically for the given temporal variation of  $\partial \bar{\eta} / \partial x$ .

The solution for  $U$  obtained in this manner includes unsteady effects which were considered negligible in the depth-resolving model formulation. However, the exact same time-varying longshore velocity  $U$  could have been obtained from a steady form of (A.1) if the pressure gradient term,  $\frac{\partial \bar{\eta}}{\partial x}$  in (A.1) were replaced by an equivalent steady pressure gradient

$$-\frac{1}{\rho} \frac{\partial p}{\partial x} = \frac{C_b}{h} |\bar{u}| U \quad (\text{A.4})$$

Thus solving (A.1) for  $U$  and subsequent evaluation of (A.4) will produce a longshore pressure gradient which, when introduced in the steady depth-resolving model, will return practically the same estimate of the longshore pressure gradient driven velocity as obtained from (A.1). If the addition of the longshore pressure gradient determined from (A.4) leads to drastic modifications of the depth-resolving model's predictions of  $|\bar{u}|$  and  $C_b$  it may be necessary to use this procedure in an iterative manner until convergence has been achieved.

## CHAPTER 134

### SEA BED STABILITY ON A LONG STRAIGHT COAST

E. Damgaard Christensen<sup>1</sup>, R. Deigaard<sup>2</sup>, J. Fredsøe<sup>3</sup>

#### Abstract

A stability analysis is used to investigate the development of large-scale periodic bottom topographies on a straight uniform coast. The work is an extension of the work by Hino (1974) and (1976), and special attention is paid to improve and refine the description of the sediment transport. The effect of the bed slope on the bed load sediment transport turns out to be very important. Further, the behaviour of suspended sediment is described by introducing lag effects that modify the predictions of the wave length considerably.

#### 1 INTRODUCTION

A coast is often irregular. Even a long straight coast can be very non-uniform in the longshore direction. A longshore bar can be crossed by more or less regularly spaced rip channels or it may be sinuous. Lippmann and Holman (1990) have shown several examples of different configurations of a coast that on a large scale is almost straight.

Here the formation of large-scale periodic bottom topographies is investigated by applying a linear stability analysis. The basic idea is to give a uniform bed a small perturbation. This perturbation affects the hydrodynamics and the sediment transport which again influences the bed form. It is then investigated whether the perturbation will grow in time or die out. For several different perturbations the one with the fastest growth is the one that would be expected to be dominant if the coast was given a random perturbation.

The linear stability analysis is only valid for an infinitesimal small bed perturbations, but it is expected that some of the main features of the fastest growing perturbation would also be found in the coastal forms that actually emerge.

<sup>1</sup>Ph.D-student, <sup>2</sup>Associated Professor, <sup>3</sup>Professor: ISVA, Danish Technical University, DK-2800 Lyngby, Denmark

An investigation of this kind was carried out by Hino (1974) and (1976). Hino used a very simple model for the sediment transport, and the present work is an extension of that analysis, investigating the effect of more sophisticated sediment transport descriptions, including the effect of the bed slope, and the gradual adaption of the suspended load transport due to changing hydrodynamic conditions.

## 2 DESCRIPTION OF WAVES, CURRENTS AND SEDIMENT TRANSPORT

The analysis considers a uniform, plane (constant slope) coastal profile with a small perturbation. The geometry and coordinate system are shown in figure 1. The "breaker line" is here defined as the line where regular waves with a deep water wave height equal to the root-mean-square wave height for irregular waves at deep water would start to break.

The chosen models for waves, currents, and sediment transport are as simple as possible, yet still represent the relevant physical processes.

Figure 1 The figure shows the definition of the x and y-directions

### 2.1 Wave description

The waves are assumed to be irregular with Rayleigh-distributed wave heights. The breaking process is described by the theory of Battjes (1972), where the local wave height distribution is taken as the Rayleigh distribution where the wave heights are limited by the water depth:  $H_b = 0.8 h$ . This model is expected to give satisfactory results on a gently sloping, monotone beach profile. The assumption of irregular waves gives a smooth distribution of the driving forces and the longshore current distribution.

The waves are described by linear shallow water theory, which is expected to give a reasonable representation of the depth refraction and radiation stress variation in the surf zone. The wave conditions are specified at the breaker line  $x_b$  where uniform waves would start to break.

## 2.2 The current description

The current is described by the depth-integrated equations for conservation of mass and momentum:

Momentum in the x-direction:

$$\begin{aligned} \rho \frac{\partial u(h+\eta)}{\partial t} + \rho \frac{\partial (h+\eta)u^2}{\partial x} + \rho \frac{\partial (h+\eta)vu}{\partial y} + \frac{\partial s_{xx}}{\partial x} + \frac{\partial s_{xy}}{\partial y} = \\ -\rho g(h+\eta) \frac{\partial \eta}{\partial x} - \tau_{bx} \end{aligned} \quad (1)$$

Momentum in the y-direction:

$$\begin{aligned} \rho \frac{\partial v(h+\eta)}{\partial t} + \rho \frac{\partial (h+\eta)uv}{\partial x} + \rho \frac{\partial (h+\eta)v^2}{\partial y} + \frac{\partial s_{xy}}{\partial x} + \frac{\partial s_{yy}}{\partial y} = \\ -\rho g(h+\eta) \frac{\partial \eta}{\partial y} - \tau_{by} \end{aligned} \quad (2)$$

Mass conservation:

$$\frac{\partial (h+\eta)}{\partial t} + \frac{\partial u(h+\eta)}{\partial x} + \frac{\partial v(h+\eta)}{\partial y} = 0 \quad (3)$$

$u$  and  $v$  are the depth-averaged velocities,  $\eta$  is the mean surface elevation,  $h$  is the still water depth,  $s_{xx}$ ,  $s_{xy}$  and  $s_{yy}$  are the radiation stresses, and  $\tau_{bx}$  and  $\tau_{by}$  are the components of the bed shear stress.

The flow resistance is described by a simple model for the turbulent interaction between the current and the oscillatory wave boundary layer, Fredsøe (1981), see also Fredsøe and Deigaard (1992), pp 56-62. This gives a flow resistance represented by a logarithmic velocity profile, but with an increased bed roughness due to the wave boundary layer.

### 2.3 Sediment transport

The morphological development is described by the conservation equation for sediment:

$$(1-n)\frac{\partial h}{\partial t} = \frac{\partial q_{totx}}{\partial x} + \frac{\partial q_{toty}}{\partial y} \quad (4)$$

where  $q_{totx}$  and  $q_{toty}$  is the total sediment transport in x and y-directions and n the porosity.

One of the main purposes of this study has been to consider the influence of the sediment transport model on the morphological stability. Three approaches have been investigated.

#### The simple approach

As a first approach the sediment transport rate is taken to be proportional to the local current velocity. This is the model used by Hino (1974).

$$\mathbf{q}_t = C_s \mathbf{V} \quad (5)$$

where  $\mathbf{q}_t$  is the sediment transport vector and  $\mathbf{V}$  is the depth-averaged velocity. The coefficient  $C_s$  is taken to be constant.

#### The bed load transport model

The transport of sand is composed of bed load transport and suspended load transport, where the bed load transport  $q_b$  is determined by the local instantaneous bed shear stress, from the combination of waves and current.

The dimensionless bed load transport  $\Phi_b$  can be expressed as a function of the dimensionless bed shear stress, the Shields parameter  $\theta$ . The formula of Meyer-Peter and Müller (1948) has been applied:

$$\Phi_b = 8(\theta' - \theta_c)^{\frac{3}{2}} \quad (6)$$

$$\text{where } \Phi_b = \frac{q_b}{\sqrt{(s-1)gd^3}} \quad \text{and} \quad \theta = \frac{\tau_b}{(s-1)gd}$$

$\theta_c$  is the critical Shields parameter,  $\theta_c = 0.05$ , d is the grain diameter, and s is the relative density of the sediment.

If the bed is sloping, there is an additional down slope component of the sediment transport. When the transport is directed up (or down) the slope, gravity

gives a down slope force component that has to be added to the force from the shear stress, giving a correction to the critical Shield's parameter:

$$\theta = \theta_c - \alpha \frac{\partial h}{\partial x} \quad (7)$$

where  $\alpha$  is from 0.05 to 0.1 cf Fredsøe and Deigaard (1992).

When the transport is along the slope, the down slope component of the gravity deflects the direction of the transport by the angle  $\psi$ , which can be found as: (Engelund and Fredsøe 1982)

$$\tan \psi = \frac{1}{1.6\sqrt{\theta}} \frac{\partial h}{\partial y} \quad (8)$$

For an arbitrary angle between the bed shear stress vector and the strike of the slope the effect of a longitudinal and transverse slope is combined.

The bed load transport is determined by the instantaneous bed shear stress, and is then averaged over the wave period. The instantaneous bed shear stress is determined from the flow resistance model, using the wave friction factor  $f_w$  on the combination of the near-bed wave-orbital velocity and the mean flow velocity at the top of the wave boundary layer.

#### The suspended load transport

The suspended sediment moves away from the bed in the water column. When the hydrodynamic conditions change, it takes some time for the grains to be entrained in the water column or be deposited. Therefore, it takes some time/length for the suspended load transport to be adjusted to a variation in the hydrodynamic conditions.

The transport of the suspended sediment is calculated by the models of Fredsøe et al (1985) and Deigaard et al. (1986) which includes the turbulent interaction between the wave boundary layer and the current and takes the turbulence generated by wave breaking into account. For the suspended sediment transport calculations the modelling system Litpack of the Danish Hydraulic Institute has been applied.

The gradual adaptation of the transport to a gradient in the hydrodynamic conditions is represented by an adaptation length  $L_s$ , by which the transport lags behind the development in the forcing terms.  $L_s$  is estimated by the time it takes for a grain to settle from the concentration profile of suspended sediment:

$$L_s = \alpha \frac{z_c}{\omega_s} V_0 \quad (9)$$

where  $z_c$  is the height from the bed of the centroid of the sediment concentration profile,  $\omega_s$  is the settling velocity of the sediment and  $V_0$  is the mean flow velocity and  $\alpha$  is a coefficient, which is expected to be of the order 1.

### 3 ZERO ORDER SOLUTION AND FIRST ORDER EQUATIONS

The stability analysis is performed by using a perturbation method. First the equilibrium conditions for the longshore current and the set up are calculated. The equilibrium is perturbed, and the perturbed equations are found. Here the difference between the steady solution and the solution with a small perturbation is called the perturbed solution or the first order solution and the steady solution is called the zero order solution. If all types of perturbations of the bottom will die out in time, the equilibrium is stable. If the perturbation grows, the bed is unstable.

To calculate the zero order solution - the profile without any bed undulations - is actually a project by itself. It usually requires a detailed on offshore description including undertow etc. This cross shore sediment transport is considered to be unimportant for the further development of sand bed undulations, and for reasons of simplicity it has been assumed that a coast with a constant slope is an equilibrium profile for the bottom.

#### 3.1 The steady solution

The equations in section 2.1 are solved in the steady state. This means that  $U$ ,  $V$ ,  $\eta$ ,  $h$  only depends on  $x$ , because the initial conditions are described by parallel bottom contours and a constant slope of the bottom. By this  $U$  and all the derivatives with respect to  $y$  is equal to zero.

When the description of the waves given by Battjes (1972) is used, a smooth set up is found from equation (1). The set up is a function of the angle of the incoming waves, the percentage  $Q_b$  of the waves that break or have broken and the root-mean-square  $H_{rms}$  of the remaining waves.

The flow resistance is described by the simple model for turbulent interaction between the wave and current boundary layer, which gives an increased flow resistance for the flow expressed as an increase in the bed roughness. The flow resistance for the current is almost quadratic.

#### 3.2 First order equations

When the steady solution is found, the bed is given a little perturbation. This perturbation affects the hydrodynamics. The response time concept is applied. The idea behind the response time concept is that the bottom perturbation will cause immediate changes of the velocities in the  $x$ - and  $y$ -directions, but quick changes in the flow motion will not result in a response from the bottom. Thus the hydrodynamics are considered to be quasi-steady, and it is only the time variation of the bed level that is included in the description.

The total velocity field, water elevation, and water depth can be expressed by:

$$\left. \begin{aligned} U &= u'(x,y) \\ V &= V_0(x) + v'(x,y) \\ \eta &= \eta_0(x) + \eta'(x,y) \\ h &= h_0(x) + h'(x,y,t) \end{aligned} \right\} \quad (10)$$

The first order perturbed equations can be found by substituting (10) into (1)-(4). All terms of higher order than one will then be omitted. The zero order terms will automatically fulfill these equations and can be cancelled out. With this we obtain equations that only contain first order terms.

The gravitational acceleration  $g$  and the distance from the shore to the breaker line  $L_B$  are used to make the equations non-dimensional. The dimensionless variables are written,

$$x \rightarrow \frac{x}{L_B}, \quad k \rightarrow k \cdot L_B, \quad c \rightarrow \frac{c}{\sqrt{gL_B}}, \quad q \rightarrow \frac{q}{\sqrt{gL_B} L_B} \quad (11)$$

Each of the four differential equations can be put on a form as:

$$\begin{aligned} & \frac{\partial w_i}{\partial t} + A_{i1} \frac{\partial u}{\partial x} + A_{i2} \frac{\partial u}{\partial y} + a_i \mu + B_{i1} \frac{\partial v}{\partial x} + B_{i2} \frac{\partial v}{\partial y} + b_i \gamma \\ & + C_{i1} \frac{\partial \eta}{\partial x} + C_{i2} \frac{\partial \eta}{\partial y} + c_i \eta + D_{i1} \frac{\partial h}{\partial x} + D_{i2} \frac{\partial h}{\partial y} + d_i h + D_{i1}^* \frac{\partial^2 h}{\partial x^2} + D_{i2}^* \frac{\partial^2 h}{\partial y^2} + D_{i12}^* \frac{\partial^2 h}{\partial x \partial y} = 0 \end{aligned} \quad (12)$$

where  $i$  is the number of equation.  $w_i$  is the variable that is derived with time in the equation,  $w_4 = h$ , for the other variables this term is cancelled out due to the response time concept. The coefficients in (12) depends on the zero order solution and the description of the sediment transport.

#### 4 SOLVING THE EQ. BY FINITE DIFFERENCES

The equations are solved numerically by finite differences. When the assumption of periodic conditions in the  $y$ -directions is applied, the dependent variables can then be written as:

$$u = U(x) \exp(iky) \quad (13)$$

$$v = V(x) \exp(iky) \quad (14)$$

$$\eta = Z(x) \exp(iky) \quad (15)$$

$$h = H(x) \exp(pt +iky) \quad (16)$$

Figure 2 shows a sketch of how the finite difference scheme is applied. The node points are distributed over three times the width of the breaking zone. The

start of the breaking zone is defined as the line where regular waves with a wave height equal to  $H_0$  would start to break.

In figure 2  $x_b$  is the distance from the coast line at still water level to the start of the "breaking line".  $x_i$  is the distance between the still water line and the actual water line. The total width of the breaking zone  $L_b$  is thus the sum of  $x_i$  and  $x_b$ .

Figure 2 Sketch of the finite difference approximation. The points are distributed over three times the width of the "breaking zone"  $L_b$

Solution method

The expressions in (13) to (16) are substituted into (12) by which four ordinary differential equations for  $U, V, Z$  and  $H$  are obtained. These are solved by introducing second or fourth order finite difference approximations for the derivatives of  $U, V, Z$  and  $H$ . For node points at the boundaries forward/backward finite differences are used, and for the node points at 2 and  $n-2$  second order finite differences are used for terms that are not given on the boundary. As boundary conditions  $U, V, Z$  and  $H$  are set equal to 0 at the right boundary (deep water), and  $U$  is set equal 0 at the coast line,  $x = -x_i$ , see figure 2.

With this, a matrix-equation is found:

$$\underline{Ax} = \underline{px} \tag{17}$$

The vector  $x$  has the dimension  $4(n-1)$  and it has the form:

$$x = (U_1, U_2, \dots, U_{n-2}, U_{n-1}, V_1, V_2, \dots, V_{n-2}, V_{n-1}, Z_1, Z_2, \dots, Z_{n-2}, Z_{n-1}, H_1, H_2, \dots, H_{n-2}, H_{n-1})$$

$px$  is a vector that originates from the terms derived with respect to time in (12).

$$px = (0, 0, \dots, 0, 0, 0, \dots, 0, 0, 0, \dots, 0, 0, pH_1, pH_2, \dots, pH_{n-2}, pH_{n-1})$$

By use of gauss-elimination equation (17) is transformed to an eigenvalue problem for  $H$ .

Matrix  $\underline{A}$  contains of 16 sub-matrices. These are named  $A_i, B_i, C_i, D_i$ :

$$\underline{A} = \begin{pmatrix} A_1 & B_1 & C_1 & D_1 \\ A_2 & B_2 & C_2 & D_2 \\ A_3 & B_3 & C_3 & D_3 \\ A_4 & B_4 & C_4 & D_4 \end{pmatrix} \quad (18)$$

The matrices  $A, B, C$  and  $D$  contains elements, respectively, for  $U, V, Z$  and  $H$ . The index refers to the equations. 1 for the x-momentum, 2 for y-momentum, 3 for conservation of mass and 4 for conservation of sediment. When the matrix  $\underline{A}$  has been calculated, it is reduced to a triangular matrix except the last submatrix  $D_4$ . The form of the matrix-equation is now:

$$\begin{pmatrix} A_1^* & B_1^* & C_1^* & D_1^* \\ 0 & B_2^* & C_2^* & D_2^* \\ 0 & 0 & C_3^* & D_3^* \\ 0 & 0 & 0 & D_4^* \end{pmatrix} \begin{pmatrix} U \\ V \\ Z \\ H \end{pmatrix} = -p \begin{pmatrix} 0 \\ 0 \\ 0 \\ H \end{pmatrix} \quad (19)$$

The matrices'  $A_1^*, B_2^*$  and  $C_3^*$  are all upper triangular matrices. It is only possible to obtain a solution to equation (19) when  $H$  is a solution to the eigenvalue problem defined by following equation:

$$D_4^* \cdot H = -pH \quad (20)$$

(20) is complex in both matrix, vector, and eigenvalue. It is solved by use of standard procedures for complex eigenvalue problems. The solution to the eigenvalue problem gives  $n-1$  eigenvalues  $\lambda_1, \dots, \lambda_{n-1}$ . Each of the eigenvalues defines a solution to the eigenvalue problem, which also give  $n-1$  eigenvectors  $H_1 \dots H_{n-1}$ .

It is now possible to find the solution that gives the fastest growth rate of the bed perturbation that is determined by the largest real part of  $p_i = -\lambda_i$ , cf. eq. (16). When the eigenvector  $H_i$  for the fastest growing mode has been found, the solution for  $U, V$  and  $Z$  are found by using back substitution.

The calculations are made for several different values of  $k$  in order to determine the wave number  $k$  that gives the largest real part of  $p$  and thus the fastest growing perturbation. This bar pattern is expected largely to be the bed form that actually emerges.

Another result that comes from the eigenvalue problem is the migration velocity, which is:

$$c_h = \frac{-Im(p)}{k} \quad (21)$$

## 5 RESULTS

As can be seen in fig. 3 the simple sediment transport model does not give a maximum for the growth factor  $\text{Re}(p)$ . Fig. 4 shows the most unstable bed configuration for different values of  $k$ . It can be seen that as  $k$  increases the bars are situated closer to the coastline.

Figure 3 The real part of the growth factor  $p$  as a function of the wave number  $k$ . The simple sediment transport model was used.  $H_b=3$  m,  $T=10$  s,  $\beta = 2.5^\circ$  and  $\theta_b = 10.0^\circ$ .

For large longshore wave numbers the bed forms are thus embedded in the nearshore region where the longshore current is growing linearly with the distance from the shoreline, see figure 4. Under these conditions there is no lower limit for the wave length of the most unstable perturbation and the stability analysis cannot predict the emerging of a bed topography.

An explanation for this behaviour is as follows. When the bars are situated closer to the coast line, the area of a bar is decreased as  $k^{-2}$ , whereby the amount of sediment needed for the instability mechanism is reduced with  $k^{-2}$ . Close to the coast line the zero order velocity profile is almost linear and the sediment transport is proportional to the zero order velocity. The sediment transport hereby reduces by  $\sim k^{-1}$  as the bars are situated closer to the coast line. This gives:

$$\text{Re}(p) \propto k^{-1}/k^{-2} = k$$

This agrees with the result shown in figure 3.

When the bed load transport model is used a maximum for  $\text{Re}(p)$  is found, see figure 5. The dimensionless wave number  $k$  is found to be around 1.0 to 1.2 for waves for an incoming angle at the breakerline between  $8^\circ$  and  $12^\circ$ . For lower angles the wave number  $k$  becomes very small for the maximum of  $\text{Re}(p)$ . For  $\theta_b = 0^\circ$  it is impossible to get any results due to the use of a quadratic resistance law which also has influence on the results for small angles of  $\theta_b$ .

Figure 4 An example of the perturbation  $h$ , for three different wave numbers  $k$ ,  $H_b = 3$  m,  $T = 10$  m,  $\beta = 2.5^\circ$  and  $\theta_b = 10.0^\circ$ .

Figure 5 The real part of the growth factor  $p$  and the translation celerity as a function of the wave number  $k$  for six different angles. The bed load model was used.  $H_b = 3$  m,  $T = 10$  s,  $\beta = 2.5^\circ$

Illustrations of the 1. order bed topography, 1. order velocity field and the "total" meandering current are shown in figure 6. The orientations of the bars disagree with the one seen on the photo in figure 7. On the photo the bars propagate from the coastline obliquely in the same direction as the current, the opposite is the case in the stability analysis. In another case, illustrated by a photo of Short (1994), the orientation of the bed forms agree with the present stability analysis. Johnson et al. (1994)

modelled the current and morphological changes around an offshore breakwater for obliquely incoming waves. At the downstream side of the breakwater some bars developed that had the same orientation as those in the present study. It has not been possible to find a final explanation for the determination of the orientation.

Figure 6 An example of the perturbation  $h$ , the 1. order current and the "total" (0. and 1. order) meandering current.  $\theta_b = 8.0^\circ$ ,  $k = 1.2$ ,  $H_b = 3$  m,  $T = 10$  m and  $\beta = 2.5^\circ$ . For the meandering current the maximum of  $h$  was set to 2 m. The scoured area is shown by the light colour

Figure 7 A photo of large periodic bottom topographies at the island Sylt, Wadden Sea Denmark/Germany, H. Dette (1994).

Figure 8a shows the dependence on the grain size. When the grain size increases the maximum of  $Re(p)$  decreases and the wave length of the most unstable perturbation increases.

The perturbation of the bed modifies the wave field. This influences on the radiation stresses and hereby on the hydrodynamics and the sediment transport. A comparison between the effects coming from the bed slope, the modification of the wave field due to the perturbation and the current is shown in figure 8b. When the modification of the wave field due to the perturbation is excluded the lowest curve is obtained where the maximum is situated at the same wave number  $k$  as for the full bed load model. When the effect of the bed slope and the effect of the modified wave field are excluded, the maximum for  $Re(p)$  is situated at a larger wave number  $k$ . Here a maximum is obtained in contrast to the simple model. This shows that a more refined model for the sediment transport gives a maximum even if the bed slope is not taken into account.

8a

8b

Figure 8 The figure shows the dependency of the grain size - 8a -, and the stability curve when the slope and/or the modification of the wave field are excluded - 8b. A: no slope and no modification of the wave field, B: no modification of the wave field, C: the full bed load model

Figure 9 Here the suspended load is included, the figure on the left hand side is found for  $\theta_b = 5.0^\circ$  and for the figure at the right hand side  $\theta_b = 10^\circ$ .  $H_b = 3$  m,  $T = 10$  m and  $\beta = 2.5^\circ$ .

Figure 9 shows the results when the suspended load is incorporated. For  $\theta_b = 5.0^\circ$  the maximum for  $\text{Re}(k)$  moves to a bigger dimensionless  $k$ , while we get the opposite result for  $\theta_b = 10^\circ$ . When the suspended load becomes dominant, it moves the maximum of  $\text{Re}(p)$  to a lower dimensionless  $k$ , and the growth rate increases.

For  $\theta_b = 10^\circ$  the effect of a phase lag is shown too. This has a stabilizing effect on the growth rate especially with big wave numbers.

## 6 CONCLUSIONS

A linear stability analysis has been used to investigate the formation of large scale periodic bottom topographies. In the analysis the effects from the slope due to the perturbation of the bed are incorporated.

When a simple sediment transport formulation is used, taking the sediment transport to be proportional to the velocity, a maximum on the stability curve is not found, and the instability of the bed forms increases with the alongshore wave number.

The bed slope affects what kind of topography that will emerge and gives a spacing between the rips of about six times the width of the breaking zone. By including the suspended load this distance decreases for small angles of the incoming waves and increases for large angles. The phase lag in the suspended load gives a smaller growth rate and a longer length of the bar.

The modification of the wave field, due to the perturbation, increases the growth rate and gives a smaller bar length.

The stabilizing effects are the slope of the bed, large grain size and phase lag in the suspended load transport. The destabilizing effects are the longshore current, and the modification of the wave field due to the perturbation of the bed. Refraction and diffraction have not been investigated. These mechanisms could have an effect on the stability of the bars.

The resulting topography has been compared to field investigations and shows that the orientation of the bars sometimes but not always is the same as in this stability analysis.

## ACKNOWLEDGEMENT

This work was founded jointly by the Danish Technical Research Council under the programme "Marin Teknik" and by the Commission of the European Communities, Directorate General for Science, Research and Development under MAST contract no. MAS2-CT92-0024 under the programme CSTAB.

## CHAPTER 135

### The Response of Gravel Beaches in the Presence of Control Structures

T T Coates<sup>1</sup>, N Dodd<sup>1</sup>

#### Abstract

Much of the research on beach control structure concentrates on sand beaches. Relatively little work has been done on gravel beaches though they are important features along temperate and sub-arctic coastlines, particularly in the UK. Until recently attempts to manage these beaches and to control erosion have relied on traditional approaches such as timber groynes, designed by past experience and engineering judgement. To improve this situation HR Wallingford have undertaken a programme of flume and wave basin physical model studies followed by the development of numerical models and design guidelines.

The most recent phase of this programme has been an investigation of beach response to detached breakwaters. This work was undertaken at a scale of 1:50 in a mobile bed, random wave basin. The breakwaters varied in length, crest elevation and distance offshore. The sea conditions varied in wave period and water level. Measurements were taken of wave heights around the structure, beach planshape development and longshore transport rates. For each breakwater configuration and sea condition an efficiency value has been derived which relates the longshore transport rate in the presence of the structure to the potential open beach rate. These efficiency values can be used to tune breakwater dimensions to the actual long term drift rates of a specific beach, thereby providing a stable beach.

This paper briefly reviews some of the previously published work, then discusses the major findings of the recent model tests and suggests methods for applying the results. The results are, at present, only applicable to a limited range of sea and beach conditions, but it is anticipated that the approach will be developed for general application. The findings are also related to a recently completed detached breakwaters and beach recharge scheme on the UK south coast.

## Introduction

Detached breakwaters, unlike groynes, have not been used for beach control in the UK until quite recently. Existing design guidelines are based on experience in other areas of the world, with the most recent publication being the CERC Technical Report "Engineering Design Guidance for Detached Breakwater as Shoreline Stabilization Structures ". The majority of research and experience available relates to sand beaches in microtidal environments (range  $< 2\text{m}$ ) with shore normal wave attack, and are therefore not directly applicable to many UK situations. In addition, much of the research concentrates on determining the shape and extent of the beach development in the lee of the structures; this approach only considers the symptoms and not the causes, as it does not directly consider the sediment transport regime at the design site.

A number of morphodynamic models are available which go some way towards predicting sand beach response. Unfortunately these models are not applicable to the shingle beaches found along much of the UK coastline. To improve this situation HR Wallingford undertook an ongoing research programme, utilizing physical models, with the aim of developing design tools and guidelines.

Powell (1990) investigated the response of shingle beaches to random waves in a flume at a scale of 1:17. The physical model results were used to develop a parametric model which predicts beach response to wave and water level conditions. This work was extended to a large scale (1:17) wave basin study in which the hydrographic conditions included oblique long crested random waves (Coates and Lowe, 1993). Modifications to the original parametric model were derived which accounted for beach profile response under oblique waves. In addition, the cross-shore distribution of longshore transport along an open shingle beach was derived; this distribution was used by Brampton and Goldberg (1991) in conjunction with Powell's parametric model to improve an earlier one-line beach plan shape model (Brampton and Motyka, 1985).

Brampton and Goldberg's model was able to predict beach plan shape development in the presence of groynes, but the authors recognised that the model over-simplified a number of aspects relating to beach response. This response was investigated by further physical modelling at a scale of 1:17 and, more recently, in a different facility at a scale of 1:50 (Coates and Lowe, 1994; Coates, 1994a; Coates, 1994b). Some of the results of the larger scale model have been incorporated into a new mathematical model (Huang, 1993) which includes an improved method of predicting profile development within a groyne field as well as transport over and around groynes. The smaller scale study investigated beach response within a multiple groyne system and it is this work that is described in this paper. The approach adopted was to investigate sediment transport, rather than morphological development, in the lee of single breakwater, followed by a preliminary investigation of beach response to pairs of breakwaters.

### Model studies

The test programme was conducted at HR Wallingford in a 23m by 24m wave basin with a maximum working depth of 0.4m. The model was designed at an undistorted scale of 1:50, according to Froude's relationships. The basin was equipped with:

- a 15m long, mobile wave paddle capable of generating waves at up to 45° relative to the beach;
- nine wave monitoring probes;
- an oblique angle camera;
- a manual sediment recirculation system.

The model layout is illustrated in Figure 1. It was designed to simulate a typical UK sand lower/shingle upper beach. The lower portion of the beach was constructed from a rigid moulding at a slope of 1:50. The upper portion comprised a mobile bed formed of crushed and graded anthracite coal formed at an initial slope of 1:7½ with a crest above the limit of wave action.

The mobile bed was designed to be similar to those used in previous model studies within the programme and to simulate typical UK beaches. The scaling relationships used in selecting the model beach material are based on a well established method which attempts to satisfy three criteria: the permeability, which governs slope, the relative magnitude of onshore or offshore movement, which determines whether erosion or accretion will occur, the threshold velocity of particle motion.

The methods published by Yalin (1963) which relate slope to a non-linear function of the voids Reynolds Number are used to satisfy the permeability requirement. The fall velocity parameter  $H_b/wT$  proposed by Dean (1973) is used to satisfy the onshore/offshore criteria while the relationship of Komar and Miller is used for the threshold of motion. At the model scale of 1:50, an assumed prototype  $D_{50}$  of 15mm and a density of 2.65T/m<sup>3</sup> then the required model sediment should have a  $D_{50}$  of 2.5mm and a density of 1.41T/m<sup>3</sup>. Anthracite coal has a density of 1.39T/m<sup>3</sup> and can be obtained in a range of grades. It is therefore an appropriate material for use as the mobile bed.

The sea condition variables were restricted to wave steepness (S) and water level (SWL). All tests were run with a 2m  $H_s$  wave height and a 30° offshore wave direction. Wave steepness values were either 0.02 (swell) or 0.06 (storm) and water levels varied from 3.0m to 4.5m relative to the initial beach toe (each test was run at a fixed SWL). Wave induced currents were investigated in a single test using  $S = 0.02$  and a range of water levels from 1m to 4m. Tidal currents were not investigated.

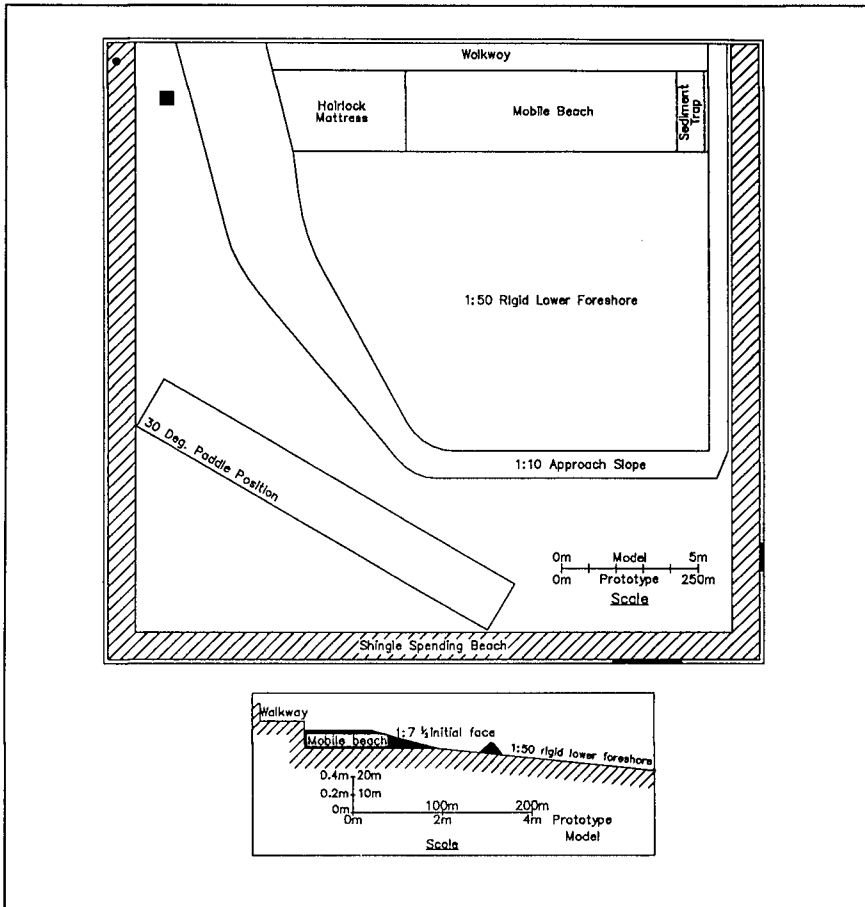

Figure 1 The wave basin facility

The test programme concentrated on single breakwaters. Structural variables included crest length ( $L_c$ ), freeboard ( $R_c$ ), offshore distance ( $X_s$ ). A short series of tests was run at the end of the programme to investigate pairs of structures. These tests investigated the influence of gap length ( $G_s$ ). A total of 34 tests were run, with an average duration of 2-3 days.

The basic structural design comprised a crest width of 4m, side slopes of 1:2 along the body of the structure and slopes of 1:3 at the ends. The rock grading was selected for minimal damage. The initial median rock weight was 6.55 tonne, with a linear grading from  $W_0 = 4.0$  tonne to  $W_{100} = 9.1$  tonne. During construction larger rocks were preferentially placed in the areas of potential damage, based on the findings of earlier research (Jones & Allsop, 1993). Figure 2 indicates the

breakwater layout and the variables. Table 1 summarizes the structural variables.

**Table 1** Structural variables

Length (m)	Distance offshore (m)	Crest elevation (m)	Gap length
60	120	4.5	N/A
60	90	3.5	60 & 90
60	90	4.5	N/A
90	150	4.5	N/A
90	120	3.5 & 4.5	N/A
90	90	3.5 & 4.5	N/A
90	60	4.5	N/A
120	120	3.5 & 4.5	N/A
120	90	4.5	N/A

**Figure 2** Basic breakwater layout

During calibration, the model was run with an open beach, fed by an unlimited supply of sediment. The transport rates and cross-shore distribution of transport were measured for each wave and water level combination. The transport rates were used to determine standard sediment input rates for all subsequent tests; these are referred to as the *calibrated* rates.

Test procedures included:

- continuous monitoring of downdrift sediment output;
- regular measurement of the cross-shore position of the crest, SWL and toe on 12 section lines to monitor planshape developments;
- regular overhead photographs of beach development; and
- measurement of wave heights seaward and landward of the breakwater.

The terms salient, tombolo, efficiency, potential drift rate and actual drift rate are used in the discussions. Salient refers to the seaward development of the beach in the lee of the breakwater; if this development reaches the breakwater at the water line then the salient is referred to as a tombolo. Efficiency, denoted as  $\eta$ , refers to the ratio of output drift relative to the potential or calibrated open beach drift for the model beach under a given sea state as expressed by the equation

$$\eta = \left( 1 - \frac{Q_o}{Q_p} \right) \times 100$$

where  $Q_p$  is the potential drift rate for a beach under a given set of wave and water level conditions and  $Q_o$  is the output drift rate immediately downdrift of the structure. Potential and actual drift rates are important in relation to breakwater design. The potential drift rate is the volume of beach material that the incident wave condition could move along an open beach if the supply of material is unlimited - in the model this is the calibrated input rate. The actual drift rate on a given beach is often much less than the potential rate due to a lack of available material or the influence of artificial structures or channels; erosion of the foreshore often occurs as a result of the difference between these two rates.

Tests were run in two stages. During the initial stage the beach was supplied with drift material at the calibrated rate. This material was transported into the lee of the breakwater where a percentage was deposited to form a salient, while the remainder was transported to the downdrift sediment trap. When the downdrift transport rate stabilized after 12,000 to 16,000  $T_m$  then the second stage commenced. The updrift sediment input position moved to a point immediately updrift of the breakwater, and the input rate was reduced to the stabilized output rate of stage 1.

Assuming that this rate had been properly defined, then no further material accreted at the salient and the output equalled the new input. Stage 2 continued for about 12,000  $T_m$  or until the input/output equilibrium was confirmed. The relationship between the stabilized output and the original calibrated input was then

used to determine the efficiency of the particular structure.

### Discussion of results

The test results are presented in a series of figures. Figures 3-8 illustrate the influence of various seastate or structural variables on breakwater efficiency. The lines join directly comparable data points to illustrate the strongest relationships. Where several similar lines are presented on the same plot, they indicate the influence of secondary variables. Figure 9 presents a summary plot combining all of the structure variables.

### *Effect of test duration on efficiency and beach development*

The standard test procedure was followed during all tests except the first test, which was run with a constant input at the calibrated rate for over  $100,000T_m$ . The test was continued until a tombolo had built out to the breakwater and transport had resumed along the seaward face. Although this final result was not of use to the establishment of a  $\eta$  value, it did serve to illustrate the potential impact of a breakwater that is too effective relative to the actual beach drift rate. The structure efficiency reached a stable level of 86% after about  $20,000 T_m$ , but as the beach continued to develop  $\eta$  increased to almost 100%. This increase in efficiency over time is an important consideration in design, as a structure that is too effective will block longshore transport, causing downdrift erosion until the beach has built out sufficiently to allow bypassing to occur.

### *Effect of wave steepness on efficiency*

Tests were run with wave steepnesses of 0.02 and 0.06. Figure 3 illustrates that the structures were about 30% more efficient under shorter period waves.

**Figure 3** Effect of wave steepness on efficiency

### *Effect of offshore distance ( $X_s$ ) on efficiency*

$X_s$  was measured from the structure centre line to the 3m contour line on the initial standard beach. Most of the tests were run with  $X_s$  values either 90m or 120m with only one test run with each of 60m and 150m.

Figure 4 illustrates that structures set at 60m, 90m and 120m had very similar impacts on efficiency. The only distance which showed a significant effect was 150m, which caused a substantial decrease in efficiency.

Insufficient data was collected for low and high values of  $X_s$  to establish any definite trends, however it is apparent that over the limited range of 90m and 120m  $X_s$  is not a dominant factor.

**Figure 4** Effect of cross-shore location of breakwater on efficiency

### *Effect of freeboard ( $R_c$ ) on efficiency*

$R_c$  is the difference in elevation from the structure crest to SWL. Changes in  $R_c$  influence the amount of wave energy that can pass over or through the breakwater. By varying both the structure crest elevation, from 3m to 4m, and the SWL from 3.0m to 4.5m,  $R_c$  values from -0.5m to 1.5m were tested. Figure 5 illustrates the effect of  $R_c$  on  $\eta$ . The results suggest that  $R_c$  is an important factor in beach response to breakwaters.

It is apparent from Figure 5 that  $R_c$  has a non-linear effect on efficiency.  $\eta$  increased by 30 - 40% as  $R_c$  increased from -0.5m to 0.5m. As  $R_c$  increased further to 1.5m then  $\eta$  only increased by 10 - 30% with the higher values being associated with the shorter structure lengths.

Figure 5 Effect of freeboard on breakwater efficiency

*Effect of crest length ( $L_s$ ) on efficiency*

$L_s$  values of 60m, 90m and 120m were tested and were found to be an important factor in determining beach response. Figure 6 illustrates the relationship between  $L_s$  and efficiency, with the lines joining data points of equal  $R_c$ .

Beach response to  $L_s$  was again non-linear. Changes in  $L_s$  from 60m to 90m resulted in efficiency increases of between 20 - 40% while changes from 90m to 120m resulted in increases of only 10 - 20%.

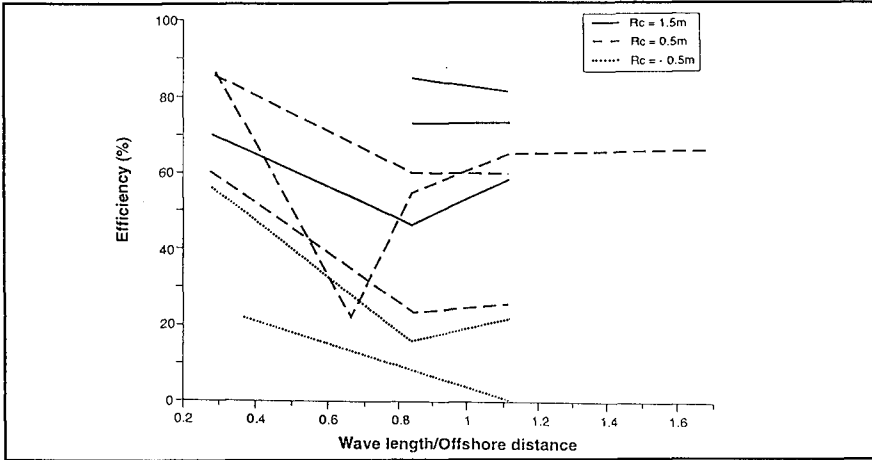

Figure 6 Effect of structure length on breakwater efficiency

*Relationship between wave length and structural dimensions*

The model data for wave steepness (or wave length),  $X_s$  and  $L_s$  were further investigated in combinations to determine any relationships. Figure 7 illustrates the influence of  $L_m/X_s$  on  $\eta$ . There are insufficient results to form any definite conclusions but the figure suggests that  $\eta$  may reach a minimum when  $0.4 < L_m/X_s < 0.9$ .

**Figure 7** Effect of wave length relative to offshore distance of structure on breakwater efficiency

Figure 8 illustrates the influence of  $L_m/L_s$  on  $\eta$ . Though the results show some scatter, there is an obvious trend of decreasing  $\eta$  with increases in  $L_m/L_s$ .

**Figure 8** Effect of wave length relative to structure length on breakwater efficiency

### Combined influence of structural variables

The individual effects of length, offshore distance and freeboard are combined into a single efficiency contour plot in Figure 9. The data set for the plot was extended by combining both the swell and storm values using the relationship  $\eta$  (swell) =  $\eta$  (storm) - 30; the plot is therefore set out for wave steepnesses of 0.02, and is only applicable to 2m  $H_s$  waves.

**Figure 9** Contour plot of efficiency relative to structure variables for a single detached breakwater (Data points corrected for a single wave steepness of 0.02)

The contour plot can be used to determine the optimum combination of structural dimensions for a given situation. Although the model variables were limited, the method used to obtain the contour plot could be extended to form a full set of design plots for detached breakwaters. Alternatively, the information derived from the study could be used to calibrate existing numerical models which predict wave energy distribution in the lee of structures, although at present none of the available models are able to fully simulate wave/structure interactions.

### Wave induced currents

Titanium dioxide was used as a neutrally buoyant tracer to monitor currents

along the model beach and in the lee of the breakwaters. This work was subjective only.

Tracer was injected in the lee of a 90m breakwater during swell wave conditions with a range of water levels. Wave induced currents transported dye from the updrift beach and the immediate downdrift beach to the head of the beach salient. From this point the dye was transported intermittently seaward around the down drift end of the breakwater. The intermittent currents had a period of about 10 - 15 seconds (model), equivalent to 8 - 12 incident wave periods. The seaward current reached strong peak velocities, particularly at water levels of between 1m and 3m. Currents at higher water levels were less well defined.

These results qualitatively support available field observations. Further field work should be undertaken as areas of potential rip currents or deposition will be important to breakwater design.

#### *Results of paired breakwater tests*

Only three tests of breakwater pairs were carried out as a post-script to the single structure study. Variables included only gap width ( $G_s$ ) and freeboard ( $R_c$ ). The results are insufficient for rigorous analysis, but the following observations can be made.

As might be expected, a larger gap width resulted in a slightly lower efficiency, while a change of freeboard from +0.5 to -0.5 resulted in a substantial drop. Comparison against single structures indicated that two emergent 60m long breakwaters with a 60m gap have a  $\eta$  value approximately equal to a single 60m structure, indicating that the efficiency data collected for the single breakwaters may be applicable to multiple structures if appropriate gap widths can be determined. However, when submerged the pair of structures became significantly more effective than a single submerged structure suggesting that the relationships may not be straight forward.

#### Design applications

The results of the model study are not yet sufficient to form the basis of a design method for detached breakwaters. Only a limited number of conditions were tested, the programme concentrated on single structures and no field verification has been undertaken. However, a number of useful guidelines can be derived which will be of use to coastal engineers and managers.

Most shingle beaches in the UK are of a type known as shingle upper/sand lower, and are subjected to high wave energy within meso (range 2m - 4m) or macro (range < 4m) tidal environments with the potential for substantial storm surges. It is these beaches which are considered here.

Detached breakwaters affect the beach by altering the inshore wave climate. Waves approaching the beach are either reflected from the structure, overtop the structure (usually breaking in the process) or diffract into the lee. The wave energy in the lee is less than on the open beach and therefore sediment which is transported along the open beach may be deposited. The percentage of deposition relative to the potential drift, for a sea condition close to those tested, can be derived from Figure 9. Efficiency at different tidal levels can be derived from the plot by varying  $R_c$  and  $X_s$ . If the actual open beach drift rate and the potential open beach drift rate can be derived from numerical modelling, desk studies and field measurements then the optimum layout can be derived.

The optimization may be based on factors apart from sediment transport efficiency. These might include cost of materials, cost of stabilizing the substrate, visual impact, navigational safety, desirability of providing safe mooring for small craft and possible use as an amenity platform for activities such as fishing. The design method assumes a strongly dominant drift direction. Substantial drift reversals driven by waves of lower energy than the design waves will cause material to be deposited in the lee of the breakwater from where it will not be eroded by subsequent conditions. This process will lead to tombolo formation and downdrift erosion. If this situation is likely then groynes may be more appropriate structures.

No single design will be satisfactory under the diversity of conditions found on most beaches, but satisfactory compromises should be possible.

### Conclusions

Shingle beach response in the presence of detached breakwaters was investigated using a 1:50 mobile bed physical model as part of an ongoing coastal research programme at HR Wallingford. The study concentrated on single detached rubble mound structures, but concluded with a brief series of tests on pairs of structures. Structural variables included length, crest elevation, distance offshore and gap width. The sea conditions only varied in wave steepness and water level.

The study conclusions are as follows.

- 1 The modelling work that has been completed provides a substantial data base for use in further physical modelling of single or multiple structures and for the development and calibration of numerical models based on wave transformation in the lee of breakwaters.
- 2 Breakwaters can be used to stabilize an existing or recharged beach where the natural drift has a strong dominant direction and both the potential and actual drift rates can be determined. Successful design depends on matching the breakwater geometry to the actual natural drift under the dominant wave and water level condition. Breakwaters on beaches with high gross transport, but

low nett transport are likely to cause unwanted areas of scour and accretion, as the structures can only be designed correctly for one drift direction.

- 3 An efficiency contour plot was derived from the study which relates the structure length/offshore distance ratio to freeboard. Application of this plot is limited as the range of sea conditions tested was restricted and no field verification data is available. However it provides a useful first step in developing design guide lines and can be used to optimize structural geometry with respect to construction costs and other design factors.
- 4 The relationships of efficiency with structure length ( $L_s$ ) and freeboard ( $R_c$ ) were clearly established.  $R_c$  is dominant when the structure crest is submerged due to the high level of wave energy transmission through and over the structure.  $L_s$  becomes the dominant factor as  $R_c$  increases above zero.
- 5 The influence of the offshore distance of the structures ( $X_s$ ) was less conclusive. Most tests were run with an  $X_s$  of 90m or 120m. These distances were too similar to show any distinct trend. Comparison of efficiency with the ratio of wave length to offshore distance ( $L_m/X_s$ ) suggests that there may be an efficiency minimum when the ratio is between 0.4 and 0.9. However the available data set is insufficient to confirm this possibility.
- 6 Tests on wave induced currents showed the potential for strong rip currents around the downdrift end of the breakwaters. The currents observed were intermittent at periods associated with 8 - 12 incident waves. They were also dependant on the depth of water in the lee of the structure, with peak currents being observed at depths of between 1m and 3m.
- 7 Breakwater efficiency also appears to be dependant on the size of the beach salient. As the salient extends out towards the structure the efficiency increases due to more of the wave energy being dissipated on the beach and less being available for transport. This applies particularly to structures with a large freeboard where the transmitted energy level is low. It is therefore important not to over design structures initially, but to allow for minor modifications after construction based on monitoring results.
- 8 The study did not investigate the potential for deposition of sand and fines in the lee of the structures, nor the influence of strong nearshore tidal currents. These aspects need further work.

## CHAPTER 136

### The Role of Rollers in Surf Zone Currents

William R. Dally<sup>1</sup>, M. ASCE, and Daniel A. Osiecki<sup>2</sup>

#### Abstract

Employing a recently developed model for the creation and evolution of the aerated region of breaking waves, the relative importance of the roller in driving and mixing cross-shore and longshore currents is explored. Modeling results using linear wave theory confirm that in the mean balances of mass, momentum, and energy, the roller plays a role comparable to (and sometimes greater than) the underlying organized wave motion. It also appears that the roller is responsible for the landward shift of the peak cross-shore and longshore current observed in laboratory and field measurements, and is as important as the net convective acceleration in cross-shore mixing of the longshore current.

#### Introduction and Background

In the investigation and modeling of nearshore circulation, it has long been suspected that a significant role is played by the aerated region of the breaking wave (see e.g. Svendsen, 1984). However, a lack of understanding and modeling capabilities of the "roller" itself has thus far stymied attempts to clarify its importance in the mean mass, momentum, and energy balances of the surf zone.

A model that describes the growth, evolution, and decay of the breaking wave roller has recently been developed by Brown (1993) and Dally and Brown (1995). This model, annotated below, calculates the time-averaged cross-sectional area of the roller (essentially its mass flux) as a function of position in the surf zone. The roller model has a single fitting coefficient, which has been calibrated by including roller terms in the equations for the mean mass and momentum balances, and then tuning comparisons to data for cross-shore currents from a single wave channel experiment. With the calibration coefficient held fixed, additional comparisons to set-up and undertow data from other experiments reported in the literature are very favorable. Of particular note is a greatly improved ability to model the cross-shore structure of set-up and currents in the transition region of the outer surf zone.

The purpose of the present investigation is, by employing the calibrated and verified roller model, to examine in detail the role played by the rollers in driving set-up and cross-shore and longshore currents. Of specific interest is the magnitude of the roller mass and momentum fluxes relative to the familiar expressions for Stokes Drift and Radiation Stress components, as derived from linear wave theory.

#### Overview of the Roller Model

Based on a depth-integrated, period-averaged energy balance, Dally and Brown (1995) propose a governing equation for the creation and evolution of the aerated region of a breaking wave that is normally incident to the beach. Generalizing this model for the obliquely incident situation, but assuming longshore uniformity, yields

$$\frac{\partial}{\partial x} (F_w \cos \alpha) + \frac{\partial}{\partial x} \left( \frac{1}{2} \rho_r c^2 \cos^2 \alpha \frac{A}{T} \right) = -\rho_r g \beta_D \frac{A}{T} \quad (1)$$

where  $x$  is the cross-shore coordinate (directed onshore),  $F_w$  is the period-averaged energy flux associated with the organized wave motion,  $\alpha$  is the local wave angle relative to shore-normal,  $\rho_r$  is the mass density of the roller (including air),  $A$  is the cross-sectional area of the roller (including air),  $T$  is the wave period,  $g$  is gravity, and  $\beta_D$  is a dissipation coefficient related to the angle of inclination of the roller as it rides the face of the wave.  $\beta_D$  is the primary calibration factor for the model, for which a value of 0.1 has been established by Brown (1993).

In Dally and Brown (1995) it is noted that the dependent variable in Eq.(1) is essentially the period-averaged mass flux in the roller  $\rho_r A/T$ . This obligingly

circumvents the need to specify/model the mass density of the aerated roller  $\rho_r(x)$ . Consequently, the volume flux of water in the roller in the direction of wave propagation,  $Q_r$ , and the momentum flux in the roller,  $M$ , are given by

$$Q_r = \frac{\rho_r A}{\rho T} \quad (2)$$

$$M = \rho_r c \frac{A}{T} = \rho Q_r c \quad (3)$$

Snell's Law is used to provide the local wave angle, and the boundary condition that  $A=0$  at the breaker line is adopted. Using linear wave theory and the wave height decay model of Dally, Dean, and Dalrymple (1985) to compute  $F$  and  $c$ , Figures 1 and 2 present results for the evolution of the volume and momentum fluxes. These quantities are nondimensionalized by their maximum values, which are found well landward of the point of incipient breaking, indicating the end of the transition region.

#### Two-Layer Governing Equations for Cross/Longshore Currents

Laboratory measurements of cross-shore flows (e.g. Nadaoka and Kondoh, 1982), and field measurements of longshore flows (e.g. Rodriguez, et al., 1994) clearly indicate that strong vertical gradients in mean discharge exist at the wave trough level. The cross-shore discharge switches from onshore-directed flow above the trough level (i.e. the Stokes Drift and roller mass flux), to offshore-directed below the trough level (i.e. the undertow) as required due to the presence of the shoreline. Although the longshore discharge does not change directions, it decays from a nearly depth-uniform current below the trough (see Visser, 1991) to zero at the wave crest level. That is, it appears that the most salient vertical structure in the mean horizontal discharge can be represented by splitting the flow in the vicinity of the wave trough level.

A complete set of governing equations for a two-layer (2D-H) current field, which includes terms associated with the roller, has been developed by Dally (1994). For the situation of longshore uniformity and steady currents, the period-averaged, depth-averaged conservation of mass reduces to

$$\frac{\partial}{\partial x} [U(h+\bar{\eta})] + \frac{\partial Q_{wx}}{\partial x} + \frac{\partial Q_{lx}}{\partial x} = 0 \quad (4)$$

in which  $U$  is the depth-averaged cross-shore current,  $h$  is

Figure 1 - Dimensionless volume ( $Q_r$ ) and momentum fluxes ( $M$ ) in the roller from numerical solution of Eq.(1), for a breaker angle of  $20^\circ$ .

Figure 2 - Same as Figure 1. Breaker angle of  $0^\circ$ .

the still water depth,  $\bar{\eta}$  is the mean water elevation, and  $Q_{wx}$  and  $Q_{rx}$  are the mean volume fluxes associated with the organized wave motion and the roller, respectively, projected in the x direction. The period-averaged, depth-averaged momentum equations for the x and y directions are

$$\lambda \frac{\partial}{\partial x} [\rho U^2 (h + \bar{\eta})] + \frac{\partial S_{xx}}{\partial x} + \frac{\partial M_{xx}}{\partial x} + \rho g (h + \bar{\eta}) \frac{\partial \bar{\eta}}{\partial x} = - \overline{\tau_{bx}} \quad (5)$$

and

$$\lambda \frac{\partial}{\partial x} [\rho UV (h + \bar{\eta})] + \frac{\partial S_{xy}}{\partial x} + \frac{\partial M_{xy}}{\partial x} = - \overline{\tau_{by}} \quad (6)$$

where V is the depth-averaged longshore current,  $S_{xx}$ ,  $S_{xy}$ ,  $M_{xx}$ , and  $M_{xy}$  are the Radiation Stress and roller momentum flux components, and  $\overline{\tau_b}$  is the mean bed stress. In this formulation the first terms in Eqs. (5) and (6) are parameterizations of the net convective acceleration associated with the vertical structure of the currents, in which  $\lambda$  is an empirical coefficient. Although the importance of the net convective acceleration to the cross-shore mixing of the longshore current has been explored by Svendsen and Putrevu (1994), this mechanism is not yet well-resolved. However, for the immediate purpose of examining the influence of the roller on the currents, the parameterized form is adequate.

Adopting the quadratic bed stress model:

$$\begin{aligned} \overline{\tau_{bx}} &= \rho \frac{f}{8} \overline{u_b (u_b^2 + v_b^2)^{1/2}} \\ \overline{\tau_{by}} &= \rho \frac{f}{8} \overline{v_b (u_b^2 + v_b^2)^{1/2}} \end{aligned} \quad (7)$$

in which  $u_b$  and  $v_b$  are the total instantaneous velocities at the bed, and the Darcy-Weisbach friction factor f is related to Manning's n by (see Smith, et al., 1993)

$$f = \frac{8gn^2}{(h + \bar{\eta})^{1/3}} \quad (8)$$

and a value of  $0.019 \text{ sm}^{-1/3}$  is used herein.

### Results and Discussion

Neglecting set-up and currents for the moment, and once again using linear wave theory and the breaker model of Dally, et. al (1985) to drive Eq.(1), the volume flux, energy flux, and momentum flux terms of Eqs.(4), (5), and

(6) can be calculated, and their relative magnitudes examined. In Figures 3 and 4, nondimensional quantities defined as

$$\begin{aligned}
 Q'_x &= \frac{Q_r}{Q_w} \\
 F' &= \frac{\frac{1}{2} \rho Q_r c^2 \cos^2 \alpha}{F_w \cos \alpha} \\
 M'_{xx} &= \frac{\rho Q_r c \cos^2 \alpha}{S_{xx}} \\
 M'_{xy} &= \frac{\rho Q_r c \sin \alpha \cos \alpha}{S_{xy}}
 \end{aligned} \tag{9}$$

are plotted versus relative still-water depth for a planar beach of 1/30 slope, with  $H_b/h_b = 0.8$ , and breaker angles of  $20^\circ$  and  $0^\circ$ . It appears that once the roller is fully developed,  $Q_r$  and  $M_{xy}$  are nominally  $1\frac{1}{2}$  times greater than  $Q_w$  and  $S_{xy}$  computed from linear wave theory, whereas  $M_{xx}$  and  $F_r$  are respectively 1 and  $\frac{1}{2}$  times the magnitude of  $S_{xx}$  and  $F_w$ .

To include set-up and currents, the complete system of five equations (energy, Snell's Law, mass, x-momentum, and y-momentum) and five unknowns ( $Q_r$ ,  $\alpha$ ,  $U$ ,  $V$ , and  $\bar{\eta}$ ) are solved numerically. Results for wave decay, set-up and undertow are shown in Figure 5 for  $0^\circ$  angle of incidence. Note that the maximum set-down and maximum cross-shore current are shifted landward of the breakpoint, in qualitative agreement with observations (e.g. Bowen, Inman, and Simmons, 1968). Dally and Brown (1995) present a comparison of similar model results to set-up and undertow laboratory data from the literature, in which it was discovered that quantitative agreement could be achieved if Stream Function wave theory was used to specify the quantities associated with the organized motion.

In contrast to Figure 5, Figure 6 displays results of the model if all roller terms are neglected (the problem reduces to four equations and four unknowns, with wave heights specified by the Dally, et al. breaker model). It is clear that the roller terms are responsible for the transition region.

Figures 7 and 8 are generated for a breaker angle of  $20^\circ$ , and a landward shift in the peak longshore current, due to the roller, is also evident. The convective acceleration is responsible for the longshore current found seaward of the breaker line, and the value for the coefficient  $\lambda$  has been chosen as 0.2 to produce a

reasonable tail. Inside the surf zone, it appears that the roller is as important as the convective acceleration in determining the cross-shore structure of the longshore current. In comparing Figure 5 with Figure 7, altering the breaker angle does not change the cross-shore structure of the dimensionless set-up or undertow.

### Conclusions

By utilizing the very simple roller model developed by Dally and Brown (1995), the long-suspected role played by the aerated region in driving and mixing surf zone currents is confirmed. Because Dally and Brown (1995) found the net convective acceleration to be negligible in the cross-shore momentum balance, it can be concluded that the roller is almost solely responsible for the observed landward shift in set-up and peak cross-shore current.

The roller also appears to contribute significantly to the landward shift in the peak longshore current, as well as to cross-shore mixing in the surf zone. In light of the findings of Svendsen and Putrevu (1994), it is reasonable to conclude that the momentum flux associated with the roller is significantly more important to the horizontal structure of the currents than the turbulent mixing (Reynolds Stress) associated with the wake left behind.

The modeling results also indicate that the roller could be of importance comparable to the net convective acceleration associated with the vertical structure of the currents (Svendsen and Putrevu, 1994); however, a more precise assessment awaits closer study of the vertical structure of the currents. Svendsen and Putrevu (1994) assume it is vertical structure in the longshore current that leads to mixing, where comparison of the laboratory measurements of Nadaoka and Kondoh (1982) for undertow to those of Visser (1991) for the longshore current indicate that it is actually the undertow that is more depth-dependent.

Finally, it is stressed that all of the modeling done herein utilizes linear wave theory to represent the organized wave motion. In light of the findings of Dally and Brown (1995) for set-up and undertow driven by normally incident waves, it is anticipated that Stream Function, or another suitable nonlinear wave theory, will be required to achieve satisfactory comparisons of the model to longshore currents observed in the laboratory and field.

## CHAPTER 137

### THREE DIMENSIONAL MORPHOLOGY IN A NARROW WAVE TANK: MEASUREMENTS AND THEORY

Robert G. Dean<sup>1</sup> and Tae-Myoung Oh<sup>2</sup>

#### ABSTRACT

Results are described from movable and fixed bed wave tank tests to examine the characteristics and causes of three dimensional beach profiles occurring in a narrow wave tank. The movable bed tests demonstrated a strongly repeatable sequence in which both the hydrodynamics and sediment transport patterns were two-dimensional over the initial stages of testing; however, after approximately 200 to 240 minutes, a horizontal circulation appeared and strengthened and resulted in a narrow channel incised adjacent to one of the tank walls. This circulation was reminiscent of a rip current system and resulted in a net landward transport of sediment. During the later stages of profile evolution, an equilibrium was reached in which the profile was steeper and the channel adjacent to the wall persisted. The fixed bed tests were conducted to examine, under controlled conditions, the mechanisms and causes of the horizontal circulation. Tests were carried out specifically to examine generation and maintenance mechanisms for rip currents and edge waves. One set of the fixed bed tests induced a jet into the surf zone and examined its interaction with incident waves. The interaction was found to exert a torque which was counter to that of the induced jet and thus would reduce its circulation. Edge wave mechanisms were examined in the second set of fixed bed tests by generating incident waves with the wave period corresponding to the edge wave length equal to twice the width of the tank for various edge wave modes. No indication of edge waves were found in the experiments. It is concluded that the sequence of profile evolution documented in the movable bed model tests is most likely caused by a long term instability and is reminiscent of and may be representative of the beach recovery stages from a storm profile.

## INTRODUCTION

The nearshore coastal zone is characterized by complex hydrodynamic and sediment transport processes. With few exceptions, three-dimensional hydrodynamic flows occur in the natural system that are associated with three-dimensional bathymetry, including beach cusps, rip currents and some bar morphologies. There has been considerable conjecture and debate in the literature as to the formation mechanisms of the three-dimensional morphology in nature and the necessary conditions for their occurrence under laboratory conditions. It is generally considered that experiments conducted in a narrow wave tank will be free of three-dimensional circulation and morphology and this raises the question of how narrow a tank must be to preclude the formation of such features.

Various mechanisms and causes have been advanced for three-dimensional features in nature, including, for beach cusps: edge waves (Komar, 1973 and Guza and Inman, 1975) and instabilities (Werner and Fink, 1993); for rip currents: combinations of edge waves with synchronous incident waves (Bowen, 1969 and Bowen and Inman, 1969), wave current interaction (Dalrymple and Lozano, 1978), instabilities (Hino, 1974) and topographic control (Dalrymple, 1978); for nearshore three-dimensional features: interaction of edge waves with incident waves (Holman and Bowen, 1982).

The motivation for the experiments presented here resulted from tests in which three dimensional hydrodynamics were found to occur. This led to the program described herein in which experiments were conducted to investigate the causes of and mechanisms associated with the three dimensional features.

## EXPERIMENTS

The experiments were conducted in both movable and fixed bed wave tank facilities.

### Movable Bed Experiments

All experiments commenced from an initially planar beach with 1:18 slope. The tank is 15.5 m long, 0.9 m high and 0.6 m wide. The median sand size was 0.21 mm with a sorting coefficient of 0.58 and a fall velocity of approximately 2.3 cm/sec. The water depth in the horizontal portion of the wave tank was 0.275 m. Regular waves with a height of 0.11 m and a period of 1.5 sec were used. Profile evolution was documented by three lines measured along the tank centerline and at quarter points across the tank width. The profiles were measured manually with a point gage and are denoted, B1, B2 and B3 with B2 being located along the tank centerline. A total of six experiments was conducted with the conditions summarized in Table 1. The experiments are referred to as: (1) Reference Test (Experiment MT01), (2) Repeat Tests (Experiments MT02 and

Table 1

## Movable Bed Experiment Conditions and Objectives

Exp. No.	Duration (min)	Water Table Level (cm)	Objectives
MT01	0-476	0.0	Reference Test
MT02	0-407	0.0	Repeatability Test
MT03	0-545	0.0	Repeatability Test
MT04	0-821	0.0	Perturbations in Bar Topography
	(0-69)	0.0	(No Change)
	(69-138)	0.0	(Bar Trough Deepened)
	(138-352)	0.0	(Asymmetric Offshore Scour Area)
	(352-821)	0.0	(Half of Bar Crest Removed)
MT05	0-1166	+11.0	Initially 3-D Berm. Elevated Water Table Level
MT06	0-1166	+16.5	Higher Water Table

MT03), and (3) Perturbation Tests (Experiments MT04, MT05, and MT06); results are presented below.

Experiments MT01, MT02 and MT03 - These experiments were all conducted with the same general conditions and the results were approximately the same confirming the general repeatability of the tests. A bar formed rapidly as shown in Figure 1. At times ranging from 210 to 270 minutes, the profile appeared to become stable. However, soon after this time, a weak horizontal circulation appeared in the tank. The circulation became stronger and a depth variation across the tank was soon evident with a narrow channel approximately 5 cm deeper than the adjacent bathymetry through the bar on the tank side with the seaward flowing currents. At this stage, the horizontal circulation was quite reminiscent of a rip current cell in nature. The morphological response to this horizontal circulation was quite surprising. It was expected that the horizontal circulation would result in a net seaward transport of sediment; however, the contrary happened. Substantial landward transport occurred with a considerable portion of the material originating from seaward of the bar. As summarized in Figure 2 for Experiment MT03, the bar moved landward during the later times

Figure 1. Mean profile evolution during early stages of Experiment MT01. Elapsed times = 0, 23, 69, 161, and 242 minutes. Note that the profile approached an equilibrium at 242 minutes.

of the experiment and the beach built seaward. At this time, the profile was essentially two-dimensional except for a narrow channel at one side of the wave tank. The remaining experiments in the movable bed tests were conducted to attempt to clarify the causes and mechanisms associated with the results, especially the circulation and transport patterns.

Experiment MT04 - In an attempt to clarify the processes, perturbations were introduced artificially into the morphology to observe the response. The experiment commenced as for the three experiments described earlier and the profile evolution was approximately the same. At a time of 70 minutes, a two-dimensional perturbation to the profile was induced by deepening the bar trough by approximately 4 cm with the sand placed seaward of the bar. The run was then recommenced and it was found that by 140 minutes, the profile had essentially returned to the pre-modification conditions. After 140 minutes, the seaward area

**Figure 2.** Mean profile evolution during Experiment MT03. Elapsed times = 0, 207, 352, 476 and 545 minutes. Note rapid change during 476 to 545 minutes with the landward movement of the bar and advancement of the beach face.

of the bar was intentionally modified from a two-dimensional to a three-dimensional area with approximately the same mean profile as before. It was expected that this modification would change the breaking and circulation characteristics over the bar region. Weak horizontal circulation occurred in the wave tank and was reinforced by a sedimentary feedback. This reinforced three-dimensional circulation transported sands from the higher perturbed area to the area immediately landward of the bar trough, and from there to the lower perturbed area seaward of the bar, resulting in a return to the pre-modified two-dimensional area at a time of 210 minutes. However, during this time, the three-dimensional flow remained too weak to cause onshore sand transport from the area seaward of the bar; hence, the profile remained nearly stable until 300 minutes at which time the bar had rotated by approximately 20 degrees. Here it is worthwhile to note that the circulation direction varied from experiment to experiment. The horizontal circulation strengthened from 300 minutes to 350

minutes and a three-dimensionality in the profile and a net onshore sand transport commenced. At 350 minutes, half of the bar crest was removed from the side of the tank with the channel present and this material was placed in the landward trough, resulting in a monotonic profile over one-half the tank width. This perturbation reinforced the three-dimensional morphology which had appeared in the tank. Within an hour, the morphology returned to its pre-perturbation condition. No additional perturbations were imposed during this experiment. During the remainder of the run, the subsequent profile evolution was approximately the same as in the three experiments described earlier. Sand was transported landward and the profile became nearly two-dimensional with the exception of a fairly deep channel adjacent to one of the side walls.

Experiment MT05 - Experiment MT05 differed from earlier tests in that a constant water level of +11.0 cm was maintained in the berm and the tests commenced with a cross-tank perturbation in the beach face of approximately 4 cm vertically. The elevated water table in the berm was maintained by a siphon and weir arrangement from an excavation in the berm. The reader is referred to Oh (1994) for the details. The perturbed beach face returned to two-dimensionality within the first 23 minutes. During the remainder of the testing, it was found that the evolution was surprisingly similar to those of previous tests, including the appearance of horizontal circulation between 210 and 240 minutes, bar rotation and landward transport of sand, and formation of a fairly deep (6 cm relative to the adjacent bottom) channel adjacent to one side wall. This experiment was extended to 1028 minutes and the profile stabilized at nearly two-dimensional conditions with relative minor seaward and landward oscillations of the bar position. No substantial effect of the elevated water table was evident which led to a decision to investigate this effect further in Experiment MT06.

Experiment MT06 - The berm water table level was maintained at + 16.5 cm in this experiment. One difference between this and previous experiments was that there was some indication that the higher water table accelerated the sequence found in previous experiments. Additionally, it appeared that the higher water table may have resulted a somewhat milder equilibrium profile slope.

Summary of Movable Bed Model Tests - Taken in their aggregate, the six movable bed model tests demonstrated a repeatable sequence as follows. During the initial stages, a two-dimensional bar formed that was stable against induced perturbations. After approximately 240 to 300 minutes a weak horizontal circulation commenced and strengthened gradually. This circulation, reminiscent of a rip current circulation, caused rotation of the bar and a relatively deep channel to be incised adjacent to one of the tank side walls. Associated with the horizontal circulation was a net landward transport of sediment, an advancement of the shoreline and a steepening of the profile. During the later stages of testing, the profile was reasonably two-dimensional except for the channel adjacent to one side of the wave tank. Finally, the only noticeable effects of elevated water tables

in the berm were to cause a slightly increased rate at which the sequence of profile evolution occurred and a possibly somewhat milder equilibrium profile slope.

### Fixed Bed Model Tests

The purpose of the fixed bed model tests was to investigate possible causes and mechanisms of known three-dimensional surf zone phenomena. Specifically, experiments were conducted to clarify the role of wave-current interaction versus wave sediment interaction in the observed rip currents and to determine whether edge waves were likely to have been caused in the movable bed model tests by periodic waves. The fixed bed wave tank is 20 m long, 0.6 m wide, and 1.5 m high and has a uniform slope of 1:20.

Rip Current Tests - One of the rip current theories is that the incident waves provide a reinforcing mechanism, eg. Dalrymple and Lozano (1978). Other investigators (LeBlond and Tang, 1974) have concluded that this interaction would be negative. Bowen (1969) and Bowen and Inman (1969) have attributed the cause of rip currents to the interaction of synchronous incident and edge waves. Hino (1974) has suggested an instability mechanism. A thorough review of rip current mechanisms has been provided by Dalrymple (1978).

A jet with discharge distributed over the water depth was directed into the surf zone as shown in planform in Figure 3. Two current strengths and wave heights were tested. Two approaches were followed to investigate the interaction of waves and currents. The first was direct and consisted of suspending a freely rotating spindle with eight vanes into the surf zone and monitoring its rotations by video. This apparatus will be referred to as a "vorticity meter" in the following discussion and is shown as "V. M." in Figure 3. Results of these tests are shown in Figure 4 in which the rotation under various sequences and combinations of waves and currents are presented. Test F101 involved only the jet and it can be seen that the vorticity meter rotated in a counterclockwise direction at a fairly constant rate. Test F102 involved only waves and there was essentially no rotation. For Test F103, the jet was operated continuously and the wavemaker was activated from  $t=60$  sec to  $t=130$  sec. It is seen that during the time that the waves affected the nearshore system, there was a counter rotation of the vorticity meter (the cumulative rotation changed from a negative to positive slope). After cessation of the waves, the vorticity meter commenced rotating in a counter clockwise direction at the same rate as prior to wave commencement. In the initial stages of Test F104, waves were operated alone during which no rotation of the vorticity meter occurred. After a time, the current was started and the vorticity meter rotated in accordance with the jet induced momentum. Later still in this experiment, the jet was stopped and the rotation ceased.

Figure 3. Schematic diagram of the vorticity measurement tests with a description of conditions for each test.

The second approach to documenting and interpreting the interaction of the waves and induced currents was through measurement of the wave height and direction fields. An example of the wave height field for the presence of the jet and a 9 cm wave height is shown in Figure 5. It is seen as expected that the wave height was enhanced in the vicinity of the seaward flowing current. The radiation stresses associated with the larger wave heights are believed to be responsible for the tendency of the waves to reduce the circulation induced by the jet. In addition to wave heights, wave crest orientations were documented by video, but are not presented here. The wave height and direction fields were used in conjunction with the mean vorticity equations to examine the driving torque due to the interaction. Due to space limitations, these equations will not be presented here; however, it was found, consistent with the vorticity meter results, that the interaction of the waves and currents exerted a torque that was counter to the induced current.

Edge Wave Tests - Experiments were conducted to evaluate the effects of edge waves by generating incident waves of the period associated with an edge wave length,  $L_r$ , of twice the width of the tank,

**Figure 4.** Cumulative rotation at a point within the surf zone as influenced by the jet and waves. Positive rotation corresponds to a counter-clockwise rotation of the vorticity meter.

$$T = \sqrt{\frac{2 \pi L_r}{g \sin[(2n + 1) \beta]}}$$

where  $g$  is gravity,  $\beta$  is the uniform beach slope and  $n$  is the mode of the edge waves. For the tank width of 0.6 m, the periods tested are given in Table 2.

Table 2

Required Incident Wave Periods for Synchronous Edge Wave Generation

n	0	1	2	3	4	5	6	7	8	9	10
T (sec)	3.92	2.27	1.76	1.50	1.33	1.21	1.13	1.06	1.01	0.97	0.94

Figure 5. Wave height distribution in the presence of a jet-induced current when  $H_0 = 9$  cm (Test F222). Wave heights are in cm. Note higher wave heights due to both refraction by current and wave-current interaction.

During these tests, the wave height was set to result in both surging and plunging breaking conditions. Initially, a smaller wave height causing surging breaking wave conditions was generated and continued for ten minutes while the wave tank was monitored visually for edge waves. After ten minutes the wave height was increased such that plunging breaking wave conditions occurred and the run was extended for an additional ten minutes. During all these experiments, no evidence of edge waves was observed.

### INTERPRETATION

The results of the tests requiring interpretation are: (1) The onset of the three-dimensional circulation after the profiles had reached a state of quasi-stability and (2) The onshore transport of sediment by the circulation that was reminiscent of a rip current. Prior to offering an interpretation, it is worthwhile to note the strong repeatability of the experiments and that the fixed bed tests demonstrated that interaction of waves and induced circulation tended to reduce the circulation rather than reinforce it. Additionally, the direction of the induced circulation varied from experiment to experiment. At any time, there are forces that tend to incise channels through the bar and other processes that tend to fill in any lower portions of the bar. The stability of the two-dimensional nature of

the profile for the early stages of the evolution from an initially planar form is believed to be due to the fact that the sand is quite mobile during this time and thus any increase in depth over the bar is rapidly filled by the available sand due to its high mobility. After some time, the profile approaches a quasi-equilibrium state and the sand is less in transit and becomes more consolidated and less mobile. On a subaerial beach, this transition from a poorly consolidated condition to a more consolidated condition is evident when, for a number of hours after accretion of a beach, the pressure due to walking will result in a depression of a centimeter or so into the beach surface. Later, after the waves have consolidated the surface, the sand is less mobile and deforms less in response to surface pressures. Returning to the wave tank results, after the material on the profile surface becomes less mobile, a local deepening of the bar will not be filled in so readily due to less material being readily available for this process. Since the local depression is more efficient hydraulically, the channel deepens gradually until a depth is reached which both relieves the mass transport within the surf zone and results in side slopes that preclude further deepening. With a substantial portion of the mass transport return flow now occurring through the deepened channel, the seaward forces that were present over the bar due to the return flow are reduced resulting in a predominance of the onshore transport processes and the occurrence of a net landward sediment transport, an advancement of the shoreline and deepening of the portions of the profile seaward of the bar. This mechanism is very similar to that of shoreline recovery through ridge and runnel systems and associated breaks in the bar through which the return flow (rip currents) of the mass transport occurs.

### SUMMARY AND CONCLUSIONS

Both movable and fixed bed wave tank tests were conducted to investigate beach profile evolution and the causative hydrodynamic mechanisms. The movable bed experiments demonstrated a repeatable sequence in which, starting from a planar bed, an offshore bar was formed and the profile appeared to approach a quasi-stable two-dimensional form after approximately 200 to 240 minutes. Following this initial stage, a weak three-dimensional circulation appeared and increased in strength causing the bar to rotate. A narrow and relatively deep channel developed adjacent to one of the side walls as a result of this circulation which is reminiscent of a rip current system. The circulation caused substantial net onshore sediment transport and resulted in significant shoreline advancement. During two of the movable bed model tests, the profile was intentionally perturbed and the processes resulted in the profile soon being returned to the form consistent with the evolutionary time without the perturbation. Effects of increased water table elevation were small and resulted in somewhat smaller evolutionary time scales and possibly a milder equilibrium beach slope.

Fixed bed tests were conducted to investigate possible mechanisms that could cause the horizontal circulation experienced. It was found that the interaction of incoming waves with an incoming jet exerted a torque counter to and thus would suppress the circulation by the jet induced circulation. Additionally, experiments especially configured to excite synchronous edge waves were not successful leading to the conclusion that edge waves were not important in driving the circulatory system.

It is concluded on a preliminary basis that the evolution observed, including the appearance of three-dimensional circulation and the associated transport are relevant to the transformation of a two-dimensional bar system in nature to a three-dimensional form and the subsequent migration of the bar to the shoreline and its recovery. The instability mechanism proposed by Hino (1974) is supported by the experiments. If further testing confirms the mechanisms identified in these experiments, a substantial contribution to the clarification of the physics of the nearshore zone will have resulted.

## CHAPTER 138

### Numerical Simulation of Finite Amplitude Shear Waves and Sediment Transport

Rolf Deigaard<sup>1</sup>, Erik Damgaard Christensen<sup>1</sup>,  
Jesper Svarrer Damgaard<sup>2</sup> and Jørgen Fredsøe<sup>1</sup>

#### Abstract

The shear instability of a uniform longshore current and the fully developed shear waves are studied in the numerical hydrodynamic model MIKE-21. The effect of the shear waves on the sediment transport, the cross-shore momentum transfer and mean velocity profile and the dispersion of suspended or dissolved matter is studied. The strength of the shear waves is calculated for a varying flow resistance and a varying momentum exchange coefficient. The formation of shear waves can be suppressed by modest rip channels in a longshore bar.

#### Introduction

Shear waves or far infra gravity waves is a phenomenon which was first observed by Oltman-Shay et al. (1989) from field measurements of wave-driven currents along an almost uniform coast. By analysing the correlation between simultaneous current measurements from different locations it was found that variations in the longshore current were actually a wave motion. The observed waves were only found in connection with a longshore current, propagating in the flow direction with a celerity of about half the maximum longshore current velocity. The observed wave lengths were so small when considering the wave periods that no theory for surface gravity waves can explain the dispersion relation for these waves. Therefore they were termed "far infra gravity waves".

Technical University of Denmark, DK-2800 Lyngby, Denmark

2 H.R. Wallingford, Howbery Park, Wallingford, Oxon Ox10, 8BA, U.K.

The formation of these waves was explained by Bowen and Holman (1989) as the result of an instability of an initially uniform longshore current. A linear stability analysis showed that the crossshore gradient (shear) in the longshore velocity profile is the cause of the instability, similar to the instability of a free shear layer. The instability of a uniform longshore current was apparently first noted by Hino (1974), who had to disregard the unsteady terms in the hydrodynamic equations in order to describe the morphological instability of a uniform sand coast. Since the paper of Bowen and Holman (1989) more refined stability analyses have been performed e.g. Dodd and Thornton (1990) and Svendsen & Putrevu (1992). One of the most important stabilizing factors is the flow resistance due to bed friction, which may cause a longshore current to be stable, analogous to a Hele-Shaw flow.

A linear stability analysis, as the ones listed above, assumes the deviation from the steady, uniform longshore current to be infinitely small and the strength of the shear waves cannot be predicted. By considering a situation very close to a neutrally stable longshore current, a non-linear perturbation analysis has been made (Dodd and Thornton, 1992), which can describe a stationary situation with shear waves. For situations which are far from neutral stability chaotic behaviour may occur, and it is not certain that analytical methods can describe such flows satisfactorily.

The formation of shear waves is strongly dependent on the coastal topography e.g. the presence of longshore bars cf. Svendsen & Putrevu (1992). The stability analyses consider a uniform coastal profile. It is not known if shear waves are formed on a non-uniform coast as for example a longshore bar with rip channels.

### The present study

The purpose of this study is to investigate some properties of shear waves by use of a numerical hydrodynamic model, that simulates the unsteady wave driven currents along a coast. The hydrodynamic model used is MIKE-21 developed by the Danish Hydraulic Institute. The model solves the complete, unsteady depth integrated flow equations. In this way it is possible to make a simulation of the fully developed shear waves on a longshore current driven by waves breaking on a given topography.

An example of a topography is given in Fig. 1 that shows a cross section of a long straight uniform coast. The profile is barred, composed of a plane profile with a slope of  $\tan(\beta) = 1:33.3$ , superposed by a bar with a shape described by a Gaussian function. The still water depth is given by

$$D(x) = D_p(x) - (D_p(x) - D_c) \exp\left(-\chi \frac{(x - x_c)^2}{x_c^2}\right) \quad (1)$$

where  $D_p(x)$  is the plane profile:

$$D_{\rho}(x) = D_0 - x \tan(\beta) \quad (2)$$

$x$  is the cross-shore coordinate. The parameters  $D_c$  and  $x_c$  determine the still water depth over the bar crest and its position.  $\chi$  determines the width of the bar. A similar bar profile was applied in the stability analysis by Svendsen & Putrevu (1992). For the profile in Fig. 1  $D_c$  is 1.5 m,  $x_c$  is 200 m, and  $\chi$  is equal to 30.

### *The wave description*

The wave conditions are modelled by the MIKE-21 NSW module, which describes refraction and breaking of irregular waves with directional spreading. The wave heights are assumed to be Rayleigh-distributed, and the wave breaking is described by the model of Battjes and Janssen (1978). The wave modules are run for a rectangular modelling domain of 400 m  $\times$  3600 m with the long side parallel with the coast line, which is situated at the east boundary. Constant boundary conditions are prescribed at the west boundary: Significant wave height  $H_s = 3.0$  m, mean wave period  $T_m = 9.0$  s, wave direction  $\alpha_0 = 45^\circ$  relative to the coast normal.

The north and south boundary conditions assume uniform wave conditions along the coast. The simulation is run on a grid  $\Delta x = 1.0$  m and  $\Delta y = 5.0$  m. Results from the wave module are shown in Fig. 1. The wave breaking is seen to reduce the wave height at the bar and at the shore line. The shore-normal radiation stress  $S_{yy}$  and the shear radiation stress  $S_{xy}$  vary according to the variation in wave height and direction.

### *The hydrodynamic simulation*

The wave module gives the basis for calculating the radiation stress field, and by differentiation of the radiation stresses, the forcing from the waves is determined. The wave-driven flow is simulated by the hydrodynamic module MIKE-21, which solves the depth-integrated equations for conservation of mass and momentum.

The flow resistance is described by the Manning formula, and the bed shear stress  $\tau_b$  is calculated as

$$\frac{\tau_b}{\rho} = \frac{gV^2}{M^2 h^{1/3}} \quad (3)$$

where  $M$  is the Manning number, which is determined by the bed roughness,  $\rho$  is the density,  $g$  is the acceleration of gravity,  $V$  is mean flow velocity and  $h$  is the water depth.

Figure 1. Bottom: coastal profile. Top: Simulated wave height variation across the profile.

The boundary conditions for the hydrodynamic simulations are specified at the offshore boundary, where the water level is kept constant, and at the upstream and down-stream boundary, where the flux is specified with a distribution across the profile corresponding to a uniform longshore current. The grid size for this hydrodynamic simulation is  $\Delta x = 2\text{m}$ ,  $\Delta y = 4\text{m}$ . The time step is  $\Delta t = 1.25\text{s}$  and the simulation period is 3.0 h. In order to avoid a surge caused by the wave set up, the soft start facility is used, increasing the driving forces gradually from zero to the steady state conditions during a period of 2000s. The topography and the boundary conditions have thus been designed - as closely as possible - to give a steady, uniform longshore current after the warm up period. It appears, however, that the instability mechanism creates an unsteady meandering motion of the longshore flow, which is similar to the shear waves observed by Oltman-Shay et al. (1989).

Figure 2a shows a vector plot of the velocity field at the downstream point of the modelling area at time  $t = 3200$  s and  $5200$  s. Fig. 2b shows the instantaneous water surface elevation along the bar crest for fully developed shear waves. The instability mechanism can clearly be seen, the shear waves become visible at some distance from the upstream boundary. They grow in amplitude to reach an approximately uniform level.

Figure 2. A: Vector plots of the velocity field at the downstream part of the bar. B: Water surface elevation along the bar crest, fully developed shear waves.

Figure 3 shows time series of the longshore and the cross-shore velocity. The time series are taken in the point on the bar crest, 125 m from the downstream boundary. The period of the shear waves is approximately 200s and the wave length is 190 m, giving a phase velocity of 0.95m/s, which is about 55% of the maximum longshore velocity speed. It is seen that the oscillations have all the characteristics of the shear waves observed in the field measurements and described by the perturbation analyses. It has been attempted to make a faster growth of the instabilities by making an abrupt change in the topography near the upstream boundary. It was found that the irregular topography did not enhance the formation of the shear waves significantly.

Figure 3. Time series of longshore (dotted line) and cross-shore (full drawn line) velocities at the bar crest.

### The sediment transport

Based on the results from the wave module and the hydrodynamic module, MIKE-21 can calculate the instantaneous sediment transport rate in every grid point of the hydrodynamic model. The sediment transport is calculated on basis of the water depth, the wave-averaged flow velocity, the wave height, period and direction and the wave breaking. The sediment transport model is based on the model by Fredsøe et al. (1985) including the effect of breaking waves according to the model by Deigaard et al. (1986). Fig. 4 shows the distribution of the calculated longshore sediment transport across the coastal profile. The time-averaged transport at a distance of 125m from the downstream boundary is shown together with a calculation corresponding to the steady uniform conditions that would be found if shear waves were not found. It can be seen that the formation of shear waves causes a reduction in the calculated longshore sediment transport of about 17% compared to the result that would be obtained by assuming steady uniform longshore current.

Due to the non-linearity of the hydrodynamics and the sediment transport the time average of the cross-shore sediment transport deviates from zero. Fig. 5 shows the time averaged cross-shore transport across the profile. The distribution is closely related to the distribution of the driving forces, i.e. the longshore current velocity profile. It tends to modify the bar profile, removing the material from the front of the bar and depositing it offshore and at the crest of the bar. The maximum cross-shore transport rate is of the order  $1 \text{ m}^3/\text{m hr}$ , which is not negligible compared to other contributions.

### Conditions close to neutral stability

The stabilizing mechanisms which may prevent the formation of shear waves in the model are the bed shear stress and the horizontal momentum exchange, modelled as a turbulent eddy viscosity term. In all runs (except when specifically mentioned) the momentum exchange coefficient  $E$  has been specified as zero.

Figure 4. The distribution of the time mean longshore sediment transport,  $q_s$ , across the bar profile. Full drawn line: actual value; dotted line: assuming steady uniform conditions.

### *The flow resistance*

The dependence of the shear waves on the flow resistance has been investigated by varying the Manning number in the example considered above. For a very large flow resistance (small Manning numbers) the longshore current is steady and uniform, but at a certain value ( $M = 21.75 \text{ m}^{1/3}/\text{s}$  in the present case) shear waves are formed with an increasing intensity for increasing Manning numbers. The intensity of the shear waves is characterized by the standard deviation of the velocity fluctuations at the bar crest. The variation of the intensity with the Manning number is illustrated in Fig. 6. It may be noted that the flow resistance in Fig. 6 corresponds to very large bed roughnesses. A  $M$  of  $21.75 \text{ m}^{1/3}/\text{s}$  corresponds to a hydraulic bed roughness of 2.5 m, a  $M$  of  $25 \text{ m}^{1/3}/\text{s}$  corresponds to 1.1 m,  $30 \text{ m}^{1/3}/\text{s}$  to 0.37 m and  $35 \text{ m}^{1/3}/\text{s}$  to 0.17 m. The actual flow resistance will depend on the physical bed roughness and on the turbulent interaction between the wave boundary layer and the current, which will cause an increase in the flow resistance

compared to a pure current situation. This mechanism has not been considered in details in the present study.

Figure 5. The distribution of the time-mean cross-shore sediment transport.

In this investigation shear waves have not been formed on a constant slope beach. A longshore current on a bar is expected to be more unstable, because it has two shear zones and can move freely onshore as well as offshore. For a given coastal profile the stability of a longshore current will depend on the formulation of the flow resistance and the distribution of the driving force ( $\partial s_{xy}/\partial x$ ) across the profile. For small deviations,  $u$  and  $v$ , from the uniform longshore current  $V_0$ , the shear stress can be linearized to give:

$$\bar{\tau}_b = \frac{\rho g}{M^2 h^{1/3}} \bar{V} |\bar{V}| = \frac{\rho g}{M^2 h^{1/3}} \left\{ \frac{u}{V_0 + v} \right\} \sqrt{u^2 + (V_0 + v)^2} \approx \tag{4}$$

$$\frac{\rho g}{M^2 h^{1/3}} \left\{ \frac{V_0 u}{V_0^2 + 2 V_0 v} \right\} = \left\{ \begin{matrix} 0 \\ \tau_{b0} \end{matrix} \right\} + \tau_{b0} \left\{ \frac{u/V_0}{2v/V_0} \right\}$$

where  $\tau_{b0}$  is the bed shear stress corresponding to  $V_0$ .  $\tau_{b0}$  is thus identical with the driving force. For given wave conditions  $\tau_{b0}$  is constant, and the flow resistance for the perturbations is proportional to  $M^{-1}$  or the Chezy coefficient. This flow resistance has many similarities to the 'strong current case' considered by Dodd

(1994). The assumption of irregular waves and the use of the Battjes and Jansen (1978) model for wave breaking give a rather smooth distribution of the driving force and the mean longshore current across a plane beach, which may give a rather weak instability mechanism.

Figure 6. The intensity of the shear waves as function of the Manning number. Full drawn line: longshore velocity, dotted line: cross-shore velocity.

#### *The stabilizing effect of the momentum exchange coefficient*

The dependence of the shear waves on the momentum exchange coefficient has been illustrated by runs similar to the runs with variable flow resistance. The Manning number is kept at  $M = 25 \text{ m}^{1/3}/\text{s}$ , which gave shear waves for  $E = 0 \text{ m}^2/\text{s}$ . Fig. 7 shows the intensity of the shear waves as a function of  $E$ .  $E$  is constant over the entire modelling area. The intensity of the shear waves is seen to decrease with increasing  $E$ , until a very low level is reached at  $E = 0.1 \text{ m}^2/\text{s}$ . An increase in  $E$  may stabilize the flow in two ways: by giving a more smooth velocity distribution of the longshore current or directly by dampning the fluctuations. In the present case with a very smooth distribution of the driving force across the profile it is expected that the latter mechanism is the most important.

#### The exchange of momentum caused by the shear waves

The shear waves cause a redistribution of the momentum across the coastal profile, analogous to the Reynolds stresses in a turbulent flow. The momentum balance is considered at a location where the shear waves are fully developed. If there is no momentum exchange, the driving and the retarding forces are in

balance, and the time-averaged bed shear stress will be identical to the radiation stress gradient  $\partial S_{xy}/\partial x$ .

Figure 7. The intensity of the shear waves as function of the momentum exchange coefficient E.

The cross shore momentum transport due to the shear waves can be calculated as

$$\overline{\rho Duv} \quad (5)$$

where an overbar signifies a time average.

Fig. 8 gives examples of "phase plots" showing the traces of the velocity vectors at three locations: at the bar crest, 40 m offshore and 40 m inshore of the crest. It is clearly seen that the correlation between the longshore and cross-shore velocity fluctuations give a non-zero cross-shore flux of momentum (defined by eq. 5) at the crest and - more pronounced - at the offshore location. At the inshore location the momentum transfer is apparently zero. Traces made at locations further offshore than the three shown here are similar to the inshore trace without any momentum transfer.

Fig. 9a shows the distribution across the coastal profile of the three elements in the momentum balance:

$$-\frac{\partial S_{xy}}{\partial x} = \bar{\tau}_b + \frac{\partial}{\partial x} \overline{\rho Duv} \quad (6)$$

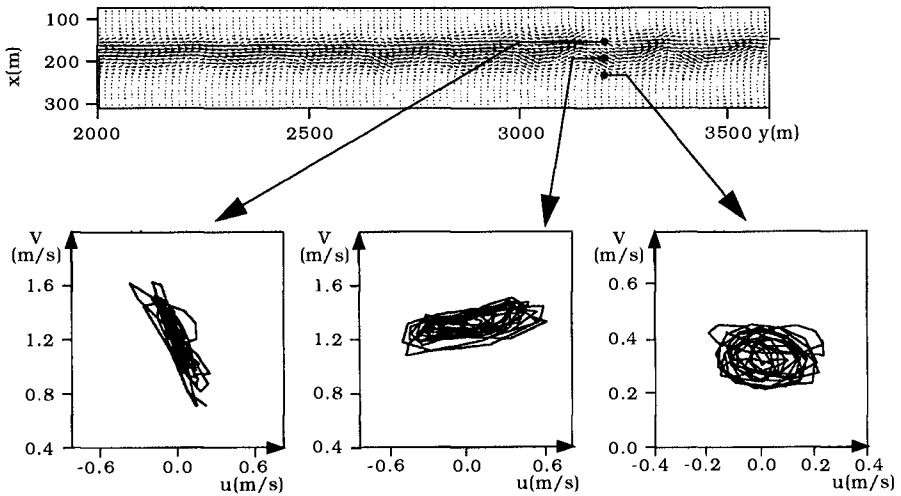

Figure 8. "Phase plots" showing the traces of the current velocity vectors at three locations.  $v$  is the longshore velocity and  $u$  is the cross-shore velocity.

It can be seen that the distribution of the mean bed shear stress is more smooth than the driving force, and the redistribution of the momentum corresponds to the transfer by the shear waves. Fig. 9b shows the mean velocity profile at this cross section together with the velocity distribution corresponding to a steady uniform longshore current. The reduction in the peak of the mean bed shear stress due to the shear waves is closely related to the reduction in the peak of the longshore velocity and the reduction in the sediment transport illustrated in Fig. 4.

In longshore current models the momentum exchange is often modelled by an eddy viscosity term. The maximum of the momentum transfer defined by Eq. 5 is close to the point of maximum gradient in the mean longshore current. The magnitude of the momentum transfer by the shear waves can be illustrated by the eddy viscosity that would be necessary to give a similar transfer of momentum. In the example considered this equivalent eddy viscosity  $E_{eq}$  is found to be

$$E_{eq} = \max(D\bar{u}\bar{v})/\max\left(D\frac{d\bar{V}}{dx}\right) \approx 0.7 \text{ m}^2/\text{s} \quad (7)$$

This is a very large value, considering for example the drastic effect of a much smaller eddy viscosity on the flow regime, cf. Fig. 7.

Figure 9. (A) full drawn line:  $\partial(S_{xy}/\rho)/\partial x$  broken line:  $\bar{\tau}_b/\rho$ , dotted line:  $\partial(D\bar{u}\bar{v})/\partial x$ . (B) Time mean longshore velocity. Full drawn line: actual velocity, dotted line: assuming steady, uniform conditions.

### Longshore non-uniformity of the coastal topography

The bar has been made non-uniform in the longshore direction by giving it a sinusoidal perturbation, representing very weak rip channels. The shear waves have been analysed for varying amplitudes of the perturbation. The strength of the shear waves is characterized by the standard deviation of the velocity fluctuations at the bar crest. Fig. 10 shows the strength of the shear waves as a function of the amplitude of the perturbation of the bar in the profile of Fig. 1. The longshore wave length of the perturbation is 400m. It is seen that the non-uniformity of the bar effectively suppresses the shear waves and that they have disappeared completely for an amplitude of 0.4 m.

Figure 10. The strength of the shear waves as function of the amplitude of the perturbation of the bar.

### Dispersion by shear waves

In addition to the exchange of momentum, the shear waves are effective for dispersing suspended or dissolved matter in the surf zone. This is illustrated by a simulation with the advection-dispersion module of MIKE-21. The hydrodynamic simulation corresponds to the example considered previously. A constant source is placed at the bar crest near the upstream boundary. The dispersion coefficient has been specified to be zero. Figure 11 shows the instantaneous concentration field of the released matter. It can be seen that the plume is deformed by the shear waves and broken up in unconnected units - 'cat eyes', which are also observed in flow visualizations of shear layers. In the case where the source is located at a point offshore of the point of maximum mean longshore current velocity, the "cat eyes" will be formed around another row of vortices.

### Conclusions

Shear waves can be simulated in a numerical model for wave-driven currents. The simulations can be used to study the formation of shear waves and the properties of the fully developed shear waves.

The shear waves are found to be effective in the cross shore exchange of momentum and matter. They reduce the longshore sediment transport and causes a cross shore transport. The present simulation can be improved in a number of ways, e.g. by including wave-current interaction in the description of the flow resistance and by including the effects of time-and-space lag in the description of the sediment transport.

## CHAPTER 139

### BEACH NOURISHMENT AND DUNE PROTECTION

Hans H. Dette<sup>1</sup> and Arved J. Raudkivi<sup>2</sup>

#### ABSTRACT

The environmentally favoured method of beach maintenance by nourishment with sand raises the question of minimization of the average annual sand requirement. In the following sand loss estimation models are compared to field data. A concept for protection of the dry beach and dune areas against erosion during stormtides is discussed as a means of reducing the required sand volumes for the beach maintenance.

#### INTRODUCTION

Sand beaches play a rapidly increasing part for general holiday and weekend activities. Consequently, the "stability" of beaches receives more and more attention. A stable sand beach assumes under a constant wave action an equilibrium form on which the hydrodynamic forces are in equilibrium with the resistance forces of sand grains to movement. The shore normal net movement of sand ceases on such a profile and the amount of sand mobilized by the wave action has a minimum. Large disturbances can be caused to the dynamic equilibrium conditions (average due to usual wave conditions) by the erosion due to heavy storms and storm tides. The sand carried by the storm waves from the high beach into the usual surf zone is after the storm "surplus" to the requirements and has to be redistributed, i.e. in the amount of loss increases.

#### BEACH NOURISHMENT

Beach nourishment is regarded today as the environmentally acceptable method of beach protection. The need for nourishment may arise from a number of causes. For example, an island may lose its beach by littoral transport that is carried beyond the ends of the island and is not returned to the beach; i.a. an open sand system. Likewise a reduction of sediment supply to a coast, by whatever cause, will lead to local erosion that may have to be counteracted by nourishment.

---

<sup>1</sup> Leichtweiß-Institute, Technical University of Braunschweig, POB 3329, 38023 Braunschweig, Germany

<sup>2</sup> University of Auckland, New Zealand, 7 Coates Rd., Howick, Auckland, New Zealand

Nourishment itself also disturbs the dynamic equilibrium of the underwater profile and leads to increased losses. The extent of the disturbance depends on the grain size of sand used in nourishment relative to the native beach sand and on the coastwise extent of the beach fill.

Detle et al. (1994) introduced the assumption that for a two-dimensional beach fill, Fig. 1, the erosion rate under constant energy flux is proportional to the volume. Hence, the eroded volume is

$$V(t) = k_2 e^{-k_1 t} = V_0 e^{-k_1 t} \tag{1}$$

for  $V(t) = V_m$  at  $t = 0$ . A renourishment is required when  $V(t) = V$  and the required volume is

$$V_n = V_m (2^{T_r/T_h} - 1) \tag{2}$$

where  $V_n$  is the volume of nourishment per m,  $V_m$  the minimum volume under an equilibrium profile (Fig. 2),  $T_r$  the renourishment interval and  $T_h$  is the half-life of the beach fill when  $V(t = T_h) = V_0 / 2$ .

Fig. 1 Cross-section of beach nourishment (schematic).

According to eqn (2) the required renourishment volume,  $V_n$ , at a constant  $V_m$  is a function of  $T_r$  and  $T_h$  only. Consequently, the same condition can be maintained with a shorter repetition interval,  $T_r$ , and smaller volume of beach fill,  $V_n$ , or with larger volumes at longer intervals.

Fig. 2 Definition of volumes  $V_0$ ,  $V_m$  at  $t = 0$  after placement of the beach fill (schematic)

The average required rate of sand supply is  $Q_n = V_n / T_r$  or

$$Q_n = \frac{V_m}{T_r} (2^{T_r/T_h} - 1) \tag{3}$$

The rate increases exponentially with  $T_r$ . Conversely,  $Q_n$  goes to minimum if  $T_r$  goes to zero, i.e. a continuous nourishment. Whether a continuous nourishment (according to demand) is practicable is another matter that is not further discussed here, except to say that hydraulic conveyance as sand by - passing has been used for a long time.

Expressing the rate of required nourishment as a ratio of  $Q_n(T_r)$  to  $Q_{min}$  as

$$\alpha = \frac{2^{T_r/T_h} - 1}{(T_r/T_h) \ln 2} \tag{4}$$

shows that both the required beach fill volume (eqn (2)) and the average sand supply rate increase exponentially with repetition interval, Table 1.

$T_r / T_h$	$V_n / V_m$	$\alpha$
0	0	1
1/2	0,41	1,20
1	1	1,44
3	7	3,37
5	31	8,94

Table 1 Dimensionless beach fill volumes  $V_n / V_m$  and average dimensionless annual sand requirement as a function of the ratio of nourishment interval to the half life of the fill,  $T_r / T_h$ .

The result also indicates that for a given  $V_m$ , which is a function of the wave climate and grain size of the beach material, the minimum required sand supply rate occurs at  $T_r = 0$ , i.e. continuous supply.

The deduction is that the optimum supply rate  $Q > Q_{min}$ , is a compromise between practical requirements and aspects that affect the half-life.

Dean (1983) showed on the basis of the Pelnard-Considère (1956) equation that the length of the beach fill,  $l$ , affects the loss rate as

$$(t_p)_2 = (t_p)_1 \frac{l_2^2}{l_1^2} \frac{H_{b1}^{5/2}}{H_{b2}^{5/2}} \tag{5}$$

where  $t_p$  is time required for a percentage  $p$  of the fill volume to be lost,  $H_b$  is the breaker height and subscripts 1 and 2 refer to particular fills.

FIELD DATA

Data are available from six beach nourishment sites on the island of Sylt in the North Sea (by the courtesy of ALW Husum). The coast is a high energy coast with a mean annual shore normal energy flux of ca. 30 000 kWh per m beach. The data from Westerland are plotted in Fig. 3. The volumes were recorded as those above the 4 m datum below mean sea level.

Fig. 3 Decay of repeated beach fill volumes in front of coastal structures at Westerland; Sylt/North Sea

The data show that the initial rate of decrease of the beach fill volume tends to support the exponential loss concept according to eqn (1). However, after about 2.5 to 3 years the slope changes appreciably and the data approach another exponential loss rate. Similar behaviour is illustrated by the data from the other five sites along the southern half of the coastline, Fig. 4. Although the scatter of data points for the reduced loss rate is substantial, the trend is unmistakable.

The relationships like eqn (5) are difficult to verify because although the fill profiles are known as a function of time the amounts of material brought into the study area by littoral transport are essentially unknown. At Westerland the three fills had different lengths. The 1972 fill was in the form of a peninsula into the surf zone with 1 ~ 350 m, extending about 250 m seaward at mean sea level. In 1978 an about 1 km long beach fill of 80 m width and in 1984 one of 1.5 km were placed. Assuming that the wave height remained the same eqn (5) indicates that the time to lose the same percentage of sand from the 1984 fill volume should be approximately 18 times that of 1972. Even for the similar fills of 1 km about 1.5 km lengths the ratio should be 2.25, yet Fig. 3 indicates that the volume was halved in approximately in the same length of time.

An additional feature of the field data is that the seaward slope of the beach fill has a strong effect on the loss of material during storms from the normally dry beach as illustrated by Fig. 5 for two successive winters with comparable storm tide histories.

Fig. 4 Decay of beach fill volumes at 5 sites in front of dunes at the west coast of Sylt/North Sea

Fig. 5 Erosion of dry beach by storm tides on the west coast of Sylt

Peak water levels above MSL were 2.86 m and 3.25 m in 1993 and 1994, respectively with residence times above 2.0 m of ca. 50 and 80 hours respectively. The flat slopes with reduced losses are well described by the Dean-type relationship

$$h = A x^n \quad (6)$$

Apparently, when the waves are able freely run up and down the slope the losses are minimized.

## DUNE PROTECTION

Substantial quantities of sand can be eroded by storm tides from the usually dry beach zone. Steep storm waves at raised water level transport large quantities of sand shore normal to the usual surf zone. Locally these quantities can reach 200 m<sup>3</sup>/m. For example, the 1990 storms eroded 1.8 x 10<sup>6</sup> m<sup>3</sup> of sand from the west coast of Sylt, averaging ca. 60 m<sup>3</sup>/m for the coastline. In many instances only a fraction of this sand is brought back to the beach face by subsequent wave action. The restoration of the dry beach and dune by wind-borne sand transport too is a slow process. Especially in open sand systems most of the "surplus" sand in the every day surf zone can be lost in littoral transport after the storm, i.e. carried beyond the ends of the island and lost from the local sand system. On an out of equilibrium underwater profile the amount of sand mobilized by the daily wave action is higher and hence also the amounts transported currents.

Consequently, for an efficient management of beach nourishment volumes and for the protection of dry beach/dune the uncontrolled transfer of large volumes of sand into the surf zone during severe storms should be avoided. Raudkivi (1989) proposed a method of reduction of the sand loss with the aid of geotextile membrane, Fig. 6.

Fig. 6 Damage limitation of the dry beach and dune by a storm tide with the aid of a geotextile membrane (schematic)

The sand seaward of the membrane may be eroded during a storm or a sequence of storms but that behind it is protected. The membrane usually is called in action only a few days in a year and is thus not comparable to a seawall. If the membrane is uncovered the sand cover has to be restored from the lower beach. The location of the membrane is a matter of optimization. Too near to the water's edge the frequency of maintenance increases, too far the amount of sand lost increases.

In general, an uncontrolled erosion of the high beach leads to an erosion escarpment. In the sand behind the escarpment (or dune) the wave impacts maintain a water table in the sand that is a little higher than the local mean water level at the escarpment. At each wave trough a step is created in the water level, Fig. 7, and the sand starts to drain. The outflow of water concentrates at the level of water in front of the escarpment and carries sand with it. This leads to an undercutting of the sand face which tends to slide down in layers. The loose sand is rapidly dispersed by waves and the process repeats itself.

Fig. 7 Drainage and undercutting of a sand face due to wave action (schematic)

The problem of drainage through a "vertical" face was treated by Nguyen and Raudkivi (1983). Fig. 8 shows the propagation of the phreatic surface back from the sand face. The drawdown,  $s$ , at a distance  $x/h_0$  is expressed in terms of a

dimensionless time  $\tau$  as

$$s = h_0 [1 - G(x/h_0, \tau)]$$

$$\tau = \left( \frac{K}{S_v h_0} \right) t \tag{7}$$

where  $K$  is the permeability of sand (m/s),  $S_v$  is the volume of water retained in the pore space ( $S_v < n$  the porosity) and  $t$  is time.

Fig. 8 Movement of the phreatic surface by drainage through a vertical face (Nguyen and Raudkivi, 1983)

The order of magnitude of the term  $(k/S_v h_0)$  is ca  $10^{-4}$ . Hence, already at  $\tau = 0.01$  the position of the phreatic surface corresponds to that at ca 2 minutes. Consequently, the water surface translation are confined to the immediate vicinity of the sand face, within a fraction of  $h_0$ , i.e. ca 10 to 20 %.

The membrane serves to restrain the sand grain during the drainage periods and to prevent the undercutting. The main requirement, apart from required tensile strength, weathering and abrasion properties, is that it must enable free flow of water, i.e. it must be more permeable than the sand. This is achieved by using an "opening size" in the membrane of about  $d_{65}$  of the sand.

During the wave impacts the wave forces are taken by the sandgrains and the membrane is stressed only by the through flow of water. The pressure waves attenuate in the sand very rapidly due to the air in the voids and in the water, c.f. studies by Nago and Maeno (1987). Consequently, any liquefaction of sand is confined to the immediate vicinity of the sand face.

A system of membranes as shown in Fig. 9 was tested in the Large Wave Flume in Hannover (Führböter, et al. 1991). Fig. 10 shows the initial profile and that after 15 hrs subject to monochromatic waves of 6 - 9 secs with wave heights most of the time 1.0 m and up to 1.3 m. The deformations of the installed membrane were generally less than 10 cm.

Fig. 9 Cross-section of the three-layered membrane tested in the Large Wave Flume in Hannover

Fig. 10 Membrane after 15 hours of wave attack with waves up to 1.3 m height in the Large Wave Flume

The membrane limits the management of beach nourishment volumes to those required to maintain the surf zone under normal sea conditions, i.e. to the supply of sand to replace that lost from the system by the daily littoral transport. The membrane preserves all the sand in the high beach and dune.

About 2 km of such a membrane (two layers) were installed as hurricane protection 1992/93 in Fiji and 300 m in the three layers in a dune in front of a building at the dune's edge on Sylt 1991 (Fig. 11). Both have performed according to expectations.

## CHAPTER 140

# PROFILE CHANGE OF A SHEET FLOW DOMINATED BEACH

Mohammad Dibajnia <sup>1</sup>, Takuzo Shimizu <sup>2</sup> and Akira Watanabe <sup>3</sup>

### Abstract

A new and detailed model for predicting the profile change of a real beach is presented. The model is based on the sediment transport formula of Dibajnia and Watanabe (1992) and therefore incorporates, explicitly, the asymmetry of the near-bottom orbital velocity and the undertow into the transport of bottom sediment. Its applicability is examined by using the data of beach profile change obtained from prototype scale laboratory experiments as well as field measurements. It is shown that quite accurate profile simulation is possible when the details of the flow field and transport mechanism are considered.

## 1. Introduction

An important phenomenon concerned in short-term prediction of nearshore bottom topography changes is the formation and disappearance of longshore bar systems. It is now clear that during storms, usually the shoreward sheet flow sediment transport due to large waves faces the seaward transport of the undertow in a region close to the breaking point and makes a bar. This bar in turn, may be washed out by the undertow of some larger waves and move to deeper waters, or it could be forced by the shoreward transport of other waves to move into shallower waters and form a smaller bar or recover the beach. Also we know that under field conditions, sheet flow movement is the predominant transport mode

over a significant part of the nearshore area including both inside and outside of the surf zone.

In the present study a numerical model for simulating the profile transformation of a real beach is presented. The model is based on sediment transport formula of Dibajnia and Watanabe (1992) which incorporates the asymmetry of near bottom orbital velocity and superimposed currents into estimating the sheet flow sand transport rates. The formula is extended here to cover suspended load as well as bed load transports. Applicability of the model is confirmed through comparison of the simulated profiles with those obtained from prototype scale laboratory experiments and field data. A new formulation for estimating the return flow velocity in the field is also presented.

## 2. Experimental and Field Data

Kajima *et al.* (1982) investigated on-offshore beach profile changes under regular waves in a prototype scale wave flume for a variety of incident wave, bottom slope, and grain size conditions. Two of their experimental cases, corresponding to extreme conditions of erosion and accretion, are selected to be tried against the present model. The conditions for each case are shown in Table 1. In this table  $\tan \beta$  is the initial bottom slope,  $d_{50}$  the median grain size of beach material,  $T$  the wave period, and  $H_0$  the deepwater wave height.

CASE	$\tan \beta$	$d_{50}$ mm	$T$ s	$H_0$ m	Breaker form
3-3	5/100	0.27	12.0	0.65	plunging
3-4	5/100	0.27	3.1	1.62	spilling

Table 1: Experimental conditions

The field measurement data are those reported by Kuriyama (1991) and have been obtained at Hazaki Oceanographical Research Facility (HORF) which belongs to the Port and Harbour Research Institute of the Japanese Ministry of transport and is located at Kashima beach, Ibaraki Prefecture, Japan. The average bottom slope at the site is about 1/60 and the median grain size,  $d_{50}$ , is 0.18 mm. The field investigations have been conducted from the 12th to 26th of September 1988, during which a strong storm has occurred. Profile survey data at the beginning and end of this period are given. Time histories of the offshore significant waves at a mean depth of about 24 m and those of wave height, bottom elevation, tidal level, and cross-shore steady current at a point inside the surf zone, P145, are also reported. The graphical data are transferred to digital data with an interval of two hours by using a digitizer and are used and demonstrated in the present paper.

### 3. Elements of The Model

#### 3.1 Calculation of the wave field

For regular waves, the time-dependent mild-slope equations and numerical scheme of Watanabe and Dibajnia (1988) are used. The equations can take care of wave shoaling, reflection, breaking, and energy dissipation in cross-shore direction. Location of the breaking point is calculated with the generalized breaker index diagram proposed by Watanabe *et al.* (1984).

As for the calculation of the waves in the field, the method proposed by Isobe (1987) for irregular waves is applied. This model is based on an energy conservation equation which contains a breaking dissipation term. The equation which can take care of wave shoaling, breaking, and energy dissipation in cross-shore direction reads:

$$\frac{d}{dx}(Ec_g) = -\frac{5}{2}P_B E \sqrt{\frac{g}{h}} \sqrt{\frac{\alpha_{1/3} - \alpha_r}{\alpha_s - \alpha_r}} f_d(kh) \tan \beta \quad (1)$$

in which  $E$  is the total wave energy,  $x$  the cross-shore distance,  $g$  the acceleration of gravity,  $\alpha$  the ratio of water particle velocity at the wave crest to the wave celerity,  $c_g$  the group velocity,  $f_d$  a function of the wave number  $k$  and the water depth  $h$  given by Isobe (1987), and  $\tan \beta$  the local bottom slope. Values of  $c_g$  and  $f_d$  should be calculated by using the peak frequency of the spectrum.  $\alpha_r = 0.135$  and  $\alpha_s = 0.4(0.57 + 5.3 \tan \beta)$  are the values of  $\alpha$  for broken waves recovered in a uniform depth region and for breaking waves on a uniform slope, respectively (see Dibajnia and Watanabe, 1988). In the above equation  $P_B$  is the breaking probability and is obtained from the following relation

$$P_B = \left\{ 1 + 2.004 \left( \frac{\alpha_b}{\alpha'_{1/3}} \right)^2 \right\} \exp \left[ -2.004 \left( \frac{\alpha_b}{\alpha'_{1/3}} \right)^2 \right] \quad (2)$$

where  $\alpha_b$  is the critical value of  $\alpha$  for breaking and  $\alpha'_{1/3}$  is the value of  $\alpha$  if the waves continue to shoal without breaking. By using  $P_B$ , Equation (1) can be used for both outside and inside of the surf zone.

For both regular and irregular waves, the change in the position of shoreline due to the setup of mean water level (and tides) is incorporated through applying a moving boundary technique which allows a variable grid size at the shoreline.

#### 3.2 Estimation of the near-bottom velocity profile

In reality, waves are nonlinear due to finite depth and asymmetric due to the bottom slope. Despite recent developments in applying Boussinesq equations to predicting the relevant properties of waves over the whole nearshore region, an empirical method is applied in the present study to estimate the near-bottom

velocity profiles. This is because that only information about significant wave height and period of the incident waves are available for the field case. Isobe and Horikawa (1981), based on laboratory experiments, proposed empirical formulas for estimation of velocity profile properties of normally incident waves on a beach with uniform slope up to the point of breaking. The validity of their relations for estimation of velocity profile of prototype-scale shoaling waves over an erodible bed has been verified by Maruyama *et al.* (1983). In the absence of a reliable theory or formulation for breaking waves, in the present work the method of Isobe and Horikawa (1981) is applied to the surf zone region as well as the offshore region. It has been shown in a separate paper (Dibajnia *et al.*, 1992) that inside the surf zone, the method of Isobe and Horikawa gives reasonable results for spilling breakers, but fails to predict the velocity profile of plunging breakers accurately.

The method is also applied to estimating the asymmetry of orbital velocity profile at the bottom for irregular waves by using values of the significant wave height and period. According to the experimental study of Sato *et al.* (1988), the asymmetry of velocity profile in the surf zone is less than those in the offshore and in the breaking region. Therefore, the estimated velocity profiles inside the surf zone are modified gradually from the breaking point to the shoreline.

### 3.3 Calculation of the undertow

Undertow is the name given to the average seaward return flow found below wave trough level. It balances the mass flux carried shoreward by breaking waves including the effect of the surface roller. Despite its simple qualitative description, a general mathematical formulation of the undertow and its vertical distribution is difficult and not yet available. For regular waves over simple bottom profiles, Okayasu *et al.* (1990) took the mass balance approach and presented a model based on the experimental results and the assumption that following the breaking, the wave energy is transferred to the roller or large vortices, is kept by them for a while, then is conveyed to the small structure turbulence and is dissipated. The time-dependent mild-slope equations of Watanabe and Dibajnia (1988) were used to estimate the rate of energy transfer. The model showed good agreement with the experiments, however, its application to more general cases is not straightforward.

A simple model based on the assumption that the mass flux of a bore propagating shoreward is proportional to the square of the wave height was presented by Sato *et al.* (1988). By assuming that the corresponding return flow is uniform over the local mean water depth,  $D$ , the steady component of near-bottom velocity was estimated as

$$U = U_w + U_b + U_e \quad (3)$$

Figure 1: Undertow velocity measured at the point P145 versus Eq. (4).

in which  $U_b$  is the undertow velocity given as

$$U_b = -A \frac{H^2}{D \cdot T} \quad (4)$$

,  $U_w$  the offshore flow compensating the onshore mass flux due to the irrotational wave motion,  $U_e$  the Eulerian mass transport velocity at the edge of the laminar boundary layer,  $T$  the wave period,  $H$  the wave height, and  $A$  a nondimensional coefficient of the order of unity. These two models are used here for calculating the undertow velocity of regular waves.

For the irregular waves in the field, in order to examine the applicability of Eq. (4) to estimating the undertow velocity caused by breaking, values of the significant wave height,  $H_{1/3}$ , and the mean water depth measured at the point P145, together with the values of the significant wave period,  $T_{1/3}$ , of offshore waves are substituted into Equation (4) and the results are compared with the measured values of the cross-shore mean current velocity at P145 as shown in Fig. 1. A large scatter is observed and it is hard to define a value for the coefficient  $A$ . Those data with a deepwater wave steepness greater than 0.023 are shown by triangle symbols. It may be seen that these data are more or less separated from the others. On the other hand, it is expected that the undertow velocity varies with the beach slope. From these two points one may conclude that the undertow velocity should depend on the surf similarity parameter,  $\xi = \tan \beta / \sqrt{H_0/L_0}$ , which is often used to classify the breaker types. Thus, the return flow velocity should vary with the breaker type, as it is indeed a breaking generated process. Also, using the bottom slope at the breaking point,  $(\tan \beta)_b$ , would be more appropriate than  $\tan \beta$ . Figure 2 shows the results of such an analysis when  $\xi_b = (\tan \beta)_b / \sqrt{H_0/L_0}$  is used instead of  $\xi$ . In this figure it is assumed, considering the incident waves, that during the first half of the measurement period the waves were breaking in deeper waters on a slope of 1/60 because they were large (see Fig. 8), and during the second half they were breaking on the bar closer to the

Figure 2: Undertow velocity measured at the point P145 versus Eq. (5).

shore with a slope of about 1/25. It can be seen that the data show a good trend which may be written as

$$U_b = -22 \frac{H_{1/3}^2}{D \cdot T_{1/3}} \cdot \xi_b \tag{5}$$

The next problem regarding the undertow of irregular waves is about its distribution in cross-shore direction. In case of regular waves there is a certain breaking point which controls the distribution. For irregular waves, however, there is not such a point and at any location some of the waves may break because waves of different heights and periods are involved. At each point it is only this breaking portion of the waves which contributes to the generation of the undertow. Thus, considering the ratio of the energy of the broken waves to the total wave energy we may write

$$U = -22 \left( 1 - \frac{E}{E'} \right) \frac{H_{1/3}^2}{D \cdot T_{1/3}} \cdot \xi_b \tag{6}$$

for irregular waves. Here,  $E$  is the total wave energy, and  $E'$  the total wave energy of an imaginary case in which the same waves shoal without breaking. P145 is a point inside the surf zone where all the waves are expected to break and hence  $E/E' \simeq 0$ . At other locations, however, because of irregularity only part of the waves may break and it is only this breaking portion of the waves which is taken into account.

### 3.4 Sediment transport rate

The sediment transport formula of Dibajnia and Watanabe (1992) is used. This formula has been made for the transport under sheet flow conditions, but is extended here to be able of estimating the suspended load and bed load transport

Figure 3: Definitions for the near-bottom velocity profile.

rates as well. The nondimensional net transport rate,  $\Phi_s$ , is obtained by

$$|\Phi_s| = \frac{q_s(1 - \epsilon)}{Wd} = 0.001 \cdot \text{sign}(\Gamma) \cdot |\Gamma|^{0.55} \tag{7}$$

where

$$\Gamma = \frac{u_c T_c (\Omega_c^3 + \Omega_t^3) - u_t T_t (\Omega_t^3 + \Omega_c^3)}{(u_c + u_t)T} \tag{8}$$

in which  $u_c$  and  $u_t$  are the equivalent sinusoidal velocity amplitudes of positive and negative portions of the near-bottom velocity profile including the steady current (Fig. 3), respectively, and are defined as

$$u_c^2 = \frac{2}{T_c} \int_0^{T_c} (u_w + U)^2 dt \quad \text{and} \quad u_t^2 = \frac{2}{T_t} \int_{T_c}^T (u_w + U)^2 dt \tag{9}$$

with  $T_c$  and  $T_t$  being their corresponding time durations, respectively, and  $u_w$  the near-bottom orbital velocity. Values of  $\Omega_j$  in Eq. (8) are obtained as follows.

$$\left\{ \begin{array}{l} \text{if } \omega_j \leq \omega_{\text{critical}} \\ \text{if } \omega_j > \omega_{\text{critical}} \end{array} \right\} \left\{ \begin{array}{l} \Omega_j = \omega_j \cdot \frac{2WT_j}{d} \\ \Omega_j' = 0 \\ \Omega_j = \omega_{\text{critical}} \cdot \frac{2WT_j}{d} \\ \Omega_j' = (\omega_j - \omega_{\text{critical}}) \cdot \frac{2WT_j}{d} \end{array} \right. \tag{10}$$

with

$$\omega_j = \frac{1}{2} \frac{u_j^2}{sgWT_j} \tag{11}$$

In the above relations  $q_{\text{net}}$  is the net volumetric transport rate,  $\epsilon$  the sediment porosity,  $d$  the sediment grain size,  $W$  the sediment fall velocity,  $s = (\rho_s - \rho)/\rho$  where  $\rho$  and  $\rho_s$  are the densities of water and sediment, respectively, and the

subscript  $j$  should be replaced by either  $c$  or  $t$ . It should be mentioned that the factor 2 in relations (10) has been mistakenly omitted in the original paper of Dibajnia and Watanabe (1992).

In order to extend this formulation to estimate suspended load and bed load transport rates, we note that in the actual phenomenon at the sea bottom there is a transition region between the rippled bottom of suspended load and the flat bed of sheet flow. Over this region, the ripple height decreases, and the net transport rate changes its direction from the seaward suspended load to the shoreward sheet flow. Furthermore, experimental results show that  $\omega_{\text{critical}} = 1$  for sheet flow transport (Dibajnia and Watanabe, 1992), while  $\omega_{\text{critical}} = 0.03$  for the transport over ripples (Suzuki *et al.*, 1994). Therefore, by gradually changing the critical value of  $\omega$  from unity to a value of 0.03, an effect similar to the above phenomenon can be simulated. Thus

$$\omega_{\text{critical}} = 1 - 0.97\sqrt{\Lambda} \quad (12)$$

in which the parameter  $\Lambda$  is given by

$$\Lambda = \left[ 1 - [(\Psi_{\text{rms}} - 0.2)/0.4]^2 \right] \cdot \min(1, 2\lambda/d_0) \quad (13)$$

where  $\Psi_{\text{rms}}$  is the Shields number estimated in terms of the root mean square of near bottom velocity profile,  $\lambda$  the ripple wavelength, and  $d_0$  the orbital diameter of water particle displacement at the bottom. In this relation it is assumed that the transition from rippled bed to flat bed occurs in a parabolic manner as the Shields number increases from 0.2 to 0.6. For  $\Psi_{\text{rms}} > 0.6$ , which corresponds to the sheet flow condition,  $\Lambda$  should be set equal to zero. When  $\Psi_{\text{rms}} < 0.2$  then  $\Lambda = 1.0$ . The last term takes care of the fact that when  $d_0$  is much larger than  $\lambda$  on a rippled bed, the net transport rate should be in onshore direction. The functional form of Eq. (13), however, needs further varification. Also, the limiting values of the Shields number in this equation should be modified if Eq. (7) is to be tried against laboratory data on net sediment transport rate.

## 4. Results and Discussion

### 4.1 Prototype scale laboratory experiments

Profile change simulation of each experimental case is conducted for 15 hours of wave action and with both of the undertow models of Okayasu *et al.* (1990) and Sato *et al.* (1988), Eq. (3). Longer time durations are not tried because of the decrease in the accuracy of these models over complicated topographies. It is assumed that the undertow velocity is uniform over the local depth. In both of the models, the calculated steady currents are multiplied by hyperbolic functions in a region from the transition point to a point which is ten times of the breaking depth far from the breaking point in the offshore direction, so as to assume values of zero in the offshore region. The position of transition point is estimated by the

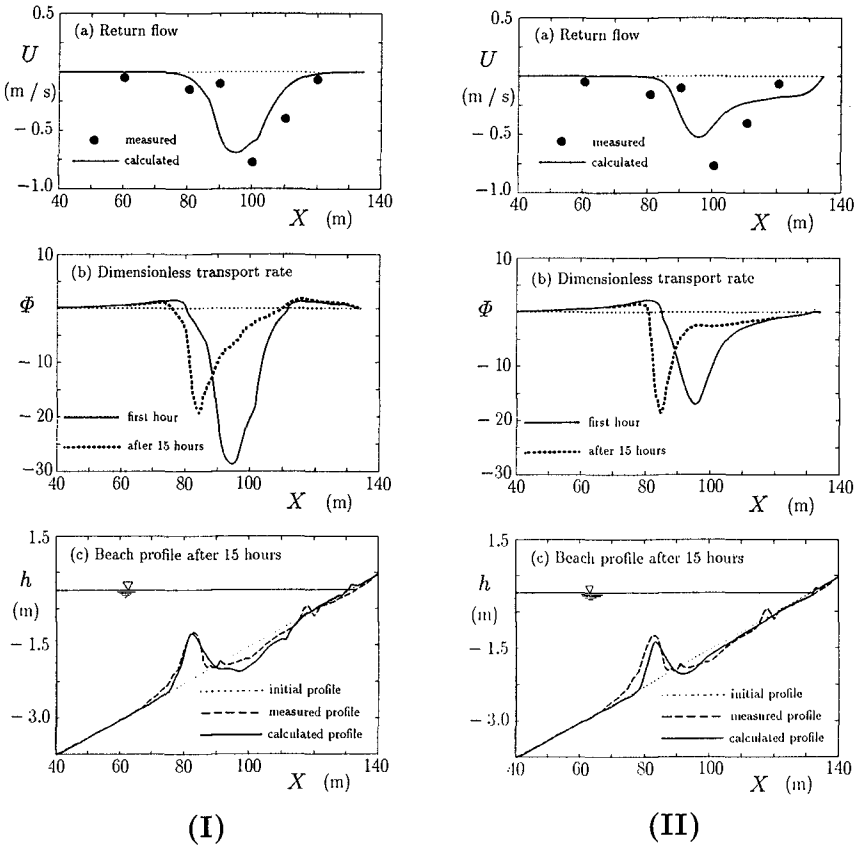

Figure 4: Simulation results for Case 3-4 with the undertow model of (I) Sato *et al.* and (II) Okayasu *et al.*.

formula of Okayasu *et al.* (1990). Steady current velocities obtained by the model of Sato *et al.* are multiplied by a hyperbolic function also in the region between the transition point and shoreline in order to obtain a more realistic distribution.

Figures 4 and 5 show the numerical simulation results and their comparison with the measurements. It is observed that the return flow calculated by Sato *et al.*'s model (with  $A = 4$ ) agree well with the experimental data for case 3-4. It should be noticed that this case has a breaker of spilling form. Therefore, the method of Isobe and Horikawa for calculation of near-bottom velocity profile is supposed to give reasonable profiles. As a result it is seen that the development of bottom profile and the position of bar are fairly well simulated. When the model of Okayasu *et al.* is applied to this case, also reasonable results are obtained.

On the other hand, the model of Sato *et al.* considerably underestimates the

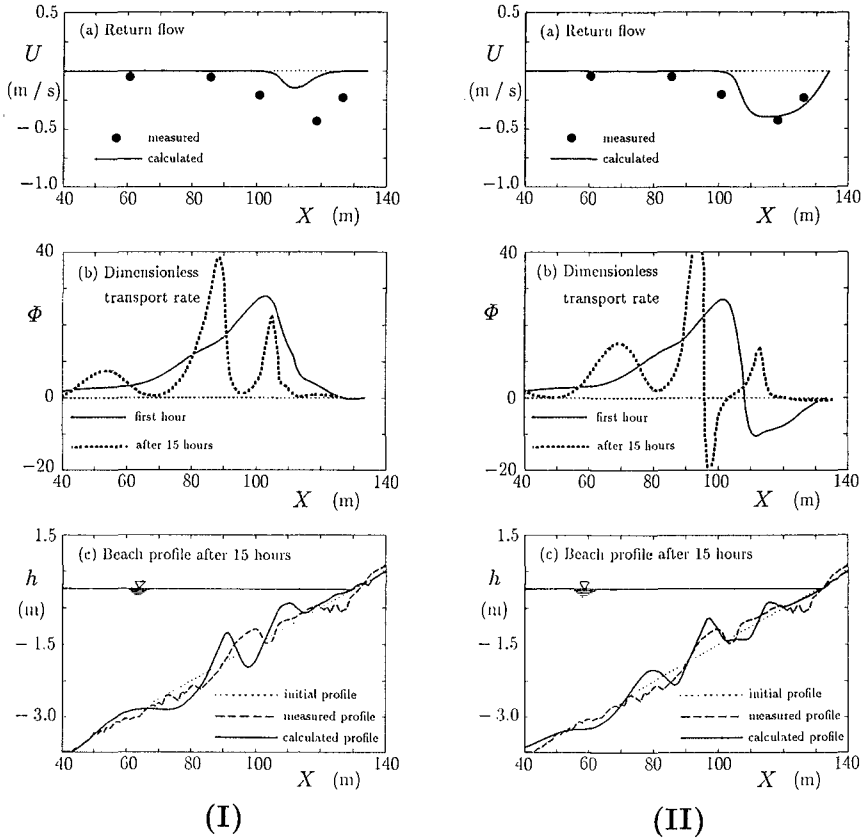

Figure 5: Simulation results for Case 3-3 with the undertow model of (I) Sato *et al.* and (II) Okayasu *et al.*.

undertow velocity of case 3-3. The performance of Okayasu *et al.*'s model in this case is better and the resulting profile is more acceptable. Strong reflection appears in the calculation of wave field for case 3-3. This reflection has much affected the transport rate distribution and consequently the profile change, specially in the offshore region. Figure 6 shows the resulting beach profile for the same case as that of Fig. 5(II) when reflected waves are removed from the wave field. A remarkable improvement is observed. In general, from the above results it is clear that the simulation of beach profile is quite sensitive to the estimation of the flow field, particularly the steady current velocity and its cross-shore gradients or distribution.

#### 4.2 Field measurements

Figure 6: Simulation results for Case 3-3 when reflection is removed (undertow model of Okayasu *et al.*).

The model described in Sec. 3 is now applied to simulating the beach profile change which has occurred during the field measurements reported by Kuriyama (1991). Using the offshore incident wave data as the input, the wave field and its corresponding profile change are calculated every two hours.

In order to examine the sensitivity of the results on the method of estimating the undertow, at first the following equation is used for estimation of the return flow and its distribution:

$$U = -A \left( 1 - \frac{E}{E'} \right) \frac{H_{1/3}^2}{D \cdot T_{1/3}} \quad (14)$$

The best agreement between the calculated and measured final profiles is obtained when  $A = 5.6$  as shown in Fig. 7. It is seen that the general features of the

Figure 7: Beach profile change by using Eq. (14) with  $A = 5.6$ .

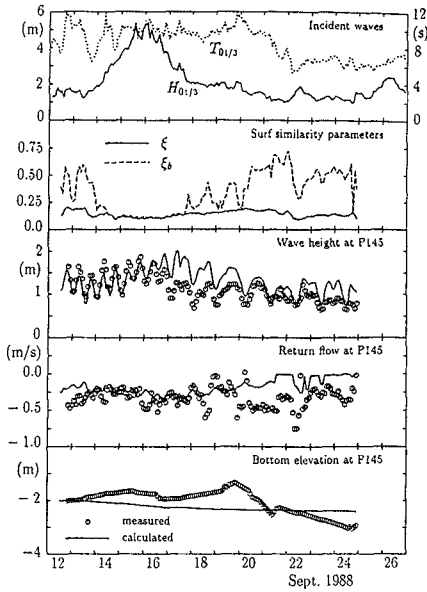

Figure 8: Time histories of deepwater incident waves, surf similarity parameter, and wave height, undertow velocity, and bottom elevation at P145.

Figure 10: Calculation results at three different times.

Figure 9: Calculated and observed breaking positions.

profile evolution, such as disappearance of the offshore bar and movement of the nearshore bar are well simulated. More details of the calculation results of this case are given in Figures 8 to 10. In Fig. 8 time variations of the deepwater incident waves and of the surf similarity parameters  $\xi$  and  $\xi_b$  are given. Also the calculated time variations of the wave height, undertow, and bottom elevation at the point P145 are plotted and compared with the measurements. The agreement between calculated and measured wave height is quite good. Estimated values of the undertow show good agreement with the measurements only during the large wave conditions when the values of  $\xi$  are nearly same as  $\xi_b$ , as was discussed in Sec. 3.3. Prediction of the bottom elevation at P145 is not satisfactory. This is attributed to the errors in estimating the cross-shore distribution of return flow, three dimensional effects, and also partly to the neglect of breaking induced turbulence. Figure 9 shows the comparison between calculated and measured breaking points. Calculated results are shown by a dashed line and are plotted on Fig. 6(2) of Kuriyama (1991). A breaking point in the calculations is defined when  $\alpha'_{1/3} = \alpha_b$  which gives  $P_B = 0.4$ . Considering the breaking of irregular waves, this is likely to correspond to the offshore limit of the breaking zone.

In Fig. 10 some of the calculation results at three different times are given. It can be seen that values of the Shields number are usually greater than 0.5 over a large portion of the domain, indicating that sheet flow is the dominant transport mode. Large values of undertow, offshoreward transport rate, and Shields number are observed for the waves of Sept. 16, 1988. It is around this time that the offshore bar disappears and it is well simulated by the model. The large waves on the other hand, have less effect on the nearshore profile, and the change in the nearshore region is mainly occurred after the storm is finished.

As for the next case, Equation (6) is used for calculating the undertow. Figure 11 shows the time variation of the undertow velocity and its comparison with the measurements at the point P145. In Fig. 12 the result of profile simulation

Figure 11: Undertow velocity at the point P145 using Eq. (6).

is given. Although an improvement in the estimation of the undertow velocity is observed, but the resulting beach profile does not show an improvement. The reason is attributed to the errors in estimation of cross-shore distribution of the undertow, determination of the bottom slope at the breaking point, effect of alongshore variation in the flow field and the existence of rip currents, and the

Figure 12: Beach profile change by using Eq. (6).

neglect of breaking induced turbulence. Further study on modelling of the flow field is thus required for more improvements.

## 5. Conclusions

A new and detailed model of beach profile change is presented. It incorporates, explicitly, the asymmetry of the near-bottom orbital velocity and the undertow, into the transport of bottom sediment. The model is examined by using the data of beach profile change obtained from prototype scale laboratory experiments as well as field measurements. It is shown that quite accurate profile simulation is possible when the details of the flow field and transport mechanism are considered.

The results show strong dependency on the distribution and magnitude of the undertow velocity. For further improvements, accurate and general models for estimation of the near-bottom orbital velocity profile in the surf zone and for undertow velocity are required. The so-called swash transport is not included in the present model and therefore the profile change around the shoreline is not well simulated. Modelling of the swash zone is left for a future study.

## CHAPTER 141

### A NONLINEAR SURF BEAT MODEL

Zhili Zou<sup>1</sup> and Nicholas Dodd<sup>2</sup>

#### Abstract

A nonlinear, short-wave-averaged (surf beat) model is presented. The model is based on that of Roelvink (1993), but the numerical techniques used in the solution are based on the so-called weighted-averaged flux (WAF) method (eg Watson et al, 1992), with time-operator splitting used for the treatment of some of the source terms. This method allows a small number of computational points to be used, and is particularly efficient in modelling breaking long waves. The short-wave (or primary-wave) energy equation is solved using a more traditional Lax-Wendroff technique. Results of validation indicate that the model performs satisfactorily in most respects.

#### Introduction

There are two classical characteristic time-scales in a system of waves: that of the individual waves and that of the wave groups. On the time scale of the wave group the short-wave averaged momentum flux ("radiation stress") and mass flux ("wave-induced mass flux") vary slowly. This variation in time and space of radiation stress and mass flux generates long waves with periods and wavelength similar to the group periods and lengths. These long waves may travel with the wave groups or they may be released as free waves if the wave groups forcing them change rapidly, e.g. due to breaking in the surf zone. The free waves either escape to deep water ("leaky modes") or are trapped at the shoreline by refraction as "edge waves". These long waves are often collectively called infragravity waves or "surf beat".

---

<sup>1</sup>Dalian University, Dalian 116024, China

<sup>2</sup>Coastal Group, HR Wallingford, Howbery Park, Wallingford, OX10 8BA, UK.

In the recent decades numerous observations have shown that the energy at surf beat frequencies can be substantial, and in some cases even exceed that of the short waves (Wright et al, 1982). Likewise, the shoreline amplitudes arising from infragravity waves can be comparable to the run-up height of short waves (Guza and Thornton, 1982; 1985). The importance of low-frequency motion for the nearshore dynamics can be inferred from the fact that natural sedimentary coasts often exhibit morphological features (bars and cusps) with length scales considerably in excess of those of the wind waves. This is found to be particularly pronounced in very shallow water. The effect of surf beat on morphology was found to increase offshore transport and to move bars in a seaward direction while reducing their amplitude (Roelvink, 1993). Recent work done at HR Wallingford (Bowers, 1992) highlighted the need for accurate numerical modelling of surf beat: physical model experiments using realistic short crested waves demonstrated the importance of surf beat as well as incident set-down in causing long waves inside harbours. This surf beat is produced by groups of waves breaking on the shoreline surrounding the harbour. Due to the large length of shoreline needed for realistic modelling of the generation of surf beat in a physical model, an efficient mathematical model of surf beat generation would be far more cost effective than extensive additional coastline moulding in a physical model together with additional lengths of wave-maker. The work in this report has been undertaken as a first step in meeting this need in that only cross-shore wave modes are considered.

In the early sixties Longuet-Higgins and Stewart developed the concept of "radiation stress", by which they explained how groups of high waves are accompanied by a depression of the mean water surface. In other words, groups of short waves force a long wave, which is known as the set-down or the bound long wave. This concept successfully explained many of the early observations of surf beat, and forms the basis of many subsequent surf beat models.

In one of the earliest such models, Symonds et al. (1982) assume that within the inner surf zone, the short waves are "saturated", meaning that the variations on wave group scale have vanished and the radiation stress gradients are constant in time. Outside the surf zone, they assume that the horizontal variation of radiation stress is negligible (and thereby do not include the effect of bound waves). In the transition region, the breaking-point moves back and forth; in this region there is a radiation stress gradient varying in time. This gradient acts as a local forcing, comparable to a wave maker which generates waves both in the onshore direction and (with opposite sign) in the offshore direction. The onshore directed wave is subsequently reflected off the beach and interferes with the offshore directed wave. Depending on the dimensionless width of the surf zone, the relative phase of the two free outgoing wave components change, resulting in an enhancing or damping of the total free wave radiated from the surf zone. The fact that such an amplitude variation with the dimensionless surf zone width exists was confirmed in laboratory experiments by Kostense(1984); however, the

quantitative agreement between the model and experiments was not entirely convincing.

Schäffer and Svendsen (1988) improved this model concept by including the forcing outside the surf zone responsible for the bound long waves. In their model this forcing is reduced in the surf zone but does not vanish completely since they relax the rigid assumption of a saturated inner surf zone. Schäffer and Jonsson (1990) compared this model with Kostense's (1984) data and found considerably better agreement; remaining discrepancies can be ascribed to the lack of bottom friction and the use of linearized equations in their model.

Roelvink (1993) developed a nonlinear surf beat model based on short-wave averaged mass and momentum conservation equations (Phillips 1977). To get the radiation stress, a mean short wave energy transportation equation was solved simultaneously, which included the effect of variation of mean water level on the energy evolution. Numerical results for incident bichromatic waves agreed with the Kostense (1984) data to different degrees depending on the bottom friction coefficient used. For incident irregular waves, a narrow band assumption was used to overcome the difficulty of determining the group velocity of irregular waves, which is needed in the calculation of radiation stress. Comparisons of numerical results with Van Leeuwen's (1992) (random) experimental data showed good agreement. This model was then applied to the study of the effect of surf beat on cross-shore beach morphology.

The numerical models mentioned above are all based on the 'wave-averaged' approach, i.e. averaging the mass and momentum conservation equations over a short wave period and using the concept of radiation stress to express the short-wave momentum flux. The disadvantage of this approach is that questionable assumptions are made about the validity of linear theory for the propagation of breaking waves within the surf zone. An alternative to this is to use short-wave-resolving models to study the full wave motion, including the generation processes of low frequency wave. This is usually done using either the nonlinear shallow water wave equations (in the inner surf zone) or the Boussinesq equations (or both). Whilst being more satisfactory from a theoretical point of view, this approach obviously involves considerably more computational time and expense than the wave-averaged approach. In this work we therefore chose to follow the wave-averaged route.

### Equations of motion

The shallow-water wave equations for the conservation of mass and momentum (in 1-D) can be written (in so-called conservation form, and in the absence of bottom friction) as

$$d_t + (du)_x = 0 \quad (1)$$

$$(du)_t + (u^2d + \frac{1}{2}gd^2)_x = gdh_x \quad (2)$$

where  $u$  is the depth-averaged fluid velocity,  $d$  is the total water depth,  $g$  the gravitational acceleration constant, and  $h$  the still water depth ( $x$  is the offshore coordinate, and  $\zeta = d-h$  is the free surface elevation). The term on the right, arising from the bottom slope w.r.t.  $x$ , is referred to as a source term. These equations resolve the primary wave motion. In order to exclude this type of motion, the original equations must be time as well as depth averaged. This results in a similar continuity equation (see below), but additional terms appear in the momentum equation. To treat these properly we start from the momentum equation of Phillips (1977) describing time and depth-averaged 1-D motion,

$$\frac{\partial}{\partial t} \int_{-h}^{\zeta} \rho u \, dz + \frac{\partial}{\partial x} \int_{-h}^{\zeta} (\rho u^2 + p) \, dz - p_b \frac{d}{dx} h + \bar{\tau}_b = 0 \quad (3)$$

where  $\rho$  is water density, and  $p$ ,  $p_b$  are pressure and pressure at the bottom respectively, and an overbar denotes an average over a short wave period. The following decomposition is made:

$$u = U + u' \quad (4)$$

where  $U$  is the long wave velocity and  $u'$  is the fluctuating component (due to the primary waves). We define

$$d = h + \zeta \quad (5)$$

so that  $d$  now denotes a mean total depth. Following Roelvink (1993) we define fluxes

$$Q_t = \int_{-h}^{\zeta} u \, dz \quad (6)$$

and

$$Q_w = \int_{-h}^{\zeta} u' \, dz \quad (7)$$

We introduce the velocity  $V$  such that

$$V = \frac{Q_t}{d} = U + \frac{Q_w}{d} \quad (8)$$

and after some manipulations, and using the shallow water assumption, the final continuity and momentum equations are arrived at:

$$\frac{\partial}{\partial t}d + \frac{\partial}{\partial x}(Vd) = 0 \tag{9}$$

$$\frac{\partial}{\partial t}(Vd) + \frac{\partial}{\partial x} [ dV^2 + \frac{1}{2}gd^2 ] = gd\frac{\partial h}{\partial x} - \frac{\partial}{\partial x}[\frac{S_{xx}}{\rho}] + \frac{\partial}{\partial x}[\frac{Q_w}{d}]^2 - \frac{\bar{\tau}_b}{\rho} \tag{10}$$

It can be seen that these equations have a similar form on the left hand side to (1) and (2). We use this correspondence to apply similar flux-conservative techniques to the solution of the wave-averaged equations (see below). The final equation to consider is the equation describing the transformation of short wave energy. It is the variation in this energy that will drive the incoming bound waves. Assuming (Roelvink, 1993) that the characteristic short wave frequency is constant in space and time we get an energy equation of the form

$$\frac{\partial E}{\partial t} + \frac{\partial}{\partial x}(c_g E) = -D \tag{11}$$

In the model, the radiation stress,  $S_{xx}$ , and the primary-wave-induced flux,  $Q_w$ , are represented by the expressions of Longuet-Higgins & Stewart (1964); bottom shear stress is represented in the usual quadratic form.  $D$ , representing the short wave decay due to breaking, is formulated using both the method of Roelvink (1993) and of Battjes & Janssen (1978). In the runs performed so far there has been little difference between the two methods. In view of this we chose Roelvink's method,

$$D ( E , d ) = \left\{ 1 - \exp \left[ - \left( \frac{H}{\gamma d} \right)^n \right] \right\} 2 \alpha f_p E \tag{12}$$

it being rather simpler. Here, following Roelvink we take  $\alpha = 1.0$  and  $n = 10$ . The parameter  $\gamma$  will vary depending on the type of wave being studied. Its value is given in each case studied.  $f_p$  is the characteristic measure of the (constant) frequency. For waves other than monochromatic waves we take it to be an average of the constituent frequencies. Using linear theory it can be shown that

$$H = \sqrt{8E/(\rho g)} \tag{13}$$

so the system is now closed.

Numerical methods

In the WAF method applied to the shallow-water wave equations the equations are solved in so-called flux-conservative form (eg (1) and (2)). Both the original shallow water wave equations and the surf beat model equations can be written in the same flux-conservative vector formulation

$$\underline{U}_i + \underline{F}_x = \underline{S} \quad (14)$$

where  $\underline{U}$  represents the conserved quantities, and  $\underline{F}$  represents the flux of these quantities. The term  $\underline{S}$  is the so-called source term, and it is this term that differs depending on whether the equations are just depth averaged or both depth and time averaged. This vector equation is solved in finite-difference form, using fluxes at intermediate locations:

$$\underline{U}_i^{n+1} = \underline{U}_i^n + \frac{\Delta t}{\Delta x} ( \underline{F}_{i-1/2} - \underline{F}_{i+1/2} ) + \underline{S}_i \Delta t \quad (15)$$

where  $t = n\Delta t$  is the initial time, and  $t = (n+1)\Delta t$  is the time at which we want to find a solution. The flux, which is found by solution of the local Riemann problem at each cell, is then averaged over the cell width at the half time level, and a total-variation-diminishing adjustment is made by means of upwinding, in order to reduce spurious oscillations. The slope term can cause problems with accuracy, but these are circumvented by making an appropriate transformation, thus allowing it to be incorporated into the local Riemann problem solution (see Watson et al. (1992) for details). The boundary condition at the seaward end allows waves to propagate out of the solution domain without reflection, and the shoreline is defined as the position at which the depth decreases below a specified amount.

For the surf beat problem, we can decompose the source term into the slope term and an additional term

$$S^* = - \frac{\partial}{\partial x} \left( \frac{S_{xx}}{\rho} \right) + \frac{\partial}{\partial x} \left( \frac{Qw^2}{d} \right) - \frac{\bar{\tau}_b}{\rho} \quad (16)$$

The problem caused by this additional term can be solved by applying the time-operator splitting (TOS) method. Firstly we solve the following equations to get an intermediate solution  $d^*$  and  $V^*$ :

$$\frac{\partial}{\partial t} d^* + \frac{\partial}{\partial x} ( V^* d^* ) = 0 \quad (17)$$

$$\frac{\partial}{\partial t} ( V^* d^* ) + \frac{\partial}{\partial x} [ V^{*2} d^* + \frac{1}{2} g d^{*2} ] = g d^* h_x \quad (18)$$

These equations have the same form as (1) and (2), so they can be solved using the same method for solving those equations, including the treatment of seaward and shoreline boundary conditions. Secondly we solve the equations:

$$d_t = 0 \quad (19)$$

$$V_t = S^* \quad (20)$$

starting with the intermediate solutions. This is the solution to equations (9) and (10) given by the TOS method. The accuracy of this solution is first order (Watson et al 1992), which is lower than that of equations (1) and (2). This decrease of accuracy due to TOS method was remedied by using a transformation similar to that of Watson et al (1992), but differing by the quantity  $S^*$ . Thus, at each time step and for the difference calculation at each grid point we transform the problem into a reference frame that is accelerating at the rate

$$a^* = -gh_x + S^* \quad (21)$$

In this frame the new variables are

$$\xi = x - \frac{a^*}{2} t \quad (22)$$

$$\tau = t \quad (23)$$

$$W = V - a^* t \quad (24)$$

$$D = d \quad (25)$$

Substitution of (22)-(25) into (9) and (10) gives

$$D_\xi + (WD)_\xi = 0 \quad (26)$$

$$W_\xi + WW_\xi + gD_\xi = 0 \quad (27)$$

Once the solution of the (26) and (27) has been found (using the same method as for (1) and (2)), the solution of (9) and (10) can be effected by using relations (22)-(25). The solutions so obtained,

$$d(x,t) = D\left(x - \frac{a^*}{2}\Delta t^2, t\right) \quad (28)$$

$$V(x,t) = W\left(x - \frac{a^*}{2}\Delta t^2, t\right) + a^*\Delta t \quad (29)$$

provide the basis for the modification of the TOS method by inclusion of the second order terms. Thus, noting that

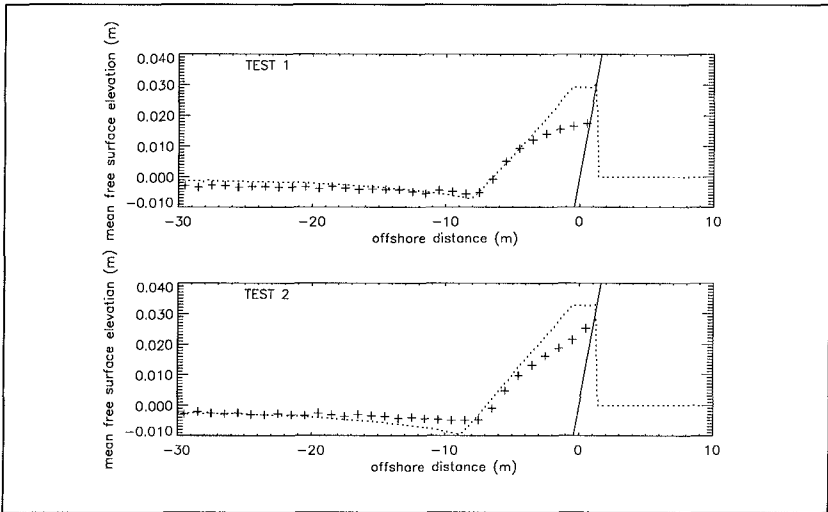

Figure 1. Mean surface elevation from model and experiments (Stive, 1983). Crosses from experiments. (a) Test 1 (b) Test 2.

Figure 2. Amplitude of bound waves vs primary wave amplitude. Diamonds from experiments (Kostense, 1984). Crosses from model.

$$d^*(x,t) = D\left(x + \frac{1}{2}gh_x\Delta t^2, t\right) \quad (30)$$

$$V^*(x,t) = W\left(x + \frac{1}{2}gh_x\Delta t^2, t\right) - gh_x\Delta t^2 \quad (31)$$

the final solutions of the surf beat model are

$$d(x, (n+1)\Delta t) = d^*(x, (n+1)\Delta t) - \frac{\partial d^*}{\partial x} (\frac{1}{2} S^* \Delta t^2) \quad (32)$$

$$V(x, (n+1)\Delta t) = V^*(x, (n+1)\Delta t) - \frac{\partial V^*}{\partial x} (\frac{1}{2} S^* \Delta t^2) + S^* \Delta t \quad (33)$$

During the numerical calculation discussed above, the short wave energy equation (11) should be solved simultaneously to give the value of energy  $E$  for the calculation of radiation stress  $S_{xx}$  and short wave mean flux  $Q_w$ . A one-step second-order Lax-Wendroff difference scheme was used to solve the equation.

### Results

The surf beat model has so far been validated only by comparison with monochromatic (Stive, 1983) and bichromatic wave tests (Kostense, 1984). Both of these tests were performed on plane beaches.

Two tests were examined in Stive's data, corresponding to spilling and plunging breaker types: Test 1 (spilling; wave height = 0.145m, period = 1.79s), and Test 2 (plunging; wave height = 0.145m, period = 3.00s). The flume consisted of a flat bed section of depth 0.70m (continuing for a length of 10m) and then a non-erodible constant slope of 1:40. In Figure 1(a) and 1(b) the mean free surface elevation in the two cases is compared with the model result. It can be seen in Fig. 1(a) that in the first case modelling is generally good everywhere other than at the shoreline, where the mean shoreline is clearly overpredicted (this is equally true of Test 2). To obtain accurate modelling of the region of the breaker point

Figure 3. Amplitude of free waves vs primary wave amplitude. Diamonds = experiments (Kostense, 1984). Asterisks = model ( $f_w=0.01$ ). Crosses = model ( $f_w=0.05$ ).

Figure 4. Amplitude of bound waves vs group frequency. Diamonds = experiment (Kostense, 1984). Crosses = model.

in Test 1, a value of  $\gamma = 0.88$  was used. The same value gave the best fit for Test 2, but in this case modelling clearly is not as good. It is not clear why modelling in this region should be inferior for Test 2. The model of Thornton & Guza (1983) of wave height decay, on which the model of Roelvink is based, works well for plunging as well as spilling breakers.

In the tests of Kostense (1984), the primary waves were made up of two frequencies generated in a water depth of 0.50m which broke on a plane cemented beach of a 1:20 slope after travelling over a horizontal stretch. Figures 2 and 3 are, respectively, the variation of the bound wave amplitude and the reflected free wave (out-going) amplitude vs the primary wave amplitude  $\zeta_1$  with  $\zeta_2/\zeta_1 = 0.2$ . and  $\Delta\omega = 0.772$ , which corresponds to series C in Kostense's experiments. Figures. 4 and 5 are, respectively, the variation of the bound wave amplitude and the reflected free wave (out-going) amplitude vs the wave group frequency  $\Delta\omega$  with  $\zeta_2/\zeta_1 = 0.2$  ( $\zeta_1 = 0.055\text{m}$  and  $\zeta_2 = 0.011\text{m}$ ), which corresponds to series A in Kostense's experiments ( $\gamma = 0.88$ ). The procedure of the calculation to simulate the experiments is as follows. For a given set of primary waves, the model is run until transients are no longer present in the solution domain. The surface elevation time series are then split into three components, viz. the incoming bound wave, the reflected free wave and an incoming free wave. The incoming free wave is negligible since it is not generated and the seaward boundary condition allows the reflected free wave to propagate out of the model area. The amplitudes of the incoming bound wave and the reflected free wave are determined by harmonic analysis as done in Kostense's experiments. Although more points are required for a more conclusive comparison to be made, Fig. 2 seems to show the bound wave amplitude increasing approximately quadratically, as expected. In fact, apart from one point the position of which seems slightly anomalous, results are very similar to those of Roelvink, as we would expect. The comparison with experiment is quite good. In Fig. 3 we perform a similar kind of comparison to that of Roelvink, by using two different values of bottom friction coefficient,  $f_w = 0.05$  and  $0.01$ . A similar trend is found with regard to the dependence of the amplitude of the outgoing free wave on the average amplitude of the primary waves. The comparison is not as good as for the incoming bound wave. This is not surprising since the reflected free wave will only emerge after the processes of short wave breaking and run-up have taken place and we only use linear theory to describe highly nonlinear processes in these regions. Nevertheless, the agreement is good in parts. The agreement in Fig. 4 is reasonably good (dependence of the bound wave on the group frequency), although it appears to deteriorate for lower values of the wave group frequency. The agreement in Fig. 5 is less than satisfactory at present. The experimental results clearly show a peak in the response at around 0.6 rad/s. More analysis needs to be done here if the interference patterns of Roelvink (1993) are to be reproduced.

Figure 5. Amplitude of free waves vs group frequency. Diamonds = experiments (Kostense, 1984). Crosses = model.

### Conclusions

A nonlinear surf beat model based on the same approach as that of Roelvink (1993) has been presented. It uses a novel (for this application) numerical scheme for its solution, which is highly efficient, especially for the case when long waves break. The comparisons done so far indicate that it performs reasonably well, but further validation is required, especially for random waves. The advantage of a nonlinear model over a linear surf beat model is that we do not have to identify beforehand the mechanism by which the free waves are generated, as is the case for linear models (eg, Symonds et al, 1982). Certain parameters are still present in the model however (unavoidably so), some of which must be calibrated for different types of applications.

## CHAPTER 142

### PIV Measurements of Oscillatory Flow over a Rippled Bed.

Earnshaw, H.C.,<sup>1</sup> Bruce, T.,<sup>2</sup> Greated, C.A.<sup>1</sup> & Easson, W.J.<sup>2</sup>

This paper presents results of a study of the kinematics of planar oscillatory flow over a rippled sea bed. The flows are mapped using Particle Image Velocimetry (PIV), a flow measurement technique yielding accurate, full field maps of an instantaneous velocity field. The practical implementation of the PIV method for this study is described, and flow maps presented for amplitude of oscillation to ripple length ratios of 0.8, 1.2 and 1.8. The generation of vortices at the ripples and their subsequent trajectories is described. Finally, the vortex strengths for the three flow regimes are investigated.

### Introduction

This paper presents detailed experimental velocity measurements of oscillatory flow over a rippled bed. The main motivations for the work are to validate numerical models (eg Block, 1993, Perrier, 1993) and eventually to help in the development of models for the prediction of sediment transport. Full field instantaneous velocity data is obtained using Particle Image Velocimetry (PIV). Existing studies using point measurement techniques (eg Sato et al, 1984 and Ranasoma and Sleath, 1992) have shown flow over a rippled bed to be very complex and turbulent but with coherent structures, primarily in the vortex shedding process (see fig. 1). By the very nature of these methods the details of this complex and constantly changing flow are lost. The numerical modelling of sediment transport over a rippled sandy bed requires accurate knowledge of the flow kinematics above the bed. Through the application of the PIV technique we hope to provide this information.

### Experiments

The tests were carried out in a towing tank six metres long, a metre wide with a water depth of half a metre. Because of the way the PIV systems are set up

Figure 1: The vortices from the previous half-cycle are swept up and over the crests of the ripples as the flow accelerates from right to left and the new lee vortices form in the troughs.

in Edinburgh it is easier to have the light sheet coming in from underneath the tank and to suspend the ripples above, as shown in fig. 2. Rather than using an oscillatory flow over stationary ripples the ripple bed was oscillated in still water. There are several advantages to doing the experiment this way round: it allows a wider variation of amplitude of oscillation and ensures there is no externally imposed shear or turbulence as well as making the experiment physically easier. The ripples were attached upside down to a computer controlled trolley which could then oscillate them in initially still water. Three amplitudes of oscillation,  $a$ , corresponding to  $a/L = 0.8, 1.2$  and  $1.8$  (where  $L$  is the ripple length) were used giving maximum velocities of 131, 196 and 294 mm/s respectively. The time period,  $T$ , for all tests was 8.46s and pictures were taken of one of the central ripples at nine phases,  $\omega t$ , of oscillation from  $0^\circ$  to  $180^\circ$ . Parameters were chosen within the EU MAST G8-M program to facilitate comparisons between the modellers and experimentalists in the group.

The ripples were solid and pre-formed from styrofoam. Again the EU MAST G8-M program decided on a 'standard' ripple shape and size. This is a sharp crested ripple (not as realistic as a rounded crest but generally easier for numerical work) 22 cm long from crest to crest and 35 mm high from crest to trough. The ripple shape was approximated to an arc of radius 19cm.

Figure 2: Ripple bed attached to the trolley above the wave tank with a scanning beam system under it

### Particle Image Velocimetry

Particle Image Velocimetry (PIV) is well documented; for a general overview see Adrian, 1991, and for applications in the field of coastal engineering see Greated et al, 1992 and Quinn et al, 1993. The advantages of PIV are that it is a non-intrusive technique and therefore does not in any way interfere with the flow and that it provides simultaneous full field data. Briefly, the flow is seeded with small, neutrally buoyant particles which scatter light and follow the flow accurately. A light-sheet is generated to illuminate the flow stroboscopically using a scanning beam system as shown in figure 2 (see also Gray et al, 1991). Typical scan rates are of the order of a millisecond. The area of interest is then photographed with a long enough camera exposure time to ensure that multiple images of each of the seeding particles are captured on the same negative. By looking at the separation of successive images of each particle a full picture of the magnitude and direction of velocity at each point in the flow can be built up.

In oscillating flows two difficulties are encountered when applying PIV. Directional ambiguity occurs because there is no way of telling which of the multiple images came first and zero and near-zero velocities cannot be measured as the images are too close together to be discriminated by the analysis system. To overcome these two problems a known shift velocity was superimposed onto the flow field such that the multiple images always occurred on the same side of the original particle thus resolving both the above problems. This technique is analogous to frequency shifting in LDA. The simplest way of including a shift velocity is to move the camera during the exposure, achieved here by mounting the cam-

era on a computer controlled turntable; the shutter is triggered when the camera is perpendicular to the tank (Bruce & Easson, 1992). The shift velocity is later subtracted from the analysed negative to reveal the true flow field.

Figure 3: Velocity map for  $a/L=0.8$ ,  $T=8.46s$  and  $\omega t=30^\circ$ .

Figure 4: Vorticity plot for  $a/L=0.8$ ,  $T=8.46s$  and  $\omega t=30^\circ$ .

### Results and Discussion

The sequences of pictures were obtained for each of the three amplitudes and show the evolution of the flow over half-cycles, where one half-cycle runs from  $0^\circ$  when the bed is stationary through  $90^\circ$  at maximum velocity to  $180^\circ$  when the

bed is momentarily stationary again. Detailed information about the generation of vortices, their trajectories and their decay can be obtained from the data.

Figure 5: Velocity map for  $a/L=0.8$ ,  $T=8.46s$  and  $\omega t=120^\circ$ .

Figure 6: Vorticity plot for  $a/L=0.8$ ,  $T=8.46s$  and  $\omega t=120^\circ$ .

Figure 3 shows a typical measured velocity field and figure 4 its derived vorticity contour plot. These are for the slowest oscillation,  $a/L=0.8$ , at phase  $30^\circ$

that is, just after the bed begins to move. The bed is accelerating from left to right, so the flow appears as right to left. The black areas on the vorticity plot correspond to areas of high negative vorticity, the colour lightens to a neutral grey background and then to areas of increasingly positive vorticity. A vortex, ejected from the crest of this ripple in the previous half-cycle, is now travelling up and away from the bed, above and to the right of the crest, whilst a new vortex is just being formed immediately to the left of the crest.

Later in the half-cycle (figure 5 and figure 6) the lee vortex has grown considerably whilst the positive vortex has dissipated a lot of its energy and has been swept across by the main flow.

These flow fields have been compared (Perrier, 1993) with the results of numerical models, in particular the Discrete Vortex Model developed by Danish Hydraulic Institute (DHI), Technical University of Denmark (ISVA) and Laboratoire National d'Hydraulic, France (LNH). Qualitative agreement was noted in the formation, shedding and trajectories of the vortices. Quantitative comparisons of the spatial flow fields are now possible for the first time. One way of approaching this would be to look more closely at the vortices and try to measure their positions and strengths as functions of time.

Figure 7: Plot showing vortex strength varying with phase for each of the three amplitudes of oscillation.

As a preliminary study the developing lee vortex has been looked at more closely. Calculations of vortex strength were made by imposing a boundary, defined by a lower vorticity level, on the vortex and summing the vorticity over all

the discrete points within the boundary. Figure 7 shows the variation of vortex strength through the half-cycles for each of the three amplitudes of oscillation. The data is rather scattered and the method needs a lot more thought but as a first calculation it does show roughly the trends expected. The negative vorticity increases towards  $90^\circ$ , corresponding to the flow's maximum velocity, and decreases again as the flow slows down at the end of the half-cycle. The faster, stronger flows generate more vorticity.

### Concluding Remarks and Future Work

These new measurements give a lot more detail than previous point measurements and have shown the expected vortices in the right places. Qualitatively they agree with previous experiments and with numerical models.

One of the main problems with these experiments is the question of the repeatability of the flow from one period to the next. Successive pictures are not taken in the same oscillation due to the camera's finite wind-on time. One sequence of pictures is taken over several oscillations. One of the next things to be done is to check how repeatable the flow is from cycle to cycle. It has been suggested that the spikes in the vortex strength curves may be due to the effect of the positive vortices moving across the field and therefore affecting the calculations of negative vortex strength. Again this possibility needs to be tested. The next step is to develop a method of quantifying the information in the pictures so the results will be of help in predicting the sediment transport over ripples.

## CHAPTER 143

# SHEAR INSTABILITY OF LONGSHORE CURRENTS: EFFECTS OF DISSIPATION AND NON-LINEARITY

Albert Falqués, Vicente Iranzo and Miquel Caballería <sup>1</sup>

### Abstract

The effect of bottom friction and turbulent lateral mixing on shear instability of the longshore current is investigated. Transition conditions for this instability as a function of non-dimensional parameters related to the basic current, topography, bottom friction and lateral mixing are found. A direct nonlinear numerical simulation of shear instability is presented. The basic flow is found to be supercritical and the amplitude of shear waves can reach at least 20% of the basic flow. A small increase in the period due to non-linearity is also found. Preliminary results suggest that far from criticality there is an important contribution of the instability to the mean flow. Some applications to field and laboratory experiments are discussed.

### 1. Introduction

In the presence of a significant wave-driven longshore current, low frequency oscillations in the current that are not due to gravity waves may appear. These oscillations, called far infragravity waves (FIG waves) because their frequency is lower than the infragravity edge waves of the same wavenumber, were first observed by Oltman-Shay et al. (1989) as strong fluctuations in the time series of longshore and cross-shore velocity components. They appear as a meandering in the current that propagates downflow. According to the spectral analysis performed by Oltman-Shay and co-workers, they are almost non-dispersive with a phase speed proportional to the peak mean longshore current,  $c \sim 0.5 - 0.7 V_{max}$ . Their period and wavelength in natural beaches are

---

<sup>1</sup> *Departament de Física Aplicada, Universitat Politècnica de Catalunya, 08034 Barcelona, Spain*

Figure 1: Time series of cross-shore (left) and longshore (right) components of the current at two alongshore locations. LIP experiment M19, from Reniers et al. 1994.

of the order of  $10^2$  sec. and  $10^2$  m. respectively. More recently, experiments have been conducted in a wave basin (Delft Hydraulics facilities, LIP project M19) in order to observe FIG waves in a laboratory beach. Preliminary analysis of data in the case of a barred beach profile (Reniers et al., 1994) indicates the presence of FIG waves of a period and a wavelength of about 25 sec. and 8 m. respectively. Time series of alongshore and cross-shore components of the current for two different current-meters in two different alongshore positions are shown in Fig.1. The incoming waves of a period of 1 sec. and strong low frequency oscillations with a period of about 25 sec. may be seen. The amplitude of these oscillations in comparison with the peak longshore current is of the order of 20% for the cross-shore component and 35% for the longshore component. These amplitudes are of the same order of magnitude as those observed by Oltman-Shay et al. (1989) at Duck (USA).

Bowen and Holman (1989) proposed a theoretical explanation for the FIG waves based on an instability mechanism of the mean longshore current. According to their theory, the longshore current may be unstable because of the shear and this instability may generate growing disturbances that progress downflow or shear waves. Their theory was developed using a very simplified analytical model that succeeded in giving the main features of the instability and matched the experimental results of Oltman-Shay et al. reasonably well. Nevertheless, their model has a number of limitations such as unrealistic geometry, inviscid flow, rigid lid and linearized governing equations and several improvements are therefore necessary in order to analyze the instability mechanism in more realistic conditions. This has been done by Dodd et al. (1992), Putrevu and Svendsen (1992), Deguchi et al. (1992), Dodd (1994), Dodd and Thornton (1992) and Falqués and Iranzo (1994).

The first aim of the present contribution is to find general transition conditions for shear instability as a function of some non-dimensional parameters involving the longshore current, the topography of the beach, the bottom friction and the lateral mixing. The second aim is to show how the linear stability analysis can be applied to any particular beach, handling actual cross-shore profiles of longshore current, bathymetry, bottom friction and eddy viscosity. Furthermore, the linear analysis can explain the initial growth and propagation of small amplitude shear waves but cannot describe properly the finite amplitude shear waves actually observed in Nature. In particular, the linear theory cannot predict the amplitude of such shear waves. This requires a nonlinear stability analysis which is our third goal.

The importance of shear instability lies in several factors. The theoretical models for the longshore current are usually based on an equilibrium between the driving forces from the incoming wave field and dissipative forces from bottom friction and lateral mixing. But the possibility of instability in such an equilibrium solution indicates that the matter is not so simple and that in some cases the longshore current may have a dynamic behaviour quite far from this equilibrium. Moreover, as several authors have pointed out (see Putrevu and Svendsen, 1992) shear instability can be a mixing factor in the surf zone which is quite stronger than the mixing due to wave induced turbulence.

## 2. Linear Analysis

We consider the shallow water equations for momentum and mass conservation with a lateral momentum diffusion given by  $\nu(x)$ :

$$\frac{\partial v_i}{\partial t} + v_j v_{i,j} + g\eta_{,i} = -\frac{c_d}{\zeta} |\bar{v}| v_i + \frac{1}{\zeta} S_{i,j} + \frac{1}{\zeta} [\nu \zeta (v_{i,j} + v_{j,i})]_{,j} \quad i = 1, 2 \quad (1)$$

Figure 2: Coordinate system and geometry.

$$\frac{\partial \eta}{\partial t} + [\zeta v_j]_{,j} = 0 \tag{2}$$

Here,  $x = x_1$  and  $y = x_2$  are the cross-shore and long-shore coordinates (see Fig.2) and repeated indexes are assumed to be summed. The derivative with respect to  $x_i$  has been indicated by the subindex  $,i$ . The total depth is  $\zeta = \eta + h$ , where  $h(x)$  stands for the still water depth and  $\eta(x, y, t)$  for the free surface elevation. We assume a quadratic bottom friction with a  $c_d(x)$  coefficient and  $S_{ij}$  are the radiation stresses.

We consider a basic undisturbed state which is a steady solution of equations (1)-(2) given by  $v_1 = 0, v_2 = V(x), \eta = \bar{\eta}(x)$ , where  $V(x)$  is the longshore current and  $\bar{\eta}(x)$  the wave set up/down. Then we superpose on the basic flow a small perturbation of the form

$$e^{ik(y-ct)}(u(x), v(x), \eta(x))$$

and upon linearization of the shallow water equations, (1)-(2), we obtain the eigenproblem:

$$ik(V - c)u + c_d V u + g \eta_x = 2\nu_x u_x + \nu(2u_{xx} - k^2 u + ikv_x + 2\frac{\bar{\zeta}_x}{H} u_x + ik\frac{V_x}{\bar{\zeta}} \eta) \tag{3a}$$

$$V_x u + ik(V - c)v + 2c_d V v + ik g \eta = \nu_x(v_x + iku) + \nu(v_{xx} - 2k^2 v + iku_x - \frac{\bar{\zeta}_x V_x}{\bar{\zeta}^2} \eta + \frac{V_x}{\bar{\zeta}} \eta_x + \frac{\bar{\zeta}_x}{\bar{\zeta}}(v_x + iku)) \tag{3b}$$

$$(\bar{\zeta} u)_x + ik\bar{\zeta} v + ik(V - c)\eta = 0 \tag{3c}$$

where the subindex  $x$  indicates differentiation with respect to  $x$ . The eigenvalue,  $c = \omega/k = (\omega_r + i\omega_i)/k$ , is the phase speed, which may be complex. The period and the wavelength are given by  $T = 2\pi/\omega_r$  and  $\lambda = 2\pi/k$ . The total depth is given by  $\bar{\zeta} = h(x) + \bar{\eta}(x)$ . In these linearized equations any perturbation in the radiation stresses has been neglected.

Given any set of current, bathymetry, bottom friction and viscosity profiles, and for any wavenumber,  $k$ , Equations (3) can be solved numerically by using spectral expansions. The details of the numerical procedure can be seen in Falqués and Iranzo (1992, 1994) or Iranzo and Falqués (1992). In that way the  $k - \omega_r$  and the  $k - \omega_i$  curves, that is, the dispersion and the instability curves can be computed. The basic flow is unstable if there is some wavenumber with positive growthrate,  $\omega_i > 0$ , and stable otherwise. The fastest growing wavelength in the linear theory, FGM, can be determined as the maximum in the  $k - \omega_i$  curve. Although shear waves observed in experiments have a finite amplitude and therefore need a nonlinear analysis, this wavelength, and its corresponding period that can be obtained from the dispersion line, are expected to give some estimate of the observed wavelength and period. This kind of analysis is presented here in two different ways: i) using analytical profiles to find general properties of shear instability, ii) using measured profiles for some particular beach.

The motivation for the first aim is as follows. For many Fluid Mechanics stability problems such as Rayleigh-Bénard convection and Couette flow, there are non-dimensional parameters say Reynolds number, Rayleigh number, etc. governing the transition between stability and instability and the sequence of bifurcations arising from the basic flow (Drazin and Reid, 1981). So far, transition conditions as a function of non-dimensional parameters have been lacking for shear instability of the longshore current. The latter stability problem has two dissipative sources, namely, bottom friction and eddy viscosity, which stabilize the flow. Our aim is to find two non-dimensional parameters related to bottom friction, viscosity, the current and the topography that govern stability. In such a way, transition lines in the plane of both parameters will be obtained and these lines will allow for a rough prediction of stability or instability for a wide class of beaches. For this purpose we will consider a basic current profile given by

$$V(x) = ax \exp(-(bx)^3) \quad (4)$$

This profile was suggested by Bowen and Holman (1989) and used by Falqués and Iranzo (1994). It can be an equilibrium solution of Equations 1-2 for a suitable radiation stress distribution. The parameters  $a, b$  are related to the maximum backshear and to the width of the current trough  $l_0 = 0.69/b$  and  $f_s = 0.79a$  where  $l_0$  is the offshore distance of the peak of the current and  $f_s$  is the maximum backshear, that is, the maximum shear at the sea-face of the current profile. Many realistic current profiles can be roughly fitted by (4) for suitable values of  $a$  and  $b$ . Concerning topography, we will consider the most simple situation, that is, plane sloping beach. Also, we will neglect the wave set-up/down which, regarding stability analysis, gives just a small correction on the total depth,  $\bar{\zeta}(x)$ . These simplifications allow us to handle only one parameter related to the bathymetry which is the beach slope,  $\beta$ . So, we assume

Figure 3: Dispersion (left) and instability (right) curves for  $F = 0.3, c_d = 0, x_b/l_0 = 1.6, \alpha l_0 = 3.5$  and for several maximum eddy viscosities.

$\bar{\zeta}(x) = h(x) = \beta x$ . Concerning lateral mixing, we consider (see Deguchi et al., 1992)

$$\nu(x) = \nu_m(h(x)/h(x_b))^{3/2} \quad \text{if } x \leq x_b \tag{5a}$$

$$\nu(x) = \nu_m e^{-\alpha(x-x_b)} \quad \text{if } x \geq x_b \tag{5b}$$

Finally, a uniform bottom friction coefficient,  $c_d$ , has been assumed. Equations (3) have been scaled using the cross-shore lengthscale of the current and its maximum backshear in such a way that we have taken  $b^{-1} = 1.45l_0$  as lengthscale and  $a^{-1} = 0.79f_s^{-1}$  as timescale. After this scaling the non-dimensional parameters in the equations are the maximum Froude number of the basic flow,  $F = (V(x)/\sqrt{gh(x)})_{max} = 0.63a/\sqrt{\beta gb}$ , the frictional parameter,  $c_d/\beta$ , and the non-dimensional maximum eddy viscosity,  $\epsilon = \nu_m/f_s l_0^2$ , which plays the role of a reciprocal Reynolds number,  $Re^{-1}$ . Concerning lateral mixing, two more parameters appear: the position of the maximum viscosity in comparison with the maximum in the current,  $x_b/l_0$ , and the non-dimensional offshore gradient,  $\alpha l_0$ .

Typical instability and dispersion lines are shown in Figure 3 for increasing viscosity from  $\epsilon = 0$  up to  $\epsilon = 0.026$ , with no bottom friction and for  $F = 0.3$ . The wavenumber  $k$ , and the complex frequency  $\omega$  have been scaled to  $b$  and  $a$ . In accordance with previous work, the dispersion relations are quite linear. The general trends we have found are that increasing bottom friction and/or eddy viscosity results in a decrease in growthrates,  $\omega_i$ , and in a small decrease in frequencies. An increase in Froude number decreases instability too. This may be because for high Froude number shear instability feeds surface gravity

modes so that instability is weakened. These general characteristics may have some exception regarding viscosity. When the eddy viscosity distribution has its maximum around the maximum in the current profile and has a strong offshore decay (large  $\alpha$ ) an increase in eddy viscosity can result in a larger growthrate. If  $\epsilon$  goes on increasing, this trend is reversed and stability is finally reached. This behaviour can be understood by considering that viscosity has two opposite effects: it dampes instability but also has a diffusive effect which propagates perturbations and therefore favours instability. Then, when  $\nu_m$  increases from a very small value the viscosity in the sea face of the current profile still remains negligible at the beginning, whereas it reaches significant values at the shore face of the profile. Since the source of the instability is mainly located in the sea face (in the region where the backshear is maximum) the damping effect is therefore negligible. On the other hand, the diffusive effects at the shore face can be important. If  $\nu_m$  continues to increase, the values of  $\nu(x)$  near the maximum backshear become large enough so that the damping effect become dominant. This is in contrast with the effects from bottom friction. Dodd (1994) found that there may be destabilizing effects due to bottom friction (curvature terms) but that the overall effect was a stabilizing one. In line with his results, we also find that the overall influence of bottom friction on shear instability is always a stabilizing one.

In any case, for each set of values of  $F, x_b/l_0, \alpha l_0$  and for each  $c_d/\beta$  we find a critical value of  $\epsilon$  such that instability requires lower values. We thus obtain a stability diagram in the  $\epsilon - c_d/\beta$  plane with transition lines that bound stability and instability regions. These lines are shown in Fig.4 for  $F = 0.14, F = 0.3$  and  $F = 0.89$ . We have set  $x_b/l_0 = 1.6$  and  $\alpha l_0 = 3.5$ . Very small sensitivity has been observed to the latter two parameters, except for the case  $x_b/l_0 \simeq 1$  and large  $\alpha l_0$  described above, which is not very realistic because  $x_b$  is usually expected to be offshore of the maximum in the current. As can be seen in Fig.4, for small Froude number instability is almost insensitive to Froude number. However, for high values some sensitivity appears and the stability region is widened.

Some experimental data sets have also been plotted in Fig. 4. This is not an easy job as only crude estimates of  $c_d, \nu$  are available, the actual current profiles are usually rather far from (4) even for suitable  $a, b$  and we have to rely on a mean beach slope,  $\beta$ . Though these limitations result in large error bar we think that the diagram can be useful in giving a rough prediction of stability or instability. Four data sets have been represented: Duck (USA), Leadbetter (USA), wave-basin experiment (LIP project M19, The Netherlands) and Trabucador (Ebro Delta, Spain). The experimental information was taken from Dodd et al. (1992), Reniers et al. (1994) and Redondo et al. (1994). The lateral mixing was estimated according to Deguchi et al. (1992). The most stable situation corresponds to Leadbetter beach and indeed no evidence of shear waves was found at this site. On the other hand, the diagram predicts

Figure 4: Transition lines for  $x_b/l_0 = 1.6$ ,  $\alpha l_0 = 3.5$  and for three Froude numbers. Four experimental data sets have also been plotted: A:Duck (USA); B:Leadbetter (USA); C:Wave-basin experiment LIP project M19; D:Trabucador (Spain).

instability for Duck data set in agreement with observations (the maximum Froude number did not exceed 0.3). The Trabucador data set also leads to instability according to the model. A complete data analysis is not yet available (Delta'93 campaign). However, a preliminary inspection indicates the presence of low frequency oscillations that might be shear waves. Regarding the wave basin experiment, the maximum Froude number reached  $F = 0.7$ , so the corresponding box in the diagram would match the transition line that would be somewhere in between the  $F = 0.3$  and the  $F = 0.89$  lines. Therefore, no conclusive analysis can be made by this way in this case and a detailed numerical simulation for the actual  $V(x)$ ,  $\zeta(x)$ ,  $c_d(x)$  and  $\nu(x)$  profiles is necessary. In any case, if we want a more accurate prediction of instability, with the period and wavelength of the shear waves, this computation for the actual profiles is needed. This kind of analysis has been made for Trabucador Beach, and for the wave basin experiment. Although a detailed analysis of the results of this latter experiment is under way, some preliminary results are already available. For instance, measurements from the longshore array of currentmeters for one of the tests with barred beach indicated the presence of shear waves with a period of approximately 25sec. and a phase speed of 0.33m/s, giving rise to a wavelength of 8.3m. In this case, a dominant mode with a wavelength of  $2\pi/k = 7.3m$  and a

period of  $2\pi/\omega_r = 27\text{sec.}$  was obtained from the numerical model. Experiments and theory were thus found to be in a fairly good agreement.

### 3. Nonlinear Stability

Only a preliminary study of the nonlinear shear instability is currently available, and a much more detailed analysis is under way. For this preliminary study, some assumptions have been made: plane sloping topography, uniform bottom friction and viscosity coefficients, a basic current given by (4) and the rigid lid assumption, that is, the vertical fluxes are much smaller than the horizontal ones (Bowen and Holman, 1989). Falqués and Iranzo (1994) showed that rigid lid hypothesis was a suitable one for low Froude number so that for  $F$  up to 0.6 only a correction less than 12% was necessary in growth rates. Therefore, rigid lid assumption is not a severe restriction for natural beaches. A further assumption regarding the mean flux that will be specified later on has been taken into account. The mass conservation equation (2) and the rigid lid hypothesis allow us to use a streamfunction for the perturbation,  $\psi(x, y, t)$ , defined by:

$$v_1 = \frac{1}{h} \frac{\partial \psi}{\partial y} \quad , \quad v_2 = V(x) - \frac{1}{h} \frac{\partial \psi}{\partial x} \quad (6)$$

Then, by taking the curl of the momentum equations (1) we end-up with a single governing equation which is

$$C \frac{\partial \psi}{\partial t} = \mathcal{M}\psi + \mathcal{N}(\psi) \quad (7)$$

where the linear operators  $C$  and  $\mathcal{M}$  are given by

$$\begin{aligned} C\psi &= \frac{1}{h} \left( \frac{h_x}{h} \psi_x - \Delta \psi \right) \\ \mathcal{M}\psi &= -VC\psi_y + \psi_y CV + \frac{c_d V}{h^2} (2\psi_{xx} + \psi_{yy} + 2(\frac{V_x}{V} - 2\frac{h_x}{h})\psi_x) + \\ &+ \nu \left( (\frac{h_x}{h})_x (C\psi + \frac{2}{h} \psi_{yy}) + \frac{h_x}{h} (C\psi)_x + \Delta(C\psi) \right) \end{aligned}$$

and the nonlinear operator  $\mathcal{N}$  is given by

$$\mathcal{N}(\psi) = \frac{1}{h} (\psi_x C\psi_y - \psi_y (C\psi)_x + \frac{h_x}{h} \psi_y C\psi)$$

The subindices  $x, y$  mean derivative with respect to  $x$  or  $y$  and the operator  $\Delta$  is the 2D horizontal Laplace operator. The operator  $C$  applied to  $\psi$  gives the vertical component of the vorticity. Hereafter, the scaling introduced in Section 2 is used. Equation (7) has to be solved in the domain  $x, y \in (0, +\infty)$   $\times$   $(-\infty, +\infty)$ . However, for technical reasons the cross-shore domain has been

cut off at some suitable offshore position,  $x = l$ . A comparison between the spectrum of the linear part of (7) and the spectrum of (3) solved without this restriction shows that the error remains very small if  $l$  is large enough compared to the width of the current. A suitable value has been  $l = 6$ . The boundary conditions at the shoreline and far offshore are:

$$\psi = \psi_x = 0 \quad x = 0, x = l \tag{8}$$

Periodicity conditions with respect to some basic wavelength,  $\lambda_0 = 2\pi/K_0$ , have been used as boundary conditions regarding the longshore coordinate. The boundary conditions at  $x = l$  just mean vanishing cross-shore and longshore velocity perturbations far offshore. Concerning the shoreline the matter is not so simple because of the singularity coming from  $h(0) = 0$ . The set of boundary conditions chosen at  $x = 0$  ensures a bounded velocity field at the shoreline and it means vanishing mass transport.

Equation (7) has been solved numerically using a spectral Chebyshev-Fourier expansion

$$\psi(x, y, t) = \sum_{k=-n}^{k=n-1} \sum_{j=0}^m a_{kj}(t) T_j(x) e^{ikK_0 y} \tag{9}$$

where  $T_j(x)$  are Chebyshev polynomials. After spatial discretization which is performed by Galerkin projection concerning  $y$  and by collocation concerning  $x$ , Equation (7) reads as a set of  $2n$  vector ordinary differential equations (one for each alongshore Fourier mode)

$$\hat{C}_k \frac{d\vec{a}_k}{dt} = \hat{M}_k \vec{a}_k + \vec{N}_k(\vec{a}_{-n} \dots \vec{a}_0 \dots \vec{a}_{n-1}) \quad k = -n, \dots, n-1 \tag{10}$$

where the  $(m+1) \times (m+1)$  matrices  $\hat{C}_k, \hat{M}_k$  and the vector functions  $\vec{N}_k$  are the discrete versions of operators  $C, M, N$  for each Fourier mode,  $k$ , and where  $\vec{a}_k = (a_{0k}, a_{1k}, \dots, a_{mk})$  stands for the  $m+1$  Chebyshev coefficients of the Fourier mode  $k$ . The equations corresponding to each Fourier mode are coupled only because of their nonlinear terms,  $\vec{N}_k$ . Time discretization proceeds by using a semi-implicit Euler scheme

$$(\hat{C}_k - \delta t \hat{M}_k) \vec{a}_k^{\tau+1} = \hat{C}_k \vec{a}_k^\tau + \delta t \vec{N}_k(\vec{a}_{-n}^\tau \dots \vec{a}_{n-1}^\tau) \quad k = -n, \dots, n-1 \tag{11}$$

Given the solution  $\vec{a}_k^\tau$  at time step  $\tau$ , Eq.11 is linear in  $\vec{a}_k^{\tau+1}$  and can be easily solved. More details and references on numerical spectral methods applied to coastal dynamics may be seen in Falqués and Iranzo, (1992, 1994) or in Iranzo and Falqués (1992).

Some sensitivity tests concerning the parameters of the numerical model were made. The model proved to be quite robust and the values of  $m = 40, n = 8, \delta t = 0.01$  were found to be suitable for the preliminary study made up to

Figure 5: Time evolution from a small initial perturbation for  $\epsilon = 0.053, \mu = 11.1$ . Time series of cross-shore and longshore velocity components (left) and final steady oscillation in the longshore component (right).

now. Owing to the linear theory outlined in Section 2 the control parameters for instability are the frictional parameter,  $\mu = \beta/c_d$ , and the non-dimensional viscosity,  $\epsilon = \nu_m/f_s l_0^2$ . Time evolution from some initial perturbations has been computed for several values of  $\epsilon, \mu$ . For any  $\epsilon$ , a critical value  $\mu_c$  was found to exist such that below it all the perturbations tend to vanish whereas above it the perturbations grow. At the beginning this growth is nearly exponential but then a saturation is reached and a final oscillatory solution is obtained. For  $\mu$  slightly higher than  $\mu_c$  its period is very close to the period predicted for the linear theory. The critical value,  $\mu_c$ , coincides with that given by the linear analysis. For instance, for  $\epsilon = 0.053$  the transition occurs at  $\mu_c = 10.0$ . One test slightly above critical conditions ( $\mu = 11.1$ ) is shown in Fig. 5. These results show that shear instability of the longshore current gives rise to a supercritical Hopf bifurcation and are in line with the weakly nonlinear analysis carried out by Dodd and Thornton (1992). Far from criticality the behaviour may be quite complicated: an energy transfer between Fourier modes occurs, the FGM mode may be no longer dominant, the final steady wave may be modulated... A further increase in  $\mu$  leads to a blow-up of the numerical model. For  $\epsilon = 0.053$  this occurs for  $\mu > 20$  and may be due to numerical instabilities that might be due in turn to a further bifurcation in the physical problem. This is currently being investigated. An example of the strongly nonlinear behaviour is shown in Figure 6 by means of a time evolution from a small initial perturbation for  $\epsilon = 0.053, \mu = 20$ . In this test, the basic wavenumber has been chosen to be  $K_0 = 0.467$ , that is, one third of the FGM (linearly dominant) which is 1.4. This means that the FGM mode corresponds to  $k = 3$  so that the simulation uses two subharmonics in addition to the superharmonics. As we can see, the first mode to grow significantly is  $k = 3$ . Apparently, it reaches a saturation.

Figure 6: Time evolution of the FGM,  $k = 3$ , its subharmonic  $k = 2$  and its superharmonic  $k = 4$  from a small initial perturbation for  $\epsilon = 0.053$ ,  $\mu = 20$ . The basic wavenumber is  $K_0 = 0.467$ .

However, it slowly loses part of its energy by feeding the other modes, specially the  $k = 2$  subharmonic and the  $k = 0$  mode. Finally, the other modes reach a saturation and a final steady modulated oscillation in all modes starts. The time unit in all these plots is the timescale defined in Section 2 and based on the maximum backshear of the basic flow. For natural beaches, 10 units may be of the order of  $1min$ . Therefore, our numerical time series of 10000 time units would represent a real time of 16 hours. This is quite enough for shear wave simulation.

According to the numerical experiments performed some preliminary properties of finite amplitude shear waves can be summarized. For each set of values of  $\mu, \epsilon$  the final finite amplitude shear waves has been computed from several initial conditions and no sensitivity to the initial conditions has been found except in the parameters range where the numerical model blows up. As expected, the flow pattern corresponding to the perturbation for near critical conditions is very similar to the linear eigenfunction although some asymmetry between crests and troughs can be noticed. However, far from criticality the streamlines are quite different from the linear ones, showing a strong mean flow component (Fig. 7). This component comes from the 0 Fourier mode and means a correction on the mean flow due to the instability. Because of the boundary conditions at the shoreline (8) the mean alongshore discharge due to the perturbation vanishes,  $\psi(l, y, t) - \psi(0, y, t) = 0$ . This is an unphysical constraint on the mean flow and has been taken because of technical reasons concerning the boundary conditions and the numerical procedures. Work is under way in order to relax this constraint by considering boundary conditions (8) only for  $k \neq 0$ . However, the present results already suggest that the mean flow component of the perturbation is not very important for near critical

Figure 7: Streamlines of the perturbation, (A): near critical conditions ( $\epsilon = 0.053, \mu = 11.1$ ), (B): strongly nonlinear ( $\epsilon = 0.053, \mu = 20.0$ ).

conditions but can have a strong influence far from criticality. The amplitude of shear waves can be defined, for instance, as the fluctuation in the cross-shore component in comparison with the mean longshore current. This ratio has been plotted in Figure 8 as a function of the control parameter  $\mu$  for  $\epsilon = 0.053$ . This provides us with a bifurcation diagram for shear instability. Notice that this amplitude can reach 20%, that is, the same order of magnitude as the amplitudes measured at Duck (Oltman-Shay et al., 1989) or in the LIP experiment (Reniers et al., 1994). This is in contrast with the weakly nonlinear analysis of Dodd and Thornton (1992), where only amplitudes of about 0.07% were obtained. The curve stops when the numerical model breaks down. Intriguingly, this occurs roughly when the amplitude of shear waves reaches the maximum value observed in experiments,  $u/V_{max} \sim 0.2$ . The relationship between the final amplitude and the linear growthrate is shown in Figure 9. In qualitative agreement with the weakly nonlinear theory a small nonlinear correction on the period of the shear waves has been found. The relative increase, shown in Figure 9, can reach 6%.

#### 4. Conclusions

Analytical profiles for the current, eddy viscosity and bottom friction coefficient, and a mean beach slope have been used to investigate the general trends for shear instability of the longshore current. The overall influence of bottom friction and lateral mixing is a stabilizing effect and a small decrease in the frequency of shear waves. However, for some eddy viscosity profiles this trend is not monotone and an increase in viscosity may eventually result in

Figure 8: Bifurcation curve showing the amplitude of the crossshore fluctuation in the current with respect to the mean longshore current for  $\epsilon = 0.053$ .

Figure 9: Left: amplitude of the final shear wave as a function of the linear growthrate. Right: Relative increase in the period of the shear wave as a function of the amplitude. ( $\epsilon = 0.053$ ).

larger growthrates. An instability diagram as a function of two non-dimensional parameters related to bottom friction, lateral mixing, the current and the bathymetry has been presented. This diagram allows for a rough prediction of shear stability characteristics for any beach and has been found to compare fairly well with four experimental data sets. A more accurate study of shear instability for a given situation requires the use of the actual profiles. This has been done for a wave basin experiment and a good agreement between numerical modelling and measurements has been found. A nonlinear numerical simulation has also been conducted. In accordance with the weakly nonlinear theory (Dodd

and Thornton, 1992) shear instability has been found to give finite amplitude waves through a supercritical Hopf bifurcation. However, the amplitudes are larger than the weakly nonlinear ones and reach at least 20% of the mean current. A small nonlinear correction on the period has also been found. Far from critical conditions shear waves can exhibit a complicated behaviour, with a modulation and with a flow pattern rather different from that predicted by the linear theory. Preliminary results suggest that for the strongly nonlinear situation there can be an important contribution of instability to the mean current.

## CHAPTER 144

### Interpretation of Shoreline Position from Aerial Photographs

John S. Fisher<sup>1</sup>  
Margery F. Overton<sup>2</sup>

#### Abstract

A review of some of the potential sources of error associated with the use of aerial photographs to map shoreline change is presented. The influence of both tides and waves in the estimation of the position of the wet sand line on the subaerial beach is included. The use of the relatively new digital photogrammetry as applied to shoreline mapping is discussed and suggested as having the potential for being a superior method for this application.

#### Introduction

Aerial photographs have been used extensively to determine shoreline positions and erosion rates. Several different features on the beach and backshore have been used as reference lines, including the bluff or dune line, the seaward vegetation line, and the water line. The latter is usually defined as the wetted line where there is a marked contrast between the wet and dry sand. This latter feature is sometimes referred to as the "wet sand line", or the "high water line". Various investigators have described formalized methods for using this line to monitor shoreline change, including Stafford (1971), Dolan et al. (1978), and Leatherman (1983). Each of these methods share basically similar techniques which include the identification of the wet sand line, the digitizing of the line, and the measurement of change, either relative to an earlier shoreline position, or relative to a reference line offshore.

---

<sup>2</sup>Associate Professor, Department of Civil Engineering, NCSU

Once the shoreline position has been determined, the rate of erosion (or accretion) can be computed by determining the change between two or more shorelines over a known period of time.

It is well recognized that the use of aerial photographs in combination with the wet sand line has inherent inaccuracies. When dealing with erosion rate these errors can be reduced by simply using a relatively long period between dates of photography. As an example, consider the case where the error in identification of shoreline position for each date is  $\pm 50$  ft. If the time between photo sets is 10 years, then the maximum potential error is 10 ft/yr (100 ft divided by 10 years). However, if the time between these photos is 50 years, this error is reduced to 2 ft/yr. Thus, where possible, one should attempt to maximize the time between photo dates. In North Carolina, where only two dates are used to determine shoreline erosion rates, a minimum of forty years between dates is usually employed.

The above discussion also makes it clear why one must be extremely careful to minimize errors when using aerial photographs and the wet sand line to compute short term erosion rates (i.e., less than 10 years).

In partial recognition of the potential errors associated with this technique to measure shoreline change rates, some investigators use multiple dates of photography and either a linear regression, or some other statistical technique to model the rate of change. The advantage of using a series of dates is that the errors associated with any one date is reduced. A discussion of the pros and cons of these different statistical tools for computing shoreline change rates is beyond the scope of this paper. For the analysis which follows we will assume that this rate is computed by simply looking at the difference beyond two dates. This is sometimes referred to as the "end point method".

#### Sources of Error

The process of measuring shoreline change from aerial photographs has several potential sources of error:

1. distortions in the photographs,
2. the georeferencing of "permanent features",
3. human error in measuring and digitizing,
4. corrections for tides, and
5. corrections for wave setup and runup.

Crowell, et al. (1991) present a thorough review of mapping accuracy as applied to shoreline change. Of particular interest in this review is the discussion of the errors associated with the aerial photos (including distortion and corrections for camera angle) and the procedures used to tie the photos to the ground.

In order to fix the aerial photograph in space it is necessary to georeference it to known features. The degree to which this is done with accuracy will of course have a significant impact on the overall accuracy of the analysis. For example, if USGS topographic maps are used to georeference the photos, one is limited to the accuracy of these maps; approximately +/- 40 ft. This error can be reduced if ground referenced points are surveyed at the site using traditional means, or GPS. One can reasonably reduce this error to +/- 1-2 ft (or less) with careful survey techniques.

The actual procedure by which the photos are digitized will also effect the probable error. For many investigations of shoreline change the photos are enlarged and the shoreline digitized directly. While this technique is relatively fast and inexpensive, it does not take advantage of the higher accuracy available from using photogrammetric techniques and analytical stereoplotters. While the former is more time consuming, it nonetheless will yield far better measurements of shoreline position as determined from the wet sand line. We estimate that a careful operator on an analytical stereoplotter can consistently determine shoreline position to within +/- 5 ft with surveyed ground control for the georeferencing. This is in contrast to an estimated error of +/- 50 ft using the more conventional techniques of digitizing directly from the photographs and USGS topographic maps for control. These error estimates represent a combination of the error involved in both georeferencing, identifying the wet dry line, and human error in digitizing this line.

Thus, for the determination of the rate of shoreline change for a period of 50 years between photographs, the larger of these two potential errors (+/- 50 ft) could produce an error in rate of up to 2 ft/yr. Alternatively, the lesser error would be 0.2 ft/yr. Depending upon the particular application, this may justify the additional effort required by the use of the analytical stereoplotter for the measurements.

In addition to the errors associated with the photographs, (georeferencing, and digitizing), one must also consider the dynamics of the wet sand line itself. Both the tide and the waves will influence this line. Consider first the influence of the tide. Most shoreline

mapping applications that the authors are aware of have not attempted to make corrections for tide. Generally the time of the photographs is dictated by the logistics of the aircraft and the lighting requirements. At best, some mapping programs attempt to collect the photographs on consistent points on the tide curve, e.g., spring low, mean, spring high, etc. For the historical photographs one generally accepts what is available, and in many cases the time of the photograph relative to the tide may not be known or obtainable.

The magnitude of the error introduced by not correcting for tide can be easily estimated. This error will be a function of the tidal range, the slope of the beach, and the time of the aerial photograph. As an example, consider a beach where the tidal range is 3 ft, the beach slope is 1:20, and the two photographs are taken at high and low tide respectively. The maximum probable error introduced by not correcting for the tide is 60 ft. This error means that if there had been no real change in shoreline position, the analysis would nonetheless have yielded a 60 ft change due to the tidal difference. If the time between the two photographs is 50 years, then this translates into an error of 1.2 ft/yr.

A similar argument can be made for the effect of wave runup and setup on the interpretation of shoreline change. In this case the wave conditions at the time of the aerial photograph will influence the position of the wet sand line. The slope of the beach, wave height, and wave period will all contribute to the relative shoreline position. For example, if one uses a simple model for wave runup, and a beach slope of 1:20, then a relatively small change in wave height and period will produce horizontal differences in shoreline position of approximately 80 ft. In terms of the previously assumed time between photographs of 50 years, this yields a difference in rate of change of 1.6 ft/yr. Again, as with the example for tide, the failure to correct for wave runup will introduce an apparent change in the position of the wet sand line even though there has not been any actual erosion or accretion of the beach.

#### Summary of Potential Errors

It is clear from the previous discussion that the potential errors in computing the rate of shoreline change from aerial photographs can be significant. Even if one is willing to use ground surveys to control the photographs and photogrammetric techniques to map the position of the wet sand line, there are still the problems associated with waves and tide. The correction for the tide would require some knowledge of the beach slope, and thus some minimum ground measurements at the time of the photographs.

Correction for waves would require this beach profile as well as an estimate of the wave conditions at the time of the photographs. The only alternative is to recognize that the potential for these errors exists, and therefore the interpretation of the data must include reasonable estimates of these errors. The actual error will of course depend upon the techniques employed and the specific conditions at the site.

### Digital Photogrammetry

Many of the problems described above can be eliminated by the use of digital photogrammetric techniques to map shoreline change. Digital photogrammetry is a process by which a three dimensional representation of the shoreline is mapped from a pair of stereo aerial photographs. This can be accomplished with an analytical stereoplotter, or alternatively, with the newer techniques using computer controlled scanners to digitize the aerial photographs. There are a number of commercial vendors for these digital systems. We are currently working with a series of products developed by Intergraph Corporation.

As with the more conventional techniques, it is still necessary to have accurate ground control in order to have an accurate model of the beach. However, in place of mapping the wet sand line, it is possible to define the shoreline as a particular datum, such as the mean high water line, or mean lower low water, etc. Since there is a 3-D model of the subaerial beach for each date of photography, there no longer is a need to correct for either tide or waves. In addition, since digital photogrammetry can achieve relatively high resolution (on the order of +/- 0.5 ft), the computation of the rate of shoreline change, even for short time periods, can be reasonably determined.

We are currently working with the Intergraph system to determine both its utility and economics when used to measure shoreline change. The results of this investigation will be presented in future publications.

### Conclusions

Aerial photographs will continue to be an important tool in the determination of shoreline change, and in the prediction of future shoreline positions. There are a number of sources of potential error in the current techniques. However, as long as these errors are understood, these techniques can continue to be employed. It is anticipated that the use of digital photogrammetry will, in time, replace today's technology, and thereby

provide a far superior mechanism for determining shoreline change from aerial photographs.

### Acknowledgments

This research is currently being supported by grants from the North Carolina Division of Emergency Management, the North Carolina Department of Transportation, the North Carolina Division of Coastal Management, and the Kenan Institute for Engineering, Science, and Technology. The assistance of Intergraph Corporation is also greatly appreciated in this research. Mr. Johnny Martin provided significant help in this research.

## CHAPTER 145

### SETTLING COLUMNS PARAMETRIC TESTS APPLIED TO COASTAL SEDIMENT CONSOLIDATION

Stéphane GALLOIS<sup>1</sup>, Alain ALEXIS<sup>1</sup>, Pierre THOMAS<sup>1</sup>

#### ABSTRACT

This paper presents a set of devices and a study both experimental and original in order to determine the influence of various parameters on the sedimentation-consolidation process of soft soils. We use this system to investigate the behaviour of a natural estuarine mud. A series of tests is performed, in which each test differs from the reference test in the value of only one parameter. We give a synthesis allowing the comparison of the action of each parameter on the mud behaviour. This systematic parametric experimental study builds an original data base, which is obviously necessary to validate theoretical modelization.

#### 1. INTRODUCTION

The behaviour of cohesive sediments is one of the main components of coastal engineering processes. These sediments are in an intermediate state between solid and liquid. Their theoretical study requires geotechnical or hydraulical modelization, both conceived with their own approach. We have proposed (ALEXIS et al., ICCE' 93) a unification of consolidation theories, pointing out the interest of the use of Gibson's law. The application of these theoretical models requires the knowledge of constitutive relationships (permeability, effective stress) of the muddy material. In this paper, we are proposing an original and experimental set of devices and study in order to determine the influence of various parameters on the sedimentation-consolidation process.

#### 2. EXPERIMENTAL SET

Our topic is to perform experiments characterised by :  
- One-Dimension-Vertical experimentation by means of

---

<sup>1</sup>Civil Engineering Laboratory E.C.N.I.U.T. St. NAZAIRE  
BP 420, F 44606 St-NAZAIRE CEDEX (FRANCE)

instrumented settling columns.

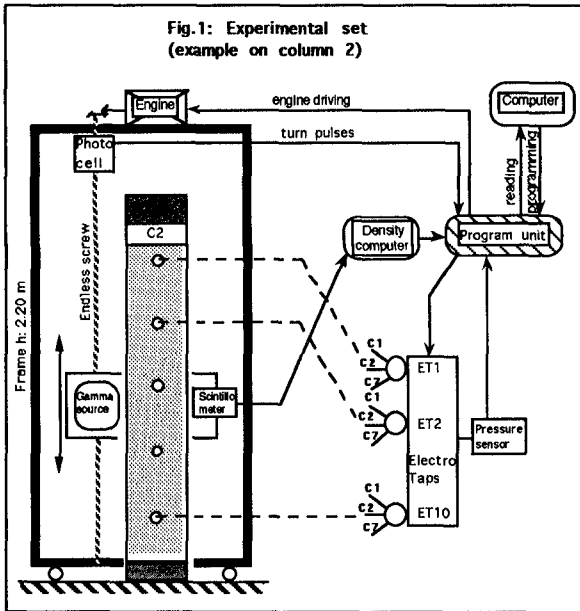

- No-disturbance of the evolutive material which is a natural mud with a natural estuarine water.
- Continuous tracking of its evolution.
- Simultaneous measurements on several columns under different conditions.

Our bibliographic research has shown the present lack of convenient experimental set.

So, we propose an original experimental set in order to reach these aims.

This experimental set needs a particular environment of the experiments to reduce the biochemical evolution of mud : the set is in a blind climatized room, the temperature is 10 degrees Celsius.

The experimental set (fig.1) is composed of a servo gammadensimetric bench and 7 columns in different conditions with acquisition, piloting and delayed processing.

The bench is 2.2 meters high.

It is shiftable for simultaneous measurements on the 7 columns.

It also uses a driving engine for moving the gammadensimeter which consists of a gamma source and its scintillometer.

The experiments require a localisation set by photocell

and 10 pressure locations for each columns.

By means of an hydraulic network, these pressure locations are connected to a unique pressure sensor by pipes via electrotaps.

These phases of acquisition, piloting, and delayed processing require a specific programmation and adaptation of program unit for the measurement and acquisition of density, pressure, position and also for piloting the driving engine and the electrotaps.

This system has several specificities:

- *experimentation systematisation*: simultaneous measurements on seven parallel columns, shifting the movable gammadensimeter to each column. All the columns are connected by plastic pipes to the pressure sensors through the set of electrotaps.

- *specific procedure*: the adjustment of the number of measurements enables the compromise between accuracy and speed: profile duration can vary from 2 min (continuous profiles) to 20 min (step by step profiles) in order to identify the mud behaviour during the initial stage of the process and to obtain a good accuracy in the final phase as well.

- *search of reliability*: the use of a unique pressure sensor allows the avoiding of drift errors and the obtaining of automatic pore pressure profiles throughout the whole experiment.

### 3. EXPERIMENTAL STUDY

#### 3.1 Experimental method

The phenomenon is characterized by its complexity because of :

- superposition of spatial and time evolutions.
- large variations of evolution with geometric conditions and composition of material.
- numerous interactions between characteristics.

So, we propose an experimental methodology.

We have 2 steps of procedure :

- on line for measurement acquisition and also for concentration and pore pressure profiles performing
- and delayed processing of profiles evolution.

So, we tackle this parametric study by changing only one parameter at a time experimentally with respect to one reference case. Our experimental approach is quite similar to partial derivative approach.

There are 16 instants of measurements in a geometrical progression of ratio 2.

Among the numerous characteristics governing the cohesive soils settling, the basic parameters are initial concentration ( $c_0$ ), initial height ( $h_0$ ), fines

proportion (less than 63  $\mu\text{m}$  in size) and organic matter content (ignition loss).

We are using a reference case and 4 other cases.

The reference case is performed with natural mud (LL=65%, PI=18%, OM=13%),  $h_0=1.50$  m,  $c_0 = 90$  g/l, temperature 10°C, natural water. In the 4 other cases, the changed parameter value is respectively:  $h_0=0.75$  m (half height),  $c_0 = 180$  g/l (double concentration), 100% fines, 0% organic matter.

At last, we will obtain 10 000 recorded data issued from measurements of position, density and pressure.

### 3.2 Results

We propose a full synthesis of our measurements results which allows the comparison between the respective influences of studied parameters upon the evolution of profiles of concentration and pore pressure concentration on the one hand, and on constitutive relationships on the other. We have chosen to present concentration profiles and permeability as examples.

#### a) General influence of parameters

A great deal of information (fig. 2 and 3) are induced by the observation of the following three special aspects of concentration profiles: soil-water interface downing speed, behaviour during sedimentation ("vertical" part of the profiles) and shape of the curve in the deposit (lower part of each profile).

These 2 figures show the concentration profiles in 5 cases, at 3 instants.

The comparative analysis of these curves and of their slopes give a lot of informations.

- The similarity of the first parts of reference curve and fines only curve implies that the influence of fines particles governs interface downing speed, and it also implies the lack of size segregation of particles during downing.

- in the highest part of profiles, the concentration is lower than initial concentration, so there is probably a swelling, that is a local decreasing of concentration.

- this hypothesis is confirmed by the importance of non-verticality of first part of double concentration profiles.

- consolidation is slowed by the thickness of deposit and by the organic matter. This can be explained in terms of draining path length and of draining speed of pore pressure.

Fig.2: Concentration profiles at  $t=5$  min, 3h and 192 h in the cases reference, fines and half height

Fig.3: Concentration profiles at  $t=5$  min, 3h and 192 h in the cases reference, double concentration and no organic matter

We propose, also, a set of measurements of excess pore pressure profiles (fig.4).

Fig.4: Evolution of excess pore pressure profiles with time

These measurements are original but quite delicate to carry out.

The figure represents the evolution with time of pore pressure excess above hydrostatic pressure for the different pressure locations.

It appears a quite regular dissipation of pore pressure.

During initial phase, there is a fast evolution of pore pressure and during final phase, after 6 hours, there is a slow evolution curves in the deposit.

We specify that accuracy is about 20 Pascal and that salinity generates a complex geochemical behaviour so, there is an instability of curves around zero over pore pressure.

#### b) Application to constitutive laws

These different results can be applied for a better knowledge of constitutive laws.

We can use density or pore pressure measurements to obtain new parameters, at each measurement point.

Density measurements give us void ratio  $e$ .

By means of an integration of profile, we can obtain total stress  $\sigma$  at each point.

The profile evolution with time gives us settling velocity  $v_s$

Pore pressure measurements  $u$  drive us to effective

stress  $\sigma'$  which is the difference between total stress and pore pressure.

Pore pressure profiles  $u$  give us hydraulic gradient  $i$ .

Then, we can determine permeability :  $k$

So, we obtain 3 essential parameters : effective stress  $\sigma'$ , permeability  $k$  and void ratio  $e$ .

Their linkage is the main part of constitutive laws study.

First, we apply that way of research to permeability.

In figure 5, we propose a set of dots, corresponding to 4 cases material at 3 instants (33 mn., 9h., 72h.).

At each instant, we can draw an average curve between the corresponding dots, whatever their case.

Fig 5 Evolution of permeability with time and void ratio

We observe that permeability decreases with time, for a constant void ratio. So, the permeability is not constant with time. This new and original result underlines the limits of validity of Darcy's law as a flow law through very little consolidated cohesive sediments.

Otherwise, we can remark the good agreement of fines

permeability values with references permeability values. We can deduce that fine fraction probably governs the mixture permeability.

The measurements in non-organic mixture, not shown here, are always close to the lowest curve. So, the permeability of non-organic mixture does not depend on time.

Second, we apply that way of research to effective stress.

Figure 6 represents effective stress and void ratio for the reference case at each instant.

Fig.6: Evolution of effective stress with void ratio and time (reference case)

We must specify that relative accuracy decreases with the decrease of effective stress because of the way of obtention of effective stress by difference between total stress and pore pressure.

We can observe gathering dots for 4 instants ranges.

Results show clearly that effective stress increases while void ratio decreases.

From 20 minute, and for a constant effective stress, void ratio decreases with time.

It is an original result : effective stress depends not only on void ratio but also on time, probably by means

of strain rate which is linked to the variation of the derivative ratio with time : $\dot{\epsilon}$ .

That creeping phenomenon could be introduced in sedimentation-consolidation process and we could research later a relation between effective stress, void ratio and derivative of void ratio with time.

#### 4. CONCLUSION

Cohesive sediments are complex materials.

Their specific behaviour implies the complexity of their study.

In this paper, we have proposed :

- an original experimental set including an automatic gammadensimetric bench.
- a systematic approach by changing only one parameter at a time.
- numerous measurements to create a data base.

Our results give the different evolution of concentration profiles for different cases of materials and tests conditions. They give also the evolution of permeability with time and so, the limits of Darcy's law for sedimentation-consolidation modelling.

At last, our results give the evolution of effective stress with time. This evolution implies a possibility of creeping during sedimentation-consolidation process.

These conclusions drive us to a significant progress in the knowledge of cohesive sediment and in the formulation of its behaviour in order to model sedimentation-consolidation process.

Now, new aims could be defined for further studies as : the research of a new flow law (for instance velocity in function of void ratio and hydraulic gradient) and of a new approach of effective stress.

#### 5 - ACKNOWLEDGEMENTS

The present research on consolidation is undertaken as part of the MAST European program Coastal Morphodynamics (contract n°035).

## CHAPTER 146

### Sediment-Cloud Based Model of Suspension over Ripple Bed due to Wave Action

Hitoshi Gotoh<sup>1</sup>, Tetsuro Tsujimoto<sup>2</sup> and Hiroji Nakagawa<sup>3</sup>

#### ABSTRACT

Sediment cloud, which is released periodically from the crest of ripples, plays a very important role in suspension over a ripple bed under the wave action. By considering the special role of the sediment cloud, suspension is divided into two subprocesses: (i) the transition process from bed-load motion to suspension as the entrainment of the sediment cloud; and (ii) the diffusion process of suspended sediment released from the sediment cloud. The trajectory of the sediment cloud is calculated by Lagrangian approach in the flow field solved by k- $\epsilon$  model of turbulence. The suspended sediment concentration is simulated by solving a diffusion equation which has the source term due to sediment cloud.

#### INTRODUCTION

Since an important role of sediment cloud on the suspension over a ripple bed was recognized from the experiment with the aid of the visualization technique (Sunamura, Bando and Horikawa (1978); Sawamoto and Yamaguchi (1979)), the model of the suspension using the characteristics of the sediment cloud began to be investigated. Sunamura (1980) proposed a formula of the sediment discharge by defining the net sediment discharge as the amount of the sediment transported more than 1.5 times of a ripple's wave length in the offshore direction. Hayakawa, Tani and Wakui (1985) applied a Lagrangian model to the suspension due to wave action over a ripple bed, by assuming the scale of sediment cloud after the experiment and solving the flow field by the Stokes's second order approximation. Swamoto and Yamaguchi

<sup>1</sup>Research Associate, Department of Civil Engineering, Kyoto University, Yoshida Honmachi, Sakyo-ku, Kyoto, 606, Japan

<sup>2</sup>Associate Professor, Department of Civil Engineering, Kanazawa University, 2-40-20, Kodatsuno, Kanazawa, 920, Japan

(1979) divided the flow field into two layers: (i) the "vortex layer" in which the transport by sediment cloud is predominant; and (ii) the "diffusion layer" in which the diffusion by turbulence is predominant. They estimated the one-cycle averaged turbulent intensity and the one-cycle averaged concentration of suspended sediment, based on their two layer model.

The applicability of a k-ε model of turbulence to the oscillating flow over a ripple bed was confirmed by comparing the prediction by the model to the body of the experimental data. Sato, Uehara and Watanabe (1986) performed the numerical simulation of oscillating boundary layer on the basis of the k-ε model with the equation of vorticity. They also simulated the trajectory of a suspended particle by a Lagrangian approach. Tsujimoto, Hayakawa, Ichiyama and Fukushima (1991) calculated the suspended sediment concentration by coupling the k-ε model with the diffusion equation of suspended sediment.

Sediment suspension in the oscillating flow is characterized by two factors: (i) the complexity of flow field; and (ii) the response of a suspended particle to the change of the flow field. The factor (ii) is divided into two processes: (a) the transition process from bed-load motion to suspension as the entrainment of the sediment cloud, and (b) the diffusion process of suspended sediment released from the sediment cloud. Although this hierarchical structure of sediment behavior makes the transport process more complicated, Sawamoto & Yamaguchi's model of two layer, "vortex layer & diffusion layer," which is the one-cycle averaged model, gives a good suggestion to explain this complexity. In this study, Sawamoto & Yamaguchi's model is developed to the unsteady condition, by regarding the sediment cloud as a moving source of diffusion.

The structure of the model is schematically shown in Fig. 1. The transition process by the motion of sediment cloud (subprocess (a)) is simulated by tracing the trajectory of sediment cloud in the flow field solved by a k-ε model; while the diffusion process of suspended sediment released from the sediment cloud (subprocess (b)) is simulated on the basis of the Murphy's diffusion equation (1984) with the sediment source term which expresses the generation of the sediment due to the sediment cloud. The former is treated by the Lagrangian model which can estimate the detailed motion of the suspension; while the latter by the Eulerian model more conveniently than Lagrangian one. This model can be regarded as a fusion of the Eulerian model and the Lagrangian one by considering their advantages.

EXPERIMENT

The experiment was conducted in U-tube type oscillating

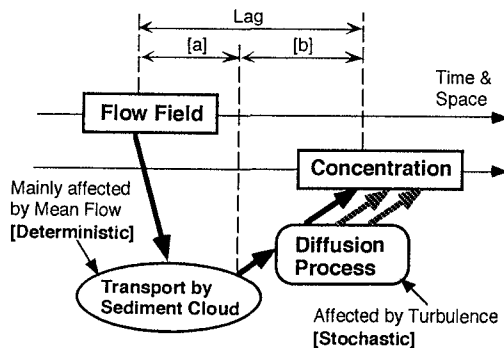

Figure 1 Constitution of the model

water tunnel with a movable bed illustrated in Fig.2. The equipment was made of acrylic resin, and the working section was 180cm long, 20cm high and 20cm wide. The access to the working section was provided by the hatches located above the central part of the water tunnel. The driving mechanism is installed to maintain the oscillation. The pump system was connected with the water tunnel at the both ends of the horizontal section, to generate the uni-directional flow. The motion of the sediment cloud was recorded by a CCD video camera from the side of the working section. The time series of the concentration of sediment near the bottom was measured by an optical turbidity meter. The test particle was a natural sand with the specific gravity 2.65 and the diameter 0.26mm. Experimental condition is shown in Table 1.

In an oscillation-current coexisting flow, the asymmetry of the flow field and that of the sediment transport due to the existence of the current bring the asymmetric ripple profile: the upstream-side slope is steeper than the downstream-side slope. The geometrical parameters of the ripple in the experimental condition is included in the range of the body of the experimental data in the wave-current coexisting flow by Watanabe, Sakinada and Isobe (1989).

Table 1 Experimental condition

Period of oscillation $T$ (s)	2.6
Amplitude of the mean velocity $U_w$ (cm/s)	19.0
Current velocity $u_c$ (cm/s)	6.2
Ripple wavelength $L_r$ (cm)	12.0

## GOVERNING EQUATIONS OVER RIPPLE BED

### *Orthogonal curvilinear coordinate over ripple bed:*

Sawamoto (1978) proposed the orthogonal curvilinear system for the symmetric ripples. Tanaka and Syuto (1984) modified the Sawamoto's system to express the asymmetric profile of ripples. The relation between the Cartesian coordinate  $(x,y)$  and the orthogonal curvilinear coordinate system  $(\xi,\eta)$ , based on Tanaka & Syuto's method, is introduced to make a conformal mapping over the ripple bed as follows:

$$\left. \begin{aligned} x &= \xi - H_r \sum_{j=1}^N a_{rj} \exp(-k_r j \eta) \sin(k_r j \xi + \theta_{rj}) \\ y &= \eta + H_r \sum_{j=1}^N a_{rj} \exp(-k_r j \eta) \cos(k_r j \xi + \theta_{rj}) \end{aligned} \right\} \quad (1)$$

where  $H_r$ =ripple wave height;  $k_r$ =ripple wave number ( $=2\pi/L_r$ ); and  $L_r$ =ripple wave length. The empirical parameter  $a_{rj}$ ,  $\theta_{rj}$  are determined by trial and error. The agreement between the measured ripple profile and Eq. 9 is fairly good as shown in Fig. 3.

*Governing equations:*

The governing equations in the orthogonal curvilinear coordinate  $(\xi, \eta)$  is given as follows:

$$h_1 h_2 \frac{\partial \phi}{\partial t} + \frac{\partial}{\partial \xi} \left( h_2 U_{OR} \phi - \Gamma_\phi \frac{h_2}{h_1} \frac{\partial \phi}{\partial \xi} \right) + \frac{\partial}{\partial \eta} \left( h_1 V_{OR} \phi - \Gamma_\phi \frac{h_1}{h_2} \frac{\partial \phi}{\partial \eta} \right) = h_1 h_2 S_\phi(\xi, \eta) \quad (2)$$

$$h_1 \equiv \sqrt{\left( \frac{\partial x}{\partial \xi} \right)^2 + \left( \frac{\partial y}{\partial \xi} \right)^2} ; h_2 \equiv \sqrt{\left( \frac{\partial x}{\partial \eta} \right)^2 + \left( \frac{\partial y}{\partial \eta} \right)^2} \quad (3)$$

where  $\phi$ =variable;  $\Gamma_\phi$ =coefficients of apparent viscosity; and  $S_\phi$ =source terms, and they are summarized in Table 2. The parameters and variables in Table 2 are as follows:  $U_{OR}, V_{OR}$ = mean velocity components in  $\xi, \eta$  directions, respectively;  $P$ =mean pressure;  $\rho$ =mass density of fluid;  $\Gamma$ =effective viscosity;  $\nu$ =kinematic viscosity;  $\nu_t$ = kinematic eddy viscosity;  $G$ =production of turbulent energy;  $w_0$ =terminal fall velocity of sediment particle;  $S_{cl}$ =source term due to the sediment cloud; and  $\Gamma_{sx}, \Gamma_{sy}$ = the coefficient of diffusion in the streamwise and vertical direction. The empirical constants are set at the recommended values by Launder and Spalding (1974) as follows:  $C_\mu=0.09$ ,  $C_{1\epsilon}=1.44$ ,  $C_{2\epsilon}=1.92$ ,  $\sigma_k=1.0$  and  $\sigma_\epsilon=1.3$ .

Although the governing equations are standard ones which are frequently used for the unsteady flow simulation, the present simulation is characterized by the sediment source term  $S_{cl}$  and its estimation mentioned later in detail. In some previous simulations, the buoyancy term, which represents the effect of suspended sediment on the flow field, is introduced into the equations of flow field. In this study, the concentration is set at the suffi-

Figure 3 Grids for the calculation

$C$	$\frac{\Gamma_s}{S_c}$	$S_{co} = \frac{1}{h_2} \frac{\partial}{\partial \eta} (w_0 C) + S_{cl}$
$G = v_t \left[ 2 \left\{ \left( \frac{1}{h_1} \frac{\partial U_{OR}}{\partial \xi} + \frac{V_{OR}}{h_1 h_2} \frac{\partial h_1}{\partial \eta} \right)^2 + \left( \frac{1}{h_2} \frac{\partial V_{OR}}{\partial \eta} + \frac{U_{OR}}{h_1 h_2} \frac{\partial h_2}{\partial \xi} \right)^2 \right\} \right.$ $\left. + \left( \frac{1}{h_2} \frac{\partial U_{OR}}{\partial \eta} - \frac{V_{OR}}{h_1 h_2} \frac{\partial h_2}{\partial \xi} + \frac{1}{h_1} \frac{\partial V_{OR}}{\partial \xi} - \frac{U_{OR}}{h_1 h_2} \frac{\partial h_1}{\partial \eta} \right) \right]$		

ciently low level at which the effect of the suspended sediment on the flow field is negligibly small, or the clear water flow assumption can be applied. By substituting Eq. 1 into Eq. 3,  $h_1=h_2(=h_{fq})$ .

**Boundary conditions and procedure of simulation:**

The wall function is applied at the bottom boundary, or the logarithmic law of the mean velocity at the lowest point of the grid. The turbulent energy and its dissipation rate at the lowest grid point are calculated based on the local equilibrium assumption.

At the top boundary, an axial symmetric condition is applied for  $U, k$  and  $\epsilon$ . The periodic boundary condition is applied for  $U, k$  and  $\epsilon$  between the both side boundaries. The present simulation does not require the boundary condition of concentration at the bottom, which is usually employed in the calculation of the concentration, because the sediment source term is added in the present simulation. Therefore, the concentration profile can be evaluated by the present simulation without giving the sediment concen-

tration at the reference level.

The governing equations are discretized by SIMPLE algorithm by Patankar and Spalding (1972), and the calculation was conducted based on TEACH code (Gosman and Ideriah (1976)). For the conversion assessment of the flow field, the following conditions are subjected: (i) the summation of the absolute residual in each cell of a continuity equation is less than 1% of the flow discharge in the streamwise direction; (ii) the absolute residual in each cell of a mean flow equation is less than 1% of the total momentum at the inflow boundary.

The procedure of the present simulation are as follows: (i) to solve the flow field ; (ii) to simulate the motion of the sediment cloud by Lagrangian method in the flow field solved in the process (i); (iii) to evaluate the sediment source term in the equation of concentration based on the trajectories of the sediment cloud determined in the process (ii); and (iv) to solve the equation of concentration in the flow field determined in the process (i) with the sediment source term evaluated in the process (iii).

### SOLUTION OF FLOW FIELD

The characteristics of the calculated flow field are discussed at the phase  $2\pi/5$  and  $7\pi/5$ . The change of the bulk mean velocity at the inflow boundary is given in the cosine pattern, hence the velocity in the current direction is maximum at the phase  $2\pi$ , and the velocity against the current direction is maximum at the phase  $\pi$ .

The calculated mean velocity field at the phase  $2\pi/5$  and  $7\pi/5$  are shown in Fig. 4. The vortex due to the separation is found in the lee side of ripples at the phase  $2\pi/5$ ; while the vortex is not clearly simulated at the phase  $7\pi/5$ . The asymmetric ripple profile affects strongly on the flow field.

Figure 5 shows the calculated distribution of the turbulent energy. At the phase  $2\pi/5$ , the high value area is recognized along the outer edge of the vortex due to the separation; while at the phase  $7\pi/5$ , the high energy area due to the vortex is not found. The non-uniformity of the turbulent energy in the streamwise direction at the phase

Figure 4 Mean velocity vector

$2\pi/5$  is smaller than that at the phase  $7\pi/5$ , hence the contour lines at the phase  $7\pi/5$  become more parallel to the bottom profile than those at the phase  $2\pi/5$ . Fig. 6 shows the calculated energy dissipation, and Fig. 7 shows the calculated kinematic eddy viscosity. Their asymmetric distributions due to the asymmetric bottom profile are found in both figures. The calculated results suggest the drastic change of the kinematic eddy viscosity, which are usually used to estimate the coefficient of the diffusion of suspended sediment.

SIMULATION OF SEDIMENT CLOUD MOTION

*Simulation model:*

The sediment cloud was defined only qualitatively in the previous studies as the mixture of sediment and fluid which is apparently like a cloud; while the quantitative

definition of the sediment cloud is not clear because the boundary between the sediment-fluid mixture and the surrounding fluid is ambiguous. In order to clarify the qualitative definition of the sediment cloud, it is here idealized as follows: a "kernel" exists at the central part of the cloud in which the all of the sediment transported by the cloud is contained. The kernel is not affected by the turbulence, hence the trajectory of the kernel is a deterministic one ruled by the mean velocity filed.

Here, the kernel is approximated by the rigid cylinder. By neglecting a rotating motion of the cylinder, the equation of the motion of the kernel is written as follows:

$$\rho \left( \frac{\sigma_{cl}}{\rho} + C_M \right) A_2 d_{cl}^2 \frac{d\mathbf{u}_{cl}}{dt} = -\frac{1}{2} C_D \rho A_1 d_{cl} |\mathbf{u}_{cl} - \mathbf{u}_f| (\mathbf{u}_{cl} - \mathbf{u}_f) + \rho (1 + C_M) A_2 d_{cl}^2 \frac{d\mathbf{u}_f}{dt} - \rho \left( \frac{\sigma_{cl}}{\rho} - 1 \right) \mathbf{g} A_2 d_{cl}^2 \quad (4)$$

where  $\mathbf{u}_{cl}$ =velocity vector of the kernel;  $\mathbf{u}_f$ =velocity vector of the surrounding fluid;  $\mathbf{g}$ =gravitational acceleration;  $d_{cl}$ =diameter of the kernel;  $C_M$ =added mass coefficient;  $\sigma_{cl}$ =density of the kernel; and  $A_1, A_2$ =one- and two dimensional geometrical coefficients. The drag coefficients  $C_D$  is given by

$$C_D = C_{D\infty} + \frac{24}{R_e} \quad ; \quad R_e = \frac{d_{cl} |\mathbf{u}_{cl} - \mathbf{u}_f|}{\nu} \quad (5)$$

Although the coefficient  $C_{D\infty}$  depends on the shape of the particle,  $C_{D\infty}$  sets 0.4 in this study. It is smaller than that of cylinder, because the real kernel is not a rigid body.

Equation 4 is applicable to the orthogonal curvilinear coordinate  $(\xi, \eta)$  only with the modification of the gravity term as follows:

$$\begin{bmatrix} g_\xi \\ g_\eta \end{bmatrix} = \frac{1}{h_{\eta q}^2} \begin{bmatrix} \frac{\partial y}{\partial \eta} & -\frac{\partial x}{\partial \eta} \\ -\frac{\partial y}{\partial \xi} & \frac{\partial x}{\partial \xi} \end{bmatrix} \begin{bmatrix} 0 \\ g \end{bmatrix} = \begin{bmatrix} -\frac{1}{h_{\eta q}^2} \frac{\partial x}{\partial \eta} g \\ \frac{1}{h_{\eta q}^2} \frac{\partial x}{\partial \xi} g \end{bmatrix} \quad (6)$$

Following the definition of the kernel mentioned above, the velocity of the surrounding fluid in Eq. 4 is given by the mean velocity of the flow field. By considering that the sediment cloud is generated by the vortex due to the separation, the diameter of the kernel  $d_{cl}$  is related to the scale of the vortex, or the ripple wave height as follows:

$$d_{cl} = \beta_{dcl} H_r \quad ; \quad \beta_{dcl} = 0.1 \quad (7)$$

Here, the kernel is treated by the deterministic equations, hence the probabilistic aspect of the suspension, namely the random motion of the suspended sediment should not be included in the kernel. In general, the number of the random suspended sedi-

ment increases with the distance from the center of the sediment cloud. Hence, the kernel with small diameter is adopted in this study.

The mass density of the kernel  $\sigma_{cl}$  is given in a following form.

$$\sigma_{cl} = \sigma \frac{q_{scl}}{q_{cl}} + \rho \left( 1 - \frac{q_{scl}}{q_{cl}} \right) \tag{8}$$

where  $q_{cl}$ =volume of the sediment cloud; and  $\sigma$ =density of sand. The volume of the contained sediment  $q_{scl}$  is estimated in a following manner. The volume of the sediment released from the sediment cloud (kernel) per unit time is assumed to be proportional to the volume of the contained sediment. Hence, the volume of contained sediment in the kernel is given by following equation .

$$\frac{q_{scl}}{q_{scl0}} = \exp \left( -\frac{\zeta_{cl}}{\beta_{cl} T_D} \right) ; \quad \zeta_{cl} = t - t_{cl0} \tag{9}$$

where  $q_{scl0}$ =initial volume of the contained sediment;  $T_D$ =life time of the sediment cloud;  $\beta_{cl}$ =the empirical constant; and  $t_{cl0}$ =starting time of the sediment cloud, or the time at which the main stream changes their direction. An observation of the motion of sediment clouds in the experiment suggested that the life time of the sediment cloud approximately coincides the period of the oscillation; and that the diffusion is active in the half period of oscillation from  $t_{cl0}$  to the time when the central position of the cloud is difficult to determine. By considering these results of the observation,  $T_D$  and  $\beta_{cl}$  are set  $T_D=T$ , (=period of oscillation); and  $\beta_{cl}=0.2$ . By setting  $\beta_{cl}=0.2$ , the volume of the contained sediment after a half period from  $t_{cl0}$  is about 10% of the initial volume of the contained sediment.

*Trajectory of the sediment cloud:*

Figure 8 shows the simulated trajectory of the kernel with the experimental data. In the simulation, the initial position of the kernel is determined by the experiment. The experimental data were obtained as a following manner: (i) the motion of the sediment cloud was recorded by a CCD video camera from the side wall of the water tunnel; (ii) the position of the center of the sediment cloud, which was defined as the position with the highest concentration of sediment by a visual judgment, in

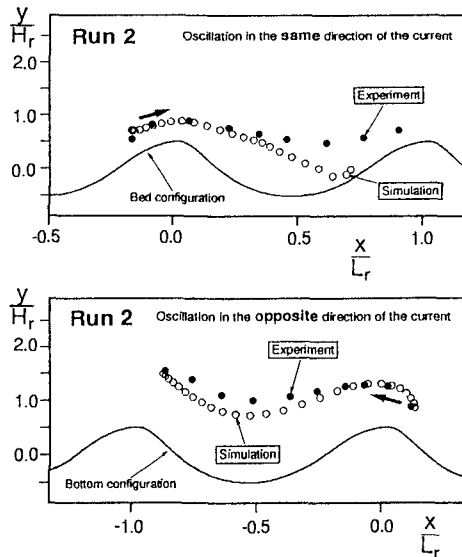

Figure 8 Trajectory of the kernel of sediment cloud

each 1/10 seconds was determined; (iii) the deterministic trajectory was determined by averaging the trajectories given in the process (ii).

When the oscillation occurs in the opposite direction of the current, the agreement between the simulation and the experiment is fairly good. While, under the oscillation in the same direction of the current, the result of the simulation deviates from the experimental result after the cloud passes the trough of the ripple. The concentration of the sediment decreases with the increase of the travelling time of the cloud, hence the reliability of the experimental results, which depends on the concentration, decreases with the increase of the travelling time of the cloud. Furthermore, the volume of the contained sediment decreases with the increase of the travelling time of cloud, therefore the role of the kernel as a source of the sediment in the diffusion equation becomes less important with the travelling time of cloud. Hence the deviation of trajectory never bring a severe error in the simulation explained in the following chapter.

### SIMULATION OF SUSPENSION

#### *Estimation of the source term:*

The sediment source term found in Murphy's diffusion equation are estimated as follows:

$$S_{cl}(\xi, \eta, t) = -\chi_{cl}(\xi, \eta, t) \frac{dq_{scl}}{dt} \quad (10)$$

Where  $\chi_{cl}(\xi, \eta, t)$  = the distribution of the suspended sediment around the center of the sediment cloud, and the uniform distribution is here supposed. Then,  $\chi_{cl}(\xi, \eta, t)$  is written as follows:

$$\chi_{cl}(\xi, \eta, t) = \begin{cases} 1 & \text{when } (\xi, \eta) = (\xi_{cl}, \eta_{cl}) \\ 0 & \text{other} \end{cases} \quad (11)$$

where  $(\xi_{cl}, \eta_{cl})$  = the location of the center of the sediment cloud.

#### *Estimation of the diffusion coefficient:*

Although the diffusion coefficient of suspended sediment is usually estimated by assuming it's similarity to the kinematic eddy viscosity, the motion of the suspended sediment is affected not only by the fluid motion, the characteristics of the variation of which is represented by the kinematic eddy viscosity; but also by the response of the particle to the change of the surrounding fluid motion. Tsujimoto and Nakagawa (1986) proposed the estimation of the diffusion coefficient on the basis of the similarity between the diffusion equation and the continuous expression of the random walk model. In this section, the diffusion coefficient is estimated based on the Tujimoto and Nakagawa's method.

By considering the equilibrium state of the random walk of suspended sediment in the vertically one-dimensional infinite space, the following relation is obtained.

$$\frac{E[\zeta^2]}{2} \frac{\partial f_s}{\partial y} = E[\zeta] \cdot f_s \quad (12)$$

where,  $f_s$ =probability density of existing height of suspended sediment, and  $\zeta$ =vertical deviation of suspended sediment during  $\Delta t$ .  $\Delta t$ =time step of random walk. On the other hand, the one-dimensional diffusion equation in a steady state which is written as follows:

$$\varepsilon_s \frac{dC_s}{dy} = -w_0 \cdot C_s \quad ; \quad C_s = C_m \cdot f_s \quad (13)$$

where  $C_m$ =depth-averaged concentration of suspended sediment. By comparing Eqs. 12 and 13 to each other, and supposing the relation  $E[\zeta]=w_0\Delta t$ , the diffusion coefficient can be written as follows:

$$\varepsilon_s = \frac{E[\zeta^2]}{2\Delta t} = \frac{E[\zeta]^2 + \sigma_\zeta^2}{2\Delta t} = \frac{w_0^2\Delta t}{2} + \frac{\sigma_\zeta^2}{2\Delta t} \quad (14)$$

The magnitude of the deviation of the suspended sediment during  $\Delta t$ ,  $\sigma_\zeta$ , is given in a following form, by introducing one-dimensional Markovian process to express the characteristics of the turbulence.

$$\sigma_\zeta^2 = 2k_{os}^2\sigma_v^2 \left[ \Delta t \cdot T_L - \Delta t^2 \left\{ 1 - \exp\left(-\frac{\Delta t}{T_L}\right) \right\} \right] \quad (15)$$

where  $\sigma_v$ =the standard deviation of the surrounding fluid velocity during  $\Delta t$ , and  $k_{os}$ =the parameter of the particle's response. Finally, by substituting Eq. 15 into Eq. 14, the turbulent Schmidt number  $S_c$  is written as follows:

$$\frac{1}{S_c} \equiv \frac{\varepsilon_s}{v_t} = \frac{\varepsilon_s}{\sigma_v^2 T_L} = \frac{1}{2} \left( \frac{w_0}{\sigma_v} \right)^2 \Xi_s + k_{os}^2 \{ 1 - \Xi_s (1 - e^{-\Xi_s}) \} \quad ; \quad \Xi_s = \Delta t / T_L \quad (16)$$

In the homogeneous turbulent flow, the Lagrangian time scale  $T_L$  can be written in the following form through a dimensional consideration as follows:

$$T_L \cong \frac{3v_t}{2k} \quad (17)$$

The Lagrangian time scale can be related to the parameters of the flow field by Eq. 17.

Figure 9 shows the distribution of turbulent Schmidt number estimated by Eq. 16 with the time step of the simulation  $\Delta t=0.01$  s. At the phase  $2\pi/5$ , at which the separation occurs, the spatial non-uniformity is strong; while at the phase  $7\pi/5$ , the spatial non-uniformity is small, or the contour line is almost parallel to the bottom configuration. Although Eq. 16 is derived by assuming the diffusion in the one-

Figure 9 Distribution of the turbulent Schmidt number

dimensional uniform field  $(-\infty, \infty)$ , the fundamental mechanism of the motion of suspended sediment: the characteristics of the response of suspended sediment to the turbulence; and the fundamental characteristics of the turbulent flow field are included in this equation. Therefore, the estimation of the diffusion coefficient based on Eq. 16 is better than the usual way of estimation, in which a linear proportionality is assumed between kinematic eddy coefficient and the diffusion coefficient.

## RESULTS OF SIMULATION AND DISCUSSION

Figure 10 shows the result of the simulation on the distribution of the concentration of suspended sediment. The value on each contour line implies the relative concentration to the initial concentration of the kernel ( $=C_{c0}$ ), and the phase shown in each figure is the phase of the bulk mean flow. Although the experiment shows that many of bed-load particles are entrained into the separation zone and high density sediment is recognized in the separation zone; the present simulation never treats the sediment in the separation zone as suspended sediment, the definition of which is the sediment in a random motion. Because the motion of the sediment in a separation zone is strongly ruled by the motion of vortex, and it is rather deterministic. Therefore, the high concentration region is not found at the phase  $2\pi/5$  in the simulation, in which the separation is found in the lee side of ripples.

The sediment cloud propagating in the opposite direction to the current (leftward in Fig. 9), which emerges at the phase  $3\pi/5$ , moves in the upstream direction (leftward in Fig. 9) with generating high density suspended sediment, and then it reaches the region above the steep slope of the upstream neighboring ripple (right-hand side mild slope in Fig. 9) at the phase  $4\pi/5$ . At the phase  $\pi$ , the sediment cloud exists above a trough of ripple, and it plays a role to push the contour lines up. At the phase  $6\pi/5$ , high concentration region due to the sediment cloud is not found clearly, and the concentration is almost uniform in the horizontal direction. While the sediment cloud propagating in the same direction to the current (rightward in Fig. 9), which emerges at the phase  $7\pi/5$  above the mild slope of the ripple, reaches the region above the steep slope in the downstream neighboring ripple. At the phase  $9\pi/5$ , the high-concentration region extends to the downstream direction. At the phase  $2\pi$ , the contour lines are almost parallel to each other, and the concentration profile is approximately uniform in the horizontal direction.

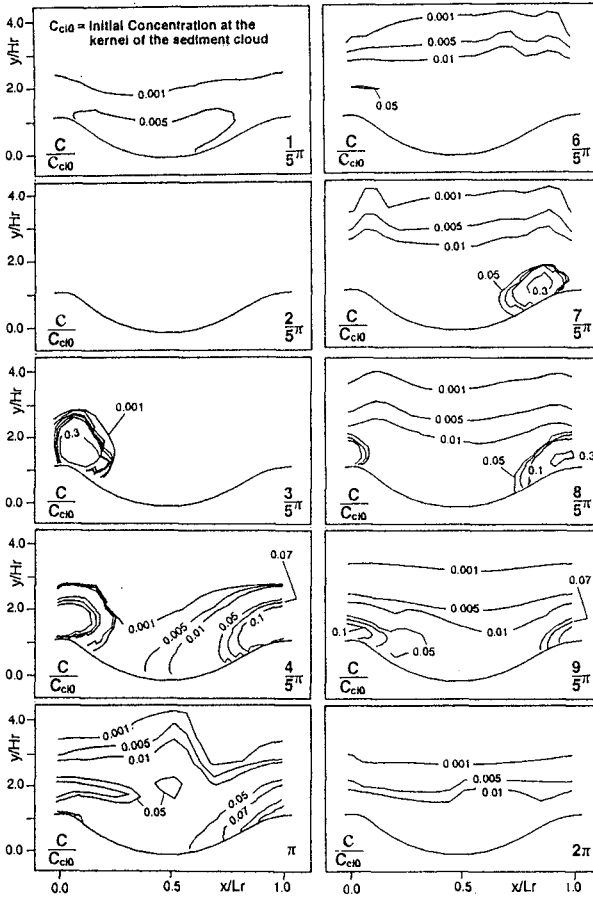

Figure 10 Concentration distribution of suspended sediment

From the phase  $2\pi$  to  $2\pi/5$ , the deposition of the sediment is promoted and the contour lines move in the downward direction, because the sediment cloud, or the source of sediment, does not exist; while, from the phase  $7\pi/5$  to  $2\pi$ , the speed of the downward motion of the contour lines is suppressed due to the existence of the sediment cloud. Although the sediment cloud moving in the same direction of the current is smaller than that moving in the opposite direction to the current, it plays a role to maintain the high-concentration region which is generated by the motion of the sediment cloud moving in the opposite direction of the current.

Figure 11 shows the comparison between the simulated time series of the concentration and that obtained by the experiment at the two points: [A] the concentration

at the point near the crest located within the trajectory of the sediment cloud; and [B] the concentration at the point near the trough. The initial volume of the contained sediment is determined to fit the peak of the concentration of the Fig.10 [A]. Although the peak-phase of the simulation is smaller than that of experiment, the relative height of the second peak to the first peak is simulated fairly well in Fig. 10 [A]. Fig. 10 [B] shows that, at the trough, the fundamental features of the experimental results are simulated: the existence of the first peak and the gradual transition from the first to the second peak.

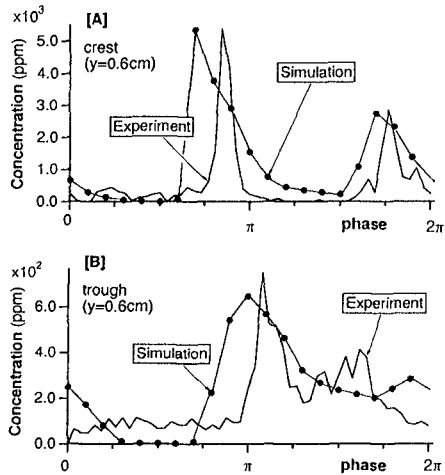

Figure 11 Time series of concentration

### CONCLUSION

The results obtained in this study are summarized as follows:

(1) The oscillation-current coexisting flow over a ripple bed is numerically simulated by a  $k-\epsilon$  model of turbulence. The result of the simulation shows that an asymmetry of the bottom-neighboring structure of the flow is induced clearly from a slight asymmetry of the ripple profile.

(2) To simulate the motion of the sediment cloud as the moving source of the suspended sediment in the field of the diffusion, the existence of a kernel is supposed at the central part of the sediment cloud. The motion of the kernel is simulated based on the equation of motion of a rigid cylinder. The result of the simulation agrees well with the experiment of the trajectory of sediment cloud.

(3) The turbulent Schmidt number is estimated on the basis of the similarity between the stochastic model of the suspension and the diffusion model. The spatial non-uniformity of the Schmidt number indicates the importance of the improvement of previous method which requires an assumption of a linear proportional relation between the kinematic eddy viscosity and the diffusion coefficient.

(4) The concentration profile is simulated by Murphy's diffusion equation with sediment source term, to connect a Lagrangian approach of the motion of sediment cloud with an Eulerian approach based on the diffusion equation. From the results of the simulation, the important role of the sediment cloud on the diffusion of suspended sediment over a ripples is clarified.

### ACKNOWLEDGMENT

The authors express their sincere gratitude to Messrs. Masaru Senba & Mikihiro

Watanabe (former Graduate Students, Kyoto University) for their help in the experiment.

## CHAPTER 147

# Wave Overtopping and Sediment Transport over Dunes

Mark W. Hancock<sup>1</sup> and Nobuhisa Kobayashi, M. ASCE<sup>2</sup>

### Abstract

Experiments were conducted on a sand beach to represent occurrences of minor to major dune overtopping by varying the spectral peak period of incident irregular waves. Both water overtopping and sand overwash rates were measured. The experimental results were compared to existing empirical formulas for equilibrium beach slopes (Kriebel, Kraus, and Larson, 1991), cross-shore sediment transport (Kraus and Mason, 1993), and irregular wave reflection (Seelig, 1983) from sand beaches. Scale and non-equilibrium effects were found to be important causes of discrepancies between predicted and measured values. Additionally, an empirical formula for the overtopping of coastal structures (De Waal and Van der Meer, 1992) was compared with overtopping measurements for the experimental dune. The empirical formula of De Waal and Van der Meer gave order-of-magnitude estimates, but could not account for the effects of the profile evolution within each test. The measured average volumetric sediment concentration was found to be independent of the normalized overtopping rate and varied by only a factor of two.

### Introduction

Wave overtopping of dunes and barrier islands has been investigated in the past using site-specific field data (e.g., Holland *et al.*, 1991). However, the quantitative understanding of the overwash process remains rudimentary, partly because of the difficulties associated with field measurements during storms. At present, there is no predictive method to generalize the findings of site-specific field data. A knowledge of the overwash process is necessary for establishing a realistic boundary condition for existing beach and dune erosion models. For example, the simple empirical model of Kriebel (1990) simulates only offshore transport at the crest of the remnant dune and does not simulate the landward transport of sand due to overwash. The latest version of the storm-induced beach erosion model SBEACH (Wise and Kraus, 1993) allows for the landward transport of sand due to dune overwash, but prediction is based on simple geometric arguments related to the runup exceedance of the dune and the transport magnitude at the landward

boundary of the surf zone.

## Experimental Setup and Procedures

The experiment to collect data on the overwash of a subaerial dune was conducted in the tow tank located in the basement of DuPont Hall at the University of Delaware and is detailed in Hancock (1994). The tow tank is 30 m long, 2.44 m wide and 1.5 m deep. Figure 1 shows the tank layout. Irregular waves were generated using a piston-type wave paddle. A gravel beach was located 25 m away from the paddle to absorb waves and reduce the effects of re-reflection from the paddle. A 9.7 m long divider wall was constructed 0.61 m from one of the tow tank side walls. The dune overwash experiment was conducted in the 0.61 m wide flume. Figure 2 shows a detail of the experimental setup, including wave gage placement, at the beginning of each test, where  $d_t$  = water depth below still water level (SWL) at gage 1;  $d_s$  = water depth below SWL at the toe of the dune;  $H_c$  = positive crest height of the subaerial dune above SWL;  $m$  = slope of the seaward dune face;  $d_p$  = water depth of the horizontal bottom in front of the wave paddle; and  $B_c$  = horizontal distance between the dune crest and the seaward edge of the basin used to collect the overtopped water and overwashed sand. The height of the collection basin was 53 cm and was less than  $(d_p + H_c)$ . The initial beach profile was limited to a 1:23.5 slope, corresponding to the fixed beach tests on irregular wave overtopping over a 1:2 smooth revetment conducted by Poff and Kobayashi (1993a).

Five moveable bed tests for spectral peak periods,  $T_p$ , of 1.2, 1.4, 1.6, 1.8, and 2.0 seconds were conducted to represent occurrences of minor to major dune overwash. These tests will herein be referred to as tests MH1, MH2, MH3, MH4, and MH5 to distinguish them from further tests which will be conducted using the same facilities and procedures. Each test consisted of a series of runs, where each run duration was 325 seconds. A test was terminated when it appeared that further runs would expose the collection basin wall directly to wave action. Data

Figure 1: Layout of the Tow Tank

Figure 2: Experimental Setup

from the four wave gages were recorded during every test run. At the end of each test run, the volumes of overtopped water and overwashed sand in the collection basin were measured. The total volume of water collected was found by adding the volume of water pumped out of the collection basin to the volume of water held in the pores of the overwashed sand. The overtopping rate,  $\bar{Q}_w$ , and overwash rate,  $\bar{Q}_s$ , were determined by dividing the total volume of water and the volume of sand (no voids), respectively, by the test duration and flume width.

Beach and dune profiles were taken before each test and after runs of noticeable profile change. Three cross sections along the beach were profiled. One profile was taken at a distance of 20 cm from the plywood wall, another along the center line, and the last 20 cm from the tow tank wall. The average of these three profiles was calculated and this average profile was assumed to be uniform across the flume. The initial profile of a test was taken over the entire length of the beach at intervals of 10 cm. After runs of interest, profiles were taken from the seaward edge of the collection basin to a point of no net sediment transport, which was approximately 250 cm from the basin edge. Depths were sampled at an interval of 1 cm in order to distinguish smaller bed features such as ripples created by the wave action. The cross-shore variation of the net sediment transport rate,  $\bar{q}_s$ , for each test run was calculated using the continuity equation of sediment and the measured profiles starting from the seaward location of no profile change. The value of  $\bar{q}_s$  at the landward boundary corresponds to the net sediment transport rate into the collection basin and should be equal to the average overwash rate  $\bar{Q}_s$  for the same duration calculated from the collected sand.

The sand used in this experiment was well-sorted with a median diameter,  $d_{50}$ , of 0.38 mm. The measured value for the specific gravity,  $s$ , was 2.66, which falls within the expected range for quartz sand. The measured value for sediment proposity,  $n_p$ , was 0.41, which is reasonable for beach sand. The fall velocity,  $w$ , of the sediment was measured to be 5.29 cm/sec.

The parameters specified to the wave generation program (Poff and Kobayashi, 1993b), which accounts for the effect of directional random wave refraction, were  $d_p$  = water depth below SWL at the wave maker;  $d_t$  = water depth below SWL at gage 1;  $(H_{mo})_p$  = spectral estimate of the significant wave height at the water depth  $d_p$ ;  $T_p$  = spectral peak period at the water depth  $d_p$ ;  $\gamma$  = peak enhancement

factor of the TMA spectrum at the water depth  $d_p$ ;  $s_{max}$  = maximum value of the directional spreading parameter at the water depth  $d_p$ ;  $\alpha$  = predominant incident wave direction at the water depth  $d_p$ ; and  $m_t$  = bottom slope at the water depth  $d_t$ . The input parameters used for each test are shown in Table 1.

Table 1: Wave Generation Input Parameters

<i>Test</i>	MH1	MH2	MH3	MH4	MH5
$T_p$ (sec)	1.2	1.4	1.6	1.8	2.0
$d_p$ (cm)	46.5	46.5	46.5	46	45.5
$d_t$ (cm)	44.3	43.4	44.8	43.7	43.2
$(H_{mo})_p$ (cm)	12.5				
$\gamma$	3.3				
$s_{max}$	10.0				
$\alpha$ (deg)	0.0				
$m_t$	1/23.5				

The initial dune profile geometry for each test was held as nearly constant as possible. However, some variability occurred due to the difficulties of manipulating significant quantities of sand. The still water level in each test was determined by matching the initial dune crest elevations of all the tests. The dimensions of the initial dune profiles for each test are given in Table 2 and are defined in Figure 2.

Table 2: Initial Dune Profile Geometry

<i>Test</i>	MH1	MH2	MH3	MH4	MH5
$d_s$ (cm)	19.0	18.5	20.0	18.5	18.0
$H_c$ (cm)	12.9	12.3	12.5	12.5	12.3
$m$	3.32	3.32	3.27	3.45	3.26
$B_c$ (cm)	40.0				

## Experimental Results

The measured time series and spectra of the incident and reflected waves varied very little from one test run to another. This implies that the incident and reflected waves were almost unaffected by the beach profile changes during each test. The mean of the measured spectral estimates of the significant wave height was 12.47 cm, which is nearly identical to the  $H_{mo}$  value of 12.5 cm specified to the wavemaker. The standard deviation of the measured  $H_{mo}$  values was 0.26 cm. The spectral peakedness parameter,  $Q_p$ , decreased with increased spectral peak period,  $T_p$ .  $Q_p$  ranged from a mean value of 5.4 in test MH1 with  $T_p = 1.2$  sec, to

a mean value of 3.1 in test MH5 with  $T_p = 2.0$  sec. Similarly, the spectral correlated parameter,  $\kappa$ , decreased with increased  $T_p$ , with a high mean value of 0.64 for test MH1 and a low mean value of 0.41 for test MH5. The average run length,  $\bar{j}$ , remained relatively constant throughout the experiment, with  $1.30 \leq \bar{j} \leq 1.87$ .

In general, the reflection coefficient,  $\bar{r}$ , tended to increase slightly with increasing spectral peak period. Within each test, the trend was that the measured value for  $\bar{r}$  decreased as the overtopping rate,  $\bar{Q}$ , increased. The values of  $\bar{r}$  ranged from 0.195 to 0.305. The values of  $\bar{Q}$  approximately doubled from test to test as  $T_p$  was increased by 0.2 sec. In each test,  $\bar{Q}$  increased during the initial runs before becoming a nearly constant value for the remainder of the runs, as can be seen in Figures 3 and 4. The normalized overtopping rates,  $\bar{Q}/(H_s\sqrt{gH_s})$  with  $H_s =$  significant wave height, ranged from 0.0 in run 1 of test MH1 to 0.00625 in run 4 of test MH5. Unlike the average overtopping rate, the measured average overwash rate trend varied significantly between tests. In test MH1,  $\bar{Q}_s$  increased during the initial runs before assuming a constant value over the final runs, as shown in Figure 3. Test MH2 displayed a similar trend in the initial runs, but after obtaining a peak value in run 3,  $\bar{Q}_s$  decreased appreciably before maintaining a nearly steady value. In tests MH3, MH4, and MH5, the value of  $\bar{Q}_s$  was relatively high in the first run, peaked in the second run, and then decreased with each remaining run. This trend is shown in Figure 4. The measured values of  $\bar{Q}_s/(wd_{50})$  ranged from 0.0 in run 1 of test MH1 to 1.82 in run 2 of test MH5. The qualitative and quantitative trends of the average sediment concentration in volume were similar for each test. The calculated values for  $\bar{Q}_s/\bar{Q}$  tended to decrease as each test progressed, with the exception of test MH1, and ranged from 0.023 to 0.056.

The parameters used to describe the dune profile evolution were selected following the examples of the equilibrium beach profile presented by Kriebel, Kraus, and Larson (1991) and the equivalent slope for a coastal structure with a berm presented by De Waal and Van der Meer (1992). Many of the profile parameters

Figure 3: Overtopping Rate,  $\bar{Q}$ , (Top) and Overwash Rate,  $\bar{Q}_s$ , (Bottom) for MH1 with  $T_p = 1.2$  sec.

Figure 4: Overtopping Rate,  $\bar{Q}$ , (Top) and Overwash Rate,  $\bar{Q}_s$ , (Bottom) for MH5 with  $T_p = 2.0$  sec.

are defined in Figure 5 where  $x$  = positive-seaward horizontal coordinate with an origin where the still water level (SWL) intersects the beach;  $d_s$  = depth relative to SWL below which there is effectively no profile change;  $H_s$  = depth below SWL equal to the average significant wave height between two measured profiles;  $B_s$  = horizontal distance from the dune crest to the depth  $H_s$ ;  $h$  = depth below SWL at a distance  $x$  seaward of the origin of the horizontal coordinate;  $H_c$  = dune crest height above SWL;  $m$  = fitted slope of the dune face from the crest to a point slightly below SWL; and  $B_c$  = horizontal distance from the dune crest to the edge of the collection basin. The concept of an equilibrium profile of the form  $h = Ax^{2/3}$  was introduced by Bruun (1954), where  $h$  is the depth at a distance  $x$  offshore from the still water shoreline and  $A$  is the profile scale factor. For this analysis,  $A$  was found by fitting the two-thirds power profile to each measured profile. An additional parameter examined was the equivalent beach slope for wave runup and overtopping,  $m_e$ , expressed as

$$m_e = \frac{H_s + H_c}{B_s} \quad (1)$$

The dune profile evolutions for tests MH1 and MH5 are shown in Figures 6 and 7. For all of the test runs,  $d_s$  was greater than  $H_s$ , probably because these tests corresponded to a high dune and a large storm surge. Also, the crest height was always greater than  $(53 - d_p)$  cm, which is the height of the collection basin above SWL. In each test, the fitted dune face slope and equivalent beach slope decreased as the profiles evolved. The range of  $m$  was 0.23-0.31 and the range of  $m_e$  was 0.11-0.30. The measured  $B_s$  values increased as the toe of the evolving beach advanced seaward and  $B_c$  went to zero. The initial value for  $B_s$  was about 84 cm in each test and the final values ranged from 173 cm in test MH1 to 119 cm in test MH5. In general, the steep dune was transformed to a more gentle beach by the waves. The fitted values of  $A$  ranged from 0.9 to 1.2 cm<sup>1/3</sup> and decreased slightly as the tests with shorter spectral peak periods, and correspondingly longer durations, progressed. Kriebel, Kraus, and Larson *et al.* (1991) used field data

Figure 5: Definition Sketch for Profile Parameters

to obtain the following equation for the equilibrium value of  $A$ :

$$A \approx 2.25 \left( \frac{w^2}{g} \right)^{1/3} \tag{2}$$

where  $w$  is the sediment fall velocity and  $g$  is gravitational acceleration. Equation 2 is applicable for a water temperature of approximately 20° C and  $1 \leq w \leq 10$  cm/sec. The measured  $w$  of the sand used in this experiment was 5.29 cm/sec, which yields  $A = 0.69 \text{ cm}^{1/3}$  for an equilibrium profile. This  $A$  value is significantly less than the fitted  $A = 0.9\text{-}1.2 \text{ cm}^{1/3}$  values, probably because the measured profiles were not in equilibrium and the experiment was a small-scale test.

Figure 6: Dune Profile Evolution with Initial Profile (—●—) and Profiles after Run 1 (---), Run 3 (—), Run 6 (---), and Run 10 (-.-) for MH1 with  $T_p = 1.2$  sec.

Figure 7: Dune Profile Evolution with Initial Profile (—●—) and Profiles after Run 1 (— — —), Run 2 (— — —), Run 3 (— — —), Run 4 (— · —), and Run 5 (· · · ·) for MH5 with  $T_p = 2.0$  sec.

The calculated net cross-shore sediment transport rates,  $\bar{q}_s$ , which is positive onshore, as a function of the distance from the collection basin for run 1 of tests MH1, MH3, and MH5 are shown in Figure 8. It is apparent from the figure that there was an appreciable seaward transport of sand at the base of the dune during the first run of each test. The magnitude of this seaward transport decreased with increased  $T_p$ . The landward transport of sand observable at the dune crest was increased in the tests with larger  $T_p$ . In all of the tests, the amplitude of

Figure 8: Average Cross-Shore Sediment Transport Rates During the First Run of a) Test MH1, b) Test MH3, and c) Test MH5.

Figure 9: Gage 4 Time Series for a) Test MH1, b) Test MH2, and c) Test MH3.

$\bar{q}_s$  between two measured profiles was appreciably smaller after the initial run. The landward transport of sand dominated after the initial run in tests MH4 and MH5.

The time series recorded by gage 4 for the first three runs of tests MH1, MH3, and MH5 are shown in Figure 9. During these early runs, it is easy to distinguish a defined baseline between overtopping events. This baseline corresponds to the time-dependent dune crest elevation relative to the initial dune elevation. In test MH1, essentially no overtopping occurred during the first 400 sec of the test. This period of limited overtopping is shorter in test MH3 and non-existent in test MH5. Once large overtopping events occurred on a regular basis, the sand elevation at gage 4 began to decrease approximately linearly with time. The location of the baseline at the end of three runs in each test demonstrates the increased erosion at the location of gage 4 as  $T_p$  increased.

## Analyses of Experimental Results

### Beach Slope

Kriebel, Kraus, and Larson (1991) reanalyzed the field data of Sunamura (1984) in terms of the sediment fall velocity,  $w$ , and proposed the following expression for the equilibrium foreshore slope,  $m$ :

$$m = 0.15 \left( \frac{wT}{H} \right)^{1/2} \quad (3)$$

Kriebel (1990) suggested that the root-mean-square wave height,  $H_{rms}$ , at breaking be used for  $H$  in Equation 3 since Sunamura did not specify this quantity for random waves. For the present analysis, the wave period  $T$  was taken to be the significant wave period,  $T_s$ .

Although the measured slopes tended to decrease as each test progressed, as already discussed, the empirical  $m$  values determined using Equation 3 remained nearly constant, with  $0.13 \leq m \leq 0.15$ , and significantly underpredicted the beach slope. Kriebel, Kraus, and Larson (1991) remarked that their analysis of field data

gave much smaller beach slopes for given  $H/(wT)$  than those observed during the small-scale tests of Dalrymple and Thompson (1976). Additionally, the empirical  $m$  values are based on an equilibrium profile. Neither the stage of the profile evolution nor memory effects can be incorporated in the parameter  $(wT_s)/H_{rms}$ . Therefore, the empirical formula presented by Kriebel, Kraus, and Larson (1991) is too simplistic to incorporate the scale and non-equilibrium profile effects of the beach evolution in this experiment.

### Cross-Shore Sediment Transport

Using field data, Kraus and Mason (1993) extended the profile parameter,  $\mathbf{P}_s$ , developed by Dalrymple (1992) to irregular waves:

$$\mathbf{P}_s = \frac{gH_{os}^2}{w^3T_p} = 26,500 \quad (4)$$

where  $H_{os}$  is the deep-water significant wave height and  $T_p$  is the spectral peak period. Offshore sediment transport was observed to occur for  $\mathbf{P}_s$  values significantly greater than 26,500.

The values of  $\mathbf{P}_s$  measured in the present experiment ranged from a high average value of 939 in test MH1 to a low average value of 553 in Test MH5. Because  $\mathbf{P}_s$  is inversely proportional to the spectral peak wave period, the onshore transport of sediment is expected to increase as  $T_p$  increases. This prediction is proven correct by Figure 8. All of the calculated  $\mathbf{P}_s$  were much less than the threshold value of  $\mathbf{P}_s = 26,500$  determined by Kraus and Mason. This would seem to indicate exclusively onshore transport of sand in this experiment. However, both onshore and offshore sediment transport are observable in Figure 8. In particular, significant bar formation occurred in test MH1 as evidenced in Figure 6. It is uncertain whether overwash occurred in the field measurements of Kraus and Mason, but it is expected that overwash would act to increase the landward transport of sand. Equation 4 does not include the slope effect on the direction of net sediment transport. Therefore, the probable reasons that offshore sediment transport occurred despite the small  $\mathbf{P}_s$  values are that this experiment was a small-scale test and that the initial foreshore slopes were rather steep.

### Irregular Wave Reflection

Seelig (1983) proposed that the average reflection coefficient,  $\bar{r}$ , for irregular waves could be expressed as

$$\bar{r} = \frac{\alpha\xi_p^2}{\xi_p^2 + \beta} \quad (5)$$

where  $\xi_p$  is the irregular wave surf similarity parameter defined as

$$\xi_p = \frac{m_i}{\sqrt{\frac{2\pi H_s}{gT_p^2}}} \quad (6)$$

with beach slope  $m_i$  at the still water intercept, significant wave height  $H_s$ , and spectral peak period  $T_p$ . Seelig recommended that for smooth slopes  $\alpha = 1.0$  and  $\beta = 5.5$ .

Figure 10 is a plot of the measured reflection coefficients of each test versus the irregular wave surf similarity parameter values found from the measured  $T_p$  and

$H_s$ . Three lines corresponding to  $\alpha = 0.65$ ,  $\alpha = 0.85$ , and  $\alpha = 1.05$  in Equation 5 are plotted in the top portion for comparison. Using  $\alpha = 1.0$  appears to be a reasonable value to conservatively estimate  $\bar{r}$ . The bottom portion of Figure 10 shows a linear least-squares fit of the data. The formula for this fit is

$$\bar{r} = 0.106 \xi_p + 0.075 \quad \text{for } 1.10 \leq \xi_p \leq 2.01 \quad (7)$$

The data points display low scatter, with a standard deviation of 0.03.

Figure 10: Reflection Coefficient,  $\bar{r}$ , versus Irregular Wave Surf Similarity Parameter,  $\xi_p$ , for Tests MH1 ( $\bullet$ ), MH2 ( $*$ ), MH3 ( $\odot$ ), MH4 ( $\square$ ), and MH5 ( $\otimes$ ). Top Plot includes the Empirical Formula of Seelig (1983) for  $\alpha = 0.65$  (—),  $\alpha = 0.85$  (---), and  $\alpha = 1.05$  (-.-). Bottom Plot includes Least-Squares Data Fit (—).

### Irregular Wave Overtopping

The empirical formulas of De Waal and Van der Meer (1992) for the prediction of irregular wave runup and overtopping on coastal structures were compared to experimental results for dune overtopping. Since De Waal and Van der Meer did not have beach test data, their formulas are examined in the context of their applicability to the dune overtopping experiment. Their formula for predicting the 2%-runup,  $R_2$ , which corresponds to the runup with an exceedance probability of 2%, is

$$\frac{R_2}{H_s} = 1.5 \gamma_f \gamma_h \gamma_\beta \xi_{p,eq} \leq 3.0 \gamma_f \gamma_h \gamma_\beta \quad (8)$$

where  $\xi_{p,eq}$  is a breaking parameter based on an equivalent slope and modified by the influence factors  $\gamma_f$  for roughness effects,  $\gamma_h$  for shallow water effects, and  $\gamma_\beta$  for oblique wave attack effects. Since the present experiment involves only normally incident waves,  $\gamma_\beta = 1.0$ . Also,  $\gamma_f$  is assumed to be approximately 1.0 since a sand beach may be treated as a smooth slope.

The form of  $\gamma_h$  suggested by De Waal and Van der Meer, and modified here for application to dunes, is

$$\gamma_h = \begin{cases} 1 - 0.03 \left(4 - \frac{d_s}{H_s}\right)^2 & \text{for } 1 \leq \frac{d_s}{H_s} \leq 4 \\ 1 & \text{for } \frac{d_s}{H_s} \geq 4 \end{cases} \quad (9)$$

where  $d_s$  is the water depth at the toe of the dune as shown in Figure 5. They suggested an expression for  $\xi_{p,eq}$  including berm effects, but for the present analysis it is assumed that  $\xi_{p,eq} = \xi_e$ , where

$$\xi_e = m_e T_p \sqrt{\frac{g}{2\pi H_s}} \quad (10)$$

with  $m_e$  = equivalent slope as defined in Equation 1. Equation 10 implies that wave runup is affected by the beach profile from the water depth  $H_s$  to the dune crest height,  $H_c$ , as shown in Figure 5. The simplified form of the normalized 2%-runup used in the dune analysis is, therefore,

$$\frac{R_2}{H_s} = 1.5 \gamma_h \xi_e \leq 3.0 \gamma_h \quad (11)$$

De Waal and Van der Meer proposed that the mean overtopping rate,  $\bar{Q}$ , was related to a "shortage in crest height",  $R_* = (R_2 - H_c)/H_s$ . By fitting about 500 data points from various overtopping tests, they came up with the following expression for the normalized overtopping rate,  $Q_*$ :

$$Q_* = \frac{\bar{Q}}{\sqrt{gH_s^3}} = 8 \times 10^{-5} \exp(3.1 R_*) \quad (12)$$

They observed a large data scatter, so that Equation 12 should be considered an order-of-magnitude estimate only.

The influence of the shallow water effects remained nearly constant throughout the present experiment with an average value of 0.82. However, the breaking parameter,  $\xi_e$  decreased as each test progressed and tended to increase with  $T_p$ , as is expected from Equation 10. The measured range of  $\xi_e$  was 0.48-1.77. The values of  $R_2/H_s$  and  $R_*$  followed the same qualitative trend as  $\xi_e$ , with  $0.60 \leq R_2/H_s \leq 2.11$  and  $-0.02 \leq R_* \leq 1.25$ . The predicted decrease of  $R_2/H_s$  due to the decrease of  $m_e$  is greater than the measured decrease of the normalized crest height  $H_c/H_s$ . As a result, the predicted  $Q_*$  decreased as each test progressed and ranged from 0.7 to 38.7. However, as shown in Figures 3 and 4, the measured average overtopping rates increased in the early runs before becoming nearly constant. The equivalent slope,  $m_e$ , for dunes and coastal structures appears to be different in light of the opposite trend. A plot of the measured ( $\ln Q_*$ ) versus  $R_*$  is shown in Figure 11. For comparison, Equation 12 is plotted in the top portion of Figure 11. It is apparent that the formula of De Waal and Van der Meer significantly underpredicts the dune overtopping rate in all but the first runs of the tests. However, the predicted values are within an order of magnitude of the measured results. A linear regression analysis of the data is shown in the bottom portion of Figure 11 and yields

$$Q_* = 3.35 \times 10^{-4} \exp(2.82 R_*) \quad \text{for } -0.02 \leq R_* \leq 1.25 \quad (13)$$

The slope of the fitted line is very close to that found from Equation 12 indicating a similar data trend, but the magnitude of  $Q_*$  found from Equation 13 is about four times greater. Bounding lines plotted for  $(2.0 \times Q_*)$  and  $(0.5 \times Q_*)$  show that there is a data scatter of a factor of about 2. Although the tests tend to fall along the fitted line, it is apparent that there are data trends within each test. Therefore, the stage of the dune profile evolution is an important factor that can not be accounted for in Equations 12 and 13.

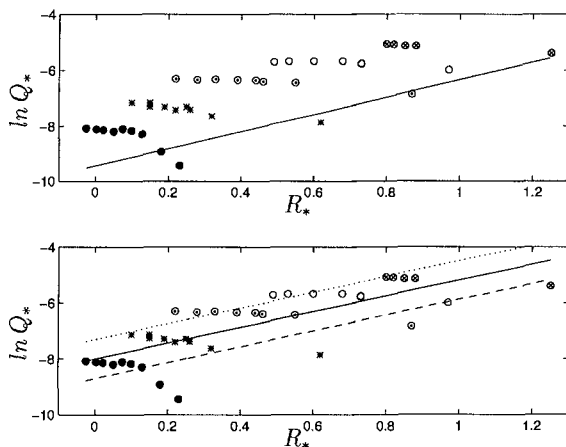

Figure 11: Natural Log of the Non-dimensional Overtopping Rate,  $Q_*$ , versus Non-dimensional 2% Runup Exceedance,  $R_*$ , of Tests MH1 ( $\bullet$ ), MH2 ( $*$ ), MH3 ( $\odot$ ), MH4 ( $\circ$ ), and MH5 ( $\otimes$ ). Top Plot includes the Empirical Formula of De Waal and Van der Meer (1992) (—). The Bottom Plot includes a Least-Squares Data Fit  $\ln(Q_*)$  (—),  $\ln(2Q_*)$  ( $\cdots$ ), and  $\ln(0.5Q_*)$  ( $---$ ).

### Irregular Wave Overwash

The average volumetric sediment concentration,  $\overline{C}_s$ , is defined as

$$\overline{C}_s \equiv \frac{\overline{Q}_s}{\overline{Q}} \quad (14)$$

which is the ratio of the sediment (no voids) overwash rate,  $\overline{Q}_s$ , to the water overtopping rate,  $\overline{Q}$ . Figure 12 shows a plot of  $\overline{C}_s$  versus  $Q_*$ . It is apparent that no relationship exists between the two parameters in this experiment. The value of  $\overline{C}_s$  did tend to decrease as the profile evolved in all of the tests except test MH1. Nevertheless, the range of  $\overline{C}_s = 0.023$ - $0.056$  is surprisingly narrow in this experiment. Therefore, if  $\overline{C}_s$  remains approximately constant,  $\overline{Q}_s$  can be predicted for estimated  $\overline{Q}$ .

Figure 12: Average Volumetric Sediment Concentration,  $\overline{C}_s$ , versus Non-dimensional Overtopping Rate,  $Q_*$ , in Tests MH1 (●), MH2 (\*), MH3 (○), MH4 (○), and MH5 (⊗)

## Conclusions

A range of minor to major occurrences of overtopping was produced in the laboratory by increasing the spectral peak period of incident waves. Both overtopping and overwash rates were measured. Scale and non-equilibrium profile effects were found to be important factors in causing discrepancies between predicted and measured beach slopes. Scale effects and initially steep dune slopes appear to have increased the offshore transport of sediment. A linear relation between the irregular wave surf similarity parameter and the average reflection coefficient was shown to be adequate for this experimental range. The empirical formula of De Waal and Van der Meer (1992) for coastal structures gave order-of-magnitude estimates of the overtopping rate but could not account for variations due to the dune profile evolution. The experimental sediment concentration was found to be independent of the normalized overtopping rate and varied by only a factor of two in the range of 0.023-0.056. This implies that a reasonable estimate of the overwash rate may be easily determined from an accurate prediction of the overtopping rate. The proposed empirical formulas for irregular wave reflection and overtopping rate will need to be verified using large-scale experiments.

## CHAPTER 148

### SEDIMENT TRANSPORT OVER RIPPLES IN WAVES AND CURRENT

G. Perrier<sup>1-3</sup>, E.A. Hansen<sup>2</sup>, C. Villaret<sup>3</sup>, R. Deigaard<sup>1</sup> and J. Fredsøe<sup>1</sup>

#### ABSTRACT

Numerical simulations are presented for the flow and the dynamics of non-cohesive sediment over 2D ripples in waves and current. For this purpose, a model based on a discrete vortex approach using the "cloud-in-cell" concept has been applied. The hydrodynamic model drives a Lagrangian model for the suspended sediment.

The characteristic vorticity structures prevailing in the vicinity of ripples are accurately replicated and sediment suspension mechanisms are successfully described. Thus, the sediment transport resulting from asymmetrical waves and combined waves and current can be predicted. Especially, the wave-related component of the transport opposes the maximum free stream velocity and contributes significantly to the total transport. In the present work, the effect of the wave-induced drift is not included.

#### INTRODUCTION

A detailed understanding of flow kinematics and suspension mechanisms of non-cohesive sediments in waves and current situations is of great interest to coastal engineers because of its importance in sediment transport predictions.

When the seabed is plane, the suspension of sediment is governed by turbulent diffusion. But when ripples occur on the bed, the prevailing process becomes convection. At each half-cycle of the oscillation, coherent vorticity structures are formed in the lee side of the ripple and trap sediment. At flow reversal, these sediment laden vortices are shed into the flow, thus giving rise to suspension.

In the field of non breaking regular waves, experimental investigations have been conducted for flows over 2D ripples (Sato *et al.*, 1984; Ranasoma and Sleath, 1992). In connection with the hydrodynamics, experimenters have studied sediment dynamics (Sleath, 1982). For asymmetrical waves, few experiments exist (Sato and Horikawa, 1986). For combined waves and current flows, whereas comprehensive experiments over flat beds are rather numerous, fewer are available for rippled beds (Murray, 1992; Villaret and Latteux, 1992).

<sup>1</sup>) ISVA, Building 115, Technical University of Denmark, DK 2800 Lyngby, Denmark

<sup>2</sup>) Danish Hydraulic Institute, Agern Allé 5, DK 2970 Hørsholm, Denmark

<sup>3</sup>) Laboratoire National d'Hydraulique, 6 Quai Watier 78401 Chatou, France

To model the flow over ripples, different methods have been developed : vorticity-stream function formulation with finite difference and spectral methods (Blondeaux and Vittori, 1990), classical turbulence models : K- $\epsilon$  (Tsujiimoto *et al*, 1991), or K-L (Huynh Thanh, 1990), and discrete vortex methods by Longuet-Higgins (1981), Block (1994) and Hansen *et al* (1994).

To model sediment suspension, the common approach is based on the turbulent diffusion equation where the sediment diffusivity relies on various assumptions (Fredsoe and Deigaard, 1992). Nevertheless, in the case of rippled beds, convection becomes the prevailing process. The diffusion assumption has been used by Tsujimoto (1991) coupled with his K- $\epsilon$  model, but most of the other models are based on a Lagrangian particle tracking (Blondeaux and Vittori, 1990; Block, 1994; Hansen *et al*, 1994).

In this study, a discrete vortex approach is adopted to achieve a 2D model for the flow, the sediment suspension mechanisms and the resulting net transport. After a brief presentation of the model, hydrodynamic calculations are performed for an oscillatory flow over fixed ripples. Then, the complete model is used to study the asymmetrical wave case and the combined sine waves and current case. Experimental conditions are listed in appendix.

## PRESENTATION OF THE DISCRETE VORTEX MODEL

The discrete vortex model (DVM) developed by ISVA-DHI is designed to compute complex instationary flows interacting with structures or stationary seabeds. The model relies on a discretization of vorticity in "vortices" and concentration in "particles" combined with a finite difference method. A detailed description is presented in Hansen *et al* (1994).

### The hydrodynamical model.

The model is based on a vorticity-stream function formulation:

$$\text{Poisson equation :} \quad \nabla^2 \psi = -\omega \quad [1]$$

$$\text{Vorticity transport equation :} \quad \frac{d\omega}{dt} = \nu \nabla^2 \omega \quad [2]$$

( $\psi$  is the stream function,  $\omega$  the vorticity and  $\nu$  the kinematic viscosity).

Using an operator splitting method, the vorticity transport equation [2] is split into :

$$\text{a convection equation :} \quad \frac{\partial \omega}{\partial t} + u \frac{\partial \omega}{\partial x} + v \frac{\partial \omega}{\partial y} = 0 \quad [3]$$

$$\text{and a diffusion equation :} \quad \frac{\partial \omega}{\partial t} = \nu \nabla^2 \omega \quad [4]$$

The convective transport is then modelled by moving the individual vortices with the velocity field ( $u, v$ ), while the diffusive transport is described by adopting a random walk technique : at each time step  $\Delta t$ , vortices are moved with a random displacement following a Gaussian distribution characterised by the standard deviation :

$$\sigma = \sqrt{2\nu \Delta t} \quad [5]$$

The Poisson equation [1] is solved on a curvilinear finite difference grid by an Alternative Direction Implicit method. The grid is generated from a solution to the Laplace equation describing a periodic potential flow over ripples.

*Cloud-in-cell technique.*

To obtain the vorticity field from the set of vortices, a cloud-in-cell technique is used to distribute the circulation of the vortices in each cell as vorticity on the four grid points at the cell corners.

*Boundary layer model at the surface.*

Vorticity can only be generated by shear forces acting on physical surfaces. On these boundaries, a turbulent boundary layer model based on the integrated momentum equation (Fredsoe, 1984) gives the time development of the boundary layer and hence, determine the strength and the motion of vortices within this zone.

*Merging method.*

To limit the growth of the number of vortices and to get a feasible calculation, a merging procedure is introduced : when two vortices with opposite signs come closer to each other than the sum of their radii, they combined into one single vortex.

*Computational domain and boundary conditions.*

In the computations, the bed is assumed stationary and a time-independent domain is used. In most of the presented simulations, the horizontal length of the domain is two ripple lengths. Vertically, various discretizations have been used. For the wave-alone case, where the vorticity is confined in the near-bed layer, a stretched net is adopted, with a height chosen so that vortices do not reach the top boundary. In the wave-current case, the boundary layer develops over the entire depth. As non-physical boundaries are difficult to represent in this kind of model, a symmetrical domain with ripples at the top has been chosen in order to satisfy the symmetry condition on the center line. In some facilities such as shallow tunnels, a real domain covering the entire depth can be used.

No-slip conditions are applied on physical boundaries while a simple stream line condition ( $\psi = \text{constant}$ ) is used at the top for the wave-alone case. To drive the flow, the time-dependent water discharge is imposed via the stream function. Besides, spatial periodicity between the two lateral boundaries is prescribed.

**The sediment transport model.**

The total sediment transport is divided into two contributions : bed load and suspended load. In the present model, it is assumed that the ripple shape is stationary and that the presence of suspended sediment does not affect the hydrodynamics. The two components of the sediment transport are modelled as follows.

\* The bed load transport rate  $Q_b$  along the ripple is modelled with the Meyer-Peter and Müller formula corrected for the slope effect :

$$\frac{Q_b}{\sqrt{(s-1)gd_{50}^3}} = 8 \left[ \theta - \theta_c \left( 1 + \frac{1}{\tan \varphi} \frac{dy_b}{dx_b} \right) \right]^{3/2} \quad [6]$$

where  $\theta$  is the local instantaneous Shields parameter,  $\theta_c$  the critical Shields parameter,  $s$  the relative density of the sediment,  $g$  the gravity,  $\varphi$  the angle of repose of the sediment,  $d_{50}$  the mean grain diameter and  $(x_b, y_b)$  are the bed coordinates.

\* The suspended sediment is discretized in computational "particles" containing a certain amount of sediment. They are characterised by their mass and their fall velocity.

The generation of these particles at the ripple surface involves two different mechanisms :

- The action of shear stresses on the bed produces a local erosion and thus creates new suspended particles. To model this, a source of sediment is located at the level  $y^*_o=2d_{50}$  ( $y^*$  is the coordinate normal to the ripple surface). Its strength  $Q_d$  is determined as a source term in the local turbulent diffusion equation in order to satisfy the bed-concentration formula of Zyserman and Fredsøe (1994) :

$$c_b(y^*_o=2d_{50}) = \frac{0.331 (\theta-0.045)^{1.75}}{1 + \frac{0.331}{0.46} (\theta-0.045)^{1.75}} \quad [7]$$

The mass of the particles is then derived from  $Q_d$ . To account for the grain sorting effect, the settling velocity is based on the mean grain diameter of the suspended fraction  $d_{50,susp}$ , fraction defined as sediment with a settling velocity  $w_s < 0.8 u_f$  where  $u_f$  is a characteristic friction velocity at the crest.

- Due to the recirculation zone downstream of the crest, the bed load is ejected into the flow at the separation point as described by Sleath (1982). This contribution is modelled by calculating  $Q_b$  at the location of maximum Shields parameter upstream of the separation. Then, a new particle is introduced just above the separation point with a mass derived from  $Q_b$  and a fall velocity based on the mean grain diameter of the bed material  $d_{50}$ .

Similarly to the hydrodynamic model, the continuity equation for the suspended sediment concentration [8] is tackled in a Lagrangian fashion.

$$\frac{dc}{dt} = w_s \frac{\partial c}{\partial y} + \nabla \cdot (\epsilon_s \nabla c) \quad [8]$$

where  $c$  is the concentration,  $w_s$  the settling velocity and  $\epsilon_s$  the sediment diffusivity. The motion of the sediment suspended over vortex ripples is dominated by convection except in the boundary layer along the ripple surface where the turbulent diffusion becomes important. Therefore, sediment particles are assumed to follow the flow paths with a fall component.

Inside the boundary layer, the motion normal to the ripple surface due to turbulent diffusion is modelled by a random walk method in the same manner as for the vorticity. Here, the standard deviation is :

$$\sigma_s = \sqrt{2\epsilon_s \Delta t_s} \quad [9]$$

where the sediment diffusivity  $\epsilon_s$  is assumed to be equal to the eddy viscosity  $\nu_t$  which has a linear variation within the boundary layer :

$$\epsilon_s = \nu_t = \kappa u_f y^* \quad [10]$$

where  $u_f$  is the local instantaneous friction velocity given by the boundary layer model,  $\kappa$  is the Von Karman's constant and  $\Delta t_s$  is the time step for sediment typically much smaller than the hydrodynamical time step  $\Delta t$ .

### Discretization parameters.

The computational grid presents 50 potential lines along a ripple length. The hydrodynamical time step is  $T/360$  (where  $T$  is the wave period) and the sediment time step is  $\Delta t_s = \Delta t/10$ . Numerical independence of the solution has been tested.

## Results processing.

After a transient regime of at least 20 cycles, any variable  $z(x,y,t)$  is decomposed into a mean (time-averaged) component  $Z$ , a periodic (phase-averaged) component  $z_w$  and a fluctuating component  $z'$ . Averaging is performed over at least 20 cycles :

$$z(x,y,t)=Z(x,y)+z_w(x,y,t)+z'(x,y,t) \quad [11]$$

Variables are then spatially averaged along horizontal lines with at least 50 points per ripple wave length. In the following angle brackets will denote space-averaged and an overbar or a capital time-averaged.

Assuming turbulent fluxes to remain small, the time and space averaged horizontal flux of suspended sediment,  $F_s = \overline{\langle u(x,y,t)c(x,y,t) \rangle}$  is found to be made of two components :

$$F_s = F_c + F_w \quad [12]$$

where  $F_c = \langle U(x,y) \rangle \langle C(x,y) \rangle$ , the current flux, represents the advection of the mean concentration by the mean velocity and  $F_w$ , the wave flux comes out from the non-zero covariance between periodic components  $u_w$  and  $c_w$ . The model provides  $F_s$  and  $F_c$ ,  $F_w$  is then obtained by subtraction.

To compute total suspended transport rates, two different methods can be used :

- Eulerian method : depth-integration of the fluxes profiles gives the transport rate  $Q_s$  and its two components  $Q_c$  and  $Q_w$ . This method is the one utilised in experiments. Particular attention must be paid to the lower integration limit and the large gradients in the near-bed region.

- Lagrangian method : the transport rate  $Q_s$  is directly computed from each "particle" contribution.

The total transport rate  $Q_t$  is the sum of the transport rate for the bed load and the transport rate for the suspended load calculated with the Lagrangian method :

$$Q_t = Q_b + Q_s \quad [13]$$

In the model, all the variables are made non-dimensional with the length scale  $L_r$  and the time scale  $L_r/U_w$  (where  $L_r$  is the ripple length and  $U_w$  the wave velocity amplitude). At the crest location  $x=0$  and at mid ripple height  $y=0$  whereas  $y_c$  denotes the vertical coordinate relative to the crest level. The positive direction ( $x>0$ ) will refer as the direction of maximum free stream velocity. As only phase-averaged and time-averaged results will be presented throughout the paper, the notation  $z$  will be used for  $Z+z_w$ .

## HYDRODYNAMIC COMPARISON

Detailed LDA velocity measurements were carried out by Ranasoma (92) over stabilised ripples fixed on a rig oscillating in a closed tank. The experiment covered various combinations of beds and oscillations. In the following, a comparison is presented for the selected test 2a with ripples in equilibrium with the flow. The ratio between wave orbital amplitude and ripple wave length  $a/L_r=0.78$  is in the range of vortex ripples, or orbital ripples as classified by Wiberg and Harris (1994). The simulated ripple shape is averaged from the measured bed profile. The initial time corresponds to maximum negative free stream velocity  $U_\infty$  relative to the bed as illustrated on figure 1.

Fig. 1. Free stream velocity history.  
Experiment of Ranasoma (1992).

The agreement between computed and measured vorticity fields at two "key" phases demonstrates the ability of the hydrodynamic model to reproduce the important flow features. The vortex formation is well predicted (intensity, size and core location) whereas small differences appear before flow reversal : in the calculation, the core of the vortex appears closer to the crest and its spatial extent is larger. The convection and the decay of the ejected vortex agree with measurements, its location after one half-cycle is only slightly higher in the calculation : fig (2.1) shows the vortex shed one half-cycle before from the neighbouring ripple which is about to pass over the crest.

2.1. Phase=7°

2.2. Phase=64°

Computed

Measured

Fig. 2. Non-dimensional vorticity field at 2 phases.  
Experiment of Ranasoma (1992).

The time-evolution of the space-averaged horizontal defect velocity (velocity relative to the free stream)  $\langle u_d(x,y,t) \rangle = \langle u(x,y,t) \rangle - U_\infty(t)$  and momentum  $\langle u(x,y,t)v(x,y,t) \rangle$  is plotted on figure 3. The velocity amplitude is in good agreement close to the bottom ( $y_c=1\text{mm}$ ) but the simulation assesses a slower decay with elevation, which is consistent with the higher location of vortices. There is a phase shift between computed and measured profiles close to the bottom ( $y_c=1\text{mm}$ ) for velocity extrema. This is associated with the location of the vortex core closer to the crest in the simulation resulting in a slightly earlier "sweep" on the bed. The momentum curves exhibit three peaks per half-cycle, each peak connected to a particular flow structure as described by Ranasoma (1992) :

- Peak (1) : the vortex sweep close to flow reversal throws upwards accelerated fluid from the crest and brings down still fluid above the trough.
  - Peak (2) : the vortex is now located in the trough. Its circulation carries up slow-moving fluid above the trough and brings down fast-moving fluid above the crest.
  - Peak (3) : the vortex has arrived above the crest of the neighbouring ripple. The combined effects of the vortex circulation, the local spatial acceleration at the crest and the separation zone in formation bring up more positive momentum from the crest than bring down negative momentum above the trough.
- The model fits well the general peak structure. The only significant discrepancies are observed for the peak (1) : it occurs slightly later in the simulation the amplitude is relatively larger.

Computed Measured  
 Fig. 3.1. Space averaged non-dimensional defect horizontal velocity.  
 (solid :  $y_c=1\text{mm}$ ; dashed :  $y_c=9\text{mm}$ ; dotted :  $y_c=20\text{mm}$ ). Experiment of Ranasoma (1992).

Computed Measured  
 Fig. 3.2. Space averaged non-dimensional momentum.  
 (solid :  $y_c=4\text{mm}$ ; dashed :  $y_c=9\text{mm}$ ; dotted :  $y_c=20\text{mm}$ ). Experiment of Ranasoma (1992).

The hydrodynamical model appears to be in very good agreement with the experiment. The slight differences are not significant.

**SEDIMENT TRANSPORT IN ASYMMETRICAL WAVES**

A series of experiments in a water tunnel with a sandy bed under asymmetrical Stokes and cnoidal wave conditions have been carried out by Sato and Horikawa (1986).

In the following, the simulation of the selected test C2-12 is presented. In this test, the driving free stream velocity signal (Fig. 4) is based on a third-order cnoidal wave with an asymmetry parameter  $U_w/\dot{U}=0.72$  and a zero time-averaged value. The ratio  $a/L_r=1.3$  and the measured ripple is  $2D$  with an asymmetry parameter  $L_u/L_r=0.65$ . The simulated ripple is "smoothed parabolic" : parabolically shaped troughs with a crest smoothed over 10 % (Fig. 5). The mean sand grain diameter is  $d_{50}=0.18\text{mm}$ . As the height of the tunnel is only about twice the ripple length, it has been chosen to use the whole height as a computational domain taking a flat smooth boundary at the top.

Fig. 4. Free stream velocity history.

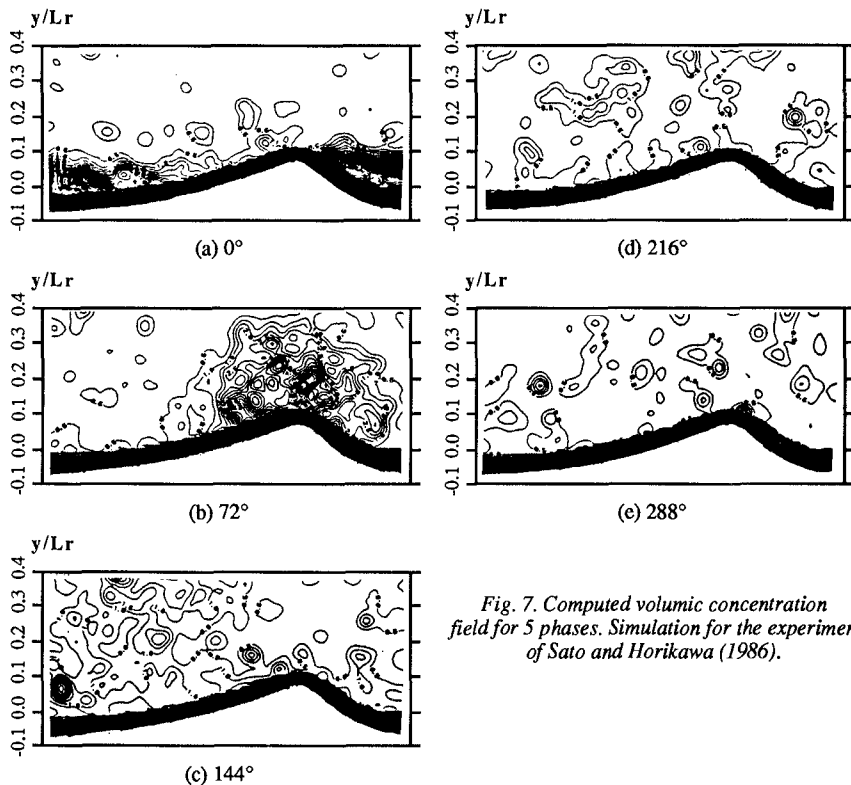

Fig. 5. Ripple shape.

Experiment of Sato and Horikawa (1986).

A snap-shot of the particles distribution is shown after flow reversal on figure (6) and the time evolution of the concentration field over a complete wave-cycle is displayed on figure (7) for 5 phases. On the steep flank of the ripple, a sand cloud forms with a large input of sediment from the crest during the short positive part of the cycle. At flow reversal, this cloud is ejected over the crest and travels in the negative direction. While convected, the cloud undergoes some diffusion and a large part of the trapped sediment falls down on the bed. During the longer negative part of the cycle, the flow motion is slow and no sand cloud formation is observed on the mild flank of the ripple, the friction velocity being too small and the slope too mild to get a sand cloud. Thus, a strong asymmetry exists between the two parts of the wave cycle resulting in a negative transport.

Fig. 6. Computed particles distribution at 108°. Experiment of Sato and Horikawa (1986).

*Fig. 7. Computed volumic concentration field for 5 phases. Simulation for the experiment of Sato and Horikawa (1986).*

The computed horizontal suspended sediment fluxes (Fig. 8) reveal that the transport occurs only in a layer  $0.5 L_r$  thick. Because of the return current in the bottom part,  $F_c$  is negative down to the crest level. The wave flux  $F_w$  is negative above the level  $y_c = 0.06 L_r \approx 0.4 H_r$  (where  $H_r$  is the ripple height) as a result of sand cloud convection processes in this region and becomes positive below. The total suspended flux is then negative except very close to the bottom.

Three representative tests for 2D ripples have been used for simulations with an increasing degree of asymmetry and flow severity. The agreement (Table 1) is close with only a small underprediction for weaker flow conditions (S3-03).

**SEDIMENT TRANSPORT IN COMBINED WAVES AND CURRENT**

In the following, two different simulations for combined waves and current are presented : experiment of Murray (1992) in a tunnel and experiment of Villaret and Latteux (1992) in a wave flume. As far as sediment transport is concerned, wave flumes and tunnels are not totally equivalent. Indeed, in a flume the presence of a wave propagating in the positive direction induces vertical velocities and an horizontal drift positive at the bottom and negative in the outer flow. This effect that might change bottom processes is not included in the model.

The value of the proper free stream current  $U_c$  to prescribe is obtained by data fitting on the space and time averaged horizontal velocity profile.

**Combined waves and current in a tunnel.**

Murray used a set of various hydraulic conditions essentially in the sheet flow regime. However, one test (WCS1) presented a rippled bed. Here, the parameter  $a/L_r=6.57$  is out of the range of classic vortex ripples and is classified as anorbital by Wiberg and Harris (1994) : the ripple shape does not depend on the wave orbital amplitude but rather on the grain diameter  $d_{50}$ . The measured ripple shape is more 3D than 2D with no asymmetry reported. In the model, we choose a symmetric "smoothed parabolic" shape as a first approximation. The sand is fine with a mean grain diameter  $d_{50}=0.14\text{mm}$ .

The time and space averaged horizontal velocity and concentration are shown on figure (9). The two-slope velocity profile is well reproduced with a break of slope at  $y/L_r \approx 0.5$  and only a slight underprediction in the lower part. The concentration profile is correct both in terms of bottom concentration and slope. Very close to the bed, the model predicts an increase in the concentration but no data points are available at these lower levels. At high elevations, the small overestimation is not significant for such low concentrations.

Fig. 9. Time and space averaged profiles.  
 solid line : DVM; squares: Experiment of Murray (1992)

The total suspended sediment flux profile  $F_s$  and the two contributions  $F_c$  and  $F_w$  presented on figure (10) appear to be in very good agreement with data. The strong reduction of the total flux by the negative wave contribution is properly predicted by the model at least above the level  $y_c/L_r=0.2$ . As we get closer to the bottom, current and wave contributions become strongly positive with a reversal of  $F_w$  at about one ripple height above the crest level. This behaviour has previously been observed by Vincent and Green (1990) for large scale ripples in the field.

Fig. 10. Non-dimensional horizontal suspended sediment fluxes profiles.

<b>Total load</b>			
$Q_t$	7.5	*	*

Table 2. Non-dimensional transport rates.  
 Experiment of Murray (1992).  
 (\* : unavailable)

To obtain transport rates, Murray used a linear extrapolation of the fluxes from the last measurement point ( $y_c/L_r=0.09$ ) down to the averaged bed level ( $y=0$ ) where  $F=0$  and then performed a depth-integration. Table 2 shows that the same Eulerian method applied to model results gives an overprediction of  $Q_s$  by a factor 2. The current contribution  $Q_c$  agrees with data while the wave contribution  $Q_w$  is underpredicted. Once considered the shape of the flux  $F_w$  profile, the reason of the discrepancy is clearly the reversal for the lower levels. The Lagrangian method gives a larger (2.7 times) transport rate because it takes indirectly account of the very large positive transport beneath  $y_c/L_r=0.09$ . The proportion of bed load in the total load is predicted as only 6.6%.

### Combined waves and current in a flume.

Villaret and Latteux (1992) have carried out combined waves and current experiments in a flume. For the selected test, the current followed the wave and the wave-induced drift is about 1 or 2 cm/s at the bottom for a velocity amplitude  $U_w=34$  cm/s. The other differences with the previous tunnel experiment are a larger current :  $U_{c1}/U_w=1.0$  for Villaret and Latteux (1992) whereas  $U_{c1}/U_w=0.5$  for Murray (1992) ( $U_{c1}$  is the current at  $y_c/L_r=1.0$ ), a finer sand ( $d_{50}=0.09$ mm) and a smaller ratio  $a/L_r=1.9$ , at the upper range of the vortex ripples regime and classified as suborbital by Wiberg and Harris (1994). The ripple was 2D but no asymmetry was reported. In the model, we use a symmetric "smoothed parabolic" shape.

The computed horizontal velocity deviates significantly from data (Fig. 11.a). The model exhibits a two-slope profile with a break of slope at  $y/L_r=0.5$  and a larger apparent roughness with even negative velocity in the near-bed wave-current boundary layer where data shows rather large positive velocities. The discrepancy at the bottom is a result of the wave drift present in the experiment but not included in the simulation.

In contrast with flat beds, the increase in the current-wave ratio  $U_c/U_w$  from the simulation of Murray (1992) to Villaret and Latteux (1992) results in a larger apparent roughness. Actually, the regime is closer to vortex ripples and the flow asymmetry is larger. Hence, shed vortices strongly reduce the velocity.

In spite of the correct bottom concentration, the calculated profile appears too steep in its lower part (Fig. 11.b.). The two-layer structure is rather pronounced attesting the large-scale mixing in the lower layer dominated by vortex convection.

(a) Non-dimensional horizontal velocity.

(b) Volumic concentration.

Fig. 11. Time and space averaged profiles.  
solid line: DVM; squares : Experiment of Villaret and Latteux (1992).

As a direct consequence of these discrepancies, the computed fluxes profiles (Fig. 12) exhibit a completely different pattern from data. At higher elevations where the concentration is overestimated,  $F_s$  and  $F_c$  exhibit maxima, while at lower levels where a return flow is predicted, fluxes disagree in amplitude and direction.

Villaret and Latteux (1992) computed  $Q_s$  from the fluxes profiles,  $Q_t$  from sand budget and  $Q_b$  by subtraction. They used a constant extrapolation of the fluxes from the last measurement point ( $y_c/L_r=0.18$ ) down to the crest level ( $y_c=0$ ) and then performed a depth-integration. The same Eulerian method is used here. As the flux  $F_s$  is small in the near-bed layer, the two methods for obtaining  $Q_s$  give similar results (Table 3). Nevertheless, the rather close agreement with data is not meaningful when the discrepancies in fluxes profiles are considered. The bed load is underpredicted and accounts for only 10% of the total transport compared to roughly 20% in the experiment.

$Q/Lr/U_w * 10^{-4}$	DVM	Exp	Ratio
<b>Bed load</b>			
$Q_b$	0.2	0.5	0.4

**DISCUSSION OF THE RESULTS AND CONCLUSIONS**

A numerical model based on a discrete vortex approach has been developed to study flow and sediment processes over rippled beds. It has been tested for a representative experiment in clear oscillatory flow and three different configurations where the free stream asymmetry induces a transport of sand in the near-bed region.

As far as hydrodynamics are concerned, the model provides a consistent prediction of the processes in the near-bed layer dominated by coherent vorticity structures. For the wave-alone case, the experiment of Ranasoma (1992) with fixed ripples has been used as a validating test. The model is able to describe rather accurately the mechanisms of generation, ejection and convection of vortices. For

combined waves and current, the model predicts a two-layer flow structure in accordance with the experimental data of Murray (1992) in tunnel.

The consistent qualitative picture of suspension processes and the good agreement of concentration profiles found by Hansen *et al* (1994) for the wave-alone case are extended here to the case of asymmetric waves and combined waves and current in tunnel. Especially, the large-scale mixing resulting from vortex shedding generates a rather uniform concentration in the ripple-influenced near-bed layer.

Regarding suspended sediment transport, detailed flux profiles provide much more information than depth-integrated transport rates. The particularity of such unsteady flows is to give rise to a wave flux in addition to the current flux. The total suspended sediment flux is then the sum of these two contributions. The current flux is always in the direction of the local current (negative for asymmetrical wave and positive for combined waves and current) whereas the wave flux opposes the direction of the maximum free stream velocity at most levels. This results from the convection of sand-laden vortices generated during the positive flow, shed into the flow at reversal and convected backwards during the negative flow. In the near-bed region, the wave flux reverses and becomes strongly onshore. This behaviour is thought to be the result of the larger amount of sand picked up from the crest during the positive flow. The fluxes data of Murray (1992) provides a successful quantitative comparison for the vortex-dominated region but no data is available to understand clearly near-bed mechanisms.

The evaluation of suspended sediment transport rates has proven the importance of the choice of the lower limit for depth-integration when the fluxes exhibit large increases close to the bed.

A discrepancy between model results and experimental data arises for combined waves and current in a flume (Villaret and Latteux, 1992). Progressive waves induce vertical velocities and a drift positive at the bottom and negative above. The absence of this physical feature in the modelling results in a conspicuous two-layer structure with a large underestimation of the horizontal velocity and a steep concentration profile in the near-bed region, whereas in the experiment the wave drift produces much more gradual profiles. The resulting computed fluxes disagree with experiment not only in magnitude but also in direction. This simulation demonstrates the need to include in the model the effect of wave propagation.

In such unsteady flows, the assumption of a steady-state ripple can be discussed. Indeed the ripple deforms locally during the wave cycle : a small volume of sand moves back and forth in the crest region and forms at each half-cycle a small cliff downstream of the crest which disappears at flow reversal (Sleath, 1982). In the simulations with sediment, the selected shape, "smoothed parabolic", is representative of the experimental bed shape (Fredsoe and Deigaard, 1992) and changing the length of the smoothed crest region has only a small influence on bottom processes. It appears from experiments that the bed is less affected by the superposition of a current on sine waves than by the wave asymmetry. Therefore, symmetric ripples have been used for combined waves and current simulations. Beside its stationary shape, the migration of the ripple is neglected based upon experiments. Nevertheless, the large increase in the computed wave flux close to the bed could be partly due to this unrepresented characteristics.

As a general conclusion, the study has demonstrated the ability of the model to replicate hydrodynamical and sediment mechanisms when the water motion induced by waves can be reckoned as oscillatory.

## CHAPTER 149

### In-Situ Determination of the Critical Bed-Shear Stress for Erosion of Cohesive Sediments

Erik-Jan Houwing and Leo C. van Rijn<sup>1</sup>

#### Abstract

A new in-situ erosion meter has been developed to measure the in-situ bed-shear strength of cohesive beds. It is assumed that the current velocity, at initiation of motion of the toplayer of the bed, can be used to compute the critical bed-shear stress. This critical shear stress is the characteristic parameter which can define different types of sediment beds.

The in-situ measurements show that the test results are determined by the prevailing hydrodynamic conditions in the field (wave activity) and recent depositions rather than by physical and biological parameters.

#### Introduction

It is commonly accepted that the strength of the inter-tidal mud flats is strongly influenced by physical-, biological- and chemical- parameters (see Amos et al., 1992; Verreer et al., 1986). Until now it is not possible to measure these parameters separately and predict the resulting strength of the bed. The best way to handle this problem is to measure the critical shear stress for erosion of the top layer of the bed. By this, all shear strength related parameters are captured in one overall parameter: the critical shear stress corresponding to the erosion of the top layer of the bed (defining the maximum shear strength of the top layer of the bed). These tests can be performed in the laboratory either by using kaolinite beds or by samples of natural beds which have to be taken from the field. Both types of tests do not seem to reflect the natural conditions of in-situ beds properly. For this reason in-situ measurements have to be carried out in order to determine the erosive resistance of cohesive sediment. Several in-situ instruments have been developed already (Amos et al., 1992a; Williamson, 1994; Gust, 1994; Cornelisse

---

<sup>1</sup>Institute for Marine and Atmospheric Research Utrecht, Utrecht University, PO Box 80115, 3508 TC Utrecht, The Netherlands.

et al., 1994). Until now, the techniques used are not accurately enough to determine the parameters controlling the entrainment of cohesive sediments. One of the major problems is that differences are found in the stresses generated by the instruments in comparison with the real values in nature (Gust, 1994). Furthermore, the measurement results are often biased and the measurement results of the available erosion instruments show significant differences. This is mainly caused by differences in the settings of the instruments (Cornelisse et al., 1994).

The in-situ Erosion Flume, presented herein, is developed to measure the shear resistance of the top layer of cohesive beds. Like most of the flume-systems the shear stress on the bed is exerted by an adjustable unidirectional flow. The shear stress exerted by the adjusted current velocity was calibrated in the laboratory. The results of the ISEF measurements will give the maximum shear strength of the top layer of the bed and is an overall representation of shear strength related parameters.

This article describes the development of the ISEF, the reproductivity tests in the laboratory and the field measurements on cohesive beds in the salt marsh region in the Netherlands Wadden Sea.

### In-Situ Erosion Flume (ISEF)

The in-situ Erosion Flume is a circulating flow system in the vertical plane. It consists of a lower horizontal test section, two bend sections and an upper section where the flow is generated by a propeller (see figure 1).

Fig.1 The in-situ erosion flume (ISEF).

The horizontal test section and the two bend sections have a rectangular cross-section with a height of 0.1 meter and a width of 0.2 meter. The bottom part of the horizontal test section is open over a length of 0.9 and a width of 0.2 meter. When the Erosion Flume is resting on the sediment bed properly, the surface of the bed will be in line with the steel bottom plates of the flume on both ends of the horizontal section. The total weight of the erosion flume is about 50 Kg. The total volume of water in the flume is 100 liter.

The propeller can be rotated at various speeds by means of an adjustable oil pressure system. The flow velocity in the horizontal section is measured with a small disc-type electro-magnetic flow meter (EMF) placed at 0.55 meter from the entrance of the horizontal test section. The measuring point is at 0.075 meter below the covering plate of the test section, which is 0.025 meter above the bed surface. The suspended sediment concentration is measured by means of an optical monitor.

The erosion process of sediment particles of the bed is related to the prevailing bed-shear stress.

The bed-shear stress can be determined from the measured velocity profile assuming a logarithmic distribution in vertical direction, which reads as:

$$u_z = \frac{u_*}{\kappa} \ln\left(\frac{z}{z_0}\right) \quad (1)$$

in which:

$u_z$  = flow velocity at height  $z$  above the bed (m/s),  $u_* = (\tau_b/\rho)^{0.5}$  = bed-shear velocity (m/s),  $\tau_b$  = bed-shear stress (Pa),  $\rho$  = fluid density ( $\text{kg/m}^3$ ),  $\kappa$  = constant of von Karman (0.4) (-),  $z$  = height above the sediment bed (m),  $z_0 = 0.033 k_s + 0.11\nu/u_*$  = zero-velocity level (m),  $k_s$  = effective bed roughness height of Nikuradse (m), and  $\nu$  = kinematic viscosity coefficient ( $\text{m}^2/\text{s}$ ).

Based on Eq.(1) the bed-shear stress can be expressed as:

$$\tau_b = \rho \kappa^2 u_z^2 \left[ \ln\left(\frac{z}{z_0}\right) \right]^{-2} \quad (2)$$

An equilibrium flow will not be established in the ISEF because of the short length of the test section. This means that the velocity distribution in the near-bed region of the horizontal section might deviate slightly from the logarithmic distribution. Introducing a calibration coefficient  $\alpha$  (close to unity) to account for this effect, and using the maximum velocity  $u_m$  at the upper edge of the boundary layer ( $\delta$ ) above the bed, Equation (2) can be expressed as:

$$\tau_b = \rho \kappa^2 (\alpha u_m)^2 \left[ \ln \left( \frac{\delta}{0.033 k_s + 0.11 \nu \left( \frac{\tau_b}{\rho} \right)^{-0.5}} \right) \right]^{-2} \quad (3)$$

The  $\alpha$ -coefficient was determined by measuring velocity profiles above a flat bed of moving (non-cohesive) sand and gravel particles at conditions just beyond the initiation of motion (Houwing and van Rijn, 1992). The  $\alpha$ -coefficient varies from 0.9 to 0.74 as function of an increasing Reynolds number. The boundary layer thickness ( $\delta$ ) was found to be about 0.025 m. In field situations, the hydrodynamic conditions just above the cohesive bed lies within the hydraulic smooth regime. Therefore, an  $\alpha$ -coefficient of 0.9 is recommended to determine the bed-shear stress. The velocity should be measured at a height of 0.025 meter above the bed.

### Reproduction measurements

Reproduction tests are essential for a correct interpretation of data and to know whether the experimental results are reliable (see Cornelisse et al., 1994). Changes in test results should be due to changes in bed composition rather than to differences in the setting of the erosion meter. It is expected that, in case of the ISEF, erosion will appear more easily along the edges of the test section as here the bed might be slightly disturbed. Besides that, small undulations on top of the bed will lead to small velocity variations thus increasing erosion on that specific location.

Cornelisse et al. (1994) found that the areal size of the test section is crucial for the reproductivity of the erosion instruments. The spatial variations in the bed properties and the turbulent stresses are averaged out when the erodible area is larger. They found a linear relationship between the reproduction error and the areal surface which reads as:  $R = 796 * A^{-0.528}$ , based on 13 tests carried out with four different erosion meters. The surface area of the test section of the ISEF measures 1800 cm<sup>2</sup> and the resulting error R is calculated to 15%.

In order to investigate the reproduction error of the ISEF three laboratory tests have been carried out similar to the tests performed with a laboratory carousel (de Jong, 1991). For each test a new bed is constructed in the test section of the ISEF. The bed consists of kaolinite and is formed by sedimentation in still fresh water. The mean density of the kaolinite bed is in the order of 350 kg/m<sup>3</sup>.

The current velocity in the ISEF is increased in steps of one hour during each experiment. The sediment concentrations are determined by means of the optical sensor. The output of the optical sensor is calibrated in situ based on pumped samples. The results of the tests show a good reproductivity (Fig. 2) and the error for the reproductivity tests is estimated to 20 % which is in agreement with the calculated 15%. The rate of erosion per exerted shear stress is up to 3 times higher for the ISEF in comparison with the test results performed by de Jong. This is probably due to a lower mean density of the initial bed used in the ISEF (350 vs 400 kg/m<sup>3</sup>).

Fig.2 Reproduction of erosion tests.

### Field measurements

The in-situ field measurements are carried out in one specific area in the salt marshes along the main coast of the Netherlands Wadden Sea. The field site is surrounded by brushwood groynes and measures 400 x 400 meter. The tide is diurnally and most of the time the field area is inundated during high water. Mean water depth lies in the order of 1 meter. The area develops into the salt marsh in landward direction and is bounded in seaward direction by low tidal flats. The bed sediment in this area can be classified as cohesive sediment. It consists of well sorted very fine sand ( $d_{50}=80\mu\text{m}$ ;  $d_{90}=100\mu\text{m}$ ;  $d_{10}=65\mu\text{m}$ ) and contains between 20 to 30 % material smaller than  $50\mu\text{m}$ .

Small variations can be found within the field area ranging from  $d_{50}\approx 75\mu\text{m}$  close to the groynes to  $d_{50}\approx 90\mu\text{m}$  near the windward side of the groynes. The density of the top layer of the bed (first 5 mm) varies from  $1050\text{ kg/m}^3$  in less consolidated regions to  $1300\text{ kg/m}^3$  in the better consolidated regions. The increase in consolidation is found going towards the salt marsh and can be contributed to the decrease in frequency in tidal flooding and to a better dewatering of the bed. The bed density is measured with use of a cylinder of 2.5 cm in diameter. This cylinder is pushed into the bed and the sediment core is pushed out carefully and slices of 5 mm thick are cut accurately. The bed density is measured in this way till 3 cm beneath the surface with a 5 millimeter interval (figure 3).

Fig. 3 Example of bed density as function of depth

The samples are weighted in order to obtain the wet bulk density, dry bulk density, moisture content and voids ratio.

The results from the ISEF-measurements will give the maximal shear strength of the top-layer of the bed for that specific location. Comparison with other ISEF-measurements will show how the erosion resistance of the bed will change both in time and in space.

Several in-situ field measurements distributed throughout the field area have been performed during the autumn and winter period of 1993 and the summer period of 1994. Five measurements are discussed here forming two identical groups where in each group the measurements are recorded for two consecutive days. Group 1 is formed by ISEF-1 and ISEF-3 and the tests are carried

out during autumn on 13 and 14 October 1993. The second group is formed by ISEF-5, -6 and -7 and is carried out during summer on 7 and 8 June 1994.

ISEF-1 is carried out in the middle of the field area where the bed is inundated twice a day (mean water depth during high water is around 1 meter) and ISEF-3 is carried out close to the salt marsh where the bed is less frequently flooded (mean water depth is about 0.15 meter). The differences in bed density, grain size and mud content ( $d_{50} < 50 \mu\text{m}$ ) are given in Table 1.

Measurement ISEF-5 is carried out on the same spot as ISEF-1: in the middle of the field area. ISEF-6 and -7 are carried out more to the west in the field area where the bed is sheltered by the groynes. Here, the bed is less consolidated and contains a higher percentage of mud.

ISEF-6 and ISEF-7 are carried out close to each other on one day. The difference between both tests is that in case of ISEF-7 the fluffy top layer, of about 5 mm thickness, is removed by a scraper exposing the underlying undisturbed bed. The bed parameters are shown in Table 1.

The ISEF is placed carefully on the sediment bed. The current velocity in the ISEF is tuned accurately during the measurements until the top layer of the bed starts to erode. It is tried to follow the same procedure during each measurement. The first minutes of the test the velocity is adjusted to 0.05 m/s. The current velocity is then increased by steps of 0.05 m/s. Each step lasts as long as one hour or until at least the erosion of the bed is arrested (concentrations become constant in time). In the latter case the exerted shear stress equals the

strength of the bed at that particular depth ( $z$ ):  $\tau_b = \tau_{s(z)}$ . With help of equation (3) the shear stress is computed. The results of the ISEF measurements are shown in figure 4 to 8.

Table 1. ISEF-measurements and bed parameters. The bed parameters are measured in the upper 5 millimeter of the bed. The grain size is computed from the fall velocity distribution from the sediment samples. The mud content is determined by filtering the sediment samples through a 50  $\mu\text{m}$  filter. The standard deviation (STD) is the deviation around the mean ( $\sigma_{n-1}$ ) calculated from five samples ( $n=5$ ).

	$d_{50}$ ( $\mu\text{m}$ )	$d_{90}/d_{10}$ (-)	mud cont (%)	Bulkdens ( $\text{kg}/\text{m}^3$ )	STD	Drydens ( $\text{kg}/\text{m}^3$ )	STD
ISEF-1	80	1.85	15	1.74	0.15	1.15	0.14
ISEF-3	76	1.55	25	1.75	0.09	1.23	0.11
ISEF-5	80	1.86	15	1.82	0.02	1.20	0.07
ISEF-6	74	1.55	25	1.60	0.13	1.01	0.17
ISEF-7	76	1.98	25	1.77	0.13	1.17	0.19

All figures show an increase in erosion of the top layer of the bed at an increasing current velocity (increasing shear stress). At low velocities erosion of the bed is non linear and erosion is arrested after a while indicating that the exerted stress equals the bed shear strength at that level. At high current velocities erosion is linear (see figure 4). It is apparent that in all cases, except for ISEF-3, most linear erosion starts around an exerted velocity of 0.20 m/s (figures 4 to 8).

One of the major problems is to measure the bed density of the top mm's of the bed which is one of the basic parameters for the bed shear strength. The amount of erosion of the bed can be recalculated to erosion depth, assuming that the measured bed density of the first 5 mm of the bed is also characteristic for the top layer of the bed. If erosion occurred equally over the entire test section (1800  $\text{cm}^2$ ), the erosion depth is limited to  $10^{-4}$  millimeter. This is not in agreement with visual observations after each test. Here it is found that at the end of the test the erosion depth can be as high as one centimetre. This difference can first of all be ascribed to the fact that the calculations are based on the mean bed density while it can be expected that the top millimeter of the bed measures a much lower density. Second, erosion of the bed will not always happen throughout the entire surface but will often be confined to patches in the test section where erosion resistance is lowest. This means that it is of major importance to measure the bed density with a much smaller interval and on a much more accurate way than in the present study.

The results of the tests show that the relationship between the exerted shear stress and the erosion rate is poor. This can be expected as in nature the composition of the bed and the density of the bed varies strongly in depth.

### Conclusions and recommendations

The laboratory and the in-situ field measurements of the ISEF show realistic results in respect to the results of other researchers. The laboratory tests show that the reproducibility of the ISEF is reasonably good. The in-situ measurements based on the ISEF measures the minimum exerted shear stress at initiation of erosion of the bed leading to the maximum bed shear strength.

The ISEF measures erosion of the top-layer of the bed due to the uni directional current only. It is found that due to wave propagation mud-beds can weaken and the bed shear strength decreases as result (Mehta, 1988). The ISEF-measurements, in this respect, will overpredict the maximal bed shear strength.

It is expected that the moment of erosion of the top layer of the bed will strongly be determined by the composition of the bed, the bed density and biological activity in the top layer of the bed (for instance the presence of diatoms). The test results have shown that if variation in sand-mud composition, bed density, grainsize distribution and biologic activity in the top layer of the bed is relatively small, the strength of the top layer of cohesive beds at different locations tend to be constant.

The strength of the top layer of the bed of intertidal mudflats are determined by the governing (preceding) hydrodynamic conditions. Wave action, especially in very shallow water depth, remoulds the bed sediment. This effect is visual in the field to several cm beneath the bed surface, depending on the wave heights. The top layer of the bed was found to have approximately constant shear strength' on a small spatial scale. The strength of the top layer of intertidal mud flats, in this case, is determined rather by the prevailing hydrodynamic conditions (wave activity) and recent depositions than by physical and biological parameters. Interdisciplinary research of physicist and biologists is needed in order to investigate the variation in shear strength of the top layer of intertidal mudflats properly. It is wise to choose research locations which differs in great extend in shear strength-related parameters. The ISEF is useful to characterize different types of cohesive sediment beds. More thorough investigation is possible if the bed density can be measured on a small vertical scale (millimeters). For this purpose the acoustic density meter which is developed by Delft Hydraulics can be recommended (Verbeek and Cornelisse, 1994).

More thorough investigation is possible if the in-situ pumped suction samples are analyzed with respect to grain size distribution during test procedure. In this way it is possible to separate the moment of resuspension of the fraction  $d < 50\mu\text{m}$  from the moment the sand fraction  $d > 50\mu\text{m}$  is resuspending.

## CHAPTER 150

# Control of Cross-shore Sediment Transport by a Distorted Ripple Mat

Isao Irie\*    Nobuyuki Ono†    Seiya Hashimoto‡  
Satoshi Nakamura§    Keisuke Murakami¶

## ABSTRACT

A method to control cross-shore sediment transport by a distorted ripple mat which is the artificial ripples of distorted cross section has been studied through hydraulic experiments and numerical simulation. First of all, the relative importance of factors affecting cross-shore sediment transport on fixed bed ripples and the condition on which sediment is definitely transported on-shoreward are obtained. Based on this condition, experiments with movable bed are carried out to see how efficiently the distorted ripple mat can be utilized in stabilizing natural/artificial beaches. Furthermore, a numerical model of beach profile change in which effects of ripple distortion are considered has been developed and beach stabilizing effects of the mat are also reproduced numerically.

## INTRODUCTION

Recently, the needs of preventing beach erosion without installing such bulky structures as offshore or submerged breakwaters have increased so as to keep a beautiful view and to enable various maritime recreational activities. In order to prevent people's lives and properties from natural disasters, sandy beach needs to be expanded so that land behind is efficiently protected even with the

temporary retreat of shoreline under severe storm waves. The idea of supplying sediment from other sources to fulfill those demands, however, will become very difficult to be adopted as the general shore protection methods in the future because every coast is more or less suffering from the shortage of sediment and cannot afford to supply for other coasts. The supply from land sources will also have by itself limitation. The expected sea level rise in coming century will make the situation more serious. Thus, the shore protection measures utilizing sandy beach can be established only when beach expansion is carried out on self sufficiency bases, that is to say, some measures must be developed to preserve shoreline through sediment supply from beaches themselves, probably from offshore sources. Controlling cross-shore sediment transport by a distorted ripple mat composed of precasted concrete blocks could be one of the hopeful measures to fulfill those demands, but no positive study seems to be carried out since the study by Innian et.al. (1972). In the present paper, effectiveness of the distorted ripple mat in stabilizing natural/artificial beaches has been studied by hydraulic experiments and numerical simulation.

### Methods of Experiments on Sediment Movement Velocity

Artificial ripples of fixed bed of different distortion as shown in **Figure 1** were set in two dimensional wave channel whose length, width and height is  $28m$ ,  $0.3m$  and  $0.5m$  respectively. The length of installation of fixed bed ripples was  $3m$  and the average water depth was  $27cm$ . The length and height of sinusoidal ripples in **Figure 1** was originally determined from the ripple dimensions of preliminary experiments with movable bed, in which standard waves of  $8cm$  in height and  $1.5$  sec. in period were acted on the horizontal movable bed composed of sediment  $0.16mm$  in median diameter (settling velocity  $W = 1.6cm/s$  at  $20^\circ C$ ). In the troughs of the fixed bed ripples shown in **Figure 1**, sediment of the same diameter as the movable bed experiments were placed with a certain volumes and the same waves were acted. After the wave action,

**Fig.1** Shape and scale of fixed bed ripples

Fig.2 Movement of the centroid of sediment placed on the fixed bed ripples

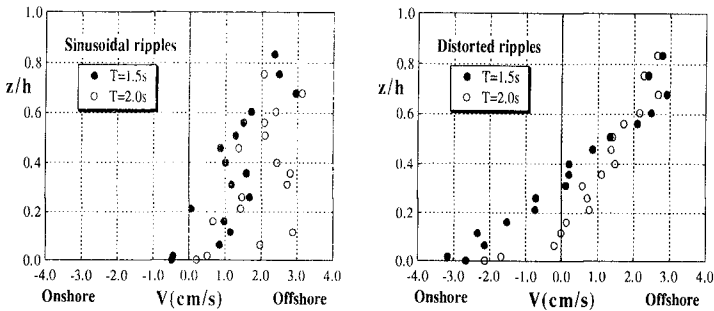

Fig.3 Vertical distribution of mean velocity for sinusoidal ripples and distorted ripples

sediment of each trough of ripples was sucked up by a nozzle and weighed by drying. From the change of horizontal distribution of sediment, movement of its centroid is obtained. As shown in **Figure 2** in which sediment movement is traced for sinusoidal ripples, the velocity of centroid movement becomes constant after a certain time of wave action and more time is required as the volume of sediment per one trough of ripples increases. The steady state of centroid movement is considered that the ratio of suspended part and settled part of sediment has attained equilibrium condition and thus the centroid movement velocity is nothing but the average movement velocity of suspended sediment. **Figure 3** shows the velocity profiles measured by a magnetic type current meter when waves of 8cm in height and 1.5 or 2.0 sec. in period are acted on sinusoidal ripples (Left) and distorted ripples (Right). It is seen that for distorted ripples, the mean velocity is onshoreward within the range of 0.2~0.3 of relative water depth above the bottom whereas it is mostly offshoreward in sinusoidal ripples. Distortion of ripples clearly creates onshore

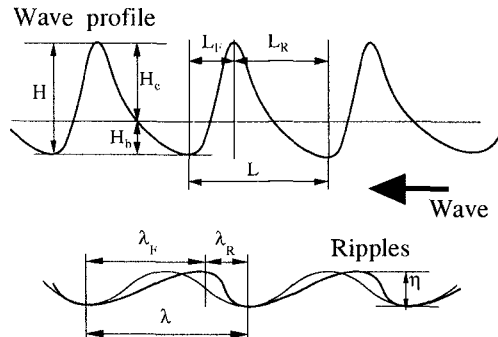

current near the bottom and this feature could be utilized for controlling cross-shore sediment transport.

### Factors Affecting Cross-shore Sediment Transport

The velocity and direction of cross-shore sediment transport on fixed bed ripples may largely depend on the relative magnitude of vortices formed on the onshore/offshore side of a ripple. As shown in **Figure 4**, three factors are picked up as the dominant factors determining the relative magnitude of vortices, that is, the unsymmetry of wave crest height and trough depth  $S_1 = (H_c - H_b)/H$ , the tilt of wave profile  $S_2 = (L_R - L_F)/L$  (related to the bottom slope  $\tan \beta$ ), and the distortion of ripples  $S_3 = (\lambda_R - \lambda_F)/\lambda$  (negative in the figure). The mean velocity of sediment placed on the fixed bed ripples is considered to be expressed (Irie et al., 1993),

$$V_g^* = \sum a_i S_i \quad (i = 1, 2, 3) \tag{1}$$

where  $V_g^*$  is nondimensional form of the mean velocity of sediment movement  $V_g$  which is positive offshoreward, that is,  $V_g^* = (V_g/U_m)(W/U_m)(h/\eta)$  in which  $U_m$ ,  $W$ ,  $h$  and  $\eta$  are the maximum orbital velocity at the bottom, the settling velocity of sediment, the water depth and the height of ripples respectively. The coefficients  $a_1$ ,  $a_2$  and  $a_3$  are determined empirically through the experiments with fixed bed ripples by changing wave characteristics (for the wave height  $H = 8\text{cm}$ ,  $T = 1.0 \sim 2.0$  sec.), the bottom slope ( $0 \sim 1/15$ ) and the rate of distortion of ripples (for  $\lambda = 5.5\text{cm}$  and  $\eta = 1.0\text{cm}$ ,  $\lambda_R = 0 \sim \lambda/4$ ). According to the experiments,  $a_1 = 0.044$ ,  $a_2 = -0.028$  and  $a_3 = 0.033$ , respectively. **Figure 5** shows the correlation of the mean velocity of sediment movement  $V_g$  between hydraulic experiments and calculation using Eq.(1). As shown in the Figure, the correlation coefficient was 0.91, indicating satisfactory validity of the empirical equation.

**Fig.4** Definition of dimensions

The criteria of onshore/offshore sediment movement when the distortion of fixed bed ripples is  $\lambda_R = \lambda/4$  ( $\lambda = 5.5\text{cm}, \eta = 1\text{cm}$ ) are examined by Monte Carlo Method using Eq.(1). **Figure 6** shows the result of calculation where the direction and extent of sediment movement are shown with respect to the bottom slope and relative wave height. The figure depicts that definite onshore sediment movement is expected if the relative wave height  $H/h$  is less than 0.5 (corresponding to the offshore zone) although it varies with the bottom slope  $\tan \beta$ .

**Fig.5** Comparison of  $V_g/U_m$  between calculation and experiments

**Fig.6** Criteria of onshore movement

**Effectiveness of Distorted Ripple Mat**

A distorted ripple mat made by precasted concrete blocks is developed as shown in **Figure 7**. As shown in the figure, one end of a unit block is

Fig.7 Distorted ripple mat

piled on the end of the other block and the plastic filter is stuck on the bottom face of the block, and thus it flexibly adapts itself to the change of movable bed and no settlement is expected. The surface profile of the distorted ripple mat is made to have the distortion characteristics of  $\lambda_R = \lambda/4$ , which corresponds to the maximum distortion in preserving strength of the concrete blocks. The effectiveness of the distorted mat in controlling cross-shore sediment transport is examined by movable bed experiments, where the distorted ripple mat was set in the offshore zone based on the results of **Figure 6**. **Figure 8** shows one result of small scale experiment carried out as the preliminary experiment in a wave flume 4m in length, 15cm in width and 20cm in height. The bed material used was glass beads with 0.08mm in diameter. After the action of waves of 2cm in height and 0.9 sec. in period, an equilibrium beach was formed and a distorted mat whose scale was almost 1/3 of the blocks shown in **Figure 7** was set in the offshore zone and waves were acted again. Sediment was supplied intermittently for beach fill at the location just onshore of the distorted mat. The distorted ripple mat checked the offshore sediment movement effectively, and most of the supplied sediment moved onshoreward and finally, as seen in the figure, a new beach is formed. **Figure 9** shows the medium scale experiment; the same scale as the experiments shown from **Figure 1** to **Figure 6**. An equilibrium beach was formed by acting waves of 8cm in height and 1.6 sec. in period on the initial each slope of 1/5 in the surf zone and 1/20 in the offshore zone. A distorted ripple mat was set in a limited range of the offshore as shown in the figure and waves were acted again. Sediment was supplied just onshore side of the distorted ripple mat. Movement of sediment can be more easily detected by spatially integrating bottom profile change onshoreward from the offshore point where no significant change takes place. The result of calculation of the present experiments is shown on the bottom of **Figure 9**. From the figure, the direction of net sediment movement on the distorted ripple mat is seen to be definitely onshoreward in spite of much sand

supply on the onshore side of it. Because of the strong effect of distorted ripple mat, the bottom is scoured just offshore side of the mat although a portion of scoured sediment is offshoreward which is considered to have caused because the initial profile was not completely in equilibrium.

## Reproduction by Numerical Calculation

A numerical model of beach profile change has been developed by taking consideration of the effects of ripple distortion on cross-shore sediment transport. In Eq.(1), the average velocity of sediment movement  $V_g$  on fixed bed ripples could be considered to represent also the velocity of suspended part of sediment on movable bed if the rate of distortion of ripples  $S_3$  is same as the one of movable bed. Thus the transport rate of suspended part of sediment in one pitch length of ripples can be obtained by multiplying  $V_g$  with the potential rate of sediment suspension. Here, we give;

$$QSS = \lambda \int C dz \quad (2)$$

$$VSG = V_g \quad (3)$$

where  $\lambda$  is the pitch length of ripples and  $C$  is the density of potential suspension of sediment at the height  $z$ . In the present study,  $C$  is obtained by the suspension formula by Skafel et.al.(1984). The important phenomena not included in the fixed bed ripples are the movement by bed shear at the surface of ripples on onshore and offshore phase of orbital velocity. As shown in **Figure 10**, sediment entrained by bed shear near the tips of ripples will be transported onshore or offshore up to the range of orbital length  $d_0$  and during this process, the entrained sediment will be partly enrolled in the rear vortices of ripples at a rate, say,  $R$  as shown by the shaded parts in the figure. The enrolled parts could be considered to contribute directly to suspended sediment whereas the rest of sediment will settle down on the bottom during half period. In finite amplitude waves, the characteristics of orbital velocity is different between onshore phase and offshore phase and thus the rate of bed shear transport is different between both phases. The rate of bed shear transport  $\Phi(t)$  is obtained from Madsen and Grant(1976) as follows:

$$\Phi(t) = 40\Psi^3(t) \quad (4)$$

where  $\Psi(t)$  is the Shields Number. In **Figure 10**, we define;

$QBO$  :Integration in space and time of sediment volume transported by bed shear and settled on the bottom on onshore phase (related to the rate of vortex enroll= $R$ )

$QBF$  :ditto but on offshore phase (also related to the rate of vortex enroll= $R$ )

**Figure 10** indicates that the centroids of  $QBO$ ,  $QBF$  and  $QSS$  have moved by the distance,  $XGL$ ,  $XGR$  and  $XBG$  in one period. Further we denote;

$VBG$  :Average movement velocity of ( $QBO + QBF$ )

$VT$  :Total average movement velocity of ( $QBO + QBF + QSS$ )

The following equation is formulated(Hashimoto et.al.,1993);

Fig.10 Onshore/Offshore sediment movement by bed shear

Fig.11 Movement and expansion of sediment in a ripple pitch length during one period of waves

$$(QBO + QBF + QSS) \times VT = (QBO + QBF) \times VBG + QSS \times VSG \quad (5)$$

Defining  $QT = QBO + QBF + QSS$ ,

$$VT = (QBO + QBF)/QT \times VBG + QSS/QT \times VSG \quad (6)$$

The total average movement velocity  $VT$  should be modified by the effect of gravity, that is, the local bottom slope  $\theta$ . Defining the modified velocity to be  $VTG$ ,

$$VTG = VT + J \cdot \sin \theta \quad (7)$$

where  $J$  is the empirical constant value.

**Fig.12** Movement and expansion of sediment placed on the trough of sinusoidal ripples of fixed bed(experiment)

**Fig.13** Movement and expansion of sediment placed on the trough of sinusoidal ripples of fixed bed(calculation)

As shown in **Figure 11**, the total volume  $QT$  in one pitch length of ripples is considered to move with the modified velocity  $VTG$  and scattered at a rate  $P$  in the range of orbital length  $d_0$  during one period. Further, this movement in one pitch of ripples is assumed to take place at random throughout the profile and each ripple experiences only one time during one period. This idea enabled to calculate dispersion process of sediment due to wave action. **Figure 12** shows the scattering process of sediment placed on the trough of sinusoidal ripples of fixed bed (at  $X = 0$  in the figure) by wave action, and the results of numerical calculation in the same condition is shown in **Figure 13**. The rate of dispersion  $P$  was selected to be 0.1 empirically. The process of sediment dispersion seems to be reproduced satisfactory. Another important feature of

the present model is the adoption of equilibrium profile. Natural beaches could be considered to be in quasi-equilibrium on long term basis. Once the beaches experience a certain impact of change such as excavation or beach filling, the beach profile change will take place being governed by the hydraulic condition in equilibrium state. In the present study, the equilibrium condition is given by the following condition.

$$VTG = VT + J \cdot \sin \theta = 0 \tag{8}$$

Here, two empirical constant values, that is,  $R$  in definition of  $QBO$  and  $QBF$ , and  $J$  in Eq.(8) could be determined if another definitive equation is available in addition to Eq.(8). In the present study,  $R$  and  $J$  were determined by comparing the beach profile change calculated by substituting a trial value of  $R$  and  $J$  (on the condition that Eq.(8) is satisfied) with movable bed experiments. As shown in **Figure 14**, initial equilibrium profile is given from laboratory experiments.

$$Z = 0.184X^{0.81} \tag{9}$$

The horizontal axis is divided into average ripple pitch length and sediment movement only in the offshore zone is calculated.

**Fig.14** Equilibrium profile used as the initial condition

**Effectiveness of Distorted Ripple Mat by Numerical Calculation**

Effectiveness of distorted ripple mat is reproduced by numerical model explained above. **Figure 15** shows the idea in calculation. Suppose the original beach profile is  $AFBC$  in the figure. We consider the case when the profile is partly excavated as  $AFGH$  and calculate resulting change of profile. We

secondly calculate the change of profile when most steep part  $FG$  is protected by the distorted ripple mat. This calculation would also correspond to the case when the original beach  $AFBC$  is filled to form  $ADEBC$ , that is to say, the beach fill is cut at half way  $E \sim B$  and thus it is examined whether or not the filled beach can be preserved by the distorted ripple mat. The results of calculation are compared with experiments and actual initial profile and excavation section are shown in **Figure 16**.

**Fig.15** Conception showing that beach cut  $AFGH$  is virtually same as beach fill  $ADEBC$

**Fig.16** Method of beach cut

Fig.17 Deformation of the slope by calculation without distorted ripple mat

Fig.18 Deformation of the slope by experiments without distorted ripple mat

Figure 17 is the result of calculation when steep slope face is not protected and Figure 18 is the result of experiments. The steep face is rapidly collapsed by wave action in both cases. Figure 19 and 20 show the result when the steep slope is protected by the distorted ripple mat for the case of calculation and experiments respectively. The initial profile is seen to be almost preserved even after 3 ~ 4 hours of wave action for both cases. This is because offshore sediment movement is checked by the distorted ripple mat and only the local minor change took place.

Fig.19 Stabilized slope by calculation with distorted ripple mat

Fig.20 Stabilized slope by experiments with distorted ripple mat

## Conclusions

Three factors, that is, the unsymmetry of wave crest height and trough depth, the distortion of wave profile and the distortion of ripples are the dominant factors affecting cross-shore sediment transport on fixed bed ripples. In the present distortion of ripples, definite onshore sediment movement is expected if the relative wave height  $H/h$  is less than 0.5, depicting that the distorted ripple mat is effective only in the offshore zone. The effectiveness of the distorted ripple mat is confirmed by both experiments with movable bed and numerical calculation.

## CHAPTER 151

### HOW MUCH VELOCITY INFORMATION IS NECESSARY TO PREDICT SEDIMENT SUSPENSION IN THE SURF ZONE?

Bruce E. Jaffe<sup>1</sup>, David M. Rubin<sup>1</sup>, and Asbury Sallenger, Jr.<sup>2</sup>

#### ABSTRACT

The time-dependent response of sediment suspension to water velocity was explored by modeling field measurements collected in the surf zone during a large storm. Both linear and nonlinear input-output models were formulated with water velocity as input and suspended-sediment concentration as output. A sequence of past velocities (velocity history), in addition to velocity from the same instant as the measurement of suspended-sediment concentration, were used as input. The velocity-history length was allowed to vary. The models also incorporated a lag between input (instantaneous velocity or velocity history) and output (suspended-sediment concentration).

Instantaneous horizontal water velocity, or velocity to a power, does not contain enough information to predict suspension in the surf zone. Unlike steady uniform flow, more than one velocity is necessary to parameterize pick-up and mixing of sediment into the water column. Using a velocity history improves predictions of suspension by more fully specifying flow conditions (including accelerations and changes in accelerations) responsible for suspension.

Suspension in the future is better predicted than suspension at the same instant as velocity measurements. Incorporating such a lag between velocity and concentration improved predictions, with optimum lag time increasing with elevation above the sea bed (from 1.5 seconds at 13 cm to 8.5 seconds at 60 cm for linear models). These lags are largely due to the time for an observed flow event to effect the bed and mix sediment upward.

Nonlinear models relating suspension to velocity do better than linear models using the same velocity history. Nonlinear models are able to exploit changing relationships between suspension and velocity history for different wave shapes. For the environmental conditions of our study, the optimal model (correlation coefficient of 0.58) used 3 seconds of velocity history (approximately one-quarter wave period) and a 1.5 second lag to predict suspension.

## INTRODUCTION

Models for sediment suspension in the surf zone are based on models developed for streams and the continental shelf. Additions of time-varying pick-up and mixing of sediment into the water have been the major changes to fluvial or continental shelf models to make them usable in the surf zone. For stream flow, a mean velocity (raised to a power) is used to determine the steady driving force for suspension. Two velocities, a mean velocity and a maximum orbital velocity, are used to determine the forcing for suspension in continental shelf sediment transport models (Smith, 1977; Grant and Madsen, 1979; Glenn and Grant, 1987). It is not obvious how much velocity information is necessary to predict suspension in the surf zone or if velocity alone is a good predictor for suspension.

There are many complexities that make it difficult to use first principles of physics to formulate models for sediment suspension. For example, it is not obvious how to model suspension in a reversing flow with velocity asymmetries caused by irregular waves. In this paper, we use a method developed by researchers studying nonlinear systems, input-output modeling, to determine which velocity information is important to predict sediment suspension. The goal of this study is to guide us in formulation of improved models.

## METHODS

The ability to predict sediment suspension from flow velocity was evaluated using input-output modeling of field measurements. Input-output modeling, employing one time series of forcing input and a simultaneous series of output response, has been described by Hunter and Theiler (1992). In this study, input is a single near-bed flow velocity or a sequence of velocities (velocity history) and output is suspended-sediment concentration.

The techniques applied in this paper are based on techniques that have been developed recently for forecasting nonlinear, nonperiodic, time series and spatial patterns (Livezey and A. G. Barnston, 1988; Farmer and Sidorowich, 1989; Sugihara and May, 1990; Casdagli, 1991; Casdagli et al., 1992; Rubin, 1992). The procedure requires splitting a time series into two parts. One part, the learning set, is used to learn the relations between input and output variables. The other part of the time series, the testing set, is used to test the predictive ability of relations determined from the learning set. Predictions are made by searching the learning set for conditions where the recent velocity history approximates the velocity history of a predictee from the testing set, and then using the concentration response of these nearest neighbors in the learning set to predict the concentration of the predictee. The general approach is outlined below; details of the computational algorithm are given by Casdagli (1991) and Rubin (1992).

The approach in this study is to relate concentration  $C$  to a sequence of velocities ( $U_t^n$  through  $U_{t+1-m}^n$ ) in the learning set by solving

$$C_t = a_0 + \sum_{i=1}^m a_i U_{t+1-i}^n \quad (1)$$

where  $m$  is the number of velocity measurements that are used to predict each  $C$ ,  $n$  is an integer, and  $t$  is time.

Eq (1) can be used for both linear and nonlinear modeling. For linear models,  $a_0$  through  $a_m$  are evaluated a single time for the entire learning set. The values of  $a_0$  through  $a_m$  are then substituted in eq (1), and each predictee velocity sequence from the testing set is substituted in eq (1) to predict concentration. The resulting model is a global, linear, multiple regression.

For nonlinear models,  $a_0$  through  $a_m$  are re-evaluated for each prediction using a subset of observations in the learning set. To solve eq (1) requires a minimum of  $m+1$  observations from the learning set, but any greater number of observations can be used. For each solution, the  $k$  observations that are most similar to each predictee sequence are used to solve eq (1). For example, if concentration is being related to a sequence of 2 successive velocity measurements, then to make a single nonlinear prediction, the entire learning set is searched to find the 3 sequences of 2 successive velocities that are closest to the predictee sequence. Eq (1) is used to solve for  $a_0$  through  $a_2$  using these 3 nearest-neighbor velocity sequences and the 3 corresponding observed concentrations in the learning set. Those values of  $a_0 \dots a_2$  and the velocities of the predictee sequence are then substituted in eq (1) to predict concentration.

Closeness of sequences is measured using least squares, and those sequences that are most similar to the predictee sequence are known as nearest neighbors. Ranking of neighbors can be visualized in two ways: (1) similarity of velocity sequences in a time series or (2) distance in velocity space. Determination of nearest neighbors can be visualized as matching a segment of velocity time series by sliding a  $m$ -point window through the time series (Fig. 1a). The most similar velocity sequences (evaluated by the squared differences between individual points in the two sequences) are defined to be the nearest neighbors. Alternately, nearest neighbors can be visualized by plotting each velocity sequences as a single point in velocity space. For a two-point sequence, the axes of velocity space are the two successive velocities (Fig. 1b). The nearest neighbor to a velocity sequence (represented as a single point) is the nearest point. Note this is computationally equivalent to the squared difference in individual dimensions. The three nearest neighbors to point A in Figure 1b are points B, C, and D.

Because  $a_0$  through  $a_m$  are re-evaluated for each prediction in nonlinear modeling, nonlinear relations between concentration and velocity can be learned and exploited for forecasting, even though eq (1) is purely linear. The advantage of using a small subset of observations (or small neighborhood) in the learning set is that the nonlinear structure of the data can be approximated most precisely using small linear pieces; the resulting model (called a local linear model) is thus more sensitive to the specific flow conditions (Fig. 2a). In contrast, the advantage of using all the observations in the learning set (a global model) is that noise reduction is greater (Fig. 2b). In the present study, we know that sediment response to forcing by velocity is nonlinear but are using the forecasting technique to learn if the system is noise-free enough that nonlinear models outperform linear models and if the nonlinearity is more complicated than  $U^n$  or  $|U|^n$ .

In addition to varying the number of nearest neighbors used to make forecasts, we can vary the number of velocity measurements (velocity history) used to predict each concentration. This velocity history can be as low as 1 point (where instantaneous concentration is related only to the simultaneously observed velocity), but increasing the velocity history to values greater than 1 can improve modeling accuracy in several ways. First, additional dynamic properties of the forcing flow can be identified. For example, with a single velocity observation, only velocity is known; with a second sequential velocity observation, acceleration can also be determined; and with a longer sequence of velocity measurements, wave shape can be identified.

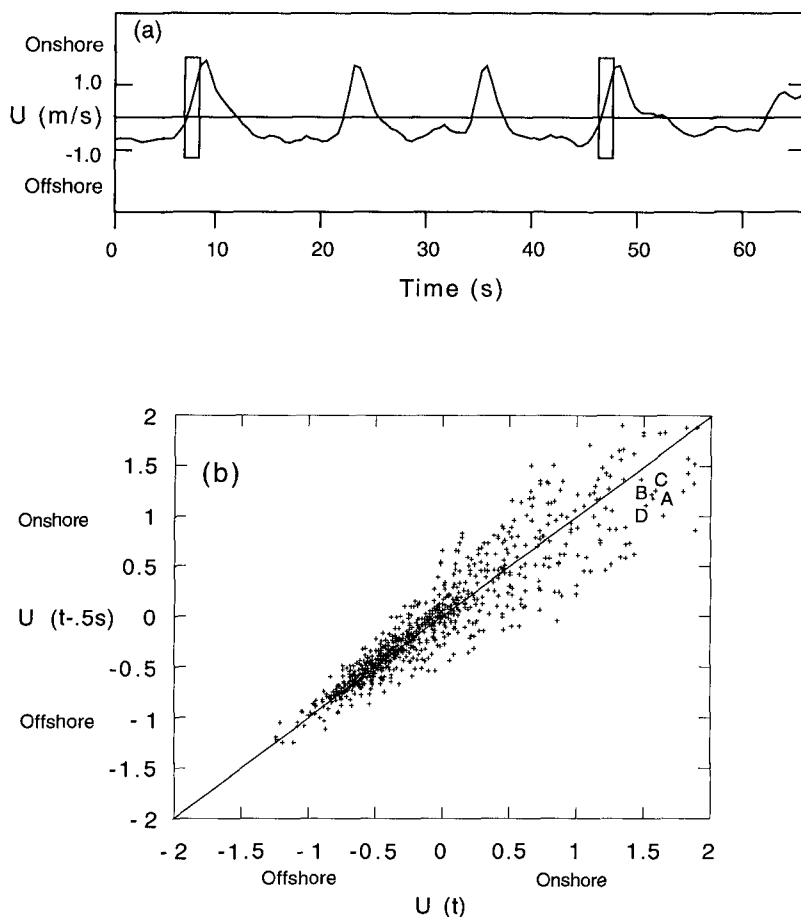

Figure 1. Two methods of visualizing selection of nearest neighbors. (a) Sliding a window the width of the velocity sequence through a time series to select similar sequences. (b) Distance in velocity space. In this case a two point sequence can be represented by a single point having coordinates given by velocity and velocity from the previous time step. The nearest neighbors to point A are points B, C, D. In both cases, the difference between sequences (a) or the distance between neighbors (b) is defined by  $\sum_{i=1}^m (U_{t+1-i} - U_{t_s+1-i})^2$ , where  $m$  is the number of points in the velocity sequence,  $U$  is the velocity in the testing set,  $U_l$  is the velocity in the learning set, and  $t$  and  $t_s$  are the times of the last point in the velocity sequences in the testing and learning set, respectively.

Figure 2. Comparison of modeling results for hypothetical steady flow transport data. Dots are data points; light lines are global linear model predictions; dark lines are local linear model predictions. For noise-free data (a), local linear models can learn the nonlinear relation between concentration,  $C$ , and velocity,  $U$ , by looking at local pieces of the curve, thereby outperforming a global linear model. For example, a threshold velocity for suspension can be predicted by a local linear model. For noisy data (b), the global linear model outperforms local linear models because of the greater noise reducing capability of the global model. These examples are based on one-dimensional models (concentration is predicted from a single value of velocity). In the case of surf-zone transport, concentration is predicted from a sequence of velocities, and the relations can not be displayed as easily. Instead, the capability of each model is quantified by the correlation coefficient for the predictions.

Second, because of the time required for settling to occur, concentration in a decelerating flow depends on previous velocities (those that caused suspension of sediment that has not yet had time to fall to the bed). If the velocity history used to predict concentration is extended too far into the past, however, forecasts become degraded because the early velocities have increasingly little relevance to the later concentration.

In applying these forecasting techniques, a large number of models are evaluated, each employing a different number of nearest neighbors  $k$ , a different number of velocity measurements  $m$  used for each forecast, a different exponent of the velocity  $n$ , or a different time from the end of the velocity sequence to the time for which concentration is forecast (lag). The models are evaluated by the correlation coefficient between predicted and observed concentrations.

## FIELD EXPERIMENT

Sediment suspension was measured during a large cooperative field experiment investigating the morphologic response of the nearshore to storms conducted at the U. S. Army Corps of Engineers Field Research Facility (FRF) at Duck, North Carolina (see Mason et al., 1984, for a description of the experiment). The FRF is located on a long straight beach with well-sorted fine sand ( $\sim 0.15$  mm median diameter) in the offshore.

As part of this experiment, the U. S. Geological Survey deployed an underwater sea sled (Sallenger et al., 1983) equipped with instruments to measure

waves, currents, sediment suspension, and profile change. Waves were measured using a pressure sensor and horizontal currents were measured at 3 elevations (0.5, 1.0, and 1.75 m above the bed) using 2.5-cm-diameter electromagnetic current meters. Suspended-sediment concentration was measured at 5 elevations (0.10, 0.13, 0.19, 0.31, and 0.61 m above the bed) using optical backscatter sensors (OBS, Downing et al., 1981). The nearshore profile was measured using an infrared range-finder sighting on prisms mounted on a 10 m mast as the sled was pulled offshore and onshore by a winch and lines and a system of blocks. The sled was moved to measurement locations where 34.1 minutes of data were collected at 2 Hz from each sensor.

## RESULTS AND DISCUSSION

Data reported in this paper were collected at one mid-surf-zone station, 100 m offshore, during the waning stages of a large extra-tropical cyclone on October 13, 1982. Offshore significant wave height was 1.6 m, and peak period was 12 s during data collection. Significant wave height at the measurement location was 1.7 m (water depth of 3.6 m). Mean currents at 0.5 m above the sea bed were directed obliquely offshore, with a 0.11 m/s cross-shore component and a 0.12 m/s longshore component. Significant orbital velocities at 0.5 m above the bed were 0.85 m/s in the cross-shore direction and 0.36 in the longshore direction. Waves were asymmetrical, with stronger, short-duration onshore flows and weaker, longer-duration offshore flows. Maximum cross-shore velocity was 2.12 m/s, directed onshore. The bed configuration was calculated to be within the planar-bed regime of Komar and Miller (1975).

### *Using instantaneous velocity to predict suspension*

A time series of suspension and horizontal water velocity (Fig. 3) shows intense suspension (referred to as suspension events by Downing, 1983; Jaffe and Sallenger, 1992) occurs irregularly. A scatter plot of concentration 19 cm above the sea bed versus cross-shore velocity (squared, to remove the sign and to make the relation between flow and concentration more in agreement with what is known for steady flow) 50 cm above the sea bed shows a lack of correlation between suspended sediment concentration and instantaneous velocity (Fig. 4). High concentrations can occur at zero velocity because sediment suspended earlier has not yet settled. Low concentrations can occur at high velocities because sediment suspended at the bed has not yet mixed high enough into the water column to reach the elevation of the sensor. The correlation between instantaneous concentration and cross-shore velocity squared is very poor, with a correlation coefficient of -0.02. Correlations between the instantaneous concentration and velocity to a higher power are also poor (Fig. 5). Other instantaneous velocity measures, longshore velocity or speed, are also poor predictors of suspension (Jaffe and Rubin, in preparation; Jaffe, 1993). More than instantaneous velocity is needed to predict sediment suspension.

### *Acceleration as a Predictor for Suspension*

Acceleration/deceleration effects on bottom turbulence have been observed by other researchers. Increased turbulence during flow deceleration was observed by Schubauer and Skramstad (1947) in the laboratory. Gordon (1975) found increased Reynolds stresses during deceleration in tidal flow (Fig. 6). Hanes and Huntley (1986) and Osborne and Greenwood (1993) measured increasing suspension during

Figure 3. Time series of cross-shore velocity ( $U$ ) and longshore velocity ( $V$ ) at 50 cm above the sea bed, and suspended sediment concentrations ( $C$ ) at 4 elevations above the sea bed (13, 19, 31, and 61 cm above the sea bed). For this time series, the testing set used in the modeling is the first 6.66 minutes (800 points) of the time series. The learning set is the measurements from 6.66 minutes to 34.1 minutes (3295 points). Intensity of suspension decreases with elevation above the bed. Note the short-lived periods of intense suspension (suspension events) throughout the record.

Figure 4. Scatter plot of concentration at 19 cm above the sea bed versus the cross-shore velocity squared at 50 cm above the sea bed. The correlation coefficient for a linear regression (global model) is -0.02. Note the high concentrations occurring at low velocities.

Figure 5. Correlation coefficient versus exponent of velocity. Correlation coefficients are for a linear model using instantaneous velocity raised to a power to predict concentration at 19 cm above the bed. The velocity and absolute value of velocity raised to a power are plotted for odd powers. Linear models using instantaneous velocity as input are not able to predict concentration well.

Figure 6. Reynolds stress versus flow speed for flood tidal flows. Note that stresses are greater during decelerating flow than accelerating flow for the same speed. Figure from Gordon, 1975.

flow deceleration over bedforms. Conley and Inman (1992) found sediment pluming events (in which sediment was lifted on the order of 10 cm into the water column) occurred during the decelerating phase of some waves over plane beds (Fig. 7).

We tested to determine if suspension was correlated with instantaneous acceleration. Sediment concentration was not well correlated ( $r=0.12$ ) with acceleration at the same instant (Fig. 8). Higher concentrations tended to occur during decelerating flow than accelerating flow. Onshore accelerating flows tended to have higher concentrations than offshore accelerating flows. Highest concentrations occurred during decelerating onshore flows under the wave crest. High concentrations also occurred at low accelerations and after flow reversals. Similar to instantaneous velocity, instantaneous acceleration was a poor predictor for suspension. However, the tendency for higher concentrations during flow deceleration indicates that it is important to include acceleration in the input for a model of sediment suspension.

#### *Using a Sequence of Velocities to Predict Suspension*

A velocity history contains more information about the state of the flow (and possibly about forces causing suspension) than a single velocity. In the previous two sections, instantaneous velocity and acceleration were found to be poorly correlated with suspension. More information is contained if two velocity points are used to define the flow (Fig. 1b). For example, a two-point velocity sequence contains information about magnitude and direction of instantaneous velocity and magnitude and sign of acceleration. Seven different flow regimes can be delineated by regions in a velocity space plot of a two-point velocity sequence (Fig. 9a). The diagonal line in Figures 1b and 9a indicate no accelerations; points off this line indicate either accelerating or decelerating flow. Contours of concentration plotted in two-point velocity space (instantaneous velocity and velocity 0.5 seconds earlier) are ordered and show that high concentrations occurred for some sequences of two velocities (Fig. 9b). For example, high concentrations occurred for decelerating strong onshore flows (A in Fig. 9b).

Longer velocity histories give information about persistence of strong flows, acceleration history, flow reversals, and wave shape, all of which could be important in predicting suspension. A representative time series of cross-shore velocity (Fig. 10) illustrates how irregular waves have different velocity sequences even where instantaneous velocities and accelerations are similar.

To test whether more information about suspension is contained in earlier flows, differing lengths of velocity histories were used as input to models. Correlations increased as more velocity history was included to relate velocity to suspension until reaching a maximum of 0.42 at a velocity history length of about one wave period. Correlation coefficients for nonlinear models were maximum (0.48) at about one-half wave period of velocity history (Jaffe and Rubin, in preparation; Jaffe, 1993). The increase in predictability primarily results from a more complete description of flow conditions causing suspension. Improved predictions were also the result, in part, of including a lag effect.

#### *Lag between Velocity and Suspension*

Because modeled concentration was measured 19 cm above the sea bed, a lag between the flow inducing suspension and the concentration response would be expected (to allow time for sediment to be carried up into the water column). Models incorporating such a lag performed better than models that did not. For a linear

Figure 7. Sediment plume rising above the bed during decelerating flow under a wave crest. Figure from Conley and Inman, 1992.

Figure 8. Concentration at 19 cm above the bed versus cross-shore flow acceleration. Triangles are onshore flows; squares are offshore flows; crosses are for periods where flow reversed. Highest concentrations occurred during decelerating (negative sign) onshore flows.

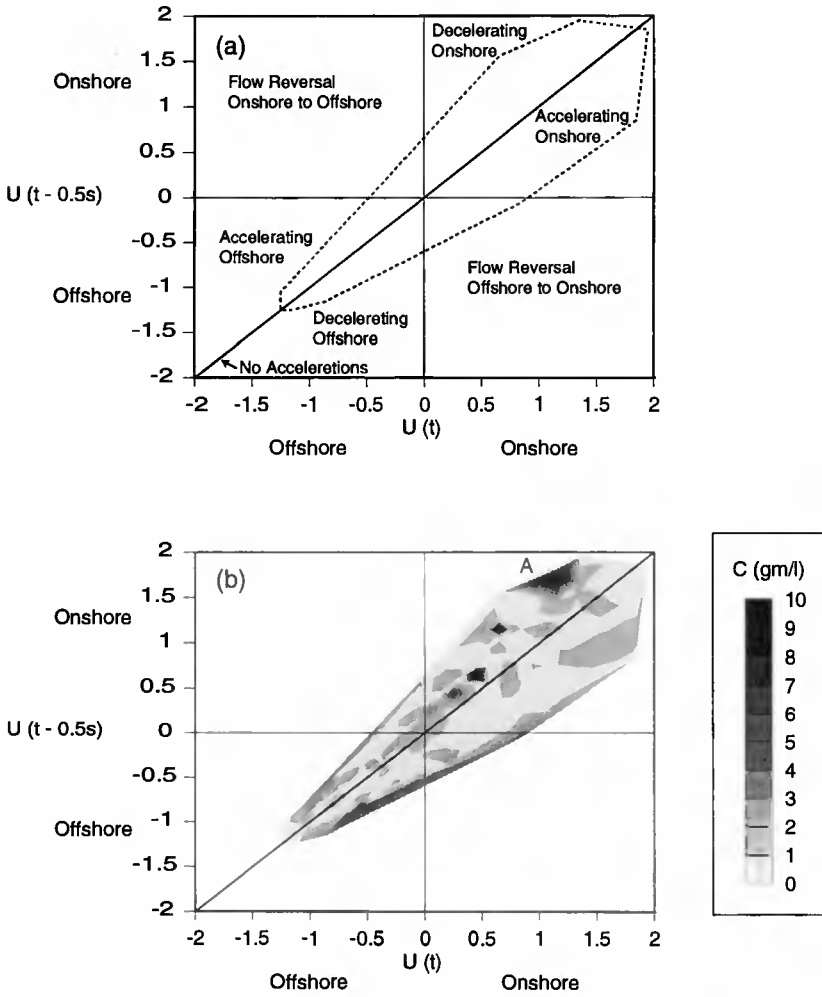

Figure 9. (a) Seven different flow regimes in a velocity space plot of a two-point velocity sequence (b) Concentration contours plotted in velocity space (instantaneous velocity and velocity from the previous time step). See Figure 1b for data density. High concentrations occurred for decelerating strong onshore flows (e.g., point A).

model with instantaneous cross-shore velocity squared as input, peak performance was obtained using velocity to predict concentration 1.5 seconds later (Fig. 11). This lag increased with elevation above the bed, increasing to 8.5 seconds at 61 cm above the bed (Jaffe and Rubin, in preparation; Jaffe, 1993). Nonlinear models and models using a velocity history also performed better when including a lag. An additional cause for a lag would be a sediment pick-up response lagging the velocity. This could occur if turbulence at the sea bed took time to build or its structure changed with time (e.g., response to flow reversal).

Figure 10. Time series of cross-shore velocity at about 300 s into the record (Fig. 3) illustrating why a velocity history is necessary to fully specify flow conditions. Points A, B, and C have similar instantaneous velocities, but different accelerations and are preceded by different velocities.

Figure 11. Correlation coefficient versus lag time between input (a single cross-shore velocity squared) and output (concentration 19 cm above the sea bed). A positive lag is concentration later than velocity. Models perform better when a lag time is included primarily because they account for the time it takes to mix sediment up into the water column.

*Best model*

Incorporating lag and velocity history into a nonlinear model gave the best predictions for suspension. Addition of nonlinearity allows differing relationships between velocity and concentrations for different velocity sequences (e.g., flow under differing wave shapes). The optimal model (correlation coefficient of 0.58) used 3 seconds of velocity history (approximately one-quarter wave period) and a 1.5 second lag to predict suspension. This nonlinear model was able to predict the suspension event at 312 seconds (Fig. 12). Just as important, suspension events were not predicted for waves between 320 and 350 seconds.

Mean concentration and cross-shore suspended sediment flux were well predicted by this model. Observed and predicted mean concentration was 1.12 and 1.11 gm/l, respectively. Observed and predicted cross-shore flux at 19 cm above the bed was 37.1 and 34.3 gm/m<sup>2</sup>/s onshore, respectively. The good agreement between predicted and observed flux was largely due to good predictions for high concentration. Low concentrations were not predicted as well; but, because their phasing relative to the wave orbital velocity is more random than high concentrations (Jaffe and Sallenger, 1992), errors in predictions were diminished by fluxes in opposite directions canceling resulting in a low contribution to net flux.

Figure 12. Time series of cross-shore velocity 50 cm above the sea bed and predicted and observed suspended sediment concentration 19 cm above the sea bed. Concentrations were predicted using the best model found through exploratory modeling, a local linear model with an input of 3 seconds of velocity squared, decimated to one point every 1.5 seconds, and a time lag of 1.5 seconds. This nonlinear model was able to predict high concentrations that occurred at 310 seconds into the record. Intermediate concentrations before and after highest concentrations are not well predicted. Correlation coefficient for 794 predicted/observed values is 0.58.

## CONCLUSIONS

- (1) Instantaneous horizontal water velocity, or velocity to a power, does not contain enough information to predict suspension in the surf zone. Unlike steady uniform flow, more than one velocity is necessary to parameterize the pick-up and mixing of sediment into the water column.
- (2) Instantaneous acceleration predicts suspension better than instantaneous velocity, but neither of the instantaneous models performs as well as models using a sequence of velocities. A sequence of past velocities (a velocity history) improves predictions of suspension by more fully specifying flow conditions (including accelerations and changes in accelerations) responsible for suspension.
- (3) Suspension in the future is better predicted than suspension at the same instant as velocity measurements. These lags are largely due to the time for an observed flow event to effect the bed and mix sediment upward.
- (4) Nonlinear models relating suspension to velocity do better than linear models using the same velocity history. Nonlinear models are able to exploit relationships between suspension and velocity history that change for different wave shapes. For the environmental conditions of this study, the optimal model used 3 seconds of velocity history (approximately 1/4 wave period) and a 1.5 second lag to predict suspension.

## ACKNOWLEDGMENTS

BEJ would like to thank his Thesis committee, Gary Griggs (Chair), Bob Anderson, and Ed Thornton for their help during the early stages of this work. This manuscript was improved by the reviews of Guy Gelfenbaum and John Dinger. We wish to thank the personnel at the Army Corps of Engineers Field Research Facility in Duck, North Carolina for their excellent help with the experiment.

## CHAPTER 152

### BEACH PROFILE SPACING: PRACTICAL GUIDANCE FOR MONITORING NOURISHMENT PROJECTS

Timothy W. Kana, Ph.D., and Christopher J. Andrassy, P.E.<sup>1</sup>

#### ABSTRACT

A search of the literature shows there are no established standards for the spacing of profiles for postnourishment monitoring. One standard that appears to apply in the United States relates to construction surveys. Most recent nourishment projects use prefill and postfill profiles at 100-foot (ft) [ $\sim 30$  meter (m)] spacing for payment purposes. Rarely is this close spacing duplicated in subsequent monitoring surveys. How accurately does such spacing reflect the actual volume of fill remaining?

Four sets of closely spaced profile surveys to closure were performed over a two-year period following the 1991 Hunting Island, South Carolina, nourishment project. Fill volumes remaining within the project area were computed to closure depth using the average-end-area method. The complete dataset at 100-ft (30 m) spacing provided the basis of comparison. Volume calculations were performed for the possible combinations of profiles at greater spacings up to 1,200 ft (365 m). The normalized results show the expected increase in error as profile spacing increases. However, the variation was generally less than  $\pm 3$  percent up to spacings of 500 ft ( $\sim 150$  m). At 1,000 ft ( $\sim 365$  m), the error band spanned 20 percent of the project volume. The Hunting Island dataset provides guidance for minimum profile spacing for nourishment projects with highly varying fill sections or irregular shoreline morphology. Spacings of 400-500 ft (120-150 m) provided a reasonably accurate result. Accuracy was greatly reduced at longer spacings. Longer nourishment projects, involving less variable fill volumes, likely can be evaluated at somewhat longer spacing with comparable accuracy. However, a disadvantage of surveying only the minimum number of profile lines is the error introduced if even one line has to be discarded from the dataset because of field survey errors.

**INTRODUCTION**

A critical aspect of beach nourishment is postproject monitoring. Periodic surveys are typically performed to determine the amount of fill remaining and establish quantitative loss rates. Beach and inshore profiles--shore-perpendicular transects from the backshore to depth of closure--are the principal database. There are no established standards for the spacing of profiles. A search of the literature shows a wide range of profile spacing, sometimes dictated by project length and economics, other times a function of the interest of the designers and owners. The more profiles obtained, the more detailed and, presumably, accurate the result. One standard that appears to apply in the United States relates to construction surveys. Most recent nourishment projects use prefill and postfill profiles at 100-foot (ft) [ $\sim 30$  meter (m)] spacing for payment purposes. Rarely is this close spacing duplicated in subsequent monitoring surveys.

Example profile spacings are given in Table 1. A typical spacing for routine beach monitoring or postproject evaluation appears to be 1,000 ft ( $\sim 300$  m), or greater. The State of Florida, for example, has one of the best established networks of profiles which are monitored at a frequency of less than once every three years (Bokuniewicz and Tanski, 1991). The State

**TABLE 1.** Typical profile spacing for beach monitoring. [Sources: Bokuniewicz and Tanski (1991), Kana and Andrassy (1993), Stauble and Grosskopf (1993).]

• Pre and Post Construction:	100 ft (30 m)
• Project Monitoring:	> 1,000 ft (300 m)
• Statewide Surveys:	
◦ Florida	1,000 ft (300 m)
◦ South Carolina	1,500 ft (450 m)
◦ New Jersey	6,500 ft (2,000 m)
◦ New York (proposed)	2,000 ft (600 m)
<i>Example Projects</i>	
Myrtle Beach (SC)	1986 750 ft (semiannual)
Ocean City (MD)	1988 1,000 ft (quarterly)

of South Carolina surveys wading depth profiles on  $\sim 1,500$  ft (450 m) spacing twice per year. The 1986 Myrtle Beach (South Carolina) nourishment project (Williams and Kana, 1987) and the 1991 Ocean City (Maryland) project (Stauble and Grosskopf, 1993) have been monitored yearly or more frequently using profiles at 700-1,000 ft (215-300 m) spacing, respectively. How accurately does such spacing reflect the actual volume of fill remaining?

To investigate that question, the authors performed four sets of profile surveys over a two-year period following the 1991 Hunting Island, South Carolina, nourishment project. Hunting Island is a 4.2-mile (7-kilometer) long barrier island bounded by large tidal deltas (Fig. 1). Background erosion rates are exceedingly high at around 25 cubic yards per foot per year (cy/ft/yr) [62.5 cubic meters per meter per year

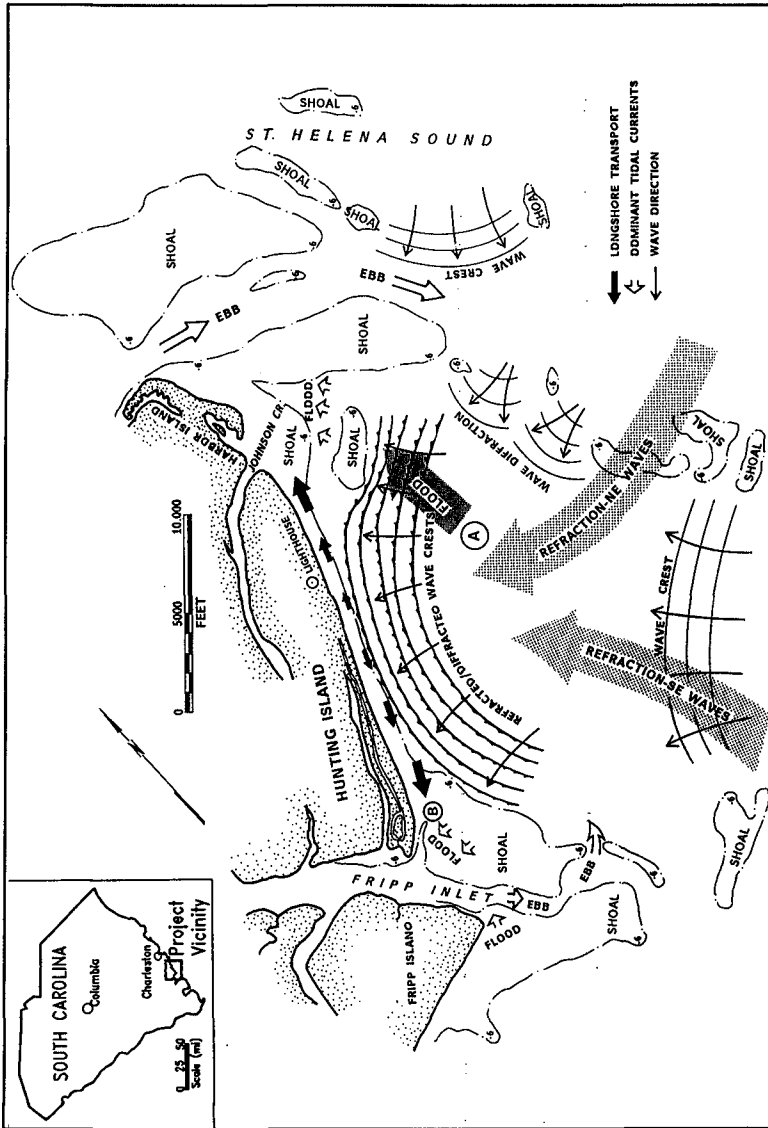

FIGURE 1. General model of coastal processes producing refraction and diffraction around shoals and sand transport away from the center of Hunting Island. Shoals are defined by the -6 ft (-1.8 m) mean low water contour as depicted on U.S. National Ocean Survey Chart No. 11513 (after CSE, 1990).

( $m^3/m$ ) (USACE, 1977; CSE, 1990). Historical surveys in connection with earlier nourishment projects indicate that as the center of the island erodes, sediment is transported toward both ends of the island. This pattern of sediment transport appears to be controlled by wave refraction and diffraction around and through ebb-tidal delta shoals associated with St. Helena Sound, Johnson Creek, and Fripp Inlet.

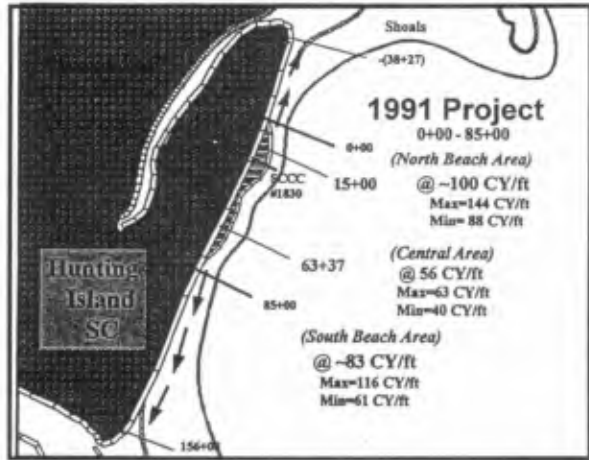

Hunting Island has been nourished five times since 1968. The first four projects were engineered by the U.S. Army Corps of Engineers and were completed in 1968, 1971, 1975, and 1980 (Table 2). The 1991 project was sponsored by the South Carolina Department of Parks, Recreation and Tourism with all funding by the state. The project involved excavation of sediment from an offshore borrow area by hydraulic dredge and placement along an ~8,500 ft (2,600 m) reach in the center of Hunting Island. Mean grain size on the beach averaged 0.20 millimeter (mm) diameter before the 1991 project. Grain size in the borrow area averaged 0.22 mm diameter. The contractor (Great Lakes Dredge & Dock Company) mobilized equipment the first week of February 1991 and completed the project on 24 March 1991, 44 days after pumping began. The pay volume was based on surveys in the borrow area with a total pay volume not to exceed 755,000 cy as per terms of the contract.

**TABLE 2.** Beach nourishment projects along Hunting Island. [Sources: USACE (1977); CSE (1991).]

[\*NOTE: USACE stations for the 1968-1980 projects run north and south from the vicinity of the lighthouse (e.g., 50+00N is 5,000 ft north; 97+00S is 9,700 ft south of the lighthouse). Total length of Hunting Island is about 21,000 ft ( $\pm 4$  miles), ranging from  $\pm 70+00N$  to  $\pm 140+00S$ .]

Project*	Construction Dates	Volume (cy)	Limits of Placement	Net Unit Cost (\$/cy)	Total Cost (\$)	
1968	Feb-Dec'68	750,000	50+00N to 50+00S*	0.58	435,178	
1971	May-Dec'71	761,324	50+00N to 50+00S	0.70	534,000	
1975	Apr-Jun'75	612,974	60+00N to 30+00S	1.58	971,540	
1980	Jan-May'80	1,412,692	24+60N to 97+00S	1.60	2,267,201	
	Subtotal	3,536,990		\$1.19/cy	\$4,207,919	
1991	Feb-Mar'91	757,644	7+00 to 85+00	\$3.80/cy	\$2,876,250	
<b>GRAND TOTAL</b>				<b>4,294,634</b>	<b>\$1.65/cy</b>	<b>\$7,084,169</b>

The 1991 project concentrated the fill at two localities (Fig. 2). One bulge in the fill was constructed along a recreational beach access ~1.4 miles (2.3 km) from the north end of the island. The second bulge was centered at the midpoint of the island. Unit fill volumes ranged from a low of 40 cy/ft (100 m<sup>3</sup>/m) between the two "bulges" to highs of about 140 cy/ft (350 m<sup>3</sup>/m) and 110 cy/ft (275 m<sup>3</sup>/m) at the north and south ends of the project, respectively.

### Profile Surveys

Profiles at 100-ft (30-m) spacing were

surveyed to the estimated depth of closure along the Hunting Island project area. Closure depth was defined based on negligible profile change for available surveys, as well as morphological evidence of nearly flat slopes with distance from shore and the initial presence of mud at the surface of the substrate (Fig. 3). Closure depths range from 11 ft to 12 ft (3.3 m to 3.7 m) below mean sea level in this mesotidal setting [mean tide range equals 6.7 ft (2.05 m)]. Profiles were analyzed for unit-volume change. Fill volumes remaining within the project area were computed the traditional way by extrapolating unit volumes after each survey over representative shore lengths using the average-end-area method. Four reference lenses were developed as follows:

- 1) *Backshore to mean high water* — At Hunting Island, this is represented by the +10 ft to +3.2 ft (+3 m to +1 m) NGVD\* contour and corresponds to the dry beach. \*NGVD — National Geodetic Vertical Datum of 1929 which in South Carolina is approximately 0.5 ft (0.15 m) below present mean sea level.
- 2) *Intertidal beach* — From mean high water (MHW) to mean low water (MLW) [-2.2 ft -0.67 m) NGVD].
- 3) *Wading zone* — From MLW to -5.0 ft (-1.5 m) NGVD.
- 4) *Lower foreshore* — From -5.0 ft NGVD to -12.0 ft (-3.65 m) NGVD.

FIGURE 2. Vicinity map of the 1991 Hunting Island nourishment project fill limits between station 0+00 and 85+00 (stationing in feet divided by 100).

FIGURE 3. Representative profiles to closure along North Beach and South Beach before and after the March 1991 nourishment (after Kana and Andrassy, 1993).

In addition to the above contour boundaries, certain cross-shore boundaries were prescribed in the analysis. In general, the starting distance for volume calculations is at the prenourishment scarp in the backshore. The seaward limit is generally prescribed at a point within 100 ft seaward of the base of the fill.

Unit volumes (quantity of sand per unit length of shoreline between given contour intervals) and unit-volume changes between prenourishment and postnourishment surveys were computed for all profiles. The variation in unit volumes before and after nourishment within the Hunting Island project area is given in Figure 4. With minor exceptions, the quantity of sand in the profile was less than 200 cy/ft (500 m<sup>3</sup>/m) [to -12.0 ft (-3.65 m) NGVD] before nourishment (February 1991) and ranged from 250 cy/ft (625 m<sup>3</sup>/m) to 350 cy/ft (875 m<sup>3</sup>/m) after nourishment (April 1991). North Beach and South Beach, by design, received the most fill. Erosion rates for the 1991 project as well as earlier projects have been exceedingly high. North Beach, in general, retained the most sand. Higher loss rates are evident at the ends of the project, particularly south of station 73+00. The average trend in unit sand volume by contour interval, retained within the project area since nourishment, is illustrated in Figure 5. These loss rates have averaged 20-25 cy/ft/yr (50-62.5 m<sup>3</sup>/m/yr) and are nearly the same as loss rates reported after the 1971 and 1975 beach fills (USACE, 1977).

FIGURE 4. Variation in sand volume per foot of shoreline by profile station and date within the project area. Computation boundaries are from the foredune-scarp to -12.0 ft (-3.65 m) NGVD.

**FIGURE 5.** Average unit-volume beach change since nourishment (February 1991) as a function of contour interval\* within the Hunting Island project area (stations 3+42 to 83+31). Note: Higher loss rate for lower beach lenses is thought to be related to variations in grain size along the profile. After Kana and Andrassy (1993).

Interestingly, the loss rate for the upper beach lenses was much lower than the underwater lenses. The dry beach to MHW (lens 1) within the project area retained 70 percent of the fill through April 1993. The intertidal beach (MHW to MLW) retained about 45 percent of the fill two years later. These two zones comprise the primary recreational zone of the beach. In contrast, the underwater lenses (mean low water to closure) retained only 27 percent by April 1993. These cross-shore variations in the rate of beach fill losses produced a steepening of the mean profile slope along the intertidal beach (see Fig. 3). Krishnamohan et al. (1993) theorize this results from the presence of a minor coarse fraction in the borrow sediments which was selectively deposited along the backshore during construction.

**Profile Spacing Criteria**

It is apparent profile spacing can increase for a given accuracy as the variance of individual profile volumes approaches the mean profile volume of a dataset. This is illustrated conceptually in Figure 6. The ideal case is where standard deviation of unit volume change is zero and all profiles in the dataset yield the exact mean volume

change. In this case, one profile line can accurately define the performance of the nourishment project. For this to occur in the field is nearly impossible, however, given the uncertainty in placement of underwater volumes, variations in sediment quality, discharge rates, and the inherent natural variation in profile geometry. More commonly, the initial condition after nourishment will show considerable variations in actual volumes, even where fill volumes are designed to be uniform.

**FIGURE 6.** Conceptual model of the relationship of profile volume variance to profile spacing. For projects where the variance of profiles is high, more closely spaced are required to yield the "true" volume change.

The Hunting Island 1991 profile dataset, in addition to yielding a certain but unknown variance due to normal problems in controlling fill placement, included a planned variation in fill volumes. Thinnest sections designed for the center reach of the project area involved an average of only 56 cy/ft (140 m<sup>3</sup>/m). In contrast, the north and south bulges involved average sections of 100 cy/ft (250 m<sup>3</sup>/m) and ~83 cy/ft (207 m<sup>3</sup>/m), respectively, as shown in Figure 2. This yielded a standard deviation in profile volume change for pre and postconstruction surveys (all profiles) of approximately  $\pm 25$  cy/ft (62 m<sup>3</sup>/m). Profile variance is also reflected in the unit volumes from station to station (see Fig. 4).

### Postproject Surveys and Profile Analysis

Pre and postnourishment surveys at 100 ft (30 m) spacing provided the basis for the initial fill volume calculation. For the 1991 Hunting Island project, payment was based on borrow area surveys rather than beach surveys. Results in the borrow area confirmed an excavation volume of 757,644 cy (579,219 m<sup>3</sup>). The initial postconstruction beach surveys confirmed an in-place volume of 715,766 cy (547,209 m<sup>3</sup>) (CSE, 1991a). This latter volume represents 94.5 percent of the excavated quantity and is considered a satisfactory result based on the confirmed mud content of 5 percent in the borrow area (CSE, 1991b).

For purposes of evaluating project performance using various profile spacings, it was assumed the entire set of profiles at 100 ft (30 m) spacing for each of three postproject surveys yielded the true sand volume change on the beach compared to pre-nourishment conditions. Volume calculations were then performed for the possible combinations of profiles at greater spacings up to 1,200 ft (365 m). There are two possible combinations using profiles at 200-ft (61-m) spacing (i.e., odd-numbered stations and even-numbered stations). At 300-ft (91-m) spacing, there are three combinations and so on up to 1,200-ft (365-m) spacing. Adjacent unnourished areas were also surveyed but at a minimum profile spacing of 500 ft (152 m). By convention, the end surveys within the project area were applied in each analysis to provide a uniform shoreline length for comparison. Thus, the two profiles at each end of the project will not necessarily be spaced the same distance as the chosen profile spacing. Because of earlier surveys at variable spacing and a desire to match profile lines, certain stations were offset slightly from 100 ft (30 m) spacing. In practice, this is common because of obstructions which prevent backshore monuments from being placed at uniform distances along the shoreline.

Table 3 and Figures 7 and 8 provide results of the analysis. It can be seen that as the profile spacing increases, the range of computed sand volume changes also increases. As Table 3 shows, the normalized volume change (as a percentage of the result for all profiles in April 1991) varied by only  $\pm 3$  percent up to spacings of 500 ft. At 800 ft, the error band increased to about  $\pm 5$  percent; at 1,000 ft, the error band spanned about  $\pm 10$  percent.

It can also be seen the percentage error reduces by April 1993 (two years post-project) when compared to the original fill volume. However, this also reflects the smaller volume being compared. If the April 1993 data are normalized against the result for all profiles in April 1993, the percent difference at 1,000-ft spacing is on the order of  $\pm 12$  percent. For a project involving about one-half million cubic yards (cubic meters), this equates to a possible range from 440,000 cy (cm) to 560,000 cy (cm), computed from various profile spacings.

**TABLE 3.** Sand volume change as a function of the number of profiles for the Hunting Island project area (stations 3+42 to 83+31). Transition profiles 0+00 to 3+42 and 83+31 to 85+00 are excluded in profile spacing analysis, but are included in references to the initial fill volume in this paper. [\*Compared to Feb'91 pre-nourishment; volumes in cy.]

Profile Spacing (ft)	Change in Sand Volume*			% Apr'91 — All Data		
	Apr'91	Nov'92	Apr'93	Apr'91	Nov'92	Apr'93

FIGURE 7. Computed sand volume changes since nourishment as a function of profile spacing for April 1991 (upper), November 1992 (middle), and April 1993 (lower) in the project area (stations 3+42 to 83+31). Averages are arithmetic and are not weighted for minor variations in profile spacing or for the fact that the ends of most profile pairs will not equal the nominal spacing, as explained in the text. After Kana and Andrassy (1993).

FIGURE 8. Normalized volume changes as a function of profile spacing for a post-nourishment survey of 90+ lines to closure at Hunting Island, South Carolina.

DISCUSSION

The Hunting Island dataset is somewhat unusual because of the project's short length and highly variable fill volumes (by design). A longer project with uniform fill volumes could probably be monitored at longer spacings. But in areas where rhythmic features are common along the shoreline (e.g., shoreline salients and offshore bars) or fill volumes are variable, the Hunting Island results provide some rules of thumb. In this case, profile spacings of 400-500 ft (120-150 m) appear to represent the practical limit for accurate results. Given the common uncertainty in performance because of no or few previous projects at most nourishment sites, initial monitoring should be performed in as much detail as possible. Errors of a few percentage points or less should be a requirement for all postproject surveys. Consider that a common goal of nourishment is restoration of a dry sand beach. The authors' experience suggests the upper portion of the profile which should contain the visible high-tide beach represents a small part of the profile volume. Variations in sand volume of 20-30 percent (the possible result from surveys involving large profile spacings) could mean the difference between a project yielding a viable high-tide beach and one that is not viable. With considerable debate regarding nourishment project performance, detailed profiling is one of the few means for objective analysis. Monitoring should favor as detailed a profile survey as possible.

Few datasets are available to develop any firm guidelines for profile spacing yet, but based on results of the recent Hunting Island nourishment project, it would appear profile spacings of less than 500 ft are required for a confident analysis of performance. The authors believe this will hold true for most large nourishment projects.

The suggested rule of thumb should be tested with additional datasets as they become available, but it provides a reasonable guide for most projects. Obviously, the main advantage of minimizing the number of profiles is lower expense of surveys. However, a disadvantage of surveying the fewest lines possible is the error due to profile spacing introduced if even one transect has to be discarded from the dataset because of field survey error.

## ACKNOWLEDGMENTS

This study was sponsored by the South Carolina Coastal Council, South Carolina Department of Parks, Recreation and Tourism, and the U.S. Army Corps of Engineers, Coastal Engineering Research Center (CERC) (contract DACW39-92-C-0110). Field surveys in 1991 were performed by Great Lakes Dredge & Dock Company.

## CHAPTER 153

# WATERTABLE OVERHEIGHT DUE TO WAVE RUNUP ON A SANDY BEACH

Hong-Yoon KANG, Peter NIELSEN<sup>1</sup> and David J. HANSLOW<sup>2</sup>

### Abstract

Watertable overheight in beaches due to waves is investigated through laboratory experiments and field tests. Infiltration from wave runup onto the exposed beach creates a significant lifting of the coastal watertable. The infiltration velocity distribution is obtained from both the laboratory and field conditions. The inland overheight for the steady state (regular waves and no tide) is found to be  $0.62 \tan \beta \sqrt{H_o L_o}$  and that for the unsteady state (irregular waves) is estimated as  $0.55 \tan \beta \sqrt{H_{oRMS} L_o}$ .

### Introduction

The time averaged watertable in beaches stands considerably above the mean sea level due to waves and tidal effects. This is of practical importance for the stability of coastal structures, for the operation of coastal sewage disposal systems and for the accretion/erosion of the beach. The elevated watertable in coastal areas also influences hydrology, e.g., agricultural and soil conservation activities. The main factors for the overheight above the mean sea level are waves and tides as seen in Figure 1 (Nielsen et al. 1988; Aseervatham et al., 1993; Kang and Nielsen, 1994).

This figure shows the watertable variation in wells just landward of the high water mark on two beaches north of Sydney. Both beaches are subject to the same tidal influences, but only Palm beach is exposed to the ocean waves while Pittwater beach is protected from wave action. The data clearly demonstrates that the wave activity is a significant factor affecting the coastal

<sup>2</sup>Coast and Flood Policy Branch, NSW Public Works, Sydney 2001, Australia

watertable elevation. In this case, the waves raise the watertable by up to 0.7m compared to the protected beach. The overheight inside the protected beach is due to the tide acting on a sloping beach face as explained by Nielsen (1990).

**Figure 1.** Field data showing the significant lifting of the watertable due to waves and tides.

This paper describes the infiltration of water due to wave runup which creates a significant lifting of the coastal watertable. The steady state asymptotic inland overheights are investigated under controlled wave conditions with different beach sands in a wave flume without tides. This overheight is compared with the field data.

### **Infiltration from wave runup**

The effect of infiltration due to wave runup is clearly visible from the measured watertable profiles shown in Figure 2. The watertable profiles exhibit humps due to wave runup infiltration between the shoreline and the runup limit. These humps are particularly noticeable during the rising tide.

To model the watertable in the area between the shoreline and the runup limit, a modified Boussinesq equation (1) which includes the runup infiltration effect must be used

**Figure 2.** Watertable profiles measured on the rising tide at Kings Beach, Queensland, Australia.

$$\frac{\partial \eta}{\partial t} = \frac{KD}{n} \frac{\partial^2 \eta}{\partial x^2} + \frac{U_f(x,t)}{n} \tag{1}$$

where  $\eta$  denotes the watertable height averaged over a few surf beats,  $K$  is the hydraulic conductivity,  $D$  the aquifer depth,  $n$  the specific yield and  $U_f$  the infiltration velocity. For pure regular waves forcing without tidal effects, the situation may be considered quasi-stationary. Thus equation (1) becomes

$$\frac{\partial^2 \eta}{\partial x^2} = - \frac{U_f(x)}{KD} \tag{2}$$

This steady situation is achieved experimentally in a wave flume.

From these equations,  $U_f$  can be derived from measured watertable profiles. Two examples are shown in Figure 3. This Figure represents the smoothed relative infiltration velocity distributions against the relative shorenormal distance from the field and laboratory data. Infiltration velocity  $U_f$  is obtained by the Finite Difference Method. The normalised infiltration velocity has a maximum approximately 2/3 of distance from the shoreline to the runup

limit for the field data and halfway between the shoreline and the runup limit for the laboratory data. Both the distributions show similar trends, but the magnitudes are different. This difference is possibly due to the assumed value of  $n=0.3$  (for field) being too large, and it seems because field is unsteady with waves running onto dry sand or  $K$  is not correctly determined.

**Figure 3.** Relative infiltration velocity as a function of non-dimensional shore-normal distance. These infiltration velocity values were obtained through equation (1) for the field data (unsteady state) and equation (2) for the laboratory data (steady state).

The general nature of  $U_1$  may be expressed by

$$U_1(x) = \begin{cases} C_1 \frac{K}{n} f(x) & \text{for } x_s \leq x \leq x_R \\ 0 & \text{for } x > x_R \end{cases} \quad (3)$$

where  $f(x)$  denotes the function of shorenormal distance  $x$ ,  $x_s$  and  $x_R$  the horizontal coordinate of the shoreline and the runoff limit respectively and  $C_1$  a dimensionless infiltration coefficient.

Substituting this expression of  $U_1$  into the equation (2), the watertable overheight  $\eta$  will be independent of  $K$  and thus independent of sand size. This fact is verified by the laboratory data in Figure 4.

### Steady state inland overheight due to waves

Flume experiments were carried out to investigate the watertable response due to wave runoff without tidal effects. Sands of two different sizes ( $d_{50}=0.18\text{mm}$  and  $0.78\text{mm}$ ) were used. The relative steady state inland overheight is plotted against the relative runoff height in Figure 4.

**Figure 4.** The relative inland overheight against the relative runoff height in a steady state.

From the regression analysis for both sand sizes, the steady state inland overheight above the still water level ( $\eta_{\infty}$ -SWL) is obtained as

$$\eta_{\infty}\text{-SWL} = 0.62(Z_R\text{-SWL}) \quad (4)$$

where  $Z_R$ -SWL is the runup height above the still water level. As mentioned earlier, the laboratory data in Figure 4 verify that the watertable overheight is independent of sand size and thus independent of the hydraulic conductivity  $K$ . In analogy with Hunt's (1959) formula for the runup of regular waves, equation (4) can then be written as

$$\eta_{\infty}\text{-SWL} = 0.62 \tan\beta \sqrt{H_o L_o} \quad (5)$$

where  $\tan\beta$  is the beachface slope. The data in Figure 4 represent deep water wave heights ranging from 60mm and 180mm, periods ranging from 1.5sec to 2.9sec and aquifer depths ranging from 370mm to 440mm.

### Runup distributions for irregular waves

It is natural to expect that the  $U_I$ -distribution is closely related to the runup distribution. In general the runup distribution has been found to be of the Rayleigh type. That is

$$P(Z_R > Z) = \exp\left[-\left(\frac{Z - Z_{100}}{L_R}\right)^2\right] \quad (6)$$

where  $Z_{100}$  is the highest level transgressed by 100% of the waves during the recording interval,  $L_R$  is the vertical runup scale of the distribution, see e.g. Nielsen and Hanslow (1991). Furthermore Saville (1962) and Battjes (1971) suggested that individual runup percentiles  $R_n$  correspond to the same wave height percentile through 'the principle of equivalency' which is based on Hunt's (1959) formula for the regular wave runup

$$R_n = Z_n\text{-SWL} = \tan\beta \sqrt{H_{on} L_o} \quad (7)$$

where  $Z_n$  is the level transgressed by  $n$  percent of waves and  $H_{on}$  the height exceeded by  $n$  percent of the deep water waves. The vertical runup scale  $L_R$  for irregular waves, which is RMS runup according to the Rayleigh distribution, can then be estimated in terms of  $H_{oRMS}$  value by

$$L_R = R_{RMS} = \tan\beta \sqrt{H_{oRMS} L_o} \quad (8)$$

where  $H_{oRMS}$  is the deep water root mean square wave height.

Relative runup height for regular waves and relative vertical runup scale for irregular waves were plotted together against beachface slope  $\tan\beta$  in Figure 5. This comparison is due to the concept that the runup length scale  $L_R$  for irregular waves plays a somewhat similar role to that of  $Z_R$  for regular waves. Both the field and laboratory runup data show the increasing function of the beachface slope.

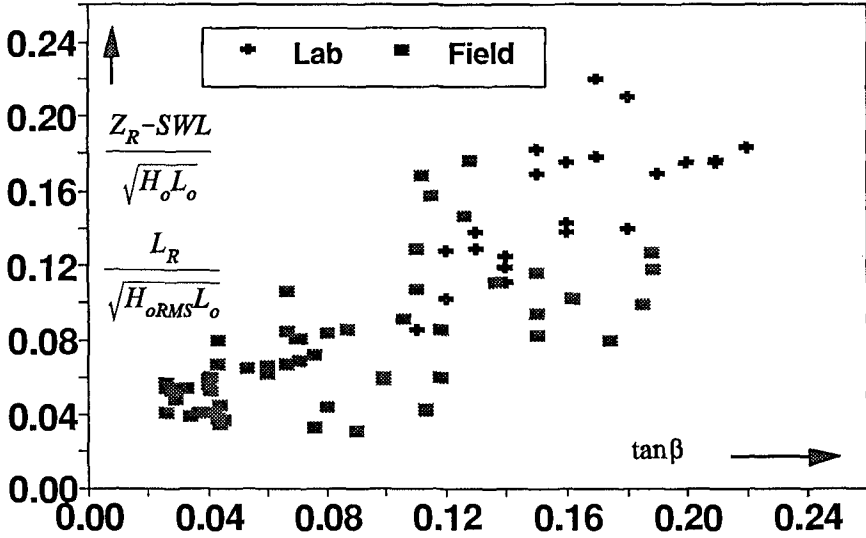

Figure 5. Comparison of runups for regular waves and irregular waves.

**Overheight for irregular waves**

The  $U_r$ -distribution due to irregular waves will be different from that due to regular waves. The reason is that while all of the regular waves run up to the same level, the runup limit, the individual waves in a train of irregular waves all reach different levels.

Field data of the watertable overheight due to waves are plotted in Figure 6. It is clearly seen that the overheight is an increasing function of the parameter  $\tan\beta\sqrt{H_{oRMS}L_o}$  which is the runup height of the RMS wave according to Hunt's formula (1959). This correlation corresponds to the overheight due to regular waves being proportional to  $\sqrt{H_o L_o}\tan\beta$ , see Figure 4. The lower group of data in the Figure 6 corresponds to a period when the exposed beach (Palm beach)

watertable does not increase much even though the RMS wave height is increasing. This is mainly due to refraction.
