Larson and Kraus (1992) summarized the results of the correlation analysis between bar and wave properties, covering (1) the correlation between geometric bar properties and wave quantities, (2) the correlation between change in geometric bar properties and wave quantities, and (3) distinguishing between onshore and offshore bar movement. The largest correlation was found between change in the geometric properties of bar volume, maximum bar height, and mass center location, and the fall speed parameter or wave steepness, with correlation coefficients of typically 0.5 to 0.8.

Several criteria were derived to predict onshore and offshore movement of the inner and outer bar. To determine the direction of bar movement, and thus the net direction of the sand transport across the bar, both change in bar volume and change in the location of bar center of mass were examined. Use of bar volume as an indicator of transport direction assumes that bar growth is associated with offshore movement, whereas a decrease in bar volume is caused by onshore movement. In the final analysis for deriving the criteria, a simultaneous increase in bar volume and offshore movement of the center of mass were required as indicators of offshore transport and similarly for onshore transport. A threshold value of 5 m<sup>3</sup>/m on bar volume change was imposed to eliminate events with minor change that were expected to be sensitive to measurement limitations.

The parameters examined to distinguish onshore and offshore bar movement were: wave steepness  $H_o/L_o$ , dimensionless fall speed  $H_o/wT$ , wave height over grain size diameter  $H_o/d_{50}$ , and a Froude number based on grain size  $Fr = w/(gH_o)^{1/2}$ , where  $H$  is wave height,  $L$  is wavelength,  $T$  is wave period,  $w$  is fall speed,  $d_{50}$  is median grain size,  $g$  is acceleration due to gravity, and the subscript  $o$  refers to deep-water conditions. Wave heights and periods associated with the significant wave were taken as the means over the analysis interval. Similar analyses have been performed by Larson and Kraus (1989) primarily for the LWT data sets and limited field data (not examining the Froude number), and by Kraus, Larson, and Kriebel (1991) for the LWT data and an extensive field data set of primarily qualitative observations of beach erosion and accretion (and including the Froude number). The strategy for obtaining the criteria was to plot the data in a diagram encompassing two non-dimensional parameters and subjectively fit a line that best separated onshore and offshore bar movement. In the choice of parameter combinations, at least one parameter contained a variable that characterized the sediment ( $w$  or  $d_{50}$ ).

$$\frac{H_o}{L_o} = 3.92 \cdot 10^{-5} \left[ \frac{H_o}{wT} \right]^3 \quad (2)$$

$$\frac{H_o}{L_o} = 4.5 \cdot 10^9 \left[ \frac{H_o}{D_{50}} \right]^{-3} \quad (3)$$

$$\frac{H_o}{wT} = 2.34 \cdot 10^5 \left[ \frac{w}{\sqrt{gH_o}} \right]^2 \quad (4)$$

Acceptable distinctions between onshore and offshore movement of both the inner and outer bar could be obtained by eqs. 2 to 4. The same exponents are obtained for the non-dimensional quantities as were noted in earlier work, but the constant multipliers have smaller values. This means that application of previous criteria for overall beach response to sand movement in the offshore produces conservative estimates for prediction of onshore sand transport of a bar. The two parameters in eq. 4 may be obtained from the parameters in eq. 2 (Kraus, Larson, and Kriebel 1991); however, the form of eq. 4 is convenient because the wave height appears inversely in the respective parameters, giving a more visually distinct separation of onshore and offshore bar movement. Reasonable predictions are also given by the simple one-parameter criteria:  $H_o/wT = 7.2$ ,  $H_o/D_{s0} = 6,400$ , and  $w/(gH_o)^{1/2} = 0.0055$ . Figs. 8 and 9 show  $H_o/wT$  versus  $w/(gH_o)^{1/2}$  used to distinguish between onshore and offshore bar movement for the inner bar and outer bar, respectively. Criteria developed for the overall response of the beach typically focus on beach evolution in the surf zone, where wave breaking prevails. The tendency for material to be transported onshore is much greater under the action of non-breaking waves in comparison with breaking waves.

## CONCLUDING DISCUSSION

Considerable information on the dynamics of natural longshore bars was obtained from a 9-year record of accurate beach profile surveys made at an average 10-day interval. Availability of data from four survey lines allowed judgement of three-dimensionality which would violate the analysis procedures, and correlations were improved by imposing censoring criteria on combined bar movement and volume. The analysis proceeded by defining bar position from a modified equilibrium profile that accounts for fining of grain size with distance offshore. The analysis covered an inner bar in 2-m depth and an outer bar in 4-m depth, which were tracked through 300 profile surveys.

For the inner bar, average depth to crest was 1.6 m, average maximum bar height 0.9 m, and average bar volume 42 m<sup>3</sup>/m. Average speed of the inner bar was 1.5 m/day for onshore movement and 2.9 m/day for offshore movement, with maximum recorded speeds of 8.7 and 18.0 m/day, respectively. Fractal box-counting analysis showed that the typical maximum duration between wave conditions that moved the inner bar offshore was 2 months.

For the outer bar, average depth to crest was 3.8 m, average maximum bar height was 0.4 m, and average bar volume was 45 m<sup>3</sup>/m. Although the outer bar had, on average, a volume comparable to the inner bar, the maximum height was considerably lower, producing a much more gentle bar shape. Average speed of the outer bar was 0.6 m/day for onshore movement and 1.1 m/day for offshore movement, with maximum recorded speeds of 6.1 and 15.2 m/day, for onshore and offshore movement, respectively. The typical maximum duration between wave conditions that moved the outer bar offshore was about 4 months.

Criteria previously developed by the authors to predict beach erosion and accretion were found to be applicable to bar movement if a multiplicative empirical coefficient in each criterion was modified. The results indicate that onshore movement of bars is more probable than previously estimated. The implication is that linear bars formed of dredged material are more likely to move onshore to nourish the surf zone and beach than previously thought.

Fig. 8. Cross-shore movement of inner bar predicted using  $w/(gH_o)^{1/2}$  and  $H_o/wT$

Fig. 9. Cross-shore movement of outer bar predicted using  $w/(gH_o)^{1/2}$  and  $H_o/wT$

Comparison of bar properties from the surveys at a North Carolina beach and results from experiments carried out in large wave tanks indicates similar geometric and dynamic properties (direction of movement and celerity) of bars in the laboratory and in the field. Thus, data sets from large wave tanks are of considerable value for investigating the fundamentals of cross-shore sediment transport and bar movement.

### ACKNOWLEDGEMENTS

This study was conducted as a part of the Dredging Research Program, U.S. Army Corps of Engineers, and performed under the Calculation of Boundary Layer Properties work unit. Contract coordination was provided by the European Research Office of the U.S. Army in London under contract DAJA45-90-C-0020. The beach profile data from Duck, North Carolina, were supplied by Mr. William A. Birkemeier, Chief, Field Research Facility. Permission was granted by the Chief of Engineers to publish this information.

## CHAPTER 171

# The Punta Umbría (Huelva) Spit

by:

Antonio Lechuga<sup>1</sup> and José María Medina Villaverde<sup>2</sup>

### 1. INTRODUCTION

The Punta Umbría spit is one of the most didactic case studies for spits which can be found along the Spanish coast. The problem the spit presents came to light in the past and has arisen once again causing difficulties for navigation in the channel. The solution adopted for the problem in the past was not totally correct from all points of view, as will be seen later in this study, and, for that reason, the problem has come up once again.

Consequently, the then General Directorate for Ports and Coasts of the Ministry of Public Works and Urban Development<sup>3</sup> commissioned the **Centro de Estudios y Experimentación de Obras Públicas (CEDEX)**, an autonomous organism of the Ministry of Public Works and Transport) to define the problem by making a report on the shore dynamics of the area. This report was undertaken in the facilities which the **Ports and Coasts Research Center** of the CEDEX has in Madrid.

### 2. STUDIES UNDERTAKEN

A report on shore dynamics involves undertaking a number of studies which progressively shed light on the overall problem. In the case of Punta Umbría, the different studies which were done can be outlined as follows:

- ✓ Historical evolution of the coast
- ✓ Geographical and geological study of the coast
- ✓ On site inspection
- ✓ Study of the maritime climate
- ✓ Wave propagation study
- ✓ Hydrodynamic study of the tides

Figure 1.- The Huelva coast.

<sup>1</sup>Ph.D. Civil Engineer. Head of the Coastal Service and Deputy Director of CEPYC-CEDEX.

<sup>2</sup>Ingeniero de Caminos, Canales y Puertos. Director of the Programme of Mathematical Models of CEPYC-CEDEX. (81, Antonio López St. 28026 MADRID, SPAIN)

Once the studies were made, a series of final conclusions were reached from all the information gathered and some precise recommendations were suggested to mitigate the problem

In the following parts of this report, the studies undertaken are commented briefly.

**3. HISTORICAL EVOLUTION OF THE COAST**

The Huelva shoreline can be characterized by the significant movement of sand which takes place, a logical consequence of the huge amounts of sand all along the coast. The proof of this is the fact that the shoreline is made up of only one beach, from Ayamonte on the border with Portugal to Punta del Malandar in the mouth of the Guadalquivir River, the border with the province of Cádiz. This immense sand formation is interrupted only by the mouths of rivers and tidal channels and above all by the Odiel wetlands, located precisely where Punta Umbría and Huelva have access to the sea.

Figure 2 portrays, generally speaking, the evolution of the Huelva coast from ancient times till our days. The present day location of the Punta Umbría spit is indicated by the circle. The arrow indicates the direction of the longshore transport of suspended sediment.

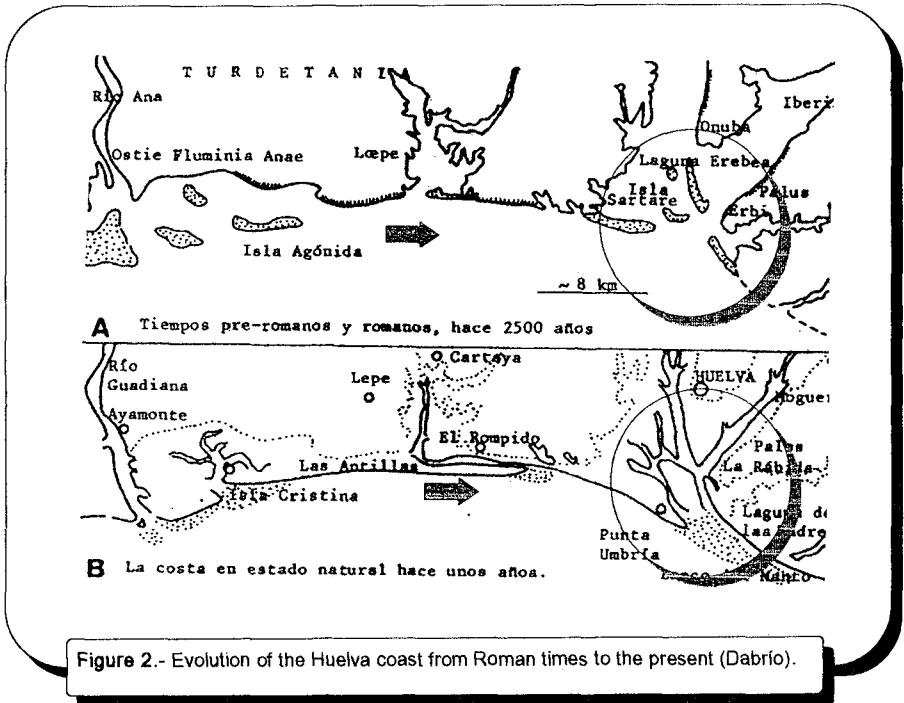

Figure 2.- Evolution of the Huelva coast from Roman times to the present (Dabrio).

As can be seen from the figures, the old rías have slowly undergone a process of sandfill and have been transformed into wetlands, which is what they are today.

<sup>3</sup>Today the General Directorate for Ports of the Ministry of Public Works and Transport.

In antiquity, the coast was made up of estuaries and cliffs and the sea occupied the low lying areas of the river valleys. As a consequence, true rías, like those found in the north-west of Spain (Galicia), were formed in what are now wetlands.

At the same time, the current of net longshore transport, induced by predominant waves from the SW quadrant, among others, and the tide action came together to form two different solid currents. The first current was produced by waves from a W->E<sup>4</sup> direction and the second one by the tide coming from alternating N->S / S->N directions depending on whether the tidal current is flood or ebb.

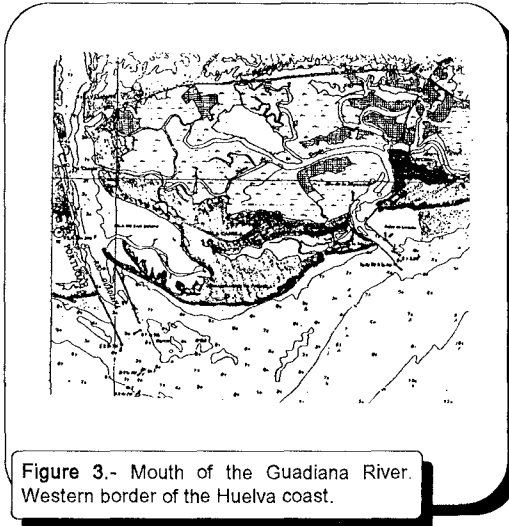

Figure 3.- Mouth of the Guadiana River. Western border of the Huelva coast.

Consequently, sand bars began to appear: the Agónida island (See figure 2A) in the mouth of the Ana river (the present day Guadiana, from the Arabic, "wadi Ana") became the present day Isla Cristina; the ría of the Piedras River became a tidal valley and began to take the shape of the Rompido spit.

Numerous ancient texts exist which date from the VI Century B.C. which confirm the existence of a great estuary in the confluence of the Tinto and Odiel rivers, called "Laguna Erebea" (See figure 2A) by some authors. The growth of the present day Punta Umbria spit in a NW->SE direction aided in the filling of the estuary and the formation of the present

Odiel wetlands, which, in turn, helped to make the spit wider. At the same time, an extensive dune field was formed on the berm.

Barrier islands and the wetlands formed in their shelter existed already in the 19th Century. Straits, narrows or "rompidos" (a local Spanish word that means "little mouth") were formed between the islands.

The net longshore transport current is at present quite significant. The progressive accumulations of sand to the West of the Punta Umbria and Huelva breakwaters, as well as in the Rompido Spit, testify to that fact. In the end of the Rompido Spit (the Punta del Gato), the sand has advanced an average of around 35 m/year. This point has been confirmed by the geological studies consulted<sup>6</sup>, as well as by measurements made on photogrammetric series in the CEPYC.

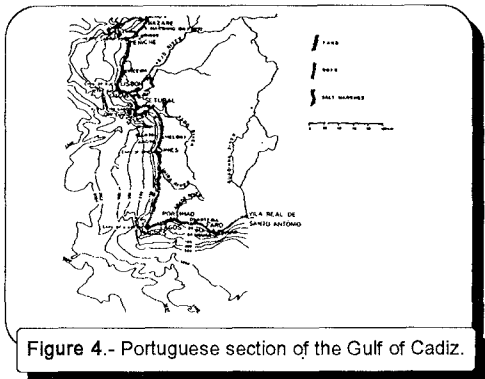

Figure 4.- Portuguese section of the Gulf of Cadiz.

#### 4. MORPHOLOGY OF COASTAL AREA

The Huelva coast extends from the mouths of the Guadiana and Guadalquivir rivers, as was previously mentioned. It is 145 km. long, forms a gentle arc, concave towards SW, and its western end faces a N-80-W direction while its eastern end faces an E-70-S direction. The waters of the Gulf of Cádiz wash its shores.

Owing to historical geological processes, sufficiently treated in the previous part, the coast is made up of coastal formations, typical of the mouths of rivers, and has a gentle equilibrium profile in its last part. The formation of sandbars, points, spits and muddy bogs are also frequent along the coast.

In the area under study, the coastal profile has two features which should be highlighted:

Figure 5.- Dynamics of the natural changing profile.

On the one hand, the mouths of the rivers have considerable extensions of tidal flats which are separated from the sea by sand barriers. These formations are created by the action of the shore current.

On the other hand, a strip of recent sand sediment has been formed between Ayamonte and Punta Umbría. This strip shelters the cliff of siliceous sand, making it inactive and unable to contribute material to the shore dynamics, at least in a direct way, since it is not attacked by the sea.

The city of Punta Umbría was built directly on a spit in the mouth of the Tinto and Odiel rivers occupying the zone of public domain in numerous cases. The design of the numerous streets of the city confirms how the city adapted itself gradually to the growth of the spit. Due to the importance of this type of formations for shore dynamics, it is worth dealing with this point a bit more in detail.

<sup>4</sup>It is interesting to observe at present how an actual river of sand is formed on days when there are storms from the West, even if the storms are not very strong. This river hugs the jetty, which forms the right bank of the Huelva channel, and becomes progressively narrower till it reaches a width of about 30 m.--depending on the intensity of the storm--at the roundhead. Later the river of sand expands throughout the width of the entrance.

<sup>5</sup>C.J. Dabrio, Historia de la Dinámica de Nuestra Costa, Cartaya, 1982.

### Spits, coastal sand formations and their influence on beach profile

Spits are sand bars built up in the direction of the current and are connected to land at one end. They are generally related to the mouths of rivers where sand formations of various types (live dunes, dead dunes, wind-deposited mantles, etc.) are generated. They develop on a small or medium scale anywhere along a coast which combines the topographical conditions and the adequate dynamics. They are more frequent along the Atlantic coast.

Due to their own physical characteristics, coastal sand formations have a very important role in the ecosystem and shoredynamics: they play the role of coastal defence, probably the most effective one that can be found, in contact with the sea and cushion the action of the sea, especially during severe storms. At the same time, they serve as a sand reserve for the beaches.

In addition, the presence of dune fields located on the berm has a determinant effect on the annual cycle of the evolution of the beach which is described in a general fashion in the next section.

### Diagram of the evolution of the beach profile

#### a) Summer profile

As waves approach the coast, they let their effects be felt on the bottom of the sea approximately from the moment where the depth is lower than half a wavelength. From that point on, the sand particles begin to shake back and forth alternatively. The beach profile undergoes modification until the force on the particles is balanced yielding a net result which generally implies a forward movement towards the shore. The finest sand particles are suspended in the area of the surf zone and are thrown along the width of the strand by the waves. Some return to the sea, but the net result still favors deposits on the strand.

#### b) Winter profile

When there is a storm, more waves reach the shore. Thus, more water is transported than in summer and consequently the sand is saturated. This forces the groundwater level to rise. This implies less filtration and eventually produces greater return currents which cause greater erosion. The beach recedes but the sand is deposited on a submerged bar, parallel to the beach and not very far from the shore. This bar acts as a filter for the waves, since it does not allow waves greater than a certain height to pass and obliges them to break due to the effect of the bottom, though this depends on the size of the sandbar.

Figure 5 illustrates this mechanism.

From the previous paragraphs, it becomes clear that if a beach is not wide enough to permit the adopting of a winter profile with a sandbar (for example, if construction was permitted too close to the shoreline), the waves will continue passing through and erode the remaining berm. For that reason, it is **essential** that each beach have a natural deposit of sand (which is usually a dune field) in the back of the beach.

## 5. PUNTA UMBRIA. A CASE STUDY

### Nature

Sand along the Huelva coast is readily available, a fact which will always be a constant problem in many points of the shore due to the resulting lack of depth for navigation. At the same time, however, it provides an efficient defence for the coast in most of its zones, as long as the sand is allowed to evolve as naturally as possible.

### Urban development

Punta Umbria has witnessed the rapid growth of its urban structure, as have the majority of coastal cities whose most important income comes from tourism. The city has grown, like other cities along the Spanish coast, without regard to coastal sand formations, either because of a lack of knowledge concerning their functioning<sup>6</sup>, or because of other reasons which do not take Nature into account.

The growth of the city has always been connected to the growth of the spit, as is reflected in the layout of the streets, which are parallel to the successive alignments of the shoreline.

The problem of the regression of the Punta Umbria beach appears to be provoked artificially by the historical invasion of the sand reserve within the public domain by the sea-front construction. This construction makes it difficult or hinders the formation of the full storm profile of the beach and, consequently, the ulterior regeneration of the summer profile.

### The construction of the jetty

The present day Punta Umbria jetty causes the dominant waves to strike the beach with very little obliqueness. This facilitates the halting of the current, almost completely, which has as its consequence the settling of the material in suspension. This material is at the mercy of the flood and ebb tidal currents which allow it to enter and deposit in the ria by the diffraction of the waves and the tidal current.

The layout of the Punta Umbria jetty has literally cut off the growth of the spit. This has caused the transformation of the part of the spit situated to the east of the jetty into a shoal which is today called Bajo de Nueva Umbria.

The aim pursued initially (to achieve the advance of the beach) has been totally successful. However, the movement of sand was not taken into account, particularly in view of the effect caused to the east of the jetty, in the mouth of the channel. The effect sought after by the construction of the jetty was based on the creation of a partial barrier to the passage of sediments, not only along the bottom but also in suspension, thus facilitating their deposit to the west. Nevertheless, the diffraction provoked on the waves produces a current due to the wave height gradient which leads the sediment into the channel. At the same time, the deficit of longshore transport is compensated by the movement of sand from the shoal, Bajo de Nueva Umbria.

---

<sup>6</sup>It should not be forgotten that Coastal Engineering is still a young and developing science. Some of its fields, such as the understanding of the evolution of the cross-shore profile of a beach, are not sufficiently developed.

The hydrodynamics of the mouth of the channel are not acceptable today, since the ebb tide almost always affects the longshore transport current induced by the obliqueness of the breaking waves, creating a problematic point in the mouth of the ría.

#### Sea level rise

A rise in the sea level brought about by climatic changes would have a greater importance along low lying coasts, as would be the case in Spain along the Gulf of Cádiz and in the Ebro Delta, as well as in other isolated areas in other regions. However, this factor has not been taken into account in this study, since it has a long term effect. A SLR vulnerability assessment for this region is now being carried out at the CEPYC.

## **6. STUDIES UNDERTAKEN**

#### Maritime climate

A study of the maritime climate, based on visual observations of waves, permitted the drawing up of the wave rose, SEA and SWELL type waves. Its aim was to determine the storms which were to be studied.

#### Wave propagation

A study of the wave propagation was accomplished by using a refraction-diffraction parabolic mathematical model<sup>7</sup> based on the resolution of the Berkhoff equations and on the jobs by Kirby and Dalrymple (University of Delaware, U.S.A.). The model permitted the definition of the behavior of the waves as they approached the coast. Various storms of varying directions and periods and in high and low tide were used to achieve this definition.

#### Hydrodynamic behavior of tidal currents

With the help of the MIKE21<sup>8</sup> mathematical model, a simulation of the tide conditions in the wetlands system of the mouth of the Odiel river was undertaken. To accomplish this, the tidal prism, which even included the Huelva ría, was taken into account.

## **7. POSSIBLE SOLUTIONS**

First of all, it is essential to bear in mind that an ideal solution does not exist. Unfortunately, the over abundance of sand along the coast means that dredging can not be avoided.

Notwithstanding this, it is believed that an ideal solution for minimizing the existing problems would involve restoring the primitive channel out to the sea, since it is the natural outlet for the ría. The best way to accomplish this would be to construct an embankment (as shown in figure 6), dredge the former course of the channel and dump what was dredged between the jetty and the embankment, according to the outline indicated in the previous figure. In this way, the spit would be restored and the incident angle between the two currents would be minimized.

## CHAPTER 172

### COMPLEX PRINCIPAL COMPONENT ANALYSIS OF SEASONAL VARIATION IN NEARSHORE BATHYMETRY

Guoxiong Liang<sup>1</sup>, Thomas E. White<sup>2</sup>, Member, ASCE  
and Richard J. Seymour<sup>1</sup>, Member, ASCE

**ABSTRACT** Both the conventional Principal Component Analysis (PCA) and the Complex Principal Component Analysis (CPCA) were applied to analyze six nearshore profiles in Siuslaw, Oregon. Results indicated that the first two components derived from CPCA always outperformed those derived from PCA. This suggests that CPCA is a better method of describing the seasonal variation in nearshore bathymetry. The relative performance of CPCA on different profiles depended upon the coherence of the variation within those profiles. Furthermore, the concept of an absolute amount of variance was used in explaining the spatial variation of the predictability of principal components.

#### INTRODUCTION

Complex principal component analysis (CPCA), developed for meteorological application (e.g., Wallace and Dickson, 1972; Barnett, 1983), has been successfully used to describe an event of a fast-moving sand bar (Liang and Seymour, 1991). In comparison with conventional principal component analysis (PCA), also known as the Empirical Orthogonal Function (EOF) technique (e.g. Aubrey *et al.*, 1980; Seymour, 1989), CPCA offers significant advantages. Besides being able to give a more compact description for the variation of the data set (fewer functions required), it can also detect propagating waves.

However, most nearshore bathymetric data sets available consist only of seasonal surveys. One may argue that the seasonal variation in nearshore profiles is more like a standing wave than a propagating feature, and thus it might be unnecessary to apply CPCA to the seasonal bathymetric data. Therefore, a test using

---

<sup>1</sup> Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA 92093-0222, USA.

<sup>2</sup> USAE Waterways Experiment Station, Coastal Engineering Research Center, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199, USA.

seasonal data appears to be a rigorous method of evaluation. In order to compare the efficiencies of CPCA and PCA in analyzing the seasonal variation in nearshore bathymetry, a set of multiple profile data from Siuslaw, Oregon, was analyzed.

### SEASONAL SURVEY DATA FROM SIUSLAW, OREGON

The bathymetric data were collected from an area that is located in the mouth of Siuslaw River, Oregon (Figure 1). The Helicopter-borne Nearshore Survey System (HBNSS) was applied to measure the seabed elevation (Pollock, in press). The survey helicopter is fitted with a 26-meter weighted cable, graduated like a surveyor's rod. The elevations are read by a shore-based surveyor's level. The horizontal positioning is obtained using a shore-based electronic total distance station (TDS) aiming at a cluster of prisms mounted on the helicopter. The HBNSS surveys were carried out every winter and summer from 1981 to 1990.

Six cross-shore profile sets, which are within an alongshore segment extending 762 m (2500 feet) from the North Jetty, were chosen for analysis. Each of them, with a length of 354 m, includes 30 grid points and 20 time steps. Some profiles show pronounced seasonal cycles (Figure 2).

### ANALYSIS TECHNIQUE AND RESULTS

To apply CPCA, a profile is required to be transformed into a complex data set such as:

$$U_j(t) = u_j(t) + i\hat{u}_j(t)$$

The real part is simply the original scalar field. The imaginary part is the Hilbert transform of the real part. On the basis of the complex data, the complex cross-correlation matrix can be computed, consisting of: the eigenvectors (functional decompositions of the data) and eigenvalues (portions of data's variation represented by each eigenvector). It is customary to evaluate the performance of these analysis tools by the percentage of the variation about the mean, which is represented by each of the principal components. A comparison of PCA and CPCA is shown in Table 1.

Table 1 Percentage of Variation Explained by PCA and CPCA

Profile	1st Component		1st & 2nd Components	
	PC	CPC	PC	CPC
1	86.57	85.65	95.43	95.47
2	77.00	75.28	88.21	89.41
3	60.35	58.65	75.36	78.33
4	56.01	55.50	71.95	73.80
5	38.83	40.71	58.77	64.22
6	36.91	41.63	55.98	64.46

Figure 1. Location map of Siuslaw, Oregon.

The first and second complex components (CPC) can explain more variation than the corresponding conventional components (PC) in every case. In some

Figure 2. An example of seasonal variation in nearshore profile (Profile 1).

profiles such as profile 6, the CPC is about 8.5% better. The data in Table 1 are shown graphically in Figures 3 and 4.

## DISCUSSION

However, it must be noted that, in some profiles (e.g. Profile 1 and Profile 2), the first conventional component can explain 1% to 2% more variation than the first complex component does. Also, the less variation contained in the first component, the better the performance of the first complex component compared to the conventional one. One possibility is that the complex analysis requires more degrees of freedom, and when artificially constrained to a very low number of functional modes (e.g., only one component), it will not behave reliably statistically. From the data in Table 1, it can be seen that once the number of components exceeds the bare minimum necessary for computation (one), the complex method performs better.

Figure 3. Variation explained by the first component.

Figure 4. Variation explained by the first and second components

However, for the case of a fast-moving bar, the first component always outperformed the conventional component (Liang and Seymour, 1991).

The data suggest that the relative performance depends upon the coherence of the variation within a profile as described in the following paragraphs. For simple variation (coherent changes), most of the variation can be explained by the first component and the complex method has no particular advantage for a single component. For more complicated variations (non-coherent changes), there is less variation explained by the first component, and CPCA is always more effective.

Figure 5 shows the conventional correlation (left) and complex correlation (right) between each grid point and grid points 5, 10, 15, 20 and 25 in Profile 1.

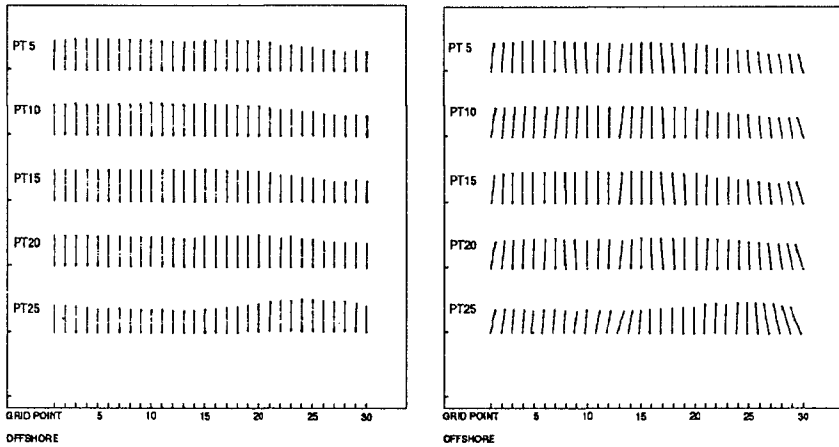

Figure 5. Comparison between conventional correlation (left) and complex correlation (right) in Profile 1.

Each correlation is plotted in a vectorial format where the magnitude is indicated by the length of the vector. Full scale (correlation equals 1.0) is indicated by the correlation between point 5 and itself. For the complex correlation, the phase is arranged like the hour hand of a clock. A vector pointing upwards (downwards) indicates that the two time series are in-phase (out-of-phase); one pointing to the right (left) indicates that the grid point time series lags (leads) the time series indicated in the left margin by  $90^\circ$ , etc. It is obvious that the complex correlation between the grid points within this profile is rather similar to the conventional correlation. Every grid point shows positive correlation with each of the other ones. The entire profile appears to be involved in highly coherent motion. In this case, the results of CPCA and conventional PCA are almost identical.

A different result is revealed in Profile 6 (Figure 6). The difference between complex correlation and conventional correlation is significant. The correlation between grid points are much poorer than those in Profile 1. Also, correlation between certain points show an out-of-phase relationship. It suggests that the motion in this profile is not as coherent as that in Profile 1. In this case, CPCA can explain more variation than conventional PCA does.

Figure 6. Comparison between conventional correlation (left) and complex correlation (right) in Profile 6.

In many instances, the first CPC may indicate a strong in-phase relationship between the time series at grid points while the second one indicates a weaker, out-of-phase relationship (Horel, 1984). In the conventional PCA, the correlation is simply a scalar. Therefore, it is not possible for it to reveal the phase relationship between different grid points. The data and results described above indicate that, within some standing-wave-like variation in nearshore profiles, both in-phase and out-of-phase correlations can exist. Therefore, since this cannot be determined *a priori*, use of the complex technique appears to be the prudent approach.

One of the other interesting observations is that the percent of the variation explained by either PC or CPC decreases monotonically with distance from the jetty (see Figures 3 and 4), a reduction in predictive capability of about one third. To understand this change better, the absolute value of the variability was calculated. Figure 7 shows the mean value (over time) of the standard deviations (in space) of the six profiles. This shows clearly that there was much greater variability close to the jetty (nearly three times that of the minimum). Figures 8 and 9 show the data of Figures 3 and 4 normalized by the standard deviations shown in Figure 7. These show that, in both PC and CPC, profile 4 is predicted best in terms of the absolute amount of variance, and Figure 7 shows that profile 4 exhibits very close to the minimum amount of absolute variance. Therefore, the performance on profile 4 could be considered to represent the basic capability of the principal component method to extract signals from the noise in the measurements and the physical processes. If this noise is uniform in magnitude, then as the absolute values of the variance increases (toward the jetty) the relative predictability ought to increase – and it does. On the other hand, if noise is somehow proportional to the signal, the relative predictability ought to remain more or less constant – and it does not. The

data set is too sparse to make conclusive statements on this hypothesis, but it might be of interest to test this on richer data.

#### ACKNOWLEDGMENTS

This research was supported by US Army Engineer Waterways Experiment Station, contract DACW39-90-K-0007. The CERC MCCP program kindly provided the observed data which made this work possible.

### ABSTRACT

Sediment samples and beach profile evolution data, collected along one profile line at "El Puntal" Spit, Santander, Spain, are studied by means of Principal Component Analysis (PCA). This analysis technique is used to separate the temporal, spatial and grain size distribution variability of the data. The results show that there is a seasonality in the grain size distribution affecting the fine sand as well as the coarse sand. The variations of the coarse sand percentage, which occur mostly within the bar-berm area, consist of an increase, in the bar zone in winter and in the berm zone in summer. The fine sand presents a different behaviour, changing all along the profile, increasing its percentage offshore the bar in winter, and in the foreshore in summer. Thus, the sediment just relocates in the cross-shore direction.

Further, a "master" grain size distribution, which is constructed by adding all the grain samples, taken from all over the profile, is shown to be

---

\* Ocean & Coastal Research Group. Departamento de Ciencias y Técnicas del Agua y del Medio Ambiente. University of Cantabria. 39005 Santander, Spain.

constant in time. It is suggested that the "master" grain distribution should be used in coastal engineering formulation.

## INTRODUCTION

Investigators have long recognized that there is a relationship between beach profile and sediment size (see Dean, 1977, for a general reference). Though, in almost all relationships proposed, the grain size distribution and grain size related parameters are usually assumed uniform in the cross-shore direction. It is also well known that the sediment characteristics of a beach profile vary both spatial and temporally. A great number of studies have investigated the changes in sediment grain size and the onshore-offshore grain size sorting across the beach profile. Most of the studies involve using statistical granulometric parameter as sample mean, mode and skewness, determined from native sand samples (see recent work by Moutzouris, 1991). Some studies use field data from sand tracers, usually natural sand tagged with fluorescent color or with artificially induced radioactivity (Murray, 1987) and other studies present results from laboratory experiments (Kamphuis and Moir, 1977). However, there is not always agreement on the results described by the different researchers, especially on the trends followed by the degree of sorting across the beach profile.

Attempts have been made to explain and quantify the processes involved in the sorting of grain size across the profile. Two major hypotheses have been proposed in the past: the hypothesis of asymmetrical thresholds under waves (see recent work by Horn, 1991) and the hypothesis of the null-point (e.g. Cornaglia, 1889). Despite the efforts undertaken to understand the processes responsible for the grain size distribution across the profile, the problem remains open and further studies are needed.

Statistical methods, such as Principal Component Analysis (PCA) or Factor Analysis (FA), provide a useful tool to objectively separate the spatial and temporal variability of beach profile data (e.g. Winant et al., 1975; Medina et al., 1991) or of sediment data (Liu and Zarillo, 1989). In all of these works, only two dimensions are considered among offshore-distance, time and grain distribution, resulting in a partial view of the problem. In the present study, sediment data is analyzed by means of the three-way PCA method in which offshore distance, time and grain distribution are used to describe the spatial and temporal structure of the grain size distribution variability.

## ANALYSIS METHOD

Historically, PCA has been carried out for data which depend on two dimensions. If more dimensions were involved, data aggregation or other techniques were used to reduce the problem to a two-dimensional problem. Solutions for three-way data were first proposed by Tucker (1966) and extended by Kroonenberg and De Leeuw (1980).

A detailed discussion of the method can be found in the paper by Kroonenberg and De Leeuw (1980). In brief, one seeks a factorization of a three-way data matrix  $Z$ , such that:

$$Z_{ijk} = \sum_{p=1}^s \sum_{q=1}^t \sum_{r=1}^u [g_{ip} h_{jq} e_{kr} c_{pqr}]$$

where the coefficients  $g_{ip}$ ,  $h_{jq}$  and  $e_{kr}$  are the elements of the columnwise orthonormal matrices  $G$ ,  $H$ ,  $E$ , respectively, and  $c_{pqr}$  are elements of the so-called three-mode core matrix,  $C$ .  $G$ ,  $H$  and  $E$  have similar interpretations as the two-mode eigenvectors and are determined so that the difference between the data and the value obtained from the factorization is minimal according to the mean squared error. In practical applications one is just interested in the first few (two or three) principal components which account for most of the data's variance. The core matrix,  $C$ , however, is no longer a diagonal matrix of eigenvalues. One could conceive of the core matrix as describing the basic relations that exist between the various collection of variables. The solution of the problem is based on the observation that the optimal  $C$  matrix can be expressed uniquely and explicitly in terms of the data modes. The latter components' matrices are optimized by an alternating least squares algorithm.

## STUDY AREA AND FIELD DATA

The study site is located on the Cantabrian Coast of Spain, Gulf of Biscay (Fig. 1). The northern coast of Spain consists of a series of pocket beaches and small inlets separated by pronounced rocky headlands. Santander Bay is one of the largest inlets on the Cantabrian Coast and is located about 200 km West of the French border. The Bay is bounded northward by "El Puntal" Spit, a sandy spit which protrudes well inside the

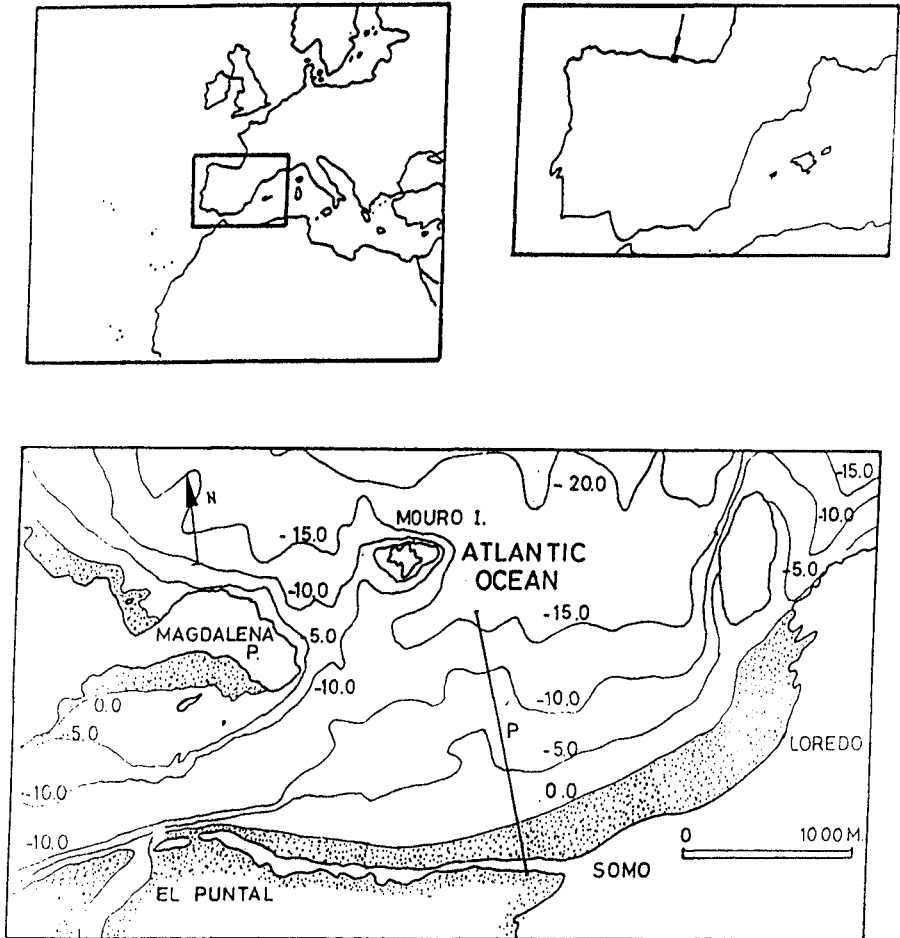

Fig. 1.- Location Map.

bay (see Fig. 1). The predominant wave approach direction is from the N/NW sector and has an annual average significant wave height of  $H_s = 4$  m. Tides along the Cantabrian Coast are semidiurnal. The mean tidal range in Santander Bay is 3 meters and the Spring tidal range is 5 meters.

A monitoring project is being carried out to evaluate the evolution of "El Puntal" Spit. The field program includes wave and current measurements, beach profile and sand samples. A detailed description of the monitoring program can be found in the paper by Losada et al. (1991). We will concentrate our work on the beach profile data and sediment sample data.

Surface sediment grab samples were collected along one profile line at the spit (Fig. 1), over a twenty-month period from May 1990 to January 1992. Profile surveys were taken about once a month, with sediment samples collected during each monthly survey. The beach profile data were collected from permanent monuments landward of the dune seaward to a depth of -15 m, which extended up to 1500 meters. Sediment samples were collected from fifteen positions (see Fig. 2) including the berm and intertidal area, the inner bar and trough area and the nearshore zone. The sediment sampling scheme attempted to locate the sample at the same distance seaward of the base line during each sampling period. Each sample was analyzed in the laboratory and grain sizes were computed by sieving according to ASTM standards using ASTM mesh N<sup>o</sup> 30 (0.59 mm) to N<sup>o</sup> 200 (0.074 mm).

Fig. 2.- Sampling Location.

## RESULTS OF ANALYSIS

### Sediment Data

Since many of the grain size distributions obtained from the samples were not even close to a log-normal distribution, the entire grain size distribution is used instead of the usual statistics such as mean grain size standard deviation, skewness or kurtosis.

Sediment data can be arranged in the form of a matrix  $Z(x,t,d)$ , where  $x$  is offshore distance,  $t$  is time (survey) and  $d$  is grain size distribution. Thus, for each survey and each location we have the complete grain size distribution of the sample. When the three-way PCA method is applied to these data, the internal structure of the data variability is separated into temporal, spatial and grain size distribution variability (eigenvectors  $G$ ,  $H$  and  $E$ ) and the importance of the different modes of variability is given by the core matrix,  $C$ . As previously stated, the method obtains matrices  $G$ ,  $H$  and  $E$  which are columnwise orthonormal, in other words, they have length one. Bartussek (1973) suggested scaling the orthonormal eigenvectors of a three-way PCA analogously to the procedure often encountered in standard PCA. One advantage of this scaling is that the so-determined scales eigenvectors are comparable within a mode and over modes. When scaling the eigenvectors, the core matrix must also be scaled to leave the model invariant.

The corresponding Bartussek core matrix values and the percentage of variation explained by each element of the matrix are given in Table 1. The total variance explained with the first two temporal eigenvectors is, from Table 1, 97.5% with most of the variance explained with the first eigenvectors ( $g_{1i}$ ,  $h_{1i}$ ,  $e_{1i}$ ). This result is not surprising since we are dealing with raw uncentered data and, consequently, the centroid, defined as some mean of the data, can explain most of the data and is the best candidate for the first eigenvector.

In Fig. 3, the first three offshore distance ( $g_{1i}$ ) and grain size distribution ( $h_{1i}$ ) eigenvectors, and the first two temporal ( $e_{1i}$ ) eigenvectors are shown. In order to interpret the results of the 3-way PCA, let us concentrate on the first temporal eigenvector ( $e_1$ ) and the associated offshore distance and grain size distribution eigenvectors.

Fig. 3.- Eigenvectors.

Table 1Frontal Planes of Core Matrix

Frontal Plane Time = 1 Down: Offshore Across: Grain size

Explained Variation

.9240	.0000	.0000	1.060	-.027	-.049
.0000	.0260	.0003	-.027	-4.957	.782
.0000	.0010	.0068	.028	-1.442	5.595

Frontal Plane Time = 2 Down: Offshore Across: Grain size

Explained Variation

Bartussek Scaled

0.002	.0016	.0003	.125	1.745	1.171
.0013	.0036	.0025	1.556	13.875	17.072
.0020	.0006	.0049	-2.874	-8.073	-35.762

The first temporal eigenvector shows an almost constant value in time, thus accounting for the mean (temporal) situation. The first offshore distance eigenvector is also characterized by an almost constant value. Consequently, if we use the first three modes eigenvectors that account for 92.40% of the variance, we obtain a mean grain size distribution in time and space. A better representation of the data can be obtained if we add the combination  $g_2, h_{12}$ , which corresponds to the second offshore distance eigenvector and the second grain size distribution eigenvector, that explains 2.66% of the variance. The second grain size distribution eigenvector accounts primarily for the fine sand and the second offshore distance eigenvectors shows a decreasing trend with a positive value at the beginning of the profile and a negative value at the end of the profile. When multiplying those eigenvectors with the corresponding Bartussek-scaled core-matrix value we get a decrease of fine sand at the beginning of the profile and an increase of

fine sand in the offshore part of the profile. Analogously, more variability of the data can be described using the combination  $g_{13}$ ,  $h_{13}$ . That combination adds 0.68% of explained variance and give information of the coarse sand ( $g_{13}$ ), which has negligible variability in the offshore part of the profile and maximum variability in the berm-bar zone of the profile ( $h_{13}$ ). With these eigenvectors, we add coarse sand at the bar location. The final representation of the mean (temporal) situation is composed of an along-profile constant grain size distribution with finer sand in the offshore part of the profile, some coarse sand at the bar location and a well-sorted material at the beach face area (we subtract fine and coarse sand). See Table 2 for an overall explanation of the sign of each term in the expansion and the action it takes over the first eigenmode.

Table 2

Grain size /Distance	Eigen-mode (1,2,2)				Action over the Eigenmode (1,1,1)
	Time	Offshore distance	Grain size	Core Matrix	
	T	X	G	CM	
>0.30 mm >400 m	+	-	-	-	- Subtracts >0.30 mm
>0.30 mm <400 m	+	+	-	-	+ Adds >0.30 mm
<0.22 mm >400 m	+	-	+	-	+ Adds <0.22 mm
<0.22 mm <400 m	+	+	+	-	- Subtracts <0.22 mm

The second temporal eigenvector (Fig. 3) shows a seasonal dependency with a maximum in the summer season and a minimum in the winter season. The eigenvectors associated with this second temporal eigenvector explain 1.70% of the variance. Among the nine possible combinations of grain size distribution eigenvectors and offshore distance eigenvectors, again the pairs  $g_{23}$   $h_{23}$  and  $g_{22}$   $h_{22}$  are the most important in terms of explained

variance. Notice that the second temporal eigenvector has a different sign depending on the season, thus the effect of the pairs  $g_{23}$ ,  $h_{23}$  and  $g_{22}$ ,  $h_{22}$  changes seasonally. In this way, the pair  $g_{22}$ ,  $h_{22}$  describes a seasonal variation of the fine sand along the profile. If we want to have a better representation of the summer data, we must add fine sand in the landward part of the profile and subtract it in the offshore area. Inversely, in winter, fine sand must be added in the offshore zone and subtracted in the landward part.

The seasonal variability of the coarse sand is controlled by the pair  $g_3$ ,  $h_3$  and bounded in the berm-bar area (see Fig. 3). In winter, more coarse sand is encountered at the bar location while the percentage of coarse sand decreases at the berm position. In summer, however, the bar suffers a decrease of coarse sand that is now located at the berm position.

#### WORKING HYPOTHESIS FOR THE CROSS-SHORE GRAIN SIZE DISTRIBUTION

Besides the information about the grain size distribution and the degree of sorting in the cross-shore direction, the eigenvector expansion suggests new ideas on the sediment transport that occurs in the cross-shore direction. The situation described by the spatial eigenvectors associated with the first temporal eigenvector is a "static" or "no-mobility" situation since it does not change in time. Actually, some sediment transport might exist, but it is balanced so that no temporal variations occur. On the other hand, the situation depicted by the eigenvectors associated with the second temporal eigenvector shows that some sediment transport is taking place since, for example, the percentage of coarse sand is decreasing at the bar location during the summer period. Further, the eigenvector expansion indicates that the coarse sand movement takes place mainly within a zone between the berm and the bar while the fine sand moves all along the profile.

Notice that the second temporal eigenvector shows a seasonal dependency with no net trend. Thus, the sediment transport in the crossshore direction is just a "sediment or grain size relocation": the coarse sand is seasonally redistributed between the bar and the berm and the fine sand between the offshore zone and the landward part of the profile.

For each of the twenty surveys, a "master" grain size sample constructed by adding all the grain samples taken over the profile is obtained. Figure 8 shows the "master distribution" for the winter and summer surveys. Except for minor deviations associated to a discrete sampling technique (only

Fig. 4.- "Master sample" grain size distribution.

fifteen samples were taken along the profile for each survey), it can be accepted that a "master grain distribution", which is constant in time, exists. Thus, the following working hypothesis may be anticipated:

*"For a beach profile within a physiographic unit, the "master grain size distribution" obtained by adding all samples taken over the active profile, doesn't depend on time".*

The application of this hypothesis should be useful to select a grain size, representative of the overall behaviour of the sand in the profile. As an example, it is suggested that parameters like "A" of the equilibrium beach profile and "K" of the longshore sediment transport formula should depend on the  $D_{50}$  of the "master" grain size distribution.

Finally, three more remarks: First, the hypothesis simplifies the field work. To know the grain size distribution in a profile, the sample may be collected anytime, since it is invariant. The unique requirement is that the samples have to be taken all over the active profile.

Second, in order to reconstruct a beach profile, the borrowed grain distribution should be as close as possible to the "master" grain distribution of the native sand.

Last, the hypothesis may be extended to 3D cases, extending the idea of "master grain size distribution" to a physiographic unit (like a pocket beach). To check this case, the development of a four-way Principal Component Analysis would be necessary.

## CONCLUSIONS

- \* The Three-way PCA of sediment grain size data is used to separate the temporal, spatial and grain size distribution variability.
- \* For the case of study, it is found that the coarse sand mobility is bounded within the bar-berm area, while the changes in percentage of the fine material take place all along the profile.
- \* A "master" grain size sample is obtained for each of the surveys. This "master" sample is constructed by adding all the grain samples taken along the profile. Comparison between the twenty master samples points out that they are almost equal. Therefore, it can be concluded that there is a "master" grain size distribution for the profile which is constant in time.
- \* Adopting the previous conclusion as a working hypothesis, it is suggested that the "master" grain distribution should be used in coastal engineering formulations to determine the required single grain size value, such as "A" in the equilibrium beach profile or "K" in the longshore sediment transport formula.
- \* One of the main advantages of this conclusion is the remarkable reduction of the field work as one field campaign at any time is enough to obtain the "master" grain size distribution.
- \* Finally, it has to be pointed out that by applying a four-way PCA, a "master" grain size distribution of a physiographic unit may be determined.

# Three-Mode Principal Component Analysis of Bathymetric Data, applied to "Playa de Castilla" (Huelva, Spain)

Raúl Medina\*  
Cesar Vidal\*  
Miguel A. Losada \*  
Antonio J. Roldan\*

### Abstract

Three-Mode Principal Component Analysis is applied to bathymetric data from a beach nourishment at "Playa de Castilla", Huelva, Spain. This approach is used to separate the temporal and spatial variability of the beach shoreface. The method is shown to describe variations occurring in the cross-shore and in the alongshore direction as well as temporal variations. The results of the analysis show a clear seasonality in the shoreface variations, with bar-berm processes involved in the cross-shore direction and complex sand variations in the alongshore direction. These alongshore variations are induced by the nourished area which avoids the formation of a uniform bar along the beach resulting in a complex sediment redistribution. The results also show an erosion trend in "Playa de Castilla". This erosion, however, is not related to the "spreading out" losses at the nourished beach but with the background erosion.

# 1 INTRODUCTION

The configuration of a sandy coast changes both in time and in space. Processes occurring in the nearshore ocean are extremely dynamic, involving the combined action of waves, currents, tides and sediment transport. Furthermore, their individual characteristics change with various scales in both space and time. Here, day-to-day hydrodynamic processes constantly adjust the beach bathymetry through on-offshore and longshore transport of sand due to the wave field, sediment supply and grain size, tide and wave induced currents and sea level.

The situation described above shows that the morphodynamics of nearshore systems are extremely complex and difficult to treat. One approach is the concept of equilibrium shoreface (equilibrium profile and equilibrium shoreline). This idea is based on the premise that the overall shape and morphology of the shoreface will be maintained with some consistency in response to the typical wave and current regime at a particular location. Once the equilibrium shape is determined, the temporal and spatial variations of the shoreface can be related to the variability of the coastal processes.

Different statistical approaches have been applied to beach profile data. Principal Component Analysis (*PCA*), also known as Empirical Orthogonal Function (*EOF*) technique, is an efficient method of objectively separating the spatial and temporal scales of variability of a beach. *PCA* is a technique of linear statistical predictors which represent a large number of data variables by a few spatial,  $e_n(s)$ , and temporal,  $f_n(t)$ , empirical orthogonal eigenfunctions which describe most of the variance of a data set  $y(s, t)$  by:

$$y(s, t) = \sum_n f_n(t) e_n(s) c_n \quad (1.1)$$

where  $c_n$  is a normalizing factor. The eigenfunctions are ranked according to the percentage of the variance defined as the Mean Square Value (*MSV*) of the data they explain, so that the first eigenfunction explains most of the *MSV* of the data.

This technique has been previously applied to cross-shore beach profile data: Winant et al (1975), Aubrey (1979), Zarillo and Liu (1988), Medina et al. (1991), and to alongshore profiles data: Losada et al. (1990), Liang and Seymour (1991), who showed that the variations in the longshore direction are as complicated as those in the cross-shore direction. In all these works, only one spatial direction is taken into account (cross-shore or alongshore) when analyzing the temporal evolution of a bathymetric data set. The assumption accepted is that the sediment transport occurring in the nearshore region may

be divided into two independent components by direction: cross-shore and longshore. This analysis may be correct in some particular cases, but it is rendered inadequate when two dimensional movements of sand are expected (e.g., response to coastal structures, beach nourishment...).

In the present study, the beach nourishment data set of "Playa de Castilla" (Huelva, Spain) is analyzed by means of the *three-mode PCA* method in which both cross-shore and alongshore variations and interactions are retained as well as time. The method is used to expand the data in the form:

$$y(x, y, t) = \sum_{p=1}^s \sum_{q=1}^t \sum_{r=1}^u [e_p(x) f_q(y) g_r(t) c_{pqr}] \tag{1.2}$$

## 2 THE 3-WAY PCA MODEL

Recently, some techniques have been developed to obtain direct solutions for *three-way* data sets. These dimensions are often referred to as *modes* and the technique is generally referred to as *three-mode* or *three-way PCA*. Procedures of this sort were first proposed by Tucker (1966), and extended by Kroonenberg and DeLeeuw (1980) and TenBerge et al. (1987).

If only some eigenfunctions (e.g.  $k$ ) are used to represent the data, equation 1.1 may be rewritten in matrix form as:

$$Y = ECF' \tag{2.1}$$

where  $Y$  is  $(n \times p)$ ,  $E$  is  $(n \times k)$ ,  $C$  is diagonal  $(k \times k)$ ,  $F$  is  $(p \times k)$  and  $()'$  denotes transpose operator.

If the data array is augmented to include a third dimension, equation 2.1 will also be augmented by the inclusion of an extra term. In matrix form:

$$Y = EC(F' \otimes G') \tag{2.2}$$

where  $\otimes$  denotes a direct product or Kronecker matrix,  $E$  is  $(n \times k)$ ,  $G$  is  $(p \times k)$ , and  $F$  is  $(r \times k)$ . Since this is a matrix equation, both  $Y$  and  $C$  have to be restated as two-dimensional arrays,  $Y$  being  $(n \times p \times r)$  and  $C$  being  $(k \times k \times k)$ .  $E$ ,  $F$  and  $G$  are columnwise orthonormal matrices and have the same interpretation as the two-mode eigenvectors. However,  $C$ , which is now called the *core* matrix, is no longer a diagonal matrix of eigenvalues. One could conceive of

the *core* matrix as describing the basic relations that exist between the various collections of variables, Kroonenberg and DeLeeuw (1980).

The solution to equation 2.2 is based on the observation that the optimal *C* matrix can be expressed uniquely and explicitly in terms of the data and the component matrices for the three modes. The latter component matrices are optimized by an alternating least squares (ALS). A detailed description of the solution can be found in the paper by Kroonenberg and DeLeeuw (1980).

## Monitoring Program

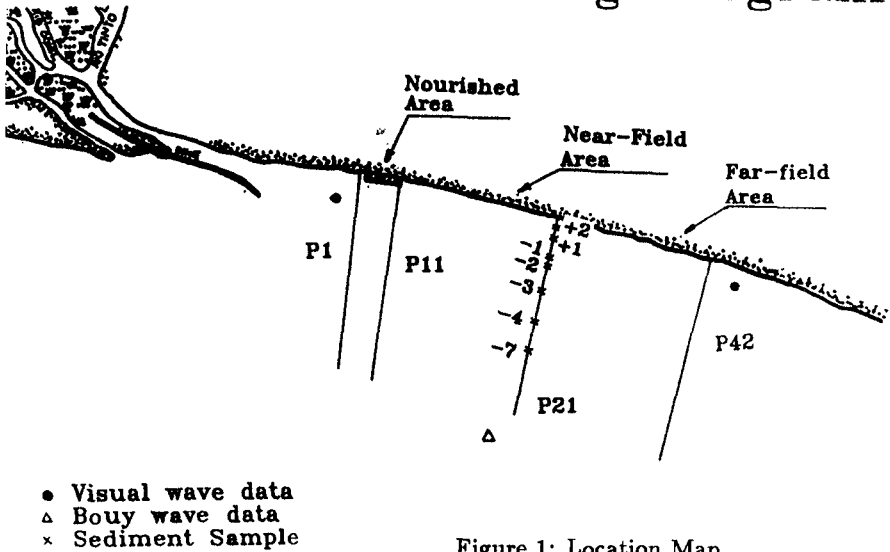

Figure 1: Location Map

### 3 STUDY SITE AND BATHYMETRIC DATA

The study area is located on the Southwest Coast of Spain (province of Huelva), between the Guadiana and Guadalquivir rivers (fig. 1). "Playa de Castilla" is a sandy beach which extends over 25 km between Mazagón and Matalascañas. Landward the beach is bounded by a rock-sand cliff which degrades into fine sand under wave action. The coastline at "Playa de Castilla" has been receding at a rate of 1.5 m/yr during the last 30 years (Fernández et al., 1990). The recession is due to two different reasons: first, the littoral drift from West to East, of about 390,000 m<sup>3</sup>/yr, and second, the reduction in the volume of sand transported by the rivers to the coast mainly caused by human construction.

An artificial nourishment of the beach of more than 1.500.000 m<sup>3</sup> of sand was carried out in 1989. The total volume of sand was pumped to the updrift edge of the beach forming a protruding area about 2 km long and 115 m wide. The borrowed sand was coarser than the native sand, being  $D_{50} = 0.63\text{mm}$  and  $D_{50} = 0.3\text{mm}$  for the borrowed sand and the native material respectively.

In order to study the beach nourishment evolution through time and space, a field measurement program was carried out during the period 1989-1992. The program included wave measurements, sand samples and bathymetry surveys. Bathymetric data were acquired bimonthly from 42 shore-normal profiles located between Mazagón and Matalascañas. Alongshore spacing of the profiles was approximately 500 meters and each profile was surveyed from the beach dune area, seaward to a depth of about 10 metres.

### 4 RESULTS OF ANALYSIS

The "Playa de Castilla" data described above are used for the 3-way PCA analysis. Of the 42 alongshore profiles, only 20 are examined. The profiles include the nourished part of the beach and 7 km down drift. For the cross-shore profiles, only the nearshore zone from the berm crest seaward to a depth of 4.0 m is selected for its variability. Within this area, very pronounced variations can be found both in the cross-shore and longshore direction. Notice that the transect spacing (500 m) was designed to resolve the long-term "spreading out" losses of the nourishment, but is not adequate to resolve the spacing of rhythmic topography, which can be spaced at several hundred meters or less.

The matrices  $E$ ,  $F$  and  $G$  in equation 2.2 are columnwise orthonormal. In other words, the components have length one. In this case, the importance of data is directly reflected by the entries of the core matrix,  $C$ , and not by the eigenvectors. Bartussek (1973) suggested scaling the orthonormal eigenvectors

of a 3-way *PCA* analogously to the procedure often encountered in standard *PCA*. One advantage of this scaling is that the scaled eigenvectors obtained are comparable within a mode and over modes. When scaling the eigenvectors (no longer orthonormals but orthogonal) the *core* matrix must also be scaled to leave the model invariant.

In figures 2a, b, c the first three cross-shore, alongshore and temporal eigenvectors are shown. The corresponding Bartussek *core* matrix values and the percentage of variation explained are given in Table 1. Notice that the first eigenvector of the three modes accounts for the 89.36%. This result is not surprising since we are dealing with raw uncentered data and, consequently, the centroid, defined as the mean of the variables, can explain most of the data. For that reason, the first eigenvectors are often highly correlated with mean vectors. Thus, the combination of the first eigenvectors gives a representation of the mean situation or mean bathymetry. Let us examine the meaning of the combinations of other eigenvectors

Figure 2a: Cross-shore Eigenvectors

Observing Figure 2a, it is clear that the second cross-shore eigenvector is very important in the upper part of the profile and it will play an important role in determining the upper profile slope. The third cross-shore eigenvector shows the typical S-shape of a berm-bar variability also encountered in standard *PCA* analysis. In Figure 2b, the nourished beach can easily be observed in the second alongshore eigenvector. The third alongshore eigenvector shows a small value with almost zero mean. In Figure 2c, the second temporal

eigenvector shows a seasonal dependence. The third eigenvector shows a net trend almost linear from negative values to positive ones. The combination of these eigenvectors explains most of the variability of the evolution of the beach (see Table 1). In order to better interpretate the variability they account for, it is useful to examine the profile or the bathymetry that is obtained by the product of one alongshore eigenvector with one cross-shore eigenvector, and use the corresponding temporal function to determine how the obtained profile or bathymetry evolves in time.

The following pair of eigenvectors is analyzed:  $e_1g_1$  and  $e_2g_2$  for time = 1;  $e_2g_1$  and  $e_3g_2$  for time = 2;  $e_2g_2$  and  $e_2g_3$  for time = 3; where  $e$  denotes cross-shore eigenvector,  $g$  denotes alongshore eigenvector and the subscript denotes the order of the eigenvector. These pairs account for the 96% of the total variance of the data (see Table 1).

- Time = 1, pair  $e_{1g_1}$  (Fig. 3a). As it was previously anticipated, the product of all the first eigenvectors represents a mean bathymetry. This mean bathymetry shows a uniform beach profile with minor changes in the alongshore direction.

Figure 2b: Alongshore Eigenvectors

Figure 2c: Temporal Eigenvectors

- Time = 1, pair  $e_{2g_2}$ . This pair is affected by the first temporal eigenfunction (Fig. 2c) which is almost constant in time and, consequently, this pair is

part of the mean bathymetry. The complexity of the bathymetry makes it impossible to achieve a solution just by the product of one cross-shore function and one alongshore function, thus this new pair must be added to the pair  $e_1g_1$  in order to obtain a better representation of the mean situation. Notice that this new pair modifies the upper part of the profile with minor changes in the offshore zone. Further, the modification at the upper shoreface has a different sign at the nourished beach and in the rest of the study area. The final mean bathymetry, achieved by the sumation of the pairs  $e_1g_1$  and  $e_2g_2$  has a much steeper profile at the nourished beach than the native beach (Fig. 3b).

Figure 3a: Mean bathymetry based on  $e_1g_1$

Figure 3b: Mean bathymetry based on  $e_1g_1$  and  $e_2g_2$

- Time = 2, pair  $e_{2g_1}$ . The most important characteristic of the bathymetries associated with the second temporal eigenfunction is the seasonality. The bathymetry achieved by the product of  $e_{2g_1}$ , for instance, must be added or subtracted to the mean bathymetry depending on the season (see Fig. 2c). In particular, pair  $e_{2g_1}$  shows a seasonal variation of the shoreface slope and of the amount of sand in the offshore part of the profile. These changes are almost uniform in the alongshore direction and are related to the erosion of the cliff.

- Time = 2, pair  $e_{3g_2}$ . As previously stated when dealing with the mean bathymetry, the seasonal changes are too complex to be represented by just one product. Consequently, if we want to obtain more information about the seasonal changes, the next pair to be added is  $e_{3g_2}$ . When combining these two eigenvectors, a shift in the location and magnitude of the bar is achieved. The complete picture of the seasonal variability can be found by adding pairs  $e_{2g_1}$  and  $e_{3g_2}$ . When adding those pairs, a clear bar is found in the native beach during the summer period, figure 4a. In the nourished area, however, no bar is formed, as can be observed in figure 4b.

Figure 4a: Seasonal variability. Native area

- Time = 3, pairs  $e_{2g_2}$  and  $e_{3g_2}$ . Only 0.66% of the total variance can be explained by the third temporal eigenvector. However, this variability is very important since it is associated with a net trend in the data. In the native beach the eigenvectors show a net erosion of the whole profile, see figure 5a. In the nourished area almost no changes have occurred during the period of study, see figure 5b.

Figure 4b: Seasonal variability. Nourished area

## 5 DISCUSSION

The transect spacing (500 m) and the survey frequency (bimonthly) were designed to resolve the long-term and long scale evolution of the beach nourishment. The results of the analysis show, however, that there is little evolution but significant seasonal variability.

The seasonal changes described by the 3-way PCA method are highly correlated with the seasonal variations of incident wave energy. It is well-known that there is an onshore-offshore movement of nearshore sediments in response to changing wave energy that builds bars and berms in a beach profile. In "Playa de Castilla" there is also a complex sand movement in the longshore direction induced by the protruding nourished area which was built with a coarser grain. The nourished area avoids the formation of a uniform bar along the beach resulting in a complex sediment redistribution. With the alongshore spacing of the transects used in the present study, it is not possible to resolve wave-like sand motions propagating in the longshore direction. This kind of motions have been cited by some authors, but largely ignored in literature. Further studies of these motions should be carried out by means of the 3-way PCA.

The evolution of "Playa de Castilla", described by the third temporal eigenvector and the combinations of pairs  $e_2g_2$  and  $e_3g_2$ , shows a net erosion of the beach as reported by (Fernández et al., 1990). However, there is no evidence of "spreading out" losses in the nourished beach. It seems that the effect of using material which is substantially coarser than the native material armors the beach in the nourishment area thereby resulting in less transport from the nourished area.

Figure 5a: Net trend. Native area

Figure 5b: Net trend. Nourished area

## 6 CONCLUSIONS

Three-Mode Principal Component Analysis has been applied to bathymetric data from a beach nourishment at "Playa de Castilla", Huelva, Spain. The method has been shown to be of great value in analyzing the variations of the shoreface during a two year period. The ability of the method to jointly analyze the cross-shore, alongshore and temporal variations and to separate these variations into orthogonal eigenvectors allow a better understanding of the processes involved. The results of the analysis show that most of the sand movement in "Playa de Castilla" has a seasonal dependency with involved bar-berm processes in the cross-shore direction and a complex sand variability in the alongshore direction induced by the protruding nourished area. The method has also shown an erosion trend in the beach. This erosion, however, is not related to the "spreading out" losses at the nourished beach but background erosion.

## 7 ACKNOWLEDGEMENTS

This work was partially supported by the Comisión Interministerial de Ciencia y Tecnología, through the Research Projects PB87-0800 and PB89-0381. The program TUCKALS 3 for 3 - way PCA analysis was provided by P. Kroonenberg.

## CHAPTER 175

### WAVE BREAKER TURBULENCE AS A MECHANISM FOR SEDIMENT SUSPENSION

G P Mocke<sup>1</sup> and G G Smith<sup>1</sup>

#### Abstract

The mechanism whereby sediment particles are suspended under broken waves in the surfzone is investigated through experimental data analysis and computational modelling. The concentration measurements referred to comprise continuous transmissometer and optical backscatter sensor (OBS) values recorded in the field as well as a large database of time-averaged recordings. The measurements analysis, which included a unique set of laboratory observations derived from a specially designed vertical mixing apparatus, clearly highlight the preeminent rôle of wave breaker turbulence in the suspension process. The wave period averaged turbulence structure is found to be well predicted by a two equation ( $k$ ,  $\varepsilon$ ) turbulence model. With the parametrization of the bottom reference concentration using relevant breaker and bottom generated turbulence variables, a scalar extension of the  $k$ ,  $\varepsilon$  model is effective in predicting published time-averaged suspended sediment distributions. Analytical relations founded on the assumption of a predominately diffusive turbulent transport regime furthermore display favourable predictive capabilities.

#### 1. Introduction

Suspended sediment concentrations in the surf zone have been measured to be up to several orders of magnitude higher than is typical for an unbroken wave regime. This is particularly evident at the higher elevations above the bed, with suspended

---

<sup>1</sup>Research Engineers, CSIR, P O Box 320, Stellenbosch, 7600, S Africa

sediment outside the surf-zone often restricted to the limited wave boundary layer.

In assessing the influence of wave breaking on the suspension process, Nielsen (1984) and Shibayama *et al.* (1986) have identified the action of the large scale vortices generated coincident with wave plunging. These essentially two-dimensional vortices are, however, restricted to a limited transition zone, shorewards of which the surf-zone is characterised by an inner bore region.

Experimental measurements through the inner region (Stive, 1980; Nadaoka and Kondoh, 1982) have revealed the presence of a turbulence generating layer in the vicinity of the surface bore from where the turbulence is transported downwards. Nadaoka *et al.* (1989) have furthermore identified an eddy structure whereby the surface bore is dominated by a nearly two-dimensional flow structure, bounded below by strongly three-dimensional obliquely descending eddies bringing highly intermittent turbulence to the bottom.

The dominant action of this turbulence for sediment suspension is verified by means of concentration measurements and visualisation studies made by Nadaoka *et al.* (1988) and Sato *et al.* (1990) in a wave flume. Computations of the turbulence structure using a 1-equation turbulence model have been shown by Deigaard *et al.* (1986) to result in favourable prediction of measured breaker zone suspended sediment concentrations. In the present exercise the suspension process is further investigated with reference to field and laboratory measurements as well as quantitative modelling.

## 2. Concentration Measurements

### Continuous

Particular reference was made to a comprehensive set of continuous measurements of suspended sediment recorded by a vertical array of seven transmissometer units. These units were fixed to a frame together with a pressure transducer and time-averaged concentration suction sampler and deployed at an exposed coastal site (Coppoolse *et al.*, 1992). A limiting factor is that transmissometer signals have a tendency to become saturated at elevated concentrations or if air-bubbles become entrained in the flow. However the analysis of a number of surf-zone time series, which also contain saturated signals, appears to demonstrate the importance of breaker turbulence for sediment suspension.

In a separate exercise, continuous measurements of suspended sediment were made by three optical backscatter sensors (OBS) deployed from a scaffold frame placed in the nearshore. The frame, which also had attached two electromagnetic current meters, a pressure transducer and wave staff, was within the surfzone except for the highest tidal conditions. It was found that elevated concentrations through the depth are not necessarily discreetly correlated with the largest wave heights and

velocities, but rather exhibit a sensitivity to a more intensive, but still intermittent, turbulence coincident with the wave groups.

A rather unique set of measurements were obtained from a laboratory experiment in which turbulence is generated from a vertically oscillating grid within a glass-walled tank. The apparatus is based on similar devices used for experiments on density gradient mixing due to diffused turbulence (E. and Hopfinger, 1986). The suspension of sand from a bed of sand at the base of the tank is recorded at various elevations using an optical backscatter sensor. Figure 1 a) is a typical time series of the measured concentrations recorded at 5 mm above the bottom. Despite a relatively constant time averaged concentration, the occurrence of intermittent suspension events due to the turbulence can be clearly seen. Figure 1 b) is a plot of time-mean concentrations evaluated at various elevations. The distribution exhibiting elevated concentrations throughout the entire depth is typical of suspended sediment measurements taken in the surf zone.

Figure 1 OBS concentrations as a) time series measured 5 mm from the bottom and b) time-averaged at various elevations

### Time averaged measurements

Analyses of experimental turbulence and suspended sediment measurements (Stive, 1980, Nadaoka *et al.*, 1988, Sato *et al.*, 1990) have indicated that phase-averaged quantities display limited variation over time. This underlines the intermittent nature of the turbulence and suspension process and also confirms the validity of using a time-averaged modelling approach.

Time-averaged concentration profiles recorded seawards of the surfzone have been shown to be relatively well described by an exponential distribution over the depth of  $\bar{C}(z) = C_b e^{-z/\ell}$ , where  $\ell$  is an integral length shown by Nielsen (1984) to scale on bed ripple dimensions. Although there is some indication (Hardenberg *et al.*, 1991) that the classical exponential relation describes surf-zone concentrations when averaged over relatively long time periods, it is inappropriate for representing the

strong vertical variability in mixing evident on the time scale of the incident waves. In the analysis of a comprehensive database of field and laboratory measurements of suspended sediment concentration profiles compiled by Van Rijn (1991) it is however assumed that the exponential distribution holds over a limited region near the bed. Hence for some 73 sets of experimental surf-zone measurements an exponential regression curve fitted through the lower three data points is extrapolated for the determination of a reference concentration  $C_b$  at the bottom.

Previous attempts to parametrize this reference value have focused primarily on the rôle of turbulence generated by mean shear near the bottom as reflected in the Shields parameter  $\theta = \tau / (\rho(s-1)gd)$ . Because of the significance of near surface generated wave breaker turbulence, however, it is of fundamental importance to also incorporate this contribution in any parametrization exercise. The energy dissipation in a breaking wave may be modelled as for a periodic bore. Thus the equivalent energy available for sediment suspension is related to this dissipation ( $D \propto H^3/hT$ ).

Complementing this parameter representing the injection of TKE into the flow is the length scale indicating the relative degree of depth penetration. It is proposed that an appropriate scale for this parameter would be the relative wave height ( $H/h$ ). Combining these scales together with the Shields parameter the best fit regression curve against the database measurements is as shown in Fig. 2 and provides the following expression for predicting the bottom reference concentration:

$$C_b = \rho K^{-0.92} (H/h)^{3.32} (H^3/hT)^{-0.92} \theta^{0.37} \quad (1)$$

where  $K = 1.51 \cdot 10^3 \text{ sm}^{-2}$  is a proportionality constant related to the energy dissipation term. In carrying out the exercise the relative importance of component terms such as the wave height was clearly evidenced.

Figure 2 Parametrization of bottom reference concentration  $C_b$  by current and wave variables

The resolution of length scale values (through transformation of the aforementioned exponential relation) for a number of breaker cases included in the Delft database showed interesting tendencies. On the whole magnitudes were relatively small in the immediate vicinity of the bottom, with in most cases a rapid increase to values of between 20 and 40% of the overall water depth at higher elevations. Such magnitudes are in accordance with quantities determined from experimental measurements by Black and Rosenberg (1991) as well as scales determined by George and Flick (private comm.) from field measurements of turbulence .

### 3. Computational Modelling

#### System of equations

The time-mean vertical distribution of suspended sediment is described by the time-independent form of the classical advection-diffusion equation:

$$0 = \frac{\partial}{\partial z} \left[ D_c \frac{\partial C}{\partial z} + w_s C \right] \tag{2}$$

where  $C$  is the sediment concentration,  $w_s$  is the sediment fall velocity and  $D_c$  is the eddy diffusivity which is assumed equivalent to the eddy viscosity  $\nu_t$  defining the turbulent momentum flux. Following the analysis of Prandtl-Kolmogorov the eddy viscosity may be related to the TKE density  $k$  ( $\overline{u_i u_j} = 2k$ ) and its rate of dissipation  $\varepsilon$  such that  $D_c = \nu_t = c_\mu k^2/\varepsilon$ , where  $c_\mu$  is an empirical constant. For a unidimensional flow the dimensionless form of the time-averaged transport equations for  $k$  and  $\varepsilon$  may be expressed in the following manner:

$$0 = \frac{\partial}{\partial z} (D_k \frac{\partial k}{\partial z}) + P_b + P + G - \varepsilon \tag{3}$$

$$0 = \frac{\partial}{\partial z} \left[ D_\varepsilon \frac{\partial \varepsilon}{\partial z} \right] + [c_{1\varepsilon} (P_b + P + G (1 - c_{3\varepsilon})) - c_{2\varepsilon} \varepsilon] \frac{\varepsilon}{k} \tag{4}$$

where the above equations have been made dimensionless by characteristic flow parameters such as the mean water depth  $h$  and the wave celerity  $c(=\sqrt{g\overline{h}})$ . The dimensionless diffusion coefficients are defined as:

$$D_k = 1/Re + \nu_t / \sigma_k , \quad D_\varepsilon = 1/Re + \nu_t / \sigma_\varepsilon \tag{5}$$

where the molecular viscosity term  $Re$ , the flow Reynolds number, is negligible in comparison to the turbulence contribution.

The forcing functions are the production  $P_b$  of TKE due to wave breaker induced turbulence and  $P = \nu_t (\partial u / \partial z)^2$  due to mean shear. The buoyancy term is expressed

as  $G = Ri D_c \partial C / \partial z$ . This term, which includes a reference dimensionless Richardson number  $Ri = g \Delta \rho / \rho h / c^2$ , expresses the effect of turbulence damping due to the gradient in concentration. The choice of empirical constants, discussed in Mocke (1991), are close to classical values (Rodi, 1980) except for  $c_\mu (= 0.3)$ .

### Boundary conditions

The main forcing function for the flow is the production of turbulence in the surface roller. This production is assumed to be imposed at the upper boundary of the flow regime, which is taken at the mean water level. Modelled according to the dissipation in a hydraulic jump the breaker production term may be expressed as:

$$P_b = A_\varepsilon \frac{gH^3}{4h^2T} D' \quad (6)$$

where  $A_\varepsilon$  is a dimensionless dissipation factor expressing the difference between energy dissipation in a wave breaker and hydraulic jump. A series of experimental measurements made by Stive (1984) found this factor to be in the range 1.3 ~ 2.0, and together with other data, suggests a dependence of this factor on the wave breaker type. The dimensionless energy dissipation  $D' = h^2 / h_t h_c$  (Svendsen, 1984), with  $h_t$  and  $h_c$  the depths below the wave trough and crest level respectively.

With the assumption of a zone characterised essentially by local equilibrium between diffusion and dissipation of turbulence, the TKE varies over depth as:

$$k(z) = k_s \exp ((z-h)/\ell_s) \quad (7)$$

where  $k_s$  and  $\ell_s$  are respectively the intensity and length scale of the turbulence at a reference surface level taken at the upper boundary ( $z=h$ ). With the rate of dissipation  $\varepsilon$  related to  $k$  through the turbulent length scale ( $\varepsilon \propto k^{3/2}/\ell$ ), the vertical distribution of  $\varepsilon$  likewise follows an exponential decay:

$$\varepsilon(z) = \varepsilon_s \exp (3/2 (z-h)/\ell_s) \quad (8)$$

Substituting the expressions for  $k$  and  $\varepsilon$  in the purely diffusive formulation of (3), the surface value  $\varepsilon_s$  may be related to  $k_s$  through the length scale  $\ell_s$ :

$$\varepsilon_s = \left( \frac{3}{2} \frac{c_\mu}{\sigma_k} \right)^{1/2} \frac{k_s^{3/2}}{\ell_s} \quad (9)$$

In terms of the previously discussed turbulence generating horizontal vortex in the surface roller and as suggested by Battjes (1975),  $\ell_s$  could be expected to scale on the wave height  $H$  ( $\ell_s = A_t H$ ) where the chosen dimensionless length factor

$A_t = 1/3$  provides a length scale approximately equivalent to the wave trough amplitude ( $h-d$ ). It is also consistent with a dimensionless length scale  $\ell/h \approx 0.2$ , which is in close agreement with estimates made from undertow measurements as well as previously mentioned concentration and turbulence measurements.

At the surface boundary, the vertical turbulent and gravity flux of sediment is assumed to be in equilibrium:

$$D_c \frac{\partial c}{\partial z} + w_s C = 0 \quad (10)$$

The lower boundary condition is not applied at the actual bottom but rather at the outer limit of the viscous boundary layer. As detailed in Rodi (1980), the bottom boundary conditions for  $k$  and  $\varepsilon$  are:

$$k_b = \frac{u_*^2}{\sqrt{c_\mu}} \quad \varepsilon_b = \frac{u_*^3}{\kappa z} \quad (11)$$

where  $u_*$  is the bottom shear velocity,  $\kappa$  the constant of Von Karman ( $\sim 0.4$ ),  $z$  the distance from the bed and  $c_\mu$  the diffusive coefficient where production and dissipation are in local equilibrium ( $=0.09$ ). A constant stress bottom boundary layer is also assumed for the quantification of TKE production due to mean shear. Assuming local equilibrium ( $P/\varepsilon=1$ ); this production may be approximated as:

$$P = \frac{u_*^3}{\kappa z} \quad (12)$$

For the determination of  $u_*$ , reference is made to the bottom roughness and the mean velocity  $\bar{u}$ . Where we do not dispose of measurements the mean velocity is reliably estimated from experimental measurements (Stive, 1980) as  $\bar{u} \approx 0.1c$ . Although the bottom boundary turbulence source is normally greatly outweighed by the surface breaker contribution, it does act as a limiting condition both in the event of low intensity breaker turbulence as well as by implicitly suppressing the turbulence scales due to wall proximity effects.

The bottom boundary condition for the suspended sediment computations relies on the parametrization relation (1), which provides the bottom reference concentration  $C_b$  for the relevant flow condition.

### Resolution procedure

The set of equations are discretized in an implicit scheme using the finite difference method. A central differencing approach is used to construct a tri-diagonal matrix which can be solved analytically by the Thomas algorithm.

#### 4. Computational Results

##### **Wave breaker turbulence**

Initial model simulations were carried out in the absence of the sediment phase in an effort to evaluate the effectiveness of the turbulence model for predicting the observed dynamic as well as measured turbulence parameters. The experimental arrangements and description of measurements are detailed in Stive (1980) and Stive and Wind (1982), Nadaoka and Kondoh (1982) and Hattori and Aono (1985).

In analyzing laser Doppler anemometer (LDA) measurements, Stive (1980) used an ensemble averaging method to separate the time varying wave motions from the purely turbulence contribution. In analogy with the turbulence characteristics of a plane wake, the turbulent kinetic energy under the breakers was computed from the two components of the turbulence fluctuations as  $k=1.33/2(\overline{u'^2}+\overline{w'^2})$ .

The measured wave parameters were exploited for the computation of the TKE breaker production rate using expression (6). This rate was adjusted by the measured dimensionless dissipation factor  $A_s$  to obtain the correct energy dissipation for determining the turbulence production forcing function.

Solving the set of equations (3) and (4), predictions of time-averaged kinetic energy are compared to measurements at different positions after breaking for Stive tests 1 and 2 (Figure 3). In general, comparisons were found to be slightly better with the spilling (test 1) rather than the plunging (test 2) wave case. Although the depth averaged value for the predictions compares favourably with that of the measurements, the simulations were found to display somewhat more variation over the vertical. This characteristic is possibly attributable to a small convective contribution present in the experimental case. However, any such comparisons should be made in consideration of the room for optimization of the model constants, the experimental separation technique employed, and the determination of  $k$  by plane wake analogy.

The significant influence of the technique used for separating wave and purely turbulent fluctuations is evident when considering the measurements of Nadaoka and Kondoh (1982). By confining turbulence to a cut-off frequency of 10 Hz, any components with frequencies lower than this value will be neglected. A consequent underestimation of actual values would appear to be evident from intercomparisons with predictions (Figure 4 a)) and the magnitude of Stive values. As is also shown in a purely numerical exercise a reduction of the breaker height by 50% results in favourable correspondence between predictions and measurements. The separation technique employed by Hattori and Aono (1985) is considered equivalent to that used by Stive (1980). Not surprisingly correspondence between predictions and measurements is favourable (Figure 4 b)).

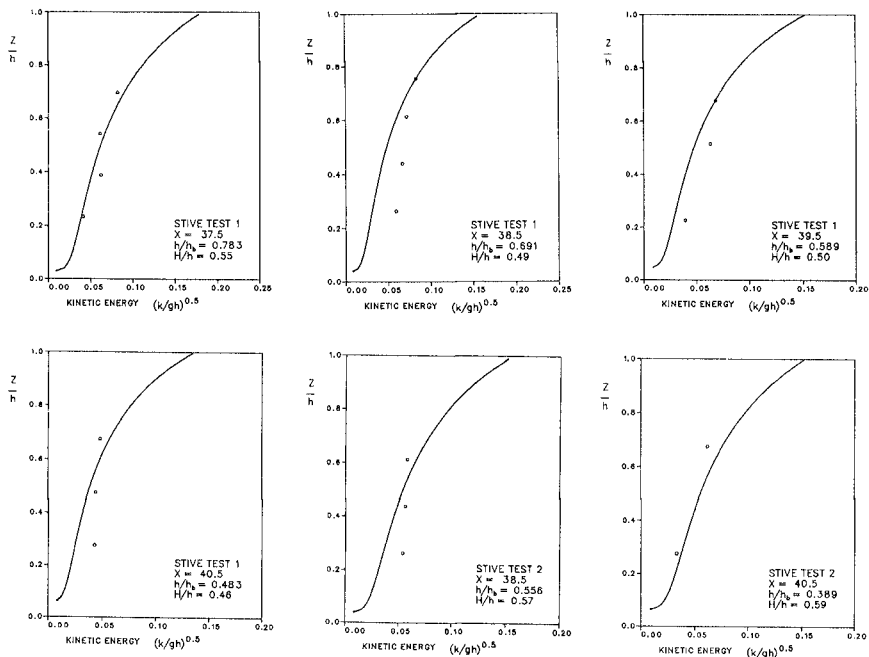

Figure 3 Intercomparison of computed (—) TKE profile and measurements (o) of Stive (1980). Tests 1 and 2.

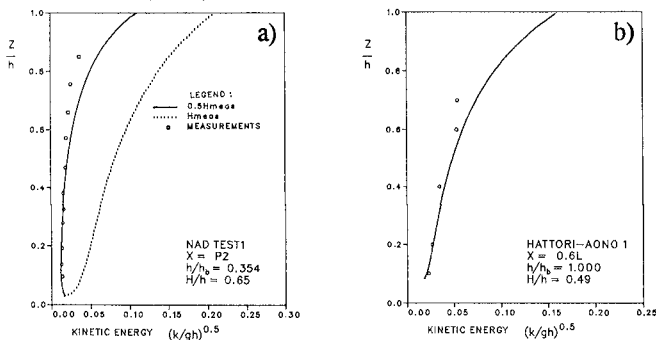

Figure 4 Intercomparison of computed (—) and measured (o) TKE profiles of a) Nadaoka and Kondoh (1982) and b) Hattori and Aono (1985).

The typical dissipation profile computed for the Stive measurements predicts a curve decaying from the surface in much the same manner as for the TKE. Lacking measurements of the dissipation profile, no comparisons with the experimental case may be made. However, the model was found to at least conceptually confirm the observation by Svendsen (1987) that only a relatively

small percentage of the energy lost in the breaker is dissipated below the wave trough level.

Penetrating downwards from the surface production source the computed length scale was found to display a near linear gradient. This is consistent with the integral length scale growth as measured under an oscillating grid by E and Hopfinger (1986). Approaching the bottom boundary the length scale reduces dramatically to attain a value determined by the imposed boundary conditions.

Due to dimensional considerations, the eddy viscosity profile displays similarities to that for  $k$  and  $\epsilon$ , indicating an appreciable variation over depth. Although not a directly measurable quantity, Stive and Wind (1986) estimated the eddy viscosity for test case 1 by considering similarity between the flow fields in breaking waves and wake flows. The resulting eddy viscosity is however considered averaged over the depth. The ensemble of computed profiles predicted depth-averaged values in close agreement with these estimations.

### **suspended sediment**

For the computation of the suspended sediment profiles the turbulence equations (3) and (4) are extended by the scalar diffusion equation (2). Model comparisons are somewhat hindered however, by the fact that presently there exists no simultaneous measurements of suspended sediment and turbulence quantities. Furthermore, there is a lack of suspended sediment measurements that also include an accurate assessment of the cross-shore wave energy loss important for determining local dissipation.

Despite these limitations the model was applied to a number of cases where suspended sediment was measured under breaking waves. In these cases, which include both laboratory and field measurements, the given wave height was exploited for determination of the breaker energy production. For the sake of consistency between cases no adjustment of the bore approximation dissipation term is made (i.e.  $A_\epsilon = 1$ ). Where the sediment fall velocity of the suspended sediment is not provided, it is estimated from the sediment size ( $D_{50}$ ) characteristics.

Although recognized as potentially significant, little attention has been given to incorporating the turbulence damping effect of a concentration gradient in previous attempts at modelling suspended sediment in the surf-zone. With the inclusion of the buoyancy term  $G$  in the equations (3) and (4) however, this contribution can be assessed.

As is in fact shown in Figure 5a) where model simulation with and without the buoyancy term are compared with field measurements of Nielsen (1984), the turbulence damping effect reduces the amount of sediment in suspension. The damping effect on local turbulence is more directly illustrated in the trace of the

mixing length scale shown in Figure 5b), where some reduction in this scale due to the more predominant concentration gradient near the bottom is evident. Superimposed on the predictions are estimates for the relative length scale as estimated from the measurements. The relatively rapid increases in length scale before attaining a magnitude between 20% and 30% of the water depth is evident in both the measured and predicted values.

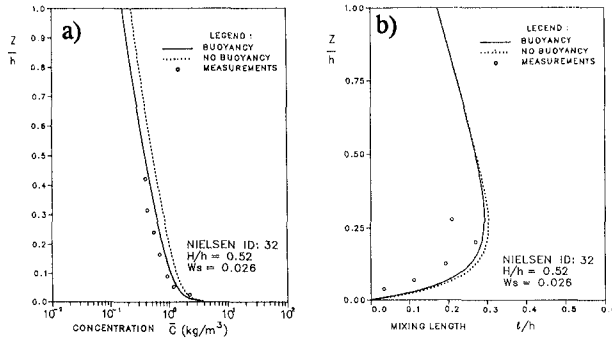

Figure 5 Predicted (a) concentration profile and (b) turbulent length scale with (—) and without (---) buoyancy effects (Van Rijn, 1991)

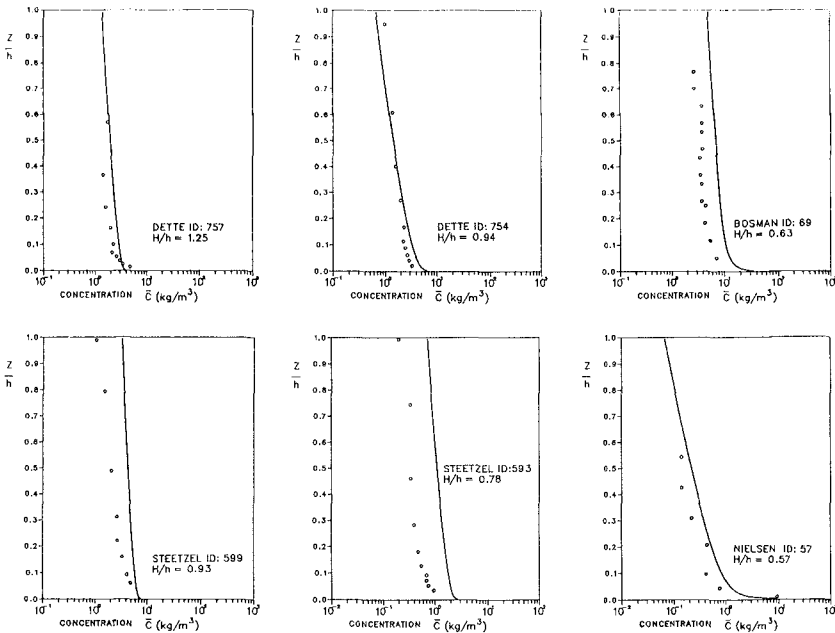

Figure 6 Comparisons between predictions (—) and experimental measurements (o) of suspended sediment as obtained from the Delft database (Van Rijn, 1991).

As may be observed from the examples of field and laboratory concentration measurements presented in Figure 6, predictions are generally in reasonable agreement with measurements. The sensitivity of the model to the wave height and bottom friction velocity and reference concentration was found to be important, with adjustments of less than 10% resulting in improved correlations in many cases.

**Analytical relations**

Assuming an exponential decay it is possible to plot profiles of  $k$  and  $\epsilon$  knowing the surface boundary values of these parameters and the relevant turbulent length scale. Following substitution of expressions (7) and (8) into the Prandtl-Kolmogorov relation the vertical distribution of eddy viscosity may be approximated by the following expression:

$$\nu_t = \nu_{t_s} \exp ( 1/2 (z-h)/\ell_s ) \tag{14}$$

It is clear that an accurate means of evaluating the surface value  $k_s$  would allow reasonable analytical predictions of the vertical profile for all the relevant turbulent parameters. From a joint analysis of  $k_s$  (as determined from the computational model) versus the non-dimensionalised breaker production term  $P_b^+ = P_b hc^{-3}$  for the Stive (1980) measurements the following relation was derived.

$$\sqrt{k_s} = 0.124 u_* \exp (128.2 P_b h.c^{-3}) \tag{15}$$

Although representing only a limited database of measurements, the above relation provides an intuitively correct approximation of the magnitude of breaker induced TKE at the reference surface level. Exploiting the relation (11) and assuming  $A_t = 1/3$ , the approximated eddy viscosity profile may be computed over the depth (Fig 6(a)). As may be seen from Figure 6(b), the resulting eddy viscosity profile predicts a concentration distribution in good comparison with measurements over most of the depth.

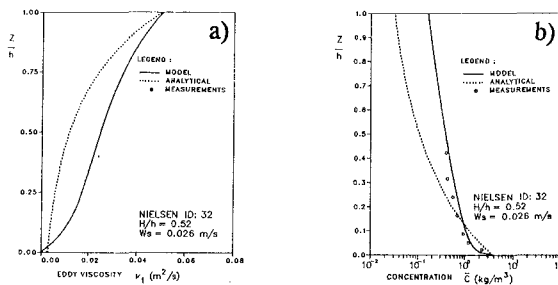

Figure 7 Intercomparison of analytical (—) and modelled (•••) (a)  $\nu_t$  profiles and (b) concentration profiles (Nielsen case 32, Van Rijn, 1991).

## 5. Conclusions

Through qualitative observation and quantitative computation and modelling, the fundamental significance of wave breaker turbulence for sediment suspension is clearly established. Despite the better understanding of surf zone processes through the increased number of flow measurement and visualization studies carried out in recent years there has been limited progress in quantitative predictive modelling of these processes. In adapting a time-independent diffusive turbulence model to the problem of breaker turbulence, a number of significant flow parameters previously measured in wave flume experiments are satisfactorily predicted.

Measurements of suspended sediment have concentrated on the suspended mass with little detail being available concerning the wave and turbulence properties. However in applying the buoyancy extended model with the given wave heights and a parametrized bottom reference concentration measured suspended sediment profiles are well represented. For further model refinement purposes it would however be desirable to have both turbulence and suspended mass measurements for identical conditions.

With the assumption of a diffusive dominated flow, it was possible to develop analytical relations approximating turbulence profiles from their parameter surface value and an appropriate length scale. With a parametrization of the surface scale of TKE using the term for breaker turbulence production, wave bore characteristics may be used for predicting the vertical distribution of suspended sediment.

## Acknowledgements

The authors thank M Stive for providing a comprehensive set of experimental data and L Engelbrecht for technical assistance.

## CHAPTER 176

### Grain-size Distribution of Suspended Sediments

Ryuichiro Nishi, Michio Sato and Kazuo Nakamura<sup>1</sup>

#### ABSTRACT

Field observations on the grain size distribution of suspended sediment in a surf zone has been carried out at Fukiage beach in 1990 and 1991. In these observations, a suction pump has been used to sample a sufficient amount of suspended sediment for grain size analysis. The instrument designed for the data collection worked well. Vertical distributions of sediment concentration for several grain sizes which compose suspended sediment are obtained. This enable us to do numerical simulations of beach evolution taking the composite character of suspended sediments into consideration. Results are compared with the ones obtained by conventional simulation method which assumes single grain size composition of beach materials, and discussed. The vertical distribution profiles of the concentration of suspended sediments are also compared with existing models and discussed.

#### 1. Preface

The beach is composed of sediment particles of various sizes and shapes. The grain size is one of the parameters that significantly affects the beach shape and evolution, i.e. the movement of bar, formation of berm, etc. Generally, the medium grain size,  $d_{50}$ , used to define suspended sediment concentration.

Regarding grain size distributions of beach material across the shore, Bascom(1970) has conducted extensive grain size analysis of

---

<sup>1</sup>Department of Ocean Civil Engineering, Kagoshima Univ.  
1-21-40 Korimoto, Kagoshima-shi, JAPAN 890

cross-shore material and proposed to use the medium grain size at the shoreline as the representative grain size of the beach. Bowen expressed the equilibrium beach profile as a function of settling velocity of sediment particle. He showed that the larger the grain size, the steeper the equilibrium beach profile. The characteristics and applications of equilibrium beach profiles,  $h=Ay^{2/3}$ , are discussed in detail by Dean(e.g. 1991). In his equilibrium beach profile model, A is a function of sediment diameter and later it is found that A is well predicted by settling velocity of sediment particle. Recently, Kato et al.(1991) has done an extensive analysis of sea bed material at Hazaki Observation Research Facility, HORF, in Chiba prefecture, Japan. However, it seems to be uncertain whether the grain size of the suspended material is the same as the sea bed material, and whether the suspended sediment which composes a wide range of grain sizes in nature can be represented by a single grain size assumption. Also, there is a few sediment transport models which considers the composition of sea bed material. Under river condition, there is evidence that the size of the bed load material is different from original bed material (see Fig.6 Chih Ted yang et al.1991).

Two field observations on grain size distributions of suspended material and sea bed material in a surfzone have been carried out at Fuklage beach in 1990 and 1991 respectively to study the effect of grain size distribution on beach profile changes due to wave action. For grain size distribution analysis of suspended material, it is necessary to obtain sufficient amount of suspended material. Therefore, a suction pump was used. The instrument was designed specifically for this observation and it worked well. This system will be shown in the next section. A similar idea to this suction pump was tested by Irie(1977) and Antsyferov(1983). Vertical distributions of suspended sediment concentration for several grain sizes were obtained.

## 2. Field observations.

Two field observations have been carried out at Fuklage beach one from 18 Oct. to 20 Oct. 1990 and the other from 9 July to 11 July 1991. This sandy beach faces East China Sea and extends 30km in north-south direction along with Satsuma peninsula, Kagoshima prefecture, Japan as shown in Fig.1. The observation base was set at Irikihama beach, however, the base position in 1991 was different from that in 1990.

To sample a sufficient amount of suspended material for sieving analysis from each depth, it is impractical to use instantaneous sand trap such as by Kana(1978) and it is also difficult to record the grain size

Fig.1 Location of Fukiage Beach

Fig.2 Measuring station (Fukiage beach)

Photo 1. Intake of suction pump

Photo 2. Installation of equipment

distribution by optical and acoustic method. To relate the grain size distribution obtained by such a bamboo trap (Fukushima et al.1955) to local wave condition cannot be achieved, because the water depth and wave condition change during the sampling time in the surfzone. Therefore, a suction pump method was designed to obtain the vertical distribution of grain size of suspended material in short period.

The intake of this suction pump under the water is shown in Photo.1 and design suction speed is faster than settling velocity of the suspended material. The speed is an order of a half meter per second, while the settling velocity of sediment is an order of several centimeters per second. The suction speed was measured before every measurement. The elevation of the intake from the sea bed is adjusted by pulling a rope attached to the suction pipe. In fact, the intake could not be well movable vertically due to the friction of the suction pipe with a sheath and misdesign of a pulley, so that a diver adjusted the elevation of the intake in the first observation. In the second observation, the position of the pulley was adjusted to the upward to avoid being buried into the sea bed and the suction pipe was modified to make less friction with the sheath.

The measuring station is shown in Fig.2. The measuring station was located in the surf zone during high water only. The working area was about 5.4m high from the sea bottom and has a surface dimension of 1.8m by 1.8m. Four capacitance type wave gauges and four pressure type wave gauges were installed between the measuring station and the shoreline. One capacitance type wave gauge is located alongshore the suction pump to relate the local wave conditions to the suspended sediment concentration. The installation of the equipment are shown in Photo.2.

The waves during two observations were relatively low and breakers were of spilling type. The wave condition of the third measurement in the first observation in 1990 is shown in Table 1.

Table 1. Wave conditions

Wave Height		Wave period	
$H_{max}$	33.7 cm	$T_{max}$	6.2 sec
$H_{1/10}$	23.0 cm	$T_{1/10}$	6.3 sec
$H_{1/3}$	18.3 cm	$T_{1/3}$	5.6 sec
$H_{mean}$	11.4 cm	$T_{mean}$	4.0 sec

The beach profiles were measured during low tide just before the measurement. Longshore bar was formed 150m offshore as shown in Fig.3. The cross shore samples of sea bed material were taken at 10m intervals.

The suspended sediment samples were taken at 5cm, 10cm, 15cm, 30cm from the sea bed in the first observation, and at 1cm, 5cm, 10cm, 20cm, 30cm, 50cm in the second observation. It took nearly 1 to 15 minutes to obtain the samples by suction pump depending on the height from the sea bed, generally speaking, the higher the suction point, the longer the suction duration due to reduced suspended sediment concentration. The suction pump was also used in the upper portion of the water column near the water surface, but was unable to collect a sufficient amount of material for the analysis.

The measurements were taken 4 times for the first observation in 1990 and three times for the second observation in 1991. In this paper, the third and the fourth measurements in the first observation are discussed. The third and the fourth measurements were carried out on 19 Oct. 1990. Sieving analyses was carried out to obtain the concentration profiles of several grain sizes of the suspended sediment. In addition, one direct sample used 2000cc polyethylene bottles has been taken by diver during the first observation.

### 3. Data analysis

Data set of grain size distribution of sea bed materials, grain size distribution of suspended materials, the concentration of several grain sizes which compose suspended sediment and total concentration have been taken.

#### 3.1 Grain size distribution

Grain size distributions of suspended material obtained at several depths were sieved, first. In addition, grain size distribution of sea bed material at the measuring station was also obtained to compare with the composition of suspended materials. The grain size distribution from the third measurement is shown in Fig.4(a). The composition of suspended material is smaller than the original sea bed material. As can be seen Fig.4(b), the representative grain size of the bed material does not directly correspond to that of the suspended material in a calm wave condition. Unfortunately, data under severe wave condition is not available.

It is reassured that small waves of short periods do not cause

Fig.3 Beach profile

Fig.4 (a) Grain size distribution of sea bed material and suspended sediment

(b) Representative grain sizes of sea bed material and suspended sediment

suspension of the entire original bed material, but only cause suspension of finer sea bed material. Under this condition, the composition of suspended materials are smaller than that of the sea bed material.

### 3.2 Suspended sediment concentration of several grain sizes

The concentrations of several grain sizes are obtained. The results are shown in Fig.5, where, the value of each grain size shown represents the average size of sieve size. The 0.34 mm material which is close to the mean grain size ( $d_{50}$ ) of the sea bed material contributes nearly 50% of the suspended material at 5cm from the sea bed level. The 0.18mm, 0.63mm, 0.09mm material contribute, in respective orders, lesser amount. This order of contributions also holds in the upper layer in the third measurement.

The vertical distribution of concentration at each grain size is assumed to follow an exponential form as shown by eq.(1) (due to Dally et al. 1980).

$$C(z) = C_a \cdot \exp\{F(z-z_a)\} \quad (1)$$

while,

$$F = \frac{-15W}{h} \sqrt{(\tau/\rho)} \quad (2)$$

where,  $C(z)$  is the suspended sediment concentration at depth( $z$ ),  $C_a$  is the concentration at the reference level ( $z_a$ ),  $z$  is a height from the sea bed,  $h$  is a water depth and  $\sqrt{(\tau/\rho)}$  is a shear velocity. The shear velocity  $\sqrt{(\tau/\rho)}$ , is computed by two different methods Noda(1968) and Dally(1980); They are :

$$\sqrt{(\tau/\rho)} = \sqrt{2\pi v/T} \cdot \frac{\pi H}{\tanh(kh)} \quad (3)$$

$$\sqrt{(\tau/\rho)} = (fH^2g/16h)^{0.5} \quad (4)$$

where  $\rho$  is the density of water,  $T$  is the wave period,  $H$  is the wave height and  $v$  is the coefficient of kinematic viscosity set to be equal to 0.01 cm<sup>2</sup>/sec (20 c) in this case.

The concentrations calculated by eq.(4) are also shown in Fig.5. These concentration curves fit quite well to the data in the lower position

Fig.5 Suspended sediment concentration of individual grain sizes based on Dally's shear velocity eq.(4)

Fig.6 Total concentration of suspended sediment

(i.e., 5cm, 10cm, 15cm), but there is disagreement between the exponential curve and the data in the upper position ( $z=30\text{cm}$ ) for the case of 0.34mm. Combining the calculations of suspended sediment concentrations for several grain sizes, the total concentration of suspended sediment is calculated and is compared to the field data. This total concentration is defined as the sum of concentrations of individual grain sizes, i.e.,

$$C_{\text{total}}(Z) = \sum_{i=1}^N C_{s,i} \cdot \exp\{F_i(Z-Z_a)\} \quad (5)$$

where, the subscript  $i$  refers to the  $i$ th grain size. The total concentration based on

the mean grain size ( $d_{50}$ ) is also calculated, shown as dotted line in Fig.6. The data from the third measurement is also shown in the figure as black circles. It is seen that the concentration calculated by eq.(5) is slightly smaller than that derived from  $d_{50}$  in lower regime, and is higher in the upper regime. However, their difference is small. This might be due to the fact that the waves were small in this measurement, only in the order of 20cm. For large waves, their difference could become larger.

#### 4. Numerical simulation of beach evolution.

In this section, simple numerical simulations of beach evolution were carried out to illustrate the effect of the composite of sea bed materials by comparing the results with the ones obtained by a conventional approach which assume single grain size ( $d_{50}$ ) composition of beach material. Two types of beach profile storm and normal profiles, or bar and berm profiles are used.

The composite characters of sea bed materials used for numerical simulation are shown in Fig.7. Case 1 assumes that the beach is composed of single size grain which is represented by mean grain size ( $d_{50}$ ) set to be 0.2mm. The mean grain sizes of case 2 and 3 are also 0.2mm, but the sorting coefficient of two cases are chosen to be 1.47 and 2.40 respectively; thus the beach is composed of composite sand size. Case 4 assumes a single grain size composition of beach material with mean grain size equal to 0.6mm. The mean grain size of case 5 and 6 are also 0.6mm, but again the sorting coefficients are chosen to be 1.45 and 2.36 respectively.

##### 4.1 Basic equation

The conventional beach evolution model proposed by Dally is applied

to the numerical simulation by taking into consideration the composite characteristics of the bed material. The suspended sediment transport is written as:

$$Q_{ss} = \int_{-h}^0 u(z) \cdot c(z) dz \quad (6)$$

where,  $u(z)$  is a mean horizontal velocity of sediment particles which consists of components; an oscillatory component due to waves, and velocity component due to mean flow,  $c(z)$  is a concentration profile as expressed in eq.(1). To calculate the suspended sediment transport rate, the water column is divided into two layers; one is the inner layer lower than  $DF(=wT)$  and the other is the outer layer higher than  $DF$ , where,  $w$  is the settling velocity. This settling velocity is obtained by Rubey's law.

$$w = \sqrt{\frac{2(\rho_s - \rho)}{3\rho}gd + \frac{36v^2}{d^2}} - \frac{6v}{d} \quad (7)$$

where,  $\rho_s$  is the density of sediment particle,  $g$  is the gravitational acceleration and  $d$  is the diameter of sediment particle.

The calculated total suspended sediment transport rate is applied to the continuity equation given below to obtain the new beach profile.

$$\frac{dh}{dt} = \frac{1}{1-\lambda} \frac{dQ}{dx} \quad (8)$$

This new beach profile is used to revise the input wave condition for the next time step.

The effect of sorting sea bed material due to waves and the silt component of bed material are excluded in the computation.

#### 4.2 Numerical results

The numerical results of beach evolution for 0.2mm mean grain size material and 0.6mm mean grain size material are shown in Fig.8 and Fig.9, respectively.

Based upon a fall velocity criterion proposed by Dean, the wave and sediment condition are expected to produce the storm profiles which are bar formation as shown in Fig.8 and normal profiles which are berm formation as shown in Fig.9. It appears that the size of the bar feature

Fig. 7 Composition of bed materials for numerical simulation

Fig.8 Numerical simulation for bar profile after 200sec

Fig.9 Numerical simulation for berm profile(200sec)

diminish with the increasing of the range of the material size in Fig.8. The position of bar crest is also located slightly shoreward for this wave condition. For the storm profile, the composite beach material appears to have a smoothing effect and the bar formation becomes lower and wider as the range of the sand size increase. For the normal profiles shown in Fig.9, it appears that the closure depth increases with the increasing of the range of the sand size. The cross shore sand transport for case 4 and 5 are onshore sediment transport while that for case 6 is consisted of onshore and offshore sediment transports to cause a different type of beach profile for this wave condition.

Generally, the results for storm and normal profiles based on a single grain size assumption are similar to these profiles produced by a narrow range of beach material, while the profiles are different from the beach profiles produced by a wide range of sea bed material.

## 5. Concluding remarks

The conclusions are ;

(1) The pumping system designed to obtain the suspended materials for grain size analysis worked well in the lower portion of the water column. In the upper portion of the water column, the data could not collect in this measurement, since the reduction of suspended sediment concentration.

(2) The representative grain size of the suspended materials decreases with increasing elevation. The mean grain size of the suspended material is smaller than that of original sea bed material.

(3) Concentration profiles of individual grain size can be represented by the widely accepted exponential equation.

(4) The total concentration defined as the sum of the individual grain size concentrations underestimates in the lower portion of the water column and overestimates in the upper region of the water column with reference to the concentration profile derived from single grain size assumption.

(5) Numerical simulations of beach profile evolution taking into account the composite nature of the suspended material have been carried out for erosional and normal profiles. The results are different from the ones with the conventional approach of using a single grain size. For bar profile, the composite beach material appears to have a smoothing effect. So the bar formation becomes lower and wider as the range of sand size increases. For the berm formation, the profile change of composite beach material becomes also wider as the range of sand size increases.

We hope that the further observations under the severe wave

condition will provide additional information about the effect of the composition of sea bed material on beach profile evolution.

#### Acknowledgements

One of the author is given an opportunity to do research and discuss with Dr.Hsiang Wang at University of Florida. It is very appreciated his kind comments, many suggestions and proofreading. Many thanks go to Ms Rebecca H.Hudson for her kind talk and proofreading, too. The authors really would like to express their special thanks to Dr.Toshiyuki Asano for his comments. The authors also would like to express their thanks to Mr.Kazuya Hamashima, Mr.Hirofumi Kowaki and Mr.Takeshi Uwada for their data collection efforts and to the other member of Coastal Engineering Laboratory, Dept. of Ocean Civil Engineering, Kagoshima University for their kind help in the field experiments.

#### ABSTRACT

The paper describes the development and application to laboratory and North Sea field data of a series of random wave and current computer models of bed boundary layer flows and associated suspended sediment concentrations. The EC-funded (MAST 1) work is part of a larger project, which also includes the laboratory testing of a new seabed shear stress meter (SSM) and the field collection of nearbed data using a special boundary layer rig (STABLE). Both two-dimensional (2DV) and one-dimensional (1DV) hydrodynamic models are described based on a mixing length closure but including simulation techniques to enable the inclusion of both long and short-crested random waves and steady currents. A 1DV suspended sediment model is also described with realistic boundary conditions to enable the simulation of vortex entrainment from seabed ripples. Application of the various models to the SSM and STABLE data shows realistic results.

#### 1. INTRODUCTION

The present paper is concerned with the computer simulation of water and sediment movements over rippled seabeds in random wave and current conditions appropriate to the North Sea. It reports on one element of a larger multi-disciplinary research programme involving engineers, oceanographers and geologists, who are studying the formation of nearshore sandbanks and their role in providing protection to adjacent coastlines.

  2. Versuchsanstalt für Wasserbau und Schiffbau, Berlin, Germany.
  3. Proudman Oceanographic Laboratory, Bidston Observatory, L34 7RA, England.

The research involves the field and laboratory testing of equipment to measure near-bed waves and currents and the associated sediment transport rates. In particular, staff from VWS, Berlin, have tested an improved seabed shear plate (SSM) to enable the direct measurement of seabed shear stress in waves and currents, Oebius (1992). Staff from the NERC's Proudman Oceanographic Laboratory have used a large bed boundary layer rig (STABLE) to provide field information on near-bed turbulence, waves, currents and sediment movements at the Brown Ridge Sandwave Site in the North Sea, Williams (1991). In addition, staff from the Department of Civil Engineering at Liverpool University have developed a series of hydrodynamic and sediment transport computer models to help with the interpretation of the data collected by both the SSM and STABLE rigs.

## 2. MODEL WORK

Four models have been developed: a two-dimensional (x, z) full-depth rough-turbulent hydrodynamic model (2DV) to study advective (mass-transport) effects on vertical mixing; a two-dimensional (x, z) bed boundary layer hydrodynamic model of wave-induced flow over bed ripples to assist with vortex entrainment ideas (2DV); a one-dimensional, rough-turbulent hydrodynamic model (1DV) to simulate wave-current interactions at arbitrary intersection angles in directional random waves; and an associated one-dimensional suspended sediment model (1DV) to study vertical sediment distributions in directional random waves and hence the effect of wave groupiness.

### 2.1. 2DV Hydrodynamic Model

The model solves simplified forms of the horizontal momentum and mass continuity equations for multi-frequency waves using a mixing length closure. The model equations are given as:-

$$\rho \partial u / \partial t + \rho u \partial u / \partial x + \rho w \partial u / \partial z + \partial p / \partial x = \partial \tau_{xz} / \partial z \quad (1a)$$

$$\partial u / \partial x + \partial w / \partial z = 0 \quad (1b)$$

where u and w are the phase-point-average turbulent-mean flow velocities in the horizontal (x) and vertical (z) cartesian co-ordinate directions, respectively; p is pressure;  $\rho$  is the fluid density; and  $\tau_{xz}$  is the horizontal component of the Reynolds stresses.

The wave-induced boundary layer is assumed to be thin and the motion outside it is assumed to be irrotational so that the pressure gradient in equation (1a) can be approximated by the equation:-

$$-\partial p/\partial x = \rho \partial u_w/\partial t + \rho u_w \partial u_w/\partial x \quad (2a)$$

$$\text{with } u_w = \bar{u}_w + \sum_{i=1}^m u_i \cos(\omega t - ikx + \phi_i) \quad (2b)$$

where  $u_w$  is the wave-induced orbital velocity at the sea surface (mean water level);  $\bar{u}_w$  is a wave-period-averaged steady velocity component;  $u_i$  are velocity amplitudes of the  $m$  Fourier frequency components making up the wave signal;  $\omega$  is the wave frequency ( $= 2\pi/T$ ,  $T$  is the wave period); and  $k$  is the wave number ( $= 2\pi/L$ ,  $L$  is the wave length).

The Reynolds stress ( $\tau_{xz}$ ) is approximated by a simple mixing length expression ( $\rho \kappa \partial u/\partial z$ ), where  $\nu_t = \kappa^2 z^2 \partial u/\partial z$  and  $\kappa$  is Von Karman's constant (0.40).

The set of equations is solved using an implicit Crank-Nicolson finite difference technique on a space-staggered grid using zero velocity at the seabed ( $z=z_0$ ), a zero velocity gradient at the water surface and repeating conditions for lateral boundaries, Kim (1993).

## 2.2. 1DV Hydrodynamic Model

The 1DV model also solves simplified flow equations using a mixing length closure. The model works for arbitrary-angled wave and current flows and uses simulation techniques involving surface wave spectra to produce appropriate model boundary conditions. The equations used in the model are given in tensor form as:-

$$\rho \partial u_i/\partial t - \partial p/\partial x_i = \partial \tau_{xz_i}/\partial z \quad (3a)$$

$$\partial p/\partial x_i = \rho \partial u_{\delta i}/\partial t + \rho g \partial H/\partial x_i \quad (3b)$$

$$\tau_{xz_i} = \rho \nu_t \partial u_i/\partial z; \nu_t = \ell^2 \partial V/\partial z; V = \sqrt{(u^2 + v^2)} \quad (3c)$$

$u_i (=u, v)$  are the cartesian velocity components in the horizontal ( $x$ ) and lateral ( $y$ ) co-ordinate directions respectively;  $x_i$  are the co-ordinates  $x$ ,  $y$  respectively;  $g$  is the acceleration due to gravity;  $\partial H/\partial x_i$  is the mean water surface slope;  $\ell$  is a mixing length ( $=\kappa z$ ) and  $u_{\delta i}$  are the  $u$ ,  $v$  components at the top of the wave boundary layer, respectively.

Equation 3 can be solved in terms of a shear velocity ( $p_*$ ,  $\tau_{xz} = \rho p_*^2$ ) - see Bakker (1974), Wong (1984) for the case of co-linear waves and currents. Alternatively, the vertical co-ordinate ( $z$ ) can be transformed by a power law and the transformed equations solved directly for  $u_i$ .

Both approaches have been used in the MAST 1 work. However the transformed co-ordinate approach is simpler to use for directional wave simulations. In this lattermost case the surface boundary conditions for the variation of velocity ( $U_T$ ) with time is obtained from simulation techniques, see for example, Ellis et al (1981).

$$U_T = \sum_{m=1}^M \sum_{n=1}^N \left[ \frac{2\pi f_m}{\sinh(k_m h)} \right] F \quad (4a)$$

$$F = a_{m,n} \cos(2\pi f_m t + \phi_m) \cos \theta_n \quad (4b)$$

where  $f_m$  is the wave frequency ( $=1/T_m$ ,  $T_m$  is the wave period);  $\phi_m$  are random phase angles in the range  $0 - 2\pi$ ;  $k_m$  is the wave number;  $h$  is the water depth;  $t$  is time; and  $a_{m,n}$  is a wave amplitude obtained by integration of the directional wave energy spectrum. Thus:-

$$a_{m,n} = \sqrt{2 S(f_m, \theta_m) \Delta f_m \Delta \theta_n} \quad (5a)$$

$$S(f_m, \theta_m) = S(f_m) \cdot G(f_m, \theta_n) \quad (5b)$$

$$G(f_m, \theta_n) = G_0 \cos^{2s}(\theta_n/2) \quad (5c)$$

$$G_0 = 2^{2s-1} \cdot \Gamma^2(s+1) / (\pi \cdot \Gamma(2s+1)) \quad (5d)$$

where  $G_0$  is a constant dependent upon parameter  $s$ , which varies with peak spectral frequency and has a typical value of 20, Goda (1985);  $\Gamma$  is the Gamma function;  $\theta_n$  is a wave direction in the range  $\pm 90^\circ$  of the dominant wave direction;  $S(f_m, \theta_n)$  is any directional surface wave energy spectrum;  $S(f_m)$  is a surface wave energy frequency spectrum;  $G(f_m, \theta_n)$  is a spectral wave energy spreading function.  $\Delta \theta_n$  is the band width of the  $n$ -th directional wave angle obtained by dividing the range of wave angles ( $\pm 90^\circ$ ) into  $n$  equal intervals and  $\Delta f_m$  is the bandwidth of the  $m$ -th frequency interval obtained from the co-cumulative energy spectrum by using equal energy bands, see Ellis et al (1981).

A zero-velocity bed boundary condition is used ( $u=w=0$ ) at  $z=z_0$ . The value of  $z_0$  can be adjusted in random wave simulations using Madsen's (1990) approach, if desired.

### 2.3. 1DV Sediment model

In order to study the vertical distribution of suspended sediment over a rippled seabed, a one-dimensional sediment model has been used. The model equations used are:-

$$\partial c / \partial t + (\bar{w} - w_f) \partial c / \partial z = \partial (\epsilon_s \partial c / \partial z) / \partial z \quad (6)$$

where  $c$  is the phase-point-averaged turbulent-mean suspended sediment concentration;  $\tilde{w}$  is the vertical wave induced fluid velocity;  $w_f$  is the effective vertical sediment diffusion coefficient.

Previous work has generally ignored the effect of  $\tilde{w}$ , and has determined  $\epsilon_s$  during the wave cycle from the hydrodynamic shear stress determined by a LDV-type model, see for example, Davies (1990). Such an approach does not include all the major processes contributing to vertical mixing, see for example, O'Connor (1991). The inclusion of extra mixing has usually been done in the past by taking a wave-period-average view of vertical sediment distributions and then using the sediment distribution itself to determine effective mixing coefficients see for example, Van Rijn (1989). In the MAST 1 work, a different approach has been used. Sediment is released into the water column at two discrete times during the wave period (at  $t = T/16$  and  $9T/16$  for a mono-wave) at a height of between one and two ripple heights above the mean bed level, as suggested by the 2DV model tests for a rippled bed, see O'Connor et al (1992). Shear-induced entrainment is also allowed during the wave period as dictated by the LDV hydrodynamic bed shear stress, see Figure 1. Additional mixing due to mass-transport is allowed by using the 2DV "flat"-bed hydrodynamic model (see Section 2.1) to provide the  $\epsilon_s$  values.

Solution of equation (6) is achieved by a number of intermediate steps. Firstly, a transformed vertical co-ordinate is used in order to resolve the large near-bed concentration gradients. The same approach was used for the LDV hydrodynamic equations. Secondly, a split operator finite difference approach is used to introduce the vortex entrainment concentrations into the water column at a height of  $1.5 \Delta_r$  above the mean bed level ( $z = 0$ ). Thirdly, the new equations are then solved sequentially using appropriate boundary conditions between the water surface (mean sea level) and the sea bed  $z=z_o$ ; the co-ordinate origin being located half a ripple height above a ripple trough.

The necessary equations are given below:-

$$\partial c / \partial t - w_f \partial c / \partial z = \partial (\epsilon_s \partial c / \partial z) / \partial z \quad (7a)$$

$$\partial c / \partial t + \tilde{w} \partial c / \partial z = S(t) \quad (7b)$$

$$S(t) = M_v / (\Delta_r T_v), \text{ for } \Delta_r \leq z \leq 2\Delta_r, \text{ and} \quad (7c)$$

$$5T/16 \leq t \leq 3T/8, \text{ or } 13T/16 \leq t \leq 7T/8$$

$$M_v = \int_0^{T/2} E_v dt \quad (7d)$$

$$E_v = (1-\alpha)E_t; E_t = A \Phi^{1.5}; T_v = T/16 \quad (7e)$$

$$\Phi = \tau_b(t) / ((\rho_s - \rho) g D_{50}) \quad (7f)$$

Where  $\tau_b(t)$  is the bed ( $z = 0$ ) shear stress from the 1DV model;  $\rho_s$  is the sediment density;  $g$  is the acceleration due to gravity;  $D_{50}$  is the 50% finer grain size of the bed sediment;  $A$ ,  $\alpha$  are model constants determined by field/laboratory tests.

Equation 7a is solved by an implicit finite difference method while equation 7b is solved as a second step using the method of characteristics. The model uses a zero flux condition ( $\epsilon_s \partial c / \partial z = -w_f c$ ) at the water surface and a surface entrainment condition at the seabed ( $\epsilon_s \partial c / \partial z = \alpha E_t$  at  $z = z_o$ ). Values of  $\epsilon_s$  are obtained from the 2DV hydrodynamic model.

### 3. MODEL APPLICATIONS

#### 3.1. 1DV Hydrodynamic Model Tests

The ability of the 1DV model to reproduce conditions in mono-frequency waves was demonstrated using the oscillating tunnel data of Jonsson and Carlsen (1975), see Wong (1984). In addition, data from the VWS flume tests, Oebius (1992) were reproduced using a suitable plate roughness ( $2D_{50}$ ) and scale factor, see Figure 2.

The ability of the Bakker version of the 1DV model to reproduce velocities near the top of the wave boundary layer (10 mm above the bed) with multi-frequency (3 components) waves, and waves and currents was demonstrated by using the small-scale flume data of Savell (1986), see Figures 3,4. Good agreement is apparent for maximum amplitude and phase. The velocity model's ability to reproduce long-crested random waves was tested for conditions approximated to those at the Brown Ridge Site ( $h = 30\text{m}$ ;  $z_o = 0.01\text{ m}$ ). Wave conditions were assumed to be described by a Pierson-Moskowitz (PM) spectrum with significant wave height of  $H_s = 2.5\text{m}$  (wind speed = 11 m/s) and a peak energy period of  $T_m = 8.1\text{ s}$ . The PM spectrum was simulated by 60 frequency components and the velocity time series used to drive the model.

The accuracy of the simulation process can be judged by Figure 5, which shows a comparison between the PM spectrum and the model spectrum obtained by subjecting the model surface elevation time series to a Fast Fourier Transform (FFT) analysis.

Typical bed shear stresses and orbital velocities from the model at the top of the wave boundary layer are shown in Figure 6 for a typical 64s time interval. The random nature of the results is clearly seen as is also the phase shift over the depth of the boundary layer.

Figure 7 shows the root-mean-square (rms) and significant amplitudes of the wave-induced orbital velocities from a direct analysis of model time series for conditions at the Brown Ridge Site. These significant values can be directly compared with the results from the LDV model operated with representative mono-frequency wave heights and wave periods - the 'design-wave' approach. Figure 8 shows the results for the mono-wave simulations using  $H_s$ ,  $T_{max}$  and  $H_s$ ,  $T_z$ . It is clear that the best comparison with the random wave model is obtained with  $H_s$ ,  $T_{max}$  and not with the more traditional  $H_s$ ,  $T_z$  combination.

The LDV model was next used to investigate the effect of short-crested seas. The Brown Ridge model with its PM spectrum was re-run with a Goda spreading function, equation 5,  $s = 20$ . Figure 9 shows the u, v velocity components for a short length of record while Figure 10 shows the corresponding instantaneous wave direction vectors. The groupy nature of the wave signal is clearly seen as is also the lateral scattering effect of the short-crested sea. Such lateral movements will add significantly to the dispersal of both sediment and pollutant within the water volume. Similar results to the LDV model have also been found with the STABLE data, see O'Connor et al (1992).

In order to examine the LDV model's ability to reproduce the correct magnitude and phase of velocities within the boundary layer, use was made of S4 current meter data collected during the STABLE deployment at the Brown Ridge Site, see Williams (1991) Field velocities for a 22 second period at 800mm above the seabed were used as the upper boundary condition in the model. Figure 11 shows the comparison of field results at 800mm and 400mm with model results at 70mm. It is clear that the model reproduces the main features of the field results.

### 3.2. LDV SEDIMENT MODEL APPLICATIONS

The ability of the LDV model to reproduce suspended sediment concentrations during a wave period was tested using laboratory data of Bosman (1982). Figure 12 shows quite a good comparison considering the difficulty in obtaining such laboratory data.

The need for the inclusion of extra mixing in LDV models is illustrated by the wave-period-average results of Figure 14. Both the 2DV and LDV hydrodynamic models were used for conditions appropriate to Bosman's (1984) laboratory studies,

and the wave-period-average mixing coefficient ( $\epsilon_s$ ) determined by period-averaging. The 1DV sediment model was then used with vortex and shear-induced entrainment to reproduce wave-period-average concentrations, Figure 13. It is clear that the extra mixing inherent in the 2DV model is essential for correct simulation of sediment profiles.

Finally, the long-crested 1DV random wave model was used to simulate suspended sediment conditions at the Brown Ridge Site, see Figure 14. The influence of groupiness in the wave and shear records is clearly seen to influence suspended sediment concentrations with the larger groups having the greatest effects. Unfortunately, no comparable field data was obtained from the STABLE deployment and consequently, more field data is needed to test model ideas further.

#### **4. CONCLUSIONS**

A range of 1DV and 2DV bed boundary layer models have been developed to assist with interpretation of field data obtained from the Brown Ridge Sandwave Site in the Southern North Sea. Comparison of model results with mono- and multi-frequency laboratory data for both velocities and shear stresses shows good results. Realistic model simulations were also obtained for both long and short-crested random wave conditions when compared with measured field data. Use of the long-crested 1DV hydrodynamic model also demonstrates the importance of using the correct wave period when using the mono-frequency "design wave" approach to predict seabed velocities and shear stresses.

An 1DV suspended sediment model was also developed with new boundary conditions which attempted to reproduce the influence of both vortex and shear-induced entrainment. Good comparisons were obtained with laboratory data. The importance of including enhanced mixing due to mass-transport currents in 1DV model simulations was also demonstrated as was the influence of wave groupiness on sediment concentrations at the Brown Ridge Field Site.

## CHAPTER 178

### TIMESCALES OF BED RESPONSE IN A LOW ENERGY SURF ZONE

Philip D. Osborne and Christopher E. Vincent

School of Environmental Sciences, University of East Anglia,  
Norwich, NR4 7TJ, United Kingdom

#### ABSTRACT

Direct and nearly continuous measurements of bed position changes, near-bed velocities and suspended sand concentrations have been made at a single location on a macro tidal beach in the south west of England. The study was conducted in 0.5-2.25 m water depth under low-energy swell conditions with weak currents present. Bed positions and suspended sand concentrations were measured using the 3 transducers of a multi-frequency acoustic backscatter sensor with 5 mm vertical resolution. Large (upto 10 cm) and rapid (upto  $1.0 \text{ cm min}^{-1}$ ) changes in bed elevation were observed in association with local hydrodynamic forcing, bedform development and bedform migration. Large-scale bedforms observed under breaking waves were highly mobile with measured migration rates of upto  $2.2 \text{ cm min}^{-1}$ . Suspended sediment concentrations and transport rates are particularly sensitive to changes in bed position changes and subject to potentially large errors (upto 30 %) without compensation for bed elevation changes relative to sensor position.

#### INTRODUCTION

Bedforms generated by waves and currents on a sandy seabed play an important role in the sand transport process by modifying near bed flows, by enhancing the entrainment and resuspension of sediment, and by influencing the timing and spatial distribution of sand re-suspension. Observations suggest that the time-scales of bed formative processes are quite different from the time-scales of waves or wave groups which also control the suspension process (Vincent et al., 1991; Vincent and Green, 1991). Therefore, knowledge of the ripple history, time-

scales of bed response and accurate positioning of instrumentation is required before the re-suspension and transport processes can be more fully understood.

High-frequency ( $> 1$  MHz) Acoustic Backscatter Sensors (ABS) have been used occasionally for measuring small-scale (both spatial and temporal) changes in sea bed position for nearly two decades (see for example, Dingler, 1974; Dingler et al., 1977; Greenwood et al., 1984; Hanes et al., 1988; Vincent et al., 1991). Despite such efforts, our knowledge of seabed dynamics under natural wave conditions remains limited by a lack of continuous high resolution measurements from a wide variety of conditions. In this paper, we focus on the analysis of measurements of seabed position obtained with a multi-transducer ABS during the Bedforms and Suspension EXperiments (BASEX) field programme. BASEX was designed to investigate the processes controlling sand re-suspension under non-breaking waves and currents, particularly the control exerted by bedforms. Measurements of bedforms, local bed elevation changes, together with suspended sand concentrations, near-bed velocities and water surface elevations, were obtained from a single location near the mid-tide position on a macro-tidal shoreface in the southwest of England. The measurements were taken over a 9 day period in August 1991 during spring tides (range upto 5 m) with mild swell and low energy wind-wave conditions. Time-series of bed positions and reconstructed bed profiles are used to examine the timescales of bed response to changing hydrodynamic conditions and to calculate bedform migration rates.

## LOCATION OF STUDY

Longsands Beach situated on Whitsand Bay, Cornwall (Figure 1) was chosen as a site for BASEX experiments for the following reasons:

- i) The beach is a macrotidal beach with up to 200 m of beach exposed at low tide during spring tides; this feature not only allowed access to the instruments at low tide but provided a range of water depths and wave conditions which could generate a variety of bedforms at a single measurement location even under relatively low energy summer swell.
- ii) The site is exposed to swell from the Atlantic Ocean with no major restrictions on wave approach.
- ii) The shoreface has a relatively simple morphology and sedimentology; the profile is essentially concave upwards with a slope of 1:15 near the mean high water mark and decreasing rather abruptly to a broad uniform slope of 1:70 at approximately 50 m offshore (Figure 2); sand samples from the latter slope were unimodal size distributions with grains ranging in size from 100 to 600 micrometres and a uniform modal size of 212 micrometres (2.25 phi) when dry sieved at 0.25 phi intervals.

## EXPERIMENTAL DESIGN

Instrumentation, consisting of a 3 frequency acoustic backscatter sensor (ABS) (Pearson and Thomas, 1990) and a Valeport 3.2 cm diameter discuss head electromagnetic current meter (EMCM) were mounted on an H-frame at approximately the mid-tide position (Figure 3). Additional instrumentation consisting of electromagnetic current meters, optical backscatterance sensors, pressure sensors and mechanical syringe samplers were also deployed, however, in this paper the analysis has been restricted to the bed position information from the ABS and nearbed current information from the 3.2 cm diameter discuss head EMCM.

Figure 3. Schematic of the instrumented H-frame.

Local bed elevations were measured with a vertical resolution of 5 mm at 3 horizontal positions approximately 0.10 m apart on a cross-shore transect using the 3 ABS transducers. SCUBA divers also made measurements of the bed profile beneath the ABS transducers by means of a bedform measurement device (Osborne and Vincent, in prep) and took detailed notes on the bedform geometry, bedform migration and suspension characteristics throughout the high-speed data collection runs. Although an underwater camera was mounted adjacent to the ABS, no information on ripple migration could be obtained due to lack of visibility.

The sensors were shore-connected and the data were recorded on a single PC-based data logging system. In order to satisfy the aims and objectives of the BASEX program there was a need for two separate approaches to computerized data collection within the same experimental design. In order to resolve the kinematics of the re-suspension process relative to wave motions and small scale ripple patterns

it was necessary to sample as rapidly as possible to achieve a high spatial and temporal resolution and also to keep runs short enough such that the bed topography did not change significantly relative to the sensors. In order to resolve the effects of different hydrodynamic conditions on bed response it was necessary to collect data over longer periods, more or less continuously, and over a number of tidal cycles. Therefore, two sampling modes were adopted for data collection during this deployment:

1. **Rapid sampling mode** produced short duration data collection runs with relatively high temporal resolution. In this case 12 acoustic profiles initially sampled at 150 kHz were collected from each transducer and averaged to one profile per transducer. The data between 0.10 - 0.65 m range at 0.005 m intervals were stored together with a single digitised value from the EMCM channels. This scheme resulted in an overall collection rate of 4.22 Hz. Available storage space allowed the collection of 1050 profiles for a run duration of 250 s.

2. In **slow sampling mode** run durations were increased to as much as 30 minutes by averaging over a larger number of acoustic profiles (24-48) and storing a smaller vertical range (0.53-0.67 m) of the acoustic data. This scheme resulted in a slower overall collection rate of 1.1-2.1 Hz but enabled continuous observation of bed elevation changes over periods of 30 minutes.

Measurements were made during daylight hours over half tidal cycles from high water down to low water or from low water up to high water.

## ACOUSTIC MEASUREMENTS OF SEA BED POSITION

ABS detect the presence of the bottom boundary due to the change in material density between the fluid and bed which cause a strong acoustic reflection (Hanes et al., 1988). The position of the sea-bed is defined as the position of maximum recorded acoustic pressure. In most acoustic profiles of the water column, the bottom location is clearly identified by a sharp peak in the backscattered pressure. It is therefore relatively simple to produce an algorithm which detects the maximum acoustic return from each profile in order to produce a time-series of bed positions (Figure 4).

Sampling the backscattered acoustic signal at a rate of 150 kHz and range-gating enabled the determination of bed position to  $\pm 0.005$  m under ideal conditions. Clearly, there are random instantaneous variations in the maximum acoustic return above and below the true bed position in Figure 4 which reduce the degree of certainty about the actual bed position at any instant in time. However, these short-term deviations, which may be due to a combination of signal attenuation by suspended sediment and bubbles, and multiple echoes, may be removed relatively easily by a combination of de-spiking and smoothing. More importantly, there are

also significant temporal trends which occur in the data. These variations in the series are interpreted as real changes in the bed position. The series in Figure 4 suggests that 3-4 cm of erosion occurred over a period of 6 minutes followed by 2-3 cm of accretion in the next 6 minutes.

Figure 4. Time-series of the position of maximum backscattered pressure after smoothing by Hanning 3 times. Resolution of the ABS is 5 mm.

### CHANGES IN SEA BED POSITION DURING A TIDAL CYCLE

Time series of bed positions were reduced to one representative value of bed position for each two minute segment of a data run. A series of reduced bed positions from one transducer, representative of a falling portion of a tidal cycle is shown in Figure 5 c. Burst-averaged zero-crossing periods of the cross-shore flow, water depths, cross-shore and shore-parallel velocities, and significant range of cross-shore flows associated with these bed positions are shown in Fig. 5 a and b. The two lines in the bed position series indicate the uncertainty in measured bed position due to sampling resolution ( $\pm 1$  bin) of the ABS. The first 30 minutes of the series shows variations in bed position of no more than 2 cm. Over the next 30 minutes, there is an accretion of 2.5 cm followed by erosion of 6 cm. During the final 15-20 minutes of the series there is a rapid accretion of 8 cm.

In general, the high tide periods (depths 1.5-2.0 m in this experiment) were characterized by near-bed wave-orbital speeds of less than  $0.75 \text{ m s}^{-1}$  and relatively small and gradual changes in vertical bed position (usually  $< 0.5 \text{ cm min}^{-1}$ ) (Figure 6). In contrast, under rapidly rising and falling water levels (depths of 0.5-1.5 m in this experiment), particularly as waves are forced to shoal and break, wave orbital speeds were greater than  $0.75 \text{ m s}^{-1}$  and bed position changes were often substantially larger and more rapid (upto  $1.0 \text{ cm min}^{-1}$ ).

## BED PROFILE RECONSTRUCTION AND BEDFORM MIGRATION

Although the 3 ABS transducers were mounted in fixed positions it is possible to use bed position information together with the detailed diver measurements of the bed beneath the transducers to reconstruct bed profiles and calculate bedform migration rates. A time sequence of bed profiles has been reconstructed (Figure 7) from the ABS bed position measurements (Figure 5) and SCUBA diver observations during the falling tide. The sequence began with small symmetric, two-dimensional vortex ripples (height = 2.5 cm and spacing = 10 cm) and ended with large asymmetric landward lunate megaripples (height = 8 cm and spacing = 40-50 cm). This increase in both height and spacing with time is clearly visible in the profiles. The profiles between 40-65 minutes also indicate shoreward migration of the bedform at a rate of approximately  $2.0 \text{ cm min}^{-1}$ .

Figure 5. Series of burst-averaged zero crossing periods of the cross-shore flow,  $T_{zu}$ , (a); water depths,  $h$ , cross-shore flows,  $u$ , shore-parallel flows,  $v$ , significant cross-shore velocity ranges,  $U_s$ , (b); and reduced bed positions (c), representative of falling portion of a spring tide.

## DISCUSSION AND CONCLUSIONS

Large and rapid changes in bed elevation were observed during spring tidal cycles under low energy swell conditions with little or no mean currents present. The largest changes in bed elevation are associated with smaller depths when wave induced cross-shore flows are large and waves are either breaking or near breaking. Changes were associated with bedform development resulting from changes in the local hydrodynamic forcing as well as with bedform migration. These processes accounted for local bed elevation changes of upto 10 cm during a series of tidal cycles in which no significant local net erosion or accretion took place.

Figure 6. Variations in the time-averaged rate of vertical bed position change as a function of water depth.

Bedform migration rates of upto  $2.2 \text{ cm min}^{-1}$  were associated with well-defined lunate mega-ripples (height = 8 cm; wavelength = 40 cm) under spilling and shoaling waves. Excluding sediment by-passing this represents a total load transport rate of approximately  $0.7 \text{ gm cm}^{-1} \text{ s}^{-1}$ . Evidently, form migration under these conditions represents a significant contribution to the net sediment transport. Bedform migration rates were  $1 \text{ cm min}^{-1}$  and less under the lower energy conditions associated with greater water depths at high tide. The observed bedform migration rates suggest that local bed elevation changes of upto  $1.0 \text{ cm min}^{-1}$  can be expected under large-scale migrating lunate mega-ripples, while rates of bed elevation change upto  $0.6 \text{ cm min}^{-1}$  can be expected under the small-scale three-dimensional and two-dimensional vortex type forms.

These findings have significant implications for measurement and interpretation of sediment transport rates in wave and current environments. As an example, Figure 8 shows time-series of de-spiked and smoothed bed position, suspended sediment concentrations at 2 cm above an arbitrary fixed bed position (indicated by the dashed line in Figure 8 a), suspended sediment concentrations at 2 cm above the measured time-varying bed position, and cross-shore velocity. The uncompensated concentration series (Figure 8 b) is representative of the type of measurements which would be obtained by a fixed point sensor such as an optical backscatterance sensor or transmissometer. There is clearly a non-stationary trend in this series which is coherent with the rising bed position. The trend is absent from the series compensated for bed position change (Figure 8 c). Interpretation of sediment re-suspension processes and computations of sediment transport rates from point measurements of sediment concentration and velocity will be subject to potentially large errors without compensation for bed position changes relative to instrument positions when large and rapid bed elevation changes occur. In the example shown, the time-integrated cross products between velocity and concentration differed by 30 % for the compensated as opposed to uncompensated series. Furthermore, the presence of migrating large-scale bedforms under relatively gentle conditions suggests that spatial variability in sediment concentrations, near-bed velocity structure and sediment transport are likely to be significant.

Figure 7. Time-sequence of reconstructed bed profiles during a falling tide.

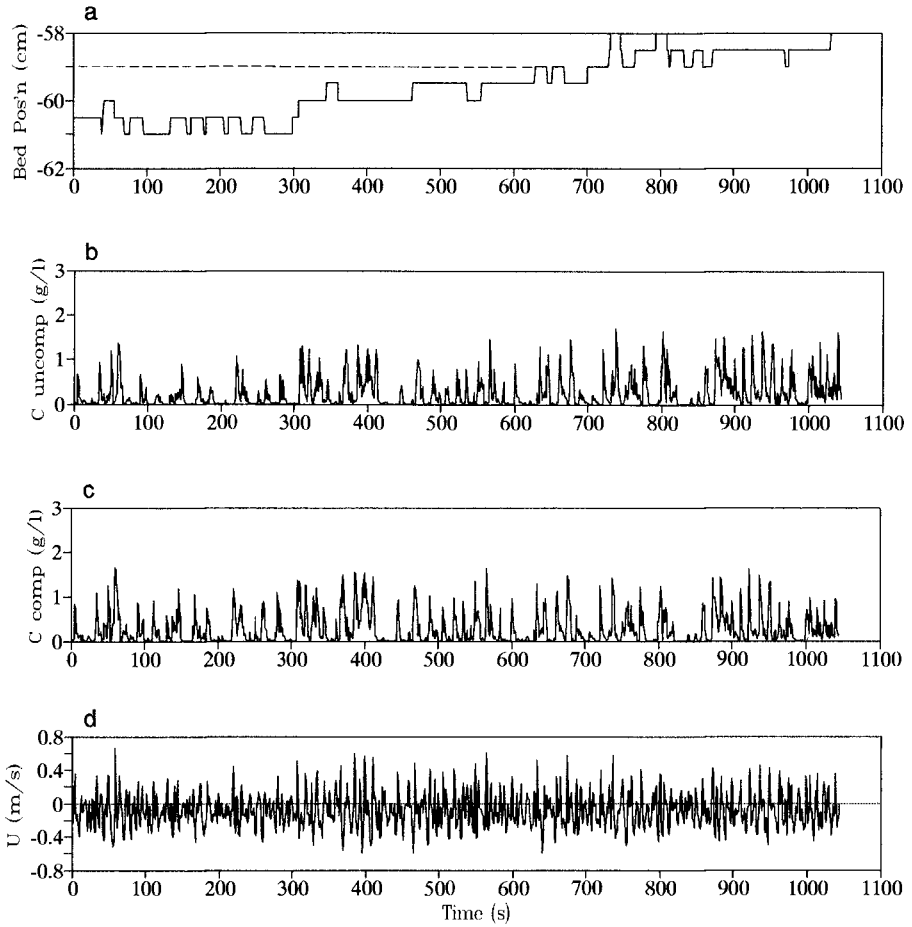

Figure 8. Time-series of: a) smoothed and de-spiked bed position; b) suspended sediment concentration at 2 cm above fixed bed (dashed line in a); c) suspended sediment concentration at 2 cm above true bed position; d) cross-shore velocity.

## ACKNOWLEDGEMENTS

The BASEX programme is a combined project involving the University of East Anglia, Bullard Laboratories, and the University of Plymouth. BASEX is sponsored by the Natural Environment Research Council. PDO also gratefully acknowledges the support of a Natural Sciences and Engineering Research Council of Canada Postdoctoral Fellowship. The authors wish to thank Drs. Malcolm Green, Mark Davidson, Paul Russell and Mr. Gareth Lloyd for their enthusiastic assistance while in the field. Particular thanks to Professor David Huntley for making the B-Band instrumentation available and for arranging access to the beach.

## CHAPTER 179

### SHORELINE CHANGE AT OREGON INLET TERMINAL GROIN

M. F. Overton (M)<sup>1</sup>, J. S. Fisher (M)<sup>2</sup>  
W. A. Dennis (M)<sup>3</sup>, and H. C. Miller (AM)<sup>4</sup>

#### Abstract

The Oregon Inlet Terminal Groin was completed in 1991. The groin was built to provide protection to the bridge crossing the inlet. A detailed monitoring program has analyzed shoreline position with the use of aerial photographs collected every two months. To date, no adverse impacts of the groin have been found on the shoreline within a 6 mile distance downdrift of the groin.

#### Introduction

Oregon Inlet is located between Bodie Island and Pea Island on the North Carolina coast, Figure 1. These islands form a part of the barrier island system generally referred to as the Outer Banks. This inlet formed in 1846 during a major storm, and has remained open to the present. During this 146 year interval the inlet has gone through many changes in width and position, with a net migration to the south of approximately 2 miles. The inlet width has varied from a minimum of about 2,000 ft to a maximum of just over 5,000 ft. While there have been numerous discussions and plans to stabilize it with jetties, Oregon Inlet remains one of the largest unimproved inlets along the east coast of the United States.

The inlet is spanned by the 2.4 mile long Bonner Bridge constructed in 1962, Figure 2. This bridge is located along the

principal highway serving the Cape Hatteras National Seashore. Peak summertime traffic is in excess of 10,000 cars per day.

The navigation channel spanned by the Bonner Bridge provides an important marine connection between Croatan and Pamlico Sounds and the Atlantic Ocean. This channel is used by both commercial and sport fishing interests. The channel is maintained by the U. S. Army Corps of Engineers. Maintenance dredging is done annually, with combined dredge volumes for the inner and outer channels in excess of 750,000 yd. The difficulty in dredging this channel has led to the consideration of an inlet stabilization project at this site. Preliminary designs by the Army Corps of Engineers call for a pair of jetties approximately 10,000 ft long.

The persistent migration of the inlet to the south has created an extreme erosion problem on the north end of Pea Island. By 1988 the portion of this island facing the inlet was eroding at an annual rate of about 80 ft/yr (NCDOT, 1988). This high erosion rate created a threat to the future safety of the Bonner Bridge. The North Carolina Department of Transportation (NCDOT) was concerned that the erosion, if left unchecked, would eventually allow storm waves to impact directly on the bridge deck at the southern end where it connects with Pea Island.

Several alternatives were considered to protect the bridge. These alternatives included beach nourishment, a series of short groins, and the selected choice of the single terminal groin (NCDOT, 1988). This latter choice was based upon the assumption that there was substantial local longshore transport to the inlet on the north end of Pea Island for the groin to trap. Thus, the groin would artificially reverse the erosion locally, and the resulting accretion would provide the needed protection to the bridge. The potential for this accretion was documented by a number of sediment budget studies undertaken as part of the evaluation of the proposed jetty project (Inman and Dolan, 1989).

Once NCDOT selected the terminal groin as the preferred solution to protect the bridge, it was necessary to obtain both state and federal permits for construction. The site for the groin is located on a National Wildlife Refuge managed by the U. S. Fish and Wildlife Service. In addition, the inlet is located along the Cape Hatteras National Seashore, managed by the National Park Service. These federal interests, as well as those of the North Carolina Division of Coastal Management necessitated unusual restrictions on the construction permit for the groin. Specifically, NCDOT is required to insure that the groin does not result in an accelerated erosion of the downdrift shoreline. This requirement led to the initiation of a detailed monitoring program to evaluate shoreline change near the groin. The current results of this ongoing monitoring are presented in this paper.

### Description of Groin

The terminal groin was designed for NCDOT by the Wilmington District of the U. S. Army Corps of Engineers. The total length of the groin section is approximately 3,100 ft. At its seaward end the water depth is about 6 ft (mlw). The top width increases from 25 ft at the landward end to 39 ft at the seaward head. Crest elevation is +9.5 ft (msl) at the head. Side slopes are 2 on 1, except at the head where they are 3 on 1. The core material is covered by a layer of rubble ranging in weight from 4 to 2500 lb, with an armor layer of rock with weights from 0.75 to 11 tons. Toe protection on the inlet side of the groin is provided by a 43 ft wide single layer of the armor stone on top of a layer of core material (NCDOT Project 6051020 plans).

### Monitoring

It was expected that a natural sand fillet would begin to form as soon as the groin construction extended beyond the natural shoreline, and that eventually this fillet would extend to the seaward end of the groin. Thus, this accretion caused by the presence of the groin would result in a northern migration of Pea Island and would serve as the needed protection for the bridge.

While the development of the sand fillet adjacent to the groin was the desired outcome of the project, the construction permit required monitoring to insure that this accretion at the groin did not come at the expense of the downdrift shoreline. Specifically, the permit required that the six miles of shoreline just south of the groin be monitored (Overton and Fisher, 1992).

The monitoring program includes the analysis of aerial photographs taken every two months as well as immediately after severe storms, and field surveys collected twice each year. In a separate effort the Corps of Engineers is also collecting data to monitor the performance of the terminal groin. These data include beach and bathymetric surveys in the project area and wave height and direction in the inlet.

The bimonthly aerial photographs are the principal data used to monitor shoreline change. The photographs are made as close to spring high tide as possible, with the shoreline defined as the position of the wet sand line.

The analysis of the shoreline change follows a modification of a procedure developed by Dolan, et al., 1978. For each set of aerial photographs, the position of the shoreline is measured relative to a fixed baseline offshore. The distance from the baseline to the shoreline is determined every 150 ft over the 6 mile length of monitored

shoreline. The shoreline position is digitized from the aerial photographs by NCDOT using an Intergraph Intermap Analytic Stereoplotter Workstation. The distance from the baseline to these digitized shorelines is then determined on a computer.

### Historical Erosion Rates

In order to determine if the terminal groin is causing accelerated shoreline erosion, a comparison is made of the measured shoreline position with the position predicted from historical rates. If the analysis indicates that current rate of erosion exceeds the historical rate, then NCDOT has agreed to correct the excess erosion by beach nourishment. Thresholds for action have been established based upon the assumption that 1 sq ft of erosion determined from the aerial photographs is equivalent to 1 cu yd of volume loss from the beach. Two thresholds are being used; 250,000 cu yd over a 1 mile shoreline segment, and 500,000 cu yd over a 3 mile segment. The threshold must be exceeded for several successive bimonthly survey intervals before remedial action is required (Overton and Fisher, 1992).

The dates selected to establish the project historical erosion rates are September 19, 1984, and October 9, 1988. The 1984 date was chosen because it is the earliest record available after the Corps of Engineers initiated large scale hopper dredging in Oregon Inlet. Since this hopper dredging may have accelerated the erosion of the north end of Pea Island, earlier photographs would potentially bias the calculation to lower erosion rates. The more recent date, October 1988, was chosen because it is the most recent date prior to a severe storm (March 1989) which caused major erosion, and therefore might bias the erosion rates to higher values.

Figure 3 shows the annual historical erosion rate based upon the September 1984 to October 1988 interval. Mile zero in this figure is the location of a United State Coast Guard (USCG) Station, Figure 2. This station is approximately 2,000 ft south of the terminal groin. In general the erosion rate along this portion of Pea Island is relatively high, with a mean value of about 27 ft/yr. The portion of the shoreline nearest the inlet is clearly the area of highest erosion, as one would expect near the inlet. In this area the erosion rate has a maximum value on the order of 100 ft/yr. These relatively high erosion rates near the inlet clearly document the need for the construction of the terminal groin.

The state of North Carolina uses a long term shoreline change rate for shoreline management purposes. This rate is determined from aerial photographs with a method similar to that used to monitor the terminal groin (McCullough, 1988). In this case the long term rate is based upon the interval from 1945 to 1986. This Long Term Rate for the project area is also shown on Figure 3. The higher erosion rates

Figure 3. Comparison of the Long Term Rate, based on 1945 - 1986 shoreline position data, and the Project Historical Rate, based on 1984 - 1988 shoreline position data.

near the groin (between mile 0.0 and 1.0) are further indication of the increase in erosion in recent years. Further south the two erosion rates appear to converge. The greater variability in the Project Historical Rate relative to the Long Term Rate is a typical difference between short and long records of shoreline change.

### Beach Nourishment

The initial plans for the terminal groin did not include beach nourishment. However, the project area has benefited from the continued maintenance dredging of Oregon Inlet for navigation purposes. The spoil from this dredging is currently being placed on the beach with the terminal groin project area. Since the groin was completed in March 1991 there have been three separate Corps projects where the beach near the groin was used as a disposal site for the dredging operations. Table 1 summarizes these nourishment events.

Table 1  
Summary of Beach Nourishment Activities

Date	Volume (cu yd)	Location (miles south of USCG)
April 1991	282,600	0.4-1.2
Sept. 1991	157,600	0.2-0.4
Aug. 1992	1,078,000	0.8-1.8

### Severe Storms

In addition to the bimonthly aerial photographs, the monitoring program includes the analysis of any severe storms that might have significant impact along the project. There have been a number of large storms since the construction of the groin. One of these, October 1991 (The Halloween Storm) is estimated to have been larger than the 1962 Ash Wednesday Storm (Dolan and Davis, 1992). The average immediate post-storm erosion along the project was about 75 ft for this storm. In general, the storm history since the construction of the groin has been one of the most severe on record. However, while there is usually considerable erosion caused by the high waves and surge, the beach appears to be able to recover most of the short-term loss during the post-storm periods (Overton and Fisher, 1992).

### Shoreline Change Near the Groin

The shoreline change within the first 3,750 ft south of the groin is shown in Figure 4. October 5, 1989, represents the shoreline position just prior to groin construction. Groin construction began in

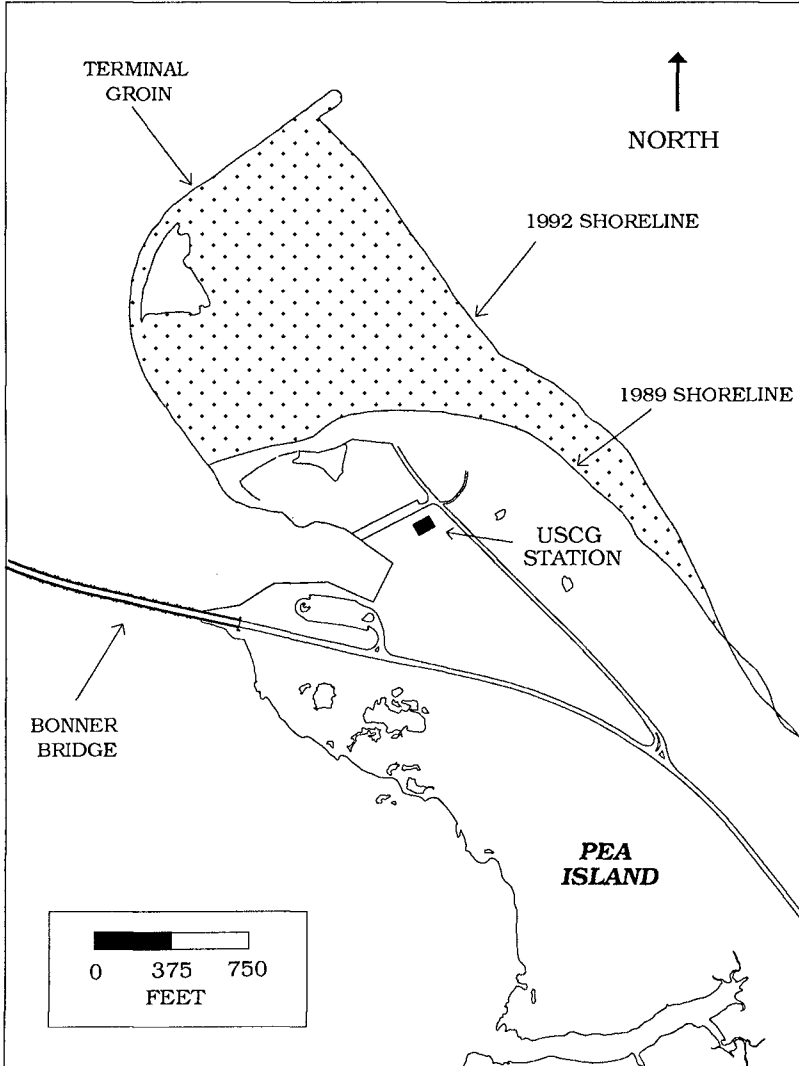

Figure 4. Detail of the groin fillet.

October 1989, and thus the most recent date, October 1992 spans a period of three years. As expected, during this interval there has been substantial accretion at the groin itself. The area of accretion above the mean high water line is estimated to be approximately 2 million sq ft. This figure clearly illustrates the effectiveness of the groin in causing the northern end of Pea Island to accrete to the inlet, thus providing the needed protection for the bridge.

#### Shoreline Change Over the Six Mile Study Area

Figure 5 compares the Project Historical Erosion rate with the Current Project Erosion Rate (defined as the erosion rate computed from October 1989 to the present date) along the six mile study area starting at the Coast Guard Station. For the two miles closest to the groin there has been almost a complete reversal from erosion to accretion. Mile zero on this figure is approximately 2,000 ft of the groin, and thus this accretion is south of the fillet area shown in Figure 4. However, the most recent dredging operation spoiled over 1,000,000 cu yd of sand within the first two mile stretch shown on Figure 5. Therefore, much of the accretion shown in this area can be assumed to be due to this nourishment activity. For the remaining 4 miles of the monitoring area there is essentially no difference between the erosion rates prior to and after groin construction based on the October 1992 shoreline position.

#### Conclusion

On the basis of the record of shoreline change since the construction of the Oregon Inlet terminal groin, there has been no adverse impact of the groin on the downdrift shoreline, Figure 5. The combination of the sand trapping of the groin and the three beach nourishment projects has resulted in substantial accretion near the groin. Further south the erosion rates before and after groin construction are essentially the same. During the three years of monitoring the "excess erosion thresholds" have been reached three times, but the beach has recovered naturally by the date of the succeeding bimonthly surveys. Thus, NCDOT has not had to take any remedial actions to mitigate the impact of the groin.

Figure 5. Comparison of the Project Historical Rate and the Current Project Rate which is based on the October 1989 - October 1992 shoreline position data.

### Acknowledgments

The authors want to thank the North Carolina Department of Transportation for their support for this project. In particular, Mr. Archie Hankins and Mr. Cecil Hinnant have provide invaluable aid in the collection of the data used in our analysis.

## CHAPTER 180

# Numerical simulation of sand in plunging breakers

C. PEDERSEN<sup>1</sup>, R. DEIGAARD<sup>2</sup>, J. FREDSSØE<sup>3</sup> AND E.A. HANSEN<sup>4</sup>

### ABSTRACT

A discrete vortex model has been applied to describe plunging breakers. The wave breaking is represented by a jet of water impinging on the surface in front of the wave crest. The suspension of sediment has been modelled by a mixed diffusion - convection scheme. Preliminary results in the form of vector plots of the flow field and concentration profiles are presented.

### INTRODUCTION

The surf zone is important for the coastal sediment transport due to the intense production of turbulence and vorticity associated with the wave breaking.

The surf zone is traditionally divided into two regions (Svendsen et al. 1978), the outer surf zone and the inner surf zone. This differentiation is in particular important for the plunging breaking case, where the flow structures in the two regions

deviate distinctively. In the outer surf zone, the first often violent transformation of the waves takes place. The wave height is reduced rapidly, and the corresponding loss in wave energy is transformed partly into small scale turbulence and partly into kinetic energy in a series of coherent large scale eddy structures, which can stretch over the entire local water depth (see eg. Miller, 1976). In the inner surf zone, the first violent transformation has ceased and the waves migrate towards the shore as turbulent bores. Due to its complex structure, modelling of the flow in the outer surf zone is scarce.

The shoaling process and the transformation of a wave until the initiation of breaking can be described by potential flow theory, and potential flow models are able to represent a plunging breaker until the time when the forward moving jet touches the water surface in front of the wave crest, fig. 1, (Longuet Higgins & Cokelet, 1976).

**Fig. 1** Jet impingement in plunging breaking wave.

Outside the surf zone the turbulence is mainly generated in the near-bed boundary layer and the sediment transport can be described by the turbulent diffusion equation in connection with a model for the combined wave-current boundary layer, (Fredsoe et al. 1985).

In the inner surf zone, the bore-like broken waves generate turbulence and vortices. The variation in time and space of the turbulence and the suspended sediment can with some accuracy be described by a turbulence model which is coupled with a boundary layer model and the turbulent diffusion equation for the suspended sediment, (Deigaard et al 1986).

The present work is dealing with the situation when the breaking wave plunges, i.e. from the moment when the description by the potential theory breaks down and before the quasi-steady bore approach has become valid. Two mechanisms are dominant for the production of turbulence and vortices.

- The flow pattern generated by the jet impingement on the surface in front of the wave crest, see fig. 2.
- The topologically generated vorticity, see fig. 3. At the instant the jet impinges on the water surface, the domain occupied by the fluid in a vertical section changes from being simply connected to being doubly connected. There is a circulation around the water enclosed core, leading to the formation of a vortex, (Battjes 1988).

**Fig. 2** Vorticity generated by impinging jet.

**Fig. 3** "Topologically generated" vortex.

The mathematical model will concentrate on the first mechanism, describing the effects from the impinging jet.

## THE HYDRODYNAMIC MODEL

### General

Despite a large interest in the plunging breaking process over the recent years, the consequent extensive experimental examinations of the mechanisms involved have not yet provided a generally accepted model for the physical process. There are numerous suggestions to how the flow-field develops from the moment of impingement by the jet on the surface, ranging from complete deflection to total penetration of the jet, (Peregrine 1983). The entrainment in- and subsequent escape of air from the water column is accentuated as a main cause for turbulent mixing by some authors, while it is considered insignificant to the flow structure by others.

The varying opinions may partly be due to the complexity of the flow and the accompanying difficulties in performing experimental investigations, but may also result from the fact, that the regime of breaker types are of a more continuous than discrete character. Plunging breaking ranges from the transition from spilling breaking to the transition to surging breaking, (Galvin 1968), spanning over large differences in the magnitudes of the processes involved.

The present study is based on a "well developed" plunging breaking wave, where the jet is assumed to penetrate the water surface in front of the crest as found by Jansen (1986). Effects from the entrainment of air include variable density, buoyancy and compressibility of the fluid. This might be of considerable importance close to the surface, but towards the bottom, the influence is assumed to be less pronounced, and as a first approach it will be neglected, assuming the density of the fluid to be uniform throughout the domain.

The formation of large-scale vortices - "breaker vortices" is generally emphasized as one of the most important features in connection with the exchange of momentum and turbulence with the lower part of the water column (see e.g. Miller 1976). This makes the breaker vortices prime factors in the agitation and suspension of sediment. Nadaoka (1989) further points to the existence of "obliquely descending" eddy structures. For simplicity it has been chosen to treat the problem two-dimensionally in a vertical plane perpendicular to the incoming wave fronts - neglecting possible three dimensional effects in the long shore direction. The observed flow field in this plane comprises the breaker vortices, which are large scale, coherent, vortical flow structures embedded in a highly turbulent region, and therefore calls for a numerical model capable of providing a fine spatial resolution.

### Discrete vortex model

The discrete vortex model (DVM) directly simulates the distribution of rotation in the fluid by modelling the rotation as "vorticity particles", which for each timestep are assigned convective and diffusive translations in space. This should fulfill the requirement of spatial resolution of the vorticity in the interior of the computational domain. A simple technique based on superposition of a jet on a non-breaking potential-theory wave has been implemented to simulate the free surface. The emphasis is put on the inner flow field composed of the wave orbital motion and the generation of vorticity due to the jet.

The implemented version of the discrete vortex model is largely similar to the one described by Asp Hansen et al. (1992) and will only be described briefly here. An extensive review of vortex methods has been given by Sarpkaya (1988). The boundary conditions at the surface are unique to the present application of the model and will be described in further detail. The governing equations, which are found from the Navier Stokes equations for incompressible flow in two dimensions combined with the continuity equation, are the vorticity transport equation:

$$\frac{d\omega}{dt} = \frac{\partial\omega}{\partial t} + u \frac{\partial\omega}{\partial x} + v \frac{\partial\omega}{\partial y} \quad (1)$$

and the Poisson equation:

$$\nabla^2 \psi = \omega \quad (2)$$

Here  $u$  and  $v$  are the velocities in  $x$ - and  $y$  direction respectively,  $\nu$  is the kinematic viscosity,  $\omega$  is the vorticity given by:

$$\omega = \frac{\partial u}{\partial y} - \frac{\partial v}{\partial x} \quad (3)$$

and  $\psi$  is the stream-function given by:

$$u = \frac{\partial \psi}{\partial y} \quad ; \quad v = -\frac{\partial \psi}{\partial x} \quad (4)$$

The vorticity transport equation consists of a convective and a diffusive part:

$$\frac{\partial \omega_{conv}}{\partial t} = -u \frac{\partial \omega}{\partial x} - v \frac{\partial \omega}{\partial y} \quad (5)$$

$$\frac{\partial \omega_{diff}}{\partial t} = \nu \nabla^2 \omega \quad (6)$$

Numerically, the governing equations are solved by letting discrete vortex particles represent the vorticity. Each particle has a position in the  $(x,y)$  plane and a circulation strength  $\Gamma$ . Further, a finite difference grid is introduced and the calculations performed according to the "cloud in cell" method (Christiansen 1973, Stansby & Dixon 1983). This involves redistribution of the rotation, represented by the discrete vortex particles, to the grid, in which a finite difference version of the Poisson equation is solved. This leads to the stream function  $\psi(x,y)$  and thereby the velocity in the grid points (equations 4). The velocity at the position of each particle is found from interpolation, and the convective movement of the discrete particles is performed. The diffusion is simulated by ascribing each particle a small displacement obtained through a random walk procedure. The displacements satisfy a Gaussian distribution, as required by equation (6).

Advancing the solution of a given problem with certain boundary conditions one timestep basically involves the following steps:

1. Solve Poisson's equation (gives  $\psi(x,y)$ )
2. Determine the velocity field from  $\psi(x,y)$
3. Apply new rotation (discrete vortices) to satisfy boundary conditions
4. Move the vortices convectively - equation (5), and approximate a solution to the diffusive transport, equation (6), by use of a random walk procedure

This is a combination of a Lagrangian and an Eulerian description. The discrete vortices are tracked and moved in a Lagrangian fashion, while the Poisson equation is solved in an Eulerian mesh, making the method numerically effective. The cloud in cell method is especially beneficial for a large number of vortices, which is

essential to satisfy boundary conditions and resolve the flow accurately.

The model is implemented in a curvilinear grid, which is generated by solving the Laplace equation for a specified flow through the computational domain.

**Boundary conditions for stream function**

To solve the Poisson equation (2) in a grid, the stream function  $\psi$  needs to be specified along all boundaries of the domain. In the curvilinear grid, the bottom is itself a streamline, implying that  $\psi_{\text{bottom}}$  is constant.

At the surface, the problem of representing a plunging breaking wave in a fixed grid has been approached by splitting the plunger into two parts: An irrotational "basis wave" and a "jet" of water. The two components are calculated separately based on the mean water level and subsequently superimposed in the model, see fig. 5.

The boundary conditions corresponding to the basis wave - a non-breaking progressive wave - are computed by employing an irrotational formulation of the present model, including a linearized free surface, to the domain and then simulate a wave flap at one side. The "free surface" is established on the basis of the kinematic (7) and the dynamic (8) boundary conditions:

$$dy = \frac{\partial \eta}{\partial t} dt + \frac{\partial \eta}{\partial x} dx \tag{7}$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial x} \tag{8}$$

**Fig. 4** Definition sketch

Introducing the stream function (4) in the kinematic condition (7) yields:

$$-\frac{\partial \psi}{\partial x} = \frac{\partial \eta}{\partial t} + \frac{\partial \psi}{\partial y} \frac{\partial \eta}{\partial x} \tag{9}$$

Linearizing the dynamic condition (8) eliminates the two convective terms:

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial x} \tag{10}$$

Using shallow water theory (hydrostatic pressure distribution) the horizontal pressure gradient is determined by the change in surface elevation:

$$\frac{\partial p}{\partial x} = \rho g \frac{\partial \eta}{\partial x} \quad (11)$$

which introduced in (10) together with the stream function (4) leads to:

$$\frac{\partial}{\partial t} \left( \frac{\partial \Psi}{\partial y} \right) = -g \frac{\partial \eta}{\partial x} \quad (12)$$

Cross differentiating and combining the kinematic and the dynamic conditions yields:

$$\frac{1}{g} \frac{\partial^2}{\partial t^2} \left( \frac{\partial \Psi}{\partial y} \right) = \frac{\partial^2 \Psi}{\partial x^2} \quad (13)$$

which has been integrated over the depth and implemented in a discrete version in the model.

When the boundary conditions ( $\psi$ ) corresponding to a non-breaking wave have been determined, breaking is simulated by decreasing the wave height from the point of breaking and superimposing a jet on the surface in front of the wave crest. The jet (or pulse) is specified as a vertical velocity component and is moved shoreward with the wave celerity (see fig. 5 & 6). The width, velocity and area of impingement of the jet are specified as functions of time. To satisfy the continuity equation at any time, the water flux introduced in the jet is taken at the crest region, see fig. 5.

**Fig. 5** Velocity components introduced to simulate jet and satisfy continuity.

**Fig. 6** Vorticity is introduced between A and B.

The sketched method is obviously quite crude, neglecting effects like the entrainment of air and the formation of a turbulent bore. Since the main interest is not the surface features, but rather the convection/diffusion of vorticity into the flow and the eventual effect on the bottom, the technique can serve as a first approach.

### Generation of vorticity.

The vorticity can only result from shear layers due to forced velocity gradients at the boundaries. At the bottom, the no slip condition has to be satisfied, while at the surface, the jet is introduced as a velocity field forced upon the initial potential flow field arising from the migrating wave. At the surface, the definition of the vorticity:

$$\omega = \frac{\partial u}{\partial y} - \frac{\partial v}{\partial x} \quad (14)$$

is used to specify the circulation. The horizontal gradient in  $v$  has already been specified through  $\psi$ , while the vertical gradient in  $u$  determines the angle of intrusion of the jet. The flux of vorticity during each timestep is calculated through the information about the production of vorticity and the vertical velocity. It is introduced as discrete particles at the position of the jet (from A to B in fig. 6).

At the bottom, the approach by Asp Hansen et al. (1992) has been implemented. Vorticity is introduced based on a calculation of the flux of vorticity in the boundary layer. The production of vorticity only depends on the velocity  $U_0$  at the outer limit of the boundary layer, while the distribution over the depth depends on the velocity profile and boundary layer thickness. Based on simplifying assumptions (a logarithmic velocity profile in the boundary layer; onset and development of a new boundary layer every time the flow reverses; only slight curvature of the boundary), the boundary layer thickness  $\delta$  and the friction velocity  $U_f$  are found from an approach introduced by Fredsøe (1984) to solve the momentum equation for the boundary layer as derived by Von Kármán:

$$\int_0^{\delta} \rho \frac{\partial u}{\partial t} dy + \frac{\partial}{\partial x} \int_0^{\delta} \rho u^2 dy - u_0 \frac{\partial}{\partial x} \int_0^{\delta} \rho u dy = -\delta \frac{\partial p}{\partial x} - \tau_0 \quad (15)$$

The outer velocity  $U_0$  is as a rough approximation taken at a fixed level above the bottom.

### SEDIMENT TRANSPORT

A widely used method to model suspended sediment is by applying a diffusion equation in the vertical direction. This requires knowledge of the vertical distribution of the turbulent quantities of the flow, e.g. represented by the eddy viscosity  $\nu_t$ , which in the present case has a highly non-uniform character. Close to the plunging point, the convection in the vertical direction due to the large scale vortical structures is expected to be dominant, for which reason the diffusion-model is not feasible.

To take full advantage of the spatial resolution of the flow provided by the discrete vortex model, the sediment is represented by a Lagrangian model when it has been brought away from the bottom. Because it is impossible to trace every single grain, the sediment brought into suspension is modelled as "concentration particles", each representing a certain amount of sediment - much like the case for the discrete vortex particles. In the outer flow, the concentration particles are relocated on a pure convective basis with a fall velocity added. The diffusion due to the small-scale turbulence, which is not resolved in the hydrodynamic model, is assumed negligible compared to the convective transport.

In the near-bed boundary layer the small scales of turbulence are important for the vertical transport of sediment through diffusion. This cannot be resolved by the hydrodynamic model, as it would require a grid with mesh-size in the order of the diameter of the sediment grains. Instead, a boundary layer description based on a diffusion process developed by Asp Hansen et al. (1992) has been employed.

The near-bed concentration of sediment  $c_b$  is required as a boundary condition for the diffusion model. The approach by Engelund and Fredsøe (1976), relating the sediment concentration at a distance of twice the grain diameter above the bed to the Shields parameter has been employed. The Shields parameter  $\theta$  is defined as:

$$\theta = \frac{U_f^2}{(s-1)gd} \quad (16)$$

in which  $s$  is the relative density of the sediment,  $g$  is the acceleration of gravity,  $d$  is the grain size and  $U_f$  is the friction velocity obtained from the boundary layer model.

For each timestep the flux of sediment through the level  $2d$  is calculated as function of  $x$  and introduced in the model as "concentration particles". From the time it is introduced till it settles on the bottom, each particle is tracked in a Lagrangian fashion. In the boundary layer a Monte Carlo simulation is used to simulate the diffusion. This is performed in a similar way as for the vortex particles by use of random displacements following a Gaussian distribution.

## RESULTS

The examples of output presented are based on the domain shown in fig. 7. The shoaling waves are propagating from right to left. Breaking is simulated from the point where  $H/D$  reaches 0.8, which occurs

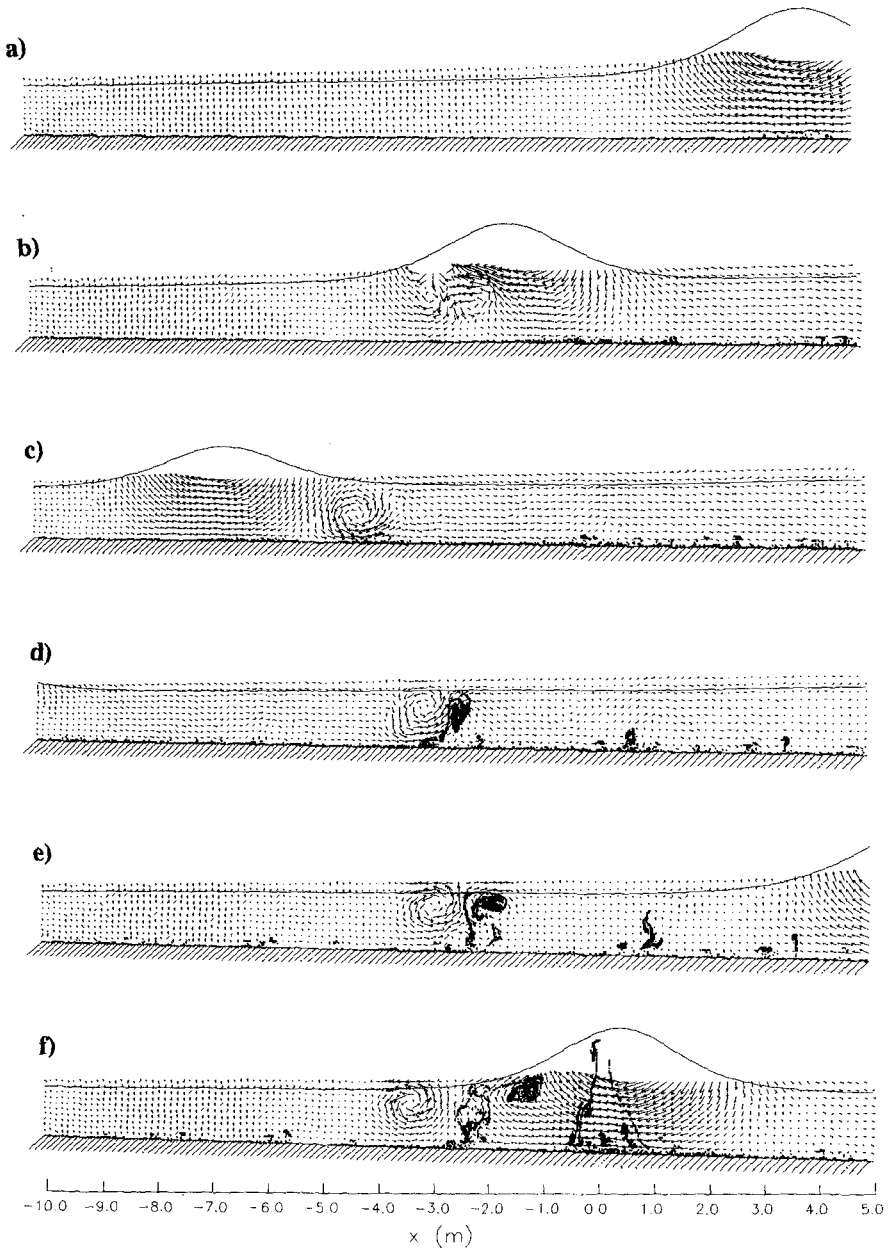

Fig. 7 Model domain

**Fig. 8** Vector plot of velocity field from waves migrating through the model domain. The time between each picture is 1.5 s with a wave-period of 6.55. The black dots superimposed on the vector plot represents suspended sediment.

at a water depth of 1.3 m. The wave period is 6.55 sec, the sediment is uniform with a grain size of  $d=0.2$  mm., a relative density of  $s=2.65$  and a settling velocity of  $w_s=0.022$  m/s.

Fig. 8 shows vector plots illustrating the velocity field at various stages. Suspended sediment, represented by concentration particles, is shown as dots. The surface profile represents the wave without the effect from the jet. Picture "a" is a situation before breaking of the first wave, while breaking is occurring in "b". Suspended sediment is still confined to the near-bed region. In "c" one major vortex structure has formed together with weaker disturbances, and in picture "d" these have started convecting sediment into the upper reaches of the flow field. This process develops further in "e" and "f", where the next wave enters the domain.

a)

b)

**Fig. 9** "Frozen" picture after 10 waves. a) Velocity vectors and particle positions. b) Contours of concentration in the domain.

Fig. 9.a depicts a situation after several waves have passed the area. The suspension of sediment is clearly associated with the large-scale vortex structures in the flow and occurs as plumes of high concentration. This is also seen in fig. 9.b, which shows a contour plot of the concentration at the same moment as 9.a. The plunge point is situated at  $x=0$ , and the mean water level is at  $y=0$ . The concentration close to the bottom is not resolved accurately in the plot because of the very high concentrations in the thin boundary layer. The concentration in the plumes reaches values of up to  $7$  g/l ( $\approx 2.6 \cdot 10^{-3}$  m<sup>3</sup>/m<sup>3</sup>).

**Fig. 10** Concentration averaged over 5 wave periods

Fig. 10 shows a contour plot of the time averaged concentration. The time averaged concentration is highest between 3m and 4m inshore of the plunge point. This coincides with the position where the major vortex formed at breaking reaches the bottom, as seen from fig. 8. The concentration in fig. 10 has been averaged over 5 wave periods after a "quasi-steady" state has been reached with balance between sediment brought into suspension and sediment settling to the bottom. A more uniform distribution could possibly be obtained by averaging over a higher number of periods. The concentration close to the side boundaries of the domain is underestimated because particles are allowed to be convected out of the domain through the boundaries under the influence of the orbital motion of the fluid, while no sediment is reintroduced through the boundaries when the flow is directed into the domain.

**Fig. 11** Time averaged concentration profiles at selected positions relative to the plunge point.

Fig. 11 shows the concentration plotted as function of the dimensionless position above the bottom ( $y/D$ ) for selected distances relative to the plunge point. The profiles differ distinctively from the "usual" diffusion profile, which can be contributed to the dominating role of convection.

## CONCLUSIONS

The discrete vortex model is capable of resolving the major vortex structures of the flow, which by convection brings sediment from the near-bottom region to the upper reaches of the water column. The small-scale turbulence in the boundary layer cannot be resolved by the discrete vortex model, as this would require too fine discretization in space and time. Instead a diffusion model has been used to simulate the suspension of sediment in the boundary layer.

Under the influence of the wave motion and the vortex structures created by the wave breaking, the sediment is convected through the model domain as unevenly distributed plumes. Preliminary results show, that with waves breaking at a water-depth of 1.3 m and sediment represented by a grain size of 0.2 mm., a relative density to water of 2.65 and a settling velocity of 0.022 m/s, the concentration in the plumes may reach values of 7 g/l ( $\approx 2.6 \cdot 10^{-3} \text{ m}^3/\text{m}^3$ ). The time-averaged concentration away from the bottom reaches a value of 1 g/l at a position approximately 2 times the local water depth in-shore of the plunge point, and decreases towards both sides.

## ACKNOWLEDGEMENT

This work was undertaken as a part of the MAST G6 Coastal Morphodynamics research programme. It was founded jointly by the Danish Technical Research Council (STVF) under the programme "Marin Teknik" and the Commission of the European Communities, Directorate General for Science, Research and Development, under MAST contract no. 0035-C.

## CHAPTER 181

### Shingle Beach Profiles and Wave Kinematics

Keith A. Powell,<sup>1</sup> Paul A. Quinn,<sup>2</sup> and Clive A. Greated<sup>3</sup>

#### Abstract

An extensive experimental project has been undertaken, in two parts, to measure both the formation of shingle beach profiles due to wave attack and the wave velocity fields using the technique of Particle Image Velocimetry (PIV). The former was achieved with moveable beach experiments carried out in the wave basin at HR Wallingford, and the latter on models in the 9.75m wave flume in The University of Edinburgh. Waves of several JONSWAP spectra, reflecting storm conditions, were allowed to impinge normally on an initial slope of 1:7, the resulting profiles were found to reach dynamic equilibrium after about 3000 wave periods. These profiles were modelled at The University of Edinburgh for the wave velocity measurements using the relatively new technique of PIV. This technique has the benefit of providing very accurate, full-field, instantaneous velocity data. In these experiments monochromatic waves were measured on smooth, impermeable beaches although the extension to multi-frequency waves on rough, permeable beaches is planned for the near future. The effect of the increased backwash component typical of these steeper beaches is dealt with in some detail.

#### Introduction

The stability of beach profiles, especially under storm conditions, is an important factor in coastal defence and environmental issues. One of the fundamental requirements for a better insight into such coastal processes, is the accurate measurement of the velocity fields of waves breaking on such beaches. In this study the relatively new technique of Particle Image Velocimetry (PIV) has been used to realise the latter. The project has been carried out in two parts. Firstly at HR Wallingford moveable beach experiments were carried out to measure the profile

change in the beach from an initial 1:7 plane slope, which is typical of the shingle beaches being modelled. The second part of the experiments, to measure the velocity fields of the breaking waves, was carried out in the 9.75m wave flume at Edinburgh University which has been custom built for PIV measurements. Shingle, or gravel, beaches are common around the U.K. coastline and as the material has a much larger diameter than sand (typically 10-50mm  $D_{50}$ ), it can tolerate steeper beach slopes and provides a good defence material (Powell, 1988).

In general, under storm conditions, the beach profile adopts a formation with a bar at the breaking point, a relatively flat breaking zone and a steep scarp formed by the run-up, just above the Still Water Line (SWL). The length of the relatively flat breaking zone is related to the energy of the incoming wavefield. A typical beach profile is shown in Figure 1.

Figure 1: General shingle beach profile formed in a storm

### Beach Profile Experiments

Experiments were carried out in the wave basin at HR Wallingford to measure the beach profile change in response to many wave conditions. The beach consisted of coal particles approximately 3.2mm  $D_{50}$ , chosen to ensure the correct sediment response at the model scale of 1:17. The beach was initially inclined at 1:7 for each experiment, and waves of various JONSWAP spectra were incident normal to the beach. Waves were created by three 5m absorbing wave boards. The beach profile was measured every 500 waves to establish beach stability and evolution. It was found that after 3000 wave periods the beach had reached dynamic equilibrium, and was therefore effectively stable.

The beach profile was measured automatically by a computer driven tactile probe which was mounted on a rig positioned above the wave basin. The rig was stepped in an offshore direction and at each step the probe was lowered until it touched the beach when the height was recorded. It was then retracted and

stepped onto the next position.

Four profiles were selected for the PIV experiments to be carried out in Edinburgh. These correspond to the profiles obtained from the wave spectra shown in Table 1.

<i>Profile</i>	$H_{sig}(m)$	$T_{mean}(s)$	$T_{peak}(s)$	<i>Steepness</i>
1	0.106	1.17	1.35	0.05
2	0.085	1.16	1.33	0.04
3	0.068	1.20	1.38	0.03
4	0.105	1.57	1.81	0.02

Table 1: Wave Parameters for Profiles to be used in PIV tests.

Figure 2 shows three of the four profiles to highlight the effect of the different wave conditions. In particular one should note that the size of the scarp increases with wave energy and tends to move quite significantly in an offshore direction, making the relatively flat breaker zone shorter with increasing wave energy.

Figure 2: Different profiles formed from the various wave conditions.

### Wave Velocity Measurements

The wave velocity fields were to be measured using the technique of Particle Image Velocimetry (PIV). This method obtains very accurate, instantaneous, full-field velocity data of the flow to be measured. It is an optical method and therefore non-intrusive. It is beyond the scope of this paper to discuss this technique in detail, however Adrian (1988) gives a good introduction and the following papers deal more specifically with hydrodynamic applications, in particular Greated et al (ICCE '92), (Gray & Greated, 1988; Quinn et al, 1991). As this is

a relatively new technique a brief outline of PIV is included.

PIV is a two stage process involving initially photographing the seeded flow which is illuminated stroboscopically. The shutter of the camera is held open for several light pulses so that multiple images of the seeding particles appear on the film. The developed negative is then analysed point-by-point on an automated system to measure the average displacement of the particles at each point. This, coupled with the knowledge of the light pulse period, yields the velocity at each point in the field. The pulsed illumination is provided by a scanning beam system. The beam of a 15W Argon ion laser is scanned by a rotating octagonal mirror along a parabolic mirror which reflects the light in a vertical "*sheet*" up into the tank. This method of illumination has proved to be the best for hydrodynamic flows (Gray et al, 1991).

The analysis method used is the so-called "Young's Fringe" method. The developed negative is probed systematically by a low power He-Ne laser with a beam diameter of about 1mm. The multiple images of the seeding particles cause interference of the laser beam and the light field transmitted by the negative is focussed by a lens forming Young's fringes on the array of a ccd camera. This is transferred to a microcomputer via a frame-grabber and a second mathematical Fourier transform is performed to obtain the autocorrelation plane, the first Fourier transform having been performed optically by the lens in front of the ccd camera. Peaks formed by the autocorrelation of a particle with its nearest image are located using a peak detection program, yielding the average displacement in that small interrogation region. As the illumination scan time is known the velocity at this point is obtained. The computer then steps the translation stage holding the negative onto the next position and the process is repeated.

The inherent accuracy of this technique is one of its main advantages, typical errors range from 1.2% for velocities with small velocity gradients across the interrogation region in the centre of the imaged flow field, to 5.9% for high velocity gradients at the edge of the imaged flow field. It is the velocity gradient across the interrogation region which causes the greatest loss of accuracy, and in extreme cases can cause signal drop-out (Quinn et al, 1991).

One practical requirement for PIV experiments is the large degree of optical access. The wave flume at Edinburgh University was designed specifically for PIV experiments and has glass walls and bottom. It is 9.75m long, 0.4m wide and 1.0m deep with a SWL of 0.75m. The waves are created by a computer driven hinged, absorbing wave maker (Salter, 1982). The laser beam illumination enters through the bottom of the tank and can illuminate a region up to 1m in length. A consequence of this is that the laser beam has to pass through the beach in order to illuminate the wave field. This is achieved by building the beach in two halves, with a 10mm gap running longitudinally down the middle. This gap is

covered by thin transparent plastic to maintain the shape of the beach and the optical access required. A section of the tank with the scanning beam system and measurement zone is shown in Figure 3.

Figure 3: The wave tank, beach and illumination system

As several beach profiles had to be made an elaborate supporting system was designed enabling all the profiles to be made with the same apparatus. Two pairs of fibre-glass "I"-beams provide the main support for the beach, individually adjustable supports are attached to this to hold the beach surface in the correct position. These supports can be located discretely along the length of the "I"-beams and continuously adjusted vertically. The beach surface is made from 10mm thick "Coplast" plastic sheet, except for the breaker region where 3mm thick perspex sheet is required to adopt the more complicated profile. A photograph of the structure of the beach is shown in Figure 4.

### PIV Experiments

As the area of interest of the beach was seaward of the scarp, it was possible to work at a larger scale of 1:10 than the experiments at HR Wallingford. The waves chosen for the present study were monochromatic waves whose frequency matched the mean frequency of the appropriate spectrum and whose height was derived from the significant wave height according to the relations given by:

$$H = \sqrt{2}H_{rms} \qquad H_{rms} = \frac{H_{sig}}{4}$$

The use of monochromatic waves may seem unjustifiable at first, however, this choice was made mainly due to the fact that PIV produces a spatial distribution of the velocity field at an instant, and so measuring a constantly varying wave field as in a JONSWAP spectrum, would provide results of dubious value. One

Figure 4: The beach structure

further consideration is that although the beach still reacts to individual waves, the average effect of the spectrum has resulted in a stable profile, hence our use of the mean wave frequency. It is intended, however, to measure bi-chromatic and possibly tri-chromatic waves in the future to represent the original spectra more accurately. This is important as the use of monochromatic waves excludes the significant effects of wave grouping and surf beat.

The wave conditions now Froude scaled in the ratio 1:10 are shown in table 2.

<i>Profile</i>	<i>Frequency(Hz)</i>	<i>Wave Height(mm)</i>
1	0.655	63.72
2	0.660	50.10
3	0.640	40.80
4	0.490	63.10

Table 2: Wave Parameters used in PIV tests.

Measurements were made all along each beach for all of the above wave conditions. At each measurement position four phases of each wave were recorded. In this way a complete flow field all along the beach could be obtained for four phases of all of the waves.

## Results

Some examples of vector plots and PIV photographs of waves measured on the first two profiled beaches are shown. The main points to note are the detail of the PIV measurements and the shape of the breaking waves.

Figures 5, 6 and 7 show vector plots of the three positions near the breaking point on beach profile 2. Figure 7 shows a surging breaker is formed on this beach. Figure 8 shows the same position with the phase changed by  $\pi$  radians. The maximum velocity in Figure 7 is  $0.35\text{ms}^{-1}$  which is considerably less than the maximum velocity in the backwash, shown in Figure 8, which is  $0.74\text{ms}^{-1}$ .

Figure 5: Profiled Beach 2,  $f=0.66\text{Hz}$ ,  $H=50.1\text{mm}$ , Posn.: 3

The photographs in Figures 9 and 11 and the vector plot in Figure 10 show three different frequency waves breaking on beach profile 1. This has a longer breaking zone than profile 2 and a less steep scarp. In all cases plunging breakers are observed.

## Discussion

One of the most significant properties of steep beaches is the increased backwash component, which is further emphasized by the length of the relatively flat breaking zone and the formation of a steep scarp just above the SWL. The effect of this scarp is to rapidly halt the run-up. This, coupled with the fact that for the higher energy waves the length of the breaking zone is shorter (Figure 2), results in the backwash being formed very quickly after the wave has broken. The returning flow can suppress the degree to which a plunging breaker is formed

Figure 6: Profiled Beach 2,  $f=0.66\text{Hz}$ ,  $H=50.1\text{mm}$ , Posn.: 2

to the extent that for the case of the second beach profile surging breakers are evident (Figure 7). In the case of a relatively long breaking zone or a plane beach, the increased length of run-up gives time for the incoming wave to break before the backwash is completely formed. This is evident from Figures 9, 10 and 11 on profile 1 where plunging breakers are still formed.

With a wall-like scarp just above the SWL a “standing-wave” is formed in the breaker zone with the almost total reflection being driven by the incoming waves. Obviously this effect is emphasized in these experiments as only monochromatic waves are being measured on an impermeable slope, however, this is perhaps the effect the beach is “trying” to achieve in order to absorb the most energy.

The formation of a “standing wave” in the breaker zone will be affected greatly by multi-frequency waves, not only because they all by definition have different periods, but also because they will break at different positions. In addition to this the permeability of shingle beaches is particularly important due to the large material size. There is significant flow into the beach above the MSL and also within the beach itself. This “draining” of water from the run-up will affect the amount of water returning in backwash.

### Conclusion

Experiments to measure the profiles of shingle beaches formed in simulated storm conditions by waves of various JONSWAP spectra have been carried out. The modelling of these beaches for wave velocity measurements using PIV has also been successful. The detail of the results obtainable from this measurement technique has been shown for the case of monochromatic waves on impermeable beaches. Whilst it is hoped that these results can be used for comparison with numerical models, the extension to measuring multi-frequency waves on imper-

meable slopes would seem the obvious next step.

## CHAPTER 182

### Beach Changes and Sediment Movement in the Surf Zone

Zbigniew Pruszek & Ryszard B. Zeidler <sup>1</sup>

#### Abstract

The South Baltic Sea coastal zone investigated in the years 1983–1989 belongs to multi-bar dissipative ones, with an average slope of 1.5% and sand grain size  $D_{50}=0.22$  mm. EOF have exhibited the most common locations of bars ( $e_{2x}$ ) and the most intensive bed changes ( $e_{3x}$ ). Particularly conspicuous are the bed changes about the inner bar (depths about 3 m). Radioisotopic iridium glass tracers have been employed in three different subzones of the shore profile; 50–60 m from shoreline (depths  $h$  of 0.8–1.2 m), 200–250 m ( $h=2-3$  m), and some 350–450 m ( $h=4-5$  m), respectively.

*During storms* the most intensive sediment motion occurs in the second subzone, where the longshore sediment transport rate  $q$  reaches 40 to 100 kg/(m·h). Closer to shoreline (first subzone), the transport rate ranges from 15 to 40 kg/(m·h), while the smallest rate ( $q \approx 3.5-20$  kg/(m·h)) is encountered in the third subzone. Under conditions of *weak or moderate oblique waves* (e.g. mean wave period and height  $\bar{T} \leq 3-4$  s and  $\bar{H} \leq 0.2$  m in the second subzone), the longshore mode also prevailed but the ratio of longshore to cross-shore rate was lower, about 1.7:1 (13.5 versus 8 kg/(m·h)).

Core samples of tracer sand have provided estimates of the vertical extent and distribution of transport rate in the bed layer. It has been found that the thickness of the bed sublayer in which all grains move in bulk reaches  $\delta \approx 2-5$  cm during storms, versus a few grain diameters to 1.5 cm under weak and moderate waves.

#### 1 Introduction

Most engineering activities take place in coastal areas shallower than 10 m. At the same time, these areas create most practical and scientific problems, and their exploration is still far from complete. Field measurements are usually a

---

<sup>1</sup> Assoc. Prof. & Professor; Polish Academy of Sciences' *Institute of Hydro-Engineering, IBW PAN, 7 Kościarska, 80-953 Gdańsk*

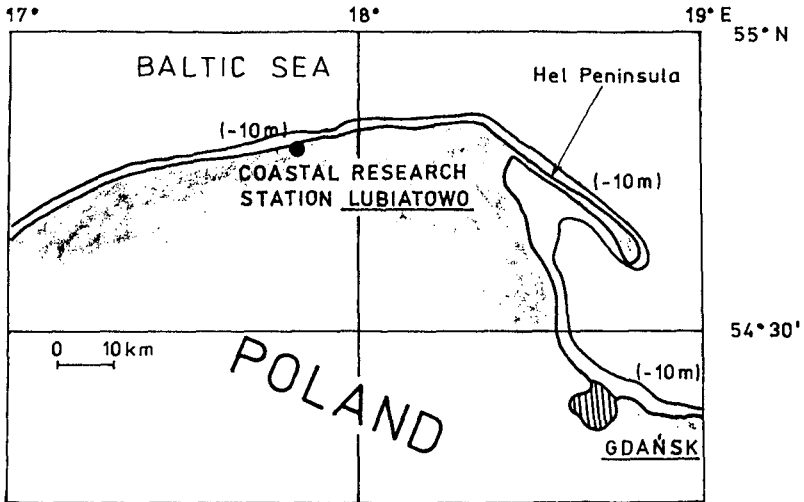

Figure 1. Location Plan of Investigation Site

prerequisite to conduct such activities. To comply with that challenge, at least in some respects, the Authors have initiated an experimental project throwing light on nearshore sediment dynamics. The paper presents results of field studies and analysis of field data relating to sediment movement and beach changes in the South Baltic Sea in the years 1983–1989.

## 2 Site Conditions

The investigations were conducted at *IBW PAN* Coastal Research Station at Lubiatowo, some 75 km NW of Gdańsk (Fig. 1.). The coastal zone belongs to multi-bar dissipative ones, with an average slope of 1–1.5% and sand quartz grain size  $D_{50}=0.22$  mm and density  $\rho_s=2650$  kg/m<sup>3</sup>. Usual maximum storm waves have  $H_s=3.5$ –4.0 m and  $T_s=7$ –8 s at the seaward boundary of the surf zone ( $h \approx 7$  m), primarily from N–NW sector.

Routine measurements of topographic features have been conducted since 1983 on a 2.7-km beach and nearshore zone extending some 800 m from shoreline. The beach profiles have been arranged every 100 m. The systematic measurements have permitted an insight into the variability of coastal features in space and time. By the use of empirical orthogonal functions (EOF) we identified the areas of most intensive dynamics, and tracer studies were carried out in such areas of pronounced bed changes (I, II and III in Figure 2), clearly coupled with underwater bars.

Radioisotopic iridium glass tracers have been employed to track the sediment movement in the three different areas of shore profile. The <sup>192</sup>Ir isotope of 74.4-day half-time had the grain diameter  $D=0.015$ –0.025 mm and density of 2668 kg/m<sup>3</sup>, thanks to its composition (48% SiO<sub>2</sub>, 17% Al<sub>2</sub>O<sub>3</sub>, 6% MgO, 5% SiO<sub>2</sub>, 5% TiO<sub>2</sub>, 5% K<sub>2</sub>O and 0.25% IrO<sub>2</sub>), thus close to natural sand.

Figure 2. Bed Topography at *IBW PAN* Coastal Research Station at Lubiatowo

The movement of the tracer sand was tracked automatically, if within a special  $10 \times 10$  m steel framework (referred to as 'Spider'), or from boat if far away from shoreline. The quantity of the tracer used was 100 g (area I) up to 1 kg (area II). Calibrated scintillation probes were employed to record the concentration of sand.

Measured simultaneously with changing bed topography and sand concentration were parameters of the controlling dynamics, i.e. wind, waves and currents. At least two series of bed topography measurements (beginning and end of tracer test) were executed. Wind was measured at an altitude of 5 m above MSL. Waves were recorded at a few locations along the shore profile. A wave-riider was deployed on a depth of 7 m, and resistance-type wave probes were installed on shallower measuring posts. Electromagnetic current meters (Interocean and Colbrook) were placed at a few spots, primarily the stationary framework ('Spider'). Examples are shown in Figure 3.

Even a casual glance at the measured hydrometeorologic data shows a considerable nonstationarity of the factors controlling the sediment movement. Periods of intensive dynamics are preceded and followed by 'dormant' or 'stagnant' waves and currents, thus sediment transport as well. Since we have been unable to log sediment and bed characteristics at every single instant, we have focused attention on average hydrodynamical factors for some typical situations labelled 'storms' (case A) and 'medium sea' (case B). An arbitrary definition has been adopted in which 'storm waves' have  $H_s \geq 0.6-0.7$  m on depths  $h \approx 2-3$  m.

Figure 3. Examples of Measured Time Series of Wind, Waves and Currents

### 3 Results

#### 3.1 Nearshore Bed Changes

Shore profile changes can be employed for reliable description of sediment movement. The profile can be presented as a sum of a certain mean component of Dean type,  $y = Ax^{2/3}$ , and disturbances coupled with bars, shoals, troughs etc (cf. Pruszek 1992). Such a decomposition permits identification of locations with intensive changes in bed and sediment features, judged from the variation of the disturbances (Fig. 4).

Empirical orthogonal functions prove to be an effective tool in analysis of coastal processes. The first three one-dimensional eigenfunctions  $e_1(x)$ ,  $e_2(x)$  and  $e_3(x)$  have exhibited the areas where the bed phenomena were most active. These areas (I, II and III) are tightly correlated with underwater bars — as seen from  $e_2(x)$  — and substantial sediment transport, coupled with conspicuous erosion and accretion, displayed in local extrema of  $e_3(x)$ . Major bed changes in our study area occur on water depths up to 5–6 m, while seasonal changes are encountered on slightly deeper water (6–8 m).

The results depicted in Figure 5 are typical of all distributions obtained within our study. Therefore it has been interesting to examine the locations of high dynamics by other tools. Accordingly, we have harnessed radioisotope sand tracers to shed more light on sediment dynamics.

#### 3.2 Sediment Movement

Radioisotopic iridium glass tracers have been employed to track the sediment movement in three different subzones of the shore profile. The first one (Area I)

	III		-	2-10	-

was spaced 50-60 m from shoreline (depths  $h$  of 0.8-1.2 m), between the steady inner bar and the ephemeral bar. Area II occurred 200-250 m from shoreline ( $h=2-3$  m), at the outer bar, most conspicuous and lasting. Area III was most distant (some 350-450 m and  $h=4-5$  m), encompassing the outermost bar, which delimits the seaward boundary of the surf zone.

### 3.2.1 Tracer Advection Velocity

Our measurements have confirmed that sediment transport usually occurs in two layers having different thicknesses and very different speeds. In situations with intensive waves (storms), slower motion some centimetres below static bed line is accompanied by much faster movement on the bed surface, measured in a few grain diameters (Fig. 6). Let alone for their position and weaker interlocking, the surficial grains are much more mobile, and their average speed is two or more times higher than its counterpart in the lower layer. As a result of such a double-layer transport, the tracer plume is smeared, the grains at the surface leading before slower cores some centimetres deeper in bed. An example illustrating this phenomenon in Area II is presented in Figure 7. Under lower waves ('medium sea'), the sediment movement is confined to the surface layer. The chief quantities measured in the three areas, including sand speed, are summarized in Table 1.

The sediment grain speeds have been computed for the effective duration of wave action, i.e. that above the incipient transport threshold. From the computed data one can see that sand speed  $\bar{v}_s$  is 1000 times smaller than the water velocity  $\bar{v}$ , that is one order of magnitude less than postulated by Kraus et al. (1982) and Drapeau et al. (1990) for oceanic coast. It should be noted that our figures have been obtained in numerous experiments executed in various years. The difference can be attributed to dissimilarities in wave and tide conditions (the Baltic Sea is known as nontidal), number of underwater bars, wave breaking etc. First and foremost, however, the duration of effective driving forces was defined differently. The values given in Table 1 characterize mean conditions of a certain category ('storm' or 'medium sea'), averaged over lapses of time with waves above the threshold corresponding to the incipient velocity of water, estimated as 8-10 cm/s by Pruszek & Zeidler (1988).

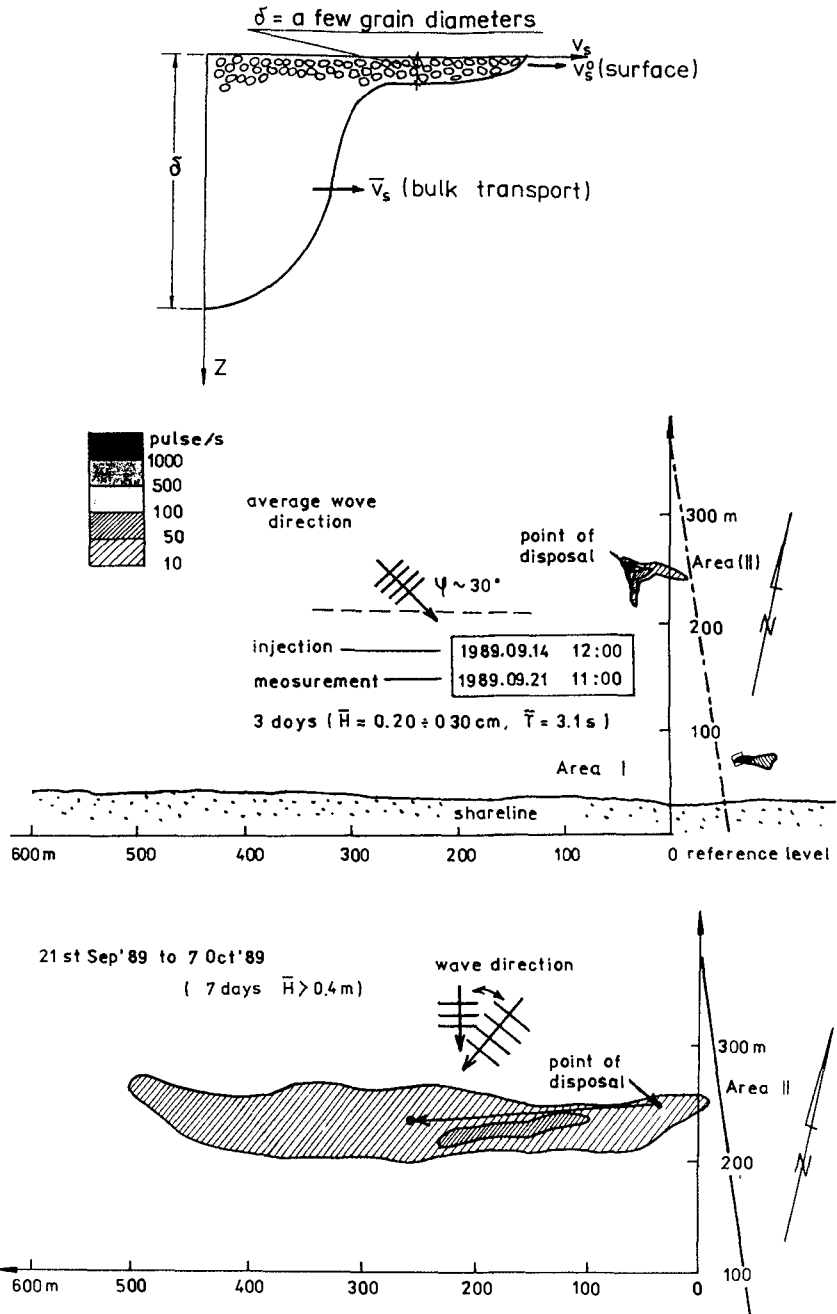

Figure 6. Schematic Sand Advection (top)

Figure 7. Distribution of Radioactive Sand Tracer from 14th to 21st September 1989 (center) and from 21st September to 7th October 1989 (bottom).

### 3.2.2 *Mixing Depth*

The thickness of the bedload layer  $\delta$ , in which all grains are assumed to move, has been found to vary from a few grain diameters to 2 cm under 'medium sea' conditions and 5 cm during storms. Since sand cores were cut out for analysis in layers 2 cm thick, it has appeared impossible to make finer distinctions.

Analysis of the measured data shows that sediment usually moves in a relatively thin layer (below 2 cm) if due to 'medium sea'; that thickness might be even smaller in view of the accuracy of the measurements. On the other hand, the thickness might increase in view of the intersecting paths of grains travelling in different directions and at different speed. This is particularly true for Area I, where meandering of longshore current brings about clear diversification of sediment movement. Further away from shoreline, the thickness  $\delta$  is much greater, from several to a few tens of centimetres, respectively for 'medium sea' and 'storm' (Fig. 8).

Upon comparison with Kraus et al. (1982) and Drapeau et al. (1990), illustrated in Figure 9, the agreement is visible with the former, thus supporting the empirical correlation

$$\delta = 0.027 H_b \quad (1)$$

### 3.2.3 *Sediment Transport Rate*

Most experiments took place upon oblique wave incidence. During storms longshore current prevails, while under case B conditions the longshore and cross-shore modes are equally important. For instance, in case B Area II, the cross-shore to longshore sediment transport rate can be estimated at 1:1.7, in absolute terms roughly 8:13.5 kg/(m·h). Incidentally, the cross-shore transport in case B situations is usually onshore (Fig. 5).

The sediment transport rate is computed from the formula

$$q_i = (\rho_s - \rho) \bar{v}_s \delta \quad (2)$$

in which

$q_i$  = transport rate in Areas I, II and III ( $i=1, 2, 3$ ),

$\delta$  = thickness of sediment motion layer,

$\bar{v}_s$  = mean sediment speed in bed layer.

The ranges of  $\delta$  along the shore profile are illustrated in Figure 6.

As could be expected, the highest transport rate takes place in Area II. During storms, the longshore rate reaches  $q=3.5-20$  kg/(m·h) in Area III, 40-100 kg/(m·h) in Area II and 15-40 kg/(m·h) in Area I. These figures become about five times smaller at 'medium sea', when only two times greater than the cross-shore rate. The gross longshore transport rate across the shore profile stretching from shoreline 700 m off shore is given in Table 2, for various external factors.

Both  $\bar{v}_s$  and  $\delta$  vary in time and space in the two cases A and B.

Finally, one can put forth

$$q = q_i \Delta l_i (\Delta \rho)^{-1} \quad (3)$$

in which

$\Delta l_i$  = width of area (I, II or III) measured along shore profile.

The total longshore transport rate in surf zone of width  $l$  varies from 1.95-6.0 m<sup>3</sup>/s in storms to 0.35-1.95 m<sup>3</sup>/s in medium sea.

B. Area II

Figure 10. Sediment Transport Rate Estimates

Figure 11. Volumetric Transport Rate; Global Rate,  $q \sim K(H_b^2 \bar{v})$

4 Comparison with Other Studies

Similar investigations have been carried out by Kraus et al. (1982) and Drapeau et al. (1990). Sediment properties ( $D$  and  $\rho_s$ ), bottom slope  $\beta$ , wave breaking index  $H_b/h_b$  etc have been encountered by us and Kraus et al. while those of Drapeau et al. were different in some respects. The difference is thought to bring about the divergence visible in Figure 11.

Major disparity arises in the proportionality factor  $K$  put forth by Kraus et al. :

$$q = \frac{3.8 \cdot 10^{-4}}{\gamma_b \tan \beta} (H_b^2 \bar{v}) = K(H_b^2 \bar{v}) \quad \text{m}^3/\text{s} \quad (4)$$

Kraus et al. give  $K=0.024$  while Drapeau et al. suggest 0.278. We have established that  $K$  depends on the intensity of wave action, and becomes 0.015–0.018 in medium sea and about 0.025–0.026 under storm conditions. The dissimilarities may be attributed to various factors controlling sediment transport phenomena such as deeper penetration of wave motion during storms and the decreasing mobility of sediment grains with depth in sea bed. Energy dissipation mechanisms, different in cases A and B, are also responsible for the scatter of  $K$ .

## 5 Discussion and Concluding Remarks

Aside from the grain speed  $v_s$ , the thickness of bedload layer  $\delta$  is difficult to measure. The magnitude  $\delta \approx 10\text{--}60$  cm given by Drapeau et al. (1982) seems overestimated. If one defines  $\delta$  as the thickness of all  $n$  grain diameters in motion, then  $\delta$  varies from a few  $D_{50}$  to 5 cm, depending on the intensity of wave motion.

Another problem can be seen in the identity of the movements of native sediment and tracer sand. It appears that the identity is complete over short spans of time (minutes or hours at most), whereupon the tracer speed can be deemed equivalent to the instantaneous sand speed. In longer time scales (days and weeks), the average velocities are usually smaller, roughly by one order of magnitude in our experiments. This is due to the random nature of grain motion.

The maximum sediment transport rate occurs in the active zones exhibited by EOF, i.e. usual wave breaking areas. Under storm waves, the longshore sediment transport rate grows locally up to 100 kg/(m·h), about five times more than its 'medium sea' counterpart. The gross transport rate across the entire shore profile, averaged over days, approaches 4 m<sup>3</sup>/s during storms or 0.85 m<sup>3</sup>/s in medium sea. These quantities refer to average conditions of mild slope (1–2%), multiple wave breaking, and medium sand ( $D_{50}=0.22$  mm,  $\rho_s=2650$  kg/m<sup>3</sup>). Since such figures are quite common throughout the world, they can be suggested as general rough estimates for similar environments and time scales of days.

The coefficient of proportionality  $K = \frac{q}{H_s^2 \bar{v}}$  has been found to vary from 0.025–0.026 in case B events to 0.015–0.018 in case A, thus in the range outlined by Kraus et al. (1982). Hence our field findings agree well with the earlier data by Kraus et al. (1982) but are in disagreement with the results published by Drapeau et al. (1990), inter alia their method of computing the total sediment transport rate. It is hoped that our results can modify and improve the engineering estimates of sediment transport.

## CHAPTER 183

Velocity measurements close to rippled beds

K.I. Mahesha Ranasoma <sup>1</sup> and J.F.A. Sleath <sup>2</sup>

### Abstract

Velocity measurements have been made with a Laser Doppler Anemometer in oscillatory flow over rippled beds. The ripples were naturally formed in an oscillating tray rig and then stabilised.

Both large-scale mixing, repeatable from cycle to cycle, and turbulence were found to have a significant effect on the velocity profile. Large-scale mixing, which is associated with vortex formulation and ejection, was seen to dominate in the immediate vicinity of the bed but turbulent mixing appeared to be more important at large height. The variation in turbulence intensity with height was found to be qualitatively similar to that previously observed with three-dimensional roughness in oscillatory flow. Time-mean velocities are not well predicted by existing theory. The present measurements show only two re-circulating cells per ripple wavelength.

### Introduction

The sea bed is frequently covered with ripples. Although much progress has been made in recent years there is still relatively little information about the way in which bed geometry changes the velocity distribution. It is the aim of the present investigation to provide more data. The results are relevant to problems such as sediment transport by waves, wave height attenuation and dispersion of pollutants in the sea.

### Experimental apparatus and test conditions

The measurements were made in the apparatus described by Lee-Young and Sleath (1988). This consists of a steady flow flume with a section of bed which can oscillate with simple harmonic motion. In the present experiments

---

<sup>1</sup> Graduate Student, Cambridge University Engineering Department, Trumpington Street, Cambridge CB2 1PZ, England.

<sup>2</sup> Reader, ditto

the steady flow was zero. The oscillating bed is 0.81m wide and 2.13m long. Disturbances generated by the ends of the bed are restricted by vertical baffles which effectively reduce the length of the working section to 1.17m. In the centre of the oscillating bed there is a sunken tray 0.70m wide x 0.70m long x 0.04m deep. Sand of medium diameter 0.41mm was placed in this tray. When the bed was oscillated at the chosen amplitude and period ripples formed on the sand. These ripples were stabilised by sprinkling with a thin coating of cement.

The velocity measurements were carried out with two different rippled beds. Bed 1 was formed by oscillating the tray with amplitude 78mm and period 2.45 secs. The ripples were of length,  $L$ , 100mm and crest-to-trough height,  $h$ , 18.4mm. Bed 2 was formed with amplitude of oscillation 40mm and period 1.25 secs. Ripple length was 50mm and height 9.1mm.

Fluid velocities were measured with a one-component DANTEC fibre-optic Laser Doppler Anemometer operated in backscatter mode. At each position the velocity was sampled 100 times per cycle for 50 cycles. Ensemble-average and root-mean-square velocities were then determined at each phase. At each position, horizontal velocity was measured first and then, by rotating the probe, the vertical velocity. Measurements were made at various vertical heights above the bed and at 11 horizontal positions (equally spaced over one wavelength of the ripple profile). The depth of water was 0.27m throughout.

Table 1 shows the test conditions. In this Table  $U_0$  is the amplitude of the velocity of the bed,  $T$  is the period of oscillation,  $a$  is the amplitude of oscillation,  $\nu$  is kinematic viscosity and  $b$  relates to the turbulence intensity (see below). Further details of the apparatus and test procedure are given by Ranasoma (1992).

### Velocities

Fig 1 shows an example of the ensemble-average velocity vectors at various phases. The velocity of the bed is maximum at  $\omega t = 0^\circ, 180^\circ$  and zero at  $\omega t = 90^\circ, 270^\circ$ . The ripple profiles in this Figure and in Fig 8 are not to scale. They are shown only to indicate position relative to crest and trough.

Measurements were only made above the level of the crests. Even so, the vortex in the ripple lee is clearly shown in Fig 1(a). As the direction of the plate reverses (Fig 1(b)), we see that the lee vortex expands and then is carried back over the crest and into the trough beyond (Figs 1(c) and 1(d)).

As might be expected, the vortex dynamics have a significant effect on the velocity profiles. Fig 2 is an example of the horizontal defect velocity at various values of  $x$  and  $y$  and Fig 3 shows the corresponding curves for the vertical velocity. The broken lines in these Figures represent the theoretical velocity which would be found with this bed profile if the flow were inviscid. In Fig 3 we see that there is an upward surge in velocity, in comparison with the inviscid solution for  $0 < \omega t < 90^\circ$  at  $x/L = 0.4$  (i.e. just to one side of the crest). At the same time and position Fig 2 shows a decrease in horizontal velocity.

These changes are clearly association with the formation and ejection of a vortex on this side of the ripple crest. In comparison, the change in vertical velocity during the other half cycle (for  $180^\circ < \omega t < 270^\circ$ ) is insignificant because the vortex is then on the far side of the crest. Over the crest ( $x/L=0.5$ ) and trough ( $x/L=0$ ) the variations in vertical velocity are more or less the same in the two half cycles because these positions are affected equally by vortices formed on either side of the crest.

Large-scale mixing

Because of the clear influence of vortex formation and ejection on the velocity records it is to be expected that the large-scale exchanges in momentum associated with the vortices would have a dominant effect on the velocity profile. Since vortex formation and ejection repeats from cycle to cycle we will analyse this effect in terms of the ensemble-average components of velocity,  $u$  and  $v$ .

In order to facilitate comparison with the spatial-mean velocity, the spatial-mean value of  $uv$  has been Fourier analysed. Fig 4 shows how the amplitude of the fundamental (i.e. the coefficient of  $\cos \omega t$ ) varies with height. A mean line has been drawn through the experimental points in Fig 4. The equation of this line is

$$\frac{\hat{uv}}{U_0^2} = 0.09e^{-1.76ky} \tag{1}$$

The origin for  $y$  is mid-height between crest and trough and  $k=2\pi/L$ .

There is also a variation in the phase of this fundamental component with height. If we draw a mean line through the experimental points for phase we obtain

$$\overline{uv} = 0.09e^{-1.76ky} \cos(\omega t - 0.46ky - 0.94) \tag{2}$$

If momentum exchange due to large-scale mixing were the only important effect (in other words, if viscosity and turbulence were negligible) we would have

$$\frac{\partial \overline{u}}{\partial t} = -\frac{\partial}{\partial y} (\overline{uv}) \tag{3}$$

Where the overbar indicates the spatial-mean value (averaged in the horizontal direction). Making use of Eqns (2) and (3) we find that the variation with height of the spatial-mean velocity would be

$$\bar{u} = 1.03 \frac{a}{L} e^{-1.76ky} \cos(\omega t - 0.46ky - 2.25) \quad (4)$$

Fig 5 shows how the amplitude of  $\bar{u}$  varies with height. Clearly Eq(4) significantly underestimates the measured values at large heights although the agreement is better as  $ky \rightarrow 0$ . The phase measurements in Fig 6 also show poor agreement with Eq(4).

We conclude that although large-scale mixing produced by the vortices may be the dominant effect at very small values of  $ky$ , other effects are more important further out. Since the flow was fully turbulent, viscous diffusion of momentum is negligible at large  $y$ . We must consequently examine turbulence.

### Turbulence

Fig 7 shows how the root-mean-square components,  $u'$  and  $v'$ , of the horizontal and vertical fluctuations in velocity vary with height. These are the mean values, averaged in the horizontal direction and in time. Sleath (1991) found that for three-dimensional bed roughness the turbulent intensity in oscillatory flow was inversely proportional to height  $y_1$ , above the bed, in the same way as for grid-generated turbulence. In other words, with suitable choice of origin for  $y_1$ ,

$$\frac{1}{v'} = by_1 \quad (5)$$

Where  $b$  is a constant for any given test.

Fig 7 shows that reasonable straight lines can be drawn through the experimental points at values of  $ky$  greater than about 1 or 2. However, there is significant divergence from the straight line closer to the bed. The apparent origin for the straight lines is at  $ky = -0.58$ , which is the level of the troughs. Values of the coefficient  $b$  obtained from the slope of the experimental curves are shown in Table I.

The present tests do not cover a sufficient range of values of  $a$ ,  $T$  and  $k_s$ , where  $k_s$  is the bed roughness length, for it to be possible to investigate whether  $b$  varies in the same way as for three-dimensional roughness. However, if we take  $k_s$  in the present tests equal to  $4h$  the values of  $b$  in Table I are significantly smaller than corresponding values for three-dimensional bed roughness. This is hardly surprising in view of the difference in bed geometry.

In order to assess the effect of this turbulence on the velocity profiles we need to make some simplifying assumptions. Following Sleath (1991), we assume that the eddy viscosity is given by

$$\epsilon_w = v'l \quad (6)$$

where the mixing length  $l$  is given by

$$l = 0.1y_1 \tag{-7}$$

and  $y_1$  has the same origin as in Eq(5). Substituting Eqns (5) and (7) into Eq (6) we see that  $\epsilon_w$  does not vary with height. If momentum exchange due to turbulent mixing is the dominant effect we have

$$\frac{\partial \bar{u}}{\partial t} = \epsilon_w \frac{\partial^2 \bar{u}}{\partial y^2} \tag{-8}$$

consequently

$$\bar{u} = A e^{-\beta_1 y} \cos(\omega t - \beta_1 y - B) \tag{-9}$$

where A and B are constants and

$$\beta_1 = (\omega/2\epsilon_w)^{1/2} = (5\omega b)^{1/2} \tag{-10}$$

Making use of the values of b shown in Table I we obtain:

$$\beta_1/k = 1.37 \text{ for tests 1,2,3,4}$$

$$\beta_1/k = 1.86 \text{ for tests 5,6,7}$$

$$\beta_1/k = 1.11 \text{ for test 8.}$$

The corresponding curves obtained from Eq (9), assuming arbitrary values of the constants A and B, are shown in Figs 5 and 6. It is clear that the slope of the curves for amplitude and phase obtained from Eq (9) is in reasonable agreement with the measurements. Unfortunately we do not have any independent estimate for the values of A and B. Nevertheless, it seems reasonable to conclude that turbulence is the dominant effect on the spatial-mean velocity profile at large  $ky$ .

Time-mean velocity

So far we have been concerned with the oscillatory component of velocity. Fig 8 shows the time-mean Eulerian velocity vectors. As expected from the theoretical studies of Blondeaux and Vittori (1991) and others, we see re-circulating fluid cells associated with each ripple wavelength. However, for the relatively large values of  $\beta L$  in the present experiments the theory predicts four cells per ripple wavelength instead of the two seen in Fig 8. Of course, there might be two cells below the lowest measured level. This is unlikely because these lower cells would be in the wrong direction for ripple formation and both inner and outer cells would be in directions opposite to those predicted by the theory. Equally, there might be re-circulating cells at larger values of  $y$  than shown in Fig 8 but the measurements of Sato et al (1984) and Horikawa and Ikeda (1990) show that this is not the case.

One possible reason for this discrepancy between theory and experiment is that the Reynolds numbers in the present tests are much larger than those for which theoretical mean streamlines have been calculated. Another possible reason is that, because of turbulence, the effective viscosity is much greater than the kinematic viscosity. Consequently, the effective value of  $\beta L$  is much smaller than the calculated value. For small  $\beta L$  the theory does indeed predict only one pair of re-circulating cells with directions of rotation similar to those in Fig 8.

The time-mean velocity is periodic in  $x$ . Fig 9 shows that the fundamental Fourier component (i.e. the term in  $\cos kx$ ) is dominant at all values of  $y$  for both the horizontal velocity  $\bar{u}_e$  and the vertical  $\bar{v}_e$ . The way in which the amplitude of this fundamental component varies with height is shown in Fig 10. Also shown in Fig 10 is the line corresponding to  $\bar{v}_e \propto \exp(-ky)$ . The fact that the experimental points for a given test lie almost parallel to this line at large  $y$  is not surprising since  $L$  is the largest length scale and is consequently dominant far from the bed.

It will be seen from Table I that  $h/L$  is almost the same for all tests and, apart from Test 8, so is  $a/L$ . Consequently, the fact that the points do not lie along a single curve in Fig 10 is an indication that either Reynolds number or  $\beta L$  (or both) have a significant effect on the time-mean velocity.

### Vorticity contours

Fig 11 shows vorticity contours calculated from the velocity measurements in Test n°2. Fig 11(a) shows the lee vortex soon after maximum bed velocity. As the velocity reverses (Fig 11(b)) the vortex is forced out into the flow, carried over the crest (Fig 11(c)) and then on over the trough (Fig 11(d)).

One interesting thing to emerge from these measurements is the relatively short life of the lee vortex once it has been pushed out from the bed by the reversing flow. In Fig 11(a), half way through the new half cycle, it is just possible to detect the old vortex to the right of the ripple crest but it is clear from Fig 11(a) that it is already very weak. This observation appears to contradict Bagnold's (1946) well-known photographs of vortex formation over rippled beds. In reality there is no contradiction. Bagnold's photographs show the trace left by the vortex in the aluminium powder on the water surface. Such a trace can remain long after the vortex which produced it has decayed to zero.

### Conclusions

The velocity measurements close to rippled beds in oscillatory flow show the following results:

- (1) The flow patterns are strongly influenced by vortex formation and ejection. Nevertheless, the measurements show that the exchanges of momentum which are repeatable from cycle to cycle (i.e. not random) are not sufficiently large to explain the observed velocity profile, except in the immediate vicinity of the bed.
- (2) It is concluded that at large distances from the bed the flow is dominated by turbulence. For large  $y$ , turbulence intensity appears to be inversely proportional to height, in the same way as for three-dimensional bed roughness in oscillatory flow. A simple turbulence model shows reasonable agreement with the trend of the velocity measurements at large  $y$ .
- (3) Time-mean velocities are not well predicted by existing theory. The present measurements show only two re-circulating cells per ripple wavelength.
- (4) Patterns of vortex formation and ejection are similar to those described by other investigators. However, once the vortex has been ejected from the lee of the ripple into the flow above it appears to decay much more rapidly than is suggested by Bagnold's (1946) photographs.

## CHAPTER 184

### FIELD OBSERVATION OF WAVE-INDUCED POREWATER PRESSURES

T. Sakai<sup>1</sup>, M. ASCE, H. Mase<sup>2</sup>, M. ASCE, D.T. Cox<sup>3</sup> and Y. Ueda<sup>4</sup>

#### ABSTRACT

Wave-induced transient porewater pressures were measured near a seabed surface at a coast facing the Japan Sea. The data are compared with the solution using a boundary layer approximation by Mei and Foda (1981). The effective bulk modulus of porewater,  $\beta$ , is estimated  $1.0 \times 10^8 \text{ N/m}^2$  so that the solution matches the observation. A similar analysis is done for the field data obtained by Zen et al. (1989) at a coast facing the Pacific Ocean. The value of  $\beta$  scatters from  $1.0 \times 10^7 \text{ N/m}^2$  to  $1.0 \times 10^8 \text{ N/m}^2$ .

#### INTRODUCTION

The wave-induced transient porewater pressure is an important quantity for a seabed stability (Sakai et al., 1992). The solution using a boundary layer approximation by Mei and Foda (1981) is simple and useful for the estimation of the wave-induced transient porewater pressures. The uncoupled analysis proposed by Finn et al. (1983) is applicable only to soft and coarse sand.

Mei and Foda (1981) modeled the seabed response to waves as a summation of an elastic response of one-phase medium and a

seepage flow near the bed surface (Fig.1). The seepage flow is appreciable only in a thin layer near the bed surface. They called this layer "boundary layer".

**Fig.1 Boundary layer approximation of seabed response to waves (Mei and Foda, 1981)**

In the solution using the boundary layer approximation, when the bottom wave pressure,  $p_b$ , is given by the small amplitude wave theory as

$$p_b = p_0 \cos(\lambda x - \omega t) = \frac{1}{2} \frac{\rho_w g H}{\cosh(\lambda h)} \cos(\lambda x - \omega t), \quad (1)$$

the porewater pressure variation,  $p'$ , is given by

$$p' = p_0 \frac{1}{1+m} \exp\left(-\frac{2\pi z}{L}\right) \cos(\lambda x - \omega t) + p_0 \frac{m}{1+m} \exp\left(\frac{-z}{\sqrt{2}\delta}\right) \cos\left(\lambda x - \omega t + \frac{z}{\sqrt{2}\delta}\right), \quad (2)$$

where  $p_0$  is the amplitude of the bottom wave pressure,  $\lambda (= 2\pi/L)$  is the wave number,  $L$  is the wave length,  $x$  is the horizontal distance in the wave propagation direction,  $\omega (= 2\pi/T)$  is the wave angular frequency,  $T$  is the wave period,  $t$  is the time,  $\rho_w$  is the density of the water,  $g$  is the gravity,  $H$  is the wave height,  $h$  is the water depth, and  $z$  is the depth beneath the seabed surface.

The first term in the right hand side of Eq.(2) is the so-called outer solution as the one-phase elastic response. The second term is the boundary layer correction. In the boundary layer correction, a

phase delay  $z/(\sqrt{\Sigma}\delta)$  exists. Eq.(2) includes two parameters  $m$  and  $\delta$ . The  $m$  is a non-dimensional parameter described by Eq.(3), and proportional to a ratio of the shear modulus of the solid skeleton  $G$  and the effective bulk modulus of the porewater  $\beta$ ,

$$m = \frac{n}{(1 - 2\nu)} \frac{G}{\beta} . \quad (3)$$

The  $\delta$  is the thickness of the boundary layer described by Eq.(4):

$$\delta = \left( \frac{KG}{\omega} \right)^{\frac{1}{2}} \left( n \frac{G}{\beta} + \frac{1 - 2\nu}{2(1 - \nu)} \right)^{-\frac{1}{2}} , \quad (4)$$

where  $n$  and  $\nu$  are the porosity and Poisson's ratio of the solid skeleton,  $K = k/\rho_w g$  and  $k$  is the permeability coefficient.

The effective bulk modulus of the porewater  $\beta$  is related to the degree of saturation of porewater,  $S$ , through an empirical equation (Mei and Foda, 1981),

$$\frac{1}{\beta} = \frac{1}{\bar{\beta}} + \frac{1 - S}{\bar{p}} , \quad (5)$$

where  $\bar{\beta}$  is the effective bulk modulus of saturated water, and  $\bar{p}$  is the fluid pressure.  $\beta$  is  $2 \times 10^9$  N/m<sup>2</sup> for saturated porewater, but it decreases rapidly to  $10^6$  N/m<sup>2</sup> due to gas content of 1%. The  $\beta$  is a dominant parameter for a momentary liquefaction (Sakai et al., 1992). In this paper, we try to estimate the value of  $\beta$  from field observation data of the wave-induced transient porewater pressure variation.

## FIELD OBSERVATION

Field observations were carried out at the Ogata Wave Observatory of Kyoto University. It is facing the Japan Sea. The measurements of the wave-induced porewater pressures were done in a sandy bed under a head of the wave observation pier, shown in Fig.2, in March 1990. The length of the pier is 256 m with a wing of 107 m length at the head. The water depth at the measuring location was about 6 m. The median diameter of the bottom sediment was reported to be from 0.2 mm to 0.5 mm (Akamura, 1989 ; Kawata et al., 1990).

**Fig.2 Pier of Ogata Wave Observatory of Kyoto Univ.**

**Fig.3 Measuring apparatus of porewater pressures**

Five pressure gauges were attached to a side wall of an aluminum pipe of rectangular section as shown in Fig.3. The length of the pipe was 3.0 m. The length between two adjacent gauges was 50 cm. The capacity of the pressure gauges was 1.0 kgf/cm<sup>2</sup>. A brass filter of 40  $\mu$ m was attached to the diaphragm of the gauge.

A part of the pipe of 2.2 m was inserted into the seabed. The highest gauge was located 30 cm above the seabed surface. The second gauge was located 20 cm below the bed surface. The bed surface around the pipe was about 7cm lower than the surrounding bed surface.

Unfortunately the waves were small during the first observation. Two months later after leaving the apparatus in the seabed, the second observation was tried again. But the output was very small compared with that of the first observation. The reason was found, after lifting out the apparatus from the seabed, that the brass filters of the upper three gauges were covered by small marine organic bodies.

Figure 4 is a part of the record on March 28th, 1990. The unit of the abscissa is second, and that of the ordinate is cm, where the porewater pressure is shown by water head. Several waves, Nos. 2 and 3 of which are shown in the figure, were selected for the following analysis. Figure 5 is a part of the record on March 30th.

Five waves were selected from the record of March 30th. Table 1 shows the wave periods and the total amplitudes of pressure head variation at five pressure gauges for five waves. The amplitude of gauge No.2 of wave No.1 is slightly larger than that of gauge No.1. The same trend was seen in two waves in the record of March 28th. At this moment it is impossible to find the reason. In the following analysis, the level of gauge No.2 is assumed to be the bed surface level.

### VALUE OF EFFECTIVE BULK MODULUS OF POREWATER $\beta$

To estimate the value of effective bulk modulus of porewater  $\beta$ , the total amplitude of  $p'$ , given by Eq.(2), was calculated at the lower three levels and compared with the measured amplitude. The value of  $p_0$  in Eq.(2) was taken to be equal to the amplitude of the measured porewater pressure at gauge No.2. The phase lag,  $z/(\sqrt{2}\delta)$ , was neglected.

The values of parameters are as follows:  $n = \nu = 0.33$ ,  $G = 1.0 \times 10^8$  N/m<sup>2</sup>, and  $k = 2.8 \times 10^{-4}$  m/sec. These values are typical

**Fig.4 Example of record of measured porewater pressures (March 28th, 1990)**

**Fig.5 Example of record of measured porewater pressures (March 30th, 1990)**

**Table 1 Total amplitude of porewater pressure head  
(March 30th, 1990)**

wave No.	1	2	3	4	5
wave period(s)	6.0	5.6	5.2	6.4	5.6
pressure gauge	total amplitude (cm)				
No.1	32	25	38	26	27

No.4	27	19	27	20	20
No.5	23	17	24	18	17

values of sandy bed. As already mentioned, the value of  $\beta$  changes very rapidly due to small content of gas in the porewater. For saturated porewater, the order of  $\beta$  is  $10^9$  N/m<sup>2</sup>. Due to 1% gas content, the order of  $\beta$  decreases to  $10^6$  N/m<sup>2</sup>. Considering this fact, three kinds of value of  $\beta$  are taken,  $\beta = 1.0 \times 10^7$  N/m<sup>2</sup>,  $2.0 \times 10^7$  N/m<sup>2</sup> and  $1.0 \times 10^8$  N/m<sup>2</sup>.  $h = 5.6\text{m} - 5.7\text{m}$ , and  $T = 5.2\text{sec} - 6.4\text{sec}$ .

From the comparison between the measured and calculated total amplitudes of pressures, it was found that the calculated result using  $\beta = 1.0 \times 10^8$  N/m<sup>2</sup> agreed best with the measured results.

As seen from Eqs. (1) and (2), the phase of the porewater pressure variation is not in phase with that of the bottom wave pressure. Then the measured time profile of the porewater pressure variation is compared with the calculated profile. The bottom wave pressure was assumed sinusoidal. **Figure 6** shows one example of the comparison. The given sinusoidal bottom wave pressure does not coincide so well with the measure porewater pressure variation of gauge No.2; However, judging from the phase shift, it is found again that the calculated results using  $\beta = 1.0 \times 10^8$  N/m<sup>2</sup> agrees best with the measured results.

#### **ANALYSIS OF DATA OF ZEN ET AL.(1989)**

Zen et al. (1989) measured the wave-induced porewater pressure in a surf zone at a coast facing the Pacific Ocean. The measurement was done at the head of an observation pier of the Port and Harbour Res. Inst. of Japanese Ministry of Transport. The

**Fig.6 Comparison of measured and calculated time profiles of porewater pressure (March 30th, 1990)**

water depth  $h$  was about 4 m (Hattori et al., 1992). The 50% sand grain size was 0.16 mm.

They showed a part of the records of three observation series. Fig.4 of Hattori et al. (1992) is that of series No.2. The waves had sharp crests as usually seen in surf zone. One wave was selected from each series, including wave No.7 in series No.2.

The time profile of the bottom wave pressure of the selected waves was decomposed into its Fourier series components. The porewater pressure variation  $p'$  was calculated for each component by using Eq.(2). The porewater pressure variation was obtained by summing up those of all components, since the boundary layer approximation solution Eq.(2) is linear. Typical values in sandy bed were used for the parameters:  $n = \nu = 0.33$ ,  $G = 1.0 \times 10^8$  N/m<sup>2</sup>, and  $k = 2.8 \times 10^{-4}$  m/sec. Three kinds of value for the bulk modulus of porewater  $\beta$  were taken,  $1.0 \times 10^7$  N/m<sup>2</sup>,  $3.0 \times 10^7$  N/m<sup>2</sup> and  $1.0 \times 10^8$  N/m<sup>2</sup>.

Figure 7 shows the comparison between the calculated and measured results for wave No.7 of series No.1. Since the figures of the time profile of the pressure variation shown in Zen et al.s paper (1989) were small, the time profile could not be read in a small interval. This is the reason why the curves are not smooth.

At the highest level, that is, 40cm below the bed surface, the amplitude of the measured pressure variation is roughly explained by the calculated curve of  $\beta = 1.0 \times 10^7$  N/m<sup>2</sup>. But the phase of the measured profile is not so delayed as the calculated one. At the second level, 90 cm below the bed surface, the value of measured peak is almost the same as the calculated one using  $\beta = 3.0 \times 10^7$  N/m<sup>2</sup> or  $1.0 \times 10^8$  N/m<sup>2</sup>. At the lowest level, 140cm below the bed surface, the tendency is the same as at the second level. The measured peak value is explained by the calculated value using  $\beta = 3.0 \times 10^7$  N/m<sup>2</sup> or  $1.0 \times 10^8$  N/m<sup>2</sup>.

From the similar comparisons for other two waves in series Nos.2 and 3, it is found that the value of  $\beta$  which explains best the measured results varies from  $1.0 \times 10^7$  N/m<sup>2</sup> to  $1.0 \times 10^8$  N/m<sup>2</sup>.

## DISCUSSION

As seen in Eq.(2), the relative importance of the boundary layer correction depends on  $m$  or  $G/\beta$ . In surf zone, a non-dimensional parameter related to the boundary layer thickness  $\delta$  given by Eq.(4) is  $kG/\rho_w g^2 T h$  (Fig.2 in Hattori et al.(1992)). The vertical profile of the non-dimensional porewater pressure variation is determined by

**Fig.7 Comparison between measured and calculated time profiles of porewater pressure ( $z = 40\text{cm}$  and  $90\text{cm}$ , wave No.7, series No.1, Zen et al.(1989))**

Fig.7 continued ( $z = 140\text{cm}$ )

two non-dimensional parameters  $G/\beta$  and  $kG/\rho_w g^2 T h$ .

When  $G/\beta$  becomes large, the correction becomes large (Fig.8). Then the scale of the vertical profile of porewater pressure variation is dominated by  $\delta$  which is assumed to be smaller than the wave length  $L$ . Also when  $kG/\rho_w g^2 T h$  becomes small, the boundary thickness  $\delta$  becomes small. In both cases, the downward decrease becomes fast.

If the value of  $kG/\rho_w g^2 T h$  is small, a smaller value of  $G/\beta$  explains the vertical profile of measured porewater pressure variation. If the value of  $kG/\rho_w g^2 T h$  is large, a larger value of  $G/\beta$  is necessary to explain the vertical profile. For a given value of  $G$ , if the value of  $k$  is small, a larger value of  $\beta$  explains the vertical profile. If the value of  $k$  is large, a smaller value of  $\beta$  is necessary. The estimation of value of  $\beta$  depends on the assumed value of  $k$ . The result of this investigation should be understood keeping this fact in mind.

**Fig.8 Two non-dimensional parameters  $G/\beta$  and  $kG/\rho_w g^2 T h$  dominating vertical profile of non-dimensional wave-induced transient porewater pressure in surf zone**

**CONCLUSIONS**

A measurement of the wave-induced transient porewater pressures was done near a seabed surface at a coast facing the Japan Sea. The value of the effective bulk modulus of the porewater  $\beta$  was estimated so that the solution using the boundary layer approximation by Mei and Foda(1981) agreed with the measured pressure variation.

- (1) The estimated value of  $\beta$  is  $1.0 \times 10^8$  N/m<sup>2</sup> under the condition of shear modulus of the solid skeleton  $G = 1.0 \times 10^8$  N/m<sup>2</sup> and the permeability coefficient  $k = 2.8 \times 10^{-4}$  m/sec.
- (2) A similar estimation for Zen et al.s data(1989) measured at a coast facing the Pacific Ocean results in from  $\beta = 1.0 \times 10^7$  N/m<sup>2</sup> to  $1.0 \times 10^8$  N/m<sup>2</sup>.
- (3) The estimation of the value of  $\beta$  should be understood keeping in mind that it depends on the assumed value of the permeability coefficient  $k$ .

## ACKNOWLEDGMENTS

The authors would like to thank Prof. Y. Iwagaki, Meijou Univ. (Emeritus Prof. of Kyoto Univ.) and Prof. Y. Tsuchiya, Disaster Prev. Res. Inst., Kyoto Univ. for their helpful discussions. Also the authors wish to thank Assoc. Prof. T. Shirai of Ogata Wave Observatory, Res. Assoc. H. Yoshioka and Engineer S. Fujiki of Disaster Prev. Res. Inst., Kyoto Univ. for their assistance of the observation.

## CHAPTER 185

# SAND TRANSPORT UNDER GROUPING WAVES

Shinji Sato<sup>1</sup>

### Abstract

Laboratory experiments as well as numerical modeling were conducted for sand transport under non-breaking grouping waves. Experiments showed that the direction of net transport of fine sand was onshore under grouping waves although it was offshore under monochromatic waves with equivalent wave height. It was also revealed that the long wave bounded to wave group plays an important role in particular for suspended load. A numerical model was developed on the basis of the second-order Stokes wave theory and one-dimensional diffusion equation of sand concentration. The validity of the model was confirmed with experimental data.

## 1. INTRODUCTION

In order to develop a proper model of sediment transport under random waves, we have to understand the mechanism of sand transport under wave groups since waves in nature usually contain various waves groups. Wave grouping may influence the amount and the direction of sand movement through direct action of a series of large waves as well as the interaction of short- and long-wave component involved in the group. For example, Shi and Larson (1984) suggested that the direction of sand transport under grouping waves will be offshore because the bound long wave will induce offshore flow under large waves when more sediment is likely to be suspended. The check of this suggestion by laboratory experiments is one motivation of the present study.

The present study aims at understanding the effect of the grouping of non-breaking waves on local sand movement through extensive laboratory experiments

Fig. 1 Experimental setup

and developing a predictive model of sand transport rate under grouping waves. Particular attention will be paid on the effects of long wave and the number of waves in a group on the direction of suspended sediment flux.

## 2. LABORATORY EXPERIMENTS

A series of experiments were performed in a wave flume in which monochromatic waves and bichromatic grouping waves were generated. Figure 1 shows the layout of experiments. A sand tray was placed at constant depth region where sand was filled to make an initially flat bed. Two kinds of sand with median diameter  $D = 0.02\text{cm}$  and  $0.07\text{cm}$  were used as bed materials. Water surface profile and near-bottom velocity at 5cm above the bottom were measured at the center of the tray by a wave gage and a ultrasonic current meter. In one run of experiments with fine sand ( $H_1 = H_2 = 6\text{cm}$ ,  $T_1 = 1.0\text{s}$ ,  $T_2 = 1.175\text{s}$ ), suspended sand concentration was also measured by an optical concentration meter at various elevations above a ripple crest and a trough. Waves were generated until significant sand transport was observed in the tray. The time duration of wave action in each run of experiments ranged from 20 to 50 minutes. Sand movement due to wave action was recorded by a VTR camera. After each run of experiments, the geometry of sand ripples was measured and a thin plate was inserted at the center of the tray. The sand on the left side and the right side of the tray was collected separately. The net sand transport rate at the center of the tray was estimated from the mass difference of dried sand in both sides of the tray.

The bichromatic waves were simulated by superimposing two sinusoidal wave components with the same heights  $H_1 = H_2$  and slightly different periods  $T_1$  and  $T_2$ . The water surface elevation  $\eta$  of the grouping wave is expressed by the linear theory as

$$\eta = \frac{H_1}{2} \cos(2\pi t/T_1) + \frac{H_2}{2} \cos(2\pi t/T_2 + \varphi) \quad (1)$$

so that the maximum wave height in the group is  $2H_1 (= 2H_2)$ . Since the energy density is proportional to  $\eta^2$ , the energy density of the grouping wave is proportional to  $H_1^2/2$ . The equivalent wave height  $H_e$  of monochromatic wave with the

**Fig. 2** Surface elevation and near-bottom velocity of bichromatic waves

same energy density as the grouping wave is therefore determined by

$$H_e = \sqrt{2}H_1 \quad (2)$$

The period  $T_l$  of the wave group and the mean period  $T_s$  of individual short-wave in the group were given as follows:

$$T_l = \frac{T_1 T_2}{|T_1 - T_2|}, \quad T_s = \frac{2T_1 T_2}{T_1 + T_2} \quad (3)$$

The ratio  $T_l/T_s$  thus indicates the number of waves in a group. These parameters will be used to analyze laboratory data although nonlinear waves were observed in the flume.

Experiments were performed for 30 runs using non-breaking grouping waves. Eleven runs of experiments were also performed by using monochromatic waves with equivalent wave heights  $H_e$ . Experimental conditions as well as measured net sand transport rates were listed in Table 1.

Figure 2 shows an example of water surface elevation  $\eta$  and near-bottom velocity  $u$  under a bichromatic grouping wave. Figure 2 (a) shows theoretical time histories estimated by the second-order Stokes wave theory. It is noticed that long waves are induced in such a way that water level decrease and offshore flow are developed under large waves. Figure 2 (b) shows  $\eta$  and  $u$  measured under bichromatic waves generated by using the linear wave variation expressed by Eq. (1) as the input to the wave generator. It was noticed that the observed waves by the linear wave input did not reproduce the phase correlation between short- and the bound long-waves well. Figure 2 (c) illustrates  $\eta$  and  $u$  where the input signal was simulated by the second-order Stokes wave theory ( *e.g.* Mansard and Barthel, 1984 ). It was found that the desired grouping waves were simulated well as shown in this figure. In the present experiments, the wave generator was controlled by input signals simulated by the second-order Stokes wave theory.

**Table 1** Experimental condition and net sand transport rates

(a) monochromatic waves

$D(\text{cm})$	$T(\text{s})$	$H(\text{cm})$	$Q(\text{cm}^2/\text{s})$

Fig. 3 Measured net sand transport rates

For 0.7mm sand bed, no ripples were developed and sand particles were transported by bed load. Sand particles were observed to be in motion during a few wave period just after the passage of the largest wave in the group. For 0.2mm sand bed, on the other hand, sand ripples were always observed and suspended transport was dominant in all the runs.

Figure 3 shows net sand transport rates measured in all the experimental runs. The positive rates means the onshore transport. The horizontal scale is  $T_s/T_l$ , which is the inverse of the number of waves in a group. Data for monochromatic waves are plotted at  $T_s/T_l = 0$ . The transport direction of coarse sand was always in the onshore direction. Fine sand was also always transported in the onshore direction under grouping waves but the transport direction was offshore in some cases of monochromatic waves. This is because coarse sand was transported by bed load and fine sand was transported primarily by suspended load. Numerical models estimating the net sand transport rate were developed for both bed load and suspended load.

Fig. 4 Net sand transport rates for coarse sand

### 3. NUMERICAL MODEL

#### 3.1 Bed load

Figure 4 shows net sand transport rates  $Q$  for coarse sand. The abscissa  $T_s/T_l$  indicates the inverse of the number of waves in a group. The symbol  $\blacktriangle$  represents measurement and the solid line indicates a numerical computation in which sand transport rate was computed by a power model expressed by

$$Q = \alpha_b w_s D \overline{(\Psi(t) - \Psi_c)u} / \sqrt{sgD} \tag{4}$$

where  $\alpha_b (=1.5)$  was a nondimensional coefficient,  $w_s$  the settling velocity of sand particle,  $\Psi(t)$  the instantaneous Shields parameter,  $\Psi_c$  the critical Shields parameter,  $s$  the specific gravity of sand particle in water and  $g$  the gravity acceleration.

The overbar indicates taking temporal average over the period of wave group.

The Shields parameter was estimated by using the laminar boundary layer theory since turbulence was observed to be weak in all the experiments with coarse sand. The second-order Stokes wave theory was used to compute velocity variation near the bottom. According to the theory, the velocity variation under a bichromatic wave was expressed by the sum of the first-order components and the second-order components as

$$u = u_1 \cos \sigma_1 t + u_2 \cos \sigma_2 t + u_{12} \cos 2\sigma_1 t + u_{22} \cos 2\sigma_2 t + u_{2a} \cos(\sigma_1 + \sigma_2)t + u_{2l} \cos(\sigma_1 - \sigma_2)t \quad (5)$$

where  $\sigma_1 (= 2\pi/T_1)$  and  $\sigma_2 (= 2\pi/T_2)$  are angular frequencies,  $u_1$  and  $u_2$  are velocity amplitudes of the first-order components and  $u_{12}$ ,  $u_{22}$ ,  $u_{2a}$ ,  $u_{2l}$  are velocity amplitudes of the second-order components. Assuming laminar flow in the bottom boundary layer, the bottom shear stress  $\tau$  is expressed by

$$\begin{aligned} \tau(t) = & \rho\sqrt{\sigma_1\nu} u_1 \cos(\sigma_1 t + \pi/4) + \rho\sqrt{\sigma_2\nu} u_2 \cos(\sigma_2 t + \pi/4) \\ & + \rho\sqrt{2\sigma_1\nu} u_{12} \cos(2\sigma_1 t + \pi/4) + \rho\sqrt{2\sigma_2\nu} u_{22} \cos(2\sigma_2 t + \pi/4) \\ & + \rho\sqrt{(\sigma_1 + \sigma_2)\nu} u_{2a} \cos((\sigma_1 + \sigma_2)t + \pi/4) \\ & + \rho\sqrt{|\sigma_1 - \sigma_2|\nu} u_{2l} \cos((\sigma_1 - \sigma_2)t + \pi/4) \end{aligned} \quad (6)$$

where  $\rho$  and  $\nu$  are the density and the kinematic viscosity of water respectively. The instantaneous Shields parameter is related to the bottom shear stress by

$$\Psi(t) = \tau(t)/(\rho sgD) \quad (7)$$

The value of  $\Psi - \Psi_c$  in Eq. (4) was set to be zero when  $\Psi$  was smaller than  $\Psi_c$ . It was confirmed in Fig. 4 that the model predicted the onshore transport of coarse sand in a good accuracy.

### 3.2 Suspended load

For fine sand sand ripples were always observed and suspended sand was dominant above rippled bed. Figure 5 shows the relationship between the ripple wavelength  $\lambda$  and the diameter  $d_o$  of water particle displacement near the bottom. The value of  $d_o$  was estimated by using the linear wave theory. For grouping waves,  $d_o$  was estimated by using energy equivalent wave height  $H_e$  and individual wave period  $T_s$ , where  $H_e$  and  $T_s$  are related to the dimensions of the grouping wave by Eqs. (2) and (3). The ripple wavelength under grouping waves was longer than that under monochromatic waves as long as  $H_e$  was used as the representative wave height.

Figure 6 shows vertical distributions of time-averaged sand concentrations  $\bar{C}$  under a grouping wave and a monochromatic wave with equivalent wave height.

Fig. 5 Wavelength of sand ripples for fine sand

It was found that sand concentration tended to be larger in grouping waves than in monochromatic waves. The eddy diffusivity  $\epsilon$  estimated from Fig. 6 was also larger in grouping waves than in monochromatic waves, which was associated with larger sand ripples observed under grouping waves.

Suspended load was modeled on the basis of the following one-dimensional diffusion equation:

$$\frac{\partial C}{\partial t} = \epsilon \frac{\partial^2 C}{\partial z^2} + w_s \frac{\partial C}{\partial z} \tag{8}$$

The boundary condition at the bed was described by a pick-up function  $p_r(t)$  which simulated intermittent ejection of sand above rippled bed (Nielsen, 1988). The entrainment of sand was assumed to occur at the time of every flow reversal. The time  $t_i$  of the  $i$ -th flow reversal was determined from the velocity variation simulated by the second-order Stokes wave theory. The boundary condition at the bed was then expressed as follows:

$$\epsilon \frac{\partial C}{\partial z} \Big|_{z=0} = -p_r(t) = -\sum_i \rho_s \alpha_s w_s D (\Psi_i - \Psi_c) u_i T_i / (\lambda \sqrt{sgD}) \delta(t - t_i) \tag{9}$$

where  $\alpha_s (=0.2)$  was a coefficient,  $\rho_s$  was the density of sand particle,  $T_i$ ,  $u_i$  and  $\Psi_i$  were the period, the velocity amplitude and the Shields parameter of  $i$ -th wave

Fig. 6 Vertical distributions of suspended sand concentration

respectively, and  $\delta(t)$  was Dirac's delta function. The Shields parameter  $\Psi_i$  was estimated by

$$\Psi_i = \frac{f_w u_i^2}{2s\bar{g}D} \quad (10)$$

where  $f_w$  was Jonsson's friction factor. For eddy diffusivity, the following relation proposed by Nielsen (1988) was employed:

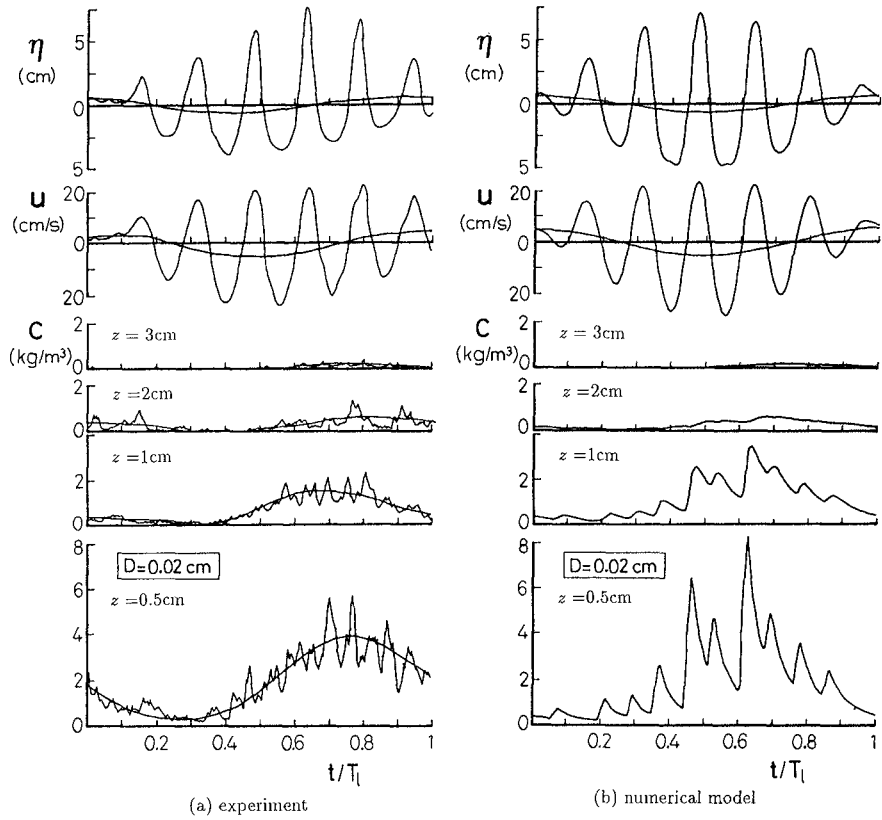

$$\varepsilon = w_s \eta (1.24 \exp[-40(w_s/\hat{u}_{1/3})^2] + 0.2) \quad (11)$$

where  $\eta$  was the wave height of observed sand ripples and  $\hat{u}_{1/3}$  was the significant amplitude of near-bottom velocity variation.

Figure 7 shows an example of temporal variation of water surface elevation  $\eta$ , near-bottom velocity  $u$  and sand concentrations  $C$  measured and simulated by the model. Sand concentrations were compared with measurements at elevations  $z=3\text{ cm}$ ,  $2\text{ cm}$ ,  $1\text{ cm}$ ,  $0.5\text{ cm}$ . The long wave component extracted by a numerical low-pass filter was also shown in the figure. It was reproduced in the model that the sand concentration becomes maximum just after the passage of largest wave in the group.

When we integrate the correlation  $\overline{Cu}$  at various heights, we can estimate suspended sand flux at the section, which can be compared with net sand transport

**Fig. 7** Comparison of numerical computation with measurements

Fig. 8 Comparison of net sand transport rates

rates estimated from the mass difference of sand in sand tray. Figure 8 shows the relationship between the net sand transport rates  $Q$  and  $T_s/T_l$ . Net sand transport rate under monochromatic wave was plotted at  $T_s/T_l=0$ . The numerical model based on the diffusion equation reproduced the experimental results that the direction of net sand transport in grouping waves was opposite to that in monochromatic waves. It is also reproduced in the model that the transport rates increased with the decrease of the number of waves in the wave group.

Figure 9 shows co-spectra between  $C$  and  $u$  for monochromatic wave and grouping wave. The co-spectrum indicates the contribution of each frequency to the total suspended load. There is a sharp peak of offshore transport for monochromatic wave. This is because under shallow water waves propagating over rippled bed, we usually have offshore transport of fine sand since more sand is accumulated in a vortex behind ripple crests during stronger onshore flow and transported offshore after the flow reversal.

Under grouping waves, to the contrary, the contribution at the peak frequency

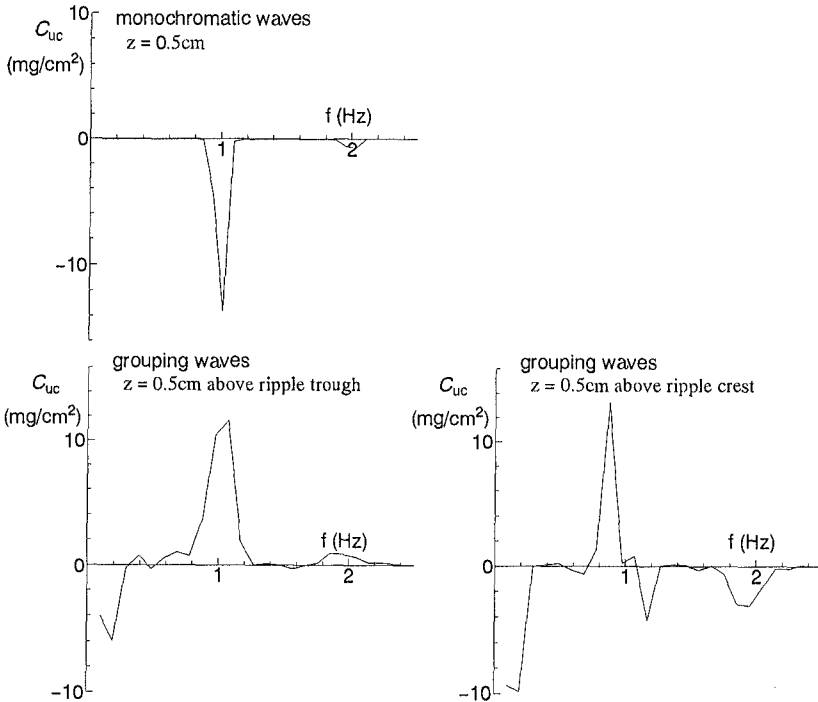

Fig. 9 Co-spectra between  $u$  and  $C$

was reversed to onshore transport. It is also noticed that a large contribution to the offshore was observed by long wave component. The reason for the reversal of the contribution at the peak frequency is explained by the asymmetry in the time history of velocity. Since offshore flow is induced by long wave component under large waves, velocity amplitude of offshore flow becomes larger than that of onshore flow. This makes suspended sand cloud created during offshore flow bigger than that during onshore flow, which results in net onshore transport of suspended sand at the peak frequency. The offshore contribution by the long wave component is explained by the same mechanism suggested by Shi and Larson (1984), that is, more sediment will be suspended under large waves which will be transported by offshore flow induced by the bounded long wave. The direction of the total net sand transport under non-breaking grouping waves will be determined by the balance of these two contributions. Net onshore transport of fine sand observed in the present experiments means that the onshore contribution by the short wave component was always larger than the offshore contribution by the long wave component within the range of experiments.

#### 4. CONCLUSIONS

Laboratory experiments showed that the direction of net transport of fine sand was onshore under non-breaking grouping waves although it was offshore under monochromatic waves with equivalent wave height. Laboratory experiments also proved that wave grouping plays an important role in particular for the case in which suspended load is predominant. A numerical model developed on the basis of diffusion equation of sand concentration was confirmed with experiments.

Extension of the model to random wave conditions will be presented in the next opportunity.

## CHAPTER 186

### QUASI-TURBULENT BOUNDARY LAYER OF OSCILLATING FLOW OVER RIPPLES

Yukio Sato<sup>1</sup>  
and  
Ken-ichiro Hamanaka<sup>2</sup>

#### ABSTRACT

When the surface waves propagate in shallow water region, the bottom boundary layer may be turbulent because of sand ripples or other kind of roughness of sea bed. But before the flow becomes fully developed turbulence, there is a state, in a certain range of the Reynolds number, in which the flow is still laminar but has separation and complex structure of vortex. This is termed as quasi-turbulent flow in the present paper. The flow structure of this boundary layer affects the mass transport and sedimentation.

In the present paper, we use a numerical method to solve the boundary layer of oscillatory flow over ripples. When we discuss the overall wave field, the sand ripples can be considered as roughness of the bottom and the flow with the separation and the vortex can be considered as disturbance around mean flow. Therefore, to discuss the averaged flow structure of wave field, the mass transport for example, it is necessary to know some kind of statistical properties of the boundary layer. A particular attention is paid to investigate the mean velocity, the Reynolds stress and turbulent viscosity. It is found that the turbulent viscosity varies along the time during the period of the oscillation. And not only it diversifies as the space derivative of the mean velocity diminishes, but also it has a complex distribution in space and time.

## 1. INTRODUCTION

Sand ripples are commonly observed on the sea bed in coastal region, which produce complex flow structures near the bed under the influence of the wave motions. This flow structures strongly affect to the development of ripples, the mass transport inside and outside the boundary layer, and the sedimentation near the bed.

In the case where the flow near the bed is fully developed turbulence, Longuet-Higgins(1958) analyzed the Eulerian mean velocity and the mass transport velocity just outside the boundary layer. He concluded that the Eulerian mean velocity and the mass transport are independent to the distribution of the turbulent viscosity. In his analysis it is assumed that the local turbulent viscosity is constant along with the time during the wave period. But the validity of this assumption seems to be questionable. Furthermore, when we discuss the mass transport inside the boundary layer, we need to know the distribution of the turbulent viscosity even if Longuet-Higgins' assumption is correct.

On the natural sea bed, the wave length of the ripples is very short compared with that of the surface wave. Therefore to investigate the flow structure inside the boundary layer, horizontally oscillating flow can be considered as a first approximation for the ambient flow. Blondeaux and Vittori(1991) investigated this flow structure in a numerical approach. Hamanaka and Sato(1991) also proposed a similar numerical method independently using the spectral method and the finite differential scheme. Both of them confirmed that their methods describe the separations and large vortex structures.

In the present paper, we use the same numerical method of Hamanaka and Sato(1991) and solve the oscillatory boundary layer on ripples under the quasi-turbulence condition. A particular attention is paid to investigate the mean velocity, the Reynolds stress and the turbulent viscosity on the same flow conditions mentioned above. Spatial averaging procedure is taken over the wave length of ripple. The turbulent viscosity is found to be dependent on time during the period of the oscillating flow. Not only it diversifies as the space derivative of the mean velocity diminishes, but also it has a complex pattern of its distribution in space and time. A similar result can be seen in the experimental measurement of Sleath (1987), in the case of fully developed turbulent boundary layer. This fact suggests that

Longuet-Higgins' assumption mentioned above is not correct. A example of this incorrectness is seen in the difference between

Tanaka's model and measurement (Tanaka,1989).

2. FORMULATION OF THE PROBLEM

In the present paper, we follow the same numerical approach of Hamanaka and Sato (1991). We consider two dimensional viscous flow oscillating over a periodic wavy bottom and assume that the wavy bottom vary sinusoidally to the direction of x axis. The vorticity equation and the Poisson equation for the stream function is employed as the governing equation.

$$\omega^* = \phi_{xy} - \phi_{yx} + \nu (\omega_{xx} + \omega_{yy}) \tag{1}$$

$$\phi_{xx} + \phi_{yy} = -\omega \tag{2}$$

where,  $\omega^*$  is vorticity,  $\phi^*$  is stream function and  $\nu^*$  is kinematic viscosity.

The flow outside the boundary layer is given by

$$u^* = \sigma^* A^* \sin(\sigma^* t^*) \quad , \quad v^* = 0 \tag{3}$$

where,  $u^*$  and  $v^*$  are horizontal and vertical velocity components outside the boundary layer. And,  $\sigma^*$  is angular frequency,  $A^*$  is amplitude of velocity.

A new coordinate system is introduced.

$$x^* = \xi^* - a^* \exp(-k^* \eta^*) \sin(k^* \xi^*) \tag{4}$$

$$y^* = \eta^* + a^* \exp(-k^* \eta^*) \cos(k^* \xi^*)$$

where,  $k^*$  and  $a^*$  are wave number and amplitude of the ripple respectively. The ripple profile is mapped into the line  $\eta^* = 0$ .

All variables are nondimensionlized with  $k^*$  and  $\sigma^*$ .

$$\xi = k^* \xi^* \quad , \quad \eta = k^* \eta^* \quad , \quad t = \sigma^* t^* \tag{5}$$

$$\phi = \frac{k^{*2}}{\sigma^*} \phi^* \quad , \quad \omega = \frac{\omega^*}{\sigma^*} \quad , \quad \nu = \frac{k^{*2}}{\sigma^*} \nu^*$$

Then, the governing equations (1) and (2) are represented in ( $\xi, \eta$ ) coordinate system.

$$\omega_t = J^{-1} \{ -\phi_\eta \omega_\xi + \phi_\xi \omega_\eta + \nu (\omega_\xi \xi + \omega_\eta \eta) \} \quad \text{----- (6)}$$

$$\phi_\xi \xi + \phi_\eta \eta = -J \omega \quad \text{----- (7)}$$

where, J is the Jacobian of transformation by Eq.(4) :

$$J = 1 - 2 a \exp(-\eta) \cos(\xi) + a^2 \exp(-\eta) \quad \text{-- (8)}$$

$$J^{-1} = 1 / J$$

The boundary conditions on the bottom are

$$\phi = \phi_\xi = \phi_\eta = 0 \quad \text{on} \quad \eta = 0 \quad \text{----- (9)}$$

and outside the boundary layer,

$$\phi_\xi \rightarrow 0, \quad \phi_\eta \rightarrow A \sin(t), \quad \omega \rightarrow 0 \quad \text{at} \quad \eta \rightarrow \infty \quad \text{-----(10)}$$

where,  $A = k^* a^*$ .

The parameters  $a$ ,  $A$  and  $\nu$  specify this problem.

The parameter  $a$  determines the bottom topography. When  $a$  is constant, the similarity law suggests two dimensionless numbers, Reynolds number (Re) and Strouhal number (S). Let the representative variable of the length scale be the wave length of the ripple profile ( $L^*$ ), the time scale, the period of oscillation ( $T^*$ ), and the velocity, the maximum velocity of oscillation ( $\sigma^* A^*$ ), then, Reynolds number (Re) and Strouhal number (S) are described as follows.

$$Re = \frac{\sigma^* A^* L^*}{\nu^*} = 2\pi \frac{A}{\nu}, \quad S = \frac{\sigma^* A^* T^*}{L^*} = A \quad \text{(11)}$$

Instead of solving this problem directly, we introduce the Fourier series expansion for  $\phi$  and  $\omega$  along the axis  $\xi$ ,

$$\phi = \sum f_m \exp(im\xi), \quad \omega = \sum g_m \exp(im\xi) \quad \text{-----(12)}$$

Substituting (12) into (7), we obtain equation (13).

$$\frac{\partial^2 f_m}{\partial \eta^2} - m^2 f_m = -H_m \quad \text{----- (13)}$$

where,  $J \omega = \sum H_m e^{im}$

In general, there can be considered two way to treat the vorticity equation. When the wave number space (Fourier coefficients) is used, the convolution sum is needed to calculate the nonlinear terms. And when the physical space is used, the inverse Fourier transform is needed in each time step. In the present paper, the latter method is used.

We introduce a new coordinate system in which finer meshes can be defined near the bottom, and coarser ones in the upper region.

$$\eta = \eta_T \frac{\exp(b\zeta) - 1}{\exp(b) - 1} \tag{14}$$

The boundary condition for (12) is on the bottom

$$f_m = 0 \quad \text{on} \quad \zeta = 0 \tag{15}$$

and outside the boundary layer

$$\frac{\partial \zeta}{\partial \eta} \frac{\partial f_m}{\partial \zeta} = \begin{matrix} A \sin(t) & , & m = 0 \\ 0 & , & m \neq 0 \end{matrix} \quad \text{on} \quad \zeta = 1 \tag{16}$$

for the vorticity equation

$$\omega = 0 \quad \text{on} \quad \zeta = 1 \tag{17}$$

The vorticity on the upper boundary is assumed to be zero, and on the bottom it is given by Thom's scheme with the bottom condition of the stream function ( Roache 1972 ).

$$\omega = -J^{-1} \left( \frac{\partial \zeta}{\partial \eta} \right)^2 \frac{2\phi(\Delta\zeta)}{\Delta\zeta} \quad \text{on} \quad \zeta = 0 \tag{18}$$

### 3. NUMERICAL PROCEDURE

The equation (6) and (13) are solved numerically by use of a forward difference scheme for the time derivative, and a central difference scheme for the spatial derivative. The vorticity at new time step is obtained through (6) with three inverse Fourier transform in the right hand side of the equation. The Fourier

coefficient of the stream function is obtained through (13) with Fourier transform of the right hand side. Then, the vorticity on the bottom is obtained through (18). In this procedure, Fourier transform and inverse Fourier transform are needed but FFT algorithm may be available in any computer system.

In this paper, the parameters  $a$  and  $A$  are fixed on 0.5 and 5.0, and several calculations is carried out with the several different value of  $\nu$ . The value of  $A$  is selected as the moving distance of water particles by oscillating flow becomes to a wave length of the ripple. The computation starts from the fluid at rest.

Table 1. gives the computational conditions which are discussed in this paper.  $M$  and  $N$  are the numbers of grids on  $\xi$ -axis and  $\zeta$ -axis respectively.  $NT$  is time step number of one period of the oscillation.

Therefore, the time step  $\Delta t$  becomes

$$\Delta t = 2 \pi / NT$$

RUN	M	N	$\eta \tau$	b	a	A	$\nu$	Re	NT	cycle

27	64	90	10	3	0.5	5	0.02	1570	12000	6

Table 1. Computational conditions

#### 4. DISCUSSION OF RESULTS

In this problem , three nondimensional parameters  $a$ ,  $A$  and  $\nu$  specify the flow. In the present calculations,  $a$  and  $A$  are fixed while  $\nu$  takes different values as shown in the table 1. This means the Strouhal number remains constant while the Reynolds number varies in the different cases. The flow with these conditions can be confirmed to be stable from the experimental measurements by Du Toit and Sleath (1981).

Fig. 1 shows the contours of vorticity of the flow with the condition of RUN 4 in the table 1, after three cycles from the rest. (a)-(h) in Fig. 1 correspond to the eight successive phases in one cycle. The fluid outside the boundary layer flows from the left to the right during the first half cycle and reverses during the next

half cycle. The bold lines show the positive vorticity ( counter-clockwise ) and the fine lines show the negative one ( clockwise ). The ambient flow is accelerated in (a), takes maximum velocity in (b), is decelerated in (c) and rests in (d).

Fig. 2 shows the contours of stream function of the same flow of Fig. 1. It is found that both the separation on the lee side of the crest and the large vortex shed from the bottom are well described in this numerical method. In Fig. 1 and Fig. 2, corresponding flows in each half cycle ((a)-(e) and (b)-(f) etc.) are almost symmetric. This means that almost stationary oscillating flow is obtained. Furthermore, in the phase of the deceleration larger separation structure is formed than in the acceleration phase. When the ambient flow reverses its direction, a cloud of vorticity is shed from the bottom and drifts with the ambient flow diminishing the intensity of its vorticity.

As mentioned in the section 1, the wave length of the ripples is very short compared with that of the surface wave in normal coastal region. Therefore the ripples can be considered as bottom roughness. In this sense, it would be reasonable to investigate the Reynolds stress and the turbulent viscosity for mean flow. In general, the averaging procedure can be taken in time, in phase or in space. But to investigate Longuet-Higgins' assumption mentioned in section 1, it will be suitable to use the spatial averaging procedure where the mean velocity is calculated from the averaged velocity over a wave length of the ripple. Then, the Reynolds stress  $R_v$  and the turbulent viscosity  $\nu_\tau$  are given by,

$$R_v = -\langle u' v' \rangle \quad \text{-----} \quad (21)$$

$$\nu_\tau = -\langle u' v' \rangle / \frac{dU}{dy} \quad \text{-----} \quad (22)$$

where

$$u = U + u' , \quad U = \langle u \rangle \quad \text{-----} \quad (23)$$

and  $\langle \rangle$  denotes the average over a wave length.

Fig. 3 shows the distribution of the mean horizontal velocity of RUN 4. Fig. 4 and Fig. 5 show the distribution of the Reynolds stress and the turbulent viscosity of the same flow. From Fig. 5, the turbulent viscosity is found to vary its value during the period of oscillation. And not only it has complex distributions but also diverges in different ways ( in positive or negative ) as the space derivative of mean velocity is diminishes. A similar result can

be seen in the experimental measurement in the case of fully developed turbulent boundary layer (Sleath, 1987).

Fig. 6 shows the contours of vorticity in the case of RUN 23. Comparing with Fig. 1, it is found that when the Reynolds number increases the intensity of vorticity becomes higher and its distribution gets much more complexity and the cloud of vortex drifts longer time with the ambient flow.

Fig. 7 and Fig. 8 show the mean velocity and the Reynolds stress of the flow of Fig. 6.

The fundamental characteristics are the same of those of RUN 4. But it can be seen from these figures that the phase shifts in the mean velocity and the Reynolds stress appears at much higher position because of the development of the boundary layer. The turbulent viscosity of this flow also has the same characteristics of RUN 4.

Let us discuss the detail of time dependence of the characteristics of boundary layer. Fig. 9(a) shows the contours of mean velocity of RUN 4 during one cycle. The bold lines denote the positive contours and the fine ones, negative ones. The height at which the mean velocity takes the maximum at each phase rises up lineally with time in each half cycle. A similar result can be seen in the turbulent intensity of fully developed turbulent oscillatory flow from the experimental measurement by Sleath (1987).

Fig. 9(b) shows the contours of the Reynolds stress of RUN 4. The Reynolds stress has two peaks in each half cycle and its intensity at the acceleration phase is higher than that at the deceleration phase.

Fig. 9(c) shows the contours of the turbulent viscosity of RUN 4. The zigzagged line where the positive contour and negative contour are close each other indicates the divergence of the turbulent viscosity. The similar result can be seen in fully developed turbulent flow (Sleath, 1987).

Fig. 10 is for RUN 23 and Fig. 11 is for RUN 27, corresponding to Fig 9 for RUN 4. As expected from the previous discussion, as the Reynolds number increases the distribution of each valuables gets higher complexity. Also it is commonly seen that the turbulent viscosity strongly depends on time and not only it has positive and negative value but also it diversifies positive way and negative way. This result suggests that the Longuet-Higgins' assumption is incorrect. A effect of this incorrectness is seen in the difference between Tanaka's model and measurement (Tanaka, 1989). He proposed a turbulent viscosity model which depends only to the height from the

bottom, and estimated the mean velocity in a fully developed turbulent oscillatory flow. Significant differences can be seen around the peak points of the mean velocity distributions.

## 5. CONCLUSION

The flow structures of oscillatory boundary layer on rippled bottom are investigated in a numerical method. It is confirmed that the turbulent viscosity depends on time and diversifies in positive and negative. This suggests that the Longuet-Higgins' assumption is unreasonable and consequently the Eulerian steady flow and the mass transport under the wave motion should be reinvestigated.

## CHAPTER 187

### LONG PERIOD WAVE AND SUSPENDED SAND TRANSPORT IN THE SURF ZONE

Tomoya Shibayama<sup>1</sup>, Akio Okayasu<sup>2</sup> and Mikio Kashiwagi<sup>2</sup>

#### Abstract

The effect of long period wave to local sand transport rate in the surf zone is analyzed by laboratory and numerical experiments. In the laboratory experiment, surface profile, near-bottom velocity and suspended sand concentration are measured simultaneously and resultant net sand transport rate is measured by mass difference during the experimental runs. It appears that the net sand transport rate is determined by three driving forces which are undertow, long wave and short wave. In mild slope condition, the effect of long wave becomes large. In order to simulate this process, a new numerical model is formulated.

#### 1. Introduction

When irregular waves travel to the shoreline, the long wave component of velocity becomes an important consideration in determining sand transport in the surf zone where sands are transported by both wave motion and turbulence due to wave breaking. For beach deformation process in field, Katoh and Yanagishima (1990) explained the erosion process of berm by the long wave effect. Irregular wave motion consists of a variety of wave periods from long wave to short wave. In this study, the role of long wave to local sediment transport rate is analyzed by laboratory experiments. Investigations are mainly

---

<sup>2</sup> Research Associate, Yokohama National University

<sup>2</sup> Graduate Student, Yokohama National University

focused on sands which are suspended by vortex motion and transported under the influence of long wave velocity. The major difference from the work by Shibayama *et al.* (1991) is that suspended sand flux is considered to be the main factor to control the effect of long wave to total transport rate in this study. In the previous work (Shibayama *et al.*, 1991), near bottom velocity and net sand transport were measured. In their analysis, bed load formula was used to simulate the process and there was no discussion on suspended sand transport because they did not measure the suspended sand concentration.

Shibayama *et al.* (1991) performed numerical simulation to estimate net sand transport rate when near-bottom velocity is given. Their analysis was based on the regular wave analysis of sediment transport rate formula proposed by Shibayama and Horikawa (1985) (also Shibayama and Irie, 1987). In their analysis, it was not possible to include suspended sand movement which is suspended more than one wave cycle. In the present analysis, suspended sand movement will be more directly included in the model.

## 2. Laboratory Experiment

Laboratory experiments were performed with the use of a wave flume which is 17 m long, 0.5 m wide, and 0.55 m deep. Uniform slopes of 1/40 (series A) and 1/20 (series B) were set at the bottom. Figure 1 shows the view of set-up. In the shallow water area, an inspection area of 3 m long and 0.5 m wide was installed where sorted sands of 0.2 mm in diameter were laid. Two inspection sections were set at the inspection area in order to compare the effect of long wave in different depth. An ultra-sonic velocimeter, optical type concentration meter and capacitance wave gage were positioned at the center of the inspection sections. Within the area, a tray was set in order to measure net sand transport rate. The tray was divided into three sections: the onshore, middle and offshore part. By measuring the change of sand mass in each section before and after the experiment, the net sand transport rate in cross-shore direction was obtained for two inspection sections. Table 1 show the conditions of waves which were used in the experiments.

Spectrum analysis was performed from the velocity history measured by the ultra-sonic velocimeter. From the calculated spectra of velocity history, it was determined that long wave component, short wave component and turbulence component had to be separated by frequencies of 0.25 Hz and 5 Hz. The velocity history and concentration time history were then divided into four components: steady flow, long wave, short wave and turbulence with the use of a band passing filter. Fig. 2 shows an example of separation of near-bottom velocity. In the figure, original time history, long wave component, short wave

and turbulence are shown. Figure 3 shows an example of the time histories of surface profile, near-bottom velocity and suspended sand concentration. Long wave components are also shown in the figure. Amplitude and period of each wave were also defined for both long wave and short wave by using the zero-down-crossing method.

The effect of long waves to local sediment transport rate were analyzed by comparing the following quantities: steady current, long wave velocity, short wave velocity, long wave concentration of suspended sand concentration, short wave concentration, and the net sand transport rate.

### 3. Results of experiment

From the above experiment, we tried to explain the net sand transport rate by using long wave and short wave component of the near-bottom velocity. This is the same way which was done by Shibayama et al. (1991). Figure 4 shows the result for the cases of which bottom slope was 1/40. From the figure, we can conclude that the larger long wave component causes the larger net sand transport even if the significant values for short wave take almost the same values. For the slope 1/20, the effect of undertow is large and therefore we judged that it is better to analyze the cases for the slope 1/40 to elucidate the effect of long wave.

Figure 5 shows the relationship between the amplitude ratio of long wave velocity to short wave velocity and the net sand transport rate for the slope of 1/40. From the figure, it can be concluded that the ratio has become larger, the net sediment transport rate has increased. In this case, the net transport direction is onshore. During the experiment, when a short wave crest comes over trough of long wave, high concentration area was frequently observed with certain phase lag. This high concentration area is transported to onshore and finally results in net sand transport in onshore direction.

Then we have tried to explain sand transport direction by using the long wave component of velocity and long wave component of suspended sand concentration. Our explanation can further be illustrated in Figure 6. If it is possible to assume that the time history of these two quantities are sinusoidal,  $-\frac{\pi}{2}$  to  $\frac{\pi}{2}$  of the phase shift between results to onshore sand transport. If it is greater than  $\frac{\pi}{2}$ , the flux becomes lesser than zero and results to offshore transport. This relationship is clearly defined in Figure 6 which shows the results of the experiments. There are 32 results in total and in 22 cases, the direction of calculated suspended sand flux and the direction of net sand transport agree. It can therefore be concluded that the transport direction can be explained by the suspended sand flux for these experimental cases.

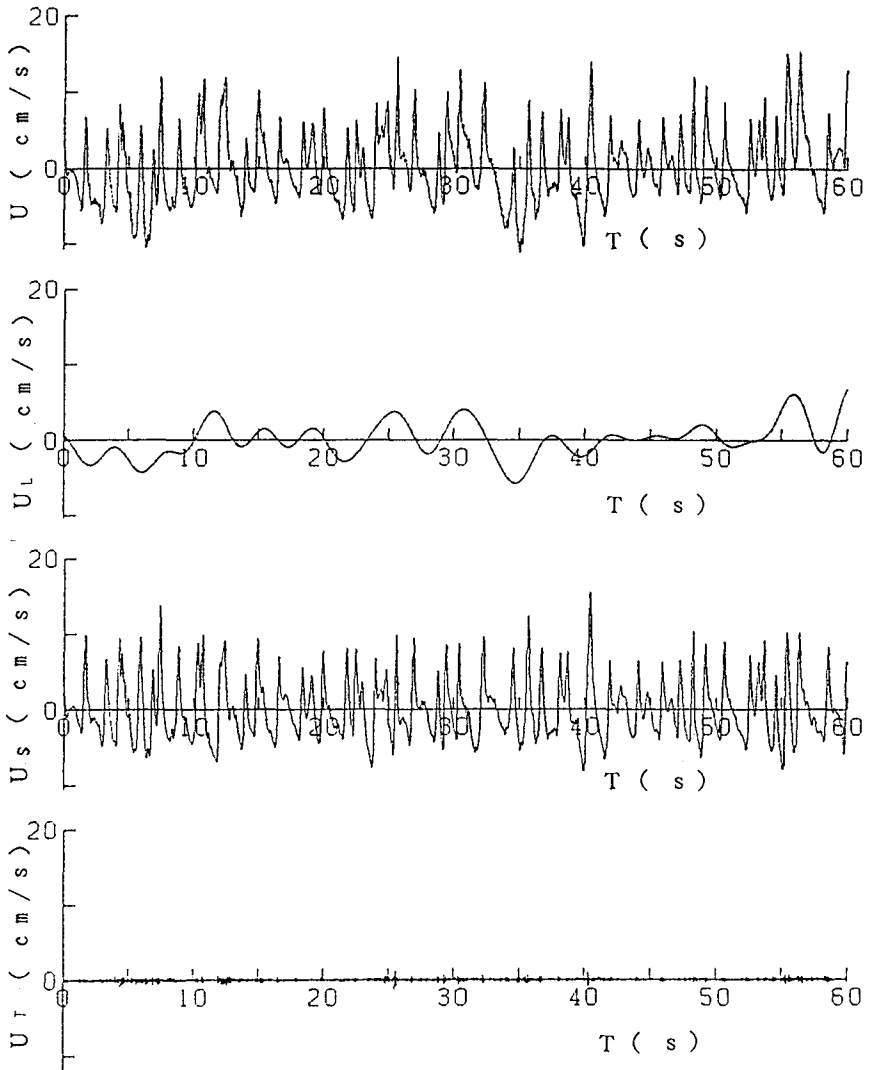

Figure 2: Example of separation.

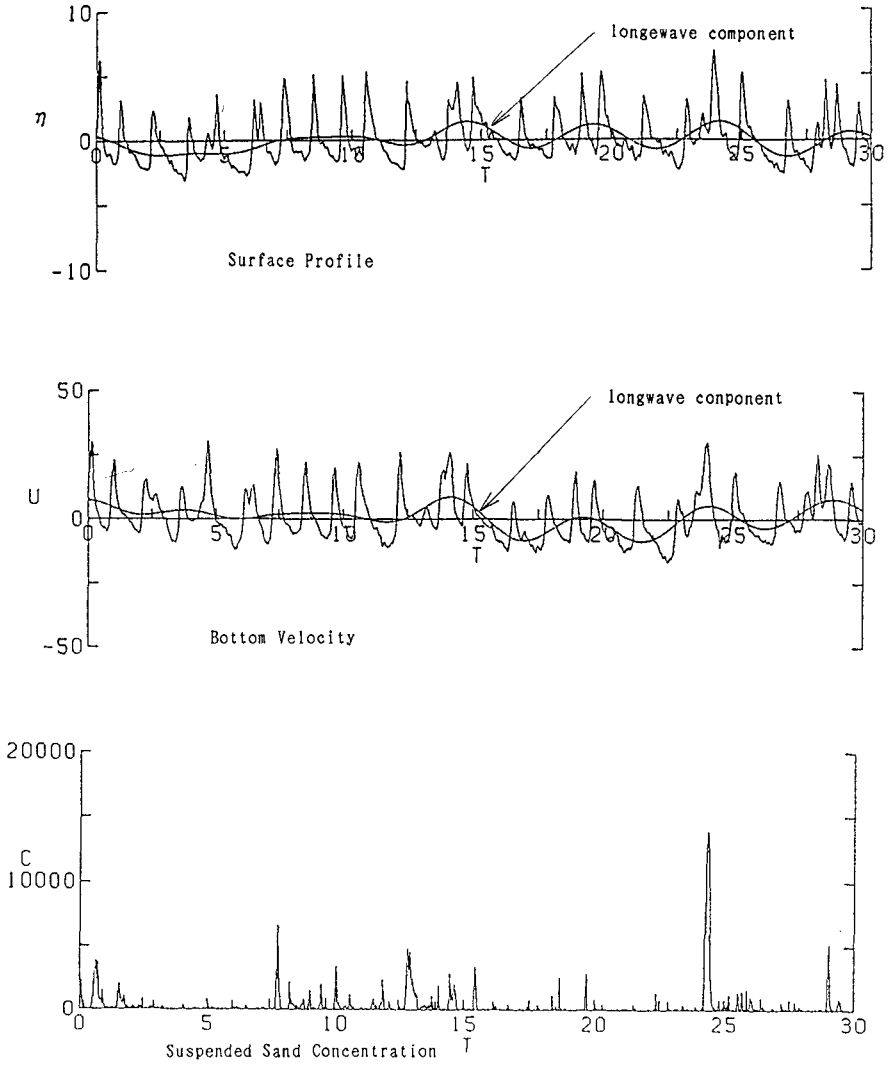

Figure 3: Example of time history.

Figure 4: Effect of short wave and long wave to net sand transport rate.

#### 4. Numerical simulation

A numerical model is formulated to examine the movement of suspended sand and the resultant net sand transport rate. From the observation, it is noticed that whether suspended sand in the vicinity of sand ripples are confined in the vortex area or not is a very important point to determine the suspended sand transport direction. Therefore it was tried to distinguish these two processes, confined or not, by using the ratio of the diameter of water particle excursion distance to ripple wave length. This value was used by Shibayama and Horikawa (1985) and the critical value of the ratio was 3. If the ratio is greater than 3, the suspended sand is not confined in vortex and transported to the same direction with flow. If the ration is smaller than 3, the suspended sand is confined in vortex area, and transported after flow direction changes. Figure 7 shows the schematic view of the difference of these two patterns.

Figure 5: The ratio of long wave component of velocity to short wave component and net sand transport rate.

For the case of suspended sand confined in the vortex area, the model of Nielsen (1988) was used (Sato *et al.*, 1991). The transport rate is given by the following formula,

$$Q = \alpha_b w_s D (\Psi - \Psi_c) u / \sqrt{sgD} \quad (1)$$

where  $\alpha_b$  is 0.2,  $w$  is fall velocity,  $D$  is sand diameter,  $\Psi$  is shields parameter,  $\Psi_c$  is critical value for initiation of the movement,  $u$  is bottom velocity and  $s$  is specific gravity of sand particle. The transport rate is integrated in time for half wave period and will be confined one ripple area and then is transported when flow direction changes. When the ratio is greater than three, suspended sand will not be confined in the vortex and Eq. (1) is directly used for transport process.

UNIT (g/cm/s)

For sand deposition process, one-dimensional diffusion equation is used to evaluate the deposition and diffusion process. It is

$$\frac{\partial c}{\partial t} = \varepsilon \frac{\partial^2 c}{\partial z^2} + w_s \frac{\partial c}{\partial z}. \quad (2)$$

The diffusion coefficient  $\varepsilon$  is given by the following formula (Nielsen, 1988),

$$\varepsilon = w_s \eta \{1.24 \exp[-40(w_s/u_b)^2] + 0.2\} \quad (3)$$

Table 2 shows the comparison between present calculation and measured net sand transport rate. The general tendency of the predictions agrees with the laboratory results but we still have discrepancy. This may be due to the effect of bed load which is not included in the present model.

## 5. Conclusions

By laboratory experiments, it was confirmed that long wave component of velocity and suspended sand concentration has an important effect on local sediment transport rate particularly in the vicinity of shoreline areas where the long wave component is large. In these areas, the relationship between the long wave component and the net sediment transport rate can be empirically obtained. It is possible to explain the direction of net sand transport from the product of long wave component of velocity and long wave component of suspended sand concentration. From numerical experiment, we can say that if movement of suspended sand is correctly estimated, then sand transport rate is correctly evaluated.

## CHAPTER 188

### OBSERVATION OF FORESHORE VARIATION IN IWO-JIMA

By Toshiyuki Shigemura<sup>1</sup>, Member, ASCE,  
Kenjiro Hayashi<sup>1</sup> and Koji Fujima<sup>1</sup>

#### Abstract

The variation of the foreshore in Iwo-jima is studied by analyzing a series of aerial photographs taken seasonally for the past 4 years since 1987, and data of various surveys obtained for the past 10 years since 1982. These observations are compared with results of numerical analysis of the effects of storm waves on the foreshore. The findings obtained through these analyses are: (1)The island is still rising at a yearly rate of more than 30 cm/year; (2)The foreshore is eroded in summer and fall when typhoons often hit the island, but is restored back in winter and spring of the following year. The seasonal variation of the foreshore area ranges from 300,000 m<sup>2</sup> to 600,000 m<sup>2</sup> depending on the magnitude and frequency of the typhoons hitting the island in a year; (3)The foreshore area is increasing at a rate of 50,000 m<sup>2</sup>/year which is caused by the upheaval of the island; (4)A one-line model can be applicable for the prediction of the short-term variation of the shoreline caused by storm waves.

#### 1. Introduction

Iwo-jima is an isolated volcanic island located in the Pacific Ocean about 1250 km south of Tokyo (24°45' to 24°49'N, 141°17' to 141°21'E). Figure 1 shows the location of the island.

The maximum length of the island is about 8.6 km and its surface area is roughly 23.2 km<sup>2</sup>. The island is relatively flat with a mean altitude of 110 m and its surface is covered with dense vegetation.

The coast is mostly rimmed by a uniform sandy beach approximately 200 m wide, fully exposed to the open sea. Since the island often experiences typhoons in summer and fall, the seasonal variation of the foreshore is quite remarkable. Further, the island has

---

<sup>1</sup> Department of Civil Engineering, National Defense Academy,  
1-10-20 Hashirimizu, Yokosuka, Kanagawa 239 JAPAN

been rising at an unusual rate of more than 30 cm/year in some places, making the variation of the foreshore more complicated. These environmental conditions have prevented us from constructing any operative port facilities in this island.

To investigate the mechanisms by which the foreshore changes, the authors have been conducting various surveys on the shore of the island since 1982, and have been taking aerial photographs since 1987.

This paper intends to clarify the following items through the analysis of these field data:

- (1) The current state of the rate of upheaval of the island.
- (2) The seasonal variation of the foreshore.
- (3) The effect of upheaval on the increase of foreshore area.
- (4) The mechanism by which the foreshore changes due to storm waves.

## 2. Field surveys and Aerial Photographs

### (1) Field surveys on the shore of Iwo-jima

To investigate the variation of the rate of upheaval, the authors have been conducting traverse, level and cross surveys on the shore of Iwo-jima since 1982, with the support of the Topographic Survey Battalion(TSB) of Japan Ground Self Defense Force(JGSDF). Figure 2 shows the location of 53 measuring points provided at an interval of roughly 300 m along the entire backshore of the island.

By using these measuring points, surveys have been carried out at a frequency of at least twice a year. So far, surveys have been conducted 16 times in the period between 1982 and 1991.

In this study, the results of the level and cross surveys will be analyzed to check the current rate of upheaval and the variation of the foreshore slope of the island.

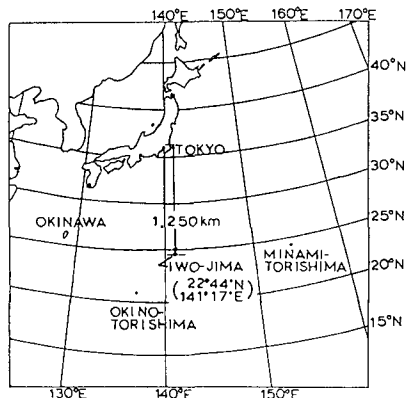

Figure 1 Location of Iwo-jima

Figure 2 Location of measuring points

## (2) Processing aerial photographs

To investigate the seasonal variation of the foreshore area, the authors have been taking aerial photographs of the island, seasonally since 1987, through the support of the Japan Maritime Self Defense Force (JMSDF). The photographs were taken vertically at an altitude of 3000 m, on three flight courses set in advance over the coast of the island. Photographs were taken at both low and high tides in each photographing operation, setting the overlapping rate to be 60%. Table 1 summarizes the details of the photographing operation.

From these photographs, mosaic maps of the island with a scale of 1/10000 were made with the aid of the TSB. So far, 15 sets of the mosaic maps have been completed. On each one, a common coordinate system was provided as shown in figure 3. Here, the X axis was placed along the runway heading in the ENE direction and the origin was placed at the western end of the runway.

Based on this coordinate system, the shoreline on each mosaic map was digitized at increments of 1 mm by using a special digitizer.

Figure 3 Coordinate system and inspection points provided for the data correction

### (3) Correction of shoreline data

Shoreline data digitized from aerial photographs may include some errors caused either by mishandling of the camera during the photography, or by the incompleteness of the mosaic. Corrections should therefore be made on each set of the shoreline data so that all the measurements should have equivalent reliability.

To carry out this correction, thirteen inspection points were selected along a road that encircled the island (see Figure 3). These points were chosen because they can be distinguished clearly on each mosaic map. They were also identified on a reference map with a scale of 1/10000, made by enlarging the latest topographical map of the island revised in 1982 by the Geographical Survey Institute of the Japanese Ministry of Construction.

The corrections to the shoreline data were performed through the following procedures in each subdivided area defined by two adjacent inspection points and the origin of the coordinate system:

(a) Superpose the origin of the subdivided area on a mosaic map on to the origin of the corresponding area on the reference map, as shown in figure 4(a).

(b) Rotate the shoreline data of the mosaic map so that the bisector of  $\theta_{mi}$  lies on the bisector of  $\theta_{ti}$ , where  $\theta_{mi}$  is an angle determined by the  $i$ -th and the  $(i+1)$ -th inspection points, and the origin of the coordinate on the mosaic map, and  $\theta_{tm}$  is the corresponding angle determined on the reference map (see figure 4(b)).

(c) Make an angle correction on the shoreline data of the mosaic map so that  $\theta_{mi}$  becomes equal to  $\theta_{ti}$ . Divide both  $\theta_{mi}$  and  $\theta_{ti}$  into increments of 1 degree to determine the length of dividing lines,  $l_m$  and  $l_t$ , where  $l_m$  is the length from the origin to the intersection point of a dividing line with the ring road on the mosaic map, and  $l_t$  is the corresponding length on the reference map (see figure 4(c)).

(d) Determine the correction factors  $r_{i,j}$  and  $r_{i,j+1}$  on every dividing line within the  $i$ -th subdivided area, where  $r_{i,j}$  is the

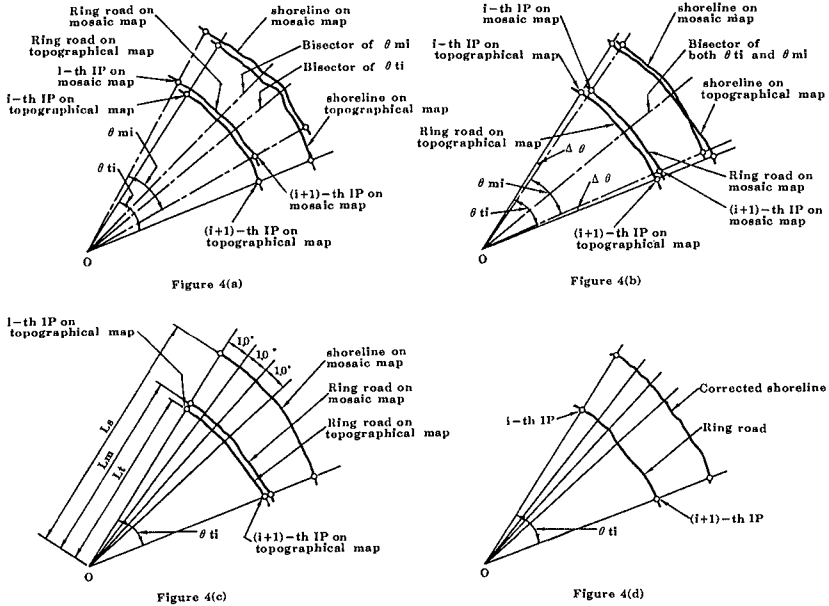

Figure 4 Correction procedures for eliminating the human errors on mosaic map

ratio  $l_t/l_m$  on the  $j$ -th dividing line, and  $r_{i,j+1}$  is ratio  $l_t/l_m$  on the  $(j+1)$ -th dividing line, both in the  $i$ -th subdivided area.

(e) Based on the values of  $r_{i,j}$  and  $r_{i,j+1}$ , determine the correction factor  $r$  for any of the shoreline data in the area surrounded by the  $j$ -th and the  $(j+1)$ -th dividing lines, and multiply each shoreline measurement of the mosaic map by  $r$  to get the corrected shoreline data (see figure 4(d)).

By performing this procedure on the original shoreline data, most of the human errors might possibly be eliminated.

However, these shoreline data, still include some errors caused by differences in tide level at the respective instants when the aerial photographs were taken. In order to eliminate this error, all of the shoreline data have to be adjusted to refer to a common level.

A datum plane (the Indian tide plane) was chosen as the reference level, and it was decided to reduce the shoreline data to this datum plane by using equations derived as follows:

Figure 5 shows a coordinate system used for the derivation of the equations. Suppose that A, B and C in this figure are points on the shoreline whose positions were digitized successively. Further, suppose that the photograph was taken when the tidal level was at an elevation  $\eta_t$  above the datum plane, and that the foreshore slope around these points is  $I_{fs}$ .

Now, we draw two lines at point B, one of them perpendicular to

the line AB and the other perpendicular to the line BC. Points  $B_1'(X_1', Y_1')$  and  $B_2'(X_2', Y_2')$  lie on these normals at the points where the elevation of the foreshore coincides with that of the datum plane. Their coordinates are determined as follows:

$$\begin{aligned}
 L &= \eta_t / I_{fs} & (1) \\
 X_1' &= X + L \sin \theta_1 & (2) \\
 Y_1' &= Y + L \cos \theta_1 & (3) \\
 X_2' &= X + L \sin \theta_2 & (4) \\
 Y_2' &= Y + L \cos \theta_2 & (5)
 \end{aligned}$$

Thus, the position of the point  $B'(X', Y')$ , the midpoint between  $B_1'$  and  $B_2'$ , can be determined by the following equations.

$$\begin{aligned}
 X' &= (X_1' + X_2') / 2 & (6) \\
 Y' &= (Y_1' + Y_2') / 2 & (7)
 \end{aligned}$$

Figure 5 Coordinate system used to determine the shoreline data at the datum plane

By using these equations, errors due to the difference in tide level can also be eliminated from the shoreline data.

### 3. Results of the analyses

#### (1) Seasonal variation of foreshore slope

As stated in the preceding Chapter, the foreshore slope near the swash zone  $I_{fs}$  is needed for converting the shoreline data digitized from a mosaic map into one at the datum plane. To get this information, analyses were made on the results of cross surveys which have been done 16 times in the period between 1982 and 1991.

Figure 6 shows the seasonal variation of mean foreshore slope  $I_{fs}$  on each of the N-W, N-E, S-W and S-E coasts. Each coast was

Figure 6 Seasonal variation of mean foreshore slope on each of the subdivided coasts

subdivided to obtain the local trend in the variation of foreshore slope and upheaval (see figure 2). The slopes used in reducing the corresponding shoreline data are the averages of all values of  $I_{fs}$  obtained at the measuring points on each coast.

The following facts were revealed through this analysis:

(a) Local values of  $I_{fs}$  vary in the range from 17 to 20% during summer and fall although they vary in the range from 15 to 19% during winter and spring.

(b) Local trends are not observed clearly in the seasonal variation of  $I_{fs}$ .

By using these values of  $I_{fs}$ , shoreline data were all converted to the datum plane.

## (2) Current state of upheaval

To investigate the current state of upheaval in Iwo-jima, results of level surveys were analyzed intensively. Figure 7 shows the local variation of mean upheaval rate determined at measuring points on each coast. Here, the mean upheaval rate at each point means the rate determined by averaging the upheaval rates observed at the same point 16 times in the period from 1982 to 1991. All rates have been converted into cms per year. Further, the abscissa indicates the distance of each measuring point measured northward from the southernmost measuring point provided on each coast (see figure 2). Through this analysis, the following facts were found:

(a) The mean upheaval rate tends to increase towards the north.

Figure 7 Mean upheaval rate at the measuring points on each of the subdivided coasts

(b) The mean upheaval rate is roughly 20 cm/year around the southern part of the island and 30 to 40 cm/year in the northern part of the island.

Tsuji et al (1969) have investigated the upheaval of Iwo-jima by comparing the elevations shown in a topographical map published by the US Army in 1952 with their surveyed data obtained in 1968. They revealed that the northern part of the island rose roughly 9 m in 16 years after 1952, while the southern part rose roughly 3 m in the same period. Further, Kosaka et al(1979) have analyzed old maps and charts of the island published prior to 1968, together with their own data surveyed in the next decade after 1968, and have reported that the island continued to rise at a rate of roughly 30 cm/year after 1952. Referring to these results, it can be concluded that the island is currently rising in the same way and at a similar rate to those revealed by earlier works.

### (3) Seasonal variation of the foreshore area

Before checking the seasonal variation of the foreshore area in Iwo-jima, we look at the time history of the total surface area, which has increased steadily since 1911.

Figure 8 shows the history of the surface area determined by analyzing old maps, charts published after 1911, and mosaic maps described in the preceding Chapter. Among these data, those prior to 1986 were introduced in the authors' previous work (Shigemura et al, 1986).

Further, data determined from the mosaic maps are shown in the upper right of this figure within a dotted rectangle. From this figure, the following facts were revealed:

(a) Iwo-jima has continued to increase its surface area in the past 8 decades, although the rate of increase has been reduced slightly after 1980.

Figure 8 Time-history of the surface area of Iwo-jima after 1911

Figure 9 Seasonal variation of the surface area of Iwo-jima after 1987

(b) The envelope for the maximum area determined from the mosaic maps seems to lie on an extension of the curve through observations prior to 1980, although the seasonal variation of surface area is quite remarkable.

Now, we consider the seasonal variation of the foreshore area more closely. Figure 9 shows the seasonal variation of surface area determined by analyzing the mosaic maps. Here it should be noted that the seasonal variation of surface area may indicate that of the foreshore area itself. The numbers shown on the abscissa indicate the typhoons which passed within a range of 500 km from the island. From this figure, the following facts were revealed:

(a) The foreshore area is eroded in the period from summer to fall when typhoons often hit the island, but is restored in the period from winter to spring of the next year in which local waves of roughly 1 m high are predominant.

(b) The seasonal variation of the foreshore area ranges from 300,000 m<sup>2</sup> to 600,000 m<sup>2</sup>, depending on the magnitude and frequency of typhoons which hit the island in a year.

(c) The foreshore area is currently increasing at a rate of roughly 50,000 m<sup>2</sup> per year, which might be caused by the upheaval of the island.

#### (4) Effect of the upheaval on the increase of foreshore area

As stated previously, Iwo-jima is a volcanic island located in the Pacific Ocean. The surface is covered with dense vegetation and there is no river on the island. The source of sediments is therefore quite limited. Nevertheless, the coast of the island is mostly rimmed by a sandy beach roughly 200 m wide. These observations seem to indicate that upheaval is the only possible mechanism for supplying sediments to the shore of the island.

To confirm this, the authors have checked the relationship between the surface area and the cumulative change in elevation that occurred in the period from 1911 to 1978. The change in elevation was determined from the work done by Kosaka et al (1979).

The results was shown in figure 10, where figures in parentheses indicate the dates of observations. Through this analysis, it was ascertained that there was quite a high correlation between the increase of surface area and the cumulative upheaval height, except for the data prior to 1945. Regression analysis on these data after 1952 indicated that the shore area increased by roughly 270,000 m<sup>2</sup> per year in this period for an up-

Figure 10 Relationship between the surface area and the cumulative change in elevation

heaval of 1 m. It should be noted that this relationship was found for foreshore areas which had been subject to waves over a certain period.

Next, the increase of the foreshore area due to the upheaval was estimated by applying various upheaval heights and foreshore slopes to the shoreline data of April 24, 1987. The results are shown in figure 11. It should be noted that the increase of foreshore area shown here is the estimated value, without accounting for the effects of waves and currents. If the mean upheaval rate were 30 cm/year, and the mean slope in the surf zone were 1/20, the increase in foreshore area would be roughly 150,000 m<sup>2</sup>/year. This might be a reasonable value considering the fact that the rate at present is roughly 50,000 m<sup>2</sup>/year.

Figure 11 Increase of foreshore area due to the given upheaval height

#### (5) The response of the foreshore to storm waves

The analyses done so far have revealed that the magnitude and frequency of typhoons would be the governing factors in the variation of the foreshore area in Iwo-jima. It was therefore attempted to predict the short term variation of foreshore transformation due to storm waves generated by typhoons, using numerical models.

Two typhoons were selected for the numerical analyses, whose characteristics are summarized in table 2.

Table 2. Characteristics of typhoons at the times when they approached most closely to Iwo-jima.

Typhoons	Date	Time	P(mb)	R-30kt	Location	DIR
#8911	July.26,1989	00:47	940.0	225 km	350km W	SE
#9813	Aug. 4,1989	14:66	950.0	275 km	370km E	WNW

In this table, R-30kt means the semi-diameter of a circle in which wind velocity is greater than 30 kt. The Location column gives the distance and direction of the center of the typhoon from the island, and the DIR column indicates the direction of the typhoon.

These typhoons were chosen because the authors have the mosaic maps produced from the aerial photographs taken just before and after these typhoons hit the island (see table 1), and it is possible to compare the

Figure 12 Passage routes of typhoons #8911 and #8913

predicted values with the observed ones.

Figure 12 shows the passage routes of these typhoons. As it is shown in this figure, both typhoons advanced into the NE direction, although typhoon #8911 passed offshore to the west of the island and typhoon #8913 passed to the east.

The numerical analysis consists of a prediction of the offshore waves, calculation of wave transformation and prediction of shoreline variation, as described below.

(a) Prediction of offshore waves generated by typhoons

Prediction of offshore waves was carried out by using the method developed by Goto and Aono (1992) which requires the following steps:

- Determine the typhoon constants at one hour intervals based on the meteorological maps published by Japan Meteorological Agency.
- Compute the wind field around the computational area.
- Select the prediction point of offshore waves at Iwo-jima and calculate the two dimensional energy spectrum  $S(f, \theta)$  which is obtained by composing the energy spectrum of waves approaching the prediction point from 16 directions along the respective wave rays.
- Determine the height and period of significant waves at one hour intervals based on the values of  $S(f, \theta)$ .

(b) Calculation of wave transformation

Wave transformation due to shoaling, refraction and diffraction was calculated as follows using small amplitude wave theory:

- Use a nautical chart published in 1981 by Maritime Safety Agency of Japan for the bathymetry around the island.
- Provide a calculation area around the island in which the depth is less than 100 m. Further, provide a square grid on the calculation area whose length is 50 m.
- Calculate the wave transformation due to shoaling, refraction and diffraction, to determine the magnitude and direction of energy flux at the breaking points. Here, use Goda's breaker formula (1973) as a breaker index.

(c) Prediction of shoreline variation

Shoreline variation was predicted by using a one-line model following the steps shown below:

- Assume the critical water depth for sand movement by waves to be 15 m, and the runup height of waves to be 1 m above mean sea level.
- Compute the longshore sediment transport flux by using the CERC formula, assuming the coefficient of longshore sediment transport rate to be 0.1.
- Assume that the longshore sediment transport flux coming into the computational area through the boundary between adjacent coastal regions to be zero.

Figure 13 shows the time-wise variation of the predicted values of significant wave height, wave period and direction of deep sea

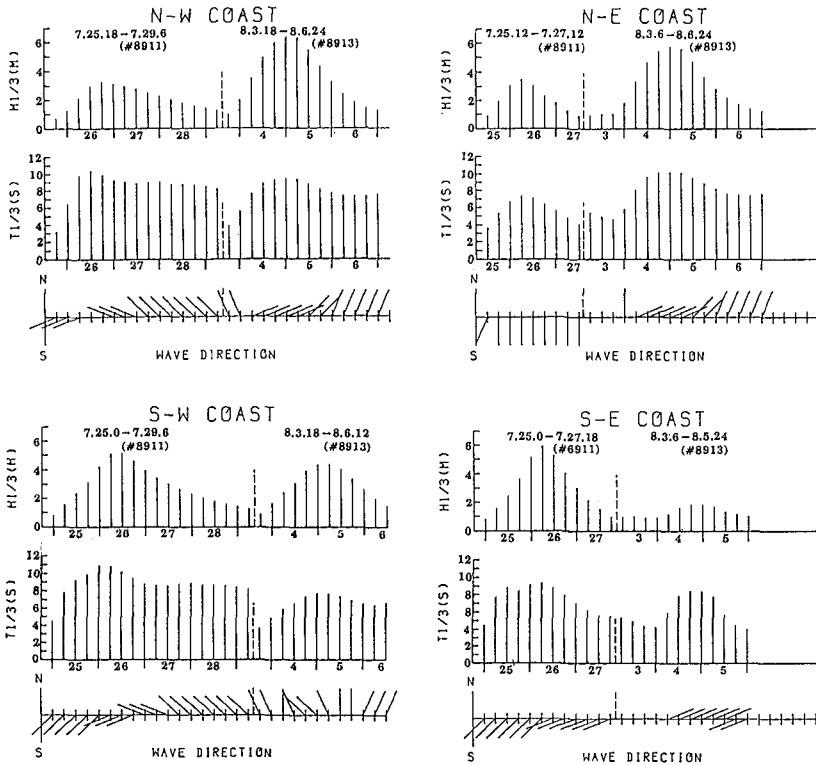

Figure 13 Time-wise variation of the predicted values of significant waves

waves generated by two typhoons. Values after successive intervals of 6 hours are shown in this figure. From this figure, the following facts can be read clearly:

- In the case of typhoon #8911, the direction of generated waves offshore of every subdivided coast at the initial stage is SW. However, it becomes WNW off the west coast, S or WSW off the east coast as the typhoon advances northward. Waves with a peak height of roughly 5.9 m appear off the in S-E coast although wave with peak height of roughly 5.1 m appears in the S-W coast. In the case of typhoon #8913, the wave direction is mainly ENE except for the case of the S-W coast at the initial stage. However, it becomes NNE except for the case of the S-E coast as typhoon advances northward. Waves with a peak height of about 6.4 m appear off the N-W coast, although waves with a peak height of roughly 5.8 m appears off the N-E coast.

Based on these offshore wave predictions, the wave transformation was calculated to determine the breaker characteristics, and

Figure 4(a) Time-wise variation of the shorelines predicted in the S-E coast

Figure 4(b) Variation of the shoreline observed in the S-E coast in the period between May 15, 1989 and Sep.9, 1989

finally the variation of the shoreline was calculated by the method stated previously. Figure 14(a) shows the time-wise variation of the shorelines predicted for the S-E coast at intervals of 24 hours. On the other hand, figure 14(b) shows the change of the corresponding shoreline determined through the mosaic maps which were made from the aerial photographs taken before and after these typhoons hit the island.

In both figures, the distance shown on the abscissa is that measured southward from the northern boundary on the S-E coast. Here, it should be noted that the predicted variation of the shorelines is based only on the two successive typhoons, although the observed variation of the shoreline is the effect of all waves (including those due to the storm waves during two typhoons) over the period from May 15, 1989 to September 6, 1989. Thus, caution should be exercised in drawing conclusions from a comparison between these two results. However, the numerical analysis clearly indicates that the northern part of the shoreline is considerably eroded by waves with SW direction generated by typhoon #8911 and is restored gradually by waves with NE direction generated by typhoon #8913. Further, the final pattern of the predicted shoreline in figure 14(a) is quite similar to that of the observed shoreline shown in figure 14(b).

Table 3 Comparison of the observed and predicted foreshore areas eroded in summer of 1989

Coasts	S(Observed)	S(Predicted)
N-E	-108,000 m <sup>2</sup>	-38,000 m <sup>2</sup>
N-W	-63,000 m <sup>2</sup>	-54,000 m <sup>2</sup>
S-E	-32,000 m <sup>2</sup>	-29,000 m <sup>2</sup>
S-W	-10,000 m <sup>2</sup>	-11,000 m <sup>2</sup>

Table 3 summarizes both predicted and observed values of foreshore variation in each subdivided coast. In the case of the N-E

coast, the predicted value of the foreshore variation is quite different from the observed value. This might be caused by the fact that both boundaries of this coast are rocky. However, the model used in this study seems to predict the variation of the foreshore area quite satisfactorily.

#### 4. Conclusions

Foreshore variations in Iwo-jima were investigated by analyzing a series of mosaic maps made from the aerial photographs which had been taken seasonally for the past 4 years since 1978. Analysis was also undertaken on the data of level and cross surveys carried out on the entire beach of the island for the past ten years since 1982. Further, numerical analysis was performed to study the short-term variation of the foreshore area due to storm waves generated by two typhoons which had hit the island in July and August, 1989. The predicted variation of the shorelines was compared with that observed in the corresponding period.

As a result, the following facts were revealed:

- (1) The island is still rising at a rate more than 30 cm/year, although the rate of upheaval increases toward the north.
- (2) The foreshore area is eroded in summer and fall when typhoons often hit the island, but is restored in winter and spring of the following year when waves of roughly 1 m high are predominant.
- (3) The seasonal variation of the foreshore area ranges from 300,000 m<sup>2</sup> to 600,000 m<sup>2</sup> per year depending on the magnitude and frequency of the typhoons hitting the island in the year.
- (4) The foreshore area continues to increase currently at a rate of roughly 50,000 m<sup>2</sup>/year, which is undoubtedly caused by the upheaval of the island.
- (5) A one-line model can be applicable for the prediction of short-term variation of the shoreline caused by storm waves.

## CHAPTER 189

### SHORE NOURISHMENT AND THE ACTIVE ZONE: A TIME SCALE DEPENDENT VIEW

Marcel J.F. Stive<sup>1</sup>, Huib J. De Vriend<sup>2</sup>, Robert J. Nicholls<sup>3</sup> and Michele Capobianco<sup>4</sup>

#### Abstract

First results towards the development of a predictive method of cross-shore spreading of beach and shore nourishments are described. Present interest in nourishment as an appropriate answer to long-term erosion motivates special attention for the time evolution of the cross-shore spreading. Hallermeier's (1981) annual shoreward boundary,  $D_p$ , of the shoal zone is probably the most applied quantitative boundary for the seaward extent of nourishments. The extension of this concept to include time-dependency is a logical and necessary step to improve our understanding of nourishment performance. Moreover, insight into the precise cross-shore variation of the spreading process is lacking.

By application of a detailed process-based, cross-shore morphodynamic model and some inductive assumptions the spreading process is studied as a function of time. The results give qualitative and quantitative indications of the spreading process, in particular concerning the evolution character of the spreading and the relation between the nourishment foot and closure depth.

#### Introduction

The seaward extent and the rate of morphodynamic activity across the active zone are of fundamental importance in designing shore nourishment (Davison et al., 1992). A valuable and useful approach to determine the seaward extent (closure depth) was developed by Hallermeier (1981), who defined it as the

<sup>3</sup> Laboratory for Coastal Research, University of Maryland, USA;

<sup>4</sup> Tecnomare S.P.A., Venezia, Italy

annual shoreward boundary of his shoal zone. Obviously, as qualitatively indicated by Hallermeier (1981), the rate of activity varies across the active zone profile. This rate will depend not only on the hydraulic impact, but also on the time scale considered. Similarly, a time scale dependence of the seaward extent of the active zone (the closure depth) can be expected. Taking 20 years of hindcast wave data at Ocean City, Maryland, and considering it on a year-to-year basis, Anders and Hansen (1990) found  $D_1$  had a mean value of about 5 m, but annual values varied from 3.7 to 7.3 m. Suggestions for the time scale dependence were made by Hands (1983) in his analysis of the Great Lakes profile responses to mean lake level variations. Insight into the time scale dependence of the closure depth and the relative activity across the active zone is of importance for more accurate prediction of nourishment behaviour and lifetime. This is particularly true in the light of the likelihood of accelerated global sea-level rise (e.g. Nicholls et al., 1992). Shore nourishment will be required to counteract the resulting shoreline recession in many parts of the world. In this context however, the coastal system is considered on longer time and space scales than has been common practice so far.

Because of the very limited field information about the cross-shore spreading of nourishments, we have chosen to initially rely on a mathematical-physical approach, using the combination of physical inductive concepts and a detailed process-based model. This approach may be termed behaviour oriented modelling. In order to analyse our results and to obtain predictive methods, we also rely on system dynamics related approaches to describe the nourishment behaviour. An example of this is the application of a diffusion-type equations to simulate in the simplest way some aspects of the observed behaviour. The coefficients of such equations are at the moment derived by using a parameter identification method with "experimental" data produced under well defined boundary and initial conditions. We plan further work to generalize our results in order to be able to handle a variation of boundary and initial conditions, and we intend to confront and verify our findings with real world data.

#### Study approach and assumptions

In order to indicate our present scale of interest we distinguish the following scales of profile behaviour (see Table 1).

As can be observed from Table 1 the time and length scales of our topic are larger than years and longer than the surfzone. This implies that we are dealing with what we would define as long term modelling: modelling on a time scale longer than can be handled by existing validated process-based (mathematical-physical) models. This, in turn, implies that we have to fall back on inductive concepts, so that we enter the field of behaviour oriented modelling (Stive et al., 1990). In practice this means that we have to adopt some

assumptions based on our physical intuition and our expectations of the process behaviour.

physical process	cross-shore length scale	approximate time scale
response to relative sea-level rise	total shoreface to inner shelf	decades to a century
spreading of structural shore nourishment	upper to middle shoreface	years to a decade
surfzone bar evolution	surfzone	storms to a year

Table 1 Time and length scales of cross-shore profile behaviour

In fact, we base some of our assumptions on the results due to an interesting application with respect to shore nourishment made by Van Alphen et al. (1990). Based on simulations with the process-based dynamic model of Roelvink and Stive (1989) the efficiency of nourishments, placed at different positions in the active zone, was systematically investigated. The simulations were run over many years with a synthesized, observed wave climate over one full year as hydraulic input. De Vriend and Roelvink (1989) were the first to conclude from the results that the spreading of the nourishments closely resembles the smoothing out of a "disturbance" on an otherwise equilibrium profile. This smoothing process shows a shoreward asymmetry: the smoothing is stronger at the shoreward side. Associated with this asymmetry, the part of these artificial disturbances tending to move onshore exceeds the part tending to move offshore. And finally, the time scale of adjustment after a disturbance increases rapidly with depth.

Stimulated by these conclusions we adopt the following approach to generate results on the spreading behaviour of nourishments. By using a synthesized or schematized wave climate as an input, pairs of profile evolutions are generated by the Roelvink and Stive model: one for an undisturbed, ideal profile (giving the "autonomous" development) and one for a disturbed, ideal profile, which is identical to the former except for the nourishment. Our basic assumption is that -until we know better- the spreading can be derived by comparing a nourished profile development with an autonomous profile development. The reasoning behind this is twofold:

(1) The autonomous profile development on the scale of years to a decade is most probably not well represented by the dynamic model, both because of

deficiencies in this model and because in reality there will be more than just cross-shore processes responsible for the profile development. So, for the time being we assume that in a practical situation, there exists in one form or other an "autonomous" profile development, which is not resolved nor affected by our approach;

(2) Because we may consider the nourishment as a profile disturbance lifting the profile away from "equilibrium" we assume that the dynamic development is more accurately computed by the dynamic model than the "equilibrium" development.

Our present, initial interest is into beach or upper shore nourishments rather than into subaqueous profile nourishments. Although we would promote the application of profile nourishment in general (Stive et al., 1991), common practice is still to feed the beach rather than the subaqueous profile.

The "ideal" profile applied as the initial profile for the calculations, which we term the Dean-Moore-Wiegel profile (DMW-profile), consists of the equilibrium profile with a grain diameter dependence in the proportionality constant (e.g. Dean, 1991). Near the waterline, however, we adopt a constant slope, related to the grain diameter and the exposure of the coast following Wiegel (1964), as follows:

$$D = Ax^{2/3} \quad \text{for } dD/dx \leq \tan\beta$$

$$D = D^* - \tan\beta(x^* - x) \quad \text{for } dD/dx > \tan\beta$$

where  $D$  is the mean still water depth,  $x$  the cross-shore distance from the virtual waterline belonging to the Dean-profile,  $\tan\beta$  the beach slope,  $A$  the proportionality constant and the parameters denoted with an asterisk are evaluated at the location where  $dD/dx = \tan\beta$ .  $D^*$  and  $x^*$  may be easily computed, but since these parameters are imposed by the Dean-profile, it is not possible to directly control the resulting DMW profile value at  $x = 0$ . In the cases presented we have chosen a grain diameter of 200  $\mu\text{m}$  (so that  $A=0.1$ ) and a corresponding beach slope for exposed beaches of 1:75.

On the resulting ideal profile we place a nourishment (i.e.; beach fill) of 100  $\text{m}^3/\text{m}$  which with a triangular shape, maximum height near the waterline and reaching from minus 2.5 m to plus 1 m, bringing the coastline some 57 m seaward. This may be considered as intermediate between a pure dry beach nourishment and a pure subaqueous nourishment. Since, in general, beach fill is spread quickly across the upper part of the profile, the present results can be considered representative for most of the commonly applied beach nourishments.

In compliance with Hallermeier (1981), we have adopted the nearshore wave climate synthesis of Thompson and Harris (1972). They provide a relatively straightforward year distribution for nearshore wave heights as a function of the yearly mean  $H_{sig}$ . Here we have assumed that this distribution may be extrapolated to reach a 10-year climate. We are aware of the fact that this assumption may not be correct. Further efforts into this are foreseen.

## Results

In our analysis of the results, we have so far concentrated on the following three questions:

- (1) How does the nourishment spread (diffusively, advectively) as a function of the process variables?
- (2) Is there a relation between the depth of closure and the "foot" of the nourishment?
- (3) How does the nourishment foot (and the depth-of-closure) evolve in time?

In the present paper we discuss results of the following calculations:

- Run 50 vs run 51, being an undisturbed DMW-profile evolution vs a nourished DMW-profile evolution subject to the same wave climate characterized by a steepness of 3% (see Figure 1);
- Run 60 vs run 61, being an undisturbed DMW-profile evolution vs a nourished DMW-profile evolution subject to the same wave climate characterized by a steepness of 1% (see Figure 2).

The principal variation between these cases is the wave steepness (all cases have a year-mean  $H_{sig}$  of 75 cm). From trial calculations it was concluded that the principal process variable is the wave steepness.

Figures 1 and 2 confirm our earlier thoughts that the beach fill spreads over the profile both diffusively and advectively. To a first approximation, the beach fill spreads like a thinning wedge with its foot going to deeper water, and with the rate of seaward propagation clearly larger for the less steep wave climate. It is interesting to note that the propagation of the nourishment foot more or less follows Hallermeier's closure depth which we have extended for the larger timescale (see Table 2). The extension of Hallermeier is simply realized by assuming that we may replace the important variable  $H_{sx}$ , the significant wave height exceeded 12 hours per year, by  $H_{sx,y}$ , the significant wave height exceeded 12 hours per y year. These results suggest that -to a first order of approximation- we may predict the spreading evolution of a nourishment by applying the suggested extension of Hallermeier for the position of the foot of the nourishment and by assuming that the nourishment volume simply decreases as a thinning wedge.

Figure 1 Cross-shore spreading of a triangular beach fill for a low steepness wave climate (SWL at 4000 m)

### Simulation of the observed behaviour

It is one of our objectives to generalize and parameterize the spreading process, both for the purpose of practical applications and scientific understanding. In the context of practical applications it is important to note that the presented computational results require relative high computation times, e.g. a 10 year simulation with a time step of one day on a 33 MHz 386 with coprocessor at 5 MIPS takes 12 hours. Our parameterization method follows the idea to identify space varying parameters in a diffusion-type equation.

In fact, we consider a class of behaviour models, basically proposed by De Vriend and Roelvink (1988) which shows a close similarity to the n-line concept (Perlin and Dean, 1983; De Vroeg et al., 1988). In general terms (e.g. Capobianco, 1992) we consider the following type of diffusion equation for the profile elevation  $z(x,t)$ :

$$\partial z / \partial t = \partial / \partial x [F(x) \partial z / \partial x] + \partial / \partial x [V(x)z] + S(t,x,z)$$

where  $F(x)$  represents partly the diffusion character and partly an advective character,  $V(x)$  the advective character and  $S(t,x,z)$  is a source function. With appropriate initial and boundary conditions the *profile elevation*  $z(x)$  can be described as a function of *cross-shore position*.

The same basic equation may be applied to describe the evolution of the

The same basic equation may be applied to describe the evolution of the *cross-shore position*  $x(z)$  as a function of the *profile elevation*, or the actual cross-shore position  $x(z)-x_e(z)$  referred to an "equilibrium profile position", or the actual cross-shore position  $x(z)-x_a(z)$  referred to an "autonomous profile position".

The vertical variation of the diffusion coefficient allows us to represent a variation of the morphological timescale with the vertical position, and an asymmetry in the longterm residual sand displacement across the profile. The calibration of this parameter is the key element of the model definition: all information, on hydraulic and sediment characteristics as well as on shorter-term dynamics is stored in it. One objective of our study is to assess -in the context of shore nourishment behaviour- whether and to what extent the diffusion model concept stands in practice, and to find simple and manageable parameterized expressions for the diffusion coefficient  $F$  as a function of boundary conditions, geometrical features and environmental parameters.

### Conclusions

The longer term objective of our study is to arrive at a predictive method to establish the cross-shore spreading of beach and shore nourishments. The present interest of coastal authorities in nourishment as an appropriate answer to long-term erosion, particularly in the light of an acceleration of sea-level rise, is our motivation to approach the problem with special interest in the time evolution of the cross-shore spreading. The currently most applied quantitative boundary for the seaward extension of nourishments is probably the annual shoreward boundary,  $D_1$ , of the shoal zone as developed by Hallermeier (1981). The extension of this concept to include time-dependency is a logical and necessary step in improving beach nourishment techniques. Moreover, insight into the more precise cross-shore variation of the spreading process is of great practical importance.

By application of a detailed process-based, cross-shore morphodynamic model and some inductive assumptions the spreading process is studied as a function of time. The results give qualitative and quantitative indications of the spreading process, in particular concerning the evolution character of the spreading and the relation between the nourishment foot and closure depth. We have extended Hallermeier's concept to longer time scales. This extension is simply realized by assuming that we may replace the important variable  $H_{sx}$ , the significant wave height exceeded 12 hours per year, by  $H_{sx,y}$ , the significant wave height exceeded 12 hours per  $y$  year. The propagation of the nourishment foot follows the time-dependent  $D_{1,ext}$  quite closely in both examples. Thus, our results suggest that -to a first order of approximation- we may predict the spreading evolution of a nourishment by applying the suggested extension of Hallermeier

for the position of the foot of the nourishment and by assuming that the nourishment volume simply decreases as a thinning wedge.

## CHAPTER 190

# METHOD FOR ARTIFICIAL BEACH NOURISHMENT

Henk Jan Verhagen<sup>1</sup>

### Why beach nourishment

For a good design, the purpose of the nourishment has to be clearly defined. In general, there are three reasons for beach nourishment:

1. combatting coastal erosion (chronic erosion)
2. preventing flooding (safety)
3. maintaining a wide recreational beach.

In the Netherlands a political decision has been made to maintain the coastline of 1990. Also, the required funds are available to do so. Thus the main purpose of nourishment in the Netherlands is to combat chronic erosion.

### Available tools

For the design, several tools are available. In general one can distinguish three kinds of tools:

1. mathematical models
2. field observations
3. physical models

Physical models are not recommended for the design of beach nourishment. This is because the process of beach change is caused primarily by irregularities in wave conditions. It is very difficult to accurately model this in a scale model. Mathematical models seem to overcome this problem but in fact they only change the problem. To use these models one needs good input data (waves, etc) and good calibration methods. In order to get them, one needs many years' measurements.

Because of the highly irregular wave climate, the predictive value of mathematical models in the Netherlands is rather low. Mathematical models are therefore used mainly for understanding coastal behaviour and comparing alternatives, and not for the quantitative design of artificial beach nourishment. A more direct design method has proved to be more effective.

When beach data (measured profiles) are used, one does not have the problem of defining a good wave climate or other boundary conditions. They are automatically correct. The main problem is that for a good statistical analysis, one needs much data. Consequently one needs a number of years' measurements. This kind of information is abundant for the Dutch coast.

---

### The Dutch Design Method

Beach nourishment in the Netherlands is designed in an extremely simple way. Experience has shown that this is a very reliable method. The method is very trustworthy, if applicable.

- step 1: Perform coastal measurements (for at least 10 years).
- step 2: Calculate the "loss of sand" in  $\text{m}^3/\text{year}$  per coastal section.
- step 3: Add 40 % loss.
- step 4: Multiply this quantity with a convenient lifetime (for example five years).
- step 5: Put this quantity somewhere on the beach between the low-water-minus-1-meter line and the dune foot.

This method is simple and straightforward. It does not require mathematical models, but good quality profile measurements are absolutely necessary.

### Problems

Of course, there are also problems with the Dutch Design Method. There is one very important general assumption:

*The beach nourishment has no influence on the long-term natural behaviour of the coast. Or, in other words, the erosion rate before nourishment equals the erosion rate after nourishment.*

This general assumption is true in The Netherlands when beach nourishment is relatively long and the seaward displacement of the water line because of the nourishment is not too great. In The Netherlands the ratio between length of a nourishment (L) and seaward movement of the water line (width of the nourishment, w), L/w, is in the order of 20 - 40. Of course, one should realise that the Dutch coast is a coast with a tidal difference of 2 - 4 meters, a tidal current along the coastline and an almost perpendicular wave attack. Provided the L/w ratio is in the order of 20 or more, this assumption is valid in most areas of the world.

The erosion rate has to be calculated as a volume per unit of time (e.g.  $\text{m}^3/\text{year}$  per m of coastline) In cases where no profile data are available, one may also use the retreat of the high-waterline, but then one implicitly assumes that also the coastal profile is constant in time. That is usually not so. Apart from that the variation in the measured data is also significantly more if one uses coastline retreat instead of volume retreat.

So in fact the first step is to measure the coastal profile for a number of years, and calculate the volume in the profile (see fig. 1). Important is to define good boundaries. The landward boundary has to be placed far enough landward that erosion (also storm-erosion) will "never" pass this boundary. "Never" has to be interpreted as: possible not in the observation period and extrapolation period. The offshore boundary has to be far enough into the sea, that no significant onshore/offshore transports take place over this boundary during normal situations. In any case one should try to place this boundary seaward of possible breaker-bars.

**Figure 1:** control profile

It is usually a problem to match the terrestrial levelling of the beach with the offshore soundings. In case of a big tidal difference this is no problem. The soundings (during H.W.) may overlap the levellings (during L.W.). In case of a smaller tidal difference this might become a problem. In such a situation nearshore sounding with the use of a Hoovercraft may solve the problem.

The next step is plotting the volume data as a function of time (see fig. 2a). Through the data in this figure one may draw a regression line. Usually a linear trend can be assumed, especially when the regression-period is in the order of ten years. This period is recommended for this type of analysis. In very special cases non-linear regression has to be applied. The slope of the regression-line indicates the erosion-rate, e.g.  $Q_m$  ( $m^3/year$ ).

As next step a nice lifetime for a nourishment is selected, for example 5 years. One may select any figure, and optimize this later on. Experience however, has shown that such an optimization usually is completely overrun by non-technical issues, like available budget, available sand, execution schemes, etc. We call this lifetime  $T$ .

The volume to be nourished is thus  $V_N = Q_m * T$  ( $m^3$ ). (see fig. 2b).

However "losses" in longshore direction are not considered. These "losses" occur, because the nourishment has always a limited length. Also there is a wash-out of finer particles (the grain-size distribution of the nourished sand is new equal to the original beach sand).

Figure 2: principle of beach nourishment design

Because the beach is somewhat further into the sea, the wave-attack is heavier, and, last-but-not-least their might be a profile adaptation outside our control volume. This last effect becomes less when we place our seaward boundary farther in a seaward direction.

For all these losses we should add something. A first estimate of this surcharge is 40%. This percentage is covering all type of losses (see fig.2c). This percentage can be fine-tuned by using measured data from the evaluation of previous nourishments in the region. We found in the Netherlands that we usually could use a somewhat lower percentage.

As an example the beach nourishment of Texel is presented [Rakhorst, 1989]. The quantity of the nourishments was determined, using linear regression, see fig. 3. As can be seen the yearly erosion-rate increased somewhat after was started with the nourishment schemes. However this change is negligible on the total quantities to be nourished. In this case the surcharge is very small (due to a wide control profile, long nourishment, correct sand).

Texel, km 25-31  
acc. Rakhorst 1989

Figure 3: Coastal volumes at Texel

An other example can be found in the nourishments on Westerland, Sylt (Führböter, 1991, and Führböter & Dette, 1992). See figure 4. One can see clearly that, after a short adaption period, the regression before nourishment. The surcharges, however, vary very much. Also they are quite big. This is mainly caused by the fact that the control volume, is only measured to the MSL-1m line, which is approx, the Low Water Line. This underlines the necessity to make the control volume wide enough.

Figure 4: Coastal volumes at Sylt (Westerland)

Westerland [Sylt]  
acc. Führböter 1991

The erosion can be described using :

$$V_t = k_2 e^{k_1 t} + Q_m \cdot t$$

The paper of Dette and Führböter describes a mathematical method to optimize the term  $K_2 \exp(k_1 t)$  in this equation. For practical reasons we do not try to optimize this in the Netherlands, because practice has learned that the effect of other aspects (available budget, time planning, etc.) have a much bigger impact than optimization of this term. Also the fact that using a wider control volume decreases the magnitude of this surcharge is a reason not to focus too much on this point.

The data from Westerland are very interesting when they are plotted in a slightly different way. In fig. 5 the same data are plotted, but now on the vertical axis the deviation from the linear trend is plotted. So in fact only the  $k_2 \exp(k_1 t)$  - part is plotted. The exponential functions can be observed very clear in the 1978 and 1984 nourishments.

Figure 5: Volume difference from linear trend (Sylt)

Westerland [Sylt]  
acc. Fuhrboter 1991

In autumn 1973 there was a big storm on this coast. Due to this storm much sand eroded from the higher part of the beach and was deposited below the low-water line. Because this deposition was outside the control-volume, it is indicated as a loss. In the calm period after the storm this sand was transported back. The erosion-line comes back to the expected e-power-line. When a wider control volume had been used, one could probably not find this storm in the record. This shows very clear that individual storms like the autumn 1973-storm, not really contribute to the slow and chronic erosion of a beach. Storms do not cause extra erosion to nourished beaches.

Of course, the design-procedure described above is not very exact. One run the risk of making two types of "design errors".

**"design error 1"**

The yearly erosion was not determined correctly, like in the Texel case. See figure 6. Because the real erosion (= slope of regression line) is more than anticipated, the life-time of the nourishment is also shorter than anticipated. So next time one has to nourish somewhat more sand, or define the life-time somewhat shorter (if one wants to use the same nourishment volume)

However one has also to conclude that every grain of the first nourishment has done his job. Only we expected too much. So every dollar invested in the nourishment was invested very well. Therefore one has to conclude that this "design error" does not lead to financial problems.

Figure 6: Design error type 1

Design error type 1:  $Q_m$  was not determined correctly

**"design error 2"**

The yearly erosion trend is determined correct, but the surcharge was somewhat too small, see figure 7. This also leads to a shorter lifetime than anticipated, and next time the design can be easily adapted by using the correct surcharge percentage. But also in this case one has to conclude that all nourished sand worked very well, and that one can not speak of a bad investment. This "design error" too does not have considerable financial consequences.

From the above one has to conclude that artificial beach nourishment has, from a financial point of view, a very big advantage. It is in fact an investment on which one has hardly any risk. Every grain of nourished sand is effective. Artificial Beach Nourishment may prove to be somewhat cheaper or more expensive than anticipated,

Design error type 2: surcharge (40%) was not determined correctly

Figure 7: Design error type 2

but what has been invested is not lost.

### Placing the sand

From a morphological point of view there is not much preference where the sand is placed in the beach profile (provided it is between the breakerline and dune-foot or swash-line). Placement outside the breakerzone might be attractive in some cases, but that is outside the scope of this paper.

The first minor storm after the placement of the nourishment will adapt the profile to the natural profile. And nature can do this much better than bulldozers and scrapers.

Experience in the Netherlands has indicated that so-called profile nourishment (i.e. try to make a natural stable profile) does not have any influence on the erosion-rate. It was only found that at very steep, relatively fast eroding beaches, a high placement lasted somewhat longer, because the profile could not adapt quickly enough to the erosion. In fact, because of high nourishment the profile was constantly too steep, and the next nourishment was due before the profile could adapt.

From an economic point of view a placement just above H.W is preferably. Usually dumping from split-barges in the breakerzone can not be realized, and one has to pump the sand ashore. The cheapest way is placing the discharge pipes just

out of the reach of the waves, which implies a nourishment-level just above H.W. The seaward slope is formed by the free flowing sand. No bunds are used.

The consequence of this method is that one has just after the nourishment a beautiful, wide, high and dry beach, but with a seaward slope which is too steep to survive the stormy season. So, the first storm in autumn will rework the profile until it reaches its natural shape, and much sand is transported from the H.W.-line to just below L.W. From a morphological point of view this is absolutely no erosion. In general the public has a different opinion. They see only the dry beach, and they see that it "disappears" after a minor storm. So they regard the nourishment as a failure.

Because of this psychological reason (for funding nourishments one needs public support) it is wise to make the shape of a nourished beach in such a way that the changes in autumn are not too big. In this way one will have more public support for nourishments.

### **The beach profile**

It is very difficult to design the new beach profile. A very good assumption is that the profile after the nourishment will eventually be the same as before the nourishment, provided the same type of sediment has been used.

Nature will form that profile. Therefore it does not matter very much where the sand is placed in the profile. After one or two small storms the complete profile is reworked by nature and the natural (stable) profile is formed. From this one may conclude that one should dump the sand where dumping is the cheapest, as long as it is landward of the breaker line.

In The Netherlands, the cheapest way is placing the sand on the beach, preferably on the higher section. All discharge pipes can be placed out of reach of the waves, and after the nourishment a beautiful, wide beach is formed. However, because the slope just under the low water line is too steep, the first storm in autumn transports sand from the beach towards the underwater shore. From a morphological point of view, this is no problem. From an economical point of view, this is the optimal solution. A number of nourishment projects in the Netherlands have been designed in this way.

However, from a political point of view this is not a good solution. The public has a beautiful beach in the summer, directly after the nourishment. But in autumn, during a minor storm, the public observes that the beach largely disappears. They do not observe that the sand is deposited just below the low water line. The public draws the incorrect conclusion that the nourishment was not successful at all. The wide beach has disappeared.

Because beach nourishment is generally paid for by a public authority, public opinion is important in acquiring sufficient funds. Therefore it is wise to design beach nourishment in such a way that the public sees that the beach is somewhat wider after the nourishment, but that there is no major adaptation in the beach shape during the first storms in autumn. If the purpose of the nourishment is to make a wide recreational beach, this is very important. If the purpose is to prevent flooding,

the best place is as high as possible on the beach. If the purpose is to combat chronic erosion, the best place is in the breaker zone.

### **Sediment size**

The size of the sediment is important. If the sediment is finer than the original material, the equilibrium slope will be more gentle. Some researchers also assume that finer material causes bigger losses. However it is not clear whether these bigger losses are caused by the more gentle beach profile or whether they are a real loss.

In order to get an impression of the effect of the grain size on the beach slope, one may use a general diagram as made by Dalrymple and Thompson [1976]. However, many beaches have slopes of 1:50 or less, and they are not in this diagram. Also the scatter of the data is too wide for practical application.

It is therefore recommended to start from the existing beach slope and use scale relations to derive the change in beach slope. These scale-relations have been developed by Vellinga [1982] and used for calculating the overfill ratio by Pilarczyk, Van Overeem and Bakker [1986]. The formula to be used is  $(l1/l2) = (w1/w2)^{0.56}$ . In this formula  $l$  is a characteristic length and  $w$  is the fall velocity of the beach material.

Suppose the volume to be nourished per meter of coastline is 500 m<sup>3</sup>, and the nourishment height is 5 m. The used sand is 250 micron instead of the original 275 micron. When the original slope was 1:75, the new slope will be 1:80. Because of the more gentle slope an extra volume of  $\frac{1}{2} \times 5 \times 5 \times (80-75) = 60 \text{ m}^3$  is necessary. This is an overfill of 12 %.

If one applies the technique of James, as presented in the US Shore Protection Manual, which is based upon the sorting out of fine particles, in this example one finds a overfill ratio of 20 %. Experience in Holland shows that the SPM method gives relatively high overfill ratios. Also it is expected that the mechanism of sorting out is not the governing mechanism, but only the fact that a more gentle slope will occur.

However, detailed research in this field, based upon a good set of prototype data is not available at this moment.

### **Conclusion**

From the above one can conclude that the presented design method for artificial beach nourishment is simple, straight forward and very reliable. No advanced models are required. The disadvantage is that beach profile data have to be available. Because of this, it is always good to have a good beach monitoring programme (profile measurements to be made once a year, at fixed profiles).

In the Netherlands all nourishment have in fact been designed using this method, except one. That nourishment was for an artificial peninsula, where (of course) no beach data were available. In that case mathematical models were used.

Directly after the nourishment, the shape of the beach is not optimal. Nature will adapt the shape of the nourishment. Also, because the nourishment protrudes into the sea, the current attack will be more. So, some extra loss has to be expected. It is

difficult to calculate this loss exactly. Our experience shows that an extra surcharge of 40 % on the designed quantity covers all losses, also the loss because of the extra current attack. A more mathematical approach to determining this loss is presented by Führböter [1991], although his assumption that an initial loss rate is proportional to the volume of sand available on the beach might not always be true.

## CHAPTER 191

### FIELD INVESTIGATION AT A MOUTH OF SMALL RIVER

Hitoshi Tanaka<sup>1</sup> and Nobuo Shuto<sup>2</sup>

#### Abstract

Field measurements have been carried out at the mouth of the Nanakita River in Japan. The maximum velocity at the throat section was kept constant, 1 m/sec, although the river mouth topography changed much rapidly in a week. It therefore seems that the equilibrium condition at the river mouth can be expressed in terms of the maximum velocity. The wave set-up height measured in the river mouth was also analyzed and was found to be responsible for the intrusion of sand into the mouth.

#### 1. Introduction

Up to now, a great number of field observation have been carried out at river mouths to understand a dynamic process of sand movement due to combined effect of wave motion, river flow and tidal current. Many of these field measurements are, however, restricted to relatively large rivers ( e.g. Ogawa, Fujita and Shuto (1984), Sawamoto and Shuto (1988) ), since they are of considerable importance from a view point of hydraulic engineering. The process of topography change at a mouth is greatly dependent on the dimensions of the river. It is therefore difficult to generalize the observed results at different river mouths with different dimensions.

1 Associate Professor, Water Resources Engineering Division, Asian Institute of Technology, G.P.O. Box 2754, Bangkok 10501, Thailand.

2 Professor, Disaster Control Research Center, Tohoku University, Aoba, Sendai 980, Japan.

We initiated a field study in 1988 at the mouth of the Nanakita River, a typical small river in Japan, to find an appropriate countermeasure against the closure of the mouth. Some interesting features are observed which are distinctly different from those seen at big rivers.

## 2. Study Area

The Nanakita River mouth is located on the Pacific Ocean coast as shown in Fig.1. The catchment area of the river is 229km<sup>2</sup> and the river length is 45km. During rainy season, the tidal discharge and the fresh water discharge are of the same magnitude except for the very short period of big floods induced by typhoon or low pressure. The river discharge during winter season becomes negligibly small as compared with the tidal discharge. Thus, a complete closure of the mouth takes place rather frequently ( Tanaka and Shuto (1991) ).

The Teizan Canal 9km long connects the Nanakita River mouth with another river mouth, the Natori River mouth. The lock gates, located at the joint with the Nanakita River, are kept partially open. Accordingly, a part of discharge of one river might flow to the other if there is a difference in water level between the two rivers.

The planform of the river mouth topography and the shape of the narrowest cross-section have been measured every two weeks since 1988. The water level variation has also been measured by means of automatic water level gauges which are installed at Stations A, B and C in Fig.1. The velocities at the mouth and in the Teizan Canal were continuously measured for 25 hours at the consecutive spring and neap tides on August 20 to 21 and 27 to 28, 1990, using propeller-type currentmeters.

## 3.Results and Discussions

### 3.1 Change of Cross-Sectional Area and Velocity In A Week

Figure 2 shows the change of the planform of the river mouth topography and the narrowest cross-section in a week. The sand spits on both sides intruded into the mouth due to wave action and, subsequently, the narrowest section shifted upstream. Distinct decrease of the cross-sectional area also took place within one week.

The time-variations of the water levels during the first observation are shown in Fig.3(a). It is noted that the water level in the river mouth was almost always

Fig.1 Map of the river mouth.

Fig.2 Change of plan topography and cross section in a week.

Fig.3(a) Time-variation of water levels.  
(August 20-21, 1990)

Fig.3(b) Time-variation of velocities.  
(August 20-21, 1990)

higher than that in the sea, while the water elevation measured in the Natori river mouth was almost identical with the sea water level. Such a difference is due to the fact that, at the Natori River mouth, where two jetties have been already constructed, the water depth at the mouth was deep enough to prevent wave motion from breaking, while at the Nanakita River, waves broke in front of the mouth, resulted in the water level rise, that is, the wave set-up.

The corresponding variation of the velocities measured at the Nanakita River mouth and in the Teizan Canal are shown in Fig.3(b). The positive velocities denote the flow into the river from the sea through the mouth or through the Teizan canal. The velocity along the Teizan Canal was always negative, which shows the flow direction in the canal was from the Nanakita to the Natori river due to the difference of water level explained above.

The observed results during the second measurement are shown in Fig.4. The water level rise is smaller than the 1st observation due to the difference of the significant wave height; during the 1st observation, the significant wave height,  $H_{1/3}$ , was 1.4m, while during the second observation,  $H_{1/3}=0.9m$ .

According to Figs.3(b) and 4(b), the maximum current velocity at the mouth was kept 1m/s by tidal and river flows, although the cross-sectional area was rapidly narrowed by waves within one week. This result suggests that the dynamic equilibrium condition of the cross-section at the Nanakita River mouth can be expressed in terms of the maximum velocity. Similar result has already been reported by Bruun (1978).

The solid lines in Figs.3 and 4 show the calculated water levels and velocities obtained using a one-dimensional model which is commonly applied in the analysis of sea-inlet-bay system ( e.g. see Bruun (1978) ). The governing equations are as follows.

Equation of motion:

$$\eta_o - \eta_R = \frac{L_c}{g} \frac{du}{dt} + (K_{en} + K_{ex} + K_{cu} + \frac{2gn^2 L_c}{R^{4/3}}) \frac{|u|u}{2g} \dots\dots\dots(1)$$

Equation of continuity:

$$u = \frac{1}{A_c} ( A_R \frac{d\eta_R}{dt} - Q_R ) \dots\dots\dots(2)$$

where  $\eta_o$  the ocean elevation,  $\eta_R$  the water level in the river mouth,  $L_c$  the length of the channel,  $u$  the velocity at the river mouth,  $K_{en}$ ,  $K_{ex}$ ,  $K_{cu}$  the coefficients of entry loss, exit loss and bend loss, respectively,  $n$  the Manning's friction coefficient,  $R$  the hydraulic radius,  $A_c$  the area of the cross-section at the river mouth,  $A_R$

Fig.4(a) Time-variation of water levels.  
(August 27-28, 1990)

Fig.4(b) Time-variation of velocities.  
(August 27-28, 1990)

the surface area of the river under the influence of tidal variation, and  $Q_R$  the fresh water discharge. The equations for the Nanakita River mouth and those for the Teizan Canal are solved simultaneously using the Runge-Kutter method. In the calculation of the latter, the energy loss due to the lock gates are considered, referring to a diagram proposed by Chow (1959). The effect of the wave set-up height at the Nanakita River mouth is also included in the numerical analysis, assuming that the sea level rise was 10% of the deep water wave height ( see Fig.6 ). The unidirectional current in the Teizan Canal as well as the oscillatory current at the river mouth is predicted very well through the numerical model.

### 3.2 Wave Set-Up in the River Mouth

As seen in the previous section, the wave set-up is remarkable in the Nanakita river mouth. Although the same phenomenon might be observed at a mouth of rivers with similar or smaller dimensions, field studies on the wave set-up at a river mouth have been very few. This is partly due to the fact that most of the field measurement up to the present have been made at big rivers which are of practical importance. At these rivers, the water depth is so large that no wave breaking takes place, consequently, no wave set-up at the river mouth.

At the Nanakita river mouth, wave set-up has great influence on the flow field near the river mouth and must be responsible for the topography change at the mouth. Thus, analysis of wave set-up height is carried out in this section. The set-up height,  $\bar{\eta}$ , can be calculated by taking difference of the water levels at the Nanakita river mouth and the Sendai port, since the water level measured at the latter station was free from the effect of wave breaking as seen in Fig.5. Furthermore, the water level rise induced by other forces such as wind and low pressure must be included equally in both records, because the distance between these stations is only 2km.

Figure 5 shows the water level variations at St.A in the Sendai port, St.B in the Nanakita river mouth and St.C in the Natori river mouth, measured on the day when the maximum set-up height of 66cm was observed at the Nanakita River mouth. As mentioned above, the Natori River mouth is protected by two jetties to keep the cross-section large, while the Sendai port is protected by a breakwater of 2 km long as shown in Fig.1. That is the reason why the water level at St.C was almost identical with the sea level at St.A and was lower than the water elevation measured in the Nanakita River mouth.

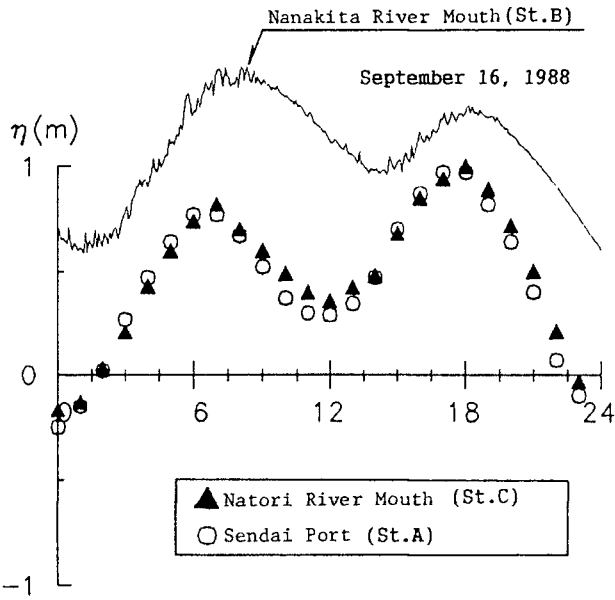

Fig.5 Water level variation (September 16, 1988).

Fig.6 Relationship between wave set-up height and steepness of deep water wave.

Figure 6 shows a correlation between the dimensionless set-up height,  $\bar{\eta}/H_0$ , and the steepness of deep water wave,  $H_0/L_0$ , where  $H_0$  and  $L_0$  are the wave height and the length of deep water waves, respectively. Theoretical curves according to the Goda's theory (1985) are also shown in the figure. Yanagishima and Kato (1990) measured the wave set-up height on the Kajima Coast in Japan and reported that the Goda's theory showed good agreement with their measurement. According to the present measurement, however, the observed data are consistently less than the predicted values by the theory. Possible reasons for this discrepancy are: (i) the wave set-up in front of the river mouth was not two-dimensional phenomenon due to the distorted bottom topography near the river mouth, and (ii) the sea water could intrude into the river mouth when the water elevation in the river mouth was lower than the sea level in the surf zone.

### 3.3 Influence of The Teizan Canal on The River Mouth Topography

At the Nanakita River mouth, the tidal discharge is very important factor to keep the mouth open ( Tanaka and Shuto (1989) ). Generally speaking, the magnitude of the flow induced by flood and ebb tides at a river mouth is of the same order, as the tidal discharge changes sinusoidally. At the Nanakita River mouth, however, the ebb tide flow is of smaller magnitude, because of the southward flow into the Teizan Canal as seen in Figs.3 and 4. This means that the tidal flow is effective to transport sand into the mouth rather than flushing sand out of the mouth.

Photo 1 was taken on February 1st, 1991, when the daily averaged fresh water discharge was  $3.7\text{m}^3/\text{sec}$ , while the tidal discharge was  $7.5\text{m}^3/\text{sec}$ . Sand deposition which is commonly designated "bay shoal" ( Bruun (1978) ) is observed in the river mouth. Dotted lines in the photograph show an upstream edge of the shoals. Such a topography is seemed to be induced by predominant current into the river mouth during the flood tide.

In order to make a quantitative estimation of the effect of the Teizan Canal, the one-dimensional analysis is carried out using Eqs.(1) and (2) under the following three conditions ( see Fig.7 ): (i) assuming that the lock gates at the joint with the Nanakita River are completely open, (ii) the lock gates are kept partially open as the present state, and (iii) the gates are closed completely to prevent the southward flow into the canal. Calculation is carried out for the days in August, 1990,

Photo 1 Aerial photograph on January 1, 1991.

when the field observations were continuously made for 25 hours.

The gross volume of water entering or exiting through the mouth and the Teizan Canal is calculated for each flood and ebb tides and is summarized in Table 1, in which the ratio of each volume to the corresponding value in Case 2 is also shown in brackets. The unit of the tabulated value is  $10^3\text{m}^3$  and the positive value shows volume of water entering into the Nanakita river through the mouth or the canal. It is seen that the flow in the Teizan Canal is always negative in Cases 1 and 2 due to the wave set-up effect. In Case 1, the discharge into the Teizan Canal will consistently increase during both flood and ebb tides as compared with Case 2, due to the enlarged cross-sectional area of the Teizan Canal. At the river mouth, the volume during the ebb tide will decrease, while that during the flood tide will increase. Thus, the entering flow into the mouth will become more predominant in Case 1. On the other hand, in Case 3, the reduction rate of the flood tide discharge will attain to 20%, while the ebb tide flow will increase by 16% at its maximum. Therefore, it can be concluded that, by closing the gates, the intrusion of sand into the Nanakita River Mouth during the flood tide will be reduced, resulting in the improvement of the river mouth closure.

#### 4. Conclusions

The principal results of the present study are as follows:

- (1) The water level at the Nanakita River mouth was higher than that in the Natori River mouth due to the wave set-up, resulting in a unidirectional flow along the Teizan Canal to the Natori River. This indicates that the tidal flow during the flood tide is effective to transport sand into the river mouth rather than flashing sand out of the mouth. Shoals in the mouth are seemed to be formed due to such a predominant flow into the mouth.
- (2) The cross-sectional area of the narrowest section at the Nanakita river mouth decreased remarkably in a week, while the maximum of the velocity at the throat section was kept constant, 1m/sec. This result suggests that the equilibrium condition at the river mouth can be expressed in terms of the maximum velocity at the narrowest section. The time-variations of water level and the velocity are successfully reproduced by a one-dimensional analysis.
- (3) Wave set-up height measured in the river mouth attained to 10-20% of the deep water wave height, slightly lower than Goga's theory.
- (4) Numerical simulation indicates that, by closing the lock gates at the joint with the Teizan Canal, sand intrusion due to tidal current into the mouth will be reduced. However, further investigation should be made to evaluate the role of the Teizan Canal not only from engineering view point but also from an environmental and ecological view points.

#### 5. Acknowledgements

The authors would like to express their grateful thanks to the members of the River Hydraulic Engineering Laboratory, Tohoku University, for their cooperation during the field observations. The appreciation is extended to the Sendai Office, Ministry of Construction, the Shiogama Office, Ministry of Transport, and the Higashi Sendai Office, Miyagi Prefecture, for their kind supply of the valuable field data. A part of this study was financially supported by a Grant-in-Aid for Scientific Research, Ministry of Education, Science and Culture ( No.01550396 ).

## CHAPTER 192

### ENTRAINMENT AND TRANSPORT OF FINE SAND BY COMBINED WAVES AND CURRENT: AN EXPERIMENTAL STUDY

by  
C. VILLARET and B. LATTEUX<sup>1</sup>

#### Abstract

Experiments have been performed in a large wave flume in order to measure sediment transport rate of fine sand under combined regular waves and current. Instantaneous velocities and concentrations are measured using ultrasonic velocimeters and optical turbidity probes. Suspended transport rates, as obtained from vertical integration of measured fluxes, are decomposed into a mean current and an oscillatory wave components. Under waves only, the wave contribution is in the direction of wave propagation. Under combined waves and current, the wave contribution is found to systematically oppose the direction of superimposed mean current.

#### 1. Introduction

From previous observations, it is well established that sediment transport is enhanced under combined waves and current, due to the stirring action of waves and advection by mean current. However, the relative contribution of both wave and mean motions to suspended sediment transport is a non-linear process which is still poorly understood (e.g Van Rijn, 1991).

Instantaneous values of velocity  $u$  and concentration  $c$  are classically decomposed into a mean component, time-averaged over the wave period ( $\langle x(t) \rangle = X$ ), and a phase-averaged oscillatory components  $x_w$ :

$$\begin{aligned}u(z,t) &= U(z) + u_w(z,t) + u'(z,t) \\c(z,t) &= C(z) + c_w(z,t) + c'(z,t)\end{aligned}$$

Assuming turbulent fluxes to be small, the time-averaged sediment flux can be written:

$$\langle u(z,t) c(z,t) \rangle = \langle u_w(z,t) c_w(z,t) \rangle + U(z)C(z) \quad (1)$$

Suspended sediment transport rates, as obtained by depth-integration of equation (1), are then decomposed into a mean current and an oscillatory wave contributions.

---

<sup>1</sup>EDF, Laboratoire National d'Hydraulique, 6 quai Watier, 78400 Chatou, FRANCE

The mean current contribution represents advection of mean concentration by the superimposed mean current or by the second-order eulerian drift induced by the wave motion (Longuet-Higgins, 1953). Under combined waves and current, eddy viscosity models have been used successfully to reproduce mean velocity and mean concentration profiles, assuming enhanced turbulence within the wave boundary layer (e.g. Grant and Madsen (1979)).

The contribution of oscillatory wave motion to suspended transport rates is produced by the asymmetry of the phase-averaged velocity forcing and concentration response. Davies (1990) numerical simulations have shown that the time lag between maximum velocities and bottom concentration peaks is an important parameter which determines the wave contribution effect to suspended sediment transport.

The principal objective of the following series of experiments is to obtain direct estimates of sediment fluxes from instantaneous velocity and concentration measurements under combined waves and current. Part 2 is a description of experimental set-up, measuring apparatus and test conditions. Measurements of mean concentration and mean velocity profiles are presented in Part 3. The effect of wave contributions to suspended transport rates is discussed in Part 4. Results of near bottom phase-averaged concentrations and diffusion of concentration peaks away from the bottom are presented in Part 5. Part 6 is a discussion of results and conclusions.

## 2. Experimental Set-Up

Experiments were carried out in a large wave flume (1.50m x 1.50m x 79m) which is equipped with a piston type wave maker. The flow is circulated through a pumping system which can generate a current in both directions. The 20 m long test section is made of a 40 cm high surelevated bottom. A 10 cm thick erodible sand bed is placed above the bottom. Two 10 m long sand traps are located on each side of the test section. The measuring section is situated in the middle of the platform as shown on Figure 1.

An optical turbidity probe (OPCON) is used to measure instantaneous concentrations. Instantaneous velocities are measured at the same elevation using 1-D ultrasonic velocimeter. The two probes are located about 15 cm apart in the same cross section and oriented at 45° from the flow direction in order to minimize disturbances of the flow field. Measurements are repeated at different elevations down to a few mm from ripple crests with at least 8 points in the near bottom 10 cm. Measurements are taken at two different lateral positions in the measuring cross section ( $y=\pm 25$  cm), in order to check the spatial variability of the signal. Instantaneous velocity and concentration measurements are phase-averaged over at least 50 wave periods in order to estimate both mean and periodic components.

Bed elevations are recorded every 4.5 mm using an electromagnetic bed profiler along three longitudinal sections ( $y=0, \pm 25$  cm) above both platform and sand traps. Measurements are made before and after each test, in order to estimate total sand volume per channel width ( $L \Delta z_b$ ) passing through the measuring section. Total transport rates in dry weight,  $Q_t$ , is given by:

$$Q_t = \frac{L \Delta z_b (1-n) \rho_s}{\Delta t} \quad (2)$$

where  $n$  is the sediment bed porosity ( $n=0.4$ ),  $\rho_s$ , the sediment density ( $\rho_s = 2.65 \text{ g/cm}^3$ ) and  $\Delta t$ , the duration of experiment. Mean bed level measurements  $z_b$  need to be corrected for small variations in the reference elevation in order to satisfy mass conservation. Test duration  $\Delta t$  must be less than one hour in order to minimize bed level variation during experiment due to erosion or deposition processes.

The sand bed is made of a well sorted fine sand with mean diameter  $d_{50}=0.09 \text{ mm}$  and mean settling velocity  $w_s = 0.7 \text{ cm/s}$ . The water depth  $h$  above the platform is  $60 \text{ cm}$ . A series of 10 tests have been carried out for wave periods  $T$  of 1.5, 2 and 2.5s and an incident wave height  $H_i$  of about 25 cm. Longitudinal reflected waves,  $H_r$ , are generally less than 10% of incident waves. For each wave condition, a mean current  $U_r$  of about 20 cm/s at a reference level  $z_r=35 \text{ cm}$  is superimposed to the wave field in or against the direction of wave propagation. Hydrodynamic conditions are summarized in Table 1 in which a positive sign means a following current.

Figure 1: Side and top views of the wave flume

### 3. Experimental Results :

#### Bedforms:

Bedforms are two-dimensional for  $T=1.5$  s and become irregular three-dimensional for  $T=2.5$  s. Bedform dimensions are obtained from statistical analysis of bed profiler data. Typical bedforms heights do not show significant variation with flow parameter ( $\delta_r = 0.65$  cm), while wave length  $\lambda_r$  slightly increases with wave period from 5 to 7 cm. (see Table 1).

Test N°	T (s)	Hi (cm)	Hr (cm)	Ur (cm/s)	$\lambda_r$ (cm)	$\delta_r$ (cm)
35	1.5	23.2	1.0	- 4.6	4.8	0.7
39	2	23.2	1.3	- 5.75	5.5	0.7
42	2.5	25.0	2.15	- 5.9	6.7	0.6
36	1.5	18.8	1.05	17.4	5.0	0.6
40	2	21.0	2.1	17.4	5.0	.65
77	2.5	17.8	2.6	17.0	5.6	.7
38	1.5	17.5	1.25	- 17.0	4.8	0.6
41	2	21.1	1.6	- 18.7	5.5	0.7
54	—	20.1	2.20	-32.75	—	—
45	2.5	21.0	1.6	-17.6	5.8	.6

Table 1: Hydrodynamic test conditions

#### Mean velocity profiles:

In the case of waves only, there is a small eulerian drift which is in the direction of wave propagation near the bottom and against it in the outer flow ( $U_r=-4$  to  $-5$  cm/s) as shown on Figure 2.

Under combined waves and current, mean velocity profiles are fitted to a logarithmic profile in order to estimate both mean friction velocity  $u^*$  and apparent roughness height  $k_a$ , assuming a Karman constant  $K=0.4$  (see Table 2):

$$U = \frac{u^*}{K} \log \left( \frac{33z}{k_a} \right) \quad (3)$$

The main effect of the waves on the mean velocity profiles is to increase the equivalent roughness height  $k_a$  as compared to physical roughness ( $k_s=1.5 \delta_r$ ). This effect is larger for opposing waves and current than for following waves and current. These results are qualitatively in good agreement with expectations from theoretical models (e.g. Grant and Madsen (1979)) and previous observations (e.g. Nap and Van Kampen (1988)).

Mean concentration profiles:

In all our experiments, sediments stay within a thin (<5cm) near bottom layer. An exponential concentration profile gives a reasonably good fit to measurements as indicated by regression coefficients  $r > 0.95$ . Results are interpreted in terms of bottom concentration  $C_0$  and suspended layer thickness  $L_s$ , according to Nielsen's (1979) model (see Table 2):

$$C = C_0 \exp\left(-\frac{z}{L_s}\right) \quad (4)$$

In the case of three dimensional bedforms ( $T=2.5s$ ), there is a lot of scatter in measurements as shown on Figure 3. Under waves only, decrease of mean bottom concentrations with wave period may be due to changes in bedforms geometry from 2D to 3D as period increases.

Under waves only, the suspended layer thickness approximately scales with bedforms height ( $L_s = 2$  to  $3 \delta_r$ ). Significant increase of suspended layer thickness is observed for a following current which is in good agreement with expectations from previous models and observations. In the case of opposing current, this effect can only be observed by increasing opposing current intensity (Test 54). In the other tests with opposing current, the suspended layer thickness is approximately the same as for waves alone. For longer waves with opposing currents ( $T=2.5s$ ),  $L_s$  is actually smaller than for waves alone.

Test N°	$u^*$ (cm/s)	$k_s$ (cm)	r	$L_s$ (cm)	$C_0$ (g/l)	r
35				1.13	35.0	-0.99
39				0.99	30.9	-0.99

#### 4. Transport rates

Suspended transport rate estimates are decomposed into a wave and a mean current contributions according to equation (1). Measurements are averaged between the two-measuring points at ( $y=\pm 25\text{cm}$ ) across measuring section. Total transport rates  $Q_t$  are estimated from bed profiler data according to equation (2). In most cases, the difference between total transport rates  $Q_t$  and suspended transport rates  $Q_s$  is less than the spatial variability of measurements (30%). This indicates that bed load transport remains relatively small. In the case of opposing currents, net suspended transport rates are also small so that bed load contributions are not negligible anymore; total transport rates are then significantly enhanced in the direction of opposing mean current due to the small bed load contributions (see Table 3).

Under waves only, total transport is in the direction of wave propagation and increases with the wave period. Contribution of the weak eulerian drift to total transport  $Q_c$  remains small. Under combined waves and current, the wave contribution  $Q_w$  to total transport systematically opposes the mean current direction. The direction of total transport depends then on the relative intensity of both contributions. In the case of following current, the wave contribution is opposed to the direction of wave propagation but remains small compared to the mean current contribution  $Q_c$ , so that net transport is in the direction of wave propagation.

Test N°	$Q_c$ $\times 10^{-4}$	$Q_w$ $\times 10^{-4}$	$Q_s$ $\times 10^{-4}$	$Q_t$ $\times 10^{-4}$

## 5. Instantaneous concentrations

### Bottom concentration:

Under waves only, the bottom phase-averaged concentration is mainly periodic at half the wave period ( $T=2s$ ) and concentration peaks occur near current reversal ( $u(t)=0$ ), as shown on Figure 4.a. Under combined waves and current, only one maximum concentration peak is observed which systematically occurs slightly after flow reversal when the instantaneous current is opposed to the mean current direction as shown on Figures 4.b and 4.c for  $T=2s$ . Near the bottom, the contribution of the wave motion to total transport is then expected to oppose to the mean flow direction.

### Diffusion of concentration peaks:

Diffusion of concentration at various elevations is shown on Figure 4.a under waves only. The first peak occurring near flow reversal when current starts to oppose direction of wave propagation, cannot be observed away from the bottom. Phase-averaged concentrations show only one maximum peak occurring when current is in the direction of wave propagation ( $u(t)>0$ ). Flux due to oscillatory motion is then expected to be positive at all elevations.

Diffusion of maximum concentration peaks away from the bottom can be observed on Figure 4.b for following current and on Figure 4.c for opposing current. Concentrations are maximum when instantaneous current is negative ( $u(t)<0$ ) in the case of following current and positive ( $u(t)>0$ ) for opposing current. Flux due to oscillatory motion is then expected to oppose the mean current direction at all elevations.

### Flux profiles:

Typical flux profiles, time-averaged over the wave period, obtained for waves only, and combined waves and current are shown on Figures 5.a, b, c ( $T=2s$ ). As expected from near bottom concentration response and diffusion of concentration peaks, sediment transport flux due to oscillatory wave motion is in the direction of wave motion in both cases of waves only and opposing current and waves and in the opposite direction for following current.

## 6. Discussion of results and conclusions:

Results obtained for the mean current and wave contributions to total sediment transport make a qualitatively consistent picture. Under combined waves and current, the wave contribution is found to systematically oppose the mean current direction. In this case, the direction of the wave contribution to total sand transport can be explained by the asymmetrical bottom concentration response. Only one maximum concentration peak is observed which occurs slightly after flow reversal when the instantaneous current starts to oppose the mean flow direction.

It is interesting to note that these results are qualitatively similar with observations by P. Murray and al (1991) in the sheet flow regime. They also found that the total sediment transport rate under combined waves and current is systematically reduced by its wave component; their observations confirm the existence of one maximum peak in the bottom concentration which occurs when the

instantaneous current is opposed to the mean flow direction. These observations suggest that the reduction of total transport by the wave contribution is a fairly general result occurring in both ripples and sheet flow regimes.

Under waves only, the effect of the eulerian drift under waves only as well as second-order Stokes component on mean phase-averaged concentrations still needs to be clarified. A similar dissymetry on the phase-averaged concentration response can be observed under waves only as under opposing current and waves so that transport due to wave motion is in the direction of wave propagation in both cases.

The effect of bedforms dimensions and of measuring technique on concentration profiles is also unclear. In the case of three dimensional bedforms ( $T=2.5s$ ), a spatial averaging technique may become necessary, considering spatial variability of signal.

## CHAPTER 193

### A TIME—DEPENDENT NEARSHORE MORPHOLOGICAL RESPONSE MODEL

Hsiang Wang<sup>1</sup>, Gang Miao<sup>2</sup> and Li-Hwa Lin<sup>3</sup>

#### Abstract

This paper presents a numerical model for computing time-dependent near-shore hydrographic changes including beach profile responses. The time scale of the model is suitable for storm events to seasonal changes. The model is very stable and is capable of handling complicated topographies including inlets and irregularly-shaped structures such as curved jetties and breakwaters.

The basic approach is similar to many previous investigations utilizing a hydrodynamic model to drive a sediment transport model. The hydrodynamic model computes fully interacted current and wave fields based on coupled mild slope wave equation and depth-averaged circulation equations. The sediment transport model is of energetic type treating the rate of sediment as the summation of two energetic mechanisms one due to the mean current and the other due to the wave induced turbulence.

The model has been successful comparing with the evolution of beach profiles in large wave tank tests as well as other 2-dimensional numerical models of profile evolution. The model is able to predict the bar formation realistically without introducing constraints such as the bar genesis. At present the model consists of four modulars that apply separately for the situation of beach with no subaerial structure but could include non-reflective bottom structure, beach with shore-connected structures, beach with shore-detached structures and beach-inlet system. Test applications are presented here with some comparisons with field data and 3-D movable bed experiments.

#### INTRODUCTION

The nearshore zone is the area where the action of waves and currents on the sea bed is most intense, and where the bed material is almost always in motion. Erosion/accretion of the beach and change in offshore bottom topography occur naturally through the transport of sediment by waves and currents. Perturbations introduced by coastal structures, beach fills and other engineering activities may result in unexpected deformation of beach shapes and nearshore topographies. In the past, the prediction of beach evolution was mainly conducted by relying on experience of similar cases and on the results of hydraulic model tests. In

---

<sup>1</sup>Professor, <sup>2</sup>Post-Doctor, <sup>3</sup>Assistant Scientist, Coastal and Oceanographic Engineering Department, University of Florida, Gainesville, FL 32611, USA

recent years numerical models have gradually been developed and applied for this purpose.

The purpose of three-dimensional models is to predict the change of bottom topography from the spatial distribution of the sediment transport rates, which are evaluated from the nearshore wave and current fields computed point by point in small areas defined by a horizontal grid placed over the region of interest. Models of 3-D beach topography change require much fewer idealizations than do the line models. In this paper, a time-dependent nearshore morphological response model was developed. Test applications are presented together with comparisons of 3-D movable model test results and some field measurements.

### OUTLINE OF THE MODEL

The model consists of three submodels for calculating (1) waves, (2) nearshore currents, and (3) sediment transport and bottom changes. The first two models are fully coupled to provide nearshore hydrodynamic condition. Nearshore waves, through radiation stresses, provide the driving force for the currents which, in turn, modifies the wave field. A compatible current and wave field is obtained through iterative process. This combined sediment transport model is then used as the driving force for the sediment transport model which also calculates bottom changes through sediment conservation equation. The change in topography again modifies the hydrodynamics. therefore, yet another level of current-wave-topographic interaction is required through frequent updating. At the first step, the initial beach topography and the geometry of the structures for the study area are given as input. Next, the wave model determines the spatial distributions of radiation stresses and near-bottom orbital velocities. The circulation model, then, computes the mean water surface level and the depth averaged mean currents using the radiation stresses from the wave model as the forcing terms and includes bottom friction, advective acceleration and the lateral diffusion terms. Finally, the sediment transport rates are computed at the local points from the wave-current conditions calculated in advance, and then the three dimensional bottom topography change is computed by solving the equation of sediment mass conservation. The wave and current fields are updated hourly to incorporate topographic changes and tidal variations.

### Wave Model

Five contemporary numerical wave models were evaluated for their suitability (Lee and Wang, 1992). Two of them originally developed by Winer (1990) and Lee and Wang (1992), respectively were selected and modified for the present purpose. Both models account for current-wave-topography induced shoaling, refraction and diffraction effects. Empirical surf zone mechanics are also incorporated.

Both models are based upon the mild-slope equation given by Kirby (1984). Winer's model is the parabolic approximation version and theoretically is valid only for small incident wave angles. It employs a Crank-Nicholson finite difference scheme to solve the complex wave amplitude,  $A$ , of the following set of equations:

$$\begin{aligned} (C_g \cos \theta + U)A_x + \frac{\sigma}{2} \left( \frac{C_g \cos \theta + U}{\sigma} \right)_x A + VA_y + \frac{\sigma}{2} \left( \frac{V}{\sigma} \right)_y A \\ - \frac{i}{2} k C_g (1 - \cos^2 \theta) A - \frac{i}{2} \left[ CC_g \left( \frac{A}{\sigma} \right)_y \right] + \frac{\kappa}{2} A = 0 \quad (1) \end{aligned}$$

$$\omega = \sigma + \vec{k} \cdot \vec{U} \quad (2)$$

$$\sigma^2 = gk \tanh kh \quad (3)$$

where  $t$  is the time,  $\nabla_h$  is the horizontal gradient operator,  $\vec{U}$  is the depth averaged horizontal velocity vector,  $C$  is the phase velocity,  $C_g$  is the group velocity and  $\sigma$  is the angular frequency. The last term in Eq. 1 is the energy dissipation term, where  $\kappa$  is the energy dissipation coefficient. This term has been added in order to deal with the wave decay and recovery after breaking. Eventually coefficient  $\kappa$  will be related to the energy dissipation due to wave breaking following the work of Dally et al. (1984). This model is exceptionally stable and efficient. It usually only requires very minor adjustment for different applications.

The other model is based upon elliptic wave equation using the Gragg's method to solve for  $\check{\phi}$  which is the wave part of the velocity potential at the mean water level:

$$\begin{aligned} -i\omega[2U \cdot \nabla\check{\phi} + (\nabla \cdot U)\check{\phi}] + (U \cdot \nabla)(U \cdot \nabla\check{\phi}) + (\nabla \cdot U)(U \cdot \nabla\check{\phi}) \quad (4) \\ - \nabla \cdot (CC_g \nabla\check{\phi}) + (\sigma^2 - \omega^2 - k^2 CC_g - i\sigma\kappa)\check{\phi} = 0 \end{aligned}$$

This model has no small wave angle restriction and can accommodate reflective boundary conditions. The model is less stable and sometimes does not converge.

### Circulation Model

The governing equations for the circulation model are the depth integrated time averaged horizontal equations of momentum (Ebersole and Dalrymple, 1979):

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} + g \frac{\partial \bar{\eta}}{\partial x} + \frac{1}{\rho D} \bar{\pi}_x - \frac{1}{\rho D} \tau_{sx} + \frac{1}{\rho D} \left( \frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} \right) + \frac{1}{\rho} \frac{\partial \tau_l}{\partial y} = 0 \quad (5)$$

$$\frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + g \frac{\partial \bar{\eta}}{\partial y} + \frac{1}{\rho D} \bar{\pi}_y - \frac{1}{\rho D} \tau_{sy} + \frac{1}{\rho D} \left( \frac{\partial S_{xy}}{\partial x} + \frac{\partial S_{yy}}{\partial y} \right) + \frac{1}{\rho} \frac{\partial \tau_l}{\partial x} = 0 \quad (6)$$

and the continuity equation

$$\frac{\partial \bar{\eta}}{\partial t} + \frac{\partial}{\partial x}(UD) + \frac{\partial}{\partial y}(VD) = 0 \quad (7)$$

where  $(U, V)$  are the depth-averaged velocity components in the  $x$  and  $y$  directions, respectively,  $D = h + \bar{\eta}$ ,  $h$  is the still water depth, and  $\bar{\eta}$  is the elevation of the mean water level due to wave setup/setdown,  $\tau_l$  is the lateral shear stress due to turbulent mixing,  $(\bar{\pi}_x, \bar{\pi}_y)$  are the bottom shear stresses,  $(\tau_{sx}, \tau_{sy})$  are the surface shear stresses,  $S_{xx}$ ,  $S_{xy}$  and  $S_{yy}$  are the radiation stress components which arise from the excess momentum flux due to waves. The radiation stress terms are forcing terms, whereas the bottom friction terms and the lateral mixing terms represent flow impedances. These equations are obtained by integrating the local  $x$  and  $y$  momentum equations and the continuity equation over the depth of the water column and then time averaging the results. The governing equations in the circulation model are solved by alternating direction implicit (ADI) scheme. In order to treat the wave-current interaction, alternate computations of waves and of currents are necessary.

### Sediment Transport Model

Like the selection of wave model, a number of proven sediment transport models, mainly for 2-D profile modeling, were evaluated. They were compared on their basic transport mechanism. This was accomplished by comparing the transport forcing function expressed in equivalent shear stress term. Table 1 shows the equivalent shear stress terms from various models. The comparison under one specific wave condition is illustrated in Figure 1. It can be seen that they all assume similar shape. The transport model following that developed by Ohnaka and Watanabe (1990) was selected because the formulation is most suitable for 3-D application. The rate of sediment transport is treated as the summation of two energetic mechanisms one due to the mean current and the other due to the wave induced turbulence. The transport due to the mean current is

Table 1: Equivalent Shear Stress from Different Sediment Transport Models

Energy Loss (Dally, Kriebel, Larson and Kraus)
$\tau_e = -\frac{2}{H} \sqrt{\frac{h}{g}} \frac{\partial(EC_d)}{\partial x}$
Time-Averaged Bottom Velocity (Dally)
$\bar{\tau} = \frac{1}{T} \int_0^T \rho \frac{t}{2} u_b^2 dt \quad u_b = \frac{H}{2} \sqrt{\frac{g}{h}} \cos \omega t$
Deficit of Moment of Momentum (Houston and Dean)
$\bar{\tau}_b = -\frac{2}{h} \frac{\partial}{\partial y} \left[ \frac{Eh}{4} \left( 1 + \frac{H^2}{2h^2} \right) \right]$
Combined Bottom Velocity (Watanabe)
$\tau_c = U^2 + V^2 + \hat{u}^2 + 2U\hat{u} \cos \theta + 2V\hat{u} \sin \theta$
$\hat{u} = \frac{\pi H}{T \sinh kh}$

$$\vec{q}_c = \frac{A_c(\tau - \tau_{cr})\vec{U}}{\rho g} \quad (8)$$

where  $A_c$  is a nondimensional coefficient (of the order 0.1 to 1.0), values of which should be empirically determined.  $\tau$  is the maximum value of the bottom shear stress in a wave-current coexistent field.  $\tau_{cr}$  is the critical shear stress for the onset of sediment movement,  $\rho$  is the density of water, and  $g$  is the gravitational acceleration. If  $\tau \leq \tau_{cr}$ ,  $\vec{q}_c$  is zero. The transport due to waves is

$$\Phi = B_w(\Psi_m - \Psi_c)\Psi_m^{1/2} \quad (9)$$

where  $\Phi = (1 - \lambda_v)q_w/w_0d$  is a dimensionless net transport rate,  $d$ ,  $w_0$  and  $\lambda_v$  are the diameter, settling velocity, and void ratio of the sediment, respectively,  $B_w$

is a nondimensional coefficient (of order 2 to 10),  $\Psi_m$  is the Shields parameter and  $\Psi_c$  is the critical value of  $\Psi_m$  for the onset of general movement of sediment. Since  $q_w$  is the absolute value of the net transport rate, a method is needed to determine the direction of the net transport. Criteria for predicting whether a beach will erode or accrete through cross-shore sand transport processes have been suggested by a number of authors. The two most commonly used parameters include one for characterizing the deepwater wave steepness,  $H_0/L_0$ , and the other one related to the relative sediment fall velocity,  $H_0/w_0T$ , also known as the Dean's parameter. A version proposed by Larson et al. (1989) in their SBEACH model was adopted here. The criterion for distinguishing beach erosion and accretion can be expressed by the following equations:

$$\frac{H_0}{L_0} \leq C \left( \frac{H_0}{w_0T} \right)^3, \quad \text{erosion}$$

$$\frac{H_0}{L_0} > C \left( \frac{H_0}{w_0T} \right)^3, \quad \text{accretion}$$

in which  $C = 0.00070$  is an empirical coefficient.

Figure 1: Comparisons of equivalent shear stresses for different transport models.

The change in local bottom elevation,  $z_b$ , or water depth,  $h$ , can readily be computed from the spatial distribution of the sediment transport rates by solving the following equation for the conservation of sediment volume

$$\frac{\partial h}{\partial t} = \frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} \quad (10)$$

$$\vec{q} = \vec{q}_w + \vec{q}_c = (q_x, q_y) \quad (11)$$

## MODEL VALIDATION AND APPLICATIONS

In order to validate the 3-D morphological response model, several large wave tank results of dune erosion were simulated. These included Saville's (1957) large wave tank tests and the case of a sand beach backed by a sloping dike tested in the BIG WAVE FLUME, Germany (Dette and Uliczka, 1986).

Figure 2 shows a comparison of measured and calculated profiles for CE Case 400, from Saville, for which: initial slope =  $1/15$ ; grain size =  $0.22 \text{ mm}$ ; wave height and period of  $1.62 \text{ m}$  and  $5.6 \text{ sec}$  in the horizontal section of the tank (depth =  $4.42 \text{ m}$ ); and constant water level. The numerical and test results are shown for simulation times of 1, 3, 5, 10, 15, and 20 hours. The numerical model satisfactorily reproduced the observed forshore erosion and main breakpoint bar development. Simulated shoreline retreat and bar growth was initially rapid and gradually slowed as the bar moved offshore to reach a location close to that of the observed bar at the end of the run (20 hr).

A similar comparison is shown in Figure 3 for the case of 'dune with foreshore':  $+2 \text{ m}$  above SWL and  $10 \text{ m}$  wide dune with 1 to 4 seaward slope down to  $1 \text{ m}$  below SWL and following 1 to 20 slope down to channel floor. The BIG WAVE FLUME is  $324 \text{ m}$  long,  $7 \text{ m}$  deep and  $5 \text{ m}$  wide. The test profile was subjected to regular waves ( $H = 1.5 \text{ m}$ ,  $T = 6 \text{ s}$ ,  $h = 5.0 \text{ m}$ ). The predicted profiles are shown at times of 62, 111, 190 and 273 minutes and are compared to the measured profiles. The computed wave height distribution across shore is also shown. The waves cut back the foreshore to produce a vertical scarp, and a bar formed near the break point which grew and moved offshore with continued wave action. The volume of the main breakpoint bar and the amount of erosion on the foreshore are rather well predicted by the numerical model. However, the bar trough is less well reproduced. The model is incapable of simulating micro features such as the bottom undulations inside the breaking zone.

The model is also compared with other 2-D dune erosion models including Kriebel and Dean (1984) and Larson et al. (1989). The comparisons of profile changes in the nearshore zone are all very close; they deviate in bar formations. Figure 4 shows the comparison between the present model and the SBEACH applied to a prototype profile and wave condition. The Kriebel's model (not shown here) almost duplicates the SBEACH in the nearshore zone but produces no bar.

The present numerical model has been applied to a variety of cases including beach nourishment, beach with submerged rocks, offshore detached breakwater, shore-perpendicular structures, inlet-beach system, etc. The model results of waves, currents and topographic changes for a region around Sebastian Inlet are given here as an illustration. Sebastian Inlet is located at the east coast of Florida between the Brevard and Indian River County line approximately 45 miles south of Port Canaveral entrance. The bathymetric map of 1989 is given in Figure 5. It is located in a littoral drift zone predominately from north to south. The inlet has been kept open by means of maintenance dredging and jetty improvements. It suffers from channel shoaling and downdrift beach erosion. Movable bed physical model and field studies were carried out (Wang et al., 1991, 1992) to seek improvement measures.

A few examples are given here to show the comparison between numerical simulation and field or laboratory results. First of all, the wave patterns under

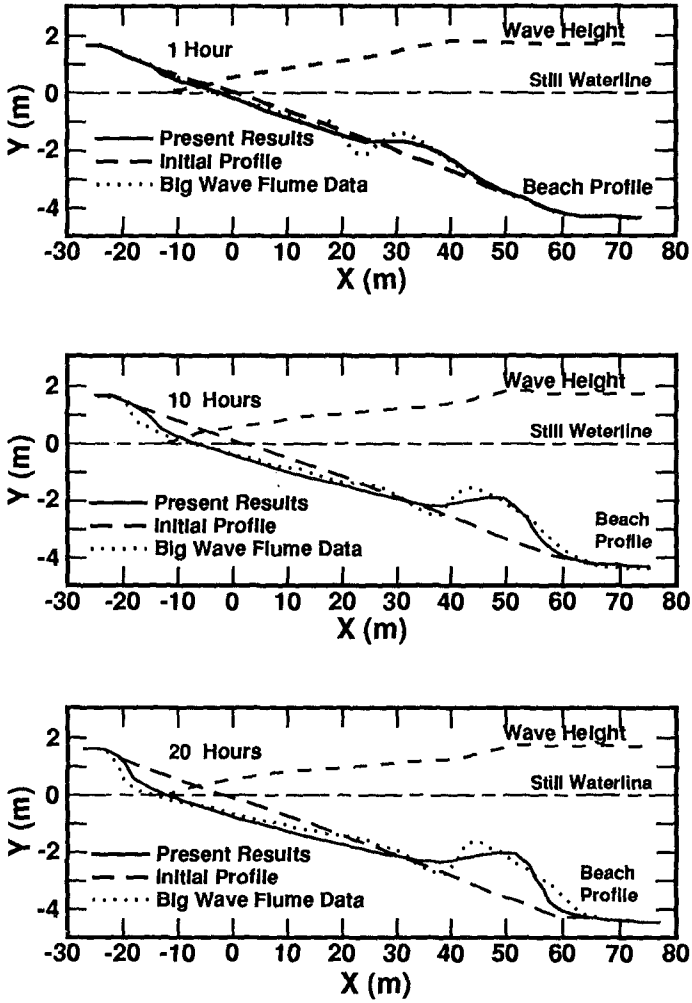

Figure 2: CE case 400, Comparison between simulated and measured beach profiles.  $t = 1, 3, 5, 10, 15, 20$  hours. Data from Saville (1957).

Figure 3: Comparison between simulated and measured beach profiles, measured data from Dr. Dette.  $t = 62, 111, 190, 273 \text{ min}$

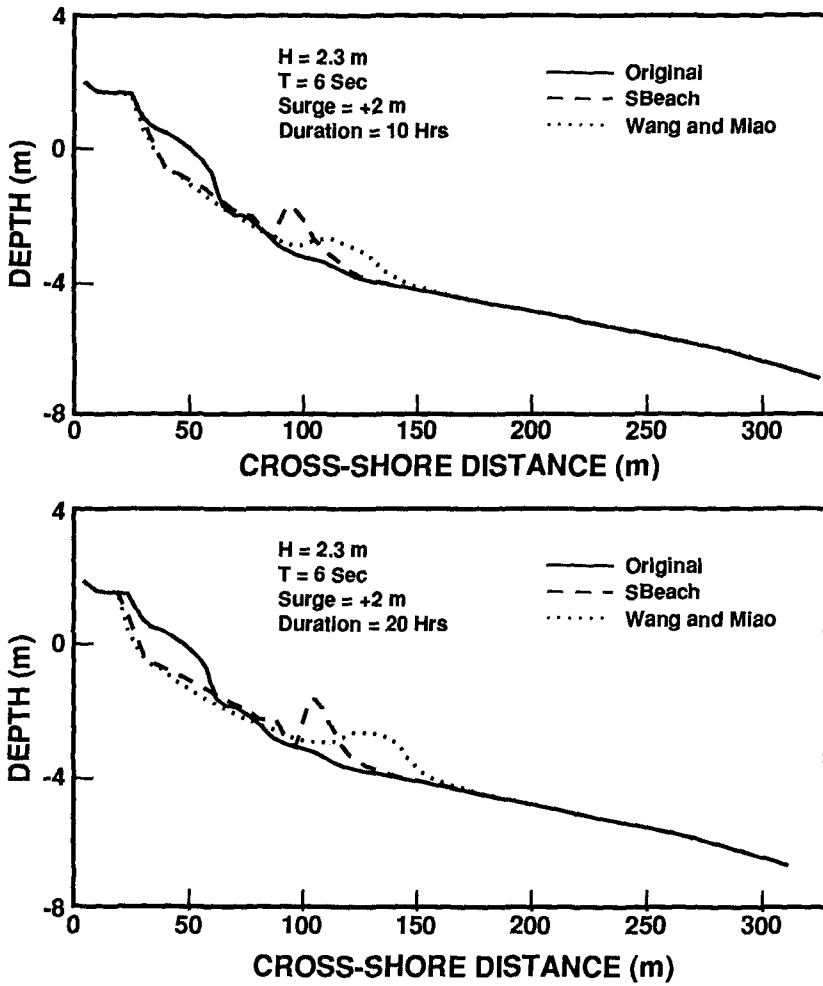

Figure 4: Comparison between present model and SBEACH model

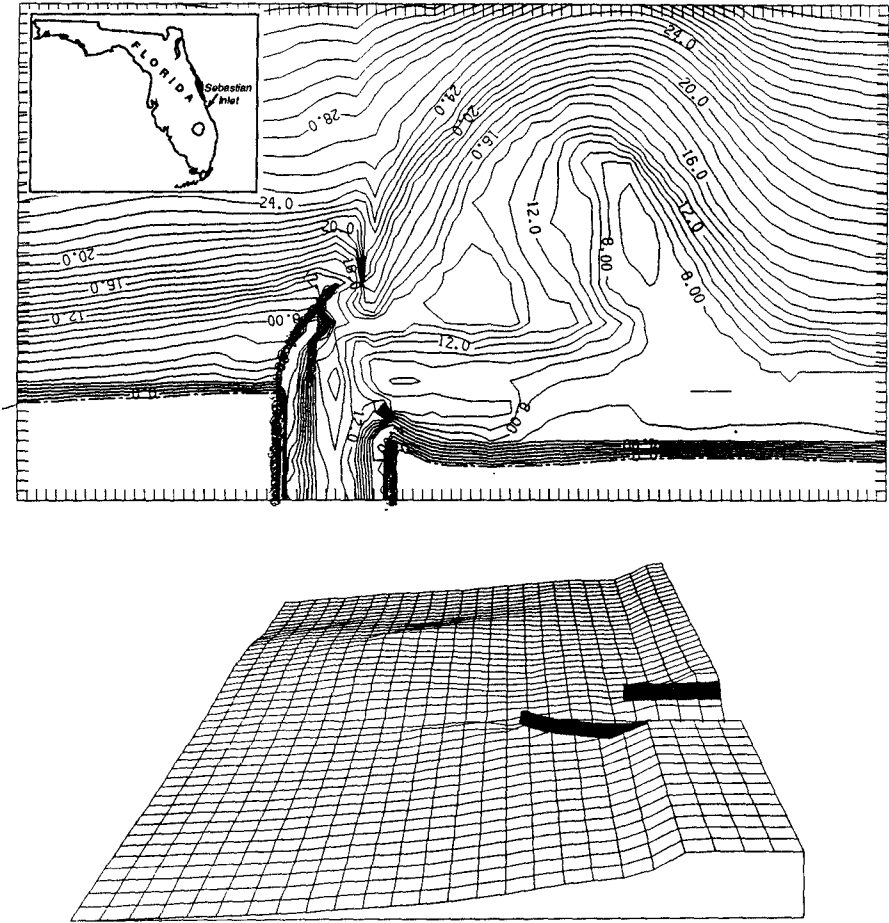

Figure 5: Sebastian Inlet bathymetric map for year 1989.

long crested conditions can be closely simulated by the numerical model. This can be seen in Figure 6 which compares wave pattern recorded by aerial photo with simulation.

The current in the inlet is tidal driven, often reaching to  $2.5\text{ m/s}$  during ebb and flood. In the vicinity and outside the inlet, the current field is very complicated. During ebb cycle, the current behaves like a jet carrying with it a rather concentrated seaward momentum. This jet when deflected by the curved north jetty directs itself towards the southeast, which gradually shaped the main flood-ebb channel. A clockwise vortex is formed on the south side behind the jet stream. During flood cycle, the current converges to the inlet like flow into a funnel. The flow pattern is influenced by both the ebb shoal and the jetties. A very strong current developed near the tip of the south jetty, causing a major scouring hole at its tip. The current patterns simulated by the numerical model are compared with those measured in the field in Figure 7. Again, like wave field simulation, the current pattern appears to be quite reasonably reproduced.

For morphological changes the numerical model is compared with movable bed physical model tests. The model has a horizontal scale of 60 using finer sand than the prototype as bed material (detail see Wang et al., 1992). The actual physical dimensions of the model are approximately alongshore and offshore. Figure 8 compares the numerical and physical model results for a specific case with the following input conditions: the offshore boundary is  $H = 2\text{ m}$ ,  $T = 8\text{ s}$ , and the incident wave angle at the offshore boundary is  $10^\circ$  (from the north-east). The tide is semi-diurnal with a range of  $1.0\text{ m}$ . The plot gives the cumulative bottom changes after a time period equivalent to 6-days in prototype. The solid lines represent accretion and dash lines represent erosion with contour interval of  $0.1\text{ m}$ . The most visible bathymetric changes occur in the nearshore region behind the ebb shoal including the area near the tip of the south jetty. Beach face is eroded by wave action and sand is carried out towards offshore forming offshore bars. Meanwhile, the ebb shoal experienced vigorous sediment motion due to wave breaking and the sediment is also carried into the nearshore region. Although the details are somewhat different the agreement can be considered good macroscopically as most of the prominent topographical changes are correctly predicted.

## CONCLUSIONS

A numerical model has been developed for computing time-dependent nearshore hydrographic changes including beach profile responses. The time scale of the model is suitable for storm events to seasonal changes. The model is very stable and is capable of handling complicated topographies including inlets and irregularly-shaped structures such as curved jetties and breakwaters.

The model has been fairly rigorously calibrated against 2-D large scale beach profile evolution tests carried out in the GWK tank and in the CERC's large tank. The model is also verified with other 2-D numerical models. The model is capable of describing the growth and movement of main breakpoint bars and corresponding berm processes with reasonable reliability. Calibration and verification for 3-D cases are limited. So far, a set of field and laboratory movable bed data concerning one specific inlet configuration has been utilized. The numerical model seems to perform well to predict wave patterns of long crested waves; gives reasonable current patterns. Consequently, the patterns of topographic changes can also be reasonably predicted. Of particular importance is the ability of the model to depict correctly the sediment transport patterns that can add to the

Figure 6: Comparisons of wave patterns from aerial photography and model at Sebastian Inlet.

Figure 7: Comparisons of current patterns from the numerical model and field measurements.

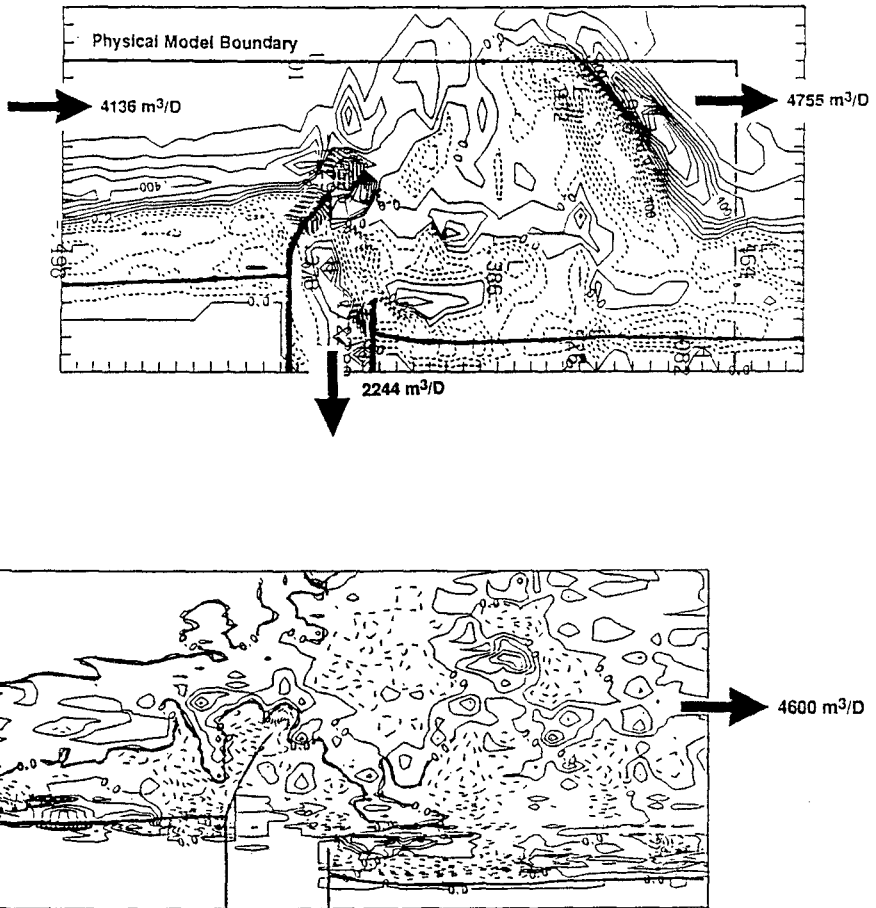

Figure 8: Comparison of bathymetric changes after 6-day NE storm.

insight to the sediment transport process. Of less confidence is the quantity of transport as well as detailed topographic changes. Work is still in progress to improve the reliability of the model as well as expanding the scope of the model.

### ACKNOWLEDGEMENTS

We would like to thank Dr. Hans H. Dette, from Leichtweib-Institut für Wasserbau Technische Universität, for providing the experimental data, and Professor H. Zhong, Mr. J. Lee, Mr. T. Kim, from COE Department of the University of Florida, for their contribution to the movable bed physical model study.

## CHAPTER 194

# TOTAL RATE AND DISTRIBUTION OF LONGSHORE SAND TRANSPORT

Akira Watanabe<sup>1</sup>

### Abstract

Longshore sand transport rate has been computed, for 2,520 cases covering field- and laboratory-scale conditions, using a general formula for local transport rate in a coexistent wave-current field proposed by the present author. The computed total transport rate has been well related to the alongshore component of wave power and two other parameters. Cross-shore distributions of the longshore transport rate have also been studied.

### 1. Introduction

Longshore sediment transport plays a very important role particularly in long-term beach evolutions. In the longshore transport, sand grains are set in motion mainly by wave action and then carried by a longshore current. However the total transport rate is usually estimated using the CERC formula or its equivalence, which relates the total rate directly with the so-called longshore component of energy flux (or power) of breakers and does not explicitly involve the longshore current velocity. The CERC-type formulas are based on the power or energetics model concept and field measurements, but their reliability and appropriate values of the coefficients are yet debatable. In addition there have been only few studies on the cross-shore distribution of the local transport rate, which is regarded as important as the total rate for various engineering problems.

Watanabe *et al.* (1986) have proposed a power-model type formula for local sediment transport rate under combined action of waves and currents, whose validity has been confirmed through numerous fundamental studies and practical applications (*e.g.*, Watanabe *et al.*, 1991). This local transport rate formula

---

<sup>1</sup> Professor, Dept. of Civil Eng., Univ. of Tokyo, Bunkyo-ku, Tokyo, 113 Japan.

is applied in the present paper to the evaluation of the total rate and cross-shore distribution of the longshore sand transport under regular waves on straight beaches.

## 2. Computational Procedure for Waves, Currents and Sand Transport

### 2.1 Computational conditions

From the standpoint of such fundamental studies as this, computation of waves, currents and sediment transport should be performed for conditions as simple as possible. It has therefore been assumed in the following computation that the shoreline and depth-contour lines are straight and parallel to each other, that incident waves are regular and uniform in the alongshore direction, and that the sediment grain size is spatially uniform. On the other hand, for the sake of generalization of discussions, the computation has been conducted for a total of 2,520 cases: six values of the sand grain diameter  $d$ , four values of the uniform bottom slope  $\tan \beta$  and a bar-type beach, and three, seven and eight values of the incident wave angle  $\theta_0$ , period  $T$  and height  $H_0$ , respectively, as shown in Table 1, covering field- as well as laboratory-scale conditions.

Table 1 Computational conditions.

$d$ (mm)	$\tan \beta$	$\theta_0$ (deg)	$T$ (s)	$H_0$ (m)
0.2	1/10	15	1.0	0.02
0.5	1/20		1.5	0.04
0.8	1/30	30	2.0	0.16
1.1			6.0	0.3
1.5	1/50	45	10.0	0.6
2.0	bar-type		14.0	1.2
			18.0	2.4

### 2.2 Computation of nearshore waves

A set of time-dependent mild-slope equations, proposed by Watanabe and Maruyama (1986) and improved by Watanabe and Dibajnia (1988), can deal with most of nearshore wave deformation such as shoaling, refraction, reflection, diffraction, breaking and recovery. For the present problem, we can reasonably neglect the wave reflection from the shore and the refraction due to the presence of currents, and then the time-dependent mild-slope equation set reduces to the following simple wave energy equation:

$$\frac{d}{dx}(H^2 C_g \cos \theta) = -n f_D H^2 \quad (1)$$

where  $x$  is the shoreward coordinate,  $H$  is the wave height,  $C_g$  is the group velocity,  $\theta$  is the wave angle, and  $n$  is the shallowness factor. The quantity  $f_D$  is the breaker-induced energy dissipation factor and defined as:

$$f_D = \frac{5}{2} \tan \beta \sqrt{\frac{g}{D}} \sqrt{\frac{(H/D) - \gamma'_r}{\gamma'_s - \gamma'_r}} \quad (2)$$

$$\gamma'_s = 0.8(0.57 + 5.3 \tan \beta), \quad \gamma'_r = 0.4(H/D)_B \quad (3)$$

in which  $D = h + \eta$  is the local mean water depth ( $h$ : the still water depth;  $\eta$ : the mean water surface elevation), and the suffix B indicates the breaking point. Equation (1) has been solved together with Snell's law and Eq. (4) for the wave setup/down to obtain cross-shore distributions of the mean water depth  $D$ , wave height  $H$ , wave angle  $\theta$ , group velocity  $C_g$ , and so on.

$$\frac{d\eta}{dx} = -\frac{1}{\rho g D} \frac{dS_{xx}}{dx} \quad (4)$$

where  $S_{xx}$  is the normal component of the radiation stress, and  $\rho$  is the water density. The location of wave breaking has been determined using a generalized breaker index expressed in terms of the ratio of the horizontal orbital velocity at the wave crest to the wave celerity (Watanabe *et al.*, 1984).

### 2.3 Computation of longshore current

Since the wave field is stationary and uniform in the alongshore direction, the longshore current velocity has been computed by the following equation (Nishimura, 1988):

$$\rho C_t \tilde{W} V_\ell - \frac{d}{dx} \left[ \mu_e D \frac{dV_\ell}{dx} \right] + \frac{dS_{xy}}{dx} = 0 \quad (5)$$

where

$$\left. \begin{aligned} \tilde{W} &= W + (\tilde{u} \cdot \sin \theta)^2 / W, \quad \tilde{u} = (2/\pi) \hat{u}_b \\ W &= \left[ \sqrt{V_\ell^2 + \tilde{u}^2 + 2 V_\ell \tilde{u} \sin \theta} + \sqrt{V_\ell^2 + \tilde{u}^2 - 2 V_\ell \tilde{u} \sin \theta} \right] / 2 \end{aligned} \right\} \quad (6)$$

$$\mu_e = \rho N \xi \sqrt{gD} \quad (7)$$

in which  $V_\ell$  is the longshore current velocity,  $C_t$  is the friction coefficient for the current,  $S_{xy}$  is the tangential radiation stress,  $\hat{u}_b$  is the near-bottom orbital velocity amplitude,  $\mu_e$  is the lateral mixing coefficient, and  $\xi$  is the offshore distance from the mean shoreline. A value of 0.01 has been adopted for  $N$ .

In most of the previous computation of nearshore currents, constant values (on the order of 0.01) have been used for the friction coefficient  $C_t$ . However, since its value significantly affects the magnitude of the longshore current velocity and the resultant sediment transport rate, we should determine  $C_t$  in a more objective and reasonable way. Hence, in the present study, local values of  $C_t$  have been estimated using a frictional law of Tanaka and Shuto (1981) for a wave-current coexistent field and empirical formulas of Sato (1987) for ripple formation due to waves.

For this, first we calculate at each local point the near-bottom orbital diameter  $d_0$  using the small-amplitude wave theory as well as the friction coefficient

$f_{cw}$  using the frictional law, in which the presence of the longshore current is ignored and the equivalent roughness  $k_s$  is set equal to the sand grain diameter  $d$ . The empirical formulas of Sato give the critical conditions for the formation/disappearance of sand ripples and the ripple size as functions of the Shields number and  $d_0/d$ . Then we evaluate the friction coefficient  $C_f$  using the frictional law, in which this time the longshore current is included and the equivalent roughness  $k_s$  is set equal to the local ripple height, if ripples exist, or to the grain diameter  $d$  in case of no ripples. (According to previous studies, the equivalent roughness is about four times as large as the ripple height. However, the ripple height itself has been employed as  $k_s$  in this study, because the ripple crest orientation is rather parallel to the longshore current direction.) Cross-shore distributions of the longshore current velocity  $V_\ell$  have been thus computed by iteratively solving Eq. (5) together with the frictional law for unknowns  $V_\ell$  and  $C_f$ .

## 2.4 Computation of longshore sand transport rate

The sediment transport rate formula proposed by Watanabe *et al.* (1986) gives local transport rate, under general conditions of combined action of waves and currents, as the summation of the transport rate due to mean currents and that due to the direct action of waves. In the present study, by neglecting the latter, the following formula has been used for the computation of local immersed-weight rate  $i_\ell$  of the longshore sand transport.

$$i_\ell(x) = (1 - \varepsilon_v) s \cdot A_c [\hat{\tau}_b(x) - \tau_{cr}] V_\ell(x) \quad (8)$$

in which  $\varepsilon_v$  and  $s (= \rho_s/\rho - 1)$  are the porosity and the immersed specific density of the sediment,  $A_c$  is a dimensionless coefficient,  $\hat{\tau}_b$  is the maximum value of the periodical bottom friction in a coexistent wave-current field, calculated by the frictional law of Tanaka and Shuto (1981) with the equivalent roughness equal to the grain diameter,  $\tau_{cr}$  is the critical shear stress for the onset of general sand movement (Watanabe *et al.*, 1986), and  $V_\ell$  is the longshore current velocity. A value of 2.0 has been adopted for the coefficient  $A_c$  on the basis of recent studies (*e.g.*, Watanabe *et al.*, 1991).

Total immersed-weight rate  $I_\ell$  of the longshore transport has been computed by the cross-shore integration of  $i_\ell(x)$ :

$$I_\ell = \int_{x_0}^{\infty} i_\ell(x) dx \quad (9)$$

where  $x_0$  is the locations of the mean water shoreline. Then total volumetric transport rate  $Q_\ell$  has been calculated by the following equation:

$$Q_\ell = \frac{I_\ell}{(1 - \varepsilon_v)(\rho_s - \rho)g} \quad (10)$$

### 3. Results of Computation and Discussions

#### 3.1 Example of computation results

As one example of the results thus computed, Figure 1 shows cross-shore distributions of the wave height  $H$ , wave angle  $\theta$ , longshore current velocity  $V_L$ , near-bottom orbital velocity amplitude  $\hat{u}_b$ , immersed-weight sand transport rate  $i_L$ , equivalent roughness  $k_s$ , friction coefficient  $C_f$  in the longshore current computation, and friction coefficient  $f_{cw}$  in the transport rate computation, when  $d = 0.2\text{mm}$ ,  $\tan \beta = 1/20$ ,  $\theta_0 = 45^\circ$ ,  $T = 10.0\text{s}$ , and  $H_0 = 1.2\text{m}$ .

The transport rate  $i_L$  becomes maximum between the breaking point and the location of the maximum  $V_L$ , as expected, not only in this case but in all the cases. The range where  $i_L$  takes significant magnitude is narrower than that for  $V_L$  and is comparable to the surf zone width. In the range of about 80m around the breaking point, the equivalent roughness  $k_s$  is equal to the grain size  $d = 0.2\text{mm}$  and hence the friction coefficients  $C_f$  and  $f_{cw}$  take common values. This is because the bottom friction in this range exceeds the critical value for the disappearance of sand ripples or the initiation of the sheet flow.

Fig. 1 Example of cross-shore distributions of computed quantities.

**3.2 Total rate of longshore sand transport**

First let us study the relation of the total immersed-weight transport rate  $I_t$  with the longshore component of wave energy flux  $P_l$  at the breaking point:

$$P_l = E_B C_{gB} \cdot \sin \theta_B \cos \theta_B \tag{11}$$

where  $E_B$ ,  $C_{gB}$  and  $\theta_B$  are the energy density, the group velocity and the wave angle of breakers. Komar and Inman (1970) have proposed the following linear relation between  $I_t$  and  $P_l$  on the basis of the energetics concept and field data:

$$I_t = 0.77 P_l \tag{12}$$

in which the proportionality constant 0.77 should be halved if the energy density is calculated from the significant wave height as in the CERC formula.

Figure 2 shows a relation between  $I_t$  and  $P_l$  obtained in the present computation for cases of  $d = 0.2\text{mm}$  and  $\tan \beta = 1/50$ . The relation is remarkably independent of the incident wave period  $T$  and angle  $\theta_0$ . The magnitude of  $I_t$  is nearly proportional to  $P_l$  under field-scale conditions, whereas it rapidly decreases under laboratory conditions, in which the maximum friction  $\hat{\tau}_b$  exceeds the critical shear  $\tau_{cr}$  only slightly in Eq. (8). Such an overall trend is consistent with previous studies (*e.g.*, Komar and Inman, 1970).

Fig. 2 Example of relation between  $I_t$  and  $P_l$ .

The relation between  $I_t$  and  $P_t$  for all the 2,520 cases is shown in Fig. 3, which indicates a trend similar to that in Fig. 2. In Fig. 3, different symbol marks are used for different grain sizes and beach slopes, but their effect on the  $I_t$ - $P_t$  relation cannot be seen clearly because of the overlapping of many marks.

Fig. 3 Relation between  $I_t$  and  $P_t$ .

In order to make this clearer, we assume the linear relation,  $I_t = \alpha_{IP} \cdot P_t$ , for the 1,440 cases under field conditions, and calculate the proportionality coefficient  $\alpha_{IP}$  for each grain size and bottom slope using the least-square method. Figure 4 (a) shows values of  $\alpha_{IP}$  normalized by the mean proportionality coefficient  $\bar{\alpha}_{IP}$  for all the 1,440 cases. It is seen in this figure that  $\alpha_{IP}$  considerably decreases as the grain diameter  $d$  increases, being much less dependent on the bottom slope except for cases of  $\tan \beta = 1/10$ . The values of  $\alpha_{IP}$  range between 0.04 and 0.23 with their average  $\bar{\alpha}_{IP} = 0.078$ , which are very much smaller than 0.77 in Eq. (12) by Komar and Inman (1970) or 0.52 proposed by Kraus *et al.* (1982), being rather close to the value of 0.06-0.12 in an empirical formula presented by Sato and Tanaka (1966). In a summary, according to the present computation, the relation between  $I_t$  and  $P_t$  is approximately expressed as:

$$I_t = (0.04 \sim 0.23) P_t \simeq 0.078 P_t \tag{13}$$

For readers' information, Fig. 5 shows the relation between  $I_t'$ , computed by Eq. (8) with the critical shear  $\tau_{cr} = 0.0$ , and  $P_t$ . They are proportional very well to each other not only for field-scale but also for laboratory-scale conditions.

Fig. 4 Dependency of proportionality coefficients on the grain size and the beach slope.

Fig. 5 Relation between  $I_t'$  and  $P_t$ .

Komar and Inman (1970) have reported another empirical formula based on field data as follows:

$$I_t = 0.28 P_t' \tag{14}$$

where

$$P_t' = E_B C_{gB} \cos \theta_B \cdot \bar{V}_t / \hat{u}_{bB} \tag{15}$$

in which  $\bar{V}_t$  is the mean velocity of the longshore current, and  $\hat{u}_{bB}$  is the amplitude of the near-bottom orbital velocity at the breaking point. Figure 6 shows the relation between  $I_t$  and  $P_t'$  in the present computation, in which  $\bar{V}_t$  has been evaluated by simply averaging  $V_t$  over the range from the breaker line to the mean shoreline. Data scattering in Fig. 6 has become small as compared to that in Fig. 3. In addition, as shown in Fig. 4 (b), the dependency of the proportionality coefficient  $\alpha_{IP'}$  on the grain size and on the bottom slope is also weak except for cases of  $\tan \beta = 1/50$ . Values of  $\alpha_{IP'}$  is still much smaller than 0.28 in Eq. (14), and the relation of the two quantities is expressed as:

$$I_t = (0.05 \sim 0.13) P_t' \simeq 0.08 P_t' \tag{16}$$

Fig. 6 Relation between  $I_t$  and  $P_t'$ .

In order that the relation  $I_t \propto P_t \propto P_t'$  holds good, the mean longshore current velocity  $\bar{V}_t$  must be proportional to  $\hat{u}_{bB} \cdot \sin \theta_B$ . Their relation is shown in Fig. 7. Although these two quantities approximately satisfy a proportional relation for an individual combination of the grain diameter  $d$  and the bottom slope  $\tan \beta$ , values of the proportionality coefficient change over the range of one-order of magnitude, depending on  $d$  and  $\tan \beta$ .

Fig. 7 Relation between  $\bar{V}_l$  and  $\hat{u}_{bB} \cdot \sin \theta_B$ .

Now let us make the following long wave approximation:

$$\left. \begin{aligned} C_{gB} &\simeq \sqrt{gD_B}, \quad \cos \theta_B \simeq 1 \\ \hat{u}_{bB} &\simeq (H_B/2) \sqrt{g/D_B} \simeq (\gamma/2) \sqrt{gD_B} \end{aligned} \right\} \quad (17)$$

for the parameter  $P_l'$  defined by Eq. (15). Then we obtain the relation:

$$P_l' \simeq (\rho g/4\gamma) H_B^2 \bar{V}_l \quad (18)$$

where  $\gamma$  is the ratio of the wave height  $H_B$  to the mean depth  $D_B$ , and is practically constant. Hence we can expect a linear relation between the total volumetric transport rate  $Q_l$  and a new parameter  $R_l$  defined as:

$$R_l = H_B^2 \bar{V}_l \quad (19)$$

which is consistent in the dimension with  $Q_l$ . The relation between  $Q_l$  and  $R_l$  is shown in Fig. 8. As expected, for the field-scale conditions,  $Q_l$  is approximately proportional to  $R_l$  as expressed by the following relation (See Fig. 4 (c)):

$$Q_l = (0.020 \sim 0.053) R_l \simeq 0.034 R_l \quad (20)$$

It is interesting (and strange in a sense) that the value of 0.034 of the mean proportionality coefficient in Eq. (20) is very close to 0.024 in the empirical formula presented by Kraus *et al.* on the basis of field data, because using the same data set they have obtained the value of 0.52 as the proportionality constant in the  $I_l$ - $P_l$  relation, which is very much larger than the value of 0.078 in Eq. (13).

Fig. 8 Relation between  $Q_t$  and  $R_t$ .

### 3.3 Cross-shore distribution of longshore transport rate

As described in 3.1 in reference to Fig. 1, the local rate of the longshore transport  $i_t$  becomes maximum between the breaking point and the location of the maximum longshore current velocity, and takes significant values over a range as wide as the surf zone. However, since the cross-shore distributions of  $i_t$  may not necessarily be similar for various conditions of the grain size, bottom slope and incident waves, it seems difficult to express them in a single normalized form. Hence here we will examine only the magnitude of the maximum local transport rate  $i_{t\max}$  and the offshore distance  $X_{i_{t\max}}$  of the point of  $i_{t\max}$ , which are regarded as the most important representative parameters in the cross-shore distributions of  $i_t$ .

First, concerning the maximum transport rate  $i_{t\max}$ , since the total rate  $I_t$  is approximately proportional to  $P_t$  and the width of the significant longshore transport zone is comparable with the surf zone width  $X_B$  (the distance between the breaking point and the mean shoreline),  $i_{t\max}$  may be related to a parameter  $S_t = P_t/X_B$ . As expected, it is seen in Fig. 9 that a fairly high correlation exists between  $i_{t\max}$  and  $S_t$ . According to Fig. 4 (d), the value of the proportionality coefficient  $\alpha_{iS} = i_{t\max}/S_t$  obtained for the field-scale cases decreases as the grain size increases, being nearly independent of the bottom slope. Under the field-scale conditions, the relation between these two parameters is expressed as:

$$i_{t\max} = (0.075 \sim 0.24) S_t \simeq 0.13 S_t \tag{21}$$

Fig. 9 Relation between  $i_{tmax}$  and  $S_t$ .

Then the relation between  $X_{i_{tmax}}$  (the offshore distance of the point of  $i_{tmax}$  measured from the mean shoreline) and  $X_B$  is shown in Fig. 10, where plotted are points more than 2,300 except for the data with  $i_{tmax} < 10^{-7}$  tf/m/s. The two parameters show such a remarkably highly proportional relation that only a small number of points can be seen because of their overlapping. According to this figure as well as Fig. 4 (e), the proportionality coefficient  $\alpha_{XX} = X_{i_{tmax}}/X_B$  takes nearly constant values depending very weakly on the grain size and the bottom slope. The relation is expressed as:

$$X_{i_{tmax}} = (0.52 \sim 0.83) X_B \simeq 0.72 X_B \tag{22}$$

#### 4. Concluding Remarks

Major conclusions of this study are as follows:

- (1) The validity of the local transport rate formula and that of the conventional total rate formulas for the longshore transport have been reinforced each other at least qualitatively.

Fig. 10 Relation between  $X_{i_{tmax}}$  and  $X_B$ .

(2) Under the field-scale conditions, the total immersed-weight transport rate  $I_t$  is approximately proportional to the longshore wave power component  $P_t$ . However, the value of the proportionality coefficient obtained in this study is very much smaller than 0.77 in Komar and Inman's formula and is rather close to the value in Sato and Tanaka's formula, decreasing as the grain size increases. It should be noted that in many examples of the actual application of the  $I_t$ - $P_t$  formula to one-line models, values between 0.05 and 0.4 have been adopted for the coefficient on the basis of the calibration using past beach change data.

(3) Under the laboratory-scale conditions, the effect of the critical shear stress  $\tau_{cr}$  cannot be neglected.

(4)  $I_t$  and  $P_t'$  as well as  $Q_t$  and  $R_t$  have also shown a highly proportional relation, respectively, particularly under the field-scale conditions. The proportionality coefficients are weakly dependent on the grain size.

(5) Concerning the cross-shore distributions of the longshore transport rate, it has been found that  $i_{tmax}$  and  $S_t$  as well as  $X_{i_{tmax}}$  and  $X_B$  are also proportional to each other.

Further study should be conducted on the effects of the beach profiles (more realistic profiles, other than uniform slopes, corresponding to given conditions of sediment grain size and incident waves), breaker-induced turbulent stresses, grain size distributions, effective bottom roughness, beach transport in the swash zone, random waves, and so on.

## CHAPTER 195

### COMBINED FLOW SAND TRANSPORT: FIELD MEASUREMENTS

RICHARD J.S. WHITEHOUSE<sup>1</sup>

#### ABSTRACT

This paper compares the results of measurements obtained from two field experiments performed to determine the effect of waves and currents ( $w+c$ ) on the transport of sand in suspension. One set of measurements are from an estuary (Maplin Sands) and the other are from the surf zone (Boscombe Pier). The vertical and temporal variation in and the correlation between some of the hydrodynamic and sediment dynamic parameters are discussed.

#### 1. INTRODUCTION

The ability to predict the transport rate of sandy sediment by combined wave plus current ( $w+c$ ) action is an important aspect of many coastal and estuarine engineering projects. Although the physically based sediment transport formulae are able to be constructed from first principles they often rely upon experimental data to aid in their formulation and for their verification.

In the complex situation of  $w+c$  flow the mean (current) component can be characterised by the depth averaged velocity  $V$  and the periodic component due to wave action by the bottom orbital velocity amplitude  $W$ . Combined flow conditions in the marine environment can be described as current dominated when the ratio  $W/V < 0.2$  or wave dominated when

-----  
<sup>1</sup>Section Manager, Sediments Research Group, HR Wallingford Ltd, Howbery Park, Wallingford, OXON OX10 8BA, UK

$W/V > 0.2$  (Soulsby and Humphery, 1990). Once waves are present they will enhance the entrainment of sand, by the so called stirring process, and hence increase the transport rate of sand over that due to the current alone. Under storm conditions in tidal channels or in the nearshore zone the waves can become the dominant entraining agent. The detailed mechanics of the entrainment process, and the resulting concentration profiles, will depend upon sedimentological factors, whether the waves and currents are small or large, and the value of the ratio  $W/V$ .

This paper presents some results from two field w+c sediment transport experiments that have been performed in two different nearshore environments, at Maplin Sands and at Boscombe in the UK. Previously Owen and Thorn (1978) and Grass (1981) have used a selection of the Maplin data to parameterise functions for the sediment transport rate under w+c. Whitehouse (1991), however, was the first to present profile data from these experiments (Boscombe).

The data provide information with which to examine the physical processes behind the entrainment of sand and the resulting near-bed concentration, the diffusion of sediment into the flow, and subsequently the rate of sand transport.

## 2. MEASUREMENTS

Detailed measurements have been made at two field sites to determine the vertical structure through the water column of hydro and sediment dynamic parameters. Over 350 measured profiles were obtained from the two experiments.

The first series of measurements were made in the Outer Thames Estuary between 1973 and 1975 from a free standing tower sited at the southern edge of Maplin Sands and adjacent to a deep water channel. The site was exposed to wind wave action and experienced strong tidal currents moving in and out of the estuary over a fine sand bed ( $d_{50}=0.141$  mm). These data were collected for the specific purpose of determining the effect of waves in enhancing current dominated sand transport, and also included data for the current alone condition.

The second series of measurements were taken under storm wave conditions in the surf zone at the seaward end of Boscombe Pier (1977-78). At this site, in Poole Bay on the south coast of the UK, the tidal streams are weak but can be enhanced under storm conditions by strong wind induced alongshore currents. The medium diameter sand present at this site was recorded as having a median size of around 0.200mm.

Background information and location maps for both of these experiments have been presented by Owen and Thorn (1978).

In both series of experiments an instrument package was mounted on a trackway to enable the vertical structure measurements to be made starting at 0.05m above the bed. Vertical profiles of the horizontal component of velocity were obtained using a self aligning propeller current meter at Maplin and at Boscombe from a 2 axis electromagnetic current meter (EM), oriented to obtain both the cross shore and alongshore components of velocity. The corresponding suspended sediment concentration profiles were obtained with a pump sampler device. The sand fraction concentrations (sediment larger than 0.04mm) were determined in  $\text{mg l}^{-1}$  as the dry mass of sediment contained in the volume of water that was sampled (20 litres).

Waves at Maplin were measured by a Waverider buoy sited 900m to the east of the tower and at Boscombe by the output from a pressure transducer mounted 1.25m above the bed. The wave velocity  $W$  at Maplin was calculated from the Waverider data and at Boscombe directly from the EM record.

At Maplin only mean velocities were recorded, averaged over 100 seconds, whilst at Boscombe waves and currents were sampled at 4Hz with record lengths of 1 minute or more.

### 3. HYDRODYNAMICS

The results of the flow measurements obtained from both experiments will be discussed further below.

#### 3.1 Maplin data

The velocity measurements taken at this site have allowed the form of the velocity profile through the tidal cycle to be determined at half hourly intervals. An example of the data are plotted in Figure 1a (no waves) in which the numbers at the tops of the profiles indicate the chronological order through the deployment. The negative current velocities, on this and subsequent graphs, represent the measurements made on the flood tide and the positive values correspond to the ebb. The current speed has been assumed to be constant above the height of the topmost measured point and the top of each line has been plotted as to represent the water surface at the time that profile was measured. The locus of points thus formed provides a trace of the water level through the tide, varying by more than 4m, and shows the out of phase relationship between tidal amplitude and tidal currents typical of many estuaries (Dyer, 1973). On the whole the sequence of velocity profiles are well behaved and exhibit the characteristics of a tidal oscillatory

boundary layer, with a mass flow asymmetry in the flood direction.

Similar datasets were obtained on 25 subsequent deployments during which wind waves were present. A detailed analysis of the velocity profiles allows for some influence of the waves on the current structure to be determined but these details will not be discussed any further here.

For practical purposes, however, Soulsby (1990, figure 10 and equation 23) has shown that an empirical current velocity profile appears to provide a reasonable approximation to the vertical structure of the tidal current for a number of estuary and continental shelf sites. The function is a modified version of the 1/7 power law, with constant velocity above mid depth

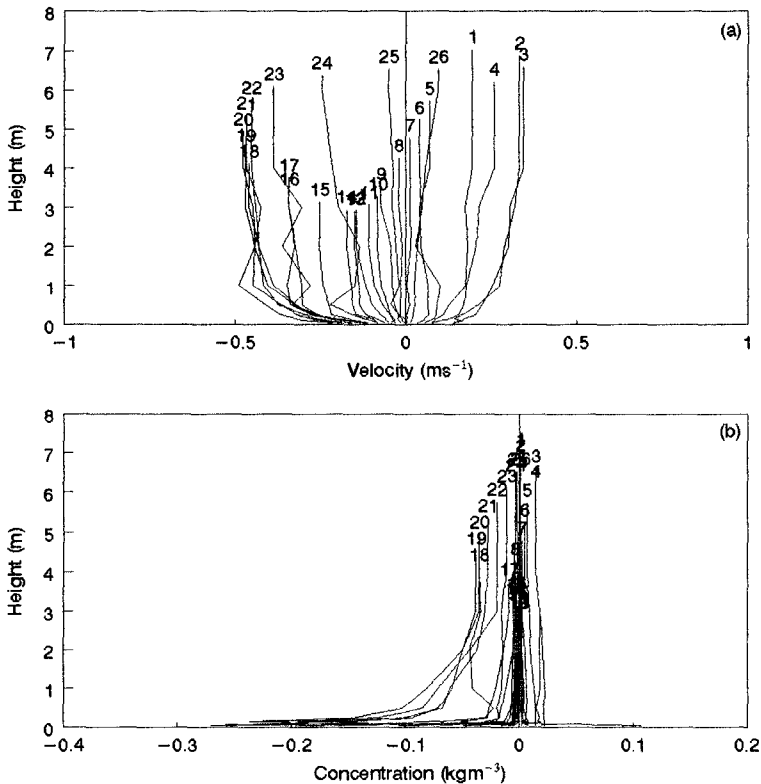

Figure 1. The evolution of (a) the tidal current velocity profile and (b) the sand concentration profile at Maplin Tower through a spring tide with no wave action (1 November 1973). Profiles 1-1 to 1-26

(Equation 1). The height above the bed  $z$  is non dimensionalised with the water depth  $h$  and the current velocity  $V_z$  at height  $z$  with  $V$ .

$$V_z = \left( \frac{z}{0.32h} \right)^{1/7} V \quad 0 \leq z \leq 0.5h \quad (1a)$$

$$V_z = 1.07V \quad 0.5h \leq z \leq h \quad (1b)$$

Five sets of profile data both with and without waves and for flood and ebb tides have been plotted with the empirical function in Figure 2 which confirms the form of Equation 1 on average. The data correspond to measurements made near to the peak excursion of the tidal velocity amplitude (Table 1). Although this profile shape will be unlikely to hold at times around slack water it can be used to approximate the vertical current structure for a large proportion of the tide.

### 3.2 Boscombe data

The EM data provide information both on the vertical structure and on the temporal variation in the velocity field for 26 deployments of the instrument package. An example of the time series data from Boscombe is plotted in Figure 3 showing the variation of the water surface elevation due to the passage of waves in 4.23m of water and the corresponding near bed velocities. The waves in the trace are typical of surf zone conditions producing the characteristic periodicity in the cross shore ( $x$ ) velocity. The record for the  $y$  component of velocity depicts the turbulent alongshore current and that for the resultant velocity is mixed accordingly.

The vertical structure data at this location does not conform to the function employed in Figure 2. Above the bottom 5 or 10% of the water

Table 1. Physical parameters for velocity profiles displayed in Figure 2

Data	Velocity $V$ ( $\text{ms}^{-1}$ )	Wave velocity $W$ ( $\text{ms}^{-1}$ )	Water depth $h$ (m)	Tide
1-3	0.303	0.000	6.59	ebb
2-12	0.251	0.038	7.30	ebb
1-22	0.422	0.000	5.75	flood
4-1	0.440	0.110	7.60	flood
5-7	0.656	0.091	5.03	flood

column the time averaged current velocity becomes approximately equal to the depth averaged value, at least to the height of the measured data which is equivalent to about 70% of the water depth for most cases. The data also indicate a veering of the velocity vector through the water column.

#### 4. SEDIMENT DYNAMICS

The time averaged sediment concentration measurements will be discussed below for both experiments.

##### 4.1 Maplin data

As with the velocity profile measurements the temporal variation in the vertical sand concentration profiles at this site with no wave action can be visualised (Figure 1b). For convenience, the data have been plotted in the same form as the velocity data in Figure 1a. Some interesting features can be observed by following the chronological sequence through the tide from slack water, profile 8.

The concentrations remain low for small flood (negative) velocities but increase markedly as the current velocity exceeds  $0.3\text{ms}^{-1}$  (profile 16), the concentration at  $0.05\text{m}$  increases from  $0.045\text{kgm}^{-3}$  at profile 16 to  $0.196\text{kgm}^{-3}$  at profile 17. Although the magnitude of the velocity has not changed

Figure 2. Comparison of selected Maplin Tower velocity profile data with the empirical function presented by Soulsby (1990)

appreciably in the half hour interval between these two observations the magnitude of the near bed sand concentration has increased by a factor of 4. The near bed concentration reaches an equilibrium at profiles 18 to 21, equal to about  $0.270\text{kgm}^{-3}$ .

Thereafter, and for the ensuing ebb tide, the near bed concentrations decrease rapidly due to the downward settling of the sand in suspension until a near vertically uniform distribution is achieved. No significant additional sand entrainment takes place on the ebb tide with the depth averaged velocity not exceeding  $0.3\text{ms}^{-1}$ . The data provide clear evidence to support the use of a threshold velocity for the entrainment of sand into suspension, for the lag in the response of the concentration profiles with increasing flow velocity and for a hysteresis in the velocity concentration correlation.

The influence of waves on the flood tide concentration profiles can

Figure 3. Time series records from the surf zone at Boscombe for: (a) the water surface elevation expressed in m of water and, (b) the x (stippled line) and y (dashes) components of fluid velocity and their resultant (solid line). The velocity measurements were taken at 0.05m above the bed starting at 1523hrs on 15-11-1978. The mean water level on (a) was at 2.98m.

be seen in Figure 4 for similar values of velocity  $V$  and water depth, one for the current alone case and one with wave activity ( $W=0.072\text{ms}^{-1}$ ,  $T_2=2.8\text{s}$ ). Under wave enhanced conditions ( $W/V=0.214$ ) the near bed sand concentration is increased by a factor of 2.7 over the current alone case due to the stirring action of the waves. Additional turbulence diffusing up from the wave boundary layer serves to enhance the sediment load and both factors produce an increase in the depth integrated flux of sand  $q_+$  (see Section 6) by a factor 1.3.

4.2 Boscombe data

The sediment concentration measurements at Boscombe relate only to w+c conditions. Vertical profile data are presented in Figure 5 for two different wave dominated conditions with similar values of the current velocity, water depth and wave period, about 6.5 seconds, but different wave heights  $H_s$ . Under the larger wave conditions the near bed sediment concentration is enhanced by more than a factor of 10 and the magnitude of  $q_+$  by a factor 6.2 above that for the smaller wave case.

Nielsen (1979) has shown in laboratory measurements that the magnitude of the near bed concentration under waves is a function of the bottom boundary layer and independent of breaker type. However, under broken waves in the surf zone there will be two contributions to the turbulence field, one from the wave boundary layer and a second from the downwards dissipation of surface generated turbulence contained within the broken wave as discussed, modelled and verified with experimental data by

Figure 4. Sand concentration profiles obtained from Maplin under current alone and wave enhanced conditions

Deigaard et al. (1986). At Boscombe the contribution of surface turbulence to supporting the suspension will be appreciable.

For similar values of the current velocity, the data presented in Figure 5 show that an increase in the magnitude of the near bed concentration is produced by the addition of the stronger wave component. The additional contribution to the turbulence energy field from the broken wave, the relative strength of which is symbolised by the ratio  $H_s/h$ , will be important in defining the suspension profiles. This particular case is complicated by the differences between the median grain sizes of the two suspension profiles.

**5. SEDIMENT ENTRAINMENT**

The relationship between the flow conditions and the near bed sediment concentration will now be considered. Sand concentration data measured at a height of 0.1m above the bed has been used for both experiments to enable a comparison to be made, denoted  $C_{0.1}$ .

**5.1 Maplin data**

The data for the variation of  $C_{0.1}$  with the depth averaged current velocity have been plotted in Figure 6. To enable the effect of the waves on the concentration to be viewed the data have been banded in terms of the wave velocity  $W$ . Current alone measurements are plotted as  $W=0$  and are indicated by the thick black line, the other data are plotted for increasing values of  $W$ . The measurements clearly show the effect that waves have in

Figure 5. Sand concentration profiles obtained from Boscombe under two different wave dominated conditions

enhancing the near bed sand concentration over a wide range of current velocities.

In some cases, however, the sand concentration is reduced below its current alone value over the range of measured current alone values ( $V < 0.5 \text{ ms}^{-1}$ ). This is not surprising given the potential for scatter in sediment transport measurements. Van Rijn (1984), for example, reports the results of an earlier analysis of well controlled steady flow flume measurements in which he found deviations in the measured total load transport rate by up to a factor of 2 for similar conditions. It is concluded that the overall trend of the data presented in Figure 6 is encouraging.

## 5.2 Boscombe data

Whitehouse (1991) reported that the near bed concentration of sand was correlated more closely with the magnitude of the wave velocity  $W$  than with the current velocity  $V$  which had been found at the Maplin site. Here we have plotted the  $C_{0.1}$  data from Boscombe in Figure 7 on the same axes as the Maplin data in Figure 6 and banded in the same fashion.

Although a direct comparison of the two data sets cannot be made, because we do not have any current alone data from this site with which to

Figure 6. The variation in  $C_{0.1}$  the sand concentration at 0.1m above the bed with current velocity  $V$  at Maplin (all data), banded in terms of the wave velocity amplitude  $W$  ( $\text{ms}^{-1}$ )

assess the grain size difference at the two sites, the larger wave velocities produce higher concentrations of sand near to the bed for a given value of  $V$ . However, the large wave orbital velocities at this site do appear to have a dominant effect in determining the entrainment of sand from the bed.

### 5.3 Vertical mixing

Once the sediment has been entrained from the bed the  $w+c$  concentration profiles for both experiments can be approximated by an exponentially decaying concentration profile over the bottom 10% of the water column, ie constant eddy viscosity.

## 6. SEDIMENT TRANSPORT RATE

The suspended sediment transport rate was determined by integration of the sand flux profiles ( $V_z C_z$  product) through the water depth, assuming that the flux goes to zero both at the bed ( $z=0$ ) and also at the water surface ( $z=h$ ).

### 6.1 Maplin data

The sediment transport rate  $q_s$  has been plotted in Figure 8a to show the variation with the current velocity, the data has been banded in terms of  $W$ . This shows that  $q_s$  increases with increasing  $V$  and in addition that the transport rate is enhanced by the addition of waves, especially obvious for the highest range of  $W$  values. However, the scatter in the data is noticeable at

Figure 7. The variation in sand concentration at 0.1m above the bed with current velocity at Boscombe (all data), banded in terms of the wave velocity amplitude  $W$  ( $ms^{-1}$ )

low values of the current velocity ( $V < 1E-1 \text{ms}^{-1}$ ) with the transport rate also appearing to be reduced below the current alone value. Further investigation of the data for those periods with small current velocities is warranted, ie during which non equilibrium conditions prevail.

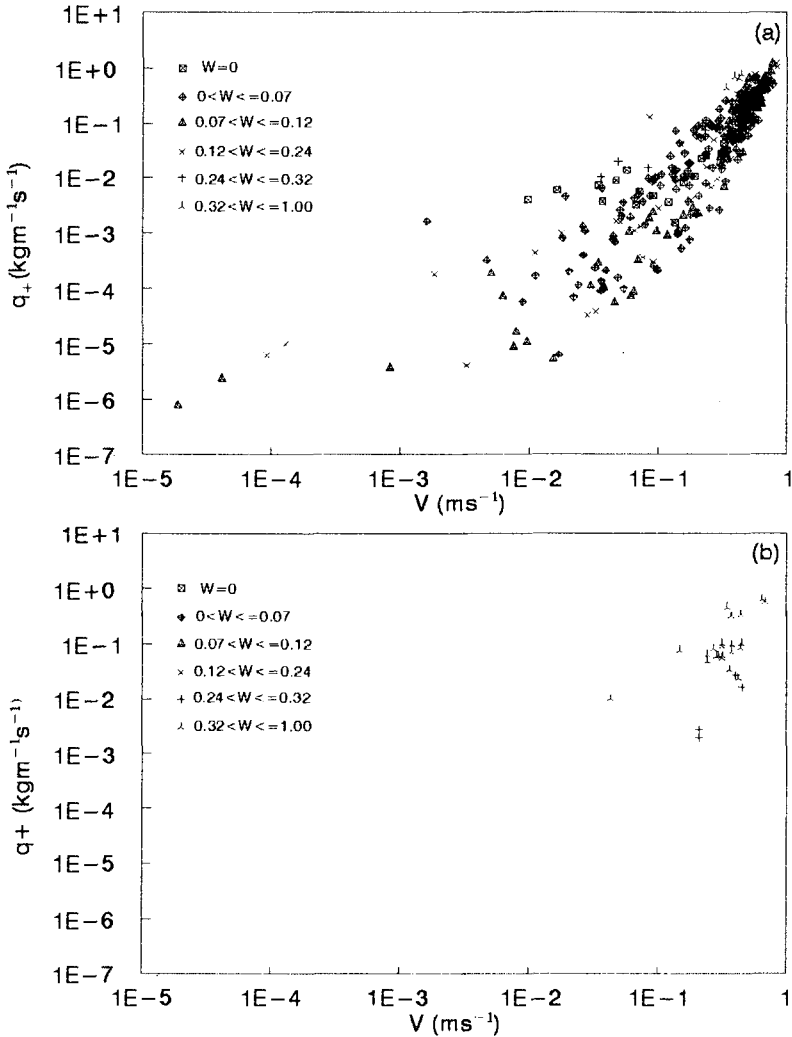

Figure 8. The relationship between the depth integrated suspended sediment transport rate and the current velocity: (a) Maplin data, (b) Boscombe data, banded in terms of the wave velocity amplitude  $W$  ( $\text{ms}^{-1}$ )

Selected data of this form have been collapsed onto a single curve using the concept of an equivalent current velocity (Grass, 1981) or a sand flux multiplier (Owen and Thom, 1978).

## 6.2 Boscombe data

The transport rate data from Boscombe have been plotted in the same axes as for Maplin (Figure 8b). The two ranges of  $W$  banded data show an increasing transport rate with increasing current velocity. However, the limited data set available at Boscombe also indicates a strong positive correlation between the wave velocity and the transport rate (Whitehouse, 1991).

## 7. CONCLUSIONS

This paper has presented the results from two field experiments performed to obtain measurements of suspended sand transport under wave and current action. The data illustrate the potential for waves to increase the near bed suspended sediment concentration above that resulting from the action of a current alone. As a consequence, more sediment is available to be mixed into the water column. This can be accomplished easily with the additional turbulence generated from the wave boundary layer and with the surface contribution to the turbulence levels from broken waves in the surf zone.

The sand transport data obtained from Maplin Sands during equilibrium periods of the tide can be used immediately in further work. The complex situation imposed at non equilibrium times in the tidal cycle, caused by the advection of suspended sand and other processes, requires an analysis in terms of more advanced physical modelling concepts.

The Maplin and Boscombe data taken in combination will be useful in enhancing the value of further analyses of  $w+c$  sediment transport because of the different environments,  $w+c$  conditions and sediment conditions covered.

## 8. ACKNOWLEDGEMENTS

The Maplin Sands measurements were made as a part of the engineering studies for the Third London Airport and the Boscombe Pier experiment was funded by the UK Department of the Environment. The original experiments were conceived and realised by Messrs M.F.C. Thorn and M.W. Owen. This analysis was undertaken as a part of the MAST G6M Coastal Morphodynamics research programme and the author would like to thank Mr P.J. Houghton and Mrs E.C. Stevenson for their contributions in analysing the raw data.

Useful comments were received from Mesrres R.L. Soulsby and M.W. Owen and from the University of Liverpool (Civil Engineering Department) during the analysis. The work was funded in part by the UK Ministry of Agriculture, Fisheries and Food, and in part by the Commission of the European Communities Directorate General for Science, Research and Development under Contract No MAST 0035-C.

## CHAPTER 196

### Numerical Simulation of Pocket Beach Formation

Takao Yamashita<sup>1</sup> and Yoshito Tsuchiya, M.ASCE<sup>2</sup>

#### Abstract

The numerical model for three-dimensional beach change prediction is constructed to simulate a pocket beach formation. The model consists of three modules of waves, currents (include beach change) and sediment transport. Wave transformation module is based on the mild slope equation of hyperbolic type, current module is horizontally two-dimensional with direct interaction with sea bottom change which is evaluated by sediment transport model formulated by Bailard.

Numerical simulation of pocket beach formation was performed under two conditions of an artificial pocket beach formation which is the typical case of beach stabilization by headlands and an empirical pocket beach which is made by combining an equilibrium bay and beach profile.

#### 1. Introduction

Beach erosion control by constructing a series of stable pocket beaches, the headland defense works by Silvester(1972), seems to be one of the effective methods to recover sandy beaches in the area which has been seriously eroded due to both reducing longshore sediment transport and increasing offshore going sediment transported by reflected waves from the sea wall. "Stabilization of Sedimentary Coastlines" is the title of Silvester's paper in Nature(1960) and "Use of Crenulate Shaped Bays to Stabilize Coasts" is the title of paper in the proceedings of 13th ICCE(1972). As can be recognized from these titles, this method is based on the idea of stabilizing beaches with pocket beach formation. Thirty years after Silvester, beach stabilization seems to be a word in vogue and the headland defense works has been recognized as a feasible way to protect sandy beaches in

---

<sup>1</sup>Instructor, Disaster Prevention Research Institute, Kyoto University, Gokasho, Uji, Kyoto 611, Japan

<sup>2</sup>Professor, ditto

place of offshore detached breakwaters which thickly parasite on Japan's eroded beaches.

Following Silvester's frontier works, studies on mechanism of beach stabilization by forming pocket beaches (crenulate-shaped or zeta-shaped bays) have been carried out by several researchers. Hsu et. al.(1987) formulated bay shaped in terms of the 2nd order polynomial. Tsuchiya et. al.(1990) classified a pocket beach into two types of statically and dynamically stable beaches. Theoretical explanation of the existence of statically and dynamically stable pocket beaches has been done by Tsuchiya and Refaat(1990) in terms of the one-line theory with nonuniform longshore sediment transport model.

This study aims to simulate an artificial pocket beach formation by the numerical model for three-dimensional beach change prediction, in which knowledge of wave theory, nearshore dynamics, shoreline change model and sediment transport model are integrated. First numerical model is constructed and then simulation of pocket beach formation is performed under the condition of typical case of stable beach construction by headlands.

## 2. Model Outline

### 2.1 Wave Transformation

The steady state mild slope equation of the elliptic type including terms of uniform currents( $\vec{U}$ ) interaction and wave energy dissipation due to breaking is employed to calculate wave field.

$$\frac{D^2\phi}{Dt^2} + (\nabla \cdot \vec{U}) \frac{D\phi}{Dt} - \nabla \cdot (CC_g \nabla \phi) + (\sigma^2 - k^2 CC_g - i\sigma W)\phi = 0 \quad (1)$$

where  $\phi$  is the velocity potential and the derivative operator is defined as  $D/Dt = \partial/\partial t + U_j \partial/\partial x_j$  (Kirby 1984).

Wave energy dissipation rate  $W$  formulated by Izumiya & Horikawa(1984) is employed here. Using the complex surface elevation  $\zeta$ , the mild slope equation can be written as:

$$\left\{ 1 + \frac{\sigma}{\omega} \left( \frac{C_g}{C} - 1 + \frac{i}{\sigma} W \right) \right\} \frac{\partial^2 \zeta}{\partial t^2} + \frac{\partial}{\partial t} (\nabla \cdot (\vec{U} \zeta)) - \nabla \cdot \left\{ \omega CC_g \nabla \left( \frac{\zeta}{\sigma} \right) \right\} = 0 \quad (2)$$

where  $\omega$  and  $\sigma$  are the absolute and intrinsic angular frequencies, respectively with the following relation

$$\omega = \sigma + \vec{U} \cdot \vec{k}, \quad \sigma = \sqrt{gk \tanh kh} \quad (3)$$

and the wave celerity and group velocity are defined respectively by

$$C = \frac{\sigma}{k}, \quad C_g = \frac{\partial \sigma}{\partial k} \quad (4)$$

For effective numerical calculation, an equivalent hyperbolic system to the elliptic mild slope equation (2) can be derived as : (Warren et. al., 1985; Madsen and Larsen, 1987; Yamashita et. al., 1990).

$$\frac{\partial P}{\partial t} - i\omega P + \omega CC_g \frac{\partial}{\partial x} \left( \frac{S}{\sigma} \right) = 0 \quad (5)$$

$$\frac{\partial Q}{\partial t} - i\omega Q + \omega C C_g \frac{\partial}{\partial y} \left( \frac{S}{\sigma} \right) = 0 \tag{6}$$

$$\frac{\partial P}{\partial x} + \frac{\partial Q}{\partial y} + \frac{1}{\omega} \left\{ 1 + \frac{\sigma}{\omega} \left( \frac{C_g}{C} - 1 + \frac{i}{\sigma} W \right) \right\} \left( \frac{\partial S}{\partial t} - i\omega S \right) + \vec{U} \cdot \nabla S = SS \tag{7}$$

where  $S, P,$  and  $Q$  are the surface elevation and line discharges in the  $x$  and  $y$  direction and  $SS$  is the wave source which is given as

$$SS = \frac{C \Delta s}{\Delta x \Delta y} a_0 e^{i\chi} \tag{8}$$

where  $\chi$  is the phase,  $a_0$  the wave amplitude,  $\theta$  the wave angle and spacial increments are defined  $\Delta x, \Delta y,$  and  $\Delta s = \Delta x / \cos \theta$  respectively.

The sponge layer boundary condition (Larsen and Dancy, 1983) is effective behind the wave source boundary and along the shoreline. An artificial dumping is introduced inside sponge layer of which dumping coefficient  $\mu(x)$  is given by,

$$\mu(x) = \begin{cases} \exp\{ (2^{-x/\Delta x} - 2^{-x_s/\Delta x}) \ln \alpha \} & \text{for } 0 \leq x \leq x_s \\ 1 & \text{for } x_s \leq x \end{cases} \tag{9}$$

where  $x_s$  is the thickness of sponge layer,  $\alpha$  the parameter being dependent on  $x_s$ . This set of equations can be solved numerically by the ADI method.

### 2.2 Sediment Transport Model

The sediment transport rate  $q_i$  can be evaluated by the model of Bailard(1982), which was calibrated by Stive(1986), in which the sediment transport rate  $\vec{q}$  consists of bed-load and suspended-load including the effects of wave asymmetry (suffix  $as$ ), mean currents (suffix  $nc$ ) and bottom slope (suffix  $sl$ ). The total sediment transport vector is calculated by,

$$\vec{q} = \frac{1}{(\rho_s - \rho)g(1 - \lambda)} (\vec{q}_{asb} + \vec{q}_{ass} + \vec{q}_{ncb} + \vec{q}_{ncs} - \vec{q}_{slb} - \vec{q}_{sls}) \tag{10}$$

where

$$\begin{aligned} \vec{q}_{asb} &= \frac{9B_b u_{orb}^4 \cos \phi_2}{C \sinh^2(kD)} \vec{i}, & \vec{q}_{ass} &= \frac{9B_s u_{orb}^5 \cos \phi_2}{5\pi C \sinh^2(kD)} \vec{i} \\ \vec{q}_{ncb} &= \frac{3B_b u_{orb}^2}{2} \vec{U}, & \vec{q}_{ncs} &= 6.4B_s u_{orb}^3 \vec{U} \\ \vec{q}_{slb} &= \frac{1.6B_b u_{orb}^3}{\tan \psi} \frac{\partial D}{\partial x} \vec{i}, & \vec{q}_{sls} &= \frac{8\epsilon_s B_s u_{orb}^5}{w_f} \frac{\partial D}{\partial x} \vec{i} \end{aligned} \tag{11}$$

where  $\vec{i}$  is the unit vector,  $\theta$ : the wave direction,  $u_{orb}$ : the near-bottom orbital velocity of wave motion(linear),  $\vec{U}$ : the near-bottom mean current vector,  $\phi_2$ : the phase lag of second harmonics of the Stokes wave theory,  $\epsilon_s = 0.02, \rho_s, \rho$ : the densities of sea water and sediment,  $g$ : the gravitational acceleration,  $\lambda$ : the sediment porosity,  $w_f$ : the sediment falling velocity and  $k$ : the wave number. Moreover, the parameters for bed-load  $B_b$  and suspended-load  $B_s$  are  $B_b = \rho C_f \epsilon_b / \tan \psi$  and  $B_s = \rho C_f \epsilon_b / w_f$ , respectively. The friction factor  $C_f$  is given by,

$$C_f = \frac{1}{2}f_w = \frac{1}{2} \exp \left\{ 5.2 \left( 2.5 \frac{D_s}{a_w} \right)^2 - 6.0 \right\} \quad (12)$$

where  $D_s$  is the characteristic grain diameter and  $a_w$  the orbital amplitude.

### 2.3 Nearshore Currents and Sea Bottom Change

Momentum equations including terms of interaction with sea bottom changes ( $\partial D/\partial x_i$ ) are derived as:

$$\frac{\partial Q_i}{\partial t} + \beta U_i \frac{\partial Q_j}{\partial x_j} = -gH \left( \frac{\partial H}{\partial x_i} - \frac{\partial D}{\partial x_i} \right) - \frac{1}{\rho} \left( \tau_i^B + \frac{\partial S_{ij}}{\partial x_j} + \frac{\partial T_{ij}}{\partial x_j} \right) \quad (13)$$

where,  $\beta$ : momentum correction coefficient,  $H$ : total depth,  $D$ : still water depth,  $Q_i$  and  $U_i$  are discharges and velocities of nearshore currents,  $\tau_i^B$ : bottom stresses and  $S_{ij}$ : radiation stresses.

$$S_{ij} = \frac{\rho g}{4} \left[ \operatorname{Re} \left( \frac{\partial S}{\partial x_i} \frac{\partial S^*}{\partial x_j} \right) \frac{1}{k^2} \left( 1 + \frac{2kD}{\sinh 2kD} \right) + \delta_{ij} \left\{ |S|^2 \frac{2kD}{\sinh 2kD} + \frac{2kD \coth 2kD - 1}{2k^2} \left( \left| \frac{\partial S}{\partial x} \right|^2 + \left| \frac{\partial S}{\partial y} \right|^2 - k^2 |S|^2 \right) \right\} \right] \quad (14)$$

where  $\delta_{ij}$  is Kroneker's delta and \* indicates complex conjugate. Furthermore, horizontal mixing is formulated as

$$-T_{ji} = \rho H \left( \nu_e \cos \left( \theta + \frac{\pi \delta_{ij}}{2} \right) \left( -\sin \theta \cos \theta \frac{\partial V}{\partial x_j} + \sin \theta \sin \theta \frac{\partial U}{\partial x_j} - \cos \theta \cos \theta \frac{\partial V}{\partial x_i} + \sin \theta \cos \theta \frac{\partial U}{\partial x_i} \right) \right) \quad (15)$$

where  $\nu_e$  is the eddy viscosity estimated by velocity scale [ $u \simeq \sqrt{gH}$ ] and the length scale [ $l$ ] is the distance from the shore.

The continuity equations of water and sediment transport are given respectively by

$$\frac{\partial H}{\partial t} + \frac{\partial Q_i}{\partial x_i} = 0, \quad \frac{\partial D}{\partial t} - \frac{\partial q_i}{\partial x_i} = 0. \quad (16)$$

The sediment transport rate  $q_i$  is evaluated by the model of Bailard(1982). The finite difference ADI method is also employed to solve the nearshore currents and sea bottom changes. The one-line model is employed to predict a long-term shoreline change under the dominant wave field calculated by the wave transformation model shown in 2.1. After determining the shoreline position of a stable beach, the sea bottom topography change is calculated up to getting the equilibrium beach topography. To save CPU time, wave field is renewed several times after calculations of nearshore currents and sea bottom change.

### 3. Pocket Beach Formation

#### 3.1 Artificial Pocket Beach Formation

An initial beach topography is assumed the uniformly sloping bottom ( $s=1/23$ ) constructed by the sand nourishment in the seriously eroded beach together with the construction of two headlands (100 and 50m long each) and groin system (see Figure 1). This beach is called an artificial pocket beach in this paper, of which dimension is typical in the headland defense works (beach stabilization works) under construction or planning in Japan's eroded coasts.

Figure 1. Initial beach topography

Operating the dominant incident waves ( $T=8s$ ,  $H=2m$ ,  $\theta=8^\circ$  are assumed here) and computing the stable shoreline position by the shoreline change model (one-line model including the effect of wave diffraction because the wave field is computed by the wave transformation model mentioned above), computations of nearshore current and sea bottom change start to obtain the statically stable topography of a pocket beach. Figures 2 (a)-(d) show the computed shoreline, beach topography, wave and current fields. It can be observed from these figures that nourished sand may not go out of headlands area to form a zeta-shaped bay in the case of dominant wave operation. Because perfect wave absorption is assumed at the boundaries such as headlands, beaches and side walls, smooth wave and current fields are computed in which wave diffraction and breaking play a main role in forming nearshore circulation.

#### 3.2 Changes in Empirical Pocket Beach

In addition to the case of an artificial pocket beach formation, an attempt of an empirical pocket beach formation is conducted. Combining the formulations of

equilibrium bays (Hsu et. al., 1987) and equilibrium beach profiles, we can get the ideal stable beach topography which is called an empirical pocket beach in this paper. The stable shoreline of the pocket beach can be assumed by an equilibrium bay formulated by equation (18) (Hsu et. al.). Fixing the critical depth of beach changes, Dean's (1981) equilibrium beach profile evaluated by equation (17) is assumed along the line between shore and critical depth to determine the topography of stable beach, then we can get the stable beach topography shown in Figure 4.

(a) Computed shoreline of the pocket beach

(b) Topography of artificial pocket beach

(c) Wave field

(d) Current field

Figure 2. Artificial Pocket Beach Formation

$$h(x) = A(D_s)x^{2/3} \quad (17)$$

$$\frac{R}{R_0} = C_0 + C_1\left(\frac{\beta}{\theta}\right) + C_2\left(\frac{\beta}{\theta}\right)^2 \quad (18)$$

where the coefficients  $C_0$ ,  $C_1$  and  $C_2$  are dependent on the incident wave angle  $\beta$  and the definition of variables are shown in Figure 3.

Figure 3. Definition of variables of equilibrium bay (Hsu et. al.)

Figure 4. Topography of an empirical pocket beach

Calculations of nearshore currents and sea bottom changes are executed under the same conditions of wave and boundary as those of the case of an artificial pocket beach. Figure 5(a) shows the shoreline position calculated by equation (18) in which the length of headland is 57m. It can be recognized that both the

embayment (about 30m at  $x=140\text{m}$ ) and the salient length of 60m are almost same as artificial bay formation.

Figures 5(b) and (c) show currents and bottom topography in which no remarkable circulation cells except behind headland is observed and change in topography is also small. This means that pocket beach is stable against dominant waves.

#### 4. Conclusions

A finite difference numerical model for sea bottom topography change was constructed by combining a wave transformation model(steady) and a three dimensional beach change model(unsteady) in which interaction between nearshore currents and bottom change was simultaneously considered. Numerical simulation of an artificial pocket beach formation was performed by the developed model together with the shoreline change model.

Applying the model to the case of artificial pocket beach of which dimension was similar to that of headland defense works (beach stabilization works) under construction in Japan's eroded coast, it was recognized that nourished sand might not go out of headlands area.

Moreover, combining the formulations of equilibrium bays and equilibrium beach profiles by Dean the initial beach topography was assumed(it was called an empirical pocket beach in this paper). It was shown that no remarkable circulation cells except behind headland are formed and topography change was also small to confirm beach stabilization.

## CHAPTER 197

### A CRITICAL REVIEW OF AVAILABLE DATA FOR CALIBRATION AND/OR VERIFICATION OF SEDIMENT TRANSPORT MODELS

Julio A. Zyserman<sup>1</sup>

#### Abstract

A survey and a critical review of existing sediment transport data in waves and/or currents has been performed. Special emphasis has been given to the applicability of the data sets for the calibration and/or verification of sediment transport models. Only data sets dealing with non-cohesive sediment have been considered in this review. The eventual need for further experimental research is discussed under the light of the results from the present study.

#### Introduction

The increased understanding achieved in recent years of the phenomena involved in the processes of sediment suspension and transport by streams and by the combined action of waves and currents in the marine environment has led to the formulation of increasingly more detailed (and complex) sediment transport models.

In spite of this improved understanding, the intricacy of the phenomena being described and an incomplete comprehension of all mechanisms involved frequently result in the introduction of crude hypotheses into the models, assumptions that have to be validated against experimental data. Some models are based on calibration factors that can only be determined from experimental results. In other cases, an empirical approach based on measured data is the only feasible way of describing phenomena that are either too complex or poorly understood to allow for a theoretical or semi-empirical description.

The preceding discussion points out the permanent need for sediment transport data of good quality. A critical data review has therefore been performed in order to identify potentially useful data sets for the calibration and/or verification of transport models.

---

<sup>1</sup> Research Engineer, Ph.D., Danish Hydraulic Institute, Agern Allé 5, DK-2970 Hørsholm, Denmark.

### General Requirements to Experimental Data

The flow chart of a generic sediment transport model is shown in figure 1. Most sediment transport models that are provided with adequate input data (hydrodynamic, sediment, bed form and miscellaneous data), will yield the sediment transport rates as output. More advanced models may be constituted by different modules; each module aiming to describe of one or several of the phenomena involved: for example, a module to determine the vertical structure of the flow, another to calculate the turbulence levels along the water column, a third one to determine the concentration profiles of suspended sediment, etc. Output of such advanced models may therefore include information such as velocity profiles (time-mean or instantaneous), concentration profiles (time-mean or instantaneous), etc. Other models may calculate the characteristics of bed forms based on the input data provided, so bed form data can in some cases be found as output from the model.

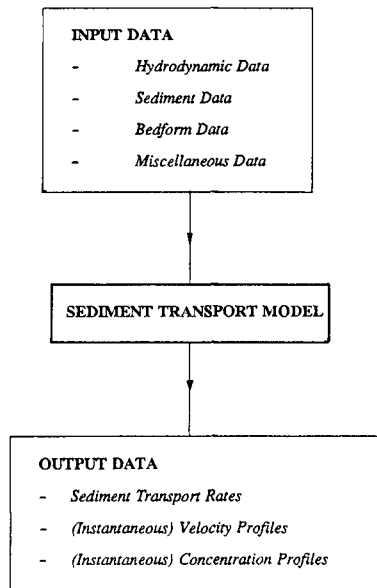

Figure 1. Flow chart of a generic sediment transport model.

It appears from the figure that the model/data interaction takes place at least at two levels, namely at the input and the output levels of the model. In the case of more complex models, the interaction could also occur at the output level of each constituent module. In order to be suitable for the purposes of calibration and/or verification of mathematical models, the data used should fulfill general and specific requirements. The general requirements will be addressed in what follows, whereas the specific ones will be discussed in the next section.

The amount of sediment transported by streams or by the combined action of waves and current in the coastal environment is determined by the complex interaction between the flow

conditions and the bed material. Enough information about all the relevant physical parameters involved should be provided to the transport model in a format suited to its particular formulation, in order to obtain an accurate characterization of the phenomena that the model intends to simulate.

Generally speaking, it can be said that the quantity of the data should be sufficient to ensure that the degree of agreement or discrepancy found between the calculated and the observed transport rates can only be attributed to the assumptions inherent to the model and not to scarce or missing information about the conditions in which the reported transport rates were determined. The data should also be of good quality, obtained under well-defined conditions and using instruments suited for the measurement of the desired magnitudes.

Another general requisite refers to the way in which the measured data is reported. Tabulated form is preferable to graphic form, since it avoids the possible inaccuracies associated with collecting values from a figure, and facilitates the process of handling the data and the supply of information to the transport model. In this connection, data on magnetic media is highly favoured, especially if they have been stored in a database, with the related advantages regarding data retrieval and search for selected ranges of one or several of the physical variables involved.

#### Specific Requirements and Classification of Experimental Data Sets

The amount and degree of detail of the data required for the calibration and/or validation of a given model depends not only on the assumptions and physical principles involved in its derivation but also on the situation the model aims to describe (transport by streams, or under combined current and waves, etc.). More complex models will require in general larger amounts of more detailed input data in order to allow for an adequate description of the phenomena under consideration. More parameters will be required in order to characterize intricate hydrodynamic conditions such as in the case of breaking waves propagating at arbitrary angles with respect to a current than in the relatively simpler situation of a steady current flowing along a laboratory flume.

One out of many possible classifications for the sediment transport data sets consists of separating between those obtained under pure-current situations and those measured in presence of waves or, eventually, in combined waves and current situations. This classification is based not only in the inherent differences between the hydrodynamic conditions but also reflects the trend usually followed when developing sediment transport models. In turn, each case can be split up into data obtained in the laboratory and data acquired in the field. Another item in the classification corresponds to the data collected in oscillating wave tunnels. These laboratory facilities are able to reproduce full-scale flow conditions (although lacking phase-differences along the tunnel and the vertical component of the wave-induced motion) under the controlled conditions of a laboratory.

The number of physical parameters required for a complete characterization of each situation depends not only on the flow condition but also on the particular sediment transport model considered. Instead of addressing a particular model formulation, it was chosen to pose requirements to the experimental data sets that were strict enough so as to ensure their suitability for the calibration and/or validation of the most advanced transport models that

are normally used, namely the deterministic-type model for sediment transport in coastal areas (see for example Zyserman et al. (1991 a) for a classification of models) and models calculating separately bed-load and suspended-load transport in the case of streams.

The requisites regarding the description of the experimental conditions and the measured transport rates vary for the different items in the classification, the major differences being, however, restricted to the characterisation of the hydrodynamic data.

The geometrical properties of the sediment can be appropriately described in any case through its median size  $d_{50}$ , other percentiles  $d_i$ , gradation  $\sigma_g$ , or, conversely, through its grading curve G.C. Another important parameter is the settling velocity  $w$ . If not specified, it can be determined if the sediment density  $\rho_s$  and the kinematic viscosity  $\nu$  or the temperature  $T$  of the water are known. The kinematic viscosity of water has been explicitly included because it is not always a function of the water temperature alone, as in the case when suspended particles of a clay-size fraction are present.

Bed forms are suitably described by means of their type, height  $h$ , length  $l$  and celerity  $a$  under all cases.

The rates of bed-load transport  $q_b$ , suspended-load transport  $q_s$  and total-load transport  $q_t$  are of course of basic interest. Concentration profiles  $c(y)$  are also important, where  $y$  is the elevation about the bottom. For measurements in water tunnels, or under combined waves and currents, the time-mean values of the transport rates  $\bar{q}_b$ ,  $\bar{q}_s$  and  $\bar{q}_t$  are of interest. Vertical profiles of time-mean concentration  $\bar{c}(y)$  and time series of the instantaneous concentration at different elevations (time series of ensemble-average concentration in the case of wave-tunnel data)  $c(y,t)$  are also relevant parameters.

In the case of pure-current flow conditions in the laboratory, the flow is adequately described if information about the dimensions of the flume (length  $L$ , width  $W$  and height  $H$ ), about the water depth  $D$ , discharge  $Q$  and/or mean velocity  $V$  and water surface slope  $I$  is provided. Additionally, vertical profiles of the horizontal velocity component  $u(y)$  could be used to check the hydrodynamic module (if any) of the model considered. The same parameters are valid to describe the flow conditions in the case of currents measured in the field, but information about the orientation  $O$  of the study reach and the cross-section  $A$  of the measuring section should be provided.

Appropriate parameters to describe the flow when considering measurements in water tunnels are the amplitude of the oscillatory motion  $a_0$  or its maximum velocity  $u_0$ , together with the period  $T$ , the discharge of the net current  $Q$  or its mean velocity  $V$ . Useful additional parameters are the vertical profiles of the ensemble-averaged velocity  $\bar{u}(y)$  and time series of the instantaneous velocity recorded at different elevation above the bed  $u(y,t)$ .

Waves plus current conditions in the laboratory can be characterized by means of the water depth  $D$ , the wave height (root-mean-square, significant, etc.)  $H_i$ , the period (peak, zero-up-crossing, etc.)  $T_i$ , the type of breaking wave (if any) and the distance to the point of breaking  $x_b$ . Information about the breaker type and the distance from the measuring position in the surf zone to the breaker line is relevant because the production of turbulence by breaking waves is usually taken equal to that of a bore or hydraulic jump. This assump-

tion may be valid in the case of spilling breakers or of breaking waves of other type in the inner surf zone, but not close to the breaking point in the case of plunging breakers. Important additional parameters are the local bed slope  $S$ , the discharge  $Q$  or the mean velocity  $V$  (when relevant), a time series of the instantaneous elevation of the water surface from which the spectrum can be determined in the case of irregular waves or, conversely, information about the spectral parameters  $\eta(t)$ . Useful additional information for the calibration/validation of the hydrodynamic module of the model (if any) is provided by  $\bar{u}(y)$  and  $u(y,t)$ .

In the case of combined waves and current in the field, the same parameters used to describe the waves and the spectrum in the laboratory can be applied. Due to the two-dimensional (in plan) nature of the problem, it is now necessary to speak about the long-shore and cross-shore components of the bed slope  $S_j$ , of the time- and depth-averaged velocity  $V_j$ , of the time-mean velocity profile  $\bar{u}_j(y)$ , and of the instantaneous velocity  $u_j(y,t)$ . Another important parameter is the angle  $\gamma$  between the current and the direction of wave propagation. Information about the beach profile  $P$  and orientation  $O$  may also be useful.

### Data Sets Reviewed

A list of the 40 data sets reviewed, arranged according to the classification discussed, is listed below. This list is by no means exhaustive, but it has been deemed that the results of their review will provide an overview of the type of data available. A more detailed description of most of the data sets can be found in Zyserman et al. (1991 b).

#### **Pure Current, Laboratory**

Barton and Lin (1955)	Guy et al. (1966)
Laursen (1957)	Lyn (1986)
Meyer-Peter and Müller (1948)	Nomicos (1956)
Stein (1965)	Vanoni and Brooks (1957)
Williams (1970)	Wang and Qian (1992)

#### **Pure Current, Field**

Anderson (1942)	Colby and Hembree (1982)
Culbertson et al. (1972)	Nordin and Dempster (1963)
Scott and Stephens (1966)	

#### **Wave Tunnel**

Hayakawa et al. (1983)	Horikawa et al. (1982)
Murray et al. (1991)	Nakato et al. (1977)
Ribberink and Al Salem (1989)	Sato and Horikawa (1986)
Sawamoto and Yamashita (1986)	Sleath (1982)
Staub et al. (1984)	Steetzel (1984)
Van der Velden (1987)	

#### **Waves (+ Current), Laboratory**

Bosman and Steetzel (1986)	Dette and Uliczka (1986)
Nap and van Kampen (1988)	Nieuwjaar and van der Kaaij (1987)
Skafel and Krishnapan (1984)	Steetzel (1987)
Vellinga (1984)	

**Waves (+ Current), Field**

Downing (1984)

Jaffe et al. (1984)

Kos'yan (1985)

Owen and Thorn (1978)

Fairchild (1977)

Kana and Ward (1980)

Nielsen (1984)

It is important to keep in mind that most of the data sets reviewed were obtained under tests not specifically aimed to the calibration and/or verification of sediment transport models, so the results of the present review must be interpreted under the light of this restriction. On the other hand, the obtention of many of the parameters required to characterize the test conditions from the point of view of sediment transport models could be done without great efforts or additional costs, and would render the data sets useful for more application than those devised when the tests were designed.

Only data sets dealing with non-cohesive sediment of sand-fraction size have been considered in the present review, with the sole exception of the bed-load transport data of Meyer-Peter and Müller, which was obtained using bed materials in the range from coarse sand to gravel.

All data sets reviewed regarding wave-tunnel measurements were obtained under simulated regular wave conditions. Only the tests of Murray et al. included a net current superimposed to the oscillatory motion.

In some cases, the experimental results were not included in the reference reviewed, but a description of the tests, the measuring techniques and the results obtained was included. The review is based on the information provided in the reference, especially in the case of data collected under large field measurement programmes. More detailed information could be possibly found in the original data sets.

**Results of Data Review**

It has been chosen to present the review in tabulated form, in order to allow for a quick interpretation of the results obtained. Tables 1 and 2 include the results for the pure current case in laboratory and the field, respectively. Table 3 refers to wave tunnel data, whereas Tables 4 and 5 deal with the waves plus current cases in laboratory and in the field.

The variables selected for the description of each case have been placed in the columns of the tables and collected in groups for hydrodynamic data, miscellaneous data, sediment data, bed form data and transport data. Information about the format in which the data is presented in the reference (tabulated (T) or graphic (G)) is also provided. Different types of bed material (both with regard to size and/or density) were used in some of the tests performed in the laboratory. This has also been indicated in the corresponding tables.

An open triangle has been used to indicate that the relevant parameter was reported for each data record of the data set, whereas a dot indicates that such information is available only for some data records. A cross means that information about the corresponding variable was not provided in the reference reviewed, but that it can be obtained from other sources,

typically related papers. Finally, an empty circle indicates that no information at all was reported on the parameter.

It can be observed upon examination of the results that, in general, data sets collected in flume experiments in the laboratory are well-documented, with good information about the hydrodynamic conditions (including velocity profiles), and satisfactory details about the sediment and bed form data. Most of those references reporting transport data do so with the total-load transport rates. The Meyer-Peter and Müller data set was intended for the collection of bed-transport data. Laursen (1957) and Guy et al. (1966) also report the suspended transport, although the manner in which it was separated from the bed-load transport differs between both references.

All the data sets reviewed under the classification of pure current in the field except that of Anderson (1942) were collected by the U.S. Geological Survey, and present therefore similar characteristics with regard to the amount and format of the information reported. All five sets provide very good details about the hydrodynamic data, although information about the discharge is missing in Anderson's data set. The bed material is defined mainly through its grading curve, and vertical profiles of velocity and concentration of suspended sediment are reported in all cases, with vertical profiles of the median grain size of suspended sediment indicated in four of them. The information about bed forms is scarce (only the type of the observed bed forms is listed) and no transport rates of any kind are reported at all, probably because of the difficulties related to the effective trapping of the sediment in the field.

The wave-tunnel data reviewed is mainly reported in graphical form. The hydrodynamic conditions of the tests are well described, but measurements of velocity profiles (both ensemble-averaged and instantaneous) are scarce. The water temperature is only reported in two cases, even though its determination is an easy task. The same applies to the grading curve of the bed material, which is mainly defined through its median size  $d_{50}$ . Measurements of the concentration of suspended sediment are also rather scarce. With regard to  $\bar{c}(y)$ , Ribberink and Al Salem, Steetzel and van der Velden measured time-averaged concentration profiles, while the other authors determined ensemble averages. Bed form data may be termed as satisfactory, whereas transport data is very scarce.

The experimental data under combined waves and current considered in the present review were obtained either from profile-evolution tests (Dette and Uliczka, Steetzel, Vellinga) or from experiments with a horizontal or sloping bed. Data is well-documented, in the sense that it is usually presented both in tabulated and in graphic form. The wave conditions and the water depth at the measuring position are well-defined, although the type of breaking waves and the distance to the breaking line are reported only in a few cases. Time-averaged velocity profiles were measured in most data sets. The sediments are described mainly through the median grain size and/or other percentiles. No grading curves are presented. All the data sets reviewed include measured profiles of time-mean concentration of suspended sediment. Neither instantaneous values of concentration nor transport rates were directly determined in any case, although the magnitude of the transport could be estimated from the time sequence of observed profile changes. Bed form data is well defined in all tests with horizontal or uniformly sloping bottom, with exclusion of the rate of migration of bed forms.

When data obtained under waves and current conditions in the field is considered, it appears that the overall quantity of information is scarce. Data are mainly presented in graphical form, with a reasonable amount of details about the local wave conditions, but are rather poor regarding the miscellaneous, sediment and bed form data. Transport data is completely missing. The lack of detailed information can of course be understood if the difficulties related to collecting data in the marine environment are recalled, especially so in the case of measurements within the surf zone.

### Conclusions

The general conclusions presented here are biased by the choice of the transport models selected when describing the particular requirements to be fulfilled by the data. Quite different conclusions may of course be reached if the results of the review are seen under the light of the requirements of transport models based on simpler principles.

It appears that information about sediment transport rates collected in pure current situations in the field is missing. This type of data is important for the verification of models developed using only laboratory data. Similar considerations apply to the characteristics of bed forms.

The total transport rate in combined wave and current motion on a plane or uniformly sloping bottom should also be determined from laboratory tests and compared to the results of similar experiments under pure current situations, in order to evaluate the influence of the waves on the time-mean transport rates.

Vertical profiles of time-mean concentration of suspended sediment were determined in most of the data sets reviewed that were obtained from wave tunnels or under combined current and waves, both in laboratory and in the field. Time-mean transport rates are missing in most cases.

The time-averaged rates of suspended transport can not be accurately evaluated by integration along the vertical of the product of time-mean concentration and velocity, due to the so-called wave-related component of the transport, which is defined as the time-average of the product of the periodic oscillatory components of the velocity and the concentration, see Murray et al (1991) and Zyserman et al. (1991 a) for a discussion. The influence of the wave-related component on the rate of suspended transport becomes more important for wave-dominated or weak-current cases.

Transport data collected from wave tunnels provide a unique possibility of evaluating the vertical structure of the wave-related component of the suspended sediment transport in real-life conditions through the measurement of the ensemble-averaged values of both the velocity and the concentration at the same position at different elevations above the bed under well-controlled test conditions. The influence of this component should therefore be evaluated for different relative magnitudes of the current-related and wave-induced velocities.

Table 5. Waves (+ Current) Situation. Field Data.

It appears that the obtention of suitable data under the combined action of waves and current in the field will require the careful planning of comprehensive survey campaigns, most probably involving the participation of a large number of researchers with interest in the different aspects related to the phenomena of sediment transport in the marine environment. In this connection, and whenever new experiments aiming to the collection of sediment transport data are being planned, the interaction between researchers and modellers can only be of mutual benefit, and would render the data sets useful for a larger number of potential users.

## CHAPTER 198

### A feasibility study of a perched beach concept in the Netherlands

Joost H.M. de Ruig<sup>1</sup>, Piet Roelse<sup>2</sup>

#### **Abstract.**

The present Dutch coastal defence policy is aimed at a full compensation of shoreline retreat, mostly by means of beach nourishment. For some parts of the coast with a small dune ridge attacked by severe erosion, a so-called 'seaward coastal defence strategy' might be more profitable. According to this strategy, measures will be taken to influence the morphological system in such a way that erosion is prevented, which will result in a stable or even progressive coastline.

An analytical policy design was chosen at the onset of the study. A number of seaward coastal defence measures will be tested following a series of selected criteria, such as effects on morphological, financial and construction aspects as well as effects on recreation and ecology. The study works from 'coarse' (entire province of Zeeland, SW-Netherlands; different coastal defence alternatives) to 'fine' (selected location; preferred coastal defence alternative). This has resulted in conclusions and recommendations with regard to the feasibility of a pilot project with a perched beach in the 'Cadzand' area.

#### **1. Introduction.**

##### **1.1 A new coastal defence policy for the Netherlands**

Major parts of the Netherlands are situated below sea level and would be flooded if there was no protection by a coastal defence

---

<sup>1</sup> Rijkswaterstaat, Tidal Waters Division, P.O.Box 20907, 2500 EX The Hague, The Netherlands

<sup>2</sup> Rijkswaterstaat, Tidal Waters Division, P.O.Box 8039, 4330 EA Middelburg, The Netherlands

system. This system consists of dunes and dikes to protect the polders and dams to close off large (former) tidal inlets. The dunes represent about 75% of this line of defence, varying in width from one hundred metres to several kilometres. They give the Netherlands its characteristic landscape and harbour unique natural values for the Northwest of Europe. They also represent an economic value: drinking water supply, recreation, industry and residential.

At present the Dutch coast is 'Delta safe'. It can withstand extreme storms and the associated water levels and waves with a frequency of 1/2000 to 1/10000 per year. This level of safety must be maintained. Constant effort is demanded, as ongoing coastal erosion causes almost half of the coastline to recede, slowly but relentlessly.

Past coastal defence was based on a problem solving policy. For large parts of the coastline, recession was tolerated: dunes underwent 'controlled retreat'. Interests and natural values in the dune area were affected to an increasing extent. Furthermore, sea dikes and other hard barriers came to protrude like bulwarks into the sea.

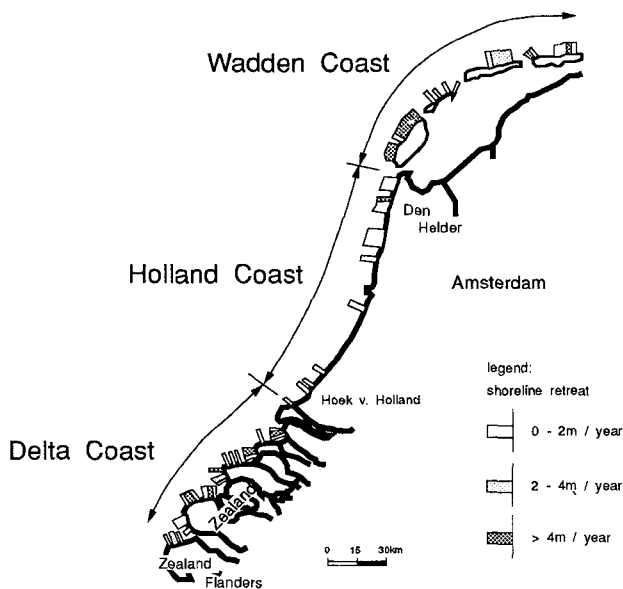

Figure 1. Pattern of erosion along the Dutch coast (Louisse & Kuik, 1990).

Coastal erosion is evident along the entire coastline: more than 50% of the dune coast suffers erosion (figure 1). A more rapid sea level rise will be felt everywhere, resulting in erosion along 80% of the sandy coastline. Not one function of the coast will be left untouched. This problem requires a reconsideration of the coastal policy. The options vary from no protection to full protection of all interests and values:

- Retreat: Coastal erosion is accepted unless polder safety is threatened;
- Selective Preservation: Special values and interests in the dune area are protected;
- Preservation: Coastal erosion is counteracted at all locations;
- Expansion Seaward: Preservation, but at some markedly eroding coastal sections with a relatively weak sea defence the coast will be reinforced by a seaward construction and natural sand sedimentation will be encouraged.

In 1990 the Dutch government made a choice for the 'preservation' alternative, which implies that the coastline will, at the least, be preserved at its 1990 position: all structural erosion will be counteracted (Ministry of Transport, Public Works and Water Management, 1990; Louisse & Kuik, 1990).

## 1.2 Dynamic preservation

By nature, the coastline of a dune coast is not fixed at one single position. Choosing for 'preservation', some allowance should be made for movements of the coastline. At some locations more aeolian dynamics (sand drifts, blow-outs, mobile dunes) will be permitted and so-called 'slufters' (wet dune valleys influenced by the tides) can be formed.

By lending the 'preservation' alternative a certain degree of dynamics, the charm and quality of the natural coasts will be safeguarded: 'preservation' changes into 'dynamic preservation'. The choice for sand nourishments, a 'soft' coastal defence method, as the major means to defend the coast is in line with this philosophy.

## 1.3 Seaward coastal defence strategy

Some parts of the Dutch coast are facing extreme erosion as well as very poor safety reserves. For these locations the application of the 'expansion seaward' alternative can be more profitable or (in time) even necessary, for instance with respect to sea level rise.

This approach is roughly investigated as the 'seaward coastal defence strategy'. According to this strategy, additional measures will be taken to influence the morphological system in such a way that the coastline will not erode any longer, but be kept in

place or even grow in a seaward direction. The effectiveness of this approach has to be compared with maintenance by beach nourishment, as well as the effects it will have elsewhere on the morphological system, nature and other interests (Pluijm, 1990).

#### 1.4 Feasibility study: working from 'coarse' to 'fine'

The difference between the several morphological systems along the Dutch coast makes it impossible to suffice with one seaward solution. In order to gain more insight into these possibilities, plans have been worked out for the most vulnerable locations.

There are two main reasons to realize these plans within the framework of a feasibility study:

- the choice for beach nourishment as the general way to keep the coast-line in its place; along each kilometre of the coast this will be the reference for other coastal defence measures;
- in principle, the effects of seaward constructions on the morphological system, nature and other interests are unknown.

The aim of the feasibility study is to select locations in Zeeland (province in the southwest of the Netherlands) where:

- in practice beach nourishment cannot stop the structural erosion, or:
- (in time) the costs of combating erosion for a seaward approach are less than for beach nourishment, and if so:
- the possible seaward construction will not have any severe negative effect elsewhere.

A stepwise working method is used in this feasibility study. That is, we work from 'coarse' (large scale: entire province of Zeeland; different coastal defence alternatives) to 'fine' (small scale: selected location; preferred seaward construction). This intention is reflected in the headings of the following chapters.

## 2. Possibilities for seaward coastal defence in Zeeland.

### 2.1 The Zeeland coast: an introduction

The Dutch coast is composed of three major units. In the south the Delta coast, consisting of (former) deltas and islands; between Hoek van Holland and Den Helder a stretch of coast not interrupted by tidal inlets (the Holland coast); and in the north the Wadden coast, consisting of series of coastal barrier islands with tidal inlets in between (see figure 1).

The province of Zeeland lies entirely within the Delta area. Its defence system is composed of dunes and dikes, which protect the

polders and dams which close off large estuaries and basins and which have been constructed during the last decades ('the Delta works'). The implementation of these works has induced major changes in hydraulic conditions and the geomorphology of the former ebb tidal deltas (Mulder et al., 1990). Although the shoals in the ebb deltas protect the coast against severe wave attack, the shifting of deep tidal channels causes much erosion. Along these channels very steep shorefaces and small beaches occur, with only little space available for nourishment. Most of the coastal sections with narrow dune ridges are protected with groynes to reduce the coastline withdrawal.

One of the estuaries in the Delta area, the Western Scheldt, is still open, being the shipping entrance to Antwerp. The estuary mouth is an active system of bars and gullies, with important impacts in the form of coastline undulations on the adjacent coastal stretches of Walcheren en Zeeland Flanders (figure 2).

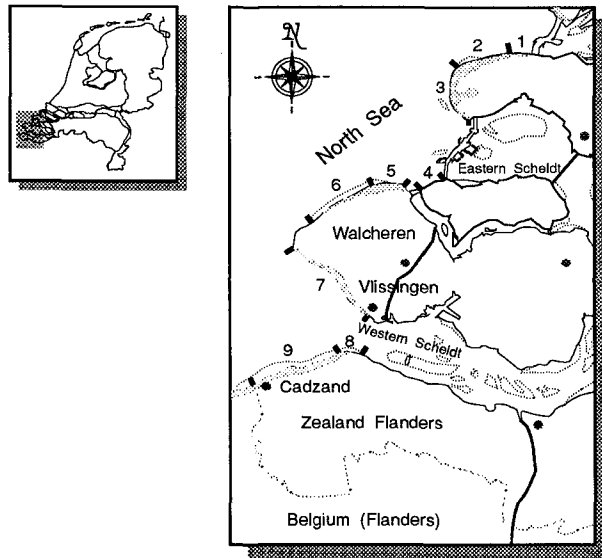

Figure 2. Division of the Zeeland coast used in the feasibility study.

## 2.2 Method

Due to the differences in morphology of the coastal zone and shoreface, the Zeeland coast has been divided into nine sections (figure 2). In this way, the necessity of a seaward defence could be determined for each section.

Ten coastal defence constructions were selected, including large dams perpendicular as well as parallel to the coastline, artifi-

cial channel shifting and perched beaches. Seven of these constructions are illustrated in figure 3.

Coastal erosion is the result of the boundary conditions of waves and tide and the resistance of the coast to these conditions. Some of the selected measures, for instance breakwaters, will act like a screen and diminish the incoming wave height. In the problem area these constructions give rise to good results. Usually, this induces a shortage of sand somewhere else, which will diminish the overall gain. Other measures will raise the resistance temporarily (beach nourishment) or permanently (shoreface protection). A perched beach shows both principles.

Figure 3. Coastal defence structures used in the feasibility study.

For each coastal section these measures were tested for different criteria and scored within a matrix (Maranus et al., 1990):

- effectiveness;
- effects on other functions and values in the coastal zone;
- costs (initial and maintenance); nullification of capital;
- flexibility and stability;
- consequences for coastal management;
- risk.

Each judgement was based on a rough estimation of the consequences a measure should have for a concerned criterion. For the purpose of the first step in a feasibility study, this seems sufficient.

### 2.3 Results

The method used selects the most promising measures for each coastal section. The necessity to intervene, however, varies and depends on the erosion rate. Both elements combined resulted in three coastal defence measures which could be more effective than beach nourishment. Among them, a perched beach concept for the coasts of SW-Walcheren and Zeeland Flanders was considered for further study.

### 3. A perched beach: theory, effects and experiences.

In general, a perched beach construction consists of a coast parallel dam (breakwater) with a sand nourishment at the landward side of it. Sometimes the nourished beach has been closed off at its extremities by groynes or large dams. In Japan and the U.S.A. it is considered as a new phase in coastal defence systems. It is based on the concept that a 'plane', rather than a 'linear structure', is able to protect the shore effectively (figure 4; Arai & Tamura, 1987; Sawaragi, 1988). The dam and the nourished beach gradually absorb the wave energy, giving the beach a more stable equilibrium profile, resulting in less erosion. The coastal defence system is strengthened and the beach is widened, which gives opportunities for recreation.

Figure 4. Evolving coastal defence: from 'linear protection system' to 'plane protection system' (after Arai & Tamura, 1987).

During the last decades some experience has been acquired with perched beaches, especially in the United States and Japan. The construction was applied with varying success. Besides the mentioned benefits, some disadvantages became clear:

- development of scour holes on either side of the dam (Sawaragi et al., 1988; Delft Hydraulics, 1990; Franco, 1990);
- blocking of natural beach nourishment during fair weather periods (Douglass & Weggel, 1987);
- possible danger for swimmers and small boats;
- high investments (with respect to beach nourishment).

#### 4. Seaward coastal defence in Zeeland Flanders.

##### 4.1 Defence alternatives

The coast of Zeeland Flanders is bordered by the main tidal channel of the Western Scheldt estuary, the Wielingen (figure 5). During the last centuries, widening and southward displacement of the channel induced a great loss of land.

Today, the 15 km long coastline and adjacent dikes and small dune ridges are defended by 85 groynes, each with a length of about 200 to 300 m. and a spacing of 100 to 300 m.

The shoals in the ebb delta protect the coast against severe wave attack; the maximum yearly significant wave height is about 3 m. The mean tidal difference reaches 3.7 m. Close to the shore, the maximum flood and ebb current amounts to 1.0 - 1.2 m/s.

Figure 5. Zeeland Flanders.

The presence of the Wielingen dominates the coastal evolution. Up till now it caused a continuous regression of the coastline, in spite of the intense coastal defence. Superimposed, we find a second order long-term fluctuation caused by so-called 'sand waves' (Verhagen, 1989;), resulting in a pattern of periods with sedimentation and erosion (figure 6).

Nowadays, the most vulnerable section of the coast lies in the neighbourhood of the Tienhonderd Polder (figure 5). The small beach is bounded by a steep shoreface and is influenced by continuous erosion since 1960. The narrow dune ridge shows poor safety reserves. Further study on seaward coastal defence structures is focused on this part of Zeeland Flanders.

Figure 6. Tienhonderd polder, Zeeland Flanders: Patterns of sedimentation and erosion.

For Zeeland Flanders, the first step in the feasibility approach selected a perched beach concept for further study (2.1). This concept is at the centre of the next step of this strategy. Two perched beach variants are considered. Beach nourishment, as the main coastal defence measure in the present policy, is the reference. For the present, it is assumed that nourishment can indeed counteract the erosion. Other well tried or far reaching possibilities have also been taken into account, which results in the following list of measures (figure 7):

- perched beach (small);
- perched beach (medium);
- large coast parallel dam/breakwater;
- large dam perpendicular to the coast;

- shoreface protection;
- beach nourishment.

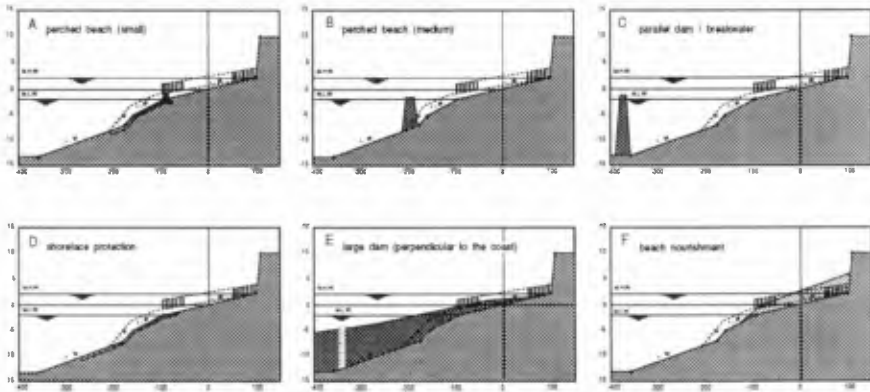

Figure 7. Tienhonderd polder, Zeeland Flanders: Possible coastal defence measures.

#### 4.2 Criteria

As in chapter 2.1, each measure has been tested for several criteria. In fact they are about the same, but testing is done with more detail. Important conditions were the effectiveness of the construction and the future erosion rate. The effectiveness was defined as the percentage of the overall erosion stopped by the construction in question. Every measure except the large dam perpendicular to the coast needs additional sand nourishments to fully counteract the structural erosion.

Indirectly, the initiation of scour holes and lee side erosion also determines the effectiveness to a high degree. Far reaching constructions such as large dams score negatively from this point of view.

The maintenance costs are directly deduced from the future erosion rate. In fact, this rate is unknown. The prediction, consisting of several variants, was based on extrapolation of the first order coastline regression and the superimposed sand waves. In general, it is expected that erosion will continue for another 30 to 40 years (figure 6). Rates of sea level rise higher than the present will lengthen this period.

The resulting costs, including additional nourishments based on the assumed future erosion rate, are brought together in table 1. It can be concluded that a large dam parallel to the coast and a medium sized perched beach cannot compete with the other coastal defence alternatives.

Table 1. Prediction of the total costs for each coastal defence alternative (Tienhonderd Polder, Zealand).

measure	costs (million dutch guilders)
beach nourishment	11 - 16
perched beach (small)	10 - 14
perched beach (medium)	16 - 19
large coast parallel dam / breakwater	48 - 58
shoreface protection	10 - 13
large dam perpendicular to the coast	14 - 15

Especially the greater constructions will influence the recreational and ecological values of the coastal area. Both threats and possibilities will develop. It is not always clear which will dominate.

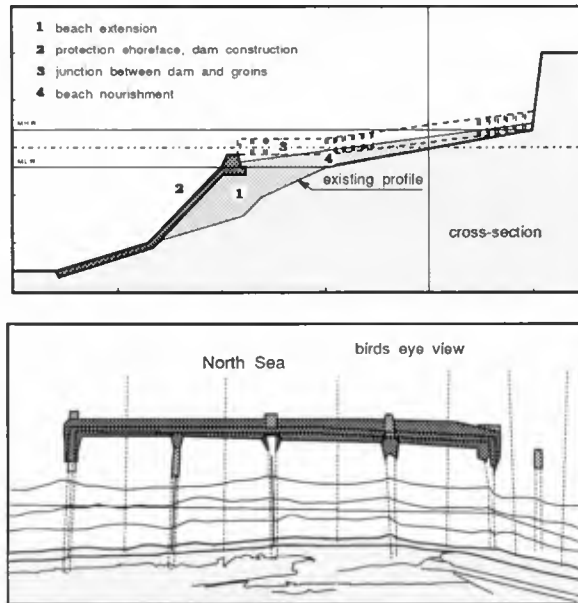

Figure 8. Tienhonderd polder, Zealand Flanders: Preferred perched beach concept.

#### 4.3 Preferred coastal defence construction

Considerations of the different aspects as mentioned above culminated in a preferred perched beach concept as shown in figure 8. In fact, the strong points of a perched beach, sand nourishment and shoreface protection are combined. First, the beach is extended in a seaward direction by means of a nourishment and will approximate his (stable) equilibrium profile. Protection of the shoreface and the construction of a small breakwater connected with the already existing groynes will conserve this situation. Erosion of the shore-face will be prevented and the landward migration of the tidal channel blocked. Finally, a complementary beach nourishment will create a perched beach. Most of this special perched beach construction is made out of sand. This yields profits from the point of view of costs and flexibility.

### 5. Perched beach concept for Zealand Flanders.

#### 5.1 Location and dimensions

The presence of the Wielingen dominates the coastal evolution. Sand losses (about  $20 \text{ m}^3/\text{m.jaar}$ ) from the coastal section of the Tienhonderd Polder are caused by seaward cross shore transport. Rip currents play an important role in this process. The sand drops into the tidal channel and is transported into the the Western Scheldt estuary.

It is expected that the perched beach construction will diminish the cross shore loss of sand and stop the landward migration of the Wielingen. The most suitable location for the breakwater and additional shoreface protection, therefore, seems to be the edge of the tidal channel. A more landward location of the breakwater will have less effect in reducing the erosion rate.

Figure 9. Effect of the perched beach construction (without additional sand nourishment) on the position of the coastline after 3 years (Delft Hydraulics, 1991).

Model computations reveal that the concept will act as an effective coastal defence measure. However, scour holes could develop at the landward side of the dam, which can reduce the effectiveness of the construction. Further study can quantify this problem. The feasibility study shows that after the construction of the perched beach sand nourishment, albeit much less in quantity, will remain necessary until about the year 2030.

The length of the coastal section with severe erosion determines the length of the construction, e.g. almost 900 metres.

As stated, the main purpose of the perched beach is to reduce the sand losses in cross shore direction. This does not mean that the long shore transport of sand remains untouched. Model computations show a distinct lee side erosion at the eastern end of the construction (figure 9; Delft Hydraulics, 1991). In practice the consequences are small. The coastline here consists of a small dike and is therefore rigid. Eastward, the dike is bordered by a nature re-serve (the 'slufter' (chapter 1.2) of the Verdrongen Zwarte polder; figure 5) that is in danger of being buried by sand.

Figure 10. Relation between the crest elevation of the breakwater and the cross shore sand transport losses (Delft Hydraulics, 1991).

The level of the breakwater crest determines the loss of sand from the beach into the Wielingen tidal channel. In general, blocking this transport needs a crest height which is close to the seawater level (Lamberti et al., 1985). The tidal difference (3.7 m) complicates this thesis. Delft Hydraulics (1991) computed a 25% to 50% (with or without additional beach nourishment, respectively) reduced initial sand loss in case of a crest level of about 1 metre below MSL. The long term profits with a raised beach level are uncertain.

Roughly, each metre crest elevation means an extra 15% reduction (figure 10). However, the other side of the picture shows a more pronounced development of scour holes and higher costs and will score negatively from a recreational point of view. A breakwater crest level between 0.5 and 1.0 metre below MSL seems to be a reasonable compromise and offers good opportunities for connection with the already existing groynes.

The width of the breakwater crest is of the utmost importance in reducing the risk of a landward scour holes. Several theories calculate the most effective width under different conditions (Sawaragi, 1988; Delft Hydraulics, 1989). Especially in consideration of costs and recreation, a decision in favour of a limited width seems to be reasonable. After that a wait-and-see policy can be followed.

## 5.2 Estimate of the cost

A comparison of different construction methods showed the cheapest way of execution:

1. extend the shoreface by means of sand fill;
2. defend the exposed new shoreface by a layer of stones;
3. construct the breakwater;
4. fill up the beach and
5. connect the old groynes with the breakwater.

In case of a construction length of about 900 metres, the costs of this operation are estimated at Hfl 7,700,000 (Dutch guilders ( $\pm$  US\$ 4,500,000)). To find out if such an investment can be cost effective, the costs of construction, maintenance and additional sand nourishment are capitalized for a period of 40 years, the expected erosion period. These costs are compared with the capitalized costs of periodical beach nourishment. In fact, the effects on adjacent coastal sections must also be capitalized (policy of dynamic preservation: no structural coastline regression is allowed). However, long term effects are difficult to calculate and are therefore only qualitatively implicated in the comparison. Besides, the effects of lee side erosion within the dike section and neighbouring nature reserve will be small.

In the estimate of costs, the uncertainty of some elements play a major role:

### *future erosion rate:*

Two realistic morphological scenarios are worked out:

- S1 (neutral to pessimistic): coastline withdrawal by continuous regression and long term fluctuations ('sand waves');
- S2 (optimistic): long term coastline fluctuations only.

*effectiveness of the measure:*

The effectiveness of a perched beach in Dutch conditions is part of the feasibility study. In the Netherlands some experience with beach nourishment exists for tide dominated coasts. Based on that experience, in the design practice an effectiveness of 50% to 80% is applied (Roelse, 1990).

*cubic metre price of sand nourishment:*

In the Delta area the sand can be borrowed relatively cheap from shoals near to the shore. Based on projects in the past years prices per  $m^3$  were taken into account varying from Hfl 10 ( $\pm$  US\$ 6) for 0.5 million  $m^3$  to Hfl 14 ( $\pm$  US\$ 8) for 0.02 million  $m^3$ .

The sensitivity of the cost comparison for those variables is illustrated in figure 11. The following example is indicated: Assuming the neutral-pessimistic scenario, a  $m^3$  price of Hfl 10 and an effectiveness of beach nourishment of 80%, a perched beach has to be at least 50% effective (50% reduced erosion rate) to be cheaper than beach nourishment only. In case the coastline development is favourable (optimistic scenario) the perched beach application can only be effective if  $m^3$ -prices rise extremely.

Figure 11. Effectiveness of beach nourishment ( $eff_s$ ) and perched beach ( $eff_h$ ) related to  $m^3$  sand price ( $P$ ).

### 5.3 Effects

The main effects on other interests focus on ecological aspects and recreation.

Recreation is of major importance to the region: Each year about 2 million overnight stays are registered.

The perched beach will initiate a wider beach, which is profita-

ble from a recreational point of view. However, the breakwater itself forms an obstacle for swimmers, surfers and small boats. During some phases of the tidal cycle, dangerous bathing conditions can exist, due to undesirable currents and scour holes.

Avoiding any hindrance results in a far seaward (and hence capital) position of the breakwater.

If there is an overall negative effect on recreation, the project will fit in the provincial planning. In that case, the perched beach is expected to act as a buffer between the crowded seaside resort of Cadzand in the southwest and the nature reserve in the northeast (see 5.1).

The ecological effects are small. In general the application of stonelike materials strengthens the natural diversity. Organisms attach to the stones and others will find shelters.

Biomasses on hard constructions can exceed those of sandy substrates by about 10 to 100 times. On the other hand, the existence of a(nother) stony breakwater within a sandy coast is not in line with preservation of the charm and quality of natural coasts.

#### 5.4 Surplus value and risks.

A decision in favour of a perched beach construction will initiate research results which, in principle, can be translated to other Dutch coasts bounded by tidal channels. Secondly, perched beach experiences are of great use in planning large seaward coastal constructions.

The seaward extension of the perched beach is limited: the main existing hydraulics and sediment transport paths will almost remain the same. Neighbouring coastal sections will hardly be affected.

The dike and the 'slufter' nature reserve downstream of the perched beach confine the risk for neighbouring coasts.

Nevertheless, if the construction produces unacceptable effects, a minor and easy operation can remove the breakwater, after which the material can be added to the shoreface protection.

## 6. Conclusions.

The feasibility study selects a perched beach construction as the most promising seaward coastal defence measure for the vulnerable section of the Tienhonderd Polder in Zeeland, the Netherlands. The construction will act as an effective coastal defence structure. Shoreface and beach protection can be achieved for a reasonable price and without harming the charm of the natural sandy coast. Attention should be focussed on the development of scour holes at the landward side of the dam. Sand nourishment, although

in much reduced quantities, will remain necessary until about the year 2030.

The costs appear to be the most important element and determines the success of the preferred perched beach. The result of a price comparison with beach and shoreface nourishment depends on the future erosion, the costs of sand mining and the effectiveness of both alternatives. Calculations of the total costs (including direct investments and repeated (capitalized) costs for beach nourishments for a period of 30 to 40 years) indicate that a perched beach is roughly as expensive as repeated beach nourishments alone.

The construction method and the location of the proposed perched beach considerably confine the risks of loss of functions and valuable interests within adjacent coastal sections.

In general, the appearance of a 'hard' structure within a sandy coast will score negatively from a recreational point of view because it can give rise to dangerous bathing conditions. On the other hand, the beach is widened and the use of stones will encourage the settlement of several aquatic species.

A final decision on the perched beach alternative is not expected before the summer of 1993. A 'yes' will make a more detailed research (especially of crest width and elevation) necessary.

## CHAPTER 199

### ARTIFICIAL SAND FILLS IN WATER

J. van 't Hoff<sup>1</sup>, M.B. de Groot<sup>2</sup>, J.C. Winterwerp<sup>3</sup>  
H. Verwoert<sup>4</sup> and W.T. Bakker<sup>5</sup>

#### 1 Introduction

Experience has been obtained on the construction of sand fills in water as part of several types of structures in the Netherlands. These include the following: (closure) dams, artificial islands or coastal extensions, covering of pipelines, trench back fills and the foundation of submerged tunnels and caissons.

Rijkswaterstaat (Ministry of Transport, Public Works and Watermanagement) Dutch contractors, research institutes and consultancy firms have been involved in the research, design and construction of a large number of projects in the Netherlands and abroad.

In-depth research was carried out especially within the frame work of the preparations of a number of Delta closures constructed with sand.

After the completion of the Deltaworks it seemed important not to leave this knowledge scattered over many study reports and design and evaluation notes, but rather to summarize the data and experience in a manual (Van 't Hoff (ed.) et al, 1992) issued by the Council of the Centre for Civil Engineering Research, Codes and Specifications (CUR).

The theoretical section of this manual provides a description of the process phenomena for the

construction with sand in water based on theory development of the physical processes supported by observations of these processes in the field and in the laboratory. In the practical section the design practice is highlighted with thirteen case histories. By means of a detailed elaboration of a practical case the theory is again more extensively verified with project experience. In this paper some results of the theory development are presented followed by an example of calculation results for a practical case.

## 2 Application of study results

The study provides a tool to predict the dimensions of a sand fill constructed in water as a function of the sand characteristics, the sedimentation processes on the fill area and method of sand placement.

## 3 Process phenomena

The processes related to the placement of sand for the construction of sand fills are shown in fig.1. After winning (I) the sand is transported to the fill area (II) by a hopper dredger or via a pipe line. Subject to the means of transport, the sand is either bottom discharged or pipe line placed (III). The sand-water jet makes craters (IV) in the sand body under construction. A sand-water mixture flows across the edge of these craters (V) as well as under water (VI). Under water loss of sand (VII) to the surrounding water can occur. Sand in the mixture flow will settle rapidly to form the slope (VIII).

Fig.1 Phases of taking up, transporting and elementary methods of sand placement.

#### 4 Dimensions of a sand fill

The dimensions of a sand fill (fig. 2) placed in water are determined by:

- the behaviour of a sand-water mixture after leaving the discharge pipe or hopper;
- the width of the crater developed during the discharging process as a result of the impact of a sand-water mixture plume or jet
- the sedimentation length
- the initial slope of the above and under water sand fill area directly after placing;
- the occurrence of flow slides;
- the water depth.

Fig. 2 Parameters determining the shape of a sand fill.

When placing sand in water the sand-water mixture forms a jet or plume with a certain initial flow rate and concentration at the point of discharge of the pipe line or hopper vessel. For a given shape and dimension of discharge opening and for given field conditions, the dimensions, concentrations and velocities along the trajectory of the jet or plume can be predicted as well as the traced path. From these characteristic parameters the dimensions of the crater, which develops when the jet hits the bottom, can be predicted.

#### 5 Crater dimensions

The crater width can be determined using either the theory of Breusers (1991) for conical or round jets and Rajaratnam (1981) for vertical plane shaped jets or the theory of Heezen and Van der Stap (1988). The theory of Breusers and Rajaratnam begins with a description of the erosion under a clear water jet followed by the determination of the influence of sand in the jet on the dimensions of the crater. With the theory of Heezen and Van der Stap the crater dimensions are directly determined from tests and experience with sand-water jets. Because of the limited available space within the context of this paper, only the results of Breusers theory will be presented briefly (fig. 3).

Fig.3. Erosion under a vertical jet.

Based on experiments Breusers recommends the following relations (see also fig. 4):

$$\frac{y_s}{d_0} = 0.075 \frac{U_0}{u_{*cr}} \quad \text{if} \quad \frac{U_0}{u_{*cr}} < 100 \quad (1)$$

$$\frac{y_s}{d_0} = 0.35 \left( \frac{U_0}{u_{*cr}} \right)^{2/3} \quad \text{if} \quad \frac{U_0}{u_{*cr}} > 100$$

In which:

$d_0$  = discharge pipe diameter (m)

$U_0$  = discharge velocity (m/s)

$u_{*cr}$  = critical shear velocity according to Shields (m/s)

$y_s$  = crater depth for clear water (m)

The vertical distance  $H$  to the point of discharge has no influence within the application range of the formula:

$$4 \left\langle \frac{H}{d_0} \right\rangle < 12 @ 20 \quad (2)$$

The effect of the presence of sand in the jet or plume on the dimensions of a crater, can be found by assuming equilibrium between erosion and sedimentation. Because of the presence of sand in the flow, the velocity of the flow on the crater edge must be higher than for clear water in order to prevent sedimentation. As a result of this the crater edge will be closer to the center line of the jet.

Fig.4. Depth of scour hole for clear water as function of  $U_0$  according to Breusers.

The presence of sand can be accounted for, by reducing the crater dimensions, calculated with formula (1), using a reduction factor which depends on the grain size diameter  $D_{50}$  and on the sand concentration ( $c$ ) in the jet. For jets with coarse sand a reduction of the dimensions of the crater upto a factor 5 is possible.

The ratio between radius and depth does not change, hence the following always applies:

$$\frac{r_{\infty}}{y} = \frac{r_{\infty s}}{y_s} = 2.5 \quad (3)$$

In which:

$r_{\infty}$  = crater radius for sand-water mixture (m)

$r_{\infty s}$  = crater radius for clear water (m)

$y$  = crater depth for sand-water mixture (m)

$y_s$  = crater depth for clear water (m)

## 6 Mixture overflow from crater

Besides the grain diameter, for the determination of the slope gradient, the specific flow rate ( $q$ ) is the most important parameter for the above water fill area and the specific sand production rate ( $s$ ) for the underwater fill area. A large specific flow rate and a large specific sand production rate result in flatter slopes. To be able to determine the values of  $q$  and  $s$  the width ( $B$ ) across which the mixture will spread after passing the crater edge must be assessed.

The specific flow ratio  $q$  and specific sand production rate  $s$  for single point discharging in an under water fill area, follow from the equations:

$$q = U_b \cdot \pi / 4 \cdot d_b^2 / B \quad (4)$$

$$s = \rho_s \cdot q \cdot c_b \quad (5)$$

In which:

$q$  = specific flow rate ( $m^2/s$ )

$U_b$  = mixture velocity in centre of jet just above sea bed ( $m/s$ )

$B$  = spreading width of mixture ( $m$ )

$d_b$  = diameter of round jet just above sea bed ( $m$ )

$s$  = specific sand production rate (solids) ( $kg/ms$ )

$\rho_s$  = density of solids ( $kg/m^3$ )

$c_b$  = volume concentration just above sea bed (-)

The question is, across what width  $B$  the mixture will spread. There is little known about this subject. For that reason the following approach must be regarded as a first attempt to estimate an upper limit  $B_{max}$  and a lower limit  $B_{min}$ . The upper limit is taken equal to the circumference of the crater edge. In principle  $B$  could become even larger after the mixture has passed the crater edge because the size of the crater increases continuously from the discharge point. However it seems very unrealistic that the mixture spreads more than the complete circumference of the crater edge. Hence, for a crater under a round (conical) jet the following applies:

$$B_{max} = 2\pi r_\infty \quad (6)$$

and for a crater under a vertical plane shaped jet with a length equal to the curtain-length or the hopper-length of the vessel from which the sand is discharged, the following applies:

$$B_{max} = 2\pi r_\infty + 2 \times \text{curtain-length} \quad (7)$$

However most likely the mixture will not spread across the complete crater circumference  $B_{max}$ , but will concentrate in a channel.

On the above water fill area the mixture flow can be distributed by means of bulldozers across the full width of the fill area determined by bunds. This is not the case on the under water fill area and hence channel formation cannot be prevented here.

The width  $B$  of this channel determines the specific flow rate  $q$  and the specific sand production rate  $s$  and therefore the under water slopes.

Based on the regime theory, the minimum width of a channel normalized for jet diameter  $d$ , can be derived from (8) (for a round jet, hence for single point discharging in an under water fill area):

$$\frac{B_{\min}}{d} = 0.6 \sqrt{\frac{U}{U_c}} \quad (8)$$

In which:

- $B_{\min}$  = lower limit of spreading width of mixture (m)
- $d$  = jet diameter (m)
- $U$  = mixture flow velocity in centre of jet (m/s)
- $U_c$  = mixture flow velocity for which erosion occurs, (Shields:  $U_c = \sqrt{\Delta g D_{50}}$ ) (m/s)

In fig. 5 this relation is plotted as a function of the flow velocity in the centre of the jet and the grain size diameter.

Fig.5. Minimum spreading width of mixture at overflow of crater edge.

## 7 Sedimentation and erosion processes

The extension of a hydraulically placed sand body is the result of sedimentation of sand from a sand-water mixture flow and in some cases the successive replacement of already deposited sand. These sedimentation and erosion processes can be determined in a quantitative way. In principle they are physically independent of each other. The net result can therefore be derived by superimposing the sedimentation- and erosion-velocity.

The sedimentation length is defined as the distance covered by the sand-water mixture flow before the volume

concentration is reduced to 10% of the initial concentration. This sedimentation length can be read from fig. 6 as a function of the specific mixture flow rate, grain size and volume concentration. Because of the hindered settling effect, the sedimentation length is strongly influenced by the concentration.

Fig.6. Sedimentation length as a function of specific flow rate, grain size and volume concentration.

## 8 Slope formation above water

The following bed-forms can be observed: terraces, cascades and channel formation.

### Terraces and cascades

Terraces and cascades develop at moderate specific mixture flow rates of the order of 0.01 to 0.3  $\text{m}^2/\text{s}$  (Winterwerp et al, 1992). The anti-dune like bed-form is composed of long, flat sloped terraces where the flow velocity is sub-critical and where sedimentation of sand takes place, see fig. 7. At the end of this terrace a steep cascade is present, where the flow velocity becomes super-critical and where erosion takes place. A hydraulic jump develops between this cascade and the

next terrace at the transition of super-critical flow to sub-critical flow. Because of the erosion of the downstream side and sedimentation at the upstream side, the system of terraces, steps and cascades propagates slowly in upstream direction. A dynamic equilibrium situation can develop between sedimentation on the terraces and erosion on the cascades at a certain average bed slope.

Fig.7. Terrace formation on fill above water level.

### Channels

At high specific mixture flow rates the mixture concentrates in deep channels and the bed-form of terraces and cascades disappears.

### Equilibrium slope above water level

The equilibrium slope is defined by the equilibrium between sedimentation and erosion. This slope is determined with field observations and large scale tilting flume tests as a function of the flow velocity, grain size and concentration (Winterwerp et al 1990). The following empirical formula for this equilibrium slope above water level could be inferred:

$$i = 0.006 \left( \frac{D_{50}}{D_0} - 1 \right) \frac{q^{-0.45}}{q_0} \quad (9)$$

In which:

- $i$  = tangent of the average slope gradient (-)
- $D_{50}$  = medium grain size diameter ( $\mu\text{m}$ )
- $q$  = specific mixture flow rate ( $\text{m}^2/\text{s}$ )
- $D_0$  =  $65 \mu\text{m}$
- $q_0$  =  $1 \text{ m}^2/\text{s}$

This equation was derived for specific mixture flow rates varying from 0.01 and 0.15  $\text{m}^2/\text{s}$  and grain size diameters of respectively 120 and 225  $\mu\text{m}$ . This relation is shown in fig. 8 together with the flume and field surveys. The equilibrium slope showed a strong relation with the specific mixture flow rate and the grain size. The concentration appears to be of minor importance, which can be explained by the effects of hindered settling.

Fig. 8. Equilibrium slopes above water, results of flume tests and field observations and calculations using formula 9.

## 9 Slope formation under water

Compared to the circumstances above water, the soil mechanics properties of the sand body during sand placement under water have a much stronger influence on the development of the slope. Because the deposited sand is always very loosely packed, it is susceptible to liquefaction. Therefore under certain circumstances the slope of the sand body will not be stable and liquefaction may occur followed by a flow slide.

Whether flow slides occur directly after the sand has settled depends on the type of sedimentation. To predict which type can be expected depends on the sedimentation length ( $L$ ), the critical slope height ( $h_{cr}$ ) and the porosity ( $n$ ).

The development of a sand slope under water is illustrated in figures 9a, -b and -c.

During hydraulic placement of sand at low to moderate specific sand production rates and with fine sand in shallow to fairly deep water, the development of the slope takes place in a discontinuous way. This has been observed during field surveys and during experiments in a large flume.

During the hydraulic placement of sand, sedimentation takes place within the first metres of the slope after the sand body has reached the water surface. It then starts to develop in horizontal direction. The slope

increases locally which may result in a critical situation and a flow slide. See fig. 9a. Sedimentation again takes place on the resulting flat slope. The alternating increase and decrease of the slope caused by sedimentation and flow slides, is a continuous process. The flow slides are now the dominating factor for the transportation of sand to the toe of the sand body. For coarser sand and for the same low specific sand production rates and shallow water, however, flow slides will be observed less readily even when the sand is very loose and the porosity of the deposited sand is well beyond the critical value.

It was found that for horizontal slope development a critical slope height exists. Beyond this critical height flow slides occur. For coarse sand this critical slope height is larger than for fine sand. The values for  $h_{cr}$  are based on experience with the construction of sand fills with grain sizes between 100 and 500  $\mu\text{m}$ . The critical slope height can be approximated by:

$$h_{cr} = 0.075D - 8.5 \quad (120 \mu\text{m} < D < 500 \mu\text{m}) \quad (10)$$

In which:

$$h_{cr} = \text{critical slope height (m)}$$

$$D = \text{grain diameter } (\mu\text{m})$$

For  $h < h_{cr}$  the under water sand slope increases up to a certain steep equilibrium angle. The development of the slope takes place in a very regular way and a kind of equilibrium situation establishes, see fig. 9b.

For high specific sand production rates ( $s > 25 \text{ kg/ms}$ ) a turbulent suspension flow will occur, for fine sand as well as for coarse sand, with hydraulic jumps propagating continuously in the upstream direction. This process is very similar to the type of mixture flow above water.

The suspension flow can extend far beyond the toe of the slope resulting in a decreasing under water slope. See fig. 9c. Although flow slides may be present these do not constitute a prevalent sand transport mechanism.

#### **Equilibrium slope below water level**

No unique value can be established for the slope of a hydraulically placed sand body because of the alternating increase and decrease of the slope. Flow slides or breach processes, if present, define the minimum slopes. The average under water sand slope is mainly defined by the grain size and the specific sand production rate.

Average under water slopes observed during the hydraulic placement of sand of various projects are shown in fig. 10 as a function of the specific production rate ( $s$ ) and

grain size. The results of flume tests with fine and medium coarse sand are given for various sand production rates, as well as the results of previously performed small scale flume tests. Since all types of measurements are collected a wide scatter is the result.

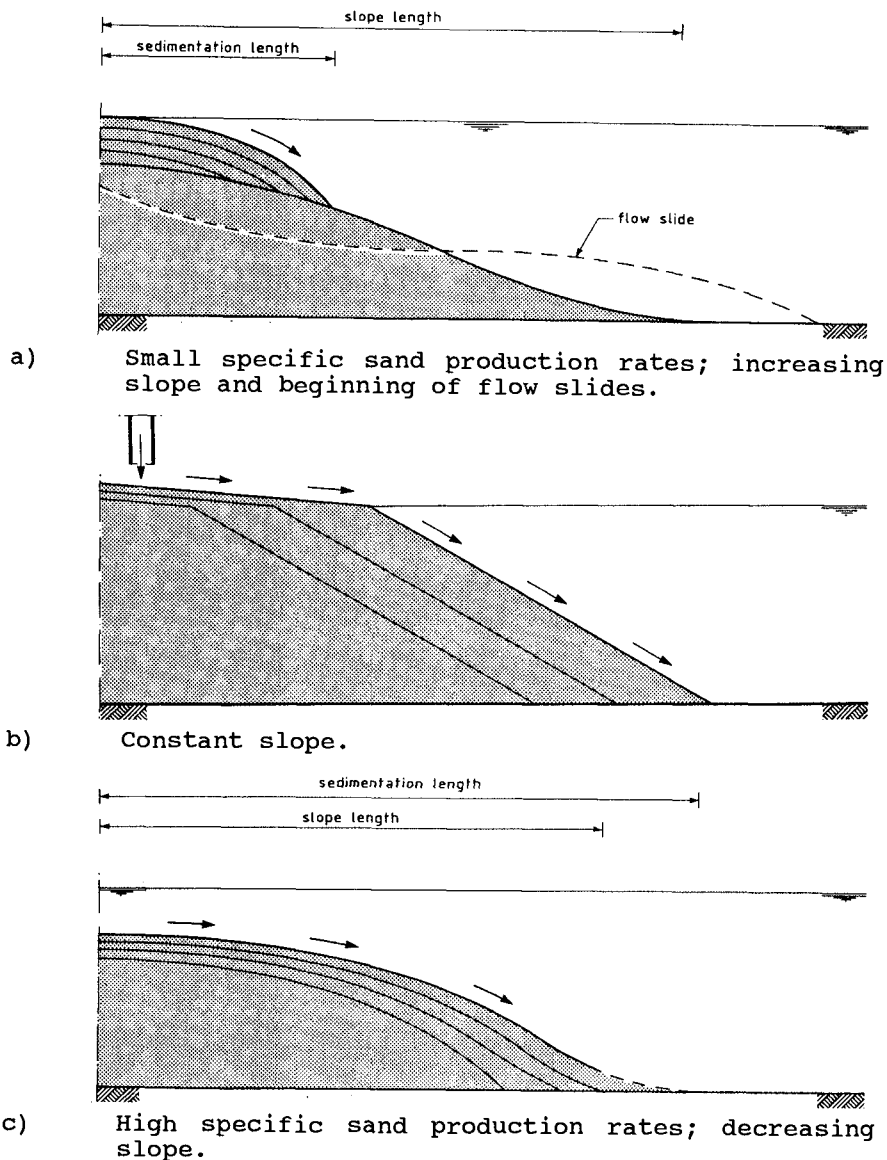

Fig.9 Development of under water sand slopes.

Fig.10. Underwater sand slopes measured in the field and in the laboratory as a function of  $D_{50}$ .

The following empirical formula applies to the average under water slope ( $i$ ) when no flow slides occur:

$$i = 0.0032D \cdot s^{-0.4} \tag{11}$$

In which:

$D$  = grain size ( $\mu\text{m}$ )

$s$  = specific sand production rate (kg/ms)

Fig.11 Building up of the artificial island Issungak for hydraulic discharging from the water surface.

It can be read from fig. 10 that in the field often flatter slopes are observed than according to formula (11). These are always practical situations for which

flow slides govern the slope formation. In these cases it is recommended not to use formula (11) but to estimate the slope on the basis of the indicated field observations.

### 10 Prediction of sand fill dimensions

Typical computational results for the building up of an artificial island at varying discharge heights are shown in fig.11 and table 1.

Table 1 Crater dimensions and sedimentation length for discharging from the water surface (Issungak).

magnitude	unit	fall height 19 m	fall height 11 m	fall height 3 m
crater width $2r_c$	m	10-40	8-30	5-20
specific flow rate $q$	$m^2/s$	1.8-2.4	1.4-1.7	0.45-1.1
specific sand production rate $s$	kg/ms	45-200	70-350	170-550
sedimentation length $L$	m	150-250	120-170	50-130
equilibrium slope $\tan \alpha$	(-)	1:7-1:12	1:8-1:14	1:11-1:17

## CHAPTER 200

### SEDIMENT TRANSPORT BY CURRENTS AND WAVES

Leo C. van Rijn<sup>1)</sup> and Aart Kroon<sup>2)</sup>

#### Abstract

Mathematical and experimental modelling of sediment transport processes in the coastal environment is presented. The convection-diffusion equation for suspended sediment particles has been used to compute the vertical distribution of the time-averaged concentrations. The computed results are compared with measured values of laboratory and field experiments (surf zone Dutch coast).

#### 1. Introduction

Many details of the complicated sediment transport processes in the coastal environment are still unknown. To get a better understanding of the most relevant processes, an integrated research programme has been set up, sponsored by the Coastal Genesis project (Rijkswaterstaat, The Netherlands), the MAST project (EEC research programme) and the Basic Research programme of Delft Hydraulics.

The research programme is focused on theoretical and experimental modelling of the processes involved. The major part of the work is related to experimental work, as follows:

- wave tunnel experiments to study the near-bed phenomena (Ribberink and Al Salem, 1991 and 1992)
- wave-current flume and basin experiments to study the vertical structure of the velocity and sediment concentration (Van Rijn et al, 1993)
- surf zone experiment near the Dutch coast (Kroon and Van Rijn, 1992).

Herein, the mathematical modelling of time-averaged sediment concentrations in the coastal environment is presented. The computed values are compared with measured results from laboratory and field experiments.

## 2. Mathematical model

### 2.1 Transport processes

The total sediment transport rate ( $q_t$ ) can be computed from the vertical distribution of fluid velocities and sediment concentrations, as follows:

$$q_t = \int_0^{h+\eta} VC \, dz \quad (1)$$

in which:

- V = local instantaneous fluid velocity at height z above bed (m/s)
- C = local instantaneous sediment concentrations at height z above bed (kg/m<sup>3</sup>)
- h = water depth (to mean surface level) (m)
- $\eta$  = water surface elevation (m)

Defining:  $V = v + \tilde{v}$  and  $C = c + \tilde{c}$  (2)

in which:

- v = time and space-averaged fluid velocity at height z (m/s)
- c = time and space-averaged concentration at height z (m/s)
- $\tilde{v}$  = oscillating fluid component (including turbulent component) (m/s)
- $\tilde{c}$  = oscillating concentration component (including turbulent component) (m/s)

Substituting Eq. (2) in Eq. (1) and averaging over time and space, yields:

$$\bar{q}_t = \int_0^h \bar{v}c \, dz + \int_0^h \bar{\tilde{v}\tilde{c}} \, dz = \bar{q}_c + \bar{q}_w \quad (3)$$

in which:

$$\bar{q}_c = \int_0^h \bar{v}c \, dz = \text{time-averaged current-related sediment transport rate (kg/sm)}$$

$$\bar{q}_w = \int_0^h \bar{\tilde{v}\tilde{c}} \, dz = \text{time-averaged wave-related sediment transport rate (kg/sm)}$$

The current-related sediment transport is defined as the transport of sediment particles by the time-averaged (mean) current velocities (longshore currents, rip currents, undertow currents). The current velocities and the sediment concentrations are affected by the wave motion. It is known that the wave motion reduces the current velocities near the bed, but the wave motion strongly increases the near-bed concentrations due to its stirring action. The wave-related sediment transport is defined as the transport of sediment particles by the oscillating fluid components (cross-shore orbital motion).

In this paper the attention is focused on the current-related transport rate.

## 2.2 Time-averaged concentration profile

Usually, the convection-diffusion equation is applied to compute the equilibrium concentration profile in steady flow. This equation reads as:

$$w_{s,m} + \epsilon_{s,cw} \frac{dc}{dz} = 0 \quad (4)$$

in which:

$w_{s,m}$  = fall velocity of suspended sediment in a fluid-sediment mixture (m/s)

$\epsilon_{s,cw}$  = sediment mixing coefficient for combined current and waves (m<sup>2</sup>/s)

$c$  = time-averaged concentration at height  $z$  above the bed (kg/m<sup>3</sup>)

Here, it is assumed that Eq. (4) is also valid for wave-related mixing.

## 2.3 Sediment mixing coefficient

For combined current and wave conditions the sediment mixing coefficient is modeled as:

$$\epsilon_{s,cw} = [(\epsilon_{s,w})^2 + (\epsilon_{s,c})^2]^{0.5} \quad (5)$$

in which:

$\epsilon_{s,w}$  = wave-related mixing coefficient (m<sup>2</sup>/s)

$\epsilon_{s,c}$  = current-related mixing coefficient (m<sup>2</sup>/s)

First, the wave-related mixing is discussed.

Measurements in wave flumes show the presence of suspended sediment particles from the bed up to the water surface (Van Rijn, 1991). The largest concentrations are found close to the bed where the diffusivity is large due to ripple-generated eddies. Further away from the bed the sediment concentrations decrease rapidly because the eddies dissolve rather rapidly travelling upwards.

Various researchers have tried to model the suspension process by introducing an effective wave-related sediment mixing coefficient (see Van Rijn 1989 and 1993).

As the existing relationships do not yield acceptable results, a new approach was presented. Based on analysis of measured concentration profiles, the following characteristics were observed (Van Rijn, 1989, 1993);

- approximately constant mixing coefficient  $\epsilon_{s,w,bed}$  in a layer ( $z \leq \delta_s$ ) near the bed,
- approximately constant mixing coefficient  $\epsilon_{s,w,max}$  in the upper half ( $z \geq 0.5 h$ ) of the water depth,
- approximately linear variation of the mixing coefficient for  $\delta_s < z < 0.5 h$ .

The mathematical formulation reads as (see Figure 1):

$$z \leq \delta_s \quad \epsilon_{s,w} = \epsilon_{s,w,bed} \quad (6a)$$

$$z \geq 0.5 h \quad \epsilon_{s,w} = \epsilon_{s,w,max} \quad (6b)$$

$$\delta_s < z < 0.5 h \quad \epsilon_{s,w} = \epsilon_{s,w,bed} + [\epsilon_{s,w,max} - \epsilon_{s,w,bed}] \left[ \frac{z - \delta_s}{0.5h - \delta_s} \right] \quad (6c)$$

Equation (6) is fully defined when the following three parameters are known:

1. Thickness of near-bed sediment mixing layer ( $\delta_s$ ).  
Based on analysis of concentration profiles measured in non-breaking waves, it was found that:

$$\delta_s = 3 \Delta_r \quad (\text{ripple height})$$

$$\delta_s = 3 \delta_w \quad (\text{sheet flow regime})$$

in which:

- $\Delta_r$  = ripple height (m)
- $\delta_w = 0.072 \hat{\Lambda}_s (\hat{\Lambda}_s / k_{s,w})^{-0.25}$  = wave boundary layer thickness (m)
- $\delta_s$  = thickness of near-bed sediment mixing layer (m)
- $k_{s,w}$  = wave-related bed roughness height (=  $3\Delta_r$  in ripple regime and  $\frac{1}{2} \delta_w$  in sheet flow regime) (m)

A. WAVE-RELATED SEDIMENT MIXING COEFFICIENT

B. CURRENT-RELATED SEDIMENT MIXING COEFFICIENT

Figure 1 Mixing coefficient distribution

2. Mixing coefficient in near-bed layer ( $\epsilon_{s,w,bed}$ )  
 This parameter was found to be:

$$\epsilon_{s,w,bed} = \alpha_b \hat{U}_\delta \delta_s \quad (8)$$

in which:

$\hat{U}_\delta$  = peak value of near-bed orbital velocity (based on significant wave height) (m/s)

$\alpha_b$  = 0.004  $D_*$  = empirical coefficient (-)

$D_*$  =  $d_{50} [(\rho_s - \rho)g / (\rho v^2)]^{1/3}$  = particle size parameter (m)

3. Mixing coefficient in upper layer ( $\epsilon_{s,w,max}$ )  
 This parameter was found to be:

$$\epsilon_{s,w,max} = 0.035 \frac{H_s h}{T_p} \quad (9)$$

in which:

$H_s$  = significant wave height (m)

$T_p$  = peak period of spectrum (s)

$h$  = water depth (m)

Second, the current-related mixing coefficient ( $\epsilon_{s,c}$ ) is presented, which reads as:

$$\begin{aligned} \epsilon_{s,c} &= \kappa \beta u_{*,c} z(1-z/h) && \text{for } z < 0.5 h \\ \epsilon_{s,c} &= 0.25 \beta \kappa u_{*,c} h && \text{for } z \geq 0.5 h \end{aligned} \quad (10)$$

in which:

$u_{*,c}$  =  $(g^{0.5} \bar{v}_R) / C$  = bed-shear velocity (m/s)

$C$  =  $18 \log(12h/k_{s,c})$  = Chézy coefficient ( $m^{0.5}/s$ )

$\bar{v}_R$  = depth-averaged velocity (m/s)

$k_{s,c}$  = current-related bed-roughness height (m)

$h$  = water depth (m)

$\kappa$  = constant of Von Karman (= 0.4)

$\beta$  = coefficient ( $\approx 1$ )

#### 2.4 Reference concentration near the bed

The reference concentration is given by:

$$c_a = 0.015 \frac{d_{50}}{a} \frac{T^{1.5}}{D_*^{0.3}} \quad (11)$$

in which:

$D_*$  = dimensionless particle parameter (-)

$T$  = dimensionless bed-shear stress parameter (-)

$a$  = reference level (m)

The T-parameter is, as follows:

$$T = [\tau'_{b,cw} - \tau'_{b,cr}] / \tau_{b,cr} \quad (12)$$

in which:

$\tau'_{b,cw}$  = time-averaged effective bed-shear stress (N/m<sup>2</sup>)

$\tau'_{b,cr}$  = time-averaged critical bed-shear stress according to Shields (N/m<sup>2</sup>)

The magnitude of the time-averaged bed-shear stress, which is independent of the angle between the wave- and current direction is given by (Van Rijn, 1990):

$$\tau'_{b,cw} = \tau'_{b,c} + \tau'_{b,w} \quad (13)$$

in which:

$\tau'_{b,c} = \mu_c \alpha_{cw} \tau_{b,c}$  = effective current-related bed-shear stress (N/m<sup>2</sup>)

$\tau'_{b,w} = \mu_w \tau_{b,w}$  = effective wave-related bed-shear stress (N/m<sup>2</sup>)

$\tau_{b,c} = \frac{1}{8} \rho f_c (\bar{v}_R)^2$  = current-related bed-shear stress (N/m<sup>2</sup>)

$\tau_{b,w} = \frac{1}{4} \rho f_w (\hat{U}_\delta)^2$  = wave-related bed-shear stress (N/m<sup>2</sup>)

$f_c = 0.24 [\log(12h/k_{s,c})]^{-2}$  = current-related friction factor (-)

$f'_c = 0.24 [\log(12h/3d_{90})]^{-2}$  = grain friction factor (-)

$f_w = \exp[-6+5.2(\hat{\Lambda}_\delta/k_{s,w})^{-0.19}]$  = wave-related friction factor (-)

$\bar{v}_R$  = depth-averaged current-velocity (m/s)

$\hat{U}_\delta$  = peak value of near-bed orbital velocity (m/s)

$\hat{\Lambda}_\delta$  = peak value of near-bed orbital excursion (m)

$h$  = water depth (m)

$k_{s,c}$  = current-related bed-roughness (m)

$k_{s,w}$  = wave-related bed-roughness (m)

$\mu_c = f'_c/f_c$  = current-related efficiency factor (-)

$\mu_w = 0.6/D_*$  = wave-related efficiency factor (-)

$\alpha_{cw}$  = correction factor related wave-current interaction (see next section), (-)

$\rho$  = fluid density (kg/m<sup>3</sup>)

$\rho_s$  = sediment density (kg/m<sup>3</sup>)

## 2.5 Current velocity profile

The current velocity profile (see Fig. 2) is represented as a two-layer system to account for the wave effects in the near-bed layer (Van Rijn, 1993):

$$v(z) = \frac{\bar{v}_x \ln(30z/k_a)}{-1 + \ln(30h/k_a)} \quad \text{for } z \geq 3 \delta_w \quad (14)$$

$$v(z) = \frac{\bar{v}_x \ln(90\delta_w/k_a) \ln(30z/k_{s,c})}{[\ln(90\delta_w/k_{s,c})] [-1 + \ln(30h/k_a)]} \quad \text{for } z < 3 \delta_w$$

in which:

- $k_a = k_{s,c} \exp[\gamma \hat{U}_\delta / \bar{v}_r]$  = apparent roughness related to wave-current interaction ( $k_{a,max} = 10 k_{s,c}$ ) (m)
- $k_{s,c}$  = physical current-related bed roughness (m)
- $\gamma = 0.8 + \phi - 0.3\phi^2$
- $\phi$  = angle between current and wave direction (in radians between 0 and  $\pi$ ;  $90^\circ = \frac{1}{2}\pi$ ,  $180^\circ = \pi$ )
- $\delta_w = 0.072 \hat{A}_\delta (\hat{A}_\delta / k_{s,w})^{-0.25}$  = maximum thickness of wave boundary layer (m)

The  $\alpha_{cw}$ -factor is given by (Van Rijn, 1993):

$$\alpha_{cw} = \left[ \frac{\ln(90 \delta_w / k_a)}{\ln(90 \delta_w / k_{s,c})} \right]^2 \left[ \frac{-1 + \ln(30h / k_{s,c})}{-1 + \ln(30h / k_a)} \right]^2 \tag{15}$$

Figure 2 Velocity profile

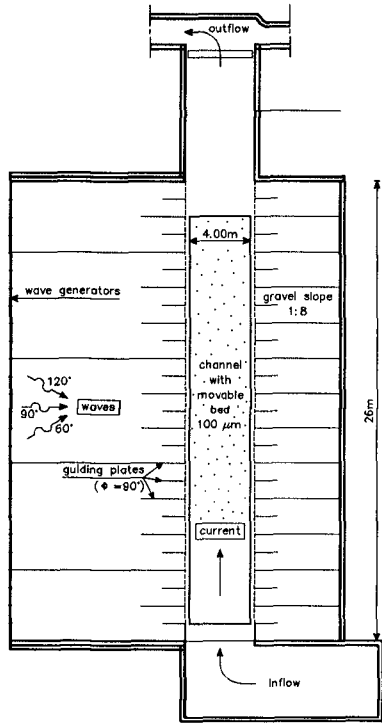

Figure 3 Plan view of wave-current basin

## 2.6 Sediment transport

The suspended load transport is given by:

$$q_{s,c} = \int_a^h vc \, dz \quad (16)$$

The bed-load transport is given by:

$$q_{b,c} = 0.25u'_{*,c} d_{50} T^{1.5} D_*^{-0.3} \quad (17)$$

in which:  $u'_{*,c} = (\tau'_{b,c}/\rho)^{0.5}$

## 3. Laboratory experiments

### 3.1 Experiments

Experiments were carried out in a wave-current basin at Delft Hydraulics to measure the current velocities and sediment concentrations under irregular non-breaking waves combined with a current. The bed material consisted of fine sand with  $d_{10} = 70 \mu\text{m}$ ,  $d_{50} = 100 \mu\text{m}$  and  $d_{90} = 130 \mu\text{m}$ . The water depth was about 0.4 m. Figure 3 shows a plan view of the experimental facility. The current was confined (by guiding plates) in a channel (width = 4 m) with a movable bed consisting of fine sand ( $d_{50} = 100 \mu\text{m}$ ). The guiding plates were placed normal to the wave crests. The (significant) wave heights generated were  $H_s = 0.07$ , 0.1 and 0.14 m. The peak period of the wave spectrum was about 2.3 s. Three current velocities (0.1, 0.2 and 0.3 m/s) were generated by varying the pump discharge. The velocity distribution across the channel was almost uniform. The velocity profiles in the middle of the channel were perfectly logarithmic. The vertical distribution of the turbulence intensity was in good agreement with values reported in the literature. Based on this, it was concluded that the effect of the guiding plates on the current was negligible. The wave propagation direction was set at  $60^\circ$ ,  $90^\circ$  and  $120^\circ$ .

The water entering the channel had no initial sediment load. Consequently, the concentration profiles were generated by erosion of sediment particles from the bed. To provide enough length for establishing equilibrium concentration profiles, the measuring section was situated at a distance of about 30 times the water depth from the channel entrance.

### 3.2 Instruments

Measurements of wave height, velocity and sediment concentration were performed from a carriage moving over rails above the channel. Water level variations were measured by use of a resistance probe near the location where the concentrations and velocities were measured (measuring period = 30 min). Characteristic wave parameters were computed from the data records.

Instantaneous sediment concentrations were measured by use of an acoustic probe; time-averaged sediment concentrations were determined from water-sediment samples using a pump sampler. This latter instrument consisted of an array of ten intake tubes of 3 mm internal diameter connected to the pumps by plastic hoses. The lowest intake tube was placed at about 0.01 m above the crest level of the bed forms. The intake openings were placed in transverse direction to the plane of orbital motion (Bosman et al, 1987). The intake velocity was about 1 m/s satisfying sampling requirements. The 10 liter samples were collected in calibrated buckets.

Instantaneous velocities were measured using an electromagnetic velocity meter (EMS) with a measuring level of about 3 mm below the probe and an acoustical probe (AZTM). The velocities were measured at the same elevations above the mean bed as those of the concentrations starting at the lowest point and working upwards. A time-averaging period of 256 s (approx. 100 waves) was applied.

Space averaging over the bed-form length was performed by moving the sediment concentration and fluid velocity instruments forward and backward over a certain longitudinal distance by use of an oscillating carriage above the channel. The velocity of the moving carriage (approx. 0.01 m/s) was small compared with the fluid velocity and large compared with the bed-form migration velocity. The error in the time-averaged velocity was less than 0.00125 m/s in the present tests. Preliminary tests showed that a space-averaging distance of 0.6 m (approx. 5 ripple lengths) was sufficiently large to give reproducible results.

### 3.3 Time-averaged concentration profiles

Analysis of the time-averaged concentration profiles shows the following results:

- concentrations increase for increasing wave height,
- current velocity does not affect the near-bed concentration; increasing current velocity results in a more uniform concentration profile (larger mixing),
- concentrations are largest when the wave direction is normal to the current direction.

Measured concentration profiles for four tests are shown in Fig. 4. Equation (4) was used to compute the time-averaged concentration profiles based on the following input data:  $d_{50} = 100 \mu\text{m}$ ,  $d_{90} = 130 \mu\text{m}$ ,  $w_s = 0.0065 \text{ m/s}$ ,  $k_{s,w} = k_{s,c} = 3\Delta_r$ ,  $\Delta_r$  = measured ripple height,  $a = 0.5\Delta_r$ ,  $\delta_s = 3\Delta_r$ ,  $\rho = 1000 \text{ kg/m}^3$ ,  $\rho_s = 2650 \text{ kg/m}^3$ .

The Bijker method (1971, 1978) was also used to compute the concentration profiles. The b-coefficient of this method was used as a calibration coefficient. A value of  $b = 1$  gave the best results.

The computed concentration profiles are shown in Fig. 4. Both methods yield reasonable results; the method of Bijker overestimates the measured concentrations at low velocities of 0.1 m/s (T14 10 90).

Computed transport rates showed reasonable agreement with measured values; most computed values are within a factor 2 of measured values.

Figure 4 Measured and computed concentration profiles

#### 4. Field experiments

##### 4.1 Site description

The field experiments were performed at the central part of the Dutch coast near Egmond aan Zee. The hydrodynamics near Egmond aan Zee are characteristic for a mixed-energy coast of a semi-enclosed sea. The incoming waves from the North Sea have a mean annual wave height of 1.3 m and come from southwestern to northern directions. The mean semi-diurnal tidal range is 1.65 m, with a maximum range at spring tide of 2.10 m and a minimum range at neap tide of 1.40 m. The tidal curve near Egmond is asymmetrical with a flood period of 4 hours and an ebb period of 8 hours. The morphology of the beach and nearshore zone in this area is characterized by an outer and an inner nearshore bar in the subtidal zone and a swash bar on the beach.

The sediments in the area are well sorted and composed of fine to medium sand. The mean grain size ranges between 250 and 350  $\mu\text{m}$ . Most of the sediments of the bed surface contain shells (especially in the troughs between the bars) or shell fragments (especially in the swash zone, close to the toe of the beach face).

##### 4.2 Measurements

Detailed measurements of the sediment transport processes in the inner nearshore zone were executed with the use of a small platform. The platform is a scaffold construction of 2.5 meter in length and width at 2.5 meter above the bed. During a measurement day the platform is positioned on a location within the inner nearshore zone. The platform is pulled through the water with a tractor and a winch standing on the beach. The platform is equipped with a capacitance wire, three electromagnetic flow devices, two optical backscatterance devices and a pump sampling system. All these instruments are installed on the seaward exposed site of the platform.

The capacitance wire (CAP) measures the free surface elevations of the water column. The three electromagnetic flow devices (EMF) measure the longshore and cross-shore velocity components in the horizontal plane at three heights above the bed.

The cross-shore micro-morphology of the bed over about 2.5 m was determined by use of a mechanical feeler system consisting of a small trolley connected to a rod movable along one side of the platform. The recorded series of the bed morphology have a spatial resolution of 0.05 m.

Herein, the time-averaged sediment concentration profiles and transport rates are discussed.

##### 4.3 Time-averaged concentrations

Time-averaged concentration profiles at different relative wave heights ( $H_s/h$ ) are shown in Figure 5 and 6.

Figure 5 shows measured concentration profiles under various wave conditions in the surf zone with water depths ranging from 0.7 to 1.2 m. The relative wave heights ( $H_s/h$ ) were in the range of 0.4 to 0.7. The near-bed concentrations are in the range of 0.2 to 2 gr/l. The near surface concentrations are in the range of 0.01 to 0.5 gr/l. A clear influence of the relative wave height can be observed. The near-bed concentrations increase for an increasing relative wave height. The concentration profiles also become more uniform for increasing relative wave height.

Figure 5 Sand concentration profiles in surf zone

Figure 6 shows concentration profiles in the swash zone with strongly plunging breaking waves. The measured concentrations are a factor 10 larger with near-bed concentrations in the range of 10 to 20 gr/l and a large mixing effect over the depth (more uniform profiles) can be observed.

Figure 6 Sand concentration profiles in swash zone

Figure 7 shows the ratio of the concentrations measured at  $z = 0.01$  m and at  $z = 0.1$  m above the bed as a function of relative wave height ( $H_s/h$ ). The ratio sharply decreases for  $H_s/h$  larger than 0.2. A constant value of 2 can be observed for  $H_s/h$  larger than 0.6 which means almost uniform concentration profiles due to the breaking process.

Figure 7 Ratio of concentration at  $z = 0.01$  m and at  $z = 0.1$  m above the bed

Figure 8 shows measured concentrations at  $z = 0.01$  m above the bed as a function of the peak orbital velocity near the bed under the wave crest. Although the scatter is relatively large, the concentrations show an increasing trend for increasing orbital velocities. The experimental results of Ribberink and Al Salem (1991, 1992) measured in wave tunnel conditions are also shown. The relatively large values at low orbital velocities are related to the presence of ripples which are gradually washed out for increasing orbital velocities ( $\hat{U} = 0.8$  m/s).

Equation (4) was used to compute the concentrations at  $z = 0.01$  m above the bed. Reasonable agreement with measured values can be observed. A similar function proposed by Bijker (1971, 1978) was also used (b-factor = 1). As can be observed the Bijker-formula yields almost constant concentrations.

Measured and computed concentration profiles for a range of conditions are shown in Figures 9 and 10. The wave-related bed roughness was taken  $k_{s,w} = 0.05$  m for ripples and  $k_s = 0.01$  m for sheet flow conditions. The significant wave height and the peak period were taken as the characteristic wave parameters. The  $\delta_s$ -parameter expressing the thickness of the near-bed sediment mixing layer in the surfzone, which is an unknown parameter, was used as a calibration parameter. A value of  $\delta_s = 0.2$  m gave good results for all conditions. The ratio of  $\delta_s/h$  shows an increasing trend for increasing values of  $H_s/h$ , see Fig. 11.

Analysis of measured and computed concentration profiles shows reasonably good results for  $H_s/h$ -values upto 0.75 (surf zone), see Figs. 9 and 10. For  $H_s/h$ -values larger than 0.75 (plunging waves in the swash zone) the computed concentrations are systematically smaller than the measured concentrations. Increase of the wave-related bed roughness from  $k_{s,w} = 0.01$  m to  $k_{s,w} = 0.04$  m yields larger concentrations, but the computed values are still a factor of 2 too small. Furthermore, a bed roughness of  $k_{s,w} = 0.04$  m in the swash zone is not realistic. Based on this, it is concluded that the time-averaged concentrations in the swash zone cannot be computed using an equilibrium model concept. The hydrodynamic processes in the swash zone with a relatively steep upsloping bed are strongly non-uniform. Vertical as well as horizontal convective processes are important and should be modeled properly.

Figure 9 Measured and computed concentration profiles

Figure 10 Measured and computed concentration profiles

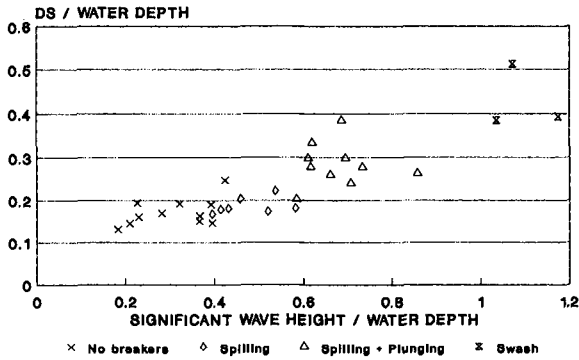

Figure 11 Near-bed sediment mixing layer ( $\delta_s/h$ )

5. Conclusions

The following conclusions are given:

- the current velocity hardly affects the near-bed sediment concentrations; the wave motion is dominant
- the sediment concentrations are maximum when the waves are directed normal to the current (in the ripple regime)
- the sediment concentrations show a large increase under plunging breaking waves, especially in the swash zone
- the concentrations in the swash zone are not locally determined (space lag)
- computed concentration profiles show reasonable agreement with measured values for relative wave heights upto  $H_s/h = 0.7$ .

## CHAPTER 201

### A WAVE-CURRENT SEDIMENT BOUNDARY LAYER

Keith Bedford<sup>1</sup> and Jongkook Lee<sup>2</sup>

#### Abstract

A two-hour set of wave-current bottom boundary layer data collected at a dredged material placement site is examined with regard to establishing whether readily measured variables such as turbulent and wave kinetic energy (TWKE) correlate with more difficult to measure near bottom data. The data, collected in Mobile Bay, Gulf of Mexico, consisted of acoustic concentration profile data and velocity measurements at 50 and 114cm above bottom. The Reynolds Stress did not correlate well with any of the near bottom data including vertical flux and total water column mass. TWKE was a much more solid correlate with these variables but still was weak in correlating with near bottom mass. The wave kinetic energy was a solid correlate with near bottom data, particularly the mass in the bottom 5cm.

#### Introduction

Material from dredging operations is often placed in water where both currents (wind driven or tidal generated) and waves exert a pronounced effect on the bottom shear stress and the resulting long term stability of the material. The purpose of this article is to report on aspects of the near-bottom structure of a wave-current bottom boundary layer at a dredged material placement site in Mobile Bay, Gulf of Mexico. The information to be presented here is extracted from a comprehensive report by Bedford *et al.* (1990) which resulted from the authors participation in a comprehensive multi-investigator field experiment performed as part of the US Army Corps Dredging Research Program.

## Field Data Acquisition and Initial Results

### Site Description and Instrumentation

The comprehensive project took place from August 18, 1989 to September 2, 1989 off shore of Mobil Bay, Alabama. The near bottom data presented here were collected by the ARMS (Acoustic Resuspension Measurement System) which was deployed on a Feeder Berm site in 5.75 m of water (low tide datum). The bottom materials were composed of fine grain sands and silts in the 40-60 micron range. While a  $1.45^\circ$  bottom slope existed on the western edge of the Feeder Berm, ARMS was placed in a flat plain almost 300 meters from this slope.

Two fifty-five hour continuously-recording data sets were collected at the site, and the data reported here came from the first deployment collected from 1301 hrs. Central Daylight time (CDT) 22 August '89 to 2033 hrs. CDT 24 August '92.

Table 1 contains a list of the instruments on the bottom sitting tripod and their sampling frequency. The uppermost Marsh McBirney current meter is used to determine wave and current magnitude and direction while vertical flux data are derived from the 50cm Above Bottom (AB) current meter. The acoustic backscatter profiler is interpreted as concentration following Libicki *et al.*, 1989 and the 1.14cm range bins provide an extremely dense profile of 1 Hertz sediment concentration profile data. ARMS wave data were corroborated with additional data supplied from the Shell Well (Shell Oil Company) site and two operational Army Corps PUV gages. The Shell Well data also contained one hour average wind speed, direction, pressure, and air-sea temperature data.

Table 1. Instrumentation and Sampling Summary

VARIABLE MEASURED	SYMBOL	MANUFACTURER	SAMPLING FREQUENCY	SPATIAL LOCATION <sup>2</sup>
Pressure	p	Celesco	2.0 Hz	
Temperature	T	Yellow Springs	1.0 Hz	114 cm
Velocity	u,v	Marsh McBirney	2.0 Hz	114 cm
Velocity	u,w	Marsh McBirney	2.0 Hz	50 cm
Conc. Profile <sup>1</sup>	C(z)	Edo Western 3MHz	1.0 Hz	130 cm

<sup>1</sup>positioned to measure of concentration in a series of 100 range bins, each 1.16cm thick

<sup>2</sup>measured as distance above bottom

In reviewing the fifty-five hour data set, our intention was to focus attention on a wave current period of the record that was suitable for a detailed comparison of the data with proposed theoretical models, particularly the Glenn and Grant (1987) model. The conditions necessary for apply-

ing this model are quite severe (as they are with most theoretically simplified boundary layer models) and include i) constant or equilibrium vertical flux, ii) no horizontal sediment flux gradient, iii) a streamline coordinate system, iv) weak to non-existent vertical tower or instrument tilt, and, for the Glenn and Grant model, v) waves and currents of somewhat equal magnitude. From the fifty-five hour data set, a two-hour period of data was exemplary in meeting all these criteria i.e. 1711 hrs. CDT to 1911 hrs. CDT 22 August '92. One of the notable features of this piece of data is that the total horizontal current vector flows due east for the entire two hours which means that the 50cm AB current vector is sampling the full streamline coordinate average velocity. These two hour data are examined in more detail in the rest of the article and will be referred to as the "data set."

### The Setting

A graphical and analytical review of the average conditions during the data set has appeared in Bedford *et al.*, 1991 and will not be repeated here. In summary, the winds were steady at 5m/sec. coming from 160° having just veered to that direction from 45° during the prior twelve hours. The tide was approaching slack tide at 1700 hrs having reached maximum ebb stage 4 hours earlier. As noted above then the current was directed the east (+x, +u) and uniformly increased over time from 15-22 and 6.5-12cm/sec at the top and bottom current meters, respectively. The significant wave height was approximately 1.0m with a peak period of 5.6 seconds. These data correspond to a wavelength of 37.0m and a bottom orbital velocity of 22cm/sec. The waves progressed to the north west (320°) in contrast to the eastward flowing current.

### Local Averages and Turbulence Definition

The definition of turbulence requires that the local temporal average value be known. This local average must be from a record sufficiently long enough to achieve stationary conditions in the fluctuation statistics. With the short period gravity waves and wave groups being analyzed here, turbulence time scales and wave period fluctuations overlap and lacking any clear theoretical guidance on how to separate wave and turbulent fluctuations the only averaging operation attempted was the traditional Reynolds uniform weight function. The selection of the averaging interval  $T$ , is difficult in time varying flows. Methods suggested by Gross and Nowell (1983) and standard run tests (Bedford *et al.*, 1987) were applied to these data with a ten-minute period selected for averaging. Correspondingly, the data set was subdivided into 12 ten-minute long frames; averages performed for each frame and combined turbulent and wave induced instantaneous fluctuations were defined relative to that local average.

### Average Concentration Field

Figure 1 contains the twelve average near bottom concentration profiles. The extremely sharp vertical gradient 10-20cm AB is a trademark of wave-current bottom boundary layers (WCBL) and separates the current driven region ( $z > 20$ cm AB) from the combined wave-current driven region ( $< 10$ cm AB). Unlike the Glenn and Grant model calculations, there is a smooth (continuous first derivative) transition region ( $10 < z < 25$ cm AB) between the two layers. Explicit comparisons of these profiles with the Glenn and Grant (1987) model are contained in the article by Bedford and Lee (1992). In summary, with no coefficient tuning of any kind, the model reproduced the profiles quite adequately. The near bottom ( $z < 20$ cm) comparison was quite good with the comparisons at or above  $z > 30$ cm being poorer than expected.

Figure 1. Profiles of the Twelve Ten-Minute Average Concentration Profiles

### Turbulent and Flux Data

#### Turbulent Parameters

With the current meter being 50 cm AB, turbulent data as well as direct flux measurements in the thin WCBL are prohibited. Following are data on the turbulent quantities at 50 cm AB. Figure 2 contains plots of  $\overline{u'w'}$  and the turbulent and wave kinetic energy (TWKE). The "Reynolds stress" varies

between  $-2$  and  $0$  with an average value of  $-1.3 \text{ cm}^2/\text{sec}^2$ . In assessing these values it should be noted that the critical erosion stress for the bottom materials at the site is estimated by the modified Shields diagram (Glenn and Grant 1987) to be  $1.34 \text{ dynes}/\text{cm}^2$  while the Achers and White value was estimated to be  $0.95 \text{ dynes}/\text{cm}^2$ . One can anticipate greater values of measured  $\overline{u'w'}$  near the bottom and therefore assume that erosion is continuous during the period.

Figure 2. Time Traces of a.) Turbulent and Wave Kinetic Energy (TWKE); and b.) Reynolds Stress  $\overline{u'w'}$

The TWKE average value is  $24 \text{ cm}^2/\text{sec}^2$  varying between  $18\text{--}31 \text{ cm}^2/\text{sec}^2$ . The ratio of the TWKE to total energy is falling continuously during the data set from  $0.45$  to  $0.2$  with the average being  $0.35$ .

#### Flux and Variance Data

The net vertical flux at  $50 \text{ cm AB}$  consists of advective ( $\overline{w\bar{c}}$ ), settling ( $w_s\bar{c}$ ) and turbulent ( $\overline{w'c'}$ ) components. For this data set  $\overline{w\bar{c}}$  is essentially zero; a requirement for boundary layer theories.

Figure 3a contains a time trace of the average concentration at  $50 \text{ cm AB}$  and the normalized root mean square (NRMS) value. As seen, the concentrations are not high being less than  $10\%$  of the average values in the bottom  $10 \text{ cm}$ . Also, the average is comprised of widely varying data achieving NRMS values of  $1.0$  but generally centering on  $0.5$ . By contrast, Fig. 3b contains the same data for  $5 \text{ cm AB}$ . Here again the NRMS is roughly  $0.5$ . The average

concentration is falling a bit more, probably in response to the slightly weakened wave field towards the end of the two hours. Figure 3c contains a plot of the total vertical flux at 50cm AB. It is seen to drop quickly during the first two frames to a value of  $-5(10^{-3})$  mg/cm<sup>2</sup>/sec and then change relatively little.

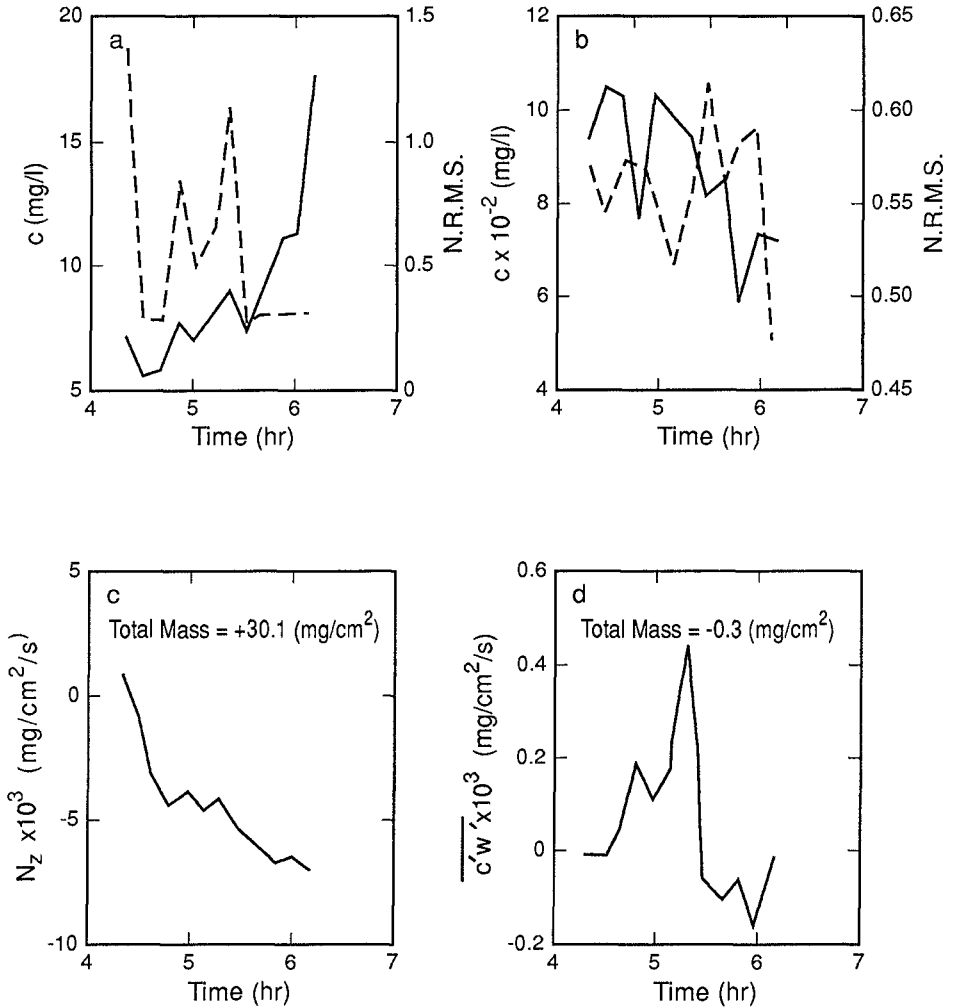

Figure 3. a.) Time Trace of Concentration at 50cm Above Bottom (AB); b.) Time Trace of Concentration at 5cm AB; c.) Time Trace of Vertical Flux,  $N_z$ , at 50cm AB; and d.) Time Trace of Turbulent Flux,  $\overline{c'w'}$ , at 50cm AB.

The net flux then is weakly depositional. Turbulent diffusive flux at 50cm AB (Fig 3d) is quite weak. These calculations assume a settling velocity for the particle size of 0.40 cm/sec. On Figures 4c and 4d the number "total mass" refers to the integrated flux or equivalent mass per square centimeter that would accumulate on (+) or erode from (-) the bottom during the two-hour data set. As easily seen, the net equivalent deposition on the bottom totals 0.1 mm; i.e. a net accumulation of virtually zero.

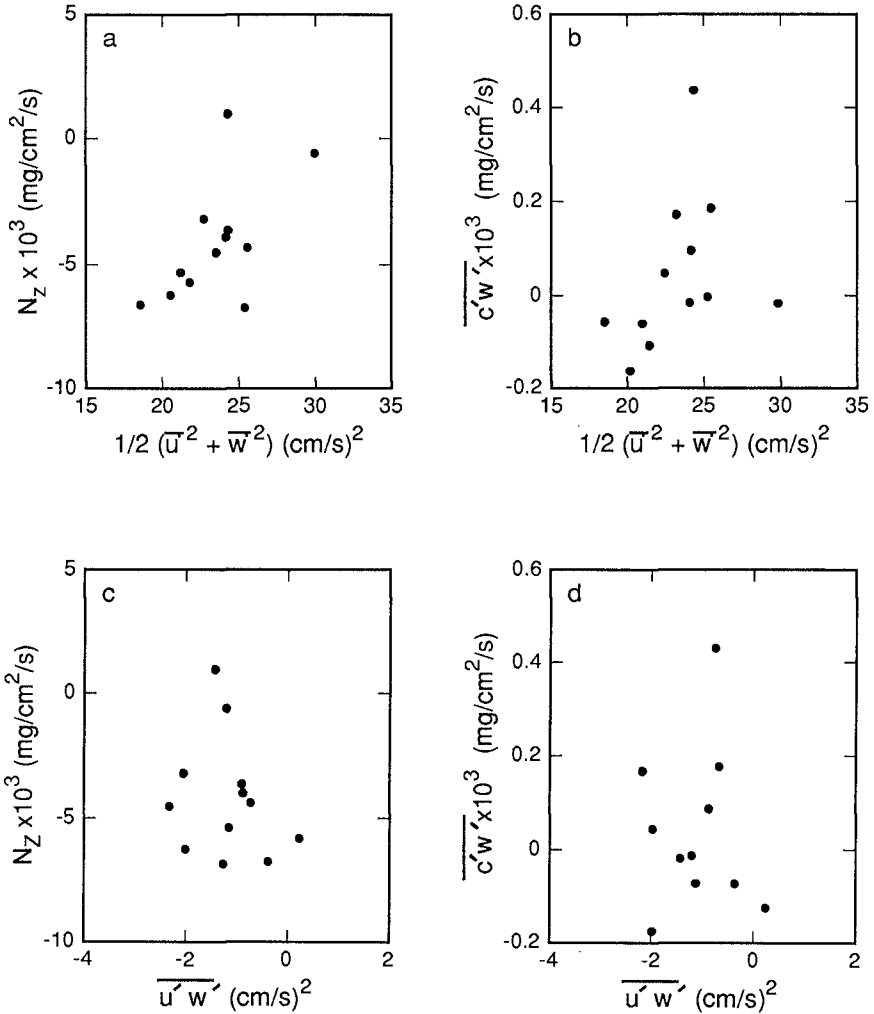

Figure 4. Scatterplots of a.) TWKE vs  $N_z$ ; b.) TWKE vs  $\overline{c'w'}$ ; c.)  $\overline{u'w'}$  vs  $N_z$ ; and d.)  $\overline{u'w'}$  vs  $\overline{c'w'}$

### Flux Correlations

Of management interest to engineers are correlations of near bottom concentration, total mass and flux rates with other measured variables. Figures 4a-d present scatterplots of the TWKE and Reynolds stress with the total flux ( $N_z$ ), and turbulent flux ( $\overline{c'w'}$ ). As can be readily seen the correlations with  $\overline{u'w'}$  or Reynolds stress are poor to nonexistent. The correlations between TWKE and the two fluxes are stronger. That the Reynolds stress is such a poor correlate should be a bit surprising as it is often thought to be strongly representative of the force necessary for erosion at the bottom. That it is such a poor correlate should bring comfort however, as it is very difficult to measure being filled with errors and subject to considerable scatter (Grant and Madsen 1986, Bedford 1992). TWKE, on the other hand, is a much simpler variable to measure and would prove to be an easier correlate to embed in empirical formulations for fluxes, etc. It should be further noted that the correlation between flux  $N_z$  or  $\overline{c'w'}$  and TWKE is at the heart of many phenomenological models of turbulence (e.g. ASCE 1988) and lends field data support to that basic hypothesis.

### Concentration and Total Mass Correlations

Correlations of the average concentrations (at 50 and 5cm AB) with TWKE were inconclusive. This is a bit discouraging, especially at 50cm AB where the nonlinear and confounding effects of ripples, sediment stratification, and vortex shedding, etc., are minimal.

Another type of correlation of a sediment profile measure, the integrated profile mass, was a good deal more successful. Here the instantaneous profiles were integrated from  $z = 0$  to various heights above bottom (e.g. 5 cm, 50 cm) and the resulting integrated mass time averaged. Figures 5a,b contain the integrated mass time variation for  $z = 50$  and 5 cm AB, respectively.  $Q_{50}$  is generally falling in accordance with the gradual decrease of wave energy.  $Q_5$ , even though an integrated and therefore a smoothed measure, is a bit more irregular, an indication of the complexity of the near bottom physics.

Figures 5c,d contain correlations between TWKE and  $Q_{50}$  and  $Q_5$ , respectively. A clear linear relationship between TWKE and  $Q_{50}$  is noted. Again, the lack of clear correlation between TWKE at 50cm AB and local near bottom activity is noted. Clearly, using remote (50cm AB) turbulence data isn't advisable in establishing values of local near bottom concentration and interfacial exchange values.

Figure 5. a.) Time Trace of Integrated Mass at 50cm AB,  $Q_{50}$ ;  
 b.) Time Trace of  $Q_5$ ;  
 c.) Scatterplot of TWKE and  $Q_{50}$ ; and  
 d.) Scatterplot of TWKE and  $Q_5$ .

While turbulence measures can be altered dramatically between 50 cm and 5cm AB by for example stratification and therefore provide poor correlation, wave data at 50 cm penetrate relatively unscathed to the near bottom region and thus might be a better correlate under certain conditions. Figures 6a,b contain scatter plots of the wave kinetic energy (as calculated by

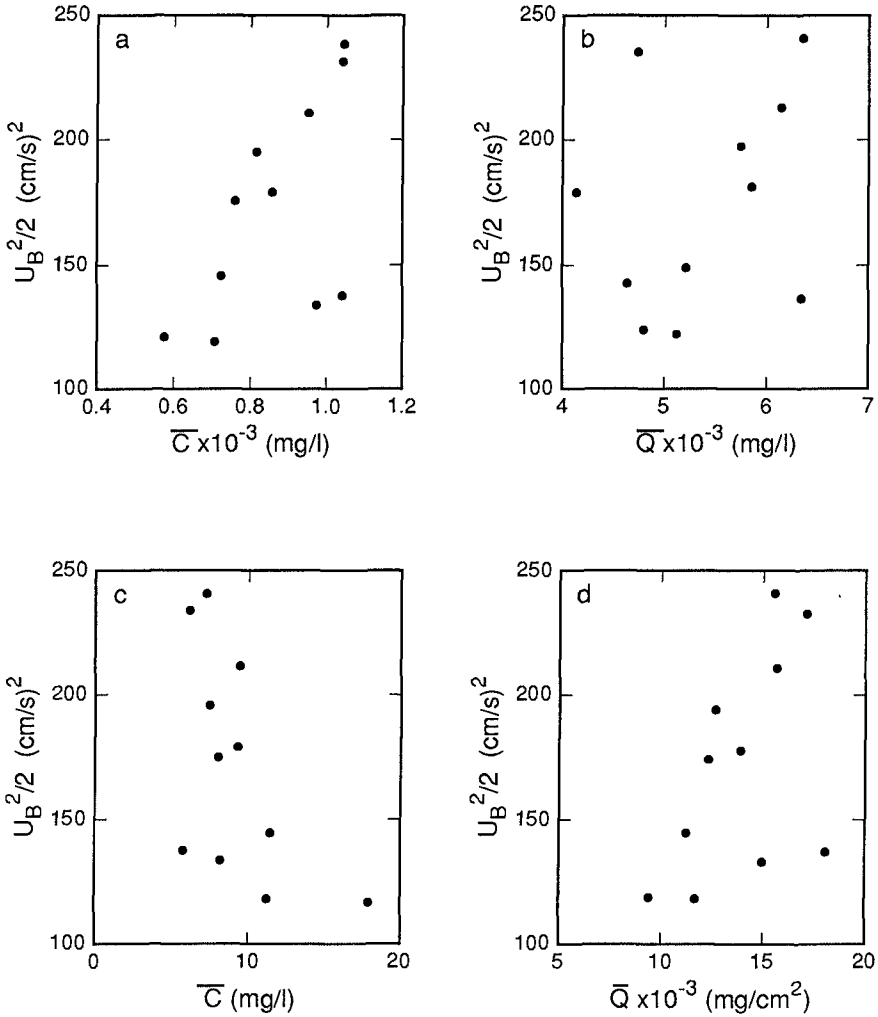

Figure 6. Scatterplots of a.) Bottom Orbital Velocity Energy,  $U_B^2/2$  vs  $C$  at 50cm AB; b.)  $U_B^2/2$  vs  $Q$ ; c.)  $U_B^2/2$  vs  $C$  at 50cm AB; and d.)  $U_B^2/2$  vs  $Q_{50}$

one half the bottom orbital velocity squared), and  $\bar{c}$  and  $Q$  at 5cm AB. Here, a clear linear relationship is at hand; reflecting not only the dominance of the wave in local bottom activity but also a relatively simple procedure for

perhaps constructing empirical relationships for bottom exchange. Figure 6c shows that  $U_b^2/2$  also correlates quite well with the integrated mass measure  $Q_{50}$ . Figure 6d, quite by contrast, shows poor correlation between  $U_b^2/2$  and  $\bar{c}$  at 50cm AB, thus indicating that a more complex suite of physical processes is at work in controlling the values of the two sediment measures.

### Shape Analyses and Correlation

Based upon a geometric shape analysis procedure developed by Velissariou and Bedford (1989) the 12 average profiles were analyzed and four relatively distinct regions separated by three "boundaries" were identified. Figure 7 contains the time series of the heights of the various boundaries. The top of the wave-current boundary layer is seen to be relatively steady at 10-11 cm AB; the transition region occupies the region between 12-24 cm AB and

Figure 7. Time Trace of the Heights of the Measured Transition Layer ( $\square$ ), the Measured Wave-Current Boundary Layer ( $\circ$ ), the Measured Mobile Layer (---) and the Calculated Wave-Current Layer (—).

below 3cm we found evidence for a mobile layer. The height of the wave-current boundary layer calculated by Glenn and Grant (1987) is also plotted and is seen to fall squarely on the geometrically determined heights.

Recognizing from the previous correlations how well TWKE and its subsumed but dominant wave kinetic energy correlated with integrated mass measures, it should come as no surprise that it also correlated very well with the total mass in the WCBL ( $Q_{11}$ ) and the total mass just in the transition layer ( $\bar{Q}_{11-24}$ ).

### Summary

The tower by which these data were collected contained an extremely robust and exotic suite of instrumentation. By examining various correlations in these robust data, we can perhaps begin to identify simpler point measurements that can be made with more readily available instruments. Clearly, these results indicate that TWKE, with its subsumed wave kinetic energy component, is a fundamental correlate with a number of important parameters including  $N_z$  ( $z=50$ ),  $\overline{c'w'}$  ( $z = 50$ ),  $Q_{50}$ ,  $Q_{11}$  (the mass in the WCBL) and  $\bar{Q}_{11-24}$  (the mass in the transitional layer). TWKE was a weaker correlate with near bottom  $Q_5$  and provided no correlation with  $C_5$ .

The wave kinetic energy in the form of  $U_B^2 / 2$  was a solid correlate with the bottom activity  $Q_5$ ;  $C_5$ .  $U_B^2 / 2$  didn't correlate well with  $C_{50}$ , nor did TWKE.

The WCBL height predicted by the Glenn and Grant model was identical to that measured by our devices indicating the soundness of that empirical representation as well.

While notable, these simplifications did come from a data set that was selected via some strong restrictions. That there are still many unexplained features and results in these data which suggests we have far to go in achieving understanding when we depart from the benign equilibrium conditions analyzed here.

### Acknowledgements

Funds for this research came from the Army Corps of Engineers Dredging Research Program Contract No. DACW-39-88-K-0040. These funds, and the advice and encouragement of Dr. N. Kraus, the contract monitor, are sincerely appreciated. Additional funds for this research provided by NOAA-Ohio Sea Grant Project RE 11/1 and the College of Engineering, The Ohio State University are also appreciated.

## CHAPTER 202

### LONGSHORE CURRENT AND LATERAL MIXING IN THE SURF ZONE

Ichiro Deguchi<sup>1)</sup>, Toru Sawaragi<sup>2)</sup> and Masanobu Ono<sup>3)</sup>

#### **Abstract**

We investigated the occurrence of FIG waves generated by a shear instability of steady longshore current on a uniformly sloping beach so that we can discuss the characteristic of Fig waves with respect to a wave breaking. We also carried out experiment to investigate cross-shore distribution of lateral mixing coefficient that determines the cross-shore profile of longshore current.

It is found that the occurrence and characteristic of FIG waves depend on a cross-shore profile of steady longshore current on the uniformly sloping beach as well as those on a beach of a constant depth analyzed by Bowen et al.(1989). The bottom slope affects FIG waves indirectly through the cross-shore profile of longshore current. The measured lateral mixing coefficient, which also gives influence on longshore currents, becomes maximum within the surf zone and decreases rapidly toward offshore. The locus where the maximum longshore current occurs, that plays an important role in the generation of FIG waves, depends on the surf similarity parameter of the incident wave.

#### **Introduction**

Various research regarding long period waves in a coastal region have been carried out. An object of the most of research is a long period wave corresponding to infragravity band. Wave number  $k_i$  of a long period wave of infragravity band is in a range of  $\sigma^2/g < k_i < \sigma^2/(g \tan \beta)$  and does not become larger than  $\sigma^2/(g \tan \beta)$ , where  $\sigma$  is the angular frequency,  $g$  is the gravitational acceleration and  $\tan \beta$  is the bottom slope.

According to recent field studies, waves of large wave numbers (short wave lengths) were observed in the lower frequency band than the infragravity band. Bowen et al.(1989) named such wave far infragravity wave (FIG wave). They analyzed the occurrence and characteristic of FIG waves and reported that a shear instability of steady longshore current caused FIG waves. However, their analysis was carried out

---

1) Assoc. Prof., 2) Prof. and 3) Research. Assoc., Dept. of Civil Eng.,  
Osaka University, Yamada-oka, Suita-city, Osaka 565, Japan

under the simplified condition where a constant water depth and a linear distribution of longshore current were assumed.

We analyzed the occurrence of FIG wave caused by the shear instability of steady longshore current on a uniformly sloping beach, a more realistic condition. We also examined the characteristic of lateral mixing coefficient that determines the cross-shore distribution of longshore current and accordingly exerts an influence on the occurrence of FIG wave greatly.

### Occurrence condition of FIG wave on a uniformly sloping beach

In this section, we analyze the characteristic of FIG wave under the condition where a steady longshore current develops on a long straight beach with parallel contours. A coordinate system is shown in Fig.1. An  $x$  axis is taken positive in the offshore direction from the still water shoreline and a  $y$  axis in the longshore direction.

Figure 1 Coordinate system

We assume that a perturbed motion is superimposed on the steady longshore current. Let cross-shore and longshore components of perturbed velocity be  $u(x, y, t)$  and  $v(x, y, t)$  and the depth averaged velocity of steady longshore current be  $V(x)$  where  $V \gg (u \text{ and } v)$ . We also express the surface displacements corresponding to the perturbed motion and a steady component as  $\eta(x, y, t)$  and  $E(x)$ .

The following fundamental equations for the steady component and perturbed component are obtained from a basic equation of a wave-induced current.

$$0 = -\frac{\partial E}{\partial x} - \frac{1}{\rho D} \frac{\partial S_{xx}}{\partial x} \quad (1)$$

$$0 = -\frac{1}{\rho D} \left( \frac{\partial S_{xy}}{\partial x} + \tau_y \right) + K_{xy} \frac{\partial^2 V}{\partial x^2} \quad (2)$$

$$\frac{\partial u}{\partial t} + V \frac{\partial v}{\partial y} = -g \frac{\partial \eta}{\partial x} \quad (3)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial V}{\partial x} + V \frac{\partial v}{\partial y} = -g \frac{\partial \eta}{\partial y} \quad (4)$$

where  $\rho$  is the density of water,  $\tau_y$  is the time averaged bottom shear stress in the longshore direction,  $S_{xx}$  and  $S_{xy}$  are the radiation stresses,  $K_{xy}$  is the lateral mixing coefficient and  $D$  is the total water depth ( $=h+E+\eta$ ).

We also suppose that a temporal variation of  $D$  is sufficiently smaller than spatial gradients of horizontal mass flux ( $uD$  and  $vD$ ) of perturbed motion in cross-shore and

longshore directions. The following equation of continuity for perturbed motion is obtained.

$$\frac{\partial uD}{\partial x} + \frac{\partial vD}{\partial y} = 0 \quad (5)$$

We define a transfer stream function  $\Psi$  by Eq.(6) that has a form of Eq.(7):

$$uD = -\frac{\partial \Psi}{\partial y}, \quad vD = \frac{\partial \Psi}{\partial x} \quad (6)$$

$$\Psi = \text{Re} \{ \phi(x) \exp [i(ky - \sigma t)] \} \quad (7)$$

where  $\text{Re}\{ \}$  expresses a real part of the complex quantity inside  $\{ \}$ ,  $\sigma$  and  $k$  are the angular frequency and the wave length of perturbed motion.

Eliminating  $\eta$  from Eqs.(3) and (4) and replacing  $(u, v)$  with  $\Psi$  by using Eq.(6), the following equation regarding  $\phi(x)$  is obtained.

$$(V - \sigma/k) \{ \phi_{xx} - k^2 \phi - (D_x/D) \phi_x \} - \phi D(V_x/D)_x = 0 \quad (8)$$

where subscript  $x$  indicates a partial differentiation regarding  $x$ . The term  $V_x/D$  indicates the background potential vortex.

Bowen et al.(1989) supposed a triangular distribution of longshore current on a beach of constant water depth. Under such assumption,  $D_x$  in Eq.(8) becomes 0. They solved Eq.(9) and discussed the characteristic of FLG waves based on the solution that is expressed by a hyperbolic function.

$$\phi_{xx} - k^2 \phi = 0 \quad (9)$$

However, there exists a bottom slope actually. Incident waves do break on the sloping bottom and longshore current generates. We examined various bottom profile where an analytical solution to Eq.(10) is obtained under the condition of  $(V_x/D)_x=0$  in Eq.(8).

$$\phi_{xx} - k^2 \phi - (D_x/D) \phi_x = 0 \quad (10)$$

It is found that when the bottom profile is expressed by Eq.(11), Eq.(10) becomes a modified Bessel's differential equation, Eq.(12).

$$D = x \tan \beta \quad (11)$$

$$\phi_{xx} - (1/x) \phi_x - k^2 \phi = 0 \quad (12)$$

A general solution to Eq.(10) is given by the first order modified Bessel functions of 1st and 2nd kind,  $I_1$  and  $K_1$  as follows:

$$\phi = p I_1(kx) + q K_1(kx) \quad (13)$$

where  $p$  and  $q$  are the integral constant. On the other hand, the surface displacement of perturbed motion is calculated by eliminating  $u, v$  from Eq.(4) by using Eqs.(6) and (7) as follows:

$$\eta = -\{ (V - \sigma/k) \phi_x - V_x \phi \} / gD \quad (14)$$

We assume the same profile of  $V_x/D$  as Bowen et al. did. According to this assumption, a distribution of longshore current becomes the full line shown in Fig.2. A notation  $X_0$  is the width of the longshore current whose velocity becomes the maximum ( $V=V_0$ ) at  $x=\delta X_0$  ( $0 < \delta < 1$ ). In the figure, the bottom profile and the distribution of longshore current assumed in the analysis of Bowen et al.(1989) are shown by broken lines.

Fig.2 Cross-shore distributions of  $V_x/D$  and  $V(x)$

The boundary conditions that the solutions in the regions of  $0 \leq x \leq \delta X_0$  and  $\delta X_0 \leq x \leq \infty$  have to satisfy are given as follows:

$$\phi(x) = 0 \quad : \quad \text{at } x=0 \text{ and } x=\infty, \text{ and}$$

Continuities of  $\phi$  and  $\eta$  : at  $x=\delta X_0$

When we eliminate integral constants in Eq.(13) by using these boundary conditions, the following dispersion relation for the perturbed motion is obtained:

$$a\sigma'^2 + b\sigma' + c = 0 \tag{15}$$

$$a = F_1 F_d \quad , \quad b = F_d / (1 - \lambda) - F_1 (k' F_d - \lambda)$$

$$c = \{1/(\delta - 1)\} \left[ \lambda \{1 - (I_{1d}/I_{11})(K_{11}/K_{1d})\} - k' F_d \right]$$

$$\lambda = 1/\delta + 1/(1 - \delta) \quad ,$$

$$F_1 = (I_{01} + I_{21}) / (2I_{11}) + (K_{01} + K_{21}) / 2K_{11},$$

$$F_d = (I_{0d} + I_{2d}) / (2I_{1d}) + (K_{0d} + K_{2d}) / 2K_{1d},$$

$$K_{jd} = K_j(k' \delta) \quad , \quad K_{j1} = K_j(k') \quad , \quad I_{jd} = I_j(k' \delta) \quad , \quad I_{j1} = I_j(k') \quad ,$$

where,  $\sigma'$  ( $=\sigma(V_0/X_0)$ ) is the non-dimensional angular frequency,  $k'$  ( $=kX_0$ ) is the non-dimensional wave number,  $I_j$  and  $K_j$  ( $j=0,1,2$ ) are the  $j$ -th order modified Bessel function of 1st and 2nd kinds.

From, Eq.(15), it is found that when  $\sigma'$  becomes a complex ( $\sigma' = \sigma'_r + i\sigma'_i$ ) with the negative imaginary part ( $\sigma'_i < 0$ ), the perturbed motion becomes unstable and the amplitude of perturbed motion increases exponentially with time. FIG waves are generated by this instability and  $\sigma'_r$  becomes a growth rate of FIG wave. This instability occurs under the following condition.

$$b^2 - 4ac < 0 \tag{16}$$

We can also see that the non-dimensional angular frequency is a function of non-dimensional wave number  $k'$  and  $\delta$  that is a parameter indicating the relative location where the maximum longshore current occurs. The bottom slope has nothing to do with the angular frequency explicitly.

Figure 3 shows the relation between  $k'$  and  $\sigma_r'$  calculated from Eq.(15). In the figure, the region where Fig waves can occur is also illustrated. Figure 4 is the relation between  $\sigma_i'$  and  $k'$  when Eq.(15) has complex solutions.

As the value of  $\delta$  increases the region where FIG wave occur spreads to the high waves number. The growth rate of FIG wave also becomes large. According to the results obtained by Bowen et al.(1989) both upper and lower limits in the wave number for the presence of FIG waves exist. However, only the upper limit in the wave number exists on the sloping beach.

Fig.3 Relation between non-dimensional angular frequency and non-dimensional wave number and occurrence range of FIG waves.

Fig.4 Growth rate of FIG wave

Figure 5 shows a relation between  $\delta$  and the maximum nondimensional wave number  $k'_m$  of FIG wave.

Fig.5 The maximum nondimensional wave number of FIG wave

Figure 6 shows the change of nondimensional celerity  $C_p'$  of FIG wave defined by  $\sigma'/k (= (\sigma/k)/V_0)$  with the non-dimensional wave number  $k'$  in the cases of  $\delta=0.3, 0.5$  and  $0.7$ . The values of  $C_p'$  of different values of  $\delta$  in Fig.6 do not show any significant difference.

Fig.6 Nondimensional celerity of FIG wave

From these results, it is found that the occurrence of FIG wave depends on only the value of  $\delta$  and the wave number and the angular frequency of FIG wave are determined by the values of  $X_0$ ,  $\delta$  and  $V_0$ . Also, the wave number of FIG wave is sufficiently larger than those of long waves of leaky mode ( $<\sigma^2/g$ ) and of edge

wave( $<\sigma^2/(g\tan\beta)$ ). For instance, when  $V_0=1\text{m/s}$ ,  $X_0=20\text{ m}$ ,  $\tan\beta=0.1$  and  $\delta=0.5$ , FIG wave exists in the region of  $k<0.15$  and  $\sigma<0.058$  from Fig.3. The wave period and the wave length corresponding to the maximum angular frequency are 108s and 41.9 m, respectively.

### Cross-shore distribution of longshore current velocity

As mentioned above, the characteristic of FIG wave deeply depends on a cross-shore distribution of steady longshore current. Many studies have been carried out about the steady longshore current on the long straight beach based on Eqs.(1) and (2). For example, an analytical solution of the velocity of steady longshore current derived by Longuet-Higgins (1970) is expressed as follows:

$$V/V_b = A(x/x_b) + B_1(x/x_b)^r \quad \text{for } x/x_b \leq 1 \quad (17)$$

$$V/V_b = B_2(x/x_b)^s \quad \text{for } x/x_b > 1$$

$$V_b = \frac{5\pi \tan\beta}{16 C_f} \sqrt{gD_b} \sin \theta_b \quad (18)$$

$$p = \pi N \tan\beta / (\gamma C_f) \quad , \quad A = 1/(1 - 5p/2) \quad ,$$

$$r = \left\{ -3/4 + \sqrt{9/16 + 1/p} \right\} \quad , \quad s = \left\{ -3/4 - \sqrt{9/16 + 1/p} \right\} \quad , \quad (19)$$

$$B_1 = A(s-1)/(r-s) \quad , \quad B_2 = A(r-1)/(r-s) \quad ,$$

where  $N$  in the expression of  $p$  is the constant relating to a lateral mixing coefficient,  $\gamma$  is the ratio of wave height to water depth,  $C_f$  is the friction factor and subscript  $b$  indicates the value at the wave breaking point.

As can be seen from Eqs.(17) and (18), the distribution and the absolute value of the longshore current velocity are determined by the values of  $p$  and  $V_b$ . Furthermore,  $V_b$  is decided by the celerity  $C_b$ , the wave direction  $\theta_b$  and  $\gamma_b$  at the wave breaking point if the assumption of  $\tan\beta/C_f = \text{constant}$  (Komar, 1976) is correct. The value of  $p$  also depends on only  $N$  and  $\gamma$ .

The point where the longshore current becomes maximum ( $x=\delta X_0$ ) and the maximum velocity of longshore current ( $V=V_0$ ) are determined by differentiating Eq.(17) with respect to  $x$ . However, we are not able to decide the width  $X_0$  of the longshore current easily. We must newly define the width of the longshore current by some methods, to evaluate the value of  $X_0$ . Here, we approximated the width  $X_0$  by the width of breaker zone  $x_b$ .

Figure 7 shows the relation between the maximum longshore current velocity and the relative location where the velocity of longshore current becomes the maximum to the breaker zone defined by  $\delta' (= \delta X_0/x_b)$ .

When we assume that the orders of  $\tan\beta/C_f$  and  $\gamma$  are 10 and 1, respectively, the value of  $p$  becomes about  $p=30N$  from Eq.(19). At this time, the value of  $p$  changes in a range of  $0.03 < p < 0.9$  with the range of  $N=0.001$  to  $0.03$ . According to these, the value of  $\delta'$  changes between 0.7 and 0.4 from Fig.7. However, the value of  $\tan\beta/C_f$  is not always constant in fact. Even  $\gamma$  changes with the bottom slope and the incident wave characteristic. Therefore, we examine the distribution of longshore current velocity and the value of  $N$  from experimental results.

Fig.7 Locus where the maximum velocity of longshore current occurs

### **Experiment on velocity distribution of longshore current and lateral mixing coefficient**

#### (1) Method of experiments and experimental conditions

Some experimental researches have already carried out about the distribution of longshore current. The steady longshore current on a long straight beach of uniform sloping beach is determined from the balance of driving force expressed by the gradient of the radiation stress, the bottom shear stress and the gradient of time and depth averaged Reynolds' stress. This relation is indicated by Eq.(2) and the solution to that is given by, for example, Eq.(17).

Among these, the time and depth averaged Reynolds' stress is usually expressed by the lateral mixing term of diffusion type using lateral mixing coefficient  $K_{xy}$ . However, it is extremely difficult to measure the coefficient, directly. Accordingly, only a few discussions have reported about the lateral mixing coefficient based on the analogy of measured diffusion coefficient  $\epsilon_{xy}$  in the surf zone under limited experimental conditions (for example Kim et al.(1982)). We carried experiments in a wave basin to measure longshore current and diffusion coefficient under a wide range of a surf similarity parameter assuming that the lateral mixing coefficient has similar property to the diffusion coefficient. Based on the measured results, we examine the dependencies of longshore current and the value of  $p$  on the surf similarity parameter and the possibility of the occurrence of FIG waves in the wave basin.

However, the longshore current that occurs in the wave basin with the limited width receives an influence of side walls of the basin. As was already pointed out by Visser(1991), the longshore current in the wave basin is different from that calculated from Eq.(17). We also examine this point based on the experimental results.

The wave basin used in the experiment is 20m long, 10m wide, and 0.6m deep. A mortar coated model uniformly sloping model beach was made at the end of the wave basin. The angle on wave incidence was  $30^\circ$  to the contour of the beach at the depth of 40cm. Two kinds of bottom slopes of 1/10 and 1/20 were examined.

Figure 8 is the illustration of the outline of the experimental set-up and Table-1 shows the experimental condition.

Fig.8 Experimental set-up

Table 1 Experimental condition

Case No.	H (cm)	T (s)	$\xi$	$x_b$ (cm)	$X_0$ (cm)	$V_0$ (cm/s)	$\delta$	$\delta'$
4	10.9	1.0	0.38	170	180	70	0.40	0.42
5	10.3	1.2	0.47	160	170	72	0.47	0.50
6	10.2	1.4	0.55	140	170	75	0.47	0.57
7	7.6	1.0	0.23	210	210	35	0.33	0.33
8	7.0	1.2	0.28	200	220	37	0.38	0.40
9	7.0	1.4	0.33	170	190	40	0.42	0.47
10	10.4	1.0	0.19	270	270	45	0.37	0.37
11	9.5	1.2	0.24	250	260	50	0.38	0.40
12	9.3	1.4	0.29	230	260	44	0.42	0.49

Case 4-6 :  $\tan\beta = 1/10$ , Case 7-12 :  $\tan\beta = 1/20$ ,

In the Table,  $\xi$  is a surf similarity parameter defined by  $\tan\beta\sqrt{H_0/L_0}$ , where  $H_0$  and  $L_0$  are the equivalent wave height and length of incident waves in deep water.

We measured wave height along 5 measuring lines by capacitance type wave gauges at an interval of 10cm in the cross-shore direction. Vertical and cross-shore distributions of water particle velocity along the center measuring line were measured by an electromagnetic current meter. We also measured loci of tracers released at the same point to evaluate longshore current velocity as advection speed and diffusion coefficient by applying a so-called one particle analysis method.

The diffusion coefficient at  $x = X_i$ ,  $\epsilon_{xy}(X_i)$ , was evaluated using the following equation:

$$\epsilon_{xy}(X_i) = \frac{1}{2} \frac{d\sigma_x(X_i, t)^2}{dt} \tag{20}$$

$$\sigma_x(X_i, t)^2 = \sum_{j=1}^{j_e} \{X_i(j, t) - \bar{X}_i\}^2 / j_e \tag{21}$$

where  $j_e$  is a number of tracers,  $\bar{X}_i$  is a mean cross-shore locus of at least 20 tracers whose initial released position is  $X_i$  and  $X_i(j, t)$  ( $j \geq 20$ ) is a position of  $j$ -th tracer after a time  $t$  released at  $X_i$ . The loci of tracers were measured by video analysis at time interval of 0.3s.

**Results and discussion**

(1) Lateral mixing coefficient

Various expressions for the lateral mixing coefficient have already proposed with respect to the steady longshore current on a long straight beach. When we normalize the lateral mixing coefficient by  $x_b \sqrt{gD_b}$  or  $\sqrt{gD_b} D_b / \tan\beta$ , many of them can be expressed by the following form:

$$\epsilon_{xy}' = \epsilon_{xy} / \{ \sqrt{gD_b} D_b / \tan\beta \} = e (D/D_b)^n \tag{22}$$

Some examples of the expression  $e$  in Eq.(22) are shown in Table 2.

Table 2 Examples of expression for lateral mixing coefficient

	$e$	$n$
Longuet-Higgins(1970)	$N (<0.01)$	1.5
James(1974)	$N \quad :D < D_b$ $N(D_b/D)^2 \quad :D_b < D$	1.5
Battjes(1975)	$M(5\gamma^2/16)^{1/3} \tan^{4/3}\beta$	1.5
Author et al.(1986)	$K F^{1/3} \gamma \tan\beta \quad :D < D_b$ $0 \quad :D_b < D$ $F = 5.3 - 3.5\xi - 0.07/\tan\beta$	1.5

According to Longuet-Higgins(1970),  $e$  becomes a constant  $N$ . Battjes' expression implies that  $e$  is a function of  $\tan\beta$  and  $\gamma$ . The author et al.(1982) also proposed that  $e$  is a function of  $\tan\beta$ ,  $\gamma$  and  $\xi$ .

Figure 9 illustrates measured cross-shore distribution of non-dimensional diffusion coefficient  $\epsilon_{xy}' (= \epsilon_{xy} \sqrt{gD_b} D_b / \tan\beta)$ . In the figure, a family of curves corresponds to the values of  $kxy'$  in the cases of  $e=0.00125, 0.0025, .005$  and  $0.008$  in Eq.(22). Numerals in the figure correspond to the case No. in Table 2.

It is found from the figure that measured diffusion coefficient does not show significant dependency on  $\xi$ . However, the values of  $\epsilon_{xy}'$  in the cases of a steep slope beach ( $\tan\beta=1/10$ ) are larger than those in the cases of a gentle slope beach ( $\tan\beta=$

1/20). In the former cases the value of  $\epsilon_{xy}'$  is in the region of 0.005-0.007 and 0.003-0.005 in the latter cases. It is also found that  $\epsilon_{xy}'$  becomes maximum near  $D/D_b=0.7-0.8$  and decreases rapidly toward offshore.

Fig.9 Cross-shore distribution of measured diffusion coefficient

(2) Cross-shore distribution of longshore current

Velocity of longshore current that was measured with an experiment differs from the velocity of longshore current in a seashore on a long straight line that is given with a solution of Eq.(2) due to an influence of a side wall of a reservoir.

Figure 10 show an example of comparison between calculated and measured longshore current velocity (Case-4). A solid line is the calculated result from the analytical solution on the long straight beach (Eq.(17)). Large open circles are the measured velocity by the electro-magnetic current meter and small circles are the advection speed of tracers. In the calculation of the velocity, we used the value of 0.005 for  $N$  in Eq.(17) according to the measured result. The value of friction factor was determined from the laminar boundary layer theory under waves and current.

Fig. 10 Cross-shore distribution longshore current (Case-4)

The decrease of the measured velocity near the wave breaking point is faster than the calculated longshore current in the wave basin.

Figure 11 is the wave-induced current pattern obtained from the numerical simulation of wave and current fields in the wave basin.

Fig.11 Simulated wave-induced current in the wave basin (Case-4)

It is found that the compensation flow generates outside the breaker zone. The broken line in Fig.10 is the cross-shore profile of longshore current in the center of the wave basin shown in Fig.11. The measure profile of longshore current is reproduced well by the simulated wave-induced current.

Although the measured longshore current in the deeper region around the breaking point is different from that of the analytical result on a long straight beach, the loci where the maximum longshore current occurs in both profiles differ a little. Therefore, we can discuss the relative location of  $\delta X_0$  to the breaker width  $x_b (= \delta')$  based on the experimental results.

Figure 12 shows the relation between  $\delta'$  ( $\delta$ ) and the surf-similarity parameter  $\xi$ . The values of  $\delta$  and  $\delta'$  are shown in Table-1.

Fig.12 Relation between  $\delta'$  ( $\delta$ ) and  $\xi$

In the figure, experimental results of Mizuguchi et al.(1978) are shown. The value of  $\delta'$  increases from 0.4 to 0.7 with the increase of  $\xi$  from 0.2 to 0.6. As I have already mentioned before, the change in the value of  $N$  corresponding to this change in  $\delta'$  is from 0.001 to 0.03 that is a little larger than the measured change in the value of  $e$ . Therefore, It seems necessary to study the reason for this discrepancy together with the dependency of  $C_f$  and  $\gamma$  on the surf-similarity parameter.

In the experiment, we found the long period fluctuations in water surface displacement and horizontal velocity whose period was about 30s. The corresponding wave length of FIG wave is estimated to be about 6m from the dispersion relation that is about 1/2 of the length of shoreline in the wave basin.

## **Conclusions**

We carried out the analysis of Fig waves on the uniformly sloping beach after the analytical investigation of Fig waves on a beach of constant depth by Bowen et al.. We also conducted experiments to examine the effect of lateral mixing on the cross-shore distribution of longshore current that determines the characteristic of FIG waves.

The main results obtained in this study are summarized as follows:

1. FIG waves on a uniformly sloping beach have upper limits in wave number and frequency.
2. The amplification factor (growth rate) of FIG wave becomes large as the locus where the maximum longshore current occurs becomes deep.
3. Measured diffusion coefficients show a little dependency on the surf-similarity parameter. They become maximum in the surf zone and decrease rapidly toward offshore.
4. The experimental results show that the locus where the maximum longshore current occurs becomes deep according to the increase of the surf-similarity parameter.

## CHAPTER 203

### LONGSHORE CURRENT INSTABILITIES: GROWTH TO FINITE AMPLITUDE.

Nicholas Dodd<sup>1</sup> and Edward B. Thornton<sup>2</sup>

#### Abstract.

The growth of shear instabilities in the longshore current to finite amplitude is studied. It is shown, by considering near-critical conditions and the self-interaction of the fastest growing mode (FGM), that the basic flow is supercritical and that, therefore, the disturbance may be expected to evolve to a finite size, with frequency equal to that predicted by linear stability theory, and final amplitude proportional to the linear growth rate. This is consistent with observation. The mean flow may therefore also be expected to evolve to a new form.

#### 1 Introduction.

The observations of Oltman-Shay *et al.* (1989) (referred to hereinafter as OSHB89), which were made in the presence of a strong longshore current and on a barred beach, show clear evidence of periodic motions at infragravity periods ( $> 50$  s), but with short wavelengths compared to edge waves of similar frequencies. The motions are not attributable to edge or any other form of surface gravity waves. These wave-like disturbances propagate alongshore in the same direction as the longshore current and with a speed proportional to the strength of that current (OSHB89), and, to a first order of approximation, they are non-dispersive (unlike edge waves). Bowen and Holman (1989) (referred to hereinafter as BH89) suggest that the observations are of a shear instability in the longshore current. The observed frequency (for a particular wavenumber  $k$ ) is then considered to be that associated with the fastest growing unstable mode (if more than one such mode is present). A detailed analysis (Dodd *et al.*, 1992—referred to hereinafter

---

<sup>1</sup>Institute for Marine and Atmospheric Research, Utrecht University, Princetonplein 5, 3584 CC, Utrecht, The Netherlands.

<sup>2</sup>Oceanography Department, Naval Postgraduate School, Monterey, CA 93943, U.S.A.

as DOT92) has confirmed that these wave-like motions are indeed shear instabilities. DOT92 also found reasonably good agreement between the shape of the observed variance spectra (especially that for the cross-shore velocity component) and that calculated from the predicted growth rate. They also demonstrated that bottom friction may provide a damping mechanism, which might explain why such instabilities are not seen more often.

So far, only the linear, temporal instability problem has been tackled. However, according to linear theory, unstable modes grow exponentially in time and so that theory may be expected to break down sooner or later, depending on the growth rates of the disturbances, which in turn depend primarily on the longshore current offshore shear and the damping (DOT92 estimate that the fastest growing shear instabilities will grow by a factor  $e$  in 300 to 400 seconds). However, the observations of OSHB89 and DOT92 were over lengths of time far exceeding these comparatively short times: typically one to four hours. This implies that the observed oscillations (instabilities) are fully developed, in some sense, and that finite-amplitude effects are of importance. Nevertheless, using just the linear stability theory, and assuming that only the fastest growing unstable mode is important (for any  $k$ ), DOT92 do notice good agreement between theory and observation (in frequency-wavenumber space). The conclusion seems to be that linearly unstable modes do grow and equilibrate (i.e., evolve to a finite amplitude and a steady form), with their final amplitudes being proportional to their linear growth rate, at least to a "first approximation".

In this paper we consider a weakly nonlinear theory. Unfortunately, this restricts us to so-called near-critical conditions (i.e., the longshore current shear is only just large enough to overcome the bottom friction and allow unstable modes to develop). Therefore, we shall also be restricted to only a small band of wavenumbers, centered on one *critical* value,  $k_c$ , whereas the linear analysis (DOT92) predicts a wider band of unstable wavenumbers whose shape and width correspond to that of the observed spectra. Notwithstanding this, it seems reasonable to expect that the analysis (based on the pioneering work of Stuart (1960) and others) will have physical relevance because it is centred on the wavenumber that will have the largest growth rate, and so and will at least reveal the qualitative long-time behaviour of the disturbances. The aim of this analysis is to confirm that the linear instabilities will evolve to a steady final form and to predict the amplitude of these forms.

In §2 the existing theory of the longshore current and of the shear instabilities of the longshore current are briefly reviewed, and the relation of each to the other is shown. In §3 finite-amplitude effects are introduced, and an evolution equation governing the long-time growth of the instabilities is derived. Results are shown in §4, and some conclusions are presented in §5.

## 2 Linear Theory.

We adopt a right-handed coordinate system in which  $y$  is the alongshore,  $x$  the cross-shore, and  $z$  the vertical coordinate. The water depth,  $z = -h$ , is assumed uniform alongshore: i.e.,  $h = h(x)$ . The total horizontal velocity field is denoted by  $\underline{u} = (u, v)$ , and we write the depth and time averaged horizontal velocity field as  $\underline{U}(x, y, t)$ , and decompose  $\underline{u}$  into

$$\underline{u} = \tilde{\underline{u}}(x, y, z, t) + \underline{U}(x, y, t), \quad (1)$$

where time averaging is performed over one period ( $T_g$ ) of the incident waves.  $\tilde{\underline{u}}$  represents deviations from the averaged velocity field; in particular, it represents the contribution to  $\underline{u}$  from the incoming wind waves, and the definition (1)  $\Rightarrow \langle \int_{-h}^{\eta} \tilde{u}_i dz \rangle = 0$ , where the triangular brackets denote the aforementioned time average.  $\underline{U}$  will only depend on the horizontal coordinates and a long timescale, and will therefore contain both the mean flow (i.e. the longshore current) and any long-time perturbations in that flow (i.e. shear instabilities in the longshore current). Similarly,  $\eta(x, y, t)$  is decomposed into  $\eta = \tilde{\eta} + \langle \eta \rangle = \tilde{\eta}(x, y, t) + \zeta(x, y, t)$ . Shear instabilities in the longshore current possess typical periods of  $O(100-1000 \text{ s})$ , and so their period is an order of magnitude greater than  $T_g$ . These timescales are clearly consistent with the above decomposition.

The shallow water momentum equations may be written as

$$\rho(\zeta + h) \left[ \frac{\partial U_i}{\partial t} + U_j \frac{\partial U_i}{\partial x_j} \right] = -\rho g(\zeta + h) \frac{\partial \zeta}{\partial x_i} - \frac{\partial S_{ij}}{\partial x_j} - \langle \tau_i \rangle, \quad (2)$$

for  $i = 1, 2$  (see Mei, 1989), where  $\langle \tau_i \rangle$  is the  $i$ th component of bottom friction, and  $S_{ij}$  are components of the radiation stress tensor. If, for the moment, we assume that all averaged quantities are time independent—and are therefore dependent on a timescale infinitely, rather than finitely longer than  $T_g$ —and make use of the assumed alongshore uniformity, then continuity  $\Rightarrow \underline{U} = (0, V(x))$  (see Mei, 1989). Therefore, the left side of (2) is identically zero, and the cross-shore momentum equation can be written as

$$0 = -g \frac{\partial \zeta_s}{\partial x} - \frac{1}{\rho(\zeta_s + h)} \frac{\partial S_{11}^{(0)}}{\partial x} \quad (3)$$

and the corresponding alongshore equation as

$$0 = -\frac{\partial S_{12}^{(0)}}{\partial x} - \langle \tau_2^{(0)} \rangle, \quad (4)$$

where  $\zeta = \zeta_s(x)$  is the mean, wave-induced change in the water level (i.e., the set-up/set-down). The superscript '(0)' is used to show that these terms are only included at their leading order (i.e., only the time-independent current  $V(x)$ , and  $\zeta_s(x)$  are included).  $\zeta_s(x)$ , can be found from (3);  $V(x)$ , is found from (4).

In the model of Thornton and Guza (1986)—referred to hereinafter as TG86—which we shall examine in detail, an analytical form is derived, by assuming that the incoming waves are narrow-banded in frequency but Rayleigh distributed in wave height, that the beach is plane with a slope  $s$ , and that the longshore current,  $V \ll \langle |\underline{u}| \rangle$  (the weak current assumption; see Mei, 1989). The alongshore momentum equation (4) then becomes

$$0 = -\frac{\partial}{\partial x} S_{12}^{(1)} - \rho c_f \langle |\underline{u}| \rangle V, \quad (5)$$

and we can write

$$V(x) = -\frac{1}{\rho c_f \langle |\underline{u}| \rangle} \frac{\partial}{\partial x} S_{12}^{(1)} = \mathcal{K}_1 h^{9/10} \{1 + \mathcal{K}_2 h^{23/4}\}^{-6/5}, \quad (6)$$

where  $c_f$  is the bottom friction coefficient, and the constants  $\mathcal{K}_1$  and  $\mathcal{K}_2$  can be found in TG86.  $\zeta_s$  is small compared with the depth for almost all  $x$ . Only very close to the idealised shoreline  $x = 0$  is  $\zeta_s > h$ . This makes virtually no difference to the ensuing analysis, so we shall ignore  $\zeta_s$  in calculations from now on, though we retain it in the derivations for the remainder of this section.

Following BH89, we may examine the linear stability of the mean, laminar, inviscid flow  $\underline{U} = (0, V(x))$  by superimposing a disturbance on that flow. Thus,  $\underline{U}$  is decomposed as

$$\underline{U} = (u'(x, y, t), V(x) + v'(x, y, t)). \quad (7)$$

Here,  $u'$  and  $v'$  represent perturbations in the components of the mean flow  $(0, V(x))$ ;  $\zeta$  is treated similarly:  $\zeta = \zeta_s(x) + \zeta'(x, y, t)$ . Thus,  $\zeta$  now consists of  $\zeta_s$  and an additional contribution due to the perturbations in the mean flow. Substituting (7) back into the momentum equations, we get

$$u'_t + V u'_y + u' u'_x + v' u'_y = -g[\zeta_s + \zeta']_x - \frac{\{S_{11}^{(1)}\}_x + \langle \tau_1^{(1)} \rangle}{\rho(\zeta_s + \zeta' + h)}, \quad (8)$$

$$v'_t + V v'_y + u' v'_x + u' v'_x + v' v'_y = -g\zeta'_y - \frac{\{S_{12}^{(1)}\}_x + \langle \tau_2^{(1)} \rangle}{\rho(\zeta_s + \zeta' + h)}, \quad (9)$$

where the superscript '(1)' denotes the inclusion of the perturbations in these quantities. If we now subtract (3) and (4) from (8) and (9) respectively, we get

$$u'_t + V u'_y + u' u'_x + v' u'_y = -g\zeta'_x - \frac{[\{S_{11}^{(1)}\}_x + \langle \tau_1^{(1)} \rangle]}{\rho(\zeta_s + \zeta' + h)} + \frac{\{S_{11}^{(0)}\}_x}{\rho(\zeta_s + h)} \quad (10)$$

$$v'_t + V v'_y + u' v'_x + u' v'_x + v' v'_y = -g\zeta'_y - \frac{[\{S_{12}^{(1)}\}_x + \langle \tau_2^{(1)} \rangle]}{\rho(\zeta_s + \zeta' + h)} + \frac{\{S_{12}^{(0)}\}_x + \langle \tau_2^{(0)} \rangle}{\rho(\zeta_s + h)} \quad (11)$$

These equations differ from (8) and (9) in that the mean motion has been subtracted out. Thus, (10) and (11) may be regarded as perturbation momentum equations.

Equations (10) and (11) are linearised by assuming that  $u'$  and  $v'$  are much smaller than the longshore current, and that, therefore, products of perturbed quantities are negligible. The quantities are further simplified by assuming that  $S_{ij}^{(1)} \approx S_{ij}^{(0)}$ .  $\zeta_s$  may also be neglected when compared with  $h$ . This gives us

$$u'_t + V u'_y = -g\zeta'_x - \frac{[\langle \tau_1^{(1)} \rangle - \langle \tau_1^{(0)} \rangle]}{\rho h} = -g\zeta'_x - \frac{\tilde{\tau}_1}{h}, \tag{12}$$

$$v'_t + V v'_y + u' V_x = -g\zeta'_y - \frac{[\langle \tau_2^{(1)} \rangle - \langle \tau_2^{(0)} \rangle]}{\rho h} = -g\zeta'_y - \frac{\tilde{\tau}_2}{h}. \tag{13}$$

Finally, a rigid-lid approximation is imposed, which enables us to introduce a stream function  $\Psi$ , where  $u' = -\Psi_y/h$  and  $v' = \Psi_x/h$ , so (12) and (13) can be combined into a single vorticity equation in  $\Psi$ . Assuming a harmonic dependence in  $t$  and  $y$ ,  $\Psi(x, y, t) = \text{Re}\{\phi(x)e^{i(ky-\omega t)}\}$ , then a stability equation analogous to the Rayleigh equation (see Drazin and Reid, 1981) is derived. The form of the stability equation depends on the form of the bottom friction terms on the right of (12) and (13). Here, we use the weak current assumption (for consistency with the TG86 model). In this case,

$$\frac{\tilde{\tau}_1}{h} = \frac{2\mu}{h} u' \text{ and } \frac{\tilde{\tau}_2}{h} = \frac{\mu}{h} v' \text{ where } \mu = c_d \langle |\tilde{u}| \rangle = c_d \frac{2}{\pi} u_0(x), \tag{14}$$

and  $c_d$  is also a bottom friction coefficient, theoretically the same as  $c_f$  and therefore determined empirically, but for our purposes treated as a parameter;  $\frac{2}{\pi} u_0$  is given by equation (16) of TG86. We write the resulting stability equation as

$$(V - i\mu/kh - c)\mathcal{L}\phi = h(V_x/h)_x\phi + (i/k)(\mu/h)_x\phi_x - (i\mu/kh)k^2\phi, \tag{15}$$

where  $\mathcal{L}\phi = \phi_{xx} - (h_x/h)\phi_x - k^2\phi$ , but we shall ignore the last two terms that appear on the right of (15) hereafter. The exclusion of these terms makes only a small difference in results (Dodd, 1992), but the simplified equation is desirable from the point of view of the ensuing weakly nonlinear analysis. Equation (15) is solved subject to the no-normal-flow boundary conditions  $\phi(0) = \phi(\infty) = 0$ . If it is assumed that  $k$  is real, then  $\omega$  and  $c = \omega/k$  are in general complex. If  $\omega$  possesses a positive imaginary part, then the mode grows exponentially (as  $t \rightarrow \infty$ ), and is therefore deemed unstable. Denoting  $\Re(\omega) = \omega_r$  and  $\Im(\omega) = \omega_i$ , then  $\omega_r$  defines the frequency,  $c_r = \omega_r/k$  the phase speed, and  $\omega_i$  the growth rate. If we ignore the bottom friction terms (i.e., put  $c_d = 0$ ), then the stability equation of BH89 is arrived at.

Results of a linear stability analysis of (15) for the  $V$  profile of TG86 are shown in Fig. 1. For  $c_d = 0$ , the fastest growing point on the growth rate curve is situated at  $k \approx .055 \text{ m}^{-1}$  (wavelength  $\lambda = 2\pi/k \approx 114 \text{ m}$ ), and has an associated period (Fig. 1c) of about 360 s. We refer to this disturbance as the fastest growing mode (FGM) (this terminology can be slightly misleading since for the TG86

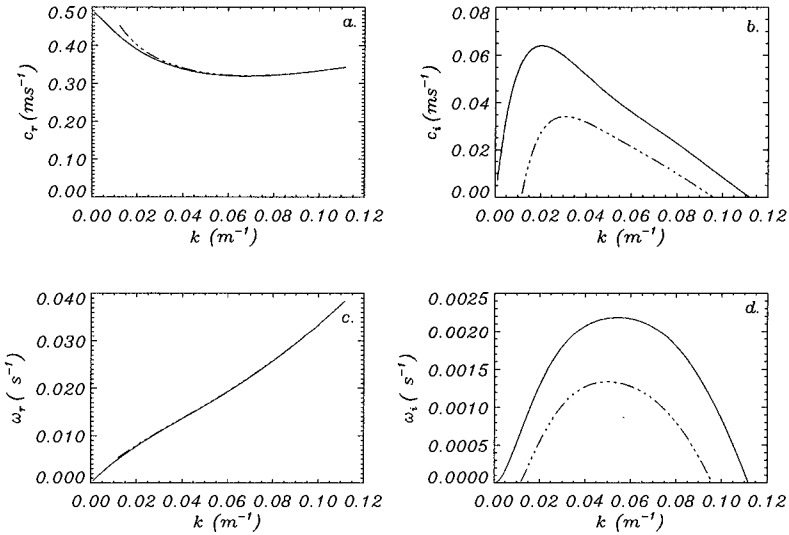

Figure 1: Linear stability for the TG86 model. (a) Real phase velocity, (b) imaginary part of phase velocity, (c) radial frequency, and (d) growth rate. Solid line:  $c_d = 0$ . Chained line:  $c_d = .003$ . ( $c_f = .009$ ).

profile there is only one unstable mode for any  $k$ ; the mode—eigenfunction—is continuously dependent upon  $k$ .

The inclusion of dissipation ( $c_d = .003$ ) reduces growth rates, though not quite uniformly. The position of the FGM is now at  $k \approx .045 m^{-1}$ . Frequencies (or phase velocities) are barely affected by the inclusion of friction. Clearly, at the FGM  $\partial\omega/\partial k = \partial\omega_r/\partial k$ , and in its vicinity,  $\partial\omega/\partial k \approx \partial\omega_r/\partial k$ , and so the group velocity will be the true velocity of displacement. It can also be seen that, to a first approximation, the motions are non-dispersive. Of course, as  $c_d$  is increased the growth rates are reduced still further, and the width of the band of unstable wavenumbers diminishes. The dimensionless parameter  $c_d^{-1}$  plays a similar rôle in this problem to that of the Reynolds number in the viscous stability problem. If  $c_d^{-1}$  is decreased beyond a critical value,  $c_{dc}^{-1}$  (and therefore  $c_d$  increased), then all (small) disturbances will be completely damped and no instability will develop. At  $c_d^{-1} = c_{dc}^{-1}$  all wavelengths are damped except for  $k = k_c$ , which is a neutral disturbance. Therefore,  $k = k_c$  and  $c_d^{-1} = c_{dc}^{-1}$  are referred to as *critical conditions*. In Fig.2, the neutral stability curve for (15) for the TG86 model is shown. If  $c_d^{-1}$  is increased slightly above its critical value, then we have so-called *near-critical conditions*

$$k = k_c \quad \text{and} \quad c_d^{-1} = c_{dc}^{-1} + \Delta c_d^{-1}. \tag{16}$$

Under these conditions, a small set of wavelengths, centred on the critical wavenum-

Figure 2: Neutral stability curve for the TG86 model. The asterisk shows the position of critical conditions  $(k_c, c_{dc}^{-1})$

ber  $k = k_c$ , becomes unstable, and propagates in the direction of the current at group velocity  $c_g \approx c_{gr} \approx c_r(k = k_c)$ . It is at these near-critical conditions that the weakly nonlinear analysis of the next section applies.

Finally, it is important to note that  $c_f$  and  $c_d$  are actually one and the same ( $= .009$ , NSTS, Feb. 4th, 1980; see TG86). The value of  $c_d = .003$  was chosen in Fig. 1 so that the effects of bottom friction could be seen without the instabilities being damped entirely (as they are for  $c_d = .009$ ). Thus, it is also important to realise that decreasing (or increasing) the bottom friction coefficient not only reduces (increases) damping of the instabilities, but also increases (reduces) the longshore current shear (cf. (6))—if we were to be consistent and put  $c_d = c_f = .003$  for the stability analysis in Fig. 1, we should expect all quantities to be three times as large. Of course, the case  $c_d = c_f = 0$ , which would predict an infinitely large  $V$ , would be physically meaningless.

From now on, we take  $c_f$  and  $c_d$  to be the same, (called  $c_d$ ) but continue to treat the bottom friction coefficient as a parameter.

### 3 Weakly Nonlinear Theory.

If we dispense with the assumption of small amplitude, then we can define mean momentum equations appropriate for the finite-amplitude disturbance by aver-

aging (8) and (9) over one alongshore wavelength  $\lambda$ :

$$\overline{u'u'_x} + \overline{v'u'_y} = -g \frac{\partial \zeta_s}{\partial x} - \frac{\{S_{11}\}_x + \langle \tau_1^{(1)} \rangle}{\rho(\zeta' + \zeta_s + h')}, \quad (17)$$

$$\overline{u'v'_x} = - \frac{\{S_{12}\}_x + \langle \tau_2^{(1)} \rangle}{\rho(\zeta' + \zeta_s + h')} \quad (18)$$

where the overbar denotes such an average. Amended perturbation equations may also be derived, by subtracting (17) and (18) from the full equations (8) and (9). If we again use the weak current assumption, we get

$$u'_t + V u'_y + u' u'_x + v' u'_y - \overline{u'u'_x} - \overline{v'u'_y} = -g \zeta'_x - 2 \frac{\mu}{h} u', \quad (19)$$

$$v'_t + V v'_y + u' V_x + u' v'_x + v' v'_y - \overline{u'v'_x} = -g \zeta'_y - \frac{\mu}{h} v'. \quad (20)$$

The difference between these equations and those of the preceding section is a different definition of what constitutes a mean.

By cross-differentiating (19) and (20) and then subtracting the second equation from the first, we get

$$\left\{ \frac{\partial}{\partial t} + u' \frac{\partial}{\partial x} + (v' + V) \frac{\partial}{\partial y} \right\} \left( \frac{\Pi + V_x}{h} \right) - \frac{X_x}{h} = \frac{\mu}{h} \left\{ \frac{\partial}{\partial y} \left( \frac{u'}{h} \right) - \frac{\partial}{\partial x} \left( \frac{v'}{h} \right) \right\}, \quad (21)$$

where  $\Pi = v'_x - u'_y$  and  $X = \overline{u'v'_x}$ . Note that all the mean motion has been subtracted out of (21). This motion may straightforwardly be retained in an equation such as (21), but we prefer to keep the equations for mean and fluctuating motions separate. Recall that, for a prescribed longshore current profile ( $V = V(x)$ ), linear theory predicts a stream function  $\Psi$  of the form  $\Psi(x, y, t) = \text{Re}\{\phi(x)e^{i(ky - \omega_r t)}e^{\omega_i t}\}$ . It has been shown (DOT92) that the frequency so predicted ( $\omega_r$ ) is in good agreement with the observed frequency for a given wavenumber,  $k$ . Furthermore, linear theory consistently predicts that  $\omega_r \gg \omega_i$ , even in the absence of bottom friction, so that it may safely be assumed that  $\Psi$  grows appreciably only over times in excess of the linear period,  $2\pi/\omega_r$ . It is, therefore, natural to regard  $e^{\omega_i t}$  as an amplitude modulation function. Clearly, however,  $\Psi$  will not continue growing without bound, and so  $e^{\omega_r t}$  must be considered to be the "short-time" expression of a more general (complex) amplitude modulation function  $a(t)$ . Thus, for the nonlinear problem we have

$$\Psi(x, y, t) = \text{Re}\{a(t)\phi(x)e^{i(ky - \omega_r t)}\}. \quad (22)$$

The initial time  $t = t_0$ , present through the constant  $a_0 = a(t = t_0)$ , provides a measure of how long the linear solution will be valid and the amplitude remain small, and therefore of how long linear theory remains applicable. By hypothesis,  $a(t) \sim e^{\omega_i t}$  as  $t \rightarrow -\infty$ , and  $a_0 \rightarrow 0$ . The long-time asymptote of  $a(t)$ ,  $a_\infty = \lim_{t \rightarrow \infty} a(t)$  (if such a limit exists) is the amplitude to which the initially small disturbances will evolve.

The weakly nonlinear problem can now be formulated by introducing a small parameter  $\epsilon$ , such that at near-critical conditions we have  $c_d^{-1} = c_{dc}^{-1} + \epsilon^2 \kappa$  (cf. equation (16)). We expect  $\omega_i$  and  $\Delta c_d^{-1}$  to be closely related, and expanding  $\omega_i$  in a Taylor series about  $c_{dc}^{-1}$  we find that  $\omega_i(k = k_c, c_d^{-1} = c_{dc}^{-1} + \Delta c_d^{-1}) = \partial \omega_i / \partial c_d^{-1}(k = k_c, c_d^{-1} = c_{dc}^{-1}) \epsilon^2 \kappa + O(\epsilon^4)$ . The amplitude  $a$  is dependent on a "slow" time coordinate  $T = \epsilon^2 t$ . We ignore the small but finite sidebands around  $k = k_c$ , and restrict ourselves to just the one, critical wavenumber; thus the disturbance will grow only by self-interaction.

Physically, we can think of the above conditions as being brought about by waves reaching the coast and building up the longshore current to the extent that the offshore shear in the current just overcomes the critical damping ( $c_{dc}^{-1}$ ), so that instabilities with wavelength  $2\pi/k_c$  develop. It is also implicitly assumed that the mean longshore current from which the instabilities begin to develop is steady.

The ansatz (22) is expanded to allow for self-interaction and for near-critical conditions:

$$\Psi = \sum_{n=1}^{\infty} \frac{1}{2} \{ \psi_n(x, t) e^{ni(k_c y - \omega_r t)} + \hat{\psi}_n(x, t) e^{-ni(k_c y - \omega_r t)} \}, \tag{23}$$

where a circumflex denotes a complex conjugate. Note that (23) still retains the phase velocity  $c_r$ , associated with the linear theory at critical conditions. The functions  $\psi_n$  are expanded as  $\psi_1 = \epsilon a \phi_1(x) + \epsilon^3 a^2 \hat{a} \phi_{11}(x) + \dots$ , and  $\psi_2 = \epsilon^2 a^2 \phi_2(x) + \dots$ , etc., where  $\phi_1(0) = \phi_1(\infty) = \phi_{11}(0) = \phi_{11}(\infty) = \phi_2(0) = \phi_2(\infty) = 0$ , etc.. Thus, the  $O(\epsilon^0)$  mean flow ( $V(x)$ ) becomes unstable, giving rise to  $O(\epsilon)$  fundamental disturbances ( $\psi_1 e^{i(k_c y - \omega_r t)}$  and c.c.). These, in turn, interact with each other, producing either 1st harmonic or mean components at  $O(\epsilon^2)$ . These components interact with components at  $O(\epsilon)$  to produce additional fundamental components and components at 2nd harmonic. This, it turns out, is as far as we need to go, and all terms of  $O(\epsilon^4)$  are ignored; for more details see Stuart (1960). Note that the mean terms are not included in (23), as they have already been subtracted from the momentum equations (see (19) and (20)); all these terms (up to  $O(\epsilon^2)$ ) are present in the mean equations (17) and (18). For the TG86 model, (18) becomes

$$\rho h \overline{u'v'_x} = - \frac{\partial}{\partial x} \overline{S_{12}} - \rho (c_{dc} + \Delta c_d^{-1}) \langle |\underline{u}| \rangle V. \tag{24}$$

More generally, we can write

$$V_2(x, t) = V_1(x) \left( 1 + \frac{\epsilon^2 \kappa}{c_{dc}^{-1}} \right) + \epsilon^2 |a(t)|^2 f(x) \tag{25}$$

where  $V_1$  is the solution at  $O(\epsilon^0)$  (i.e., the TG86 model, (6), at critical conditions).  $\Psi(x, y, t)$  and (23) are substituted into (21), and the various harmonics are collected (see Dodd (1992) for the resulting equation). The mean equation

(up to  $O(\epsilon^2)$ ), is already given by (25). For the fundamental, the equation is (at  $O(\epsilon)$ ) the linear problem of the previous section, (15) (but at *critical* conditions so that  $\mu = \mu_c = c_{dc}|\underline{u}|$  and  $k = k_c$ ). At 1st harmonic ( $O(\epsilon^2)$ ) there is an inhomogeneous equation—inhomogeneous because the fundamentals force the first harmonic by self-interaction. Finally, the fundamental also has a contribution at  $O(\epsilon^3)$ . It is this equation that requires a secularity (or compatibility) condition for its unique solution, and this condition yields the amplitude evolution equation. From this equation, and its c.c., it is easy to derive

$$\frac{d|a|^2}{dt} = 2\sigma|a|^2 - \ell|a|^4, \quad (26)$$

where  $\ell$  is a real constant called the Landau constant, and it can be shown that  $\sigma \approx \omega_i$ . All these equations and expressions are given in Dodd (1992).

The equation (26) is readily integrated to give

$$|a|^2 = \frac{C e^{2\omega_i t}}{\left(1 + \frac{\ell}{2\omega_i} C e^{2\omega_i t}\right)} \quad \text{where} \quad C = \frac{2\omega_i |a_0|^2 e^{-2\omega_i t_0}}{2\omega_i - \ell |a_0|^2}, \quad (27)$$

and where  $\sigma$  has been replaced by  $\omega_i$ . We are only concerned with cases where the longshore current is linearly unstable, i.e.,  $\omega_i > 0$ . In this case, as  $t \rightarrow \infty$ ,  $|a|^2 \rightarrow 2\omega_i/\ell$ , for any  $a_0$ , as long as  $\ell > 0$ . The flow may then be expected to evolve to a new, steady form (i.e., to equilibrate). When  $\ell > 0$  the flow is said to be supercritical. Conversely, if  $\ell < 0$ , then any infinitesimal disturbance will become unbounded after a finite time. In this case, the flow is deemed subcritical, because this breakdown can occur *below* critical conditions, for a *finite* disturbance (see Drazin and Reid, 1981). Physically, we expect the flow to settle down to a new steady form after some time, and that this form will have a period  $2\pi/\omega_r$  (i.e.,  $\ell > 0$ ). For a sufficiently small value of  $t$  the disturbance  $a(t)$  amplifies like  $\exp(\omega_i t)$ , corresponding to linear instability.

## 4 Results.

For the TG86 model,  $k_c \approx .0453 \text{ m}^{-1}$ , and  $c_{dc}^{-1} \approx .0083527$ . Finding the value of  $\ell$  requires a lot of computation: the linear (fundamental) problem must first be solved; then the problem for the first harmonic; and finally the the integrals needed to find  $\ell$  must be calculated. At the above critical conditions, it was found that  $\ell \approx 12300 \text{ s}^{-1}$ . For  $\Delta c_d^{-1} = 40$  (corresponding to a decrease in the bottom friction coefficient of about .0028 from critical conditions),  $a_\infty = \sqrt{2\sigma/\ell} \approx .00052$ . This figure is only meaningful when it multiplies the appropriate quantities. In Fig. 3 the resulting amplitudes of the velocities of with the fundamental and 1st harmonic disturbances are shown. The longshore current maximum is about  $.53 \text{ ms}^{-1}$ , so the fundamental disturbances reach about .066 of this value. The velocities associated with the first harmonic are at  $O(\epsilon^2)$ , and are therefore smaller

Figure 3: Moduli of complex perturbation velocities:  $\Delta c_d^{-1} = 40$ .

still. Also at this order is the term representing the deformation of the longshore current; it and  $V(x)$  are shown in Fig. 4. The effect of the mean deformation on the TG86 profile can just be discerned in Fig. 4a. For a larger value of  $\Delta c_d^{-1}$  these amplitudes would all be larger ( $|a| \propto \sqrt{\Delta c_d^{-1}}$ ), and vice versa. However, even with  $\Delta c_d^{-1} = 40$ , a large band of unstable wavenumbers is admitted, whose effects on each other are ignored in this analysis. Furthermore, the larger  $\Delta c_d^{-1}$  becomes, the further away from critical conditions we get, and the ordering assumptions behind the analysis breaks down. Nevertheless, for  $\Delta c_d^{-1} = 200$ , the same velocities are shown in Fig. 5. The perturbation velocities reach about  $0.075 \text{ ms}^{-1}$  (about one sixth of the current maximum), which is more typical of the observations of OSHB89, and DOT92.

The analysis of the previous section actually applies for any near-critical conditions; i.e., we can find a Landau constant for any point on the neutral curve shown in Fig. 2. We calculated its value for  $k_c = k_1 = .0209 \text{ m}^{-1}$  and  $k_c = k_2 = .08085 \text{ m}^{-1}$  (both of which share the same critical value of  $c_d = c_{dc} = .00689$ ,  $c_{dc}^{-1} \approx 145$ ). For  $k_1$ ,  $\ell_1 \approx 6900 \text{ s}^{-1}$ , and for  $k_2$ ,  $\ell_2 \approx 200,000 \text{ s}^{-1}$ . Although these values are not absolute indicators of the resulting perturbation amplitudes (because they depend on the normalisation of  $\phi_1$ , which was not uniform for the numerical scheme used herein), they do tell us that (1) for resulting amplitudes for  $k_1$  are bigger than for  $k_2$ , and (2) for all values of  $k$  tried so far,  $\ell > 0$ . Of course, these and all other such points on the neutral stability curve will only

Figure 4: (a)  $V(x)$  for TG86 (solid line), and modified mean current due to instability, (b) mean component due to instability:  $\Delta c_d^{-1} = 40$ .

exhibit instability *after* the overall critical condition (i.e., that at  $k \approx .0453 \text{ m}^{-1}$ ) has been surpassed, and will therefore be of lesser importance.

## 5 Conclusions.

It has been shown that, at least for the TG86  $V$  profile and for the stability equation (15), the longshore current is supercritical and disturbances may be expected to evolve to a finite, steady amplitude ( $\ell > 0$ ). This is in agreement with the observations of OSHB89 and DOT92. Only three positions on the neutral stability curve have been examined, but it seems very likely that  $\ell > 0$  for all  $k$  between  $k_1$  and  $k_2$  at least. Most importantly, this is true for the overall critical condition at  $k = .0453 \text{ m}^{-1}$  (see Fig. 2).

At true near-critical conditions (represented here by  $\Delta c_d^{-1} = 40$ ), the fundamental disturbances evolve to only about 1/15th of the  $V$ -maximum, whereas the observed disturbances were more typically one third of this value. This may be indicative of a number of things: (a) The  $V$  and  $h$  profiles measured at Duck, North Carolina (where the observations of OSHB89 were made) were significantly different from the TG86 model, and the barred beach profile and stronger current shear there may give rise to larger amplitudes (though without doing the weakly nonlinear analysis for these data it is hard to say). If this were so, it might provide

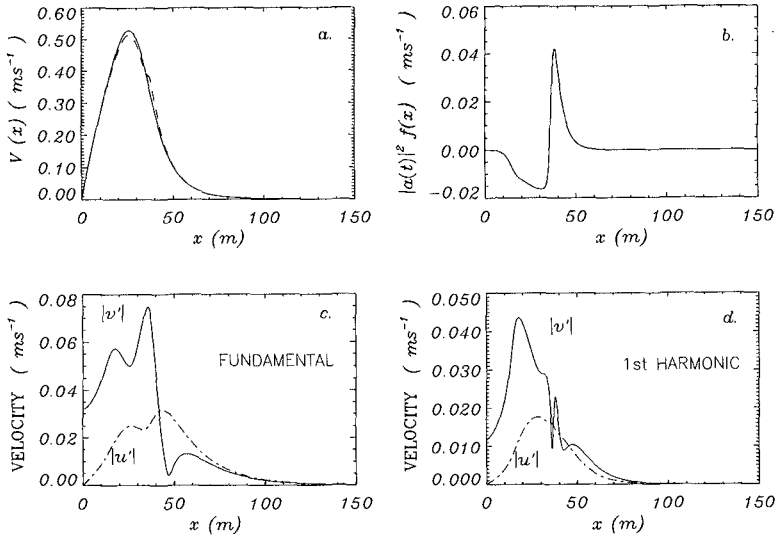

Figure 5: Linear stability for the TG86 model. (a) Original (solid line) and modified mean current, (b) mean component due to instability, (c) and (d) moduli of complex velocities due to instabilities:  $\Delta c_d^{-1} = 200$ .

a further, accompanying (and highly intriguing) mechanism for explaining why longshore currents on a plane beach do not ‘apparently’ become unstable: even if an instability were to develop, it will be restricted by nonlinearity to a small amplitude. Of course, linear growth rates for Duck are much larger than those for the TG86 model (Santa Barbara, California; DOT92), but the weakly nonlinear analysis only applies for near-critical conditions. The problem is then one of whether or not  $V$  continues to increase above critical conditions faster than do the instabilities that would presumably appear as soon as these conditions are first exceeded. In the time series shown by OSHB89 (Fig. 8 of that paper) it appears that the instabilities develop rather faster than  $V$ , as they seem to be established well before the end of the record. Whether this is true in general is not known. If it is not, then the weakly nonlinear approach would not be appropriate.

(b) Though near-critical conditions may be appropriate, the simple model presented here, in which only one wavenumber  $k_c$  is important, may be unrealistic, because  $k_c$  is only a ‘first among equals’ (Drazin and Reid, 1981), wavenumbers immediately to the sides of  $k_c$  having growth rates only infinitesimally smaller than that for the FGM. Thus there will be a group of wavenumbers propagating at group speed  $c_g \approx \partial\omega_r/\partial k$  (see §2). In this case, the appropriate analysis is that of the Ginzburg-Landau equation. The stable solutions given by the theory presented here (stable only to *self-interaction*), may no longer be so for other

wavelengths (there may be a side-band instability), and disturbances may evolve further to a larger amplitude. Work on this topic is now under way.

It is clear that, whatever their eventual amplitude, instabilities will in some measure modify the mean longshore current profile. The appropriate equation for determining this profile would therefore be an equation like (24). However, some confusion seems to have arisen concerning this new, mean profile: the profile produced by the instabilities is only the mean *component* of a fully developed *finite* disturbance; *the flow is stable to disturbances of wavenumber  $k_c$ , and it is no longer laminar, and the methods of linear stability can no longer be applied to it.* Therefore, any new, large shears apparent in the new profile should not be interpreted as leading to new instabilities.

This work provides justification for the growth rate scaling of DOT92. The final amplitude is indeed proportional to the growth rate, and the very large value of  $\ell$  for  $k_2$  indicates that the amplitudes will decrease rapidly with increasing  $k$  ( $\omega_r$ ).

Finally, two points should be mentioned: (1) The rigid-lid assumption does in fact break down in the weakly nonlinear analysis, but only at  $O(\epsilon^3)$ . This produces a small correction to the growth rate; (2) Bottom friction is not the only form of damping of the instabilities; turbulence induced by wave breaking will also have a direct effect, and should be examined in future studies.

## CHAPTER 204

### PROFILE DEVELOPMENT OF DUNES DUE TO OVERFLOW

by Henk J. Steetzel<sup>1)</sup> and Paul J. Visser<sup>2)</sup>

#### Abstract

The set-up and preliminary results of a series of model investigations on dune breaching is presented. Based on these 2DV-tests the insight into the processes related to the lowering of the crown of a sandy dam during overflow conditions has been enlarged significantly. Although dam erosion is mainly due to transport processes on the inner slope, the angle of the outer upstream slope showed to be very important also. Coarser sand results in larger erosion rates, whereas the effect of packing is only minor.

#### 1. Introduction and background

The Technical Advisory Committee on Water Defences (TAW) in The Netherlands is completing a probabilistic design method for dunes and dikes, which determines its optimal cross section as a function of both construction and expected damage costs (deaths, loss of property, etc.) due to failure of the structure. In order to be able to determine the damage costs, it is necessary to predict the rate of inundation of the polder governed by the discharge rate through a breach.

The effect of a local dike breach in terms of costs, is mainly governed by the final level and speed of inundation. Apart from for example the dimensions of the low-lying polder behind the breach, this level will definitely be related to the flow rate through the breach and thus by its dimensions. These dimensions, e.g. the breach width and depth, will not be constant. Moreover they increase in time, affecting the total discharge rate and thus the expected inundation level and damage costs.

  - 2) Scientific Officer, Delft University of Technology, Faculty of Civil Engineering, P.O. Box 5048, 2600 GA Delft, The Netherlands

Detailed knowledge of the process of breach growth to predict the inflow rate is therefore indispensable.

## 2. Approach

### 2.1 Introduction

The process of breaching of dunes and dikes is a very complex phenomenon [Delft Hydraulics, 1988], as clearly confirmed by a field experiment described in [Visser et al., 1990]. As a first result, an useful theoretical model to describe the breaching process is presented by Visser [Visser and Steetzel, 1992].

The final objective of the long-term research program is to enlarge the insight in the obviously rather complicated three-dimensional processes which control the breach growth, this in order to assess the rate of water inflow through an eroding breach into a polder with a mathematical model. This study can be seen as a follow-up on dune erosion studies [Steetzel, 1993], in order to predict the profile development and consequences of a dune failure during a critical storm surge.

### 2.2 Successive research phases

The inflow rate through a breach will mainly be controlled by the decrease of the maximum crown level in the breach (say increase in breach depth) and the increase in the width of the breach along the axis of the defence structure.

Focusing in more detail on a specific cross-section, the development of the breach dimensions, say breach width and breach depth, will depend on:

- the outer hydraulic conditions (water level, intensity of wave attack),
- the dimensions of the structure (crown height, crown length and both the inner and outer slopes) and
- its composition (material present and kind of foundation) as well as
- the inner condition, namely the level of the polder.

Some physical model tests have been carried out to study the breaching process for a sandy structure. The results of these tests are used to develop, calibrate and (afterwards) verify a mathematical model. To study erosion processes in detail, initially a series of two-dimensional model tests were conducted in the Schelde flume of the Delft Hydraulics [Delft Hydraulics, 1991]. Simultaneously, a general applicable mathematical model is being developed in order to compute and predict profile developments and inflow rates for all kinds of hydraulic and geometric conditions.

In a following phase also some tests on three-dimensional breaching have been carried out in a basin, merely to study the processes which control the growth of the breach width.

### 2.3 Outline of present contribution

This paper focuses in more detail on the set-up and results of a series of first model investigations on 2DV-breach growth, which were carried out at the end of 1991. These tests provide the development of the breach along the breach axis. At the end of this paper some concluding remarks are made on both the results of these tests and the next phases of the research program. A related paper on this subject is presented by Visser and Steetzel [1992].

## 3. Model investigations

### 3.1 Model facility

The vertical development of a uniform structure due to overflowing water was investigated in the 50 meter long Schelde flume of the Delft Hydraulics, as shown schematically in Figure 1. The effective width of the flume at the dam location was 0.40 m. A pumping system was installed in the flume to recirculate the overflowing water in order to maintain a more or less constant high outer water level for as long as possible.

### 3.2 Initial cross-section

At about 35 m from the wave board, a sandy dike-like structure was built having a 1.30 m long ( $L_{c,0}$ ) and a 0.70 m high horizontal crown ( $Z_{c,0}$ ). At the top of the crown a temporary defence structure was placed.

In these tests it is assumed that for some reason an initial, small breach is present at the beginning of a test (at  $t = t_0$ ). Consequently, in these 2DV-tests the initial outer water level was chosen to exceed the crown level by 0.05 m. After removal of the sandbag (in fact the start of a test denoted as  $t=t_0$ ), water started flowing down the inner slope and the erosion of the dam occurred.

Figure 1 Model set-up, initial profiles (showing three slopes) and measuring positions of water levels and velocities (latter denoted by o-symbols)

In this test set-up three different outer slopes have been tested, ranging from 1 in 4 to 1 in about 35. Furthermore the grain size as well as the bed porosity of the dam have been varied.

### 3.3 Instrumentation

In order to allow a good recording of the erosion process, extensive instrumentation was installed in the flume. In the upstream inflow section, four sets of two electromagnetic velocity meters were placed. Furthermore at 7 positions wave gauges were present to record the development of the local water level.

At the position of the sand dam itself, the glass wall of the flume was utilized with a square (0.10 m) grid. By recording each of the tests with three simultaneously operating video-cameras, the development of the dam profile has been determined by analyzing these recordings with great accuracy.

Model set-up, including initial profiles and position of measuring devices is presented in Figure 1. In this way the profile development due to initial overflow (video-recordings) and a range of seven instantaneous velocity profiles and water depths were monitored during the breaching process.

### 3.4 Test program

The relative, quantitative effect of next parameters has been investigated:

- the seaward bottom slope, ranging from a 1:4 (dike) to 1:15 and a 1:30/40 slope (schematized dune erosion profile);
- the effect of waves on the breaching process, by comparing profile development with and without the presence of wave attack;
- the effect of sediment diameter, by comparing results of  $D_{50} = 105 \mu\text{m}$  and  $D_{50} = 218 \mu\text{m}$ ;
- the effect of porosity, by comparing results of two different porosities (with typical values of 38 and 45 % respectively).

An overview of the tests performed is presented in Table 1.

test number	brief description
T0	Essay experiment
T1, T2 and T3	Set of similar tests with mutually different angles of the outer slope
T4	Repetition of previous test (T3) with additional wave attack
T5 and T6	Repetition of both test T1 and T3 respectively using coarser sand for dam construction
T5A	Repetition of test T5 to check on the reproducibility of a test
T7	Repetition of test T5 for a more loosely packed dam

Table 1 Overview of test program

In total, the development of the sandy dam has been investigated in nine tests. In test T0 - T4 fine sand was utilized, while in the other tests (T5 - T7) coarse dune sand was used to construct the dam.

#### 4. Direct test results

##### 4.1 General

From each of the tests performed, two sets of data were obtained. The direct results, as discussed in this section, consist out of the observed profile development as well as the recordings of water level and water velocities during the erosion process. After analyzing these data, detailed information on the discharge rates and the apparent transport rates have also been obtained. Some examples of latter dataset are presented in the next chapter.

##### 4.2 Profile developments

The schematic development of the cross-section of a dam during the erosion process is shown in Figure 2.

Figure 2 Schematic three-phase development of cross-section:  
I - increasing steepness of inner slope, II - decreasing crown length, III - decreasing crown level

In these tests, three subsequent stages (I, II and III respectively) can be distinguished. Initially the increasing transport rate on the inner slope results in a steepening of this slope up to a critical value. In phase II, the erosion of this slope remains nearly constant in time, resulting in a decrease of the length of the crown ( $L_c$ ). After erosion of the complete crown (at  $t = t_2$ ), the maximum crown level ( $Z_c$ ) starts to reduce. During this third phase, the discharge rate starts to increase strongly.

The grid on the glass wall allowed a direct assessment of both the instantaneous dam profile as well as the water depth contour. Figure 3 shows the observed development of the cross-shore profile (based on the analyses of the video-recordings) in test T5A. The numbers indicate the time in seconds with respect to the actual start of the test. Contours are presented at 20 seconds intervals.

Lowering of the crown started after about 140 s ( $= t_2 - t_0$ ). The average speed of reduction of the crown length amounts about 0.01 m/s. As can be observed, the total duration of such a test lasted only 5 to 6 minutes. At the end the total dam was washed out and, for the most part, in suspension circulating in the flume.

Figure 3 Measured development of cross-section during erosion process (for test T5A)

#### 4.3 Water levels and velocities

The recordings of both water level and flow velocities are very important, since the water motion over the inner slope dominates the process under investigation. The observed velocities on the inner slope range from 0.5 to 3.0 m/s. Moreover the data at the begin of the inflow section will be used as a boundary condition for the mathematical model.

#### 4.4 Additional measurements

During the test program additional measurements were carried out to assess water temperature, grain size distribution and actual volumetric porosity.

### 5. Interpretation of results

#### 5.1 Introduction

A thorough analysis of the results has provided valuable information on the water motion as well as on the sediment transports during the breaching process. The outcomes will also be used in order to check and improve the computational model. As can be seen readily from the former figure, the erosion is taking place at the inner slope of the dam.

#### 5.2 Crown development

The development of the maximum crown elevation for all tests is shown in Figure 4.

In the first stage of decreasing crown length, the crown level remains constant. Next, say from about 140 s, the level decreases. The actual rate of decrease differs for some tests due to the different test conditions. Most clear is the effect of the outer slope,

showing a relative decrease of this rate for the more gentle slopes (as present in tests T2, T3 and T6).

Figure 4 Overview of development of maximum crown level  $Z_c$  for all nine tests performed

### 5.3 Crown discharge rates

From the simultaneously measured velocities and water levels the magnitude of the rate of crown discharge has been estimated. An example of the computed development (for the same test T5A) is shown in Figure 5. In this figure both the instantaneous estimate at a frequency of 25 Hz (denoted by the small dots) as the filtered signal are presented. Furthermore the actual start of the test (denoted by  $t_0$ ) and the start of lowering of the crown level (denoted by  $t_2$ ) can be observed. At  $t = t_2$  the discharge starts to increase dramatically up to a more or less constant magnitude which is related to the installed pump capacity.

Figure 5 Development of computed (crown) discharge  $Q_c$  (for test T5A); both instantaneous estimate and smoothed signal (denoted by dots and line respectively) are shown

#### 5.4 Transport rates

As a result of the observed and recorded profile development, the apparent transport rate  $S$  was computed from the sediment balance equation at several moments and positions for each test. Figure 6 shows in the down-left corner a detail of the inner slope of the dam in test T5A at  $(t - t_0) = 100$  s.

The calculated transport distribution on a horizontal grid is shown at the top of the figure. The same distribution on a vertical grid is presented on the right, showing a near-linear downward increase of the transport and thus indicating a more or less equilibrium shape of the inner slope for this particular case. From visual observations of the transport process it has been concluded that this increasing transport rate is related to an increase in the thickness of the near-bottom suspension layer (sheetflow layer). The mean concentration within this layer has been estimated to be about 40 to 50% by volume.

Figure 6 Computed transport distribution ( $S$ ) at inner slope of test T5A after  $(t - t_0) = 100$  s; both  $S = F(x)$  (upper figure) and  $S = F(z)$  (right-hand figure) are presented

## 6. Conclusions

### 6.1 General

Studying breaching processes in a model facility is difficult because of the speed of the processes involved, although in the present tests very accurate data on the breaching process have been obtained. Moreover the repetition of an identical test (test T5 and T5A) showed an almost perfect reproduction of the principal results. Some of the main conclusions are summarized hereafter.

### 6.2 Effect of seaward bottom slope

The influence of the seaward bottom slope is very important and primarily related due to volumetric effects. A relatively steeper outer slope results in a larger erosion rate.

### 6.3 Presence of wave attack

The presence of wave attack leads to accelerated erosion and speeds up the erosion process significantly.

#### 6.4 Sand diameter

Coarser sand increases the erosion rate by 15 to 25 %. This seems mainly due to the effects of hindered erosion present in case of finer material.

#### 6.5 Sand porosity

Effects of sand porosity are relatively small, although a loosely packed dam shows an about 5 % increased transport rate (for coarse sand).

### 7. Next research items

#### 7.1 Introduction

Although very interesting and useful findings have already been obtained, a continuing further analyses of the large amount of available data will enlarge the insight in the processes responsible for the breaching phenomena further.

#### 7.2 Computational model

In the development of the numerical mathematical model, one of the major problems to be dealt with is the formulation of the transport rates.

The sediment transport at high velocities is not yet well understood. Literature review, e.g. [Voogt et al, 1991], indicated that standard formulae tend to overestimate the transport rate. The transport on the inner slope seems to be affected by at least non-local effects and hindered erosion.

The dynamical, computational model will be based on the water motion according to the quasi-steady 'long wave' equations. Crown discharges will be iteratively derived using 'backward fitting', after which the super critical downward flow along the inner slope is computed. The sediment transports will initially be based on an adapted energetics-based Bagnold-formula (see [Visser, 1988]), although ongoing analyses of all the available test results may lead to other formulas.

#### 7.3 Further testing

Some additional tests on three-dimensional breaching in a basin have been carried out also. Next phases of the research program will have to enlarge the insight into the effect of clay and the presence of partial revetments on the breaching process.

Both the results of the computational model as the outcomes of the 2DH/3D-model investigations will be discussed in a forthcoming paper.

## 8. Acknowledgements

The present study is carried out at Delft Hydraulics on behalf of the Technical Advisory Committee on Water Defences of the Ministry of Transport and Public Works (Rijkswaterstaat) in The Netherlands. W.Th.J.N.P. Bakker, J. van de Graaff and A.W. Kraak are acknowledged for their comments and stimulating support during the preparation and elaboration of the tests.

## CHAPTER 205

### THE CONTRIBUTION OF SUSPENSION EVENTS TO SEDIMENT TRANSPORT IN THE SURF ZONE

Bruce Jaffe<sup>1</sup> and Asbury Sallenger, Jr.<sup>2</sup>

#### ABSTRACT

Suspension of sand in the surf zone is intermittent. Especially striking in a time series of concentration are periods of intense suspension, suspension events, when the concentration is an order of magnitude greater than the mean. We used field data collected in the inner half of the surf zone during a large storm (greater than 1.5 m wave heights and 13 second periods) to define and describe suspension events and determine the contribution of events to the sediment transport.

Large suspension events were found throughout the inner half of the surf zone, occurred about once every 1 to 2 minutes, and each had a duration of about 5 seconds. These events tended to occur during onshore flow under the wave crest, resulting in an onshore contribution to the suspended-sediment transport. Even though large events occurred less than 10 percent of the total time, at some locations onshore transport associated with suspension events was greater than the offshore directed transport during non-event periods, causing the net suspended sediment transport to be onshore. Events and longshore velocity were not correlated. However, events did increase the longshore suspended-sediment transport by approximately the amount they increase the mean concentration, ranging from 15 to 55 percent depending on the definition used for events. Because of the lack of correlation, the longshore suspended-sediment transport can be adequately modeled as the vertical integration of the product of the time-averaged longshore velocity and the time-averaged concentration.

## INTRODUCTION

Ever since the first surf-zone deployment over 25 years ago of a fast-response instrument that monitored the amount of sediment in suspension (Brenninkmeyer, 1976a,b), researchers have observed short periods of intense suspension when sediment reaches high (order 1 m) into the water column. These intense suspensions were separated by longer quiescent periods when sediment concentrations were an order of magnitude less and suspension was confined to near the bed (order 10 cm). Brenninkmeyer, 1976a, called these intense periods "sand fountains". We will refer to them as "suspension events" following the terminology of Downing (1983).

Models for sediment suspension currently are not able to predict the occurrence of suspension events in the surf zone. In this paper, field data are used to objectively define event periods from a suspended-sediment concentration time series collected in the surf zone during a large storm. The average properties of suspension events are described and the contribution of events to the longshore and cross-shore suspended sediment transport are determined. We show that large suspension events tend to occur during onshore flow under wave crests and result in an onshore transport that can dominate the net suspended transport.

## EXPERIMENT SETTING AND METHODS

A large cooperative field experiment investigating the morphologic response of the nearshore to storms was conducted at the Army Corps of Engineers Field Research Facility (FRF) at Duck, North Carolina in the Fall of 1982 (see Mason and others, 1984, for a description of the experiment). The FRF is located on a long straight beach with bi-modal sand on the foreshore (1.0 mm and 0.3 mm modes), sand and pebbles in the longshore trough, and fine sand (~0.15 mm) offshore.

As part of this experiment the US Geological Survey deployed an underwater sea sled (Sallenger and others, 1983) equipped with instruments to measure waves, currents, sediment suspension, and profile change. Waves were measured using a pressure sensor and horizontal currents were measured at 3 elevations (0.5, 1.0, and 1.75 m above the bed) using 1" Marsh-McBirney electromagnetic current meters. Suspended-sediment concentration was measured at 5 elevations (0.10, 0.13, 0.19, 0.31, and 0.61 m above the bed) using optical backscatter sensors (OBS, Downing, 1981). The nearshore profile was measured using an infrared range-finder sighting on prisms mounted on a 10 m mast as the sled was pulled offshore and onshore by a winch and lines and a system of blocks.

Sled measurements were carried out for a two-week period during which one large extra-tropical cyclone (northeaster) and a smaller storm generated large waves and strong currents at the field site. The standard daily measurement regime was a starting profile extending several hundred meters offshore, processes measurements at up to 8 locations across the surf zone, and an ending profile to determine changes during the processes measurements. The entire procedure took about 6 hours and bracketed the time of high tide to minimize sea-level changes through the measurement period. At each of the measurement locations, 34.1 minutes of data were collected at 2 Hz for each sensor.

The largest profile response occurred during the northeaster of October 10-15. A linear bar formed on October 10th (Sallenger and others, 1985, Mason and others, 1984) and evolved into a crescentic bar by October 15th. The position of the bar crest on the sled transect moved offshore during the 10th, 11th, and 12th at rates as great as 2.2 m/hr and then migrated onshore on October 13th. The data presented in this paper were collected on October 13th.

The waves and currents were influenced by the barred profile of October 13th (Fig. 1). Because of the length of line pulling the sled, it was limited to operating in the inner six-tenths of the surf zone. Measurements were made at 7 locations between 17 and 224 m offshore, in water depths ranging from 2.3 to 4.3 m. The wave period ranged between 13 and 15 seconds. The standard deviation of the horizontal velocity was maximum at the bar crest, lowest in the trough, and fairly uniform at the measurement locations seaward of the bar. The magnitudes of the 34.1-minute-averaged speed and cross-shore velocity at 0.5 m above the bed increased toward the beach and had maximums at the measurement location nearest the deepest part of the longshore trough. The cross-shore mean currents at 0.5 m above the bed were directed offshore at all measurement locations (Fig. 1).

Figure 1- Conditions in the inner half of the surf zone at the Army Corps of Engineers Field Research Facility at Duck, NC during October 13, 1982. Shown from bottom to top are: 1) nearshore profile and measurement locations, 2) depths, 3) RMS wave heights, 4) standard deviation of the horizontal velocity at 50 cm above the bed, 5) mean horizontal speed and cross-shore velocity.

## DEFINITION OF SUSPENSION EVENTS

Figure 2- Time series of suspended sediment concentration at 13 cm above the bed for 7 measurement locations.

Suspension of sediment was intermittent at all measurement locations and at all OBS sensor elevations on October 13th. At 13 cm above the bed, concentrations were highest at the bar crest and at the offshore measurement location (Fig. 2, Figure 7 in Jaffe and others, 1984) and lowest in the longshore trough. At the 3 higher sensors (19, 31, and 61 cm) suspension was also intermittent with the intensity of suspension and the rate of occurrence of intense suspension decreasing higher in the water column (for example, see Fig. 3). For the 10-minute period shown in Figure 3 the intense suspension occurred during the passage of wave groups (intense suspension associated with wave groups was also observed by Hanes and Huntley, 1986). Suspension events were not associated with wave groups for other locations in the surf zone. Intense suspension was observed at other measurement locations following a strong offshore flow (also observed by Downing, 1983 at a beach in Washington). Since all of the measurement position were well within the the calculated plane-bed regime (Komar and Miller, 1975, Grant and Madsen, 1982), suspension events were not due to vortices associated with small-scale bedforms. Osborne (this volume) has recently found that larger, irregular bedforms sometimes form under the conditions observed at some of the measurement locations, so we can not rule out flow disturbances from this class of bedform creating suspension events. It is beyond the scope of this paper to

Figure 3- A 10-minute time series for the middle-surf-zone location (6). From the bottom, the hydrostatic approximation to sea level ( $h$ ), cross-shore ( $U$ ) and longshore ( $V$ ) water velocities at 50 cm above the bed, and sediment concentrations (ppt) at 13, 19, 31, and 61 cm above the bed. The time period corresponds to 2 through 12 minutes shown in Figure 2.

determine the processes responsible for producing suspension events. This paper will, however, quantify the characteristics of these periods of intense suspension and their contribution to transport in the surf zone.

Before quantitatively describing the character and transport contribution of the intense suspension periods, an objective criteria must be developed to distinguish these periods from less energetic periods of suspension. One simple definition would be to call periods when the concentration exceeds a threshold value a suspension event. The choice of threshold level will dictate how many events occur and their characteristics. For example, if 20 ppt was chosen as the event threshold there would be no events in the longshore trough ( locations 1 and 2) and some periods where suspension was episodic and intense at other measurement locations would not be considered events (a good example is location 6). To make the choice less arbitrary, event thresholds used in this paper were based on the statistical properties of the concentration distribution. Using the statistics for each location makes the definition of an event scale with the overall intensity of suspension at that location. The distribution of concentrations measured in the surf zone were skewed, with many low values and fewer high values (Fig. 4). Several event thresholds based on the mean and standard deviation of the concentration distribution were tried in order to define events. Two event thresholds are used in this paper to define events. A event was defined to occur when the concentration was greater than the mean plus one standard deviation (Fig. 5). Large events occur when the concentration exceeds the mean plus three standard deviations. In order to include the beginning and end of the event, an event start/end threshold was chosen. In this

Figure 4- Frequency distribution of sediment concentrations at 13 cm above the bed for the middle-surf-zone location (6).

Figure 5- Suspended-sediment time series showing definition of suspension events

Figure 6- Application of suspension event definitions to the 10-minute series in Figure 3. From bottom to top are: 1) the concentration time series, 2) all events shaded, 3) large events shaded.

paper, the event start/end threshold used was the mean concentration.

Using the above definitions, time series of suspended-sediment concentrations at 13 cm above the bed were transformed to event time series to allow an automated analysis of suspension events (Fig. 6). Characteristics of events, including duration, rate of occurrence, and percent of the total time and concentration, are discussed in the next section.

## PROPERTIES OF SUSPENSION EVENTS IN THE SURF ZONE

Time series of large suspension events are shown for the 7 measurement locations in Figure 7. The measurements were not synoptic, so no information about phasing between events at different cross-shore locations can be extracted from the figure. The number of large events in the 34.1 minute records varies from a low of 15 near the bar crest (location 3) to a high of 37 at the mid-surf-zone location (6). Events tend to occur in packets and there are long intervals of several minutes or more between events at all measurement locations.

Figure 7- Large event time series for the 7 measurement locations.

The mean behavior of both events and large events are shown in Figure 8. On the average, large events occur about every minute away from the bar crest and every two minutes at the bar crest (Fig. 8a). Events defined with a lower threshold occur more frequently, but the cross-shore structure is similar to the structure for larger events. In the longshore trough these events occur about 5 times a minute (once every 12 seconds) which is less than the wave period, 13 seconds.

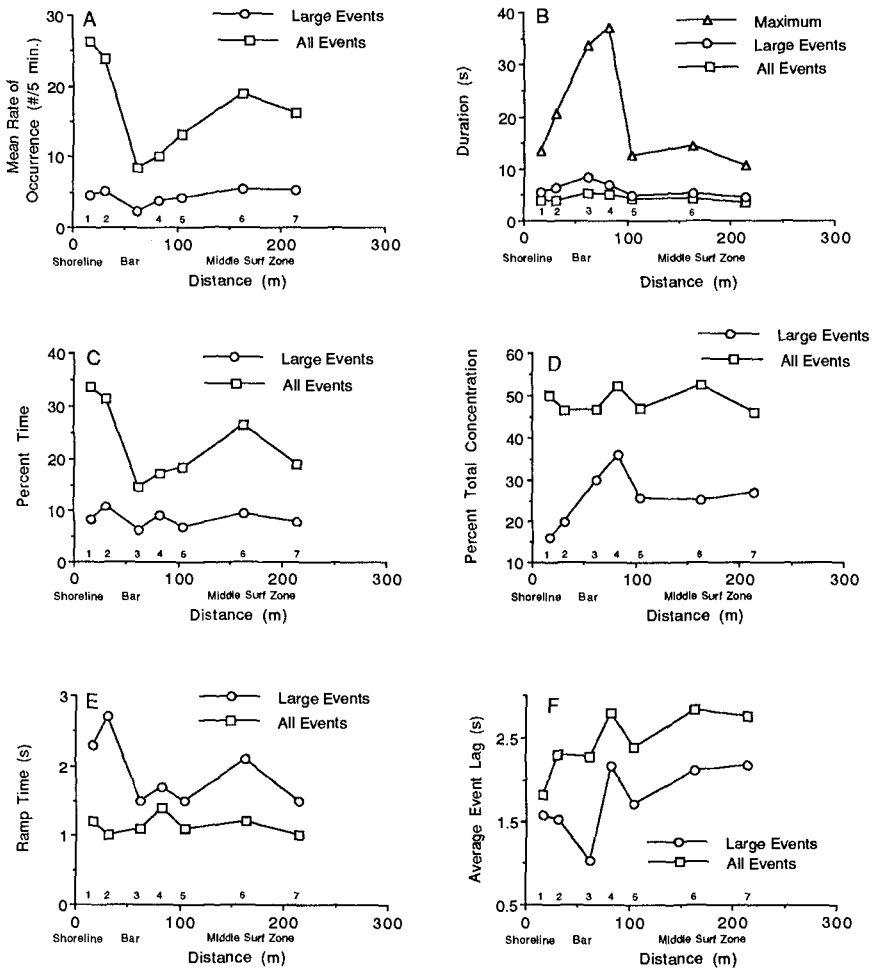

Figure 8- Average event properties for large and all events showing; a) mean rate of occurrence, b) duration, c) percent of the time events occur, d) percent of the total concentration, e) ramp time, and f) average lag of the event relative to the velocity zero up-crossing.

Both large and small events last an average of about 5 seconds, with larger events lasting longer (Fig. 8b). The maximum event duration, about 35 seconds, was near the bar crest where conditions were most energetic. At other locations in the surf zone the longest events lasted 15 or 20 seconds. The quickest events were only 1 or 2 seconds long. Typically, there was a wide distribution of event durations at each measurement location.

Because events occur infrequently and do not last long the percent of time that events occupy is relatively low, about 10 percent for large events and 15 to 35 percent for all events (Fig. 8c). However, the contribution of events to the total concentration is large, about 15 to 35 percent for large events and 45 to 55 percent for all events (Fig. 8d).

Events are typically asymmetric with a rapid increase in concentration and a more gradual decrease. The ramp time, the time from the start of the event until the maximum concentration, averages between 1.5 and 2.7 s for large events and between 1.0 and 1.4 s for all events (Fig. 8e). The ramp time for large events is minimum near the bar crest, one of the most energetic measurement locations. The shortest ramp time combined with the longest average duration makes events near the bar crest the most asymmetrical. Events are the most symmetrical in the trough of the bar.

Events tend to start several seconds after the flow reversal from offshore flow under the wave trough to onshore flow under the crest. On the average, large events start from 1.0 to 2.2 seconds after the velocity zero up crossing (Fig. 8f). The minimum lag time is at measurement location 3, the landward side of the bar crest. Lags are longest at the seaward side of the bar crest (location 4) and the middle-surf-zone locations (6 and 7). When all events are included the average lag time increases, ranging from 1.8 to 2.8 seconds. The distribution of lag times is not symmetrical about the average for large events. For instance, at the middle-surf-zone location (6) the largest number of events was near 0 lag time from the velocity zero up crossing, but the average was several seconds after the crossing because of a few events with long lag times.

## CONTRIBUTION OF SUSPENSION EVENTS TO TRANSPORT

Because suspension events occur infrequently and last for a short time one might think their contribution to the total suspended sediment transport is not very large. On the other hand, because suspension events increase the overall mean concentration by a significant amount, it could be postulated that events are significant to the total transport. To determine the event contribution to transport we made four calculations; 1) transport during large events, 2) transport during all events, 3) transport during non-event periods, and 4) total transport (2 + 3). These transport calculations were for one elevation and used the concentration measured 13 cm above the bed and horizontal velocity measured at 50 cm above the bed. The results, presented below, show that event contributions to longshore and cross-shore transport were very different.

### *Longshore Transport*

Events increase the longshore suspended sediment transport by approximately the amount they increase the mean concentration. For large events, the contribution ranged between 15 and 35 percent at all measurement locations on October 13th. For all events, the contribution was about 50 percent.

There is no preference for events to occur when the longshore velocity is either higher or lower than the mean. The contribution of events to longshore transport,  $\overline{VC}_{event}$ , is approximately equal to the product of the mean longshore velocity,  $\overline{V}$ , the mean concentration during events,  $\overline{C}_{event}$ , and the percentage of time events occurred,  $P_{event}$ . During non-event periods, the concentrations are also not correlated to the longshore velocity so the non-event transport,  $\overline{VC}_{non-event}P_{non-event}$  is approximately  $\overline{V} \overline{C}_{non-event} P_{non-event}$ . The total longshore suspended transport can be adequately calculated by  $\overline{V} (\overline{C}_{event} P_{event} + \overline{C}_{non-event} P_{non-event})$ , or  $\overline{V} \overline{C}_{total}$ . The time variation of the concentration is not needed to accurately predict the longshore suspended sediment transport. However, the vertical structure of the mean velocity and concentration must still be known because suspended-sediment concentration is high near the bed where longshore velocity is low and low higher up in the water column where velocities are higher.

### *Cross-shore Transport*

Suspension events make a significant contribution to the cross-shore suspended-sediment transport. Figure 9 shows the contributions of large events and non-event periods to the total cross-shore transport. The average transport during large events is onshore for all measurement locations seaward of the longshore trough. Transport during non-event periods, moving in the same direction as the near-bottom current, is offshore for all measurement locations. The total suspended-sediment transport is approximately, but not exactly, equal to the sum of large event and non-event periods because transport during small events is slightly offshore. The total transport is offshore for the longshore trough (measurement locations 1 and 2), landward side of the bar crest (3), and middle-surf-zone (6) locations, near zero seaward of the bar at location 5, and onshore on the seaward side of the bar crest (4) and the farthest seaward location (7).

The timing of suspension relative to the wave-induced oscillatory flow results in an average onshore transport during large events. For example, two events at the beginning of the time series in Figure 10 qualitatively show that the most intense suspension occurs during or just after the onshore flow under the wave crest. The average large event starts about 1 to 1.5 seconds after the velocity zero up-crossing (Fig. 8f) when the flow is onshore. Because the maximum

Figure 9- Cross-shore transport 13 cm above the bed for large events, non-event periods, and total. Small event transport is not shown but is small and offshore directed.

Figure 10- Time series of velocity and concentration showing the tendency for events to occur during onshore flow

concentration is reached quickly, about 1.5 to 2.5 seconds later (Fig. 8e), it too usually occurs during onshore flow.

Ensemble averages for the cross-shore velocity and concentration for three different measurement locations are shown in Figure 11. These averages included all large suspension events and were constructed using the velocity zero up-crossing time for reference for both the velocity and concentration time series. The phase of

events in the longshore trough varied widely resulting in an average large-event concentration with no distinct peak. This lack of phasing between the concentration and velocity resulted in a near zero net transport during large events for longshore trough measurement locations (Fig. 9). Large events at the bar crest and the middle surf zone tended to occur shortly after the velocity zero up-crossing resulting in a peak in the concentration (Fig. 11) and a net onshore transport contribution (Fig. 9).

Figure 11- Ensemble averaged velocity and concentration for all events at measurement locations in the bar trough, bar crest, and middle surf zone. The time series are averages of velocities and concentrations for large suspension events with the velocity zero-upcrossing as the common time reference. .

## DISCUSSION

We have found that much of the net cross-shore suspended sediment transport at 13 cm above the bed was contributed by large suspension events. To accurately model the cross-shore transport the event magnitude and phase with velocity must be well predicted. Without modeling the large events, the predicted transport will be more strongly influenced by the mean current velocity (offshore) which would result in a predicted transport in a different direction than the actual transport at some measurement locations.

The results show that events are not as significant to predicting longshore suspended transport because events are not strongly correlated with the longshore velocity. However, inability to model events would result in an underprediction of the magnitude of the longshore transport up to about 50 percent, but unlike the cross-shore transport the direction would be accurately modeled.

Event transport is one part of the "fluctuating flux" addressed in Jaffe and others, 1984. The results in this paper support the conclusion that the time dependency of the flux (transport) is important to the net cross-shore flux, but not to the longshore flux (Jaffe and others Figures 8 and 9). Not addressed in this paper, but still an important property of the cross-shore transport is the tendency for low concentrations (less than the mean) to be correlated with offshore flow.

An improvement to this study would be to assess the vertical variation of events and their contribution to transport. Although we do not expect the conclusions to be significantly altered, the changes in concentration/velocity phasing in the vertical would be helpful information for modeling events.

The definitions for suspension events could possibly be improved. Because the concentration distribution was used to generate the statistics (mean and standard deviation) for the event definitions, it could be argued that instead of defining suspension events we are just looking at a tail of the distribution, which will always exist, so events will always exist. Although it is true there will always be concentration values in the tail, the timing of these high concentration values is not related to the distribution. For example, all the points in the tail could occur in one section of the time series and create one event or they could occur as single points equally spaced in time or a large number of other possibilities. Our definition does a good job of choosing the points that are visually striking when examining a time series of suspension.

## CONCLUSIONS

1) Suspension events, periods of intense suspension, can be defined on the basis of the concentration distribution. Two types of events were defined in this paper: 1) event periods when the concentration exceeded the mean plus one standard deviation, and 2) large events periods when the concentration exceeded the mean plus three standard deviations.

2) Large events were found throughout the inner half of the surf zone, occurred about once every 1 to 2 minutes, and lasted about 5 seconds.

3) Large events tended to occur during onshore flow under the wave crest, resulting in an onshore contribution to the suspended-sediment transport. Even though large events occurred less than 10 percent of the total time, at some locations their onshore transport was greater than the offshore transport during non-event periods. As a consequence, net suspended sediment transport was onshore.

4) Events were not correlated with the longshore flow and increased the longshore suspended sediment transport by approximately the amount they

increased the mean concentration, ranging from 15 to 55 percent depending on the definition used for events. Because concentration and longshore velocity were not strongly correlated, the longshore suspended sediment transport can be adequately predicted as the vertical integration of the product of the time-averaged longshore velocity and the time-averaged concentration.

## ACKNOWLEDGEMENTS

Discussion with David Huntley and Philip Osborne improved this paper. Discussions with Reggie Beach were important in formulating the problem. This manuscript was also improved by the reviews of Guy Gelfenbaum and Jeff List. We wish to thank the personnel at the Army Corps of Engineers Field Research Facility in Duck, North Carolina for their help with the experiment.

## CHAPTER 206

### THE SHORT TERM PROFILE RESPONSE OF SHINGLE SPITS TO STORM WAVE ACTION

Bradbury A P <sup>1</sup> and Powell K A <sup>2</sup>

#### Abstract

The profile performance and the conditions giving rise to overtopping and overwashing of shingle barrier beaches have been examined in an extensive programme of field work and physical model studies. The hydraulic performance of Hurst Spit, on the south coast of the UK, has been examined in detail, and the studies have been used to design a management programme for this barrier beach. This has included the design of a beach replenishment scheme and quantification of overtopping thresholds and alarm conditions, for a range of beach geometries. An extensive series of 3-dimensional physical model tests are discussed and a dimensionless parametric framework is suggested, which provides a method of estimating the conditions that will result in crest accumulation, breaching and crest lowering of shingle barrier beaches, for a wide range of beach geometries.

#### Introduction

Shingle spits often provide the only natural defence from wave attack to the areas of low lying land in their lee. They are hydraulically efficient structures, maximising wave energy dissipation through the high permeability of the shingle. Barrier beaches are particularly important at sites where they protect low lying land, often at the mouths of large tidal inlets. Important sites around the UK include Hurst Spit, Chesil Beach and Orfordness. These beaches are typically less than 100 metres wide above mean water level and may have a crest width of less than 5 metres.

<sup>2</sup> Coastal Group, HR, Wallingford, Oxon, OX10 8BA, UK

The natural beach crest is generally formed at a level which is just below the maximum level of wave run-up. This is controlled by a combination of wave conditions, and water levels, and the shingle size and grading. The crest of a shingle barrier beach may be exceeded by wave run-up, resulting in overtopping under extreme conditions. The beach crest is often able to dissipate energy as waves pass over the crest, restricting both water and shingle movement to the seaward side of the beach crest. Under these circumstances any shingle that is pushed or carried to the crest by the wave run-up is deposited at the crest, thus causing the crest level to increase. The high permeability of the beach usually ensures that most wave energy is dissipated before it reaches the lee face of the beach. When the combined effects of freeboard, crest width and wave conditions reach a critical condition however, often during periods of extreme water levels resulting from tidal surges, the beaches become susceptible to overtopping which cannot be confined within the crest. This may result in crest rollback, crest lowering, fan formation and subsequent sudden, and often spectacular failure of the shingle bank. Whilst the leeward position of a shingle beach with a seawall or cliffs on its landward side is fixed, a barrier beach with no retaining wall on its landward side is free to move landwards or "rollback" when waves reach the leeward crest of the beach.

Previous field studies of shingle barrier beach development have discussed various stages of crest evolution (Nicholls, 1985) resulting in:

- a) crest level raising by overtopping;
- b) crest rollback;
- c) crest level lowering by overwashing;
- d) breaching;

Field observations of the performance of barrier beaches have been discussed in some detail by several authors and the sedimentology of the crest features of sand barrier beaches has been studied extensively (Leatherman and Williams, 1977). Whilst the field studies have provided a valuable description of the development of these beaches, they have not quantified the complex interaction of wave and water level conditions, sediment size and the geometry of the beach, which result in the formation of these features. There is a particular dearth of information with respect to shingle barrier beaches, which typically have a  $D_{50}$  grain size in excess of about 5mm.

Recent examples of severe storm activity on Hurst Spit, UK, have demonstrated that catastrophic failure of shingle barrier beaches may occur, resulting in extensive flooding and damage to low lying land in the lee of the beach. The problems of diminishing shingle supply to Hurst Spit present a significant problem to the management of the beach and remedial action was urgently required to maintain the integrity of the beach. This problem presented the opportunity to examine at full scale a barrier beach which was becoming subject to overtopping under storms of increasing frequency.

Recent research on restrained shingle beaches by Powell (1990) and van der Meer (1988) has provided parametric empirical frameworks to predict the profile performance of restrained shingle beaches, but these studies have not examined the evolution of barrier beaches. The processes which result in the dramatic evolution of these beaches are difficult to quantify and as a result coastal managers have little guidance on their management. If natural or renourished shingle barrier beaches are to be used as effective coast protection structures, it is essential that the hydraulic performance of the crest evolution is clearly understood.

### Objectives

The studies were commenced with the intention of providing an understanding of the hydraulic performance of the Hurst Spit shingle bank, and to provide a management strategy to ensure that the spit would continue to provide protection to the land in its lee. This required identification of the conditions that cause crest lowering of the beach, the design of a major beach replenishment scheme and the identification of appropriate alarm conditions for future maintenance of the beach.

In the course of the studies the objectives were extended to investigate the hydraulic performance of shingle barrier beaches of a wide range of geometries, subject to a wide range of wave and water level conditions, thus providing an empirical method to allow the crest processes of these beaches to be quantified.

The study has been divided into three main phases of experimental work.

- a) field studies;
- b) wave climate studies;
- c) 3-dimensional physical model studies.

### Field work

The main focus of the studies has been on the hydraulic performance of Hurst Spit, UK. The spit which is approximately 2.5 kilometres long, protects an extensive area of low lying land, and has a long history of rapid evolution (Nicholls, 1989). Reduced shingle supply to the spit by longshore transport has resulted in a declining beach volume. Consequently, the frequency of overtopping events has increased. The features which result from wave run-up and the overtopping processes discussed in this paper have all been observed, and detailed measurements of beach profile response have been recorded on a regular basis. The field work and wave climate studies were carried out at Hurst Spit, UK, over a five year period between 1987 and 1992.

The beach is surveyed quarterly and also following severe storms along 20 profile lines, at approximately 100m intervals. Wave conditions and tidal conditions have also been monitored at this site, thus allowing the beach response to be quantified with respect to the hydraulic parameters.

The beach is characterised by a coarse grain size  $D_{50}$  of about 16 mm. The beach crest is generally between 2 - 4 metres above mean high water, with a crest width of 3 - 10 metres. Wave rider records indicate a nearshore wave climate with storms regularly occurring with significant wave heights in excess of 2.5 metres. The complex offshore bathymetry results in different incident wave conditions along the length of the spit. The beach profile response is therefore different at each profile position. The significant wave height of the 1:100 year return period storm varies from 1.8m to 3.5m (in 7 metres of water), from east to west.

The storms of the winter of 1989 have provided data of some considerable interest. Large scale overwashing of the spit occurred in December 1989, resulting in crest lowering along an 800 metre length of the beach. The seaward toe of the beach was rolled back by as much as 60 metres whilst the leeward toe was moved by as much as 80 metres in a single storm event. Crest lowering in the same event resulted in reduction of much of the beach below the level of the peak water level of the storm, a reduction in crest level by as much as 3 metres. Whilst offshore wave conditions were only moderate during this storm, an extreme tidal level resulting from a storm surge at the peak of the storm resulted in a very low freeboard and increased wave conditions at the toe of the beach. This dramatic event provided valuable data about the response of Hurst Spit under extreme conditions and provided excellent data for calibration of the physical model. More severe wave conditions monitored on other occasions at lower water levels also resulted in overtopping and crest rollback, thus providing calibration data for events closer to the threshold of crest roll back.

Further field work is ongoing to provide additional validation of the empirical methods developed in the laboratory and to assess performance of the proposed beach renourishment, which has been designed in conjunction with these studies. The conditions that occurred during the field work programme provided the rare opportunity to carry out concurrent measurements of waves, tides and beach profiles, for a series of severe storms. Whilst the field studies provided a considerable amount of quantitative information about the processes, the restricted number and random nature of the natural storm events provided insufficient data alone to generate a statistically valid method for the prediction of the beach crest evolution. It was therefore necessary to examine the beach response in a more controlled environment to enable threshold conditions to be defined.

Overwashing of Hurst Spit in December 1989

Profile response of Hurst Spit to storm of December 1989

### Physical Model Tests

Recent developments in physical modelling techniques for shingle beaches have provided an appropriate method of study. The use of distorted sediment scaling to produce model beaches with appropriate permeability and sediment movement characteristics to reproduce the correct profile response of the beach has been discussed by Powell (1989). Since detailed physical model studies had not however previously been used to examine the profile response of overtopping shingle barrier beaches, it was necessary to carry out a series of calibration tests to prove the validity of the modelling techniques for this type of beach.

The model tests were conducted in a 3-dimensional wave basin under random wave conditions. The model was constructed at a scale of 1:40, with an active beach frontage of 1000 metres. Model variables included a range of significant wave heights from 1 - 4.5 metres, wave periods of between 6 - 12 seconds and four static water levels. The four water levels provided a variable freeboard between the beach crest and the static water level and also provided the opportunity to examine the effects of varied breaking wave conditions at the toe of the structure. Many of the tests were carried out with normally incident waves, although a large number of tests were also carried out with the beach subject to oblique wave attack, within the range 5-15°. The material used to represent the model beaches was a graded anthracite, scaled to reproduce both the correct beach permeability, threshold and direction of sediment motion and thereby the correct profile response of the beach.

A number of hydraulic variables were kept constant throughout the test programme. These included sediment size and grading, spectral shape (JONSWAP), and storm duration.

The test programme was divided into three phases

- a) validation of the test methodology
- b) evaluation of the hydraulic performance of Hurst Spit
- c) evaluation of the hydraulic performance of an extensive range of barrier beach geometries.

Field data collected from Hurst Spit provided the basis for the design of the first two phases of laboratory tests, ensuring that model beaches, foreshore geometry, sediment size characteristics, wave and water level conditions were all modelled correctly. This provided a typical structure for validation of the test methodology and for examination of the processes identified by field observations.

The test conditions were extended to include a wider range of variables as the studies developed. The third phase of testing provided a means of examining

a much wider range of conditions and beach geometries, which might be applicable to sites elsewhere. A wide range of wave conditions, water levels and shingle bank geometries have been examined in a systematic series of tests on the profile response of an extensive range of beach geometries. In excess of 3000 beach profiles were measured in more than 200 physical model tests. Concurrent measurements were also made of wave and water level conditions

The seaward slope geometry has been described by the three stage schematised shingle beach profile proposed by Powell (1990). Additional beach geometry characteristics appropriate to barrier beaches have been defined in terms of beach cross section area, crest level, crest width and beach span at each of a number of beach levels. The primary geometric variables which have been used in the analysis of the beach profile performance are the beach crest level and the crest width. A range of freeboards from 0.5 metres to 6 metres were examined, with beach crest widths ranging from 2 metres to 20 metres.

Pre and post storm profiles were recorded by surveying the beach before and after each test. Profiles were recorded using a computer driven incremental bed profiler, sampling levels at a constant survey interval of 2 metres along each profile line. A number of profiles were recorded along the beach frontage for each test. This provided the basis for the examination of the spatial variation of the beach performance. The tests were generally run for a prototype duration of 3 hours. Video recordings were made of each test from an aerial camera. These recordings were later used in the analysis of the evolution of the crest features.

Schematised shingle beach profile (after Powell, 1990)

## Results

The physical model was validated by reproduction in the model of severe storms that occurred on Hurst Spit in 1989. Field measurements of wave and water level conditions during the storms, and beach profiles monitored before and after the storms have provided the basis for the comparison of the performance of the physical model with Hurst Spit. The results of the physical model provided a remarkably good reproduction of the profile response of Hurst Spit to these storms and demonstrated the validity of the modelling methods for this type of structure.

Observations made during the test programme provided an explanation for many of the features formed during the tests. A number of threshold conditions were identified, both visually and by parametric analysis of the beach profile response to various hydraulic conditions. The first threshold condition occurs when the combination of wave conditions, water level and beach geometry causes crest accumulation. This process is described well by earlier studies (Powell, 1990) which have quantified wave run-up and berm formation. Crest accumulation occurs when waves reach the crest with sufficient energy to spill onto the crest, but with insufficient energy to wash the whole of the way over the crest. The hydraulic conditions giving rise to this process are confined to a very narrow band for any given beach crest width. The validity of the run-up formulae are further restricted by the initial beach crest width which may prevent the predicted beach profile from being reached, if the combination of crest position and crest height require a wider beach to achieve the dynamic equilibrium profile. The formulae do however provide an excellent method of defining the lower boundary conditions for thresholding of damage by overtopping, by reference to both the initial profile and the post storm predicted profile. An appropriate alarm condition for each profile geometry can therefore be derived by reference to the conditions causing crest accumulation. This method has been used to provide an empirical assessment of the alarm conditions for Hurst Spit, thus providing management guidance on the maintenance requirements following beach renourishment. Similarly the threshold geometry for given wave and water level conditions can be calculated to provide the required profile to withstand any event. Accumulations of material at the crest of up to 1.2 metres were measured during the model tests.

A further threshold, resulting in crest lowering, is reached if the combination of wave and water level conditions and beach geometry reach the lee face of the beach. The numeric definition of this threshold is however somewhat more complex, as there is a strong dependency on the crest width as well as the wave conditions. Tests indicated a wide spatial variation in the conditions that resulted in crest lowering and also some scatter in the results of profile response close to this threshold. The spatial variation may be a function of very small localised variations in the initial beach geometry. The beach crest is extremely sensitive to small changes in freeboard and crest width and caution should therefore be exercised when assessing the vulnerability of the beach to crest lowering.

Process development observed in the model helps to explain some of the scattered results measured close to the crest lowering threshold. Small washover fans normally form at first, unless the storm water level is very extreme. These are followed by the formation of more extensive breaches through the bank as the storm progresses, resulting in large scale crest lowering. The size and method of formation of a washover fan is dependent upon the crest width, crest level and wave and water level conditions. If the crest is very narrow a wide breach may form quite rapidly, as waves are able to overtop the bank and lower the crest quickly. If however the crest is rather wider, the rate of formation and size of the overwash fan will be significantly slower and smaller. Once the crest level has been lowered the rate of crest lowering increases rapidly, as the frequency of waves reaching the crest increases. The width of the initial overwash fan ranged in size from approximately 4 metres to 25 metres wide, depending on the shingle bank geometry immediately prior to overtopping. Similarly, the length of the initial fan could extend landwards from approximately 1 metre to 15 metres. The rate of landward progression of the overwash fan is also strongly dependent on the topography of the land in the lee of the beach. Following from the initial formation of an overwash fan the beach plan shape may evolve very rapidly. The fans are quickly widened by outflanking of the upstanding ridges formed on either side of the fan, by overtopping waves. The fan itself provides a preferential flow path for the overtopping waves and a gully forms through the centre of the fan. As the waves flow across the mound the sediment fan is liquified and flows with the wave to the lee side. The fan may then extend landwards very rapidly, moving as much as 10-15 metres in a single wave. As the fan reaches the base of the shingle bank it tends to spread and forms an enlarged head area which accumulates as more material is washed across the crest.

The wave grouping following the initial fan formation is also extremely important. If the waves following the initial fan formation are small, a ridge may form seawards of the crest ridge. This in turn is pushed upwards towards the crest, and can prevent further overtopping. In many instances the wave grouping enables a fan to form, but permits the initial breach to heal. This demonstrates the need to study these processes with random as opposed to regular waves.

As the storm progresses, the width of the shingle bank is reduced, due to the beach attempting to reach a dynamic equilibrium profile for those conditions. Undermining of the beach crest occurs and the crest width is consequently thinned. This may occur even when waves do not reach the crest of the shingle bank, thus demonstrating the importance of both the span and the crest level of the shingle bank. In certain instances the bank can be cut back to such an extent that a breach may form as a result of waves breaking through a narrow ridge as opposed to the more normal failure mechanism occurring by overtopping.

In addition to overtopping, percolation of water occurred through the

permeable model shingle bank, resulting in the formation of streams and washout fans on the lee side of the spit. This process has been noted at a number of locations on Hurst Spit. This condition occurs most commonly where the spit has been cut back by wave action to a small cross section profile, but where waves are too small to reach the crest of the beach. The fact that this process was observed in the model serves as an additional marker that indicates that the physical model is able to reproduce the permeability of the bank correctly.

Profile response of model barrier beaches

### Parametric analysis

Many of the test conditions resulted in the formation of a run-up berm below the level of the beach crest. The measured post storm profiles for these conditions were initially compared with the functional relationships derived by Powell(1990) in earlier studies on restrained shingle beaches. This comparison confirmed the validity of the parametric framework for these conditions, with the results of the studies falling well within the error bands suggested for each of the functional relationships. The coarse grain size resulted in the formation of a steep upper beach slope below the crest berm. The parametric framework maintained validity even as the run-up level increased above the original beach crest, provided that the beach crest width was wide enough to allow deposition of beach material at the crest. The functional parameters to describe crest height ( $h_c$ ) and crest position ( $p_c$ ) given below however, became unstable as the wave and water level conditions became more severe, or as the crest width became narrower.

$$p_c D_{50} / H_s L_m = -0.23 (H_s T_m g^{1/2} / D_{50}^{3/2}) - 0.588$$

$$h_c / H_s = 2.86 - 62.69 (H_s / L_m) + 443.29 (H_s / L_m)^2$$

These equations are corrected for breaking wave conditions by use of the correction factors:

$$p_c = 3.03 (H_s / D_w) + 0.12$$

$$h_c = (H_s / D_w) + 0.41$$

The crest evolution changes from accumulation to crest lowering when the wave and water level conditions in combination with the beach geometry cannot reach a dynamic equilibrium profile within the existing beach cross section. There is therefore a complex relationship between the hydraulic parameters and the beach geometry which defines the threshold of overwashing resulting in crest lowering. This relationship is very sensitive to small changes in freeboard and crest width conditions.

The effects of each of the hydraulic variables are examined in turn. The main influence of the significant wave height is on the crest position ( $p_c$ ). As  $H_s$  increases, the horizontal distance from the beach and the static water level intersection (0,0) is increased. If the dynamic equilibrium position for the wave conditions lies further landward than the width of the unconfined beach crest, the dynamic equilibrium crest position cannot be achieved and the beach crest will be breached, resulting in crest lowering. The situation is further complicated by the other hydraulic variables which in certain combinations may allow the beach crest to reform landwards of its original position.

The effect of increasing the wave period is to raise the crest level of the beach. If there is insufficient beach material available within the crest however, a

raised crest will fail to form and overwashing will occur. The rate of overwashing increases dramatically with increasing period, due to the larger volume of water in longer period waves. Both the wave height and the period variables may reach a threshold condition whereby the beach is overtopped without the crest reforming above the peak run-up level. In this instance crest lowering may occur.

The effects of static water level are twofold. Firstly there is a simple relationship which reduces the exposure of cross sectional area of the beach above static water level, as the water level rises. In this instance the dynamic equilibrium profile moves further landwards as the freeboard is reduced. There clearly comes a point where the freeboard becomes so small that virtually any wave condition may pass over the crest, resulting in rollback and crest lowering. The second relationship is more complex and relates to the breaking wave height at the toe of the beach. This clearly results in larger incident wave conditions at the shoreline as the water depth increases, for the same offshore conditions. Wave run-up is therefore increased. This is reflected by the adjustment factors for wave breaking given in Powell's model.

The test results were very sensitive to small changes in the model test variables and these have resulted in some scatter close to the threshold conditions. The effects of wave grouping appears to have a significant effect on the crest evolution and this appears to contribute to the lack of consistency of certain of the results whilst close to the threshold conditions. Whilst wave grouping was not quantified, it is certainly a feature which must be considered. Observations made during testing identified a number of instances when the beach would be overtopped, causing crest lowering in a period of severe wave activity. Later the same beach section would heal during the same test during periods of less intense wave activity, occasionally resulting in the formation of a higher run-up crest than the initial profile.

Further examination of the data resulted in the formation of a new parametric framework designed to examine the vulnerability of the beach to overtopping and rollback, and to define damage thresholds. Whilst Powell's model of profile response works well within a range of conditions, it becomes more unstable as the freeboard is reduced, the wave period is lengthened or the wave height is increased. The influence of the beach crest width is clearly very important but further work is required before the effects of this variable can be quantified with statistical validity.

The framework proposed for the analysis in this study considers the beach as a simple geometric structure subject to variables defined by freeboard, shallow water breaking wave height and shallow water wave length. A critical freeboard parameter  $C_f$  is proposed. The formula suggests limits for the safe use of Powell's earlier studies and suggests an inundation threshold value beyond which the level of the beach will be reduced below the static water level of the storm peak, for the range of conditions tested in these studies.

The threshold formula is given by:

$$C_f = \frac{C_H}{(H_{sb}^2 L_{ms})^{1/3}}$$

where  $C_f$  is the critical freeboard parameter

$H_{sb}$  is the shallow water breaking wave height calculated from:

$$H_{sb} = 0.12 L_m [1.0 - \exp(-4.712 D_w (1.0 + 15m 1.33) / L_m)]$$

$L_{ms}$  is the shallow water wave length given by

$$L_{ms} = T_m (g D_w)^{1/2}$$

$C_H$  is the freeboard from static water level to the beach crest

When  $C_f > 0.7$  no crest lowering will occur and Powell's parametric framework is valid for profile prediction

and where  $C_f < 0.1$  and  $C_w$  (crest width)  $< 20m$  inundation of the beach will occur, lowering the beach crest below the storm peak static water level.

where  $0.7 < C_f < 0.1$  the beach may respond by crest lowering or crest accretion, depending on the beach crest geometry.

The detailed beach crest evolution is clearly more complex than these simple equations can quantify at this stage. Further crest data analysis is required to refine the findings of these studies which have provided a first step towards quantification of the crest evolution of a barrier beach.

### Conclusions

The processes resulting in crest development of shingle barrier beaches have been examined in field studies and a 3-dimensional physical model, and threshold conditions for each stage of development have been defined. The tests have indicated that the profile response of the crest of shingle banks is very sensitive to small changes in freeboard or wave conditions, when close to the

critical condition which results in either raising or lowering of the crest level. A range of combinations of wave and freeboard conditions have been identified that result in either raising of the unconfined crest level by overwash deposition, or a reduction in the crest level due to wave overtopping. The complex form of the overwash features results in a wide spatial variation. Several types of feature including throat confined overwash fans have been examined in the model. The crest width has been identified as an important parameter in determining the response of the crest geometry to wave action.

The physical model has been used as a design tool for a beach renourishment scheme at Hurst Spit and has provided alarm conditions and damage thresholds for the proposed beach renourishment.

The tests discussed in this study complement the results of an earlier study (Powell, 1990) to predict the profile response of shingle beaches to wave attack. Data has been compared with the parametric empirical model of shingle beach profile response. A critical freeboard parameter has been defined together with suggested limits for the applicability of Powell's parametric model of beach profile response to shingle barrier beaches.

### INTERACTION BETWEEN WATER WAVES AND VEGETATION

by

Hiroshi Deguchi <sup>2</sup>

and

Nobuhisa Kobayashi <sup>3</sup>

#### 1. INTRODUCTION

The presence of densely growing vegetation has been observed to result in wave damping and shoreline sediment deposition. Submerged or flooded vegetation, seaweed stands, reed stands and mangrove forests act as a buffer zone against wave attack on the rear beaches. Recently, a new method for shoreline protection by use of artificial seaweed has been attempted (Rogers 1986; Jenkins and Skelly 1987).

Besides the function of shoreline protection, these vegetated areas play an important role in estuarine and nearshore ecosystems. Since the hydrodynamic process is one of the most important governing factors of the ecosystems, the interaction between water waves and vegetation needs to be quantified. Furthermore, the need of improved understanding of this mechanisms may increase since accelerated sea level rise may result in more flooding in vegetated areas (ASCE Task Committee 1992)

One of the authors initiated a study by conducting experiments on wave damping using artificial seaweed (Asano et al. 1988). Recently, an analytical model was developed to describe the vertically two-dimensional problem of small amplitude waves propagating over submerged or subaerial vegetation

Figure 1: Definition sketch of two layer model

(Kobayashi, Reichle and Asano 1992). This analytical model is referred to as the previous model in this paper.

In the previous model, the effect of vegetation on the flow field was assumed to be expressible in terms of the drag resistance against the fluid motion, whereas the decrease in the drag resistance due to the swaying motion of vegetation was neglected. An analytical solution was obtained for the monochromatic waves whose height decayed exponentially. The comparisons with the artificial seaweed experiments yielded the calibrated drag coefficients  $C_D$  varying in a wide range and affected by the vegetation motion. The calibrated values of  $C_D$  were on the order of 0.1 for the tests with swaying vegetation. A greater value of  $C_D$  would have been resulted if the relative velocity between the fluid and vegetation motion had been used for the drag resistance.

The present paper extends the previous model by including the interaction between the wave and vegetation motion. The present model consists of analyses for the flow field and the swaying motion of an individual vegetation stand. Both solutions are connected by a linearized damping coefficient  $D$  which is determined iteratively. The interaction effects are hence included in the converged solution. The calculated results are compared with the artificial seaweed experiments. The measured wave attenuation is reproduced well by the extended model using a drag coefficient of the order of unity.

## 2. SOLUTION FOR FLOW FIELD

A two-layer model consisting of an upper fluid layer of depth  $h$ , and a lower fluid layer of depth  $d$ , is shown in Fig. 1. The depth  $d$  of the lower layer is the mean height of swaying vegetation and is less than the vegetation length

$l_0$ . In this linearized analysis, small-amplitude monochromatic waves are assumed to propagate in the positive direction of the horizontal coordinate  $x$  and be attenuated by the vegetation. The vertical coordinate  $z$  is taken to be positive upward with  $z = 0$  at the still water level (SWL). Viscous shear stresses acting on the interface and the bottom are neglected because the drag resistance of the vegetation is predominant for most practical applications.

The linearized momentum equations in the upper and lower layers, which are indicated by the subscripts 1 and 2, respectively, may be expressed as

$$\frac{\partial \mathbf{u}_1}{\partial t} = -\frac{1}{\rho} \nabla p_1 \tag{1}$$

$$\frac{\partial \mathbf{u}_2}{\partial t} = -\frac{1}{\rho} \nabla p_2 - \frac{1}{\rho} \mathbf{F} \tag{2}$$

in which,  $t$  = time;  $\mathbf{u} = (\mathbf{u}, \mathbf{w})$  = water particle velocity vector;  $\rho$  = fluid density; and  $p$  = dynamic water pressure due to waves.

The drag force vector per unit volume,  $\mathbf{F}$ , in (2) is assumed to be given by

$$\begin{aligned} F_x &= \frac{1}{2} \rho C_D b N u_r |u_r|, \\ F_z &= 0 \end{aligned} \tag{3}$$

in which  $C_D$  = drag coefficient;  $b$  = area per unit height of each vegetation stand normal to the horizontal velocity;  $N$  = number of vegetation stands per unit horizontal area; and  $u_r = (u_2 - u_v)$  is the relative velocity between the horizontal fluid velocity  $u_2$  and the swaying velocity of vegetation,  $u_v$ . The drag force is assumed to be dominant and the inertia force is neglected in (3).

In order to derive an analytical solution, (3) is linearized as follows:

$$\frac{1}{2} \rho C_D b N u_r |u_r| = \rho D u_2 \tag{4}$$

The damping coefficient  $D$  is determined in such a way that the mean square of the error,  $\overline{E_r^2}$ , of the difference between both sides of (4) is the minimum. The condition of  $\partial \overline{E_r^2} / \partial D = 0$  gives

$$D = \frac{1}{2} C_D b N \frac{\int_{-(h+d)}^{-h} u_r |u_r| u_2 dz}{\int_{-(h+d)}^{-h} u_2^2 dz} \tag{5}$$

The unknown coefficient  $D$  depends on  $u_2$  and  $u_r$  and will be determined by iterations using the solutions for  $u_2$  and  $u_v$  as will be explained later.

Eq.(2) can then be linearized as

$$\begin{aligned} \frac{\partial u_2}{\partial t} &= -\frac{1}{\rho} \frac{\partial p_2}{\partial x} - D u_2, \\ \frac{\partial w_2}{\partial t} &= -\frac{1}{\rho} \frac{\partial p_2}{\partial z} \end{aligned} \tag{6}$$

The momentum equations (1) and (6) as well as the continuity equations for both upper and lower layers are subject to the following linearized boundary conditions at the free surface, interface and bottom boundaries:

$$\begin{aligned} \frac{\partial \eta_1}{\partial t} &= w_1, & p_1 &= \rho g \eta_1 & \text{at } z &= 0, \\ \frac{\partial \eta_2}{\partial t} &= w_1 = w_2, & p_1 &= p_2, & \text{at } z &= -h, \\ w_2 &= 0 & & & \text{at } z &= -(h + d) \end{aligned} \tag{7}$$

where  $\eta_1$  = free surface elevation above SWL;  $\eta_2$  = displacement of the interface; and  $g$  = gravitational acceleration.

In the following,  $\eta_1$  is assumed to be expressible in a sinusoidal form with a complex wave number  $k = (k_r + ik_i)$  as follows:

$$\eta_1 = a_0 \exp\{i(kx - \sigma t)\} \tag{8}$$

in which,  $i^2 = -1$ ;  $a_0$  = wave amplitude at  $x=0$ ; and  $\sigma$  = angular frequency. From the real part of (8), the local wave amplitude is found to decay exponentially

$$a = a_0 \exp(-k_i x) \tag{9}$$

where  $k_i$  = exponential decay coefficient.

The solutions for the horizontal fluid velocities  $u_1$  and  $u_2$  can be shown to be given by

$$u_1 = \frac{gk a_0}{\sigma} \left\{ \cosh(kz) + \frac{\sigma^2}{gk} \sinh(kz) \right\} \exp\{i(kx - \sigma t)\} \tag{10}$$

$$u_2 = \frac{g\alpha^2 a_0}{\sigma k} \left\{ \cosh(kh) - \frac{\sigma^2}{gk} \sinh(kh) \right\} \frac{\cosh[\alpha(z + h + d)]}{\cosh(\alpha d)} \exp\{i(kx - \sigma t)\} \tag{11}$$

with

$$\alpha = k / \sqrt{1 + i(D/\sigma)} \tag{12}$$

Substituting (10) and (11) into (1) and (6) yields the solutions for the pressures  $p_1$  and  $p_2$

$$\begin{aligned} p_1 &= \frac{\rho \sigma}{k} u_1 \\ p_2 &= \frac{\rho(\sigma + iD)}{k} u_2 \end{aligned} \tag{13}$$

The continuity equations together with (10) and (11) yield the solutions for the vertical fluid velocities  $w_1$  and  $w_2$ , which are omitted herein.

Furthermore, the vertical displacement of the interface,  $\eta_2$ , is given by

$$\eta_2 = a_0 \left[ \cosh(kh) - \frac{gk}{\sigma^2} \sinh(kh) \right] \exp\{i(kx - \sigma t)\} \quad (14)$$

Lastly, the dispersion relation is given by

$$\sigma^2 = gk \frac{k \tanh(kh) + \alpha \tanh(\alpha d)}{k + \alpha \tanh(\alpha d) \tanh(kh)} \quad (15)$$

Eq. (15) can be solved to find the unknown complex wave number  $k$  for given  $\sigma$ ,  $h$ ,  $d$ ,  $g$  and  $D$ .

In the case of weak damping  $\sigma \gg D$ , (15) can be expressed more explicitly. Eq.(12) is simplified as

$$\alpha \simeq k \left(1 - i \frac{D}{\sigma}\right)^{1/2} \simeq k \left(1 - i \frac{D}{2\sigma}\right) \quad (16)$$

Since  $\alpha = [k(1 - i\epsilon) + O(\epsilon^2)]$  with  $\epsilon = D/2\sigma$ , (15) becomes

$$\sigma^2 = gk \tanh[k(h+d)] \left[ 1 - i\epsilon \frac{2kd + \sinh(2kd)}{\sinh[2k(h+d)]} \right] \quad (17)$$

The real and imaginary parts of (17) yield the following equations

$$\sigma^2 = gk_r \tanh[k_r(h+d)] \quad (18)$$

$$\frac{k_i}{k_r} = \epsilon \frac{2k_r d + \sinh(2k_r d)}{2k_r(h+d) + \sinh[2k_r(h+d)]} \quad (19)$$

Eq.(18) is the ordinal dispersion relation for small-amplitude water waves, so the presence of vegetation does not change the real wave number  $k_r$  as long as  $\epsilon = (D/2\sigma)$  is much smaller than unity. On the other hand, (19) implies that  $k_i/k_r = O(\epsilon)$

The above analytical solution for the flow field is the same as that obtained by Kobayashi et al. (1992) except that  $D$  was given by (5) with  $u_r = (u_2 - u_v)$  replaced by  $u_2$ .

### 3. SOLUTION FOR VEGETATION MOTION

The behaviour of a vegetation colony under wave action is complex because the vegetation and fluid motions may generate turbulence stresses along the interfacial boundary and among the vegetation stands. However, it is observed that each stand does not move in random but a group of stands sway

Figure 2: Model of vegetation motion

in an organized manner. As long as the vegetation motion is not so large, it may be treated as a horizontal swaying motion as shown in Fig.2.

As a first attempt, the vegetation motion due to wave action is simply modelled as a forced vibration with one degree of freedom. The buoyancy and stiffness of the vegetation material are considered as the restoring forces of the vibration. The horizontal displacement of a vegetation stand from the vertical  $z$ -axis is denoted by  $\xi$ , while the differentiations with respect to  $t$  and  $z$  are indicated by the over dot and the subscript  $z$ , respectively. The equation of the motion for each stand may be expressed as follows:

$$\begin{aligned} \rho_v b \hat{t} \ddot{\xi} + C_1 \dot{\xi} + EI \xi_{zzzz} &= \frac{1}{2} \rho C_D b |u_2 - \dot{\xi}| (u_2 - \dot{\xi}) \\ &+ \rho (C_M - 1) b \hat{t} (\ddot{u}_2 - \ddot{\xi}) + \rho b \hat{t} \dot{u}_2 - (\rho - \rho_v) g b \hat{t} \xi_z \end{aligned} \tag{20}$$

in which  $\rho_v, b, \hat{t}, EI, C_1$  and  $C_M$  are the density, width, thickness, bending stiffness, attenuation constant, inertia coefficient of the vegetation strip, respectively. It is noted that  $\dot{\xi} = u_v$  and  $u_r = (u_2 - \dot{\xi})$  in (5). The inertia force is included on the right hand side of (20) for completeness, although it is neglected in (3). Assuming that  $C_1 = 0, (\dot{\xi}/u) \ll 1$  and  $\xi$  may be approximated by  $\xi = \{(z + h + d)/d\} \zeta$  with  $\zeta$  being the horizontal displacement at the top of the vegetation strip, (20) may be simplified as follows:

$$\begin{aligned} \frac{1}{2} \{ \rho (C_M - 1) + \rho_v \} V \ddot{\zeta} + \frac{1}{2} \rho C_D |u| A \dot{\zeta} + \left\{ \frac{8EI}{d^3} + (\rho - \rho_v) g \frac{V}{d} \right\} \zeta \\ = \frac{1}{2} \rho C_D A u |u| + \rho C_M V \dot{u} \end{aligned} \tag{21}$$

in which  $A = bd$  and  $V = b \hat{t} d$ . In the derivation of (21), it is assumed

$$\int_{-(h+d)}^{-d} EI \xi_{zzzz} dz = \frac{8EI}{d^3} \zeta \tag{22}$$

which is the relation for the displacement at the top of a cantilever under uniform loading. In addition,  $u$ ,  $\dot{u}$  and  $|u|$  in (21) should be taken as the depth-averaged values of  $u_2$ ,  $\dot{u}_2$  and  $|u_2|$  in the region  $-h \geq z \geq -(h+d)$ .

#### 4. WAVE DAMPING CHARACTERISTICS

##### (1) Interaction Between Fluid and Vegetation Motion

In this analytical model, wave damping due to vegetation is described by the imaginary wave number  $k_i$  as expressed in (9). The linearized damping coefficient  $D$  governs the magnitude of  $k_i$  through the term  $\epsilon$  in (19). On the other hand, the motion of vegetation is determined by (21) if the fluid velocity  $u_2$  of the waves is known. The interaction effect between the wave and vegetation is expressed through the damping coefficient  $D$  which is iteratively calculated by (5) using the relative velocity  $u_r$  between the wave and vegetation motion.

The height of the lower layer,  $d$ , is determined by the following approximate relation based on the length of vegetation,  $l_0$ , and the amplitude of  $\zeta$ , denoted by  $\hat{\zeta}$

$$d = \frac{l_0 + \sqrt{l_0^2 - \hat{\zeta}^2}}{2} \quad (23)$$

which implies that  $d$  decreases from  $d = l_0$  as  $\hat{\zeta}$  is increased from  $\hat{\zeta} = 0$ .

The calculation proceeds in the following order:

- (i) Starting from the condition of no vegetation motion, for which  $u_v = 0$  and  $d = l_0$ , the fluid velocity and complex wave number are calculated.
- (ii) The motion of vegetation is then computed using (21) where the swaying velocity  $u_v$  is calculated at every vertical point over a whole wave period.
- (iii) The damping coefficient  $D$  is determined by (5) using the relative velocity  $u_r = (u - u_v)$ .
- (iv) The depth of the lower layer is calculated by (23).
- (v) The fluid velocity and complex wave number are re-calculated using the obtained damping coefficient  $D$ .
- (vi) The computation is repeated until the convergence of the solution is achieved.

##### (2) Calculated Results

The final expression of the vegetation motion given by (21) has many parameters. Although a sensitivity analysis on the wave decay coefficient  $k_i$  and the wave celerity  $c = \sigma/k_r$  may be made using the non-dimensional parameters, the variations of  $k_i$  and  $c$  are herein illustrated using the dimensional parameters whose ranges are related to the artificial seaweed experiment. In the following computations, use is made of  $h = 27\text{cm}$ ,  $l_0 = 25\text{cm}$ ,  $N = 0.149\text{cm}^{-2}$ ,  $C_M = 2.0$ ,  $b = 5.2\text{cm}$ ,  $E = 9.8 \times 10^7\text{g}/(\text{cm}\cdot\text{sec}^2)$ ,  $I = bl^3/12$ .

(a)

(b)

(c)

Figure 3: Computed wave decay coefficient  $k_i$

Figure 4: Computed wave celerity  $c$

Fig. 3 (a),(b),(c) shows the variations of  $k_i$  with respect to the frequency ( $\sigma/2\pi$ ) for different values of  $C_D$ ,  $a_0$  and  $\hat{t}$ , respectively. The wave decay coefficient  $k_i$  increases with the drag coefficient  $C_D$  as well as with the wave amplitude  $a_0$ . The dependence of  $k_i$  on the wave amplitude results from the quadratic drag resistance used to estimate  $D$  in (5). Meanwhile, the increase of  $\hat{t}$  results in the increase of the moment of inertia  $I$ , however, the stiffness of the vegetation material changes the wave decay coefficient very little. The change of the specific gravity  $s$  of the vegetation material, which modifies the restoring force by buoyancy, does not affect the decay coefficient much, although the computed results are not presented here.

On the other hand, the wave celerity  $c$  varies very little with the drag coefficient  $C_D$  as shown in Fig. 4. The other parameters  $a_0$ ,  $\hat{t}$ , and  $s$  are also found to have negligible effects on  $c$ .

## 5. COMPARISON WITH EXPERIMENT

### (1) Wave Damping Experiment by Using Artificial Seaweed

The extended model is compared with the artificial seaweed experiment conducted by Asano et al. (1988). The experiment was performed in a wave tank which was 27m long, 0.5m wide and 0.7m high as shown in Fig. 5. The model seaweed was made of polypropylene strips whose specific gravity was 0.9. The length, width and thickness of each strip was  $l_0 = 25\text{cm}$ ,  $b = 5.2\text{cm}$  and  $\hat{t} = 0.03\text{mm}$ , respectively. Each strip was bound to a heavy wire netting such that the strip was normal to the side walls of the tank and could bend with little torsion under the action of monochromatic waves generated in the tank. The number of strips placed uniformly over the area of  $4\text{ m}^2$  was 4400 and 5960. Correspondingly, the number of strips per unit horizontal area was  $N = 0.110$  and  $0.149\text{ cm}^{-2}$ . The water depth above the vertical strips was

Figure 5: Experimental setup

Figure 6: Measured wave amplitudes fitted to exponential decay model

$h = 20$  and  $27\text{cm}$ . In total, sixty test runs were performed.

Six capacitance wave gauges were used to measure the free surface oscillations. Excluding the data from the two gauges at both ends, the data from the remaining four gauges were used in the data analysis because this wave damping model does not account for the presence of lateral boundaries. The location of the second gauge in Fig.5 was taken herein to be the location  $x=0$  and the analysis domain was  $0 \leq x \leq 6$  m.

A regression analysis based on the method of least squares was performed using (9) in which the exponential decay of the local wave amplitude  $a$  is characterized by the initial amplitude  $a_0$  at  $x = 0$  and the exponential decay coefficient  $k_i$ . Fig. 6 shows the measured values of  $a$  at  $x=0, 2, 4$  and  $6$  m for the 60 runs, normalized as  $a/a_0$  as a function of  $k_i x$  where the fitted values of  $a_0$  and  $k_i$  are used for each run.

## (2) RESULTS AND DISCUSSION

The comparisons on the decay coefficient  $k_i$  are shown in Fig. 7, where the circles indicate the measured values. The experimental results are shown separately for the large wave runs ( $a_0 = 4.5 \sim 6.0\text{cm}$ ) and for the small wave runs ( $a_0 = 2.8 \sim 4.2\text{cm}$ ), while the computed results are based on the average wave amplitude;  $a_0=5.25\text{cm}$  for the former and  $a_0=3.50\text{cm}$  for the latter.

The previous model of Kobayashi et al.(1992) reproduced the measured wave decay coefficients only when the drag coefficient  $C_D$  of the order 0.1 was used for the swaying vegetation. The present model including the swaying motion of the vegetation is shown to yield much better agreement with the same data set, using a more realistic value of the drag coefficient of approximately 0.5.

Fig. 8 shows the comparison between the measured and calculated values of the wave celerity  $c$ . Slight overestimation of  $c$  by the present model is apparent for low frequency waves. The agreement with the measured celerity becomes slightly worse when the swaying motion of vegetation is considered.

Besides the wave damping measurements, the horizontal displacements of the top of the vegetation strip under waves were measured. Fig. 9 shows the measured data points in comparison with the computed curves. As the wave frequency  $f$  decreases, the present model tends to overpredict the displacement  $\zeta$ .

Judging from Figs. 8 and 9, the limitations of the present model seems to arise when the swaying motion becomes large. It was observed for low frequency waves that the vegetation swayed considerably and may have generated turbulence along the interface and among the vegetation strips. The present model, however, does not account for the turbulent stress. The modeling of the swaying vegetation is so simple that the complex large swaying motion could not be reproduced very accurately. The drag resistance of the vegetation may no longer be expressible by (3) which neglects the vertical component of the drag resistance.

Although the drag coefficient  $C_D$  is herein taken to be 0.5 as the best value for the measured decay coefficients,  $C_D$  should be a function of Reynolds number defined by the relative velocity and vegetation size. In addition, the proximity effects of surrounding strips on  $C_D$  should be examined because natural vegetation usually grows densely as a colony.

## 6. CONCLUSIONS

The present paper has presented an analytical solution for water waves propagating over submerged vegetation and a mathematical expression for

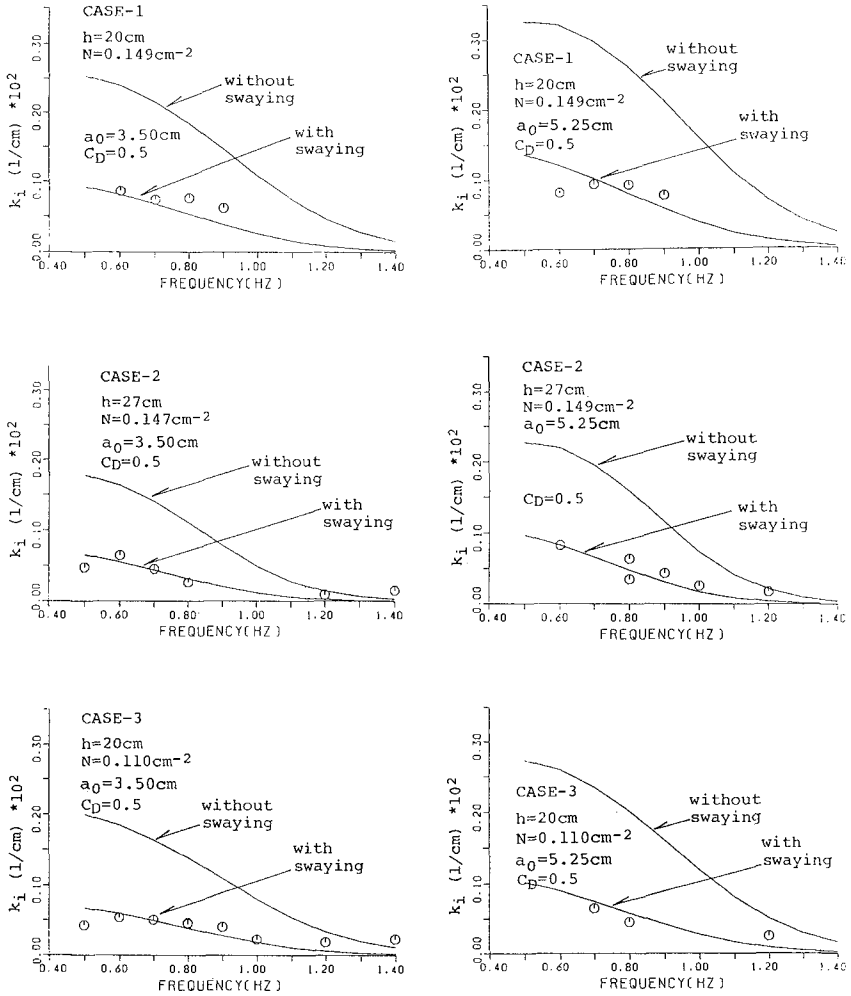

Figure 7: Comparisons between measured and computed decay coefficient  $k_i$

Figure 8: Comparisons between measured and computed wave celerity  $c$

Figure 9: Comparisons between measured and computed horizontal displacement of top of vegetation strip

vegetation motion swayed by the water waves. Both solutions have been linked by the linearized damping coefficient  $D$  through which the interaction effects between the water waves and vegetation motion have been accounted for. The properties of the wave decay coefficient and wave celerity have been examined by performing a sensitivity analysis.

The present model has been compared with the artificial seaweed experiment. The drag coefficient  $C_D$  has been calibrated using the exponential decay coefficient fitted for each run. The calibrated values have been found to be approximately 0.5 which is greater than the values of the order 0.1 obtained by the previous model which neglected the vegetation motion. The drag coefficient of about 0.5 appears to be more realistic. Although the present model is valid only when the swaying motion is not large, the capability for predicting the wave decay has been improved herein by including the vegetation motion in the model.

#### ABSTRACT

Puerto Miranda oil terminal, located in the Maracaibo Strait, Venezuela (see figures 1 and 2), is one of the main venezuelan oil industry loading facilities of crude oils. Ships access the terminal from the Gulf of Venezuela by a 40 km long, 300 m wide and 13.7 m depth main channel, which is periodically dredged in order to keep the design depth. A secondary channel leads from the main channel to the terminal itself ( See figure 3). Over the last few years the increase in sedimentation rates in the secondary channel has motivated the need for studies that would determine alternatives to reduce dredging costs.

A previous work [0], based on the circulation and sedimentation patterns in the area under study, proposed the construction of a new access channel with a different orientation regarding the prevailing current direction, that would reduce the sedimentation rate and dredging frequency.

The venezuelan oil industry through its R & D filiate (INTEVEP), has developed a 2-D finite element mathematical model to simulate suspended sediment transport and a 2-D finite difference circulation model for coastal regions.

In this work, these models are applied to determine the evolution of the secondary old and new dredged access channels to Puerto Miranda oil terminal. Both models were calibrated and validated with field data and results are presented for the complex circulation and sedimentation patterns that occur in the area of Puerto Miranda terminal.

## CIRCULATION MODEL

The circulation model solves the Shallow-Water equations by the MacCormack finite difference scheme as implemented by García and Kahawita [2]. This explicit model has been previously applied to several river and coastal problems, and for this case has been calibrated and validated using field measurements including tidal elevations and velocities at various locations.

In order to resolve the complex circulation patterns that exist in the area, two finite difference grids are used. The first is formed by  $250 \times 250$  m cells and covers a region that includes the El Tablazo bay and the Maracaibo Strait. This grid has 11,480 nodes for a total of 34,440 degrees of freedom, since two velocity components and one tidal elevation is calculated for each node. The tidal elevations and velocities resulting from the simulations on this grid are then transferred to a finer grid composed of  $50 \times 50$  m cells just around the Puerto Miranda area. Results for each time step for several tidal cycles is recorded in a binary file for latter interfacing with the sediment transport model.

Figure 4 shows the comparison between the tidal gage and the model results for the week Apr-01-1989 to Apr-07-1989. These were obtained after adjusting the depth varying Manning coefficient until model results compared favorably with measurements. To investigate how the model performed for a different tidal period, the week of Nov-

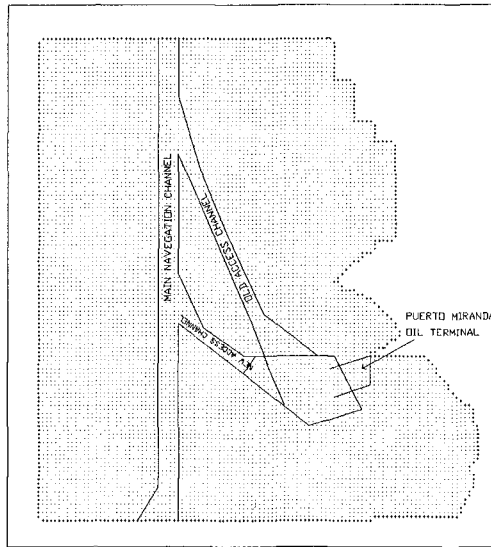

Figure 3.- Puerto Miranda oil terminal area showing the main navigation channel, the old access channel and the proposed or new channel. Points indicate fine grid where velocities are calculated.

08-1989 to Nov-14-1989 was chosen and the model was applied using the same Manning coefficients. As can be seen in figure 5 the model results reproduce correctly the tidal measurements.

Figure 6 and 7 present two flow fields for the fine grid around Miranda terminal. It can be appreciated the occurrence of large scale eddies that have also been observed in the area.

### SEDIMENT TRANSPORT MODELLING

Sediment transport modelling involves the process of advection, erosion and deposition.

For general flow conditions the suspended sediment transport modelling can be formulated in terms of four partial differential equations. Two momentum equations and one conservation of water mass equation that forms the so-called Saint Venant equations, solved by the hydrodynamic model [2], and the two-dimensional (vertically averaged) convection-dispersion sediment mass conservation equation that can be expressed in the following form:

$$\frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} + v \frac{\partial c}{\partial y} = \frac{\partial}{\partial x} (D_x \frac{\partial c}{\partial x}) + \frac{\partial}{\partial y} (D_y \frac{\partial c}{\partial y}) + \frac{1}{h} S \tag{1}$$

Figure 4.- Comparison of measured tidal elevations with model results (Apr-01-89 to Apr-07-89). Measurements taken from Punta de Palmas tidal gage at the entrance of Maracaibo Strait.

where  $c(x, y, t)$  is the sediment concentration averaged along the vertical direction  $z$ ,  $u(x, y, t)$  is the mean flow velocity in the horizontal  $x$  direction,  $v(x, y, t)$  is the mean flow velocity in the horizontal  $y$  direction,  $h(x, y, t)$  is the flow depth,  $D_x$  and  $D_y$  are the turbulent dispersion coefficients in  $x$  and  $y$  directions respectively, and  $S$  is the source-sink term.

Equation (1) is obtained by integrating the three-dimensional convection-diffusion equation along the vertical direction.

The source-sink term  $S$  takes into account the erosion and deposition processes. The vertical deposition is equal to  $w \partial c / \partial z$ , being  $w$  the sediment settling velocity which for fine particles is given by the Stokes law and  $c$  is the local concentration.

In this study we consider that the sediment concentration is zero at the free surface. In that case, integrating the vertical deposition term gives  $w C_o$  where  $C_o$  is the sediment concentration in the bottom layer that will be taken proportional to the average vertical concentration. In this manner, the source term, corresponding to deposition, is proportional to the local bottom sediment concentration and to the settling velocity  $w$ . (See [1]).

The sink term, also called erosion or resuspension term, determines the remaining boundary condition to satisfy the equilibrium in the bottom layer. There are many for-

Figure 5.- Comparison of measured tidal elevations with model results (Nov-08-89 to Nov-15-89). Measurements taken from Punta de Palmas tidal gage at the entrance of Maracaibo Strait.

mulae available to represent this term that go from those obtained by semi-analytical methods through integration of the movement equations of the sediment particles to those obtained empirically. The analytical formulae usually come in terms of integrals that complicates the application of the mathematical model and do not give much better results for the extra effort required [4], [5]. On the other hand, the empirical formulations are given in terms of the flow variables and are generally of simple mathematical form giving reasonable results. In this work the formulation for the sink (erosion) term will be based on an empirical formulation proportional to the square of the velocity,  $q^2 = u^2 + v^2$ , and inversally proportional to the local flow depth  $h$ .

Using the source and sink term so defined,  $S$  can be written as:

$$S = \alpha w c - \beta \frac{q^2}{h} H\left(\frac{\tau_b}{\tau_c} - 1\right) \tag{2}$$

where  $\alpha$  and  $\beta$  are proportionality factors,  $\tau_b$  is the bottom surface shear stress,  $\tau_c$  is the bottom surface critical shear stress for the initiation of sediment movement which is determined by the Shields criterion [6].  $H(\tau_b/\tau_c - 1)$  is the Heavieside function defined as  $H = 1$  for  $\tau_b \geq \tau_c$  and  $H = 0$  for  $\tau_b < \tau_c$ ,

The bottom layer equilibrium equation expressed as:

$$(1 - p) \frac{\partial z}{\partial t} = S \tag{3}$$

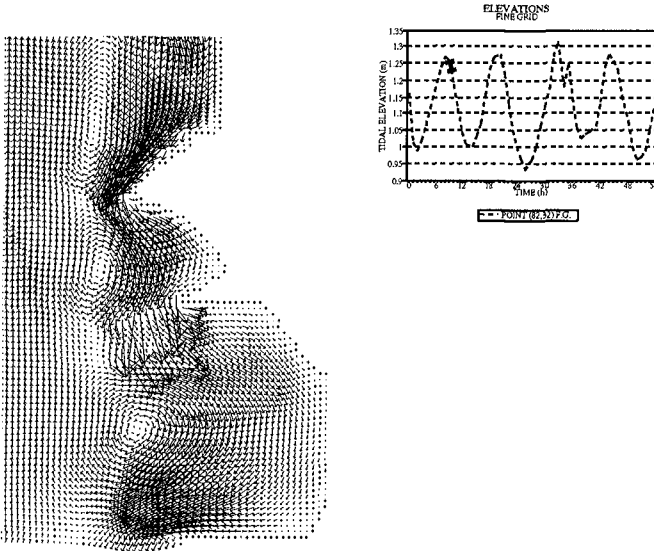

Figure 6.- Flow field in the Puerto Miranda terminal area for the tidal elevation at 9 hours shown in box.

defines the time evolution of the bottom elevation  $z$ , being  $p$  the porosity of the bed sediment.

Lin et al [1], make a mass balance in the bottom layer considering the layer thickness equal to two times the sediment diameter  $d$  and following Einstein sediment transport theory, obtain the following approximate relation for  $\alpha$  and  $\beta$  in equation (2):

$$\alpha \approx \frac{1}{3} \left( \frac{h}{2d} \right)^{w/\psi k u^*} \quad \text{and} \quad \beta \approx \phi \alpha \tag{4}$$

where  $\psi$  and  $\phi$  are empirical coefficients,  $u^* = \sqrt{\tau_b/\rho}$  is the shear velocity in the bottom,  $\rho$  is the water density and  $k = 0.40$  is the Von-Kármán constant in the logarithmic equation for the turbulent vertical velocity distribution.

Finally, the bottom layer equilibrium equation is expressed as:

$$\frac{\partial z}{\partial t} = \frac{1}{3} \left( \frac{h}{2d} \right)^{w/\psi k u^*} \frac{1}{(1-p)} \left[ w c - \phi \frac{q^2}{h} H \left( \frac{\tau_b}{\tau_c} - 1 \right) \right] \tag{5}$$

The parameter  $\phi$  can be determined applying equation (5) in a bottom control point of the region where the erosion and deposition rates are equal (zone of no change in the bottom elevation  $\partial z/\partial t = 0$ ). Applying this condition:

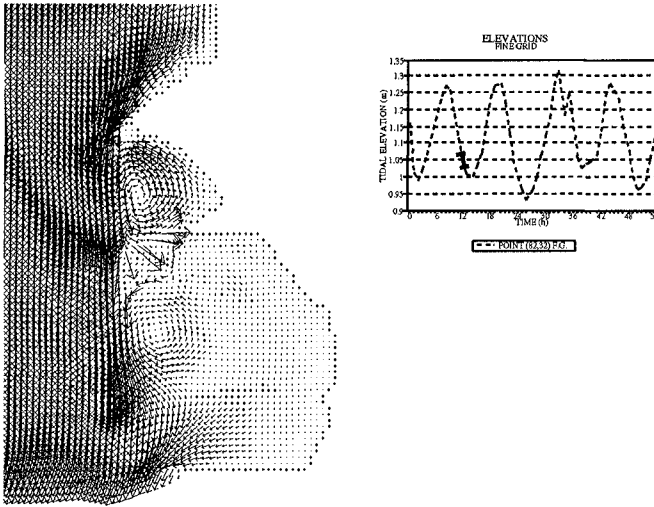

Figure 7.- Flow field in the Puerto Miranda terminal area for the tidal elevation at 12 hours shown in box.

$$\phi = \left( \frac{w c h}{q^2} \right) \tag{6}$$

In the model the bottom shear stress  $\tau_b$  will be calculated by:

$$\tau_b = \frac{\rho g q^2}{C^2} \tag{7}$$

where  $g$  is the gravity acceleration and  $C$  is the Chezy coefficient that for turbulent flow can be expressed in terms of the Manning  $n$  as  $C = h^{1/6}/n$ .

Substituting equations (2, 4, 5, 6 and 7) in equations (1) and (3) we obtain a system of two partial differential equations for  $c(x, y, t)$  and  $z(x, y, t)$  in terms of three parameters:  $D_x, D_y, \psi$ . These parameters have to be determined in the calibration process. The final system is given by:

$$\begin{aligned} \frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} + v \frac{\partial c}{\partial y} &= \frac{\partial}{\partial x} \left( D_x \frac{\partial c}{\partial x} \right) + \frac{\partial}{\partial y} \left( D_y \frac{\partial c}{\partial y} \right) + \frac{1}{h} \alpha w c - \beta \frac{q^2}{h} H \left( \frac{\tau_b}{\tau_c} - 1 \right) \\ (1 - p) \frac{\partial z}{\partial t} &= \alpha w c - \beta \frac{q^2}{h} H \left( \frac{\tau_b}{\tau_c} - 1 \right) \end{aligned} \tag{8}$$

with the corresponding expressions for the parameters given by equations: (4), (6) and (7).

The model described has three calibration parameters given by the two dispersion coefficients,  $D_x$  and  $D_y$ , and one of the erosion or deposition factors,  $\alpha$  or  $\beta$ . This is possible since, given a fluvial control point where the bottom elevation is constant, then  $\partial z/\partial t = 0$  and from equation (2) we obtain a relation between  $\alpha$  and  $\beta$ .

Starting from a system equivalent to equations (5) and (8) but for one-dimensional problems, Lin et al [1] simulated the sediment transport of the Qiantang river in China. In that reference it is shown that with the preceding approximations, the suspended sediment discharge hydrogram can be accurately predicted for a series of tidal cycles.

In the present work, the two-dimensional system given by equations (5) and (8) that model the sediment transport of fine non-cohesive sediments was solved numerically by the *finite element method*. In any event, for the application of the model, the velocity and depth field is determined by the hydrodynamic model. Then, equation (8) is solved for the sediment concentration given proper initial and boundary conditions and the bottom elevation evolution is obtained applying equation (5).

The finite element mesh is composed of 750 cuadrilateral elements and is superimposed over the  $50 \times 50$  m. finite difference grid in the area of the terminal. Since the nodes of the finite element mesh do not generally have corresponding nodes of the finite difference grid, interpolation of the velocity and tidal elevations is required.

The sediment model was calibrated comparing computed bottom elevations with a series of bathymetries available for the terminal zone. Two calibration parameters were used to reproduce the field measurements. Figure 8 presents the bottom elevation results along a transversal section in the old access channel computed by the model together with the profile obtained from the bathymetries of November 1988 and May 1989. The results in figure 8 show that the model reproduces the evolution of the old access channel with adequate resolution.

Once calibrated, the sediment model was used to predict the bottom evolution of the whole region. The results of this computations, shown in figure 9 indicate that the model correctly reproduces the bottom profile evolution in other areas.

## CONCLUSIONS AND RECOMENDATIONS

In this work, a circulation model and a suspended sediment transport model have been applied to predict the velocity and sediment deposition in the area of Puerto Miranda oil terminal, located in the Maracaibo Strait, Venezuela.

Model results predict the evolution of the dredged access channels to the terminal. Both models were calibrated and validated with field data and results are presented for the complex circulation and sedimentation patterns that occur in the area of Puerto Miranda.

Figure 8.- Bottom elevation results along a cross section of the old access channel. Comparison of computed elevations with measured data.

Figure 9.- Bottom elevation results along a cross section of the maneuvering zone. Comparison of computed elevations with measured data.

The proposed models correctly reproduce the measured bottom profile evolution. Field measurements of sediment fall velocity, vertical distribution of suspended

sediment concentrations as well as bed load transport at various locations in the access channel and its surroundings are recommended in order to evaluate the importance of bed load sediment transport (not considered in this model) with respect to suspended sediment transport in the long range sedimentation process acting in Puerto Miranda.

## CHAPTER 209

### Dispersion Process and the Settlement Pattern of Mud Dumped in Oceans

Eiji Yauchi <sup>1</sup> and Ken Katoh <sup>2</sup>

#### Abstract

The settlement of mud lumps dumped in oceans from barges was studied theoretically and the results were compared with data from field and laboratory experiments. The settling pattern and the load of initial turbidity were estimated by a non-dimensional dispersion index and the rate of turbidity load.

## 1 INTRODUCTION

Mud deposited on the bottom of rivers, lakes, or oceans are known to cause many problems. These problems can be classified into two groups. One is the siltation problem within channels, or basins at ports and harbors. As a result of the siltation, the port management body is forced to carry out dredging on a regular basis at a great deal of operational costs. The second problem is a consequence of the dredging, namely the disposal of the dredged mud either in the water or on land. In many instances, land disposal is infeasible because of the high salt content or the fineness of particles in the dredged mud. As a result, disposal of dredged mud in water is increasingly becoming a more frequently used option and therefore requires a more thorough study of its environmental impact.

While the dispersion characteristics of sand dumped in water are mainly affected by the diameter and specific weight of sand, the dispersion and settlement characteristics of dumped mud are affected by water content or cohesion, among other factors. As this field has not been studied sufficiently, the load of initial turbidity, or the falling velocity of dumped mud, has been taken to be the same as for cohesionless sand particles. However, dredged mud with low water content has a lower turbidity than sand and in numerical simulations the turbid area is seen to be larger than observed in the field.

In this paper, the results of a theoretical investigation of the settlement characteristics of mud lumps are presented along with a comparison of theoretical results with data from field and laboratory experiments.

## 2 LABORATORY EXPERIMENT

### 2.1 EXPERIMENTAL APPARATUS

Experiments were conducted in the laboratory to investigate the settling characteristics of dumped mud. The tank used in the tests was 0.5 m wide, 2.5 m long and 1.0 m high, as shown in Fig.1.

Figure 1: Experimental Apparatus

Figure 2: Shear Meter

The water content of the mud was varied from 170% to 700% and the mud was dumped into the tank from a scaled down model of a 3 cm wide, 4 cm long, and 2 cm high barge. The dispersion process and the settlement pattern were monitored by a video camera. The load of initial turbidity was calculated from the observed dispersion of the mud and diffusion coefficient (Yauchi et. al. :1989).

The shear stress of mud was measured using a vane shear meter shown in Fig.2, specially developed in order to measure the shear strength of soft mud. A stepping motor and a high-sensitivity torque meter were fitted to the axis of the shear meter and its rotation is maintained at a speed of 0.1 deg/s with an accuracy of 0.5%. The range of this shear meter is 1 pa to 10 kpa.

### 2.2 EXPERIMENTAL RESULTS

Fig.3(a) shows the result at a water content of 320% and at this water content the mud reached the bottom as one lump. At a higher value of water content, 429% as

shown in Fig.3(b), the mud lump begins to disintegrate and at a still higher value, 633%, depicted in Fig.3(c), the mud lump disperses.

Based on the experiments, the settlement of mud lumps was classified into three patterns, lump-settling, partial-dispersion and full-dispersion, as shown in Fig.4. Table 1 summarizes the results of the experiments.

### 3 THEORETICAL ANALYSIS

#### 3.1 SETTLEMENT PATTERN AND MODELING

Two models were considered in the theoretical analysis of the settlement pattern of mud lumps. The models are shown in Fig.5.

Figure 5: Modeling Type

In the first model, the mud lump is considered to be an elastic solid and in the second the mud lump is treated as a fluid with a high viscosity. If the mud lump is modeled as solid matter, the stress in the mud lump is easily analyzed by structural mechanics. While, if the mud lump is dealt with as a fluid, forces such as van der Waals' forces must be incorporated in the analysis. However, the measurement of van der Waals' forces is not easy and it is probably not very influential in the settling of mud lumps because of the big volumes of mud involved, over  $500m^3$ . Therefore, in this study, the mud lumps are assumed to remain intact and are treated as elastic matter.

#### 3.2 FORCES ON AND RESISTANCE OF MUD LUMPS

The main forces acting on mud lumps during settling are (a) drag force, (b) skin friction, (c) vortex force behind the mud lump and (d) a fluctuating force due to rotation of the mud lump. If the mud lumps are assumed not to rotate and the effect of skin friction is omitted, the governing forces are drag force and vortex force. The vortex force is affected by the shape of the mud lumps and the falling Reynolds number. Thus if, the effect of the vortex force is included in a drag coefficient the only governing force that needs to be considered is the drag force.

The resistance of mud lumps is measured by the shear, compressive and tensile strengths. As these strengths are almost proportional to each other the shear strength was taken as the measure because it could be easily measured in situ.

#### 3.3 NON-DIMENSIONAL DISPERSION INDEX

In laboratory tests the mud lumps begin to break at the center because of the bending moment. In this study the mud lumps were modeled as thin plates, as shown in Fig.6. The mud lump start disintegrating when the shear from the bending exceeds the shear strength of the mud. The equilibrium equation can be expressed as Eq.1,

$$\frac{\partial^4 w}{\partial x^4} + 2\frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4} = \frac{p}{\gamma} \quad (1)$$

where,  $w$  is the displacement,  $p$  is the force acting on the mud lump, and  $\gamma$  is the stiffness of the mud lump.

Figure 6: Schematic of a Thin Plate

It is difficult to obtain general solutions because Eq.1 is a non-linear equation. Thus, its solution is carried out analytically by considering the conditions of dumping mud.

The shape of the mud lumps dumped from barges is taken as rectangular parallelepiped. The mud lump starts to disintegrate at the center of mud lump at the region of high bending moment. Therefore, the mud lumps are considered to be simply supported. When the shape of mud lumps is a  $a \times b \times h_{mud}$  rectangular parallelepiped domain, the boundary conditions are as per Eq.2.

$$\begin{aligned} w &= 0 \quad |_{x=0, x=a, y=0, y=b} \\ M_x &= 0 \quad |_{y=0, x=0, x=a, y=0, y=b} \\ M_y &= 0 \quad |_{x=0, x=a, y=0, y=b} \end{aligned} \tag{2}$$

When Eq.2 is used together with Eq.1, Eq.3 known as Navier’s solution is obtained.

$$w = \frac{1}{\pi^4 \gamma} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{a_{mn}}{(m^2/a^2 + n^2/b^2)^2} \sin \frac{m\pi x}{a} \sin \frac{n\pi y}{b} \tag{3}$$

The maximum bending moment at the center of the mud lumps is given by Eq.4 and Eq.5.

$$M_x = \frac{16pa^2\lambda_{ab}^2}{\pi^4} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{(\lambda_{ab}^2 m^2 + \delta n^2)}{mn(\lambda_{ab}^2 m^2 + n^2)^2} \tag{4}$$

$$M_y = \frac{16pa^2\lambda_{ab}^2}{\pi^4} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{(\delta \lambda_{ab}^2 m^2 + n^2)}{mn(\lambda_{ab}^2 m^2 + n^2)^2} \tag{5}$$

Representing the section modulus of the mud lump by  $Z$ , the flexural stress in the mud lump can be expressed by Eq.6.

$$\sigma_x = M_x/Z_x, \quad \sigma_y = M_y/Z_y \tag{6}$$

A new parameter defined by the shear and bending stresses in the mud lumps is introduced for determining the settlement pattern.

$$\Psi = \frac{\sigma_{max}}{\tau_{mud}} \tag{7}$$

$\Psi$  is denoted as the non-dimensional dispersion index.

### 3.4 RATE OF TURBIDITY LOAD

Both the turbidity load and the variation of the non-dimensional dispersion index must be considered in order to be able to estimate the turbidity in numerical simulations. A new factor, the rate of turbidity load,  $\phi$ , is defined to represent the load of initial turbidity. The factor  $\phi$  is based on the rate of the load of initial turbidity,  $q$ , and the maximum turbidity load,  $q_{max}$ , as expressed in Eq.8.

$$\phi = q/q_{max} \tag{8}$$

The rate of turbidity load  $\phi$  increases as the non-dimensional dispersion index increases. The factor  $\phi$  is taken as a measure of the probability of dispersion of dumped mud lumps, as shown in Fig.7.

Figure 7: Probability of Disintegration of Mud Lumps

where,  $\eta$  is the fluctuation of  $\Psi$ ,  $\eta_0$  is the standard deviation of  $\eta$ , and  $B$  is a constant.

If the bending stresses in a mud lump,  $\sigma$ , is taken to be distributed randomly, the mud lump shows signs of dispersion when  $\sigma$  is greater than  $\eta_1$  or  $\sigma$  is less than  $\eta_2$ .

Thus,  $\phi$  is equal to one minus the integral between  $\eta_2$  and  $\eta_1$  of the density function of the bending stresses. In this paper the bending stresses were modeled by a Gaussian distribution, as shown in Eq.9.

$$\begin{aligned} \phi &= 1 - \frac{1}{\sqrt{\pi}} \int_{\eta_{*2}}^{\eta_{*1}} e^{-t^2} dt \\ \eta_{*1} &= B_*/\Psi - 1/\eta_0, \\ \eta_{*2} &= -B_*/\Psi - 1/\eta_0, \\ B_* &= B/\eta_0, \end{aligned} \tag{9}$$

where  $\eta_0$  and  $B_*$  are determined by the critical values of the disintegration process.

### 3.5 SETTLING VELOCITY

The settling velocity is an important factor in the evaluation of the the rate of turbidity load. The terminal velocity of a particle settling in a fluid is given by Eq.10.

$$w_f = \sqrt{(4/3)(s-1)gd/C_D} \quad (10)$$

where,  $s$  is the specific weight,  $d$  is a representative diameter, and  $C_D$  is the drag coefficient of the mud lump.

In this study, Wadell's representation equation is used in incorporating the shape factor, defined as  $C_D$ .

### 3.6 CRITICAL VALUES OF THE DISINTEGRATION PROCESS

In this study, the rate of turbidity load is defined by the rate of bending stress and shear strength of mud lump. However, the critical values of the disintegration process are defined in terms of the rate of bending stress and tensile strength. The relationship between tensile strength,  $\sigma_t$ , cohesive force,  $c$ , and shear strength,  $\tau_{mud}$  of clay are given by Eq.11 and Eq.12.

$$\sigma_t = 2c \frac{\cos \theta_0}{1 + \sin \theta_0} \quad (11)$$

$$\tau_{mud} = \sigma_t \tan \theta_0 + c \quad (12)$$

where,  $\theta_0$  is the angle of internal friction.

If the clay is assumed to be ideal,  $\theta_0 = 0$  and  $\sigma_t = 2\tau_{mud}$ , the critical values of the disintegration process of mud lumps can be expressed as follows.

$$\Psi_c = 2.0 \quad (13)$$

In the field, mud usually contains some sand and benthos, etc, and these reduce the tensile strength. Therefore in this study,  $\Psi_c$  is determined from laboratory experiments, as shown by Eq.14.

$$\Psi_c = 1.5 \sim 2.0 \quad (14)$$

Furthermore, we obtain  $\eta_0 = 1.0$  and  $B_* = 4.0$  from Eq.14 and Eq.9, when we take  $\eta_0 = 1.0$  and  $\eta_* = 1.0$ .

### 3.7 COMPARISON WITH EXPERIMENTAL DATA

Fig.8 compares the theoretical results with those from laboratory experiments. Here,  $C_D = 2.01$  and the Poisson rate,  $\delta = 0$ , are assumed.

On the whole, the theoretical predictions were in good agreement with the experimental data. In particular, they were in good agreement at the range of  $\Psi > 20$ , though the assumption of the mud lump being elastic can no longer be applied because at such values the lump is more like a fluid than a solid. The non-dimensional dispersion index is related to the settlement pattern and each pattern was classified using this index, as shown in Eq.15.

$$\begin{aligned} \Psi < \Psi_1 & : \text{Lump - settling type} \\ \Psi_1 \leq \Psi < \Psi_2 & : \text{Partial - dispersion type} \\ \Psi_2 \leq \Psi & : \text{Full - dispersion type} \end{aligned} \quad (15)$$

Figure 8: Theoretical Predictions and Laboratory Data

From Fig.8,  $\Psi_1$  and  $\Psi_2$  were determined to be equal to  $1.5 \sim 2.0$  and  $10 \sim 20$ , respectively.

#### 4 FIELD EXPERIMENT

Field experiments were carried out to validate the theoretical predictions. Field measurements were made within a circle of 700 m radius centered around the dumping point at a depth of 41 m. The 50 percentile diameter of the mud used in the tests was  $0.7 \mu\text{m}$  and the mud contained some organic matter. The vertical and horizontal profiles of turbidity, water temperature and salinity, and the falling velocity were measured with the help of six turbidimeters, six salinometers, and three velocimeters. The three dimensional profile of the turbidity was, also, measured by means of an echo-sounding turbidimeter.

Fig.9 shows the vertical turbidity profile. Here, the abscissa is turbidity, and the ordinate is depth.

For small water contents, turbidity could be measured only at the bottom layers. Turbidity measured in the upper layers became larger as the water content of the mud increased. The dispersion indexes are 1.2, 2.6 and 40.1, respectively. The field data are in good agreement with the theoretical predictions.

#### 5 CONCLUSIONS

The settlement pattern of mud lumps dumped in oceans were classified into three patterns. The settlement pattern and the turbidity load can be estimated by the non-dimensional dispersion index,  $\Psi$ , and the rate of turbidity load,  $\phi$ .

## CHAPTER 210

### PORT OF LISBON IMPROVEMENT OF THE ACCESS CONDITIONS THROUGH THE TAGUS ESTUARY ENTRANCE

I. B. Mota Oliveira<sup>1</sup>

#### ABSTRACT

The Port of Lisbon authority is aiming at the reception of container ships of the fourth generation. For that a deeper and wider artificial channel has to be dredged through the outer bar. The set of studies undertaken (data collection, site investigations, mathematical and physical modelling) put into evidence the importance of the opening of a secondary bar, some 50 years ago, over the general morphological behaviour of the estuary entrance. So a recommendation has been made to close it using an artificial sand dike.

#### 1- INTRODUCTION

The Port of Lisbon takes advantage of the excellent conditions offered by the lower reach of the river Tagus estuary, as a natural harbour.

The port facilities are distributed along the banks of the estuary, mainly along the north bank: 16 km of quays (13 km in the north bank) with depths from 4 up to 17m (CD); 98 ha of reveted embankments; 1100 ha of total dry area under the port authority control (Administração do Porto de Lisboa - APL). In addition the estuary shelters: a major ship repair yard; a navy base; some important industry terminals (steel mill, chemicals, food processing, cement, etc); fishing facilities; small craft (yachting) harbours.

With an annual traffic of 17 million tons (1991), the port of Lisbon is the main portuguese port. General cargo accounts for about 26% of that tonnage, being 39% for liquid bulks and 35% for dry bulks. General cargo is already containerised at a level of 60%, equivalent to about 285 000 TEU.

The Tagus estuary - Figure 1 - affords excellent depths in the lower reach, a "corridor" of some 12 km in length with approximately parallel banks between the entrance and the Praça do Comércio Square in Lisbon. On the contrary, it is very difficult to get here new embankments: on the north side, because of the neighbouring town, namely the historic zone, against which the port is really compressed; on the south side, because of the very steep margins. From Praça do Comércio upstream the situation is reversed: it is easier to get new embankments but natural depths diminish progressively, sedimentation problems in channels and basins worsen and maintenance dredging becomes critical.

Professor, INSTITUTO SUPERIOR TÉCNICO, UTL. Lisboa, Portugal

Figure 1 - The River Tagus Estuary

The estuary has a total area of the order of 250 km<sup>2</sup> which, with a spring tide amplitude of almost 4 m, generates a tidal prism around  $1\ 000 \cdot 10^6$  m<sup>3</sup>. The tidal amplitude varies along the estuary and it is worth mentioning that, on account of a small resonance effect, the amplitude inside the estuary is greater than in the outside, growing continuously from the estuary entrance up to the Praça do Comércio Square.

The tidal prism is the main agent in maintaining the excellent depths across the Tagus outer bar: almost 12 m in spring low water and 15 m in mean high water - Figure 2. That explains why only in the last two or three decades the bar began to cause some significant constrains to the navigation of the largest ships calling the port of Lisbon. As a matter of fact, the first dredging works in the outer bar, at a level of (-13.5 m CD), were carried out only in 1969.

It should be mentioned that this bar was crossed by tankers of the 300 000 dwt class (and even 500 000 dwt), mainly empty ships bounded for the repair yard of LISNAVE, within the estuary.

The port authority (APL) is now aiming at the reception of container ships of the so called fourth generation, almost without navigation restrictions in the outer bar (Length: LOA=290 m; Beam: B=32 m; Draft: D=13 m). Several studies were undertaken, including data collection, site investigations, mathematical and physical modelling, improvements in aids to navigation, etc.

The main purpose was to establish the geometry of an artificial channel through the outer bar (alignment, depth, width) and to estimate the corresponding mean annual volume of maintenance dredging. In addition, the evaluation of the

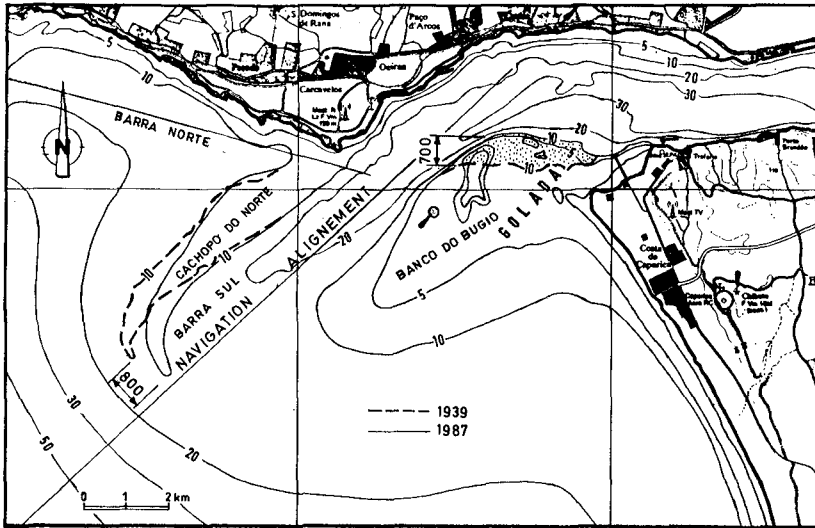

Figure 2 - The Entrance of the Tagus Estuary

general consequences of the closing of the Golada was also considered.

Golada is a secondary bar over the "Banco do Bugio", this latter being a big shoal that defines the southern bank of the main entrance channel - Figure 2. It is a morphologically very unstable area, with very small depths, which in the beginning of this century had yet the nature of a sand spit that, at least in low water, allowed the pedestrian access to the Bugio lighthouse (in effect a fortress of the last years of the 16th century).

During the forties this secondary bar (Golada) "broke" through the Banco do Bugio. So, another question to be answered by the study was: what have been the consequences of that event over the stability of the main outer bar or, what would be the consequences of an artificial closing of the Golada, namely upon the maintenance conditions of the artificial channel to be cut through the main bar?

Only a brief summary of those studies and of their main results can be presented in this paper.

## 2 - ARTIFICIAL CHANNEL THROUGH THE OUTER BAR

### 2.1 - Alignment

It was decided to open the artificial channel according to the "traditional" navigation route, that is to say, the alignment that has been used by pilots for many decades to cross the bar and to navigate along the lower reach of the estuary - Figure 2. In fact, a different alignment would imply:

- a second set of navigation aids ;
- additional steering problems in the transition between the two alignments; the risk of a ship grounding would be particularly high in an outgoing trip during the ebb phase, when ship and tidal velocities add each other; indeed in the area of the channel ebb currents are stronger than flood ones and, in an outgoing manoeuvre, the ship passes from an almost unrestricted

- navigation area, upstream the channel, to a confined path width.
- the change of navigation habits that has been established for a long time (may be, the main reason).

On the other hand, the advantages of the new alignment (mainly, a somehow shorter length of the artificial channel) seems almost irrelevant in relation to those negative points.

## 2.2 - Cross-Section

### 2.2.1 - Depth

In order to obtain the total required depth of the channel the loaded draft of the reference ship must be added to the corresponding "underkeel allowance", that is to say, the clearance between the keel of the standing still ship in calm water and the nominal level of the channel bed. The underkeel allowance faces a number of different ship movements (rolling, pitching, squat), and includes the net clearance which accounts for the minimum allowance under the keel when the ship moves along the channel under the most unfavourable conditions.

In a case like the bar of the Tagus estuary, facing openly the Atlantic Ocean, the most important movements of the ship are by far those resulting from the wave action. In theory, the maximum immersion of the ship due to rolling and pitching could be obtained through the "amplitude response operator" of the ship, relating those movements with the wave period, for a given water depth and angle of wave attack.

Indeed in our case that operator for the "project ship" was not known. Nor physical or mathematical modelling had been foreseen to establish the channel depth.

A bibliographical study was made, taking advantage of the known performance of artificial channels cut in environmentally similar conditions. The main steps of the study were as follows.

Based on data of the "Oceanographic Atlas of the North Atlantic Ocean. Section IV, Sea and Swell" (U. S. Naval Oceanographic Office), the deep water wave climate was defined. By means of regular wave diffraction diagrams, the local wave climate (in the area of the artificial channel) was established in terms of wave heights and angles relative to the channel alignment. In what concerns wave heights, their frequencies have been characterised by height intervals of 0.5 m, from 1.5 m to 4.0 m. In a word, for the mean year it was obtained

Hs < 1.5 m	285	days/year	(78.1 %)
1.5 m < Hs < 4.0 m	77	"	(21.1 %)
Hs > 4.0 m	3	"	( 0.8 %)

After a careful analysis of some case studies ( Richards Bay, South Africa; Ashdod, Israel; Antifer, France; Europort, Netherlands; Inkoo and Tahkoluoto, Finland ) the hypothesis was made that the maximum sinkage (s) of the project ship (rolling and/or pitching) due to a certain wave would be equal to its height (H):  $s=H$ . Taking into account the velocity of the ship and the depth of the channel, a maximum squat of 0.6 m was considered and an underkeel clearance of 0.6 m was accepted. So, the maximum overdraft (underkeel allowance) needed in the presence of a wave height H will be  $Z=H+1.2$  m.

"Distribution" of tide levels in the region of the outer bar was defined by means of a level duration curve. If we think of time intervals while the tide levels remain below a certain value (Tl), we have as an example the following "probabilities"  $pTl = p(\text{tide level} < Tl)$ :

$Tl = 0.7$  m CD,  $pTl = 2\%$ ;  $Tl = 2.7$  m CD,  $pTl = 75\%$ .

Let C be the channel bottom level and D the draft of the project ship (13m).

In order to cross the bar in the presence of a wave height  $H$  a minimum tide level

$$Tl = C + D + Z = C + D + H + 1.2 \text{ m} \quad (1)$$

will be necessary ( $C$  and  $Tl$  are referred to Chart Datum;  $C$  is negative).

If a given wave height  $H$  occurs, the channel will be "inoperative" for any tide level below the value given by expression (1). A measure of the "inoperativeness" ( $Inop$ ) of the channel can be obtained as follows

$$Inop = \sum_i pHi * pTl \quad (2)$$

in which  $pHi$  is the probability associated to the local wave height interval  $(Hi-0.5 \text{ m}) < H < Hi$

Three channel bottom levels were "tested":  $C = -17; -16; -15$  (m CD). The "inoperativeness" can be expressed as a percentage of the total time or, alternatively, it can be thought as the percentage of the number of "project ships" that will suffer some waiting time to cross the artificial channel. In effect the arrivals are random. Taking into account that a ship calling the port crosses the estuary entrance twice, the results obtained were

Channel bottom level (m CD)	Inop (%)	Ships suffering some waiting time to cross the bar
- 15	11.1	1 out of 4 or 5
- 16	3.2	1 out of 16
- 17	0.6	1 out of 85

A nominal bottom level  $C = -16$  m CD was recommended to the port authority. For a tide level of 0.7 m CD (98% exceedence), the project ship ( $D = 13$  m) will afford an overdraft of 28.5% ( $16.7 \text{ m} / 13 \text{ m} = 1.285$ ), which compares with the reference cases: Richards Bay, 35%; Ashdod, 35%; Europort, 32%; Antifer, 10%; Inkoo, 15%.

Of course, the channel has to be built at a somewhat lower level to account for sedimentation between dredging works

### 2.2.2 - Width

Considering the small length of the artificial channel ( $\approx 4$  km) and the relatively small number of ships having to travel within it, a one lane channel was considered suitable in this case. The channel width was assessed preliminarily by means of empirical rules. In a second approach, a mathematical model was elaborated to simulate the ship manoeuvring in the channel.

According to CIERGNA (Commission Internationale pour la Reception des Grands Navires) of PIANC (Buletin n° 35, 1980) the width of a one lane channel should not be smaller than  $5B$ ,  $B$  being the ship beam; in some very severe conditions, for instance strong transverse currents, according to the same commission that width could reach the value of  $10B$ .

In the case of the Lisbon outer bar, ebb and flood currents flow more or less parallel to the navigation channel. On the other hand, strong winds can represent a critical problem on account of the high free-board of the project ship (container ship), in as much as they can occur perpendicularly to the ship path.

The cases mentioned previously (Richards Bay, Ashdod, etc) were carefully analysed, namely the "adimensional" widths ( $n B$ ) when related to their specific environment conditions. Values between  $5 B$  (Tahkoluoto) and  $8.4 B$  (Antifer) were found.

Figure 3 - Ship Motion Controlled by a) One Operator and b) All Operators, for a Given Set of Environmental Conditions

The importance of aids to navigation systems is pointed out by CIERGNA and is put into evidence by the case studies analysed: the poorer the system, the wider the channel has to be.

As a first approximation a width of 300m, corresponding to 9.4 B ( $B=32$  m), was adopted; the capabilities of the present aids to navigation was taken into consideration. It has to be said that pilots claim for an even wider channel (350 m).

A numerical model (SIMNAV) was then elaborated by Laboratório Nacional de Engenharia Civil - LNEC. Its characteristics and capabilities are described by Santos and Rita (1991). It simulates the ship manoeuvring in coastal waters, calculating the time evolution of the ship heading and position, taking into account the motion in the horizontal plane.

The following testing parameters were considered:

- Loading conditions of the ship: fully loaded; in ballast.
- Tide levels: mean tide level; spring low water.
- Currents: tidal currents as obtained from the 2D hydrodynamic model ( see item 3.3).
- Local wind: calm; 50 km/h perpendicular to the ship path.
- Local waves: no waves;  $H=3$  m,  $T=11$  s,  $\alpha=45^\circ$ .

The most unfavourable conditions were obtained combining waves 3 m high with transverse winds of 50 km/h.

Four different operators conducted a reasonable number of manoeuvres in the model for each environment situation. The operator controls the ship by varying the rudder angle and the available torque at the propeller axis. Figure 3 presents a single trip and the superposition of all the trips made by the four operators for the same testing conditions.

The variable considered in the verification of the channel width was the maximum distance per trip between the channel axis and the ship's centre of gravity -  $Y$ . Curves of probability of exceedence of  $|Y|$  were obtained. The conclusion of the model study was: the acceptable channel width will be somewhere between 272 m and 300 m.

### 2. 3 - Maintenance Dredging

The navigation channel through the Lisbon outer bar was firstly dredged in 1969 at a

Figure 4 - Infill Process of the Channel Critical Zone

level of (-13.5 m CD); a second and a third dredging took place in 1972 and 1985, at levels of (-15.5) and (-15) respectively.

The subsequent morphological evolution was monitored regularly through a reasonable number of hydrographical surveys. While analysing this evolution we looked into nature as a one to one scale model of itself.

The channel infill process is governed by a complex interaction of tidal currents and a rough and varied wave climate. We have assumed that a exponential law can characterise such a process as a whole, when time scales of several years (at least two or three) are considered. Such a law states that, if a morphological situation is artificially driven away from its natural equilibrium, the difference will diminish exponentially with time. Accordingly we can write

$$V(t) = V_e - (V_e - V_0) \exp(-Ct) \tag{3}$$

where:  $V(t)$  is the channel infill volume at time  $t$ ;  $V_e$  is the volume corresponding to the natural equilibrium situation;  $V_0$  is the volume at  $t=0$ , in principle immediately after the conclusion of the dredging work.

The sand volume at the date of each survey, laying on the volume to be occupied by the artificial channel (bottom: -16 mCD; width: 300 m; side slopes: 1/20), was evaluated. Due to its longer duration (13 years) and to its deeper initial bottom level, only the period between the second and the third dredging was considered in this study.

In theory we would have known  $V_e$  and  $V_0$ , the only unknown to be determined being  $C$ . Indeed, owing to the great scatter of data obtained (reflecting the normal morphological instability of an outer bar controlled by a rough and varied wave climate), we only had first approximations to those values.

The following approach was used: several  $V_e$  values were considered and, for each one of them, several  $V_0$  values were taken; the pair  $V_e, V_0$  determining the best fit of the theoretical curve to the "experimental" points (highest correlation coefficient) was chosen.

The "critical" zone (a 1400 m long reach facing the tip of "Cabeça do Pato" (Duck Head) where the infill rate is the highest), and the whole channel where considered separately. Figure 4 pertains to the critical zone only.

The following values were obtained:

	$V_e$ ( $m^3$ )	$V_0$ ( $m^3$ )	$C$ ( $month^{-1}$ )	Correlation Coefficient
Total channel	3 800 000	790 000	$5.4 \cdot 10^{-3}$	0.924
Critical zone	2 200 000	254 000	$7.0 \cdot 10^{-3}$	0.980

Some comments:

- the "best" value of  $V_e$  for the critical zone compares quite well, and the one of the whole channel compares fairly well, with those measured in the last survey done before the first dredging (1969);
- the higher correlation coefficient obtained for the critical zone is in agreement with its greater physiographical homogeneity when compared with the diversity encountered along the whole channel
- as expected, the  $C$  value is higher in the critical zone than in the whole channel.

After some manipulations over the expression (3), with the corresponding values of  $V_e$ ,  $V_o$  and  $C$ , the following results were obtained

	Over dredging (m)	Initial bottom level (m CD)	Infill volume after 39 months (m <sup>3</sup> )
Critical zone	1.00	-17	680 000
Outside the critical zone	0.5	-16.5	300 000

A final conclusion could be drawn: the artificial channel, with a nominal bottom level of (-16 mCD), will require a maintenance dredging of the order of one million cubic meters every three years.

### 3 - THE TAGUS ESTUARY ENTRANCE. HYDROMORPHOLOGICAL ANALYSIS

#### 3.1 - Past Evolution

The most important event in this century of the Tagus entrance morphological evolution has been the opening, some 50 years ago, of a secondary bar named the Golada over the "Banco do Bugio" - Figure 2. Despite the fact that some people charge the borrow dredgings in the Bugio with being the cause of that event, the analysis of old hydrographic surveys shows that the Golada has passed through narrowing and widening phases in the last 140 years.

If we characterise the amount of closing of this secondary bar looking at the total area over the "Banco do Bugio" above CD level, Figure 5 shows that over the last 140 years the situation has been more of instability than of equilibrium. As a matter of fact, during the last few years an important shoal has been growing in the middle of this secondary bar above low water level.

In the Golada flood currents and waves largely prevail over the ebb currents in what concerns sand transport capacity. As a consequence, a volume of sand of  $36 \cdot 10^6$  m<sup>3</sup> has been accumulating over the northern slope of the "Banco do Bugio" since 1939, forcing it to advance northwardly some 700 m - Figure 6. In the meantime, the estuary main channel was narrowed and its tidal current pattern was changed. Accumulation rates in (m<sup>3</sup>/year) are shown in Figure 6.

The accumulation process has been the result of two opposite actions: the "bringing in" action of flood currents and waves entering through the Golada, and the "flushing out" action of ebb currents in the main entrance channel, more or less parallel to the northern slope of the shoal, "sweeping" the sands downstream in the direction of the main outer bar. So, the sand transport rate through the Golada can be seen as the sum of two parcels: the shoal accreting rate and the ebb flushing rate over the same shoal.

We can assume that the latter equals the rate of erosion of the shoal northern slope registered in the 1929/39 period, when the Golada was almost closed

Figure 5 - Morphological Evolution of the Estuary Entrance. Characterization by means of three parameters

DATE	V (10 <sup>6</sup> m <sup>3</sup> )	Δ V (10 <sup>6</sup> m <sup>3</sup> )	r (10 <sup>6</sup> m <sup>3</sup> /Year)
1929	124,5		
1939	117,5	-7,0	-700
1954	118,7	+1,2	+80
1970	142,0	+23,3	+1450
1980	149,5	+7,5	+750
1985	153,3	+3,8	+760

Figure 6 - Northern Slope of the Bugio Bank. Evolution after 1929

(700 000 m<sup>3</sup>/y) - Figure 6 . Some impressive results are then obtained: the sand inward transport rate through the Golada was at least of the order of  $2.2 \cdot 10^6$  m<sup>3</sup>/y in the 1954/70 period and, during the most recent times (1980/85), has been still of the order of  $1.5 \cdot 10^6$  m<sup>3</sup>/y.

Over the same period (1929/1985) the tip of the "Cachopo Norte" (northern shoal of the outer bar - Figure 2) advanced 800 m in a direction almost perpendicular to the navigation channel - Figure 7. It seems that, if there had been no dredgings, the bathimetric (-10), which we considered the best one to characterize the position of that shoal, would have already overpassed the axis of the navigation channel to the south.

In Figure 7 the advancing rates of the "Cachopo Norte" are presented. It is worth mentioning the value of 22.5 m/y during the 1954/70 period. In this period the accreting rate in the "Banco do Bugio" northern slope was the highest.

### 3. 2 - Interpretation

If an entrance outer bar is in a stable morphological condition, this means that a dynamic equilibrium exists everywhere between the opposite actions (transport capacities) of flood currents and waves, on the one hand, and ebb currents, on the other hand.

Assuming that the wave climate has not changed in the last few decades, the advance of the "Cachopo do Norte" is most likely related to the weakening of ebb currents. Indeed, a part of the tidal prism started to flow through the Golada after its opening, and no longer through the main channel. The contribution of the Golada to this flow has been changing with time; according to physical model results, it would have been of the order of 8% and 12% for the ebb and for the flood mean spring tidal prism, respectively, in a morphological situation similar to the one registered in 1985.

Indeed, a fairly good correlation was verified between the opening of the Golada (wet area of the cross section) and the rate of advance of the "Cabeça do Pato" (Duck Head, as it is known the tip of the "Cachopo do Norte"). In Figure 5 the curve ACD (area above CD level) characterizes the degree of closing of the Golada; the smaller ACD, the greater the opening of this secondary bar. If we consider a sudden opening of the Golada, the resulting physiographical desequilibrium over the main outer bar area will determine the shoreward advance of the "Duck Head" at a rate that will be "proportional" to the importance of that desequilibrium, that is to say, to the degree of opening of the Golada. So, in Figure 5 the curve ACD(t) must be compared not with the curve s(t) - s is the distance of the "Duck Head" to the channel axis - but with its derivative.

On the other hand, the critical infill rate zone of the artificial channel is located just in front of the "Duck Head"; as a result of its continuous advancing, the channel infill rate will be aggravating. So, in order to reduce the maintenance dredging effort in the future artificial channel, a decision to close the Golada using a sand dike was made by the port authority (APL). This dike should be built with dredged material from the artificial channel.

It should be stressed that the closing of the Golada would afford some other "secondary" advantages, namely the sheltering of the lower reach of the estuary against the wave energy entering through this secondary bar.

### 3. 3 - Physical and Mathematical Modelling

In order to assess the general "functioning" of the Tagus estuary entrance, a study program was initially set up in which a vertically integrated 2D finite element model of the lower reach of the estuary (including a near-field ocean zone) would be used in connection with a physical model. Mathematical and physical model would be matched at the Lisbon bridge cross-section, that is to say, upstream boundary conditions of the mathematical model would be obtained from the physical model.

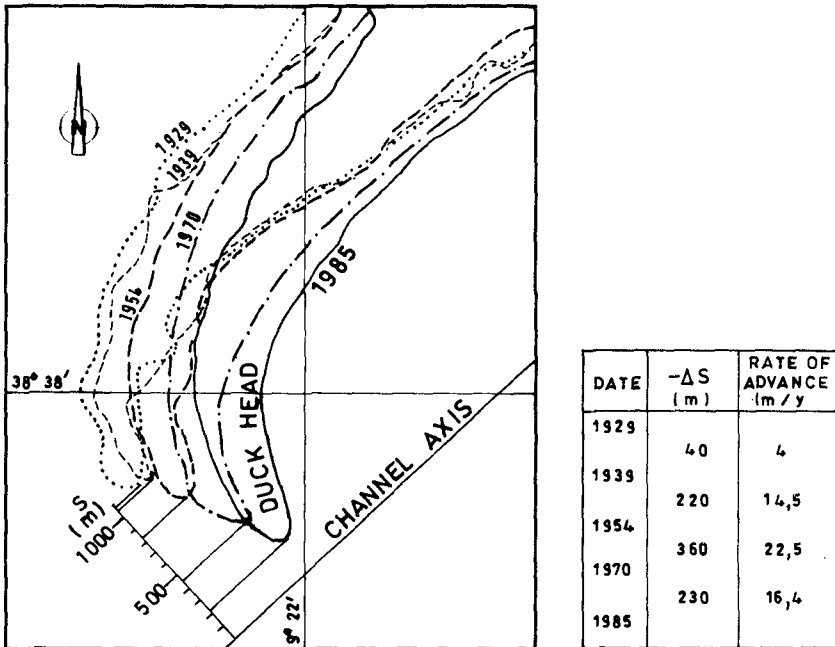

Figure 7 - Advance of the "Duck Head" after 1929

Due to operational reasons the use of the existing physical model had to be abandoned for that purpose, and the initial plan had to be changed: the 2D finite element model was then extended to the whole estuary. However, a strong schematization of the upper estuary region was made. Even so, levels and currents were correctly reproduced in the Lisbon bridge cross-section; velocities and levels were recorded in nature during several tidal cycles.

Three main situations were simulated: the present (reference) situation; the situation immediately after the closing of the Golada; the situation in the long run after the closing. In this third case it was admitted that, after the closing, the northern slope of the "Banco do Bugio" will recede naturally or/and artificially, to its position in the forties, that is to say, some hundred meters to the south. The artificial navigation channel through the outer bar was not considered; in fact, it was assumed that the influence in the hydrodynamics would only be felt locally.

Hourly velocity fields for two tidal periods and tide level curves in some reference stations were obtained, as well as residual currents in some restricted areas. Assuming as a first approximation that the bed load transport capacity depends on  $V^3$  ( $V$  - depth mean velocity), integral values of  $V^3$  were also obtained for the ebb and for the flood tidal periods in some grid points over the outer bar.

Some important results are:

- a - over the outer bar ebb currents significantly prevail over flood currents, as it could be expected;
- b - the predominance of ebb over flood currents will increase as an immediate consequence of the closing of the Golada;
- c - that predominance will increase even more in the long term with the

natural or artificial receding of the shoal accumulated in the northern slope of the Bugio;

d - with the closing of the Golada, the estuary global tidal prism will increase slightly (3%).

The last result is rather unexpected; indeed, how can the parcial closing of the estuary entrance improve its tidal prism?

The most likely explanation lays on the enhancement of the resonant effect within the estuary, which is responsible for a tidal range inside the estuary greater than in the outside. In fact, the estuary can be hydrodynamically interpreted as a great tidal basin connected to the ocean by a relatively straight and narrow channel - Figure 1. The closing sand dike of the Golada will make this channel somewhat longer; as a consequence, the estuary natural period will increase (Baines, 1957), becoming closer to the tidal forcing one (M2) and so intensifying the existing resonant phenomenon.

The results b) and c) mentioned above mean that the tendency of the "Duck Head" to advance in the direction of the artificial channel will be reversed if the Golada is closed. So a decision was taken to close it.

#### 4 - THE "CHANNEL DREDGING AND CLOSING OF THE GOLADA" PROJECT

The dredging of an artificial channel with the geometric characteristics presented in Chap. 2 (length: 4km; width: 300m; bottom level: -16.5 and -17m CD; slopes: 1/ 20) will produce a volume of sand of  $3.5 \cdot 10^6 \text{ m}^3$ . This sand would be used either in the building of a closing sand dike of the Golada or in the nourishment of the Caparica beaches, just to the south of the estuary entrance - Figure 8.

In order to adjust the sand dike to the present morphology of the Bugio bank, it would have a somehow sinuous outline. The total sand volume would amount to  $4.5 \cdot 10^6 \text{ m}^3$  of which approximately  $1.0 \cdot 10^6 \text{ m}^3$  would be deposited around the Bugio lighthouse. The Bugio bank itself would be the borrow area for this building sand or, alternatively, the sand removed from the artificial channel would be used for the same purpose.

The sand volumes resulting from future maintenance dredgings of the artificial channel would be deposited on the seaward (westward) tip of this dike, that is to say, around the Bugio lighthouse in order to compensate for the sand losses due to currents and wave erosion. In the long term the south face of this closing dike would evolve to a continuous sand beach from the Bugio lighthouse to Caparica, resembling the morphological situation of some decades ago when the Golada was almost closed naturally.

#### 5 - ENVIRONMENTAL ASSESSMENT

In the final stage of the studies an Environmental Impact Study was made. Environmental authorities raised a lot of questions. Even the influence of the artificial channel through the outer bar over the estuary hydrodynamics had to be analysed to conclude, as expected, that it will have no practical effect. A lot of additional analysis were performed, namely:

- hourly fields of  $V = V1 - V2$  in all the entrance area (velocity differences after (Af) minus before (Bf), after being in the short term (Af1) and in the long term (Af2); Af1 - immediately after the closing; Af2 - after the receding of the northern slope of the Bugio bank to the 1939 position)
- residual values ( $V_r$ ) of the velocity vector  $V$  (Bf, Af1, Af2)

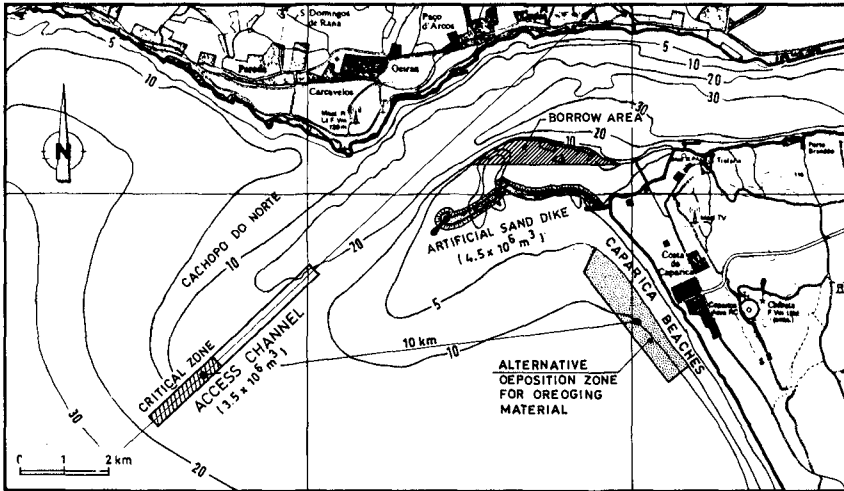

Figure 8 - The "Channel Dredging and Closing of the Golada" Project

- differences of  $V_r$  (Af1 - Bf; Af2 - Bf)
- hourly fields of  $V^3$  (Bf, Af1, Af2)
- residual values ( $V_r3$ ) of  $V^3$  (Bf, Af1, Af2)
- lagrangean simulation of the dispersion of particles emitted every 20 min in three points of the estuary lower reach (Bf, Af1, Af2).

Very recently the dredging of the channel has been approved. On the contrary, the closing dike of the Golada was rejected on the basis that its beneficial effects on the natural maintenance conditions of the artificial channel were not clearly demonstrated.

## CHAPTER 211

### A MIXING MECHANISM IN THE NEARSHORE REGION

Uday Putrevu, Associate Member, ASCE and Ib A. Svendsen,<sup>1</sup> Member, ASCE.

#### ABSTRACT

A dispersive mixing caused by the interaction of the longshore currents and the undertow is found to exist in the nearshore region. It is found to depend critically on the depth variation of both the cross-shore and the longshore currents. The effect is calculated for the simplest possible current profiles which yield a non-zero contribution. It is demonstrated that the dispersive mixing totally dominates the mixing in the nearshore region, exceeding the effect of turbulence by an order of magnitude even inside the surf-zone. In consequence, accounting for this interaction of the nearshore currents makes it possible to model longshore currents using realistic turbulent mixing levels. The vertical variation of those currents become part of the results provided. The predicted depth variation of the longshore currents is shown to be consistent with the only set of such measurements presently available.

#### 1. INTRODUCTION

Longshore currents on beaches have been analyzed using the concept of radiation stress since the pioneering works of Bowen (1969), Thornton (1970) and Longuet-Higgins (1970). These works clearly demonstrated that a lateral mixing (presumably due to turbulent fluctuations) needs to be included to give predictions of the cross-shore structure of the longshore currents that resemble measured currents in laboratory and field experiments. The works cited above, and the numerous models proposed later, differ primarily in the assumptions related to the lateral mixing due to turbulence.

---

<sup>1</sup>Postdoctoral Fellow and Professor, respectively, Center for Applied Coastal Research, Department of Civil Engineering, University of Delaware, Newark, DE 19716, USA

Models to predict vertical structure of nearshore currents have been proposed by Svendsen (1984), Dally & Dean (1984), Stive & Wind (1986), Svendsen *et al.* (1987) and Svendsen & Hansen (1988) for the cross-shore current (the undertow) and by Svendsen & Lorenz (1989) for the three dimensional current structure.

Svendsen & Putrevu (1990) developed the principles for 3D nearshore circulation modelling using analytical solutions for the 3D current profiles in combination with a numerical solution of the depth integrated 2D horizontal equations. Like Svendsen & Lorenz (1989), however, they neglected the current-current and the wave-current interaction terms. They pointed out that there is an order of magnitude difference between the eddy viscosity required to model accurately the vertical profiles and the eddy viscosity required for lateral mixing to achieve realistic results for the longshore current on a long, straight coast. This contradicts all physical arguments which point to the two being the same order of magnitude.

Svendsen & Putrevu (1992; hereafter referred to as SP92) found that the current-current and wave-current interactions neglected in previous investigations provide the additional lateral mixing. The effect involves the vertical structure of both cross- and longshore currents and turns out to be a generalization of the mechanism for longitudinal dispersion found by Taylor (1954) for pipe flow, Elder (1959) for open channel flow and Fischer (1978) for currents on the continental shelf. It is found to exist even on a long, straight coast with no alongshore variations.

In the present paper we present an analysis of this effect under the simplest possible conditions in order to illustrate the core of the mechanisms involved. It is shown that the dispersion effect is crucially linked to the overall slope of the longshore current profile. It disappears completely for a depth uniform longshore current.

The paper is organized as follows: Section 2 deals with the basic equations and outlines the assumptions involved. Section 3 discusses the dispersion caused under the vertical structure of the currents assumed here. A numerical example is presented in section 4. In section 5 we give a qualitative interpretation of the what we believe to be the essential nature of the dispersion mechanism. The paper concludes with a summary and an discussion of the important results of the paper in section 6.

## 2. BASIC EQUATIONS FOR A LONG STRAIGHT COAST

SP92 derived the basic equations governing the wave averaged nearshore circulation. For a long, straight coast with no alongshore variation these equations are

Depth Integrated continuity

$$\frac{d}{dx} \left[ \int_{-h_0}^{\bar{\zeta}} U dz + Q_w \right] = 0 \quad (1)$$

Depth Integrated Cross-Shore Momentum Equation

$$\frac{1}{\rho} \frac{dS_{xx}}{dx} = -g(h_0 + \bar{\zeta}) \frac{d\bar{\zeta}}{dx} \quad (2)$$

Depth Integrated Alongshore Momentum Equation

$$\frac{1}{\rho} \left[ \frac{d}{dx} (S_{xy} + S'_{xy}) + \tau_{by} \right] + \frac{d}{dx} \left[ \int_{-h_0}^{\bar{\zeta}} UV dz + \overline{\int_{\zeta_t}^{\zeta} (u_w V + v_w U) dz} \right] = 0 \quad (3)$$

In the above  $u_w$  and  $v_w$  are the wave induced velocities in the  $x$  (cross-shore) and  $y$  (alongshore) directions respectively.

These equations differ from the equations found in Phillips (1977) or Mei (1983) in that they allow for the currents to have a vertical variation. Dealing with wave averaged equations, one has to clearly define what is meant by a "current" above wave trough level where there is water only part of the time. When evaluating the terms in these equations, we assume that the mathematical expression defining the currents below trough level is valid above that level also. Such an assumption is implicitly made by Phillips (1977) and Mei (1983). For the case of depth uniform currents, the equations above reduce to the equations found in Phillips and differ slightly from those found in Mei (1983) owing to a difference in the definition of the current velocity.

In (1) - (3) the wave averaged quantities  $Q_w$  (volume flux),  $S_{xx}$  and  $S_{xy}$  (radiation stress components) are defined as

$$Q_w = \overline{\int_{-h_0}^{\zeta} u_w dz} = \overline{\int_{\zeta_t}^{\zeta} u_w dz} \quad (4)$$

$$S_{xx} = \overline{\int_{-h_0}^{\zeta} (\rho u_w^2 + p) dz} - \frac{1}{2} \rho g h^2 \quad (5)$$

$$S_{xy} = \overline{\int_{-h_0}^{\zeta} \rho u_w v_w dz} \quad (6)$$

Figure 1 shows the definitions of the geometrical parameters.  $S'_{xy}$  represents the turbulent radiation stress (depth integrated Reynolds' stress) and is defined by

$$S'_{xy} = \overline{\int_{-h_0}^{\zeta} \tau_{xy} dz} \quad (7)$$

where  $\tau_{xy}$  represents the Reynolds' stress.

Figure 1: Definition sketch

Using a perturbation expansion based on slowly varying depth SP92 showed that at the lowest order the following equations govern the vertical variation of the cross- and alongshore currents

#### Depth Dependent Cross-Shore Momentum

$$\frac{\partial}{\partial z} \left( \nu_{tz} \frac{\partial U}{\partial z} \right) = g \frac{d\bar{\zeta}}{dx} + \overline{u_w \frac{\partial v_w}{\partial x}} \quad (8)$$

#### Depth Dependent Alongshore Momentum

$$\frac{\partial}{\partial z} \left( \nu_{tz} \frac{\partial V}{\partial z} \right) = \overline{u_w \frac{\partial v_w}{\partial x}} + U \frac{dV_b}{dx} \quad (9)$$

Of particular importance here is the last term in (9) which represents the lowest approximation to the current-current interaction.

SP92 solve these equations for arbitrary  $\nu_{tz}$  and  $u_w, v_w$  distributions.

### 3. SOLUTION FOR DEPTH UNIFORM UNDERTOW

In the present paper we analyze the effect of the interaction terms in (3) for the simple situation where the undertow is constant over depth and the longshore current is quadratic. The longshore current profile corresponds to assuming that  $\nu_{tz}$  and the wave induced velocities are depth uniform (cf. eq. 9). Hence, we assume the following

$$U(\xi) = U_0 = \frac{-Q_w}{h} \quad (10)$$

$$V(\xi) = V_b + b_v \xi + a_v \xi^2 \quad (11)$$

where  $\xi = z + h_0$  is the distance from the bed (see figure 1). While simplifying the analysis, this situation captures the essential nature of the interaction term and the simpler algebra helps exposing the mechanisms involved.

The parameters  $a_v$  and  $b_v$  are then given by

$$a_v = \frac{1}{2\nu_{tz}} \left( u_w \frac{\partial v_w}{\partial x} + U \frac{\partial V_b}{\partial x} \right) \tag{12}$$

as indicated by (9) and

$$b_v = \frac{f_w u_0}{\pi \nu_{tz}} V_b \tag{13}$$

where  $u_0$  is the amplitude of the near bottom wave induced velocity. The equation for  $b_v$  is derived from the bottom boundary condition

$$\rho \nu_{tz} \frac{\partial V}{\partial z} \Big|_{z=-h_0} = \tau_{by} = \frac{\rho f_w u_0 V_b}{\pi} \tag{14}$$

(see Svendsen & Putrevu 1990).

Using (10) and (11) we find that

$$\int_{-h_0}^{\bar{\zeta}} UV dz = -Q_w \left( V_b + \frac{b_v h}{2} + \frac{a_v h^2}{3} \right) \tag{15}$$

and

$$\overline{\int_{\zeta_t}^{\bar{\zeta}} V u_w dz} \approx V(\bar{\zeta}) \overline{\int_{\zeta_t}^{\bar{\zeta}} u_w dz} = Q_w (V_b + b_v h + a_v h^2) \tag{16}$$

The  $Uv_w$  term in (3) is small for small angles of incidence which is the typical situation on long, straight coasts. Hence, this term is neglected in the following.

Equations 15 and 16 clearly show that the terms representing the interaction of the currents oppose one another and for the case of a depth uniform longshore current ( $a_v = b_v = 0$ ) they exactly cancel one another. In total (15) and (16) give

$$\int_{-h_0}^{\bar{\zeta}} UV dz + \overline{\int_{\zeta_t}^{\bar{\zeta}} V u_w dz} = \frac{Q_w h^2 \overline{u_w \partial v_w / \partial x}}{3\nu_{tz}} + \frac{Q_w f_w u_0 h}{2\pi \nu_{tz}} V_b - \frac{Q_w^2 h}{3\nu_{tz}} \frac{dV_b}{dx} \tag{17}$$

Substituting (17) into (3) then leads to

$$\frac{1}{\rho} \frac{d}{dx} (S_{xy} + S'_{xy}) + \frac{\tau_{by}}{\rho} + \frac{d}{dx} \left( \frac{Q_w h^2 \overline{u_w \partial v_w / \partial x}}{3\nu_{tz}} + \frac{Q_w f_w u_0 h}{2\pi \nu_{tz}} V_b - \frac{Q_w^2 h}{3\nu_{tz}} \frac{dV_b}{dx} \right) = 0 \tag{18}$$

The solution of (18) requires the specification of the way in which we parameterize the turbulent radiation stress  $S'_{xy}$  (the bottom stress  $\tau_{by}$  is given by equation 14). For the turbulent radiation stress we use

$$S'_{xy} = \rho h \nu_{tz} \frac{dV_b}{dx} \tag{19}$$

SP92 show that using  $V_b$  in (19) instead of the mean velocity  $V_m$  is consistent to the order of validity of (3). The calculation of  $V_b$  using (18) still requires the specification of  $Q_w$  and  $S_{xy}$ . These are related to the wave motion and are assumed to be known in wave averaged models.

Introducing the definitions

$$D_c = \frac{Q_w^2}{3\nu_{tz}} \quad (20)$$

$$F_1 = \frac{\alpha_y h^2 Q_w}{3\nu_{tz}} \quad (21)$$

$$F_2 = \frac{f_w Q_w u_0 h}{2\pi\nu_{tz}} \quad (22)$$

we may rewrite the equation governing the longshore current in this simplified situation as

$$\frac{d}{dx} \left\{ h (\nu_{tz} + D_c) \frac{dV_b}{dx} \right\} - \frac{d}{dx} (F_2 V_b) - \frac{f_w u_0}{\pi} V_b = \frac{1}{\rho} \frac{dS_{xy}}{dx} + \frac{dF_1}{dx} \quad (23)$$

which clearly demonstrates that the interaction provides mixing - this can be seen from the  $D_c$  term of (23). In addition to the dispersion effect the interaction also produces other effects that are reflected in the  $F_1$  and  $F_2$  terms. The general results for  $D_c$ ,  $F_1$  and  $F_2$  were given by SP92.

#### Discussion of the dispersion effect

Before we proceed any further it is worthwhile to discuss the nature of the dispersion at this stage. We first notice from (20) that the dispersion coefficient  $D_c$  is proportional to the square of the volume flux due to the waves and inversely proportional to the vertical eddy viscosity. This result is analogous to the longitudinal dispersion in pipe flow found by Taylor (1954). The dispersion coefficient  $K$  is given by an expression of the form (see, *e.g.*, Fischer *et al.* 1979, p. 94)

$$K = \frac{d^2 \langle u_d^2 \rangle}{\langle \nu_{tz} \rangle} I \quad (24)$$

where  $d$  is a characteristic length,  $u_d$  is the deviation of the velocity from its cross-sectional average,  $\langle \nu_{tz} \rangle$  is the cross-sectionally averaged mixing coefficient and  $I$  is a dimensionless integral of order 0.1. The angular brackets in (24) represent cross-sectional averaging.

Here  $u_d$ ,  $d$  and  $\langle \nu_{tz} \rangle$  are analogous to our  $U_0$ ,  $h$  and  $\nu_{tz}$  and (20) is analogous to (24). In the present case the contributions to the dispersion also come from the fact that the waves and the fact that the currents are modified by the dispersion which is not the case in simple dispersion of contaminants analyzed by Taylor and others.

We may get a preliminary estimate of the size of the dispersion coefficient relative to  $\nu_{tz}$  by noticing that we typically have (inside the surf-zone)

$$Q_w \sim 0.1 \frac{H^2}{h} \sqrt{gh} \quad (25)$$

$$\frac{H}{h} \sim 0.7 \quad (26)$$

and

$$\nu_{tx} \sim \nu_{tz} \sim 0.01h\sqrt{gh} \quad (27)$$

(see, e.g., Svendsen *et al.* 1987). These estimates imply that

$$D_c \sim 0.08h\sqrt{gh} \quad (28)$$

Comparison of (28) and (27) indicates that with these simplifying assumptions the dispersive effect is about eight times stronger than the lateral mixing. The more detailed calculations of SP92 show that accounting for the actual vertical structure of the undertow enhances this effect approximately by a factor of two. Thus, we see that  $D_c \gg \nu_{tz}$  and we can expect the mixing for the longshore current is dominated by the dispersion.

#### 4. A NUMERICAL EXAMPLE

The numerical example presented below will demonstrate the conclusion of the previous paragraph. In the calculations we have used some simplifying assumptions which do not change the nature of the problem (though they do influence the accuracy of the predictions). These assumptions are:

- Use linear long wave theory to calculate  $S_{xy}$  and  $\alpha_y$ .
- Use  $H \propto h$  inside the surf-zone and  $H \propto h^{-1/4}$  outside the surf-zone.
- Use  $Q_w = 0.1(H^2/h)\sqrt{gh}$ .

The eddy viscosity variation used is given by

$$\nu_{tx} = \nu_{tz} = \begin{cases} 0.01h\sqrt{gh} & \text{inside surf zone} \\ [0.8(h/h_b)^4 + 0.2]\nu_{tb} & \text{outside surf zone} \end{cases} \quad (29)$$

where  $\nu_{tb} = 0.01h_b\sqrt{gh_b}$ . The variation of the eddy viscosity outside the surf-zone represents an estimate based on the assumption that  $\nu_t \propto l\sqrt{k}$  and the measurements of Nadaoka & Kondoh (1982) of the turbulence outside the surf-zone. These measurements show that while the intensity of the turbulence decays seaward of the break point, there is still some residual turbulence even far seaward of the break point (see their figure 9).

Figure 2: Variation of  $\nu_{tx}$  and  $D_c$

Equation 18 is then solved with boundary conditions  $V_b = 0$  at the shoreline and  $V_b \rightarrow 0$  as  $h/h_b \rightarrow \infty$ . Since the RHS of (18) is discontinuous at the breaker point, the solution has to be matched at that point. The matching conditions used are

$$V_b(x_{b+}) = V_b(x_{b-}) \quad (30)$$

$$\left. \frac{\partial V}{\partial x} \right|_{x_{b+}} = \left. \frac{\partial V}{\partial x} \right|_{x_{b-}} \quad (31)$$

where  $x_b$  represents the breaker location.

Figure 2 shows the variations of the dispersion coefficient and the eddy viscosity with cross-shore location. As mentioned earlier, over the entire nearshore region the dispersion coefficient is significantly larger than the eddy viscosity showing that the dispersion due to current-current interaction totally dominates the nearshore mixing.

The resulting cross-shore distribution of the near bottom longshore current is shown in Figure 3. This figure also shows the solution obtained by neglecting the dispersive mixing. A comparison of the two solutions demonstrates, as expected from the enhanced mixing due to current-current interaction, that the dispersion has significant influence on the cross-shore structure of the longshore current. Specifically, we see that accounting for the current dispersion does bring the

Figure 3: Cross-shore distribution of the near bottom longshore current

cross-shore distribution in line with what the measurements indicate without having to take recourse to a large mixing coefficient (see, *e.g.*, Visser 1984).

Once  $V_b$  is calculated, we may calculate the longshore current profiles using (11) and (13). The profiles so calculated are shown in figure 4. We first notice that the individual longshore current profiles do not show very strong variation with vertical location. This means that the cross-shore distribution of the near bottom longshore current shown in figure 3 is representative of all vertical locations. Second, we notice that the longshore current increases with distance from the bed in the region  $0 < h/h_b < 0.7$  while it decreases with distance from the bed in the region  $h/h_b > 0.7$ . As demonstrated in the next section, this turns out to be the essential feature that is responsible for the dispersion.

The only experimental investigation that reports systematic measurements of the vertical structure of longshore currents is Visser (1984) for a long, straight beach. These measurements consistently confirm the pattern predicted above. As an example, we reproduce in figure 5 one set of Visser's measurements (experiment 2). The measurements clearly show a longshore current increasing with distance from the bed inside the surf-zone (the first four panels) and decreasing with distance from the bed outside (last four panels). Considering the crucial dependence of the dispersion on this trend we believe that the experimental confirmation of the trend predicted by the computations is extremely encouraging.

Figure 4: Computed vertical variation of the longshore current

5. QUALITATIVE INTERPRETATION OF THE DISPERSION MECHANISM

Equation 17 shows that the dispersion coefficient,  $D_z$ , originates from the  $U\partial V/\partial x$  term in the forcing for the depth variation for the longshore currents. Since this term contributes to the curvature of the longshore current which, in turn, contributes to the overall slope of the longshore current profile it suggests that it is the overall slope of the longshore current that controls the dispersion. This is discussed further below.

As remarked in the discussion below (16) the contributions from below and above trough levels counteract one another. The overall effect depends on which of the two is stronger. We see that (15) and (16) may be written as

$$\int_{-h_0}^{\bar{\zeta}} UV dz = -Q_w \left( \frac{1}{h} \int_{-h_0}^{\bar{\zeta}} V(z) dz \right) \tag{32}$$

and

$$\int_{\bar{\zeta}}^{\zeta} V u_w dz = Q_w V(\bar{\zeta}) \tag{33}$$

Thus for the undertow variation used here the contribution from above trough level will dominate if

$$V(\bar{\zeta}) > \frac{1}{h} \int_{-h_0}^{\bar{\zeta}} V(z) dz \tag{34}$$

This corresponds to a longshore current that increases with distance from the bottom (figure 6a) which, as figure 4 shows, occurs for  $h/h_b < 0.7$  in the ex-

Figure 5: Measured vertical variation of the longshore current (from Visser 1984)

Figure 6: Sketch of the vertical variation of the longshore current  
 a)  $V(\bar{z}) > \frac{1}{h} \int_{-h_0}^{\bar{z}} V(z) dz$       b)  $V(\bar{z}) < \frac{1}{h} \int_{-h_0}^{\bar{z}} V(z) dz$

ample considered. Hence, in this region the net effect of the interaction is to convect the longshore current momentum shorewards and depending on the sign of  $\partial V/\partial x$  this may increase or decrease the local value of  $V$ . Though the shoreward transport of the longshore momentum is at the surface with a smaller seaward transport below, the profile is maintained by the driving force and the vertical mixing. Conversely, in the region  $h/h_b > 0.7$  (in the present example) the situation is reversed. In particular, outside the surf-zone this represents the major source of longshore momentum flux in the seaward direction which is equivalent to mixing.

Hence, although the cross-shore transport of the longshore momentum (equivalent to dispersion or mixing) is provided by cross-shore currents, the net effect depends crucially on the vertical variation of the longshore currents. This is also consistent with the fact that for depth uniform longshore currents we get no dispersion effects.

## 6. SUMMARY AND CONCLUSIONS

It has been demonstrated that the dispersive mixing caused by the interaction of the longshore currents and the undertow totally dominates the mixing in the nearshore region. Even inside the surf-zone it is an order of magnitude stronger than the direct turbulent mixing. In the example given in section 4, the effect was calculated for the simplest possible case which leads to a non-zero value, *viz.*, a depth uniform undertow and a longshore current that varies quadratically with

the vertical coordinate. It turns out that even though the example considered here underestimates the dispersive effect substantially in comparison to the more complete version of the theory given in SP92, it captures the essential nature of the dispersion mechanism and allows us to demonstrate the same in a rather simple manner.

The results show that the nearshore circulation on a beach is essentially a 3D phenomenon with the dispersion caused by the nonlinear interaction of the nearshore currents being a very important contribution. It depends crucially on the vertical profiles of the current, in particular in the longshore direction. While the turbulence contributes very little to the lateral mixing directly it is still very important because the turbulence has a strong influence on the shape of the current profiles.

The existing laboratory measurements support our predictions of the vertical structure of the currents which forms a part of the results. This is very encouraging considering the crucial dependence of the effect on the current profiles. More confirmation of the predictions, both in the laboratory and the field, would be particularly useful.

## CHAPTER 212

### Formation and Reduction Processes of River Deltas ; Theory and Experiments

Hossam El-din A.A. Refaat<sup>1</sup> and Yoshito Tsuchiya<sup>2</sup>, M.ASCE

#### Abstract

Beach erosion has recently been recognized as accelerating due to change in sediment sources from rivers. This can be considered as reduction processes of river deltas. In this paper, the formation and reduction processes of river deltas are first investigated theoretically by introducing the non-uniformity of longshore sediment transport into the equation of continuity of shoreline changes. Theoretical solutions to shoreline changes in the formation and reduction processes are well explained. Secondly, experiments both on the formation and reduction processes were carried out. The theoretical results of the processes compared favorably with the experimental ones.

#### 1. Introduction

Delta resulted from the relative importance of deposition of river sediments which build the delta seaward, versus the action of waves and currents which transport the sediments and erode the delta. If the rate of sediment deposition from the river is greater than the rate of sediment removal by the longshore currents, the formation process of river delta will take place. On the contrary, if the rate of sediment deposition from the river is less than the rate of sediment removal by the longshore currents, beach erosion occurs resulting in the reduction of river delta. Historically, the term *delta* was first applied by the Greek historian Herodotus, circa 450 B.C., to the triangular alluvial deposit at mouth of the Nile River.

The processes of formation and reduction of river deltas have been investigated through the study of analytical solutions of the so-called one-line theory. The one-line theory was first introduced by Pelnard-Considére (1956), and it has been demonstrated to be adequate in practical applications. Several authors have presented analytical solutions for the one-line theory (e.g. Bakker and Edelman, 1964; Iwagaki, 1966; Tsuchiya, 1973, 1978; Tsuchiya and Yasuda, 1979; Kraus, Hanson and Harikai, 1985; and recently Hanson and Larson, 1987). The fundamental assumption of this theory is that the bottom profile moves in parallel to itself without changing shape. The second major assumption of the theory is that the longshore sediment transport takes place averaging over the beach profile down to a certain offshore limiting depth of the sediment drift zone.

2. Theory of Formation and Reduction Processes of River Deltas

In the formation and reduction processes of river deltas, the non-uniformity of longshore sediment transport along the shoreline must be introduced. Tsuchiya and Refaat (1992) recently developed theoretical approaches to the longshore sediment transport in the non-uniform condition. Introducing this theoretical formulation of the total rate of non-uniform longshore sediment transport, a set of the governing equations of shoreline change is proposed.

2.1 The governing equations and the field equations of delta formation process

The equations governing the formation and reduction processes of river deltas are composed of the equations of continuity of shoreline change and total rate of longshore sediment transport. Taking the coordinate system as shown in Fig. 1, the equation of continuity of shoreline change is expressed as (Tsuchiya ; 1978) :

$$\frac{\partial y_0}{\partial t} + \frac{1}{(1-\lambda)h_k} \frac{\partial Q_x}{\partial x} = \frac{1}{B h_k} Q_R(t) \delta(x-x_0) \tag{1}$$

in which  $y_0$  is the shoreline position from the datum line,  $x$  is the longshore distance from the origin,  $t$  is the time,  $\lambda$  is the porosity of beach sediment,  $h_k$  is the limited water depth of littoral drift,  $B$  is the river width,  $Q_x$  is the total rate of longshore sediment transport, and  $Q_R(t) \delta(x-x_0)$  is the sediment input effective to the shoreline change from a river located at  $x=x_0$  where  $\delta(x-x_0)$  is Dirac's delta function.

The phenomenon of longshore sediment transport around the river deltas are non-uniform owing to the non-uniform characteristics of waves and the effect of the boundary conditions of both longshore currents and beach changes on the longshore sediment transport. The equation of longshore sediment transport in the unsteady, nonuniform condition is given by Tsuchiya and Refaat (1992) as:

$$\frac{\partial Q_x}{\partial t} + \frac{\alpha_2}{\alpha_1 k} \frac{\partial}{\partial x} \left[ \frac{Q_x}{h_b} \right] = k f(x) - \frac{\alpha_3 \sqrt{g} \gamma C_f}{\alpha_1 \sqrt{h_b}} Q_x \tag{2}$$

where

$$f(x) = \frac{\gamma^2}{16} g h_b^2 \left\{ \sin 2\alpha_b - 2 \cos^2 \alpha_b \frac{\partial y_b}{\partial x} - (5\beta_1 - 6\beta_2 + 6\beta_3 \sin^2 \alpha_b) \frac{\partial h_b}{\partial x} - 2\beta_3 h_b \sin 2\alpha_b \frac{\partial \alpha_b}{\partial x} \right\} \tag{3}$$

where  $\alpha_b$  is the breaker angle which is defined as the angle between the wave crest and the shoreline,  $t$  is the time,  $g$  is the acceleration of gravity,  $y_b$  is the offshore distance of the breaking point from the shoreline,  $k$ ,  $\alpha_i$  and  $\beta_i$  ( $i = 1, 2, 3$ ), are the coefficients being nearly constants (Tsuchiya and Refaat, 1992).

In order to express the total rate of longshore sediment transport by a function of the breaker angle and breaker depth, and their derivatives, it can be expressed by Taylor series up to the first order as:

$$Q_x = Q_0 + \frac{\partial Q_x}{\partial \alpha_{b0}} (\alpha_b - \alpha_{b0}) + \frac{\partial Q_x}{\partial h_{b0}} (h_b - h_{b0}) + \dots \tag{4}$$

in which  $Q_0$  denotes the total rate of longshore sediment transport at the initial wave conditions presented by the subscript 0. Reference Fig. 1 the small changes in the breaker angle and depth can be expressed geometrically as:

$$\Delta \alpha_b = \alpha_b - \alpha_{b0} \approx - \frac{\partial y_0}{\partial x} \quad \text{and} \quad \Delta h_b = m \Delta y_0 \tag{5}$$

Substituting Eqs. (4) and (5) to Eq. (1) yields

$$\frac{\partial y_0}{\partial t} + \epsilon_1 \frac{\partial y_0}{\partial x} - \epsilon_2 \frac{\partial^2 y_0}{\partial x^2} = q_R(t) \delta(x - x_0) \tag{6}$$

where

$$\epsilon_1 = \frac{m}{(1 - \lambda) h_k} \left( \frac{\partial Q_x}{\partial h_b} \right)_{h_{b0}}, \quad \epsilon_2 = \frac{1}{(1 - \lambda) h_k} \left( \frac{\partial Q_x}{\partial \alpha_b} \right)_{\alpha_{b0}},$$

$$\text{and } q_R(t) = \frac{1}{B h_k} Q_R(t) \tag{7}$$

The coefficient  $\epsilon_2$  which has the dimensions of length squared over time, is interpreted as a diffusion coefficient. While the coefficient  $\epsilon_1$  having the dimension of length over time, is interpreted as the traveling speed of shoreline towards the longshore direction. In Eq. (7) it is clearly seen that the coefficient  $\epsilon_1$  is proportional to the beach slope. Thus, the coefficient  $\epsilon_1$  can not be ignored when the beach slope changes along the delta. By specifying initial and boundary conditions in the areas which represent conditions prevailing in a specific shoreline evolution, the analytical solutions are directly applicable.

2.2 Solution to shoreline changes in the formation process of river delta by normally incident waves

Since the river delta has an infinite length and waves are approached the shoreline normally, the coefficient  $\epsilon_1$  becomes very small and can be neglected. The general solution of river delta formation can be expressed from Eq. (6) (Carslaw and Jaeger, 1959) as:

$$y_0(x, t) = h_k q_{R0} \sqrt{\frac{t}{\epsilon_2}} \text{jerfc} \left( \frac{x - x_0}{2 \sqrt{\epsilon_2 t}} \right) \quad \text{for } t > 0 \text{ and } -\infty < x < \infty \tag{8}$$

where jerfc denotes the integral of the complementary error function erfc.

In Fig. 2 the solution to Eq. (8) is illustrated. The dimensionless sediment input used to normalize the shoreline position is expressed as:

$$\frac{h_k q_{R0}}{\epsilon_2} = \frac{q_{R0}}{\left( \frac{\partial Q_x}{\partial \alpha_b} \right)_{\alpha_{b0}}} \tag{9}$$

which can be interpreted as a ratio of the sediment input from the river to the derivative of longshore sediment transport rate with respect to the breaker angle.

2.3 Solution to shoreline change in the formation process of river delta by obliquely incident waves

When the waves approach the delta coast obliquely, the expected shape of the delta will be asymmetric. Consider the case where a river mouth has a finite width,  $2a$ , the continuity equation of sediment transport in the full form of Eq. (6) is applied as:

$$\frac{\partial y_{01}}{\partial t} = -\epsilon_1 \frac{\partial y_{01}}{\partial x} + \epsilon_2 \frac{\partial^2 y_{01}}{\partial x^2} + q_{R0} ; -a \leq x \leq a \tag{10}$$

and

$$\frac{\partial y_{02}}{\partial t} = -\epsilon_1 \frac{\partial y_{02}}{\partial x} + \epsilon_2 \frac{\partial^2 y_{02}}{\partial x^2} ; |x| > a \tag{11}$$

The problem consists of two coupled partial differential equations. By specifying the boundary conditions, which are the beach must be continuous at all times over the two zones and the shoreline is unaffected by the sediment input from the river as  $x$  approaches infinity. The solution to Eqs. (10) and (11) are then obtained as:

$$y_0(x, t) = \begin{cases} \exp\left[\frac{3\epsilon_1}{2\epsilon_2}x\right] F_1(x, t) ; & -\infty < x \leq -a \\ \exp\left[\frac{3\epsilon_1}{2\epsilon_2}x\right] F_2(x, t) ; & -a \leq x \leq 0 \\ \exp\left[-\frac{\epsilon_1}{2\epsilon_2}x\right] F_2(x, t) ; & 0 \leq x \leq a \\ \exp\left[-\frac{\epsilon_1}{2\epsilon_2}x\right] F_1(x, t) ; & a \leq x < \infty \end{cases} \tag{12}$$

where

$$F_1(x, t) = 2q_{R0}t \left\{ j^2 \operatorname{erfc}\left(\frac{x-a}{2\sqrt{\epsilon_2 t}}\right) - j^2 \operatorname{erfc}\left(\frac{x+a}{2\sqrt{\epsilon_2 t}}\right) + \frac{\epsilon_1 a}{\epsilon_2} j^3 \operatorname{erfc}\left(\frac{x-a}{2\sqrt{\epsilon_2 t}}\right) - \frac{\epsilon_1 a}{\epsilon_2} j^3 \operatorname{erfc}\left(\frac{x+a}{2\sqrt{\epsilon_2 t}}\right) \exp\left(-\frac{\epsilon_1}{\epsilon_2}a\right) \right\} \tag{13}$$

and

$$F_2(x, t) = q_{R0}t \left\{ 1 - 2j^2 \operatorname{erfc}\left(\frac{a-x}{2\sqrt{\epsilon_2 t}}\right) - 2j^2 \operatorname{erfc}\left(\frac{a+x}{2\sqrt{\epsilon_2 t}}\right) + \frac{2\epsilon_1 a}{\epsilon_2} j^3 \operatorname{erfc}\left(\frac{x-a}{2\sqrt{\epsilon_2 t}}\right) - \frac{2\epsilon_1 a}{\epsilon_2} j^3 \operatorname{erfc}\left(\frac{x+a}{2\sqrt{\epsilon_2 t}}\right) \exp\left(-\frac{\epsilon_1}{\epsilon_2}a\right) \right\} \tag{14}$$

Fig. 1. The coordinate system used in the formation.

Fig. 2. Shoreline evolution in the formation of river delta of infinite length.

Fig. 3. Shoreline evolution in the formation of river delta by obliquely incident waves

The function  $\text{ierfc}$  is the integral of the complementary error function and  $n$  exponent represents  $n$  time integrations of the complementary error function. The time evolution of river delta by Eq. (12) is illustrated in Fig. 3. It is well understood in this figure that the asymmetric plane shape of the delta is clearly formed by obliquely incident waves.

**2.4 Solution to shoreline changes in the reduction process of river delta**

The reduction process of river delta occurs due to decrease or lack of sediment deposit from the river. Generally, the basic equations describe the shoreline changes in reduction process of river delta are the same equations used to describe the shoreline changes in formation process of river delta except that the river sediment discharge is no longer considered. Therefore, the linear partial differential equation described the shoreline change is given as:

$$\frac{\partial y_0}{\partial t} + \epsilon_1 \frac{\partial y_0}{\partial x} - \epsilon_2 \frac{\partial^2 y_0}{\partial x^2} = 0 \tag{15}$$

By specifying the initial and boundary conditions in the areas which represent conditions prevailing in a specific shoreline evolution, the corresponding analytical solutions are directly applicable. In the following cases of reduction of river delta, the initial shoreline position will be determined with the aid of the formation process of river delta.

**(1) Reduction of river delta of infinite length by normal incident waves**

Since the river delta has an infinite length and waves are assumed to approach the shoreline normally, the coefficient  $\epsilon_1$  becomes very small and can be neglected. Also, the reduction process will take place symmetrically with respect to the center of the river delta. Thus, the solution to shoreline changes is obtained as:

$$y_0(x, t) = \frac{h_k q_R}{2 \epsilon_2 \sqrt{\pi}} \sqrt{\frac{A}{t}} \int_{-\infty}^{\infty} \text{ierfc} \left( \frac{x'}{2 \sqrt{\epsilon_2 A}} \right) \exp \left\{ -\frac{(x-x')^2}{4 \epsilon_2 t} \right\} dx' \tag{16}$$

In Fig. 4 the solution to Eq. (16) is illustrated. In this figure the reduction

Fig. 4. Time variation of shoreline change in the reduction process of river delta of infinite river length.

process of river delta is taking place symmetrically with respect to the center of the river. The rate of reduction of river delta at the center of the river is diminished with time, while the shoreline at the longshore ends of the river delta is replenished with time. The final stage for the configuration of the delta will become a straight beach.

(2) Asymmetric change of shoreline position of river delta

When the waves approach the coast of river delta obliquely, the shoreline change is expected to occur asymmetrically. Consider the case where the river mouth has a finite width,  $2a$ , the general solution to shoreline change is obtained as:

$$y_0(x, t) = z_0(x, t) \exp\left(\frac{\epsilon_1}{2\epsilon_2} x - \frac{\epsilon_1^2}{4\epsilon_2} t\right) \quad \text{for } t > 0 \text{ and } -\infty < x < \infty \quad (17)$$

where

$$z_0(x, t) = \frac{1}{2\sqrt{\pi\epsilon_2 t}} \left[ \int_{-\infty}^{-a} F_1(x') \exp\left\{-\frac{(x-x')^2}{4\epsilon_2 t} + \frac{\epsilon_1 x'}{\epsilon_2}\right\} dx' + \int_{-a}^0 F_2(x') \exp\left\{-\frac{(x-x')^2}{4\epsilon_2 t} + \frac{\epsilon_1 x'}{\epsilon_2}\right\} dx' + \int_0^a F_2(x') \exp\left\{-\frac{(x-x')^2}{4\epsilon_2 t} - \frac{\epsilon_1 x'}{\epsilon_2}\right\} dx' + \int_a^{\infty} F_1(x') \exp\left\{-\frac{(x-x')^2}{4\epsilon_2 t} - \frac{\epsilon_1 x'}{\epsilon_2}\right\} dx' \right] \quad (18)$$

In Fig. 5 the solution to Eq. (18) is illustrated. The asymmetric shape of the delta is clearly seen in this figure. Since the waves approach the shoreline obliquely, the longshore sediment is predominant. Consequently, most of the sediment moves in the predominant direction of littoral drift. As a result, the

Fig. 5. Time variation in shoreline change in the reduction process of river delta by obliquely incident waves in the case where  $\epsilon_1 a / \epsilon_2 = 0.2$ .

reduction rate of the shoreline on the upcoast side is greater than that on the downcoast. The final stage for the configuration of the delta may become an inclined straight beach which the waves tend to approach normally. Also, the river mouth moves predominantly in the direction of littoral drift, as the reduction process of river delta takes place.

### 3. Experiments on Formation and Reduction Processes of River Deltas

The main objectives of this experimental study are, to demonstrate the process of formation and reduction of river deltas, to determine the changes of beach profile along the shoreline of river delta, and finally to study the effect of oblique wave incident on the symmetrical configuration of the river delta, and on the formation and reduction processes of river deltas.

#### 3.1 Experiments on Formation Process of River Deltas

##### (1) Experimental setup

The experiments were performed in the fan-shaped wave basin (semicircular part :  $r=17.5$  m ; rectangular part :  $35 \times 10$  m) of Ujigawa Hydraulics Laboratory, Disaster Prevention Research Institute, Kyoto University. A smooth concrete beach was constructed with a slope of 1:10. The beach was roughed by bonding light weight aggregate, the same material as the one whose used for modeling river sediment discharge, on to the smooth concrete. The wave guide walls, which are composed of smooth steel plates, were installed in the normal to the wave generator. On the land side, a sediment feeder machine with a controlling speed motor discharging sediment at a constant rate, was set about 1.0 m from the initial shoreline. Two smooth asbestos pipes were connected to the sediment feeder machine at the output opening in order to carry the sediment to the desire position of the point source, (see Fig. 6).

##### (2) Experimental procedure

Measurements of sediment discharge rate were performed: 1) at the beginning of the experiments, and 2) at every 10 min interval time during the experiments, then the rate of sediment discharge was calculated as the average value of the measured sediment ratios. Measurements of shoreline positions were made at 10 min intervals along the delta at 13 stations (50 cm interval distance), see Figure 12. At the end of each experiment, beach profiles as well as shoreline changes were measured every 10 cm interval distance along the delta. The formation process of river delta was observed by taking photographs every 10 minutes interval time.

Measurements of wave heights in the constant depth part were made using capacitance type wave gauges. While on the sloping part, the measurements were made using a wave gauge mounted on a carriage controlled by a personal computer. The angles of incoming wave incidence were measured in the constant depth part by measuring the angles of inclination of the wave generator to the beach. Snell's law and linear wave theory were used to estimate the angles of wave incidence at the breaker line. The longshore currents were visually observed by using colored paper tracers.

##### (3) Experimental results

Six experiments were performed, (see Table 1), for a still water depth in the constant depth part of 30 cm, a wave height of 2.0 cm and a wave period of 0.8 sec. The incoming waves were normally incident during the experiments series A and series B, while they were oblique incident during experiments C-1 and D-1, with  $7.5^\circ$  and  $15^\circ$ , respectively. The experimental results are drown as follows :

a) **General description of the formation process;** Once the sediment feeder machine supplies sediment to the wave basin, the sediment particles spread along the coast by the effect of the longshore current. Figure 7 shows the behaviors of the growth of river delta in experiments series A. The configuration of the shoreline of river delta in this experiment is nearly symmetric with respect to the center of the river.

Table 1. Experimental conditions of formation process of river delta.

Run	No.	$Q_s$ cm <sup>3</sup> /sec	Run time (min)	$\alpha_0$ (deg.)
Series A	A-1	7.06	50	0
	A-2	7.06	30	0
Series B	B-1	15.08	30	0
	B-2	8.12	30	0
Series C	C-1	11.0	90	7.5
Series D	D-1	11.0	180	15.0

(a) Plane view.

(b) Side view.

Fig. 6. Schematic diagram of experimental arrangement of formation and reduction processes of river deltas.

b) River delta configuration in case of oblique wave incidence; In the case of oblique wave incident, an asymmetrical shape of river delta is expected. Figure 8 illustrates the measured data of shoreline positions in Run C-1 where the angle of wave incident is  $7.5^\circ$ . The black symbols represent the measured data at the upcoast side, whereas the measured data at the downcoast side are represented by the white symbols. It is clear that asymmetrical river deltas are formed in the case of oblique wave incidence. In general, oblique waves generate strong longshore currents, consequently, most of the river sediment discharge is moved in the predominant direction of littoral drift and deposited on the downcoast side. Therefore, the growth rate of the shoreline on the downcoast side is faster than that on the upcoast side.

c) Variation of beach profile and beach slope along a delta coast; The beach profiles measured along the river delta for experimental Run A-2,  $t = 80$  min, for the selected sections are illustrated in Fig. 9. It is seen from this figure that the beach profiles are convex in shape.

Figure 10 demonstrates the variation of beach slope along the river delta for Run B-1,  $t = 30$  min, represented by a white symbol, and Run B-2,  $t = 60$  min, represented by a black symbol, respectively. It is obvious from this figure that; 1) in Run B-1, the beach slope around the river mouth is steeper than the beach slope at the longshore ends of the river delta, where the configuration of river delta was also sharply curved, and 2) when the rate of river sediment input was reduced by half in Run B-2, the configuration of the shoreline of the river delta changed, becoming more gently curved, and therefore the variation of beach profiles along the river delta lessened.

#### (4) Applicability of analytical solutions to experiments

The measurements of shoreline evolution of a river delta for experimental runs A-1 and A-2 are compared with the analytical solution given by Eq. (8), the results are shown in Fig. 11. It is seen from the comparison that the evolution of the shoreline near the river mouth is well predicted. However, near the longshore ends of the river delta less agreement between the measured and computed shoreline position is observed. This may be due to the effect of the roughness of fixed bed in the wave tank, which induced rapid transport of the sediment downcoast, causing the shoreline to rapidly decrease.

### 3.2 Experiments on Reduction Process of River Deltas

#### (1) Experimental procedure

The initial shoreline and beach profile in this experiment simulated the final ones in the experiment of the formation process of river delta presented in the previous section, (Series A and B). An experiment was halted once no remarkable longshore current existed, with only cross-shore movement. To verify this condition, color tracers were used and the trajectories were observed. Measurements of shoreline changes were made in the same way as in the formation process of river delta.

#### (2) Experimental results

Two experiments were performed, A-3 and B-3, with a still water depth of 30 cm, a wave height of 2.0 cm and a wave period of 0.8 sec. The incoming waves were normally incident during the experiments.

a) General description of river delta reduction process; The reduction process of the river delta is significantly different from the formation process of the river delta. Figure 12 shows the process of river delta reduction for experiment A-3. Due to the lack of sediment input, the shoreline of the delta rapidly becomes to a nearly straight, resulting in erosion near the center of river delta and deposition near the longshore ends of the river delta.

b) Variation of beach profiles; The variation of the beach profiles at selected experiment A-3, is shown in Fig. 13. It is noted that the beach profile changes from a convex type which was in the formation process to a concave one. This phenomenon is completely different from the formation process, and may be due to the rapid erosion in the surf zone to maintain the longshore sediment transport by waves.

### 4. Conclusions

The formation and reduction processes of river deltas were investigated theoretically and experimentally in this paper. The formation and reduction processes are governed by the relation between the rates of sediment input from rivers and longshore sediment transport by waves and currents. From the results of the theoretical solutions, the following conclusions can be drawn:

(1) The solutions of formation process of river deltas of infinite and finite river mouth widths were obtained from linearized equations of shoreline change. It was theoretically found that the configuration of river delta becomes asymmetric when the dimensionless quantity  $\epsilon_1 \rho / \epsilon_2$  is greater than zero.

Fig. 12. Time variation of shoreline change in the reduction process of river delta in the case of Series B.

Fig. 13. Variation of beach profiles formed along the shoreline of river delta in the reduction process, Run B-3.

(2) By normal wave incidence, the reduction of the river delta takes place symmetrically with respect to the center of the river. The shoreline at the vicinity of the river mouth is rapidly eroded, while the shorelines at the longshore ends of the river delta retreat slowly. At the final stage, the configuration of the river delta may become a straight beach. By oblique wave incidence, the reduction of the river delta takes place asymmetrically, at a faster rate of reduction on the upcoast side of the delta than on the downcoast side. Also, the river mouth moves predominantly in the direction of littoral drift, as the reduction process of river delta takes place.

In order to understand the physical processes of formation and reduction of river deltas, and to compare the results of the formation process with the theoretical one, experiments on the formation and reduction processes of river deltas were carried out. The following conclusions can be drawn from the experiments:

(1) In the formation process, the shoreline of river delta propagates symmetrically with respect to the center of the river, when the waves is normally incident. On the contrary, by obliquely waves incidence, the shoreline of river delta propagates asymmetrically with respect to the center of the river at faster rate of formation on the downcoast side than that on the upcoast side.

(2) On the contrary of the formation process of river deltas, in the reduction process, the shoreline of river delta is rapidly eroded. It was noted in the reduction process that the beach profile changes from convex type, which was shown in the formation process, to a concave-upward one. This fact is completely different from the formation process, and may be due to the rapid erosion in the surf zone to maintain the longshore sediment transport by waves.

(3) Since the waves approach the shoreline obliquely, the longshore sediment transport is predominant. Consequently, the reduction rate of the shoreline on the upstream coast side is greater than that on the downstream coast side. The final stage for the configuration of the delta may be an inclined straight beach where the waves tend to approach it normally.

(4) In comparison, all experimental parameters in the theoretical solutions must be determined experimentally. It was concluded from the comparison that the evolution of the shoreline near the river mouth is well-predicted.

Finally, further extension of the present study should be directed towards both theoretical investigations of formation and reduction processes of river deltas as one of diffusion processes, which is the task of the near future.

## CHAPTER 213

# Theoretical Study of the Wave Attenuation in a Channel with Roughened Sides

A.J. Roldán. \*, M.A. Losada\*, I.J. Losada\*

### Abstract

An eigenfunction expansion method is used to analyze the propagation of a plane wave train along a rectangular channel, the side walls which are provided with regularly spaced thin vertical strips. The presence of such strips may produce cross-channel seiching and energy dissipation. The method is extended to take into account the dissipation of energy at each pair of strips. Analytical solutions are obtained for the general case. Theoretical results of wave attenuation along the channel are compared to laboratory experiments, Battjes (1965).

## 1 INTRODUCTION

A harbor is a partially enclosed area connected to the sea by an opening. Sometimes the connection to the sea is through a channel of finite width and length. Entrance channels bounded by rubble-mound jetties are a common way to control wave propagation along the channel and to the harbor. Others, are channels with roughened sides, Battjes (1965) or with corrugated boundaries, Liu (1987). Further references can be found in Liu (1987).

Battjes (1965), did a semiempirical study of the attenuation of water waves in a rectangular channel, the side walls of which had been provided with

---

\*Ocean & Coastal Research Group. Departamento de Ciencias y Técnicas del Agua y del Medio Ambiente. Universidad de Cantabria. 39005 Santander, Spain.

regularly spaced roughness strips. Such strips were found to be highly effective wave dampers. However, the damping effectiveness of the strip sharply decreases when resonance occurs in the space between the strips.

In this paper the eigenfunction expansion method (hereafter called EFEM) is used to analyze the propagation of a plane wave train down a channel provided with thin vertical strips, regularly spaced. The wave solutions are expanded in eigenfunctions over the channel width. Dalrymple and Martin (1991), examined periodically spaced offshore breakwaters, matching eigenfunction expansions at the downwave and upwave side to show that a single incident wave train can generate directional wave trains downwave of the openings. Losada et al. (1992), used a two-dimensional (over the depth and across the channel cross-section) EFEM to analyze the generation and propagation of linear water waves down a wave flume, consisting of a wavemaker, an abrupt expansion, a breakwater and a fully absorbing ending wall. The EFEM method allowed the proper description of the wave motion, including cross-channel seiching as well as the prediction of the reflection and transmission which occurs at the channel junction and the porous structure. In order to evaluate the wave attenuation along the channel under seiching regime, (frictionless case), and energy loss regime, (friction case), an EFEM is used, providing matching conditions at each pair of strips which take into account a loss of kinetic energy.

## 2 FORMULATION OF THE PROBLEM

Figure 1 shows a rectangular channel.

Fig.1.- Definition Sketch

The channel is symmetric about its centerline with constant depth  $h$ , the side walls of which are provided with regularly spaced strips attached vertically to them and extended as flat, thin (theoretically infinitesimal) plates into the channel.

The cross sectional width of the channel is  $2b$ . The gap between aligned pairs of strips is  $2l$  and the distance between two consecutive pairs of strips is denoted by  $s$ . The channel has  $N$  pairs of strips at the centerline of the channel at the still water level, with  $z$  directed upwards and  $x$  pointing downwave. Region 1 is defined by  $x \leq 0$ . Between two consecutive strips a new region is defined. A total of  $N - 1$  regions are defined. Region  $N + 1$  is extended over  $x \geq (N - 1)s$ .

The waves propagate down the channel in the positive direction. Then, as they encounter the first row of strips they get scattered by the roughness elements, partially reflected, and partially transmitted into Region 2. The transmitted waves in Region 2 diffract into the wider channel, dissipating energy through the formation of vortices, jets and eddy zones and reflecting from the side walls. They are then partially reflected and partially transmitted and dissipated after encountering the next row of strips. The transmitted and reflected waves are subsequently scattered and dissipated back and forth between the successive rows of strips until they encounter Region  $N+1$  where they are partially reflected, dissipated and transmitted into the leeward semi-infinite fluid region. As the waves propagate down the channel, they decrease in magnitude.

For an incompressible fluid and irrotational motion, the wave field outside the strip regions can be specified by the velocity potentials:  $\phi_1$  in Region 1 and  $\phi_{N+1}$  in the leeward region. The linear boundary value problem for water of constant depth,  $h$  in a channel of width  $2b$ , is well known. In the regions enclosed by strips it is assumed that the wave field is also describable by a velocity potential,  $\phi_n$ , with  $2 \leq n \leq N$ . Since the solution in the adjacent regions must be continuous at each interface, continuity of mass flux and pressure must be required over the water column and across the channel width. Then, following Mei et al. (1974), it is possible to incorporate to the pressure matching condition a head drop consisting of a loss of kinetic energy due to flow separation and an apparent inertia.

The boundary value problem can be completely solved if the potential,  $\phi_j(x, y, z, t)$ , in the  $j$ th region, is known for  $j = 1, 2, \dots, N+1$ . For each constant depth region, the Laplace's equation and the non-flow boundary conditions at the bottom and at the vertical channel boundaries are assumed to hold. The potentials in each region can be separated as:

$$\Phi_j(x, y, z, t) = \Re[\phi(x, y)I_j(z)e^{i\sigma t}] \quad (2.1)$$

where

$$I_j = \frac{ig \cosh k(z+h)}{\sigma \cosh kh} \quad (2.2)$$

where  $g$  is the gravitational constant,  $T$  is the wave period,  $t$  stands for time and  $\sigma = 2\pi/T$ , is the wave frequency. The wave number in each region,  $k_j$ , satisfies, for any  $j = 1, 2, \dots, N+1$ , the linear dispersion relationship

$$\Gamma_j = \frac{\sigma^2 h}{g} = k_j h \tanh k_j h \quad (2.3)$$

Because of the constant depth in all regions, eq. (2.3) has real roots  $k_{j1}$ , where  $k_{j1} \geq 0$  and has an infinite number of purely imaginary roots,  $k_{jm}$ , with  $m \geq 1$ .

The potentials  $\phi_j$  must solve the following problem

$$\frac{\partial^2 \phi_j}{\partial x^2} + \frac{\partial^2 \phi_j}{\partial y^2} + k_j^2 \phi_j = 0 \quad -h \leq z \leq 0 \quad (2.4)$$

$$\frac{\partial \phi_j}{\partial z} = 0 \quad z = -h \quad (2.5)$$

$$\frac{\partial \phi_j}{\partial z} - \frac{\Gamma_j}{h} \phi_j = 0 \quad z = 0 \quad (2.6)$$

Every potential has to satisfy a non-flow condition across the boundaries given by

$$\frac{\partial \phi_j}{\partial y} = 0 \quad y = \pm b \quad (2.7)$$

Finally, it is assumed that the downwave end of the channel, Region  $N+1$ , is fully absorbent. To take into account this absorbing character, it is enough to specify a radiation condition, requiring that the potential in that region is a downstream progressive wave.

## 2.1 Matching Conditions

Since the solution in adjacent regions must be continuous at each interface, continuity of mass flux and pressure must be required over the water column and across the channel width.

### Frictionless Case

At the strips, the matching conditions for the frictionless case are

$$(\phi_j)_x = (\phi_{j+1})_x = 0 \quad \text{at } x = (j-1)s \quad \text{and } l \leq |y| \leq b \quad (2.8)$$

$$(\phi_j)_x = (\phi_{j+1})_x \quad \text{at } x = (j-1)s \quad \text{and } |y| \leq l \quad (2.9)$$

$$\phi_j - \phi_{j+1} = 0 \quad \text{at } x = (j-1)s \quad \text{and } |y| \leq l \quad (2.10)$$

for  $j = 1, 2, \dots, N + 1$

which guarantee the non-flow condition through the strips and the continuity of mass flux and pressure in the gap.

### Friction Case

Based on a model of quadratic loss and scattering of long waves Mei, Liu and Ippen, (1974), Losada (1991), proposed a similar model to apply for the case of wave scattering by thin vertical barriers. In this model the continuity of pressure at the interface is obtained based on the Bernoulli equation. Thus, the analytical solution satisfies the following matching conditions (2.8) and (2.9), and a new condition given by,

$$\frac{ig}{g}(\phi_j - \phi_{j+1}) = \frac{f}{2g}(\phi_{j+1})_x |(\phi_{j+1})_x| + \frac{L}{g}(\phi_{j+1})_{xt}, x = (j-1)s \quad \text{and } |y| \leq l \quad (2.11)$$

for  $j = 1, 2, \dots, N + 1$

where,  $f$  and  $L$  are two empirical coefficients related to the loss of kinetic energy and apparent inertia respectively at each pair of strips. Following Mei (1974), we will use the following expression for  $f$ :  $f = [(2b/c.2l) - 1]^2$ , with  $c = 0.62 + 0.38(l/b)^3$ .

The good agreement between the analytical and experimental solutions for the case of thin vertical plates, suggests the extension of the model to the multi-strips case. Losada (1991), showed that the proposed approximation gives the

best results for the intermediate and shallow water waves. Furthermore, he showed that for relatively long waves, the apparent inertia term is not too important in comparison to the friction term. In this paper only the friction term will be considered. Moreover, eq. (2.11) will be linearized, therefore

$$\phi_j - \phi_{j+1} = \frac{-ig}{\sigma} C_{ej}(\phi_{j+1})_x \quad (2.12)$$

where  $C_{ej}$  is an equivalent friction term. Following Mei (1974),

$$C_{ej} = \frac{f}{2g} \frac{8}{3\pi} \left| \frac{\partial \phi_j}{\partial x} \right| \quad (2.13)$$

which depends on the potential value at each gap and it is not known before the solution is completed. To solve the problem an iterative procedure has to be used.

### 3 FULL SOLUTION

The potentials  $\phi_j$  for the frictionless and friction cases in each region satisfy the same boundary value problem, and therefore have the same analytical expression. They differ only in the matching conditions, that is, in the numerical value of the coefficients. Because of the constant water depth along the channel the potential  $\phi_j(x, y)$  at each region is

$$\phi_1(x, y) = \sum_{n=0} [A_n^{(1)} e^{-iq_n x} + B_n^{(1)} e^{iq_n x}] \cos(n\lambda y) \quad (3.1)$$

$$\phi_j(x, y) = \sum_{n=0} [A_n^{(j)} e^{-iq_n(x-(j-2)s)} + B_n^{(j)} e^{iq_n(x-(j-1)s)}] \cos(n\lambda y) \quad (3.2)$$

$$\phi_{N+1}(x, y) = \sum_{n=0} [A_n^{(N+1)} e^{-iq_n(x-(N-1)s)}] \cos(n\lambda y) \quad (3.3)$$

where  $q_n = \sqrt{k^2 - (n\lambda)^2}$ ,  $\lambda = \pi/b$ .

The inclusion of the Fourier terms,  $\cos(n\lambda y)$ ,  $n = 1, 2, \dots, \infty$  for all velocity potentials assures no flow through the channel walls. There is an infinite number of eigenvalues,  $\lambda_n = n\lambda$ . The corresponding eigenfunctions form a complete orthogonal set in the domain  $(-b \leq b)$ .

The wave field at each region consists of the incident plane wave train propagating down the channel and the reflected plane wave trains, which are

independent of the  $y$  coordinate ( $n = 0$ ) plus progressive and evanescent standing waves travelling in the negative  $x$  direction. The evanescent modes occur when  $\lambda_n \geq k$ , leading to a dampened motion in the  $x$  direction. The progressive standing wave modes consist of two intersecting wave trains travelling at

$$\theta = \cos^{-1}\left(\frac{\sqrt{k^2 - (n\lambda)^2}}{k}\right) \quad (3.4)$$

to the  $x$  axis.

Note that eqs. (3.1) to (3.3) do not include a family of vertical evanescent modes, which has to be included to satisfy the matching conditions at each interface. However, for intermediate and shallow water waves, the relative error between the plane wave approximation and the full solution is small.

The unknowns of the problem are  $A_m^{(j)}$  and  $B_m^{(j)}$ , with  $m = 0, 1, 2, \dots, n$  and  $j = 1, 2, \dots, N + 1$ . The incident plane wave train is defined by  $A_0^{(1)} = 1$  and  $A_m^{(1)} = 0$ , with  $m \geq 1$ . In order to satisfy the radiation condition in the leeward region,  $B_m^{(N+1)} = 0$ , with  $m \geq 0$ .

Substituting the expression of the potentials into the mass flux condition, eq. (2.9), an expression from  $B_m^{(j)}$  as a function of  $A_m^{(j)}$  can be found.

Next, the two remaining matching conditions are to be prescribed on the velocity eq. (2.8) (non-flow through the strips) and on the pressure eq. (2.10) or on the momentum eq. (2.11). Here, a mixed boundary condition must be prescribed (Dalrymple and Martin, 1991, and Losada et al., 1991).

### 3.1 Dual Series

The two remaining matching conditions to be satisfied at the gap are known as dual series relations, (Sneddon, 1966). They have to be solved for the values of the coefficients  $A_n^{(j)}$ . The two conditions can be combined to make one mixed boundary condition. This condition is

$$G(y) = 0 \quad \text{at } 0 \leq |y| \leq b \quad (3.5)$$

To determine the  $A_n^{(j)}$  several techniques can be used, e.g. least squares method, which requires the value of

$$\int_{-b}^b |G(y)|^2 \cdot dy \quad (3.6)$$

to be a minimum.

Minimizing this integral with respect to each of the  $A_n^{(j)}$  leads to the following system of equations

$$\int_{-l}^l G^{*(2)}(y) \frac{\partial G^{(2)}(y)}{\partial A_n^{(j+1)}} + 2 \int_l^b G^{*(1)}(y) \frac{\partial G^{(1)}(y)}{\partial A_n^{(j+1)}} dy = 0 \quad n = 0, 1, 2, \dots, \infty$$

$$j = 1, 2, 3, \dots, N \quad (3.7)$$

where  $G^*$  is the complex conjugate of  $G$  and  $G^1$  and  $G^2$  are the matching conditions at the gap and at the strip respectively. Truncating eq. (3.7) to  $M$  terms and solving for the  $M * N$  values of  $A_m^{(j)}$  simultaneously, a complex system of  $M * N * N$  matrix equations is obtained which can be solved with the IMSL routine, LEQT1C.

Dual Series for the Frictionless Case

Taking into account the non-flow condition at each pair of strips, eq. (2.8), and matching the pressure using eq. (2.10), we get the mixed matching condition  $G(y) = G_1(y) + G_2(y)$ , which for each  $j = 1, 2, 3, \dots, N$ , is

$$\sum_{n=0}^{\infty} \{-4(e^{-\alpha i q_n s})^* I_{mn} A_n^{*(j)} + \{4I_{mn} + 2[iq_n(\delta e^{-2iq_n s} - 1)]^* [iq_m(\delta e^{-2iq_m s} - 1)] J_{mn}\} A_n^{*(j+1)} + 2 \sum_{p=j+2}^{N_p} \delta(iq_n)^*(e^{-2iq_n s} - 1)^*(e^{-iq_n(p-(j+1)s})^* [iq_m(\delta e^{-2iq_m s} - 1)] J_{mn}\} A_n^{*(p)} - 2\delta(iq_n)^*(e^{-iq_n(N-j)s})^* [iq_m(\delta e^{-2iq_m s} - 1)] J_{mn}\} A_n^{*(N+1)} = 0 \quad (3.8)$$

where  $\delta = 0$ , if  $j = N$  and  $\delta = 1$  otherwise, and  $I_{mn} = \int_{-l}^l \cos(n\lambda y) \cos(m\lambda y) dy$ , and  $J_{mn} = \int_l^b \cos(n\lambda y) \cos(m\lambda y) dy$ .

Dual Series for the Frictional Case

The non-flow condition at each strip is the same as for the frictionless case. The continuity of pressure, eq. (2.10) can now be written as:

$$G^{(2)}(y) \equiv \sum_{n=0}^{\infty} \{2e^{-\alpha i q_n s} A_n^{(j)} - [2 - C'_{ej} i q_n (\delta e^{-2iq_n s} - 1)] A_n^{(j+1)}\}$$

$$\begin{aligned}
 &+ \sum_{p=j+2}^N C'_{ej} i q_n \delta (e^{-2i q_n s} - 1) e^{-i q_n (p-(j+1))s} A_n^{(p)} \\
 &- C'_{ej} i q_n \delta e^{-i q_n (N-j)s} A_n^{(N+1)} \} \cos(n \lambda y) = 0 \quad (3.9)
 \end{aligned}$$

where  $C'_{ej} = -(ig/\sigma)/C_{ej}$

Substituting eqs. (3.9) and the corresponding  $G^{(1)}(y)$  into eq. (3.7) and truncating the series to M terms, we get a set of  $M^*N^*N$  matrix equations that can be easily solved.

### 4 THEORETICAL RESULTS

The reflection coefficient,  $C_r$ , is defined as the absolute value of the most progressive coefficient  $B_0^{(1)}$  of the reflected potential in Region 1. Similarly, the transmission coefficient,  $C_t$ , is defined as the absolute value of the most progressive coefficient,  $A_0^{(N+1)}$ , of the transmitted potential in Region  $N + 1$ .

For the frictionless case, the propagation of a wave train down a channel in two separate cases, one using two pairs of strips and the second using ten pairs of strips, is examined for the following characteristics:  $T = 1.373s$ ,  $h = 0.6m$ ,  $2b = 3.0m$  and  $2l = 2.6m$ .

Figure 2 shows  $C_r$  versus  $ks$  where,  $k$  is the wavenumber. Resonant conditions occur at  $ks = p\pi$ ,  $p = 1, 2, \dots$ . Further results have shown, that increasing the gap to  $2l = 2.8m$ , the amplitude of the resonance is reduced.

Fig.2.- Reflection Coefficient versus  $k.s$  (without friction)  
 ( $T=1.373 s$ ,  $2.b=3.0 m$ ,  $2.l=2.6 m$ ,  $h=0.6 m$ ,  $M=10$ )

Note, that the resonant conditions are stronger for the channel with a larger number of strips.

Figure 3 shows the dependency on  $C_r$  on the relative gap width  $l/b$ . This time the separation of the strips is  $s = 0.4$ . A sharp increase in  $C_r$  occurs, by decreasing the relative gap from 70% to a 60%.

Fig.3.- Reflection Coefficient versus  $l/b$  (without friction)  
 ( $T=1.373$  s,  $2.b=3.0$  m,  $s=0.4$  m,  $h=0.6$  m,  $M=10$ )

Battjes, (1965) reported experimental values of the wave attenuation in a channel with roughened sides. The wave height was measured in eight equidistant points in each cross-section and the average of these heights was taken to represent the wave attenuation at each respective section.

Results without friction have shown that the analytical model underpredicts the wave attenuation measured in the experiments. Further, the amplitude attenuation depends linearly on  $x$ . A similar behavior is obtained if the friction coefficient is kept constant along the channel, as Battjes, (1965) suggested.

Figure 4 shows the evolution of the averaged wave height along a channel, including the friction effect, for the following case:  $h = 0.6$  m,  $T = 1.98$  s,  $2l = 2.9$  m,  $s = .2$  m,  $N = 195$  strips and  $M = 5$ .

This time the overall agreement between analytical and experimental results is good.

Because of time computation, theoretical results were stopped after 195 strips.

Fig.4.- Wave Height Evolution ( $T=1.98$  s,  $2b=3.0$  m,  $2l=2.9$  m,  $s=0.2$  m,  $h=0.6$  m,  $N=195$ ,  $M=5$ )

The wave height contourlines for,  $h = 0.6m$ ,  $T = 1.373s$ ,  $2l = 2.6m$ ,  $2b = 3.0m$ ,  $s = 0.67m$ ,  $N = 20$  and  $M = 25$  are presented in Figure 5. In this case the wave height varies from the input wave height,  $1m$  to  $0.3m$ .

Fig.5.- Wave Height Contourlines

Further analysis has shown, for the same values of the parameters, that the wave height attenuation in a mid-channel section presents an oscillating behavior, due to the resonant conditions caused by the strips.

Finally, it could be also observed that there is also an oscillating behavior present, if we the wave height variations across the channel were analyzed in different sections.

## 5 CONCLUSIONS

Wave propagation in a channel with roughened sides has been studied, using an eigenfunction expansion method (EFEM).

This method is valid to reproduce the wave field in the channel, showing, as the most important characteristic, the wave attenuation with an oscillating behavior.

The model does also reproduce the resonant conditions and the cross-channel variations, due to the presence of the lateral walls and the thin strips.

Frictional effects have been considered using a semi-empirical approach based on Mei et al. (1974). This effect is included in the matching conditions corresponding to the momentum equation at each strip. By applying the EFEM, the local friction effect proposed by Mei et al. is extended to the whole channel width and depth.

Comparison of the analytical results with the experimental data by Battjes (1965), proves the validity of the method.

## CHAPTER 214

### LOCAL SCOUR AROUND A LARGE CIRCULAR CYLINDER ON THE UNIFORM BOTTOM SLOPE DUE TO WAVES AND CURRENTS

Eiichi Saito\* and Tomoya Shibayama, M.ASCE\*\*

#### 1. Introduction

In recent years, many kinds of coastal structure, such as man-made island, large-scale piers, marinas and so on, are constructed in the coastal area. Local scour occur around a coastal structure due to waves and currents. The scouring around a structure is important in the estimation of stability of the structures. However, there are no standard of judgement of measures against scour around coastal structures. There are few investigations for mechanism of local scours around a large-scale structures. The dimension of large-scale structure is comparable to the wave length, and the wave field around them is complicated owing to the presence of diffracted waves. The mechanism of sand movement around a large circular cylinder were first investigated experimentally by Toue and Katui(1985). Saito et al.(1990) presented a numerical model for the bottom topography changes around a large circular cylinder. The model consisted of three submodels, that is, wave model, current model and sand transport model. In the model, the wave field was evaluated by using the linear theory derived by McCamy and Fuchs(1954). The current field was evaluated as sum of the depth-integrated current induced by the spatial variation of the radiation stress and the mass transport velocity in the vicinity of the bed. The sand transport rate was calculated in terms of the

\*\*Assoc. Prof., Dept. of Civil Eng., Yokohama National Univ., Hodogaya-ku, Yokohama 240, Japan

bottom shear stress and near-bottom current velocity. The change of bottom topography was calculated by using the mass conservation equation of the sand. Later, Katsui and Toue(1992) improved the model by using the wave-current friction factor. These investigations, however, were performed under uniform water depth conditions. Since real sea bottom has a slope, wave breaking and additional current appears. The mechanism of sand movement seems to be different. The purpose of the present study is to investigate the mechanism of the local scour around a large circular cylinder installed on the uniform bottom slope due to waves and currents by both laboratory experiment and numerical simulation.

**2.Laboratory Experiment**

Experiments were performed in a 9 times 9m wave basin with a 1/20 slope. About 2.5 times 2.3m test bed was made in the basin. A circular cylinder with a diameter of 52.2cm was installed at the center of the test bed. Two types of test beds, fixed and sand, were used in the experiment. Well-sorted sand with a median diameter of 0.2mm were put in the test section. Experimental equipment is shown in Fig.1, and experimental conditions are listed in Table 1.

Fig.1 Experimental Set-up(Fixed Bed)

Table 1 Experimental Conditions

Case	1	2
Test Bed	Fixed	Sand
Incident Wave Period $T$ (s)	1.02	
Incident Wave Height $H_0'$ (cm) (at uniform water depth)	9.4	
Deepwater Wave Height $H_0$ (cm)	9.1	
Water Depth at Cylinder $h_c$ (cm)	11.5	
Diameter of Circular Cylinder $D$ (cm)	52.2	
Measured Values	•Wave Height •Steady Current	•Wave Height •Change of Bottom Topography

In the case of fixed bed (case1), the distribution of wave height and the variation of steady current velocities around a cylinder were measured with a horizontal spacing of 10cm. Steady current were measured by using ultra-sonic type current meter or electromagnetic current meter at both upper level and lower level for one measuring point. We set the upper level at 8cm below the mean water level to prevent the current meter from being exposed to the air when the wave trough comes. And we set up the lower level at 1cm above the bottom. In the shallow water area, steady current only at lower level was measured. Measuring points are shown in Fig.2. The whole pattern of current direction was also observed by using dye injection.

In the case of sand bed (case2), the development of sand ripples and change of bottom topography during experimental run were measured by using a bottom profiler. Measuring points are the same with those in Fig.2. The measurements were carried out at 1,2,4 and 6 hours after wave generation. The scouring depth and the depositing height along the cylinder surface were also measured by using scales printed on the cylinder surface. The distribution of wave height were also measured at same point as case 1. The measurements were carried out from 0 ~ 2 hours and from 5 ~ 7 hours upon the initiation of wave action to estimate the influence of the change of bottom topography on the wave height distribution. In this study, the physical meaning of large circular cylinder is considered to be the

Fig.2 Measuring Points

cylinder which causes obvious diffracted waves. In this experiment, diffracted waves, which passed around behind the cylinder, were observed obviously. Jo(1986) proposed the criteria of large cylinder by using the parameter  $D/L$  and K.C.number( $K.C.=u_b \cdot T/D$ ), where  $D$  is the diameter of the circular cylinder,  $u_b$  the orbital velocity amplitude near the bottom,  $T$  the wave period. The criteria of large cylinder is listed in Table 2. When we calculate these parameters by using the experimental conditions listed in Table 1, we obtained  $D/L=0.52$  and  $K.C.=0.70$ . As a result, the circular cylinder with a diameter of 52cm is considered to be a large circular cylinder in the present experiments.

Table 2 Criteria of Large Cylinder

$D/L$	Small Diameter < 0.2 < Large Diameter
K. C. Number	Small Diameter > 4.0 ~ 5.0 > Large Diameter

The experiments were carried out with the scale of 1/50. Prototype according to the Froude law are listed in Table 3.

Table 3 Prototype Conditions

Case	1	2
Incident Wave Period T(s)	7.21	
Incident Wave Height H <sub>0</sub> ' (m) (at uniform water depth)	4.70	
Deepwater Wave Height H <sub>0</sub> (m)	4.55	
Water Depth at Cylinder h <sub>c</sub> (m)	5.75	
Diameter of Circular Cylinder D(m)	26.1	

**3. Numerical Model**

A numerical model was developed to predict bottom topography changes around structures. The model consists of three sub-models, that is, wave model, current model and sand transport model. The outline of each sub-model is described below.

**3.1 Wave Model**

The wave field was evaluated by using the time dependent mild slope equation derived by Watanabe and Maruyama(1986). It is possible to calculate wave fields around structures on the bottom slope accurately. The equation is as follows:

$$\left. \begin{aligned}
 &\frac{\partial \eta}{\partial t} + \frac{1}{n} \cdot \frac{\partial n Q_x}{\partial x} + \frac{1}{n} \cdot \frac{\partial n Q_y}{\partial y} = 0 \\
 &\frac{\partial Q_x}{\partial t} + C^2 \frac{\partial \eta}{\partial x} + f_D \cdot Q_x = 0 \\
 &\frac{\partial Q_y}{\partial t} + C^2 \frac{\partial \eta}{\partial y} + f_D \cdot Q_y = 0
 \end{aligned} \right\} (1)$$

where

$$Q = \sqrt{Q_x^2 + Q_y^2}, \quad Q_r = 0.25 \sqrt{g h^3}$$

$$f_D = 2.5 \tan \beta \sqrt{(g/h)(Q/Q_r - 1)} \quad (: Q > Q_r)$$

where  $\eta$  : the water elevation,  $Q_x, Q_y$ : the components of the flux in the x-direction and y-direction,  $C$ : wave phase velocity,  $n$ : the ratio wave group velocity to wave phase velocity,  $\tan \beta$  : bottom slope,  $h$ : water depth,  $g$ : acceleration of gravity

### 3.2 Current Model

The steady current, that is, time averaged and depth-integrated current induced by the spatial variation of the radiation stress, was calculated through numerical calculation by using depth-integrated continuity equation and momentum equation expressed as follows:

$$\left. \begin{aligned} \frac{\partial \zeta}{\partial t} + \frac{\partial U (h + \zeta)}{\partial x} + \frac{\partial V (h + \zeta)}{\partial y} &= 0 \\ \frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + V \frac{\partial U}{\partial y} + F_x - M_x + R_x + g \frac{\partial \zeta}{\partial x} &= 0 \\ \frac{\partial V}{\partial t} + U \frac{\partial V}{\partial x} + V \frac{\partial V}{\partial y} + F_y - M_y + R_y + g \frac{\partial \zeta}{\partial y} &= 0 \end{aligned} \right\} \quad (2)$$

where  $\zeta$  the mean water level elevation,  $U, V$ : the components of steady current in the x-direction and y-direction,  $F_x, F_y$ : the components of bottom friction term,  $M_x, M_y$ : the components of lateral diffusion term,  $R_x, R_y$ : the components of radiation stress term.

### 3.3 Sand Transport Model

In the experiments, a large quantity of suspended sand movement and obvious steady current were observed near the cylinder. It seemed from experiments that the sand transport direction agreed with the steady current direction in particular near the cylinder. Therefore, the net sand transport rate  $Q$  was calculated by using the following equation under the wave-current field obtained by Shibayama et al. (1989):

$$Q = \frac{\Phi \omega d}{(1 - \lambda)} \quad (3)$$

$$\Phi = 0.9 \Theta^{1.2} \quad (4)$$

$$\Theta = \frac{(\tau_m - \tau_c) u}{\rho (s g d)^{1.5}} \quad (5)$$

where  $\tau_m$  the maximum value of bed shear stress,  $\tau_c$  the critical value of bed shear stress for initial sand movement,  $u$  the steady current velocity,  $\lambda$  the porosity,  $d$  the diameter of sand,  $w$  the fall velocity of sand,  $\rho$  the water density, and  $s$  the specific gravity of sand in water. The change of bottom topography was calculated by using the sand mass conservation equation of sand:

$$\frac{\partial z_b}{\partial t} = - \text{div } Q \quad (6)$$

where  $z_b$  is the bed level.

By using the three sub-models described above, the quantity of local scour and deposition was calculated by using finite difference method with a rectangular calculation grid with a size of 2cm under the same conditions as laboratory experiment.

#### 4. Laboratory Results and Comparison with Numerical Results

##### 4.1 Wave Field

In the experiments, wave breaking was observed at an onshore side of the cylinder. Fig.3 shows the comparison of the distribution of wave height. Fig.3(a) is measured on the fixed bed and Fig.3(b) is measured on the sand from 5 to 7 hours after the wave generation. The numerical results by the time dependent mild slope equation is shown in Fig.3(c). Scour and deposition around 3 to 4cm was observed around a cylinder 6 hours after the wave generation. Therefore, Fig.3(b) shows the distribution of wave height after the bed topography changed in some degree. No significant change exists between Fig.3(a) and Fig.3(b), which means that no great variation in the wave field was developed in this case, even when the bed topography changes with time. Since calculated value, which was shown in Fig.3(c), was a little small compared with two measurements, the overall agreement between the measurements and the calculations is obtained. It is confirmed that the wave field around a large circular cylinder could be evaluated in a good accuracy by the time dependent mild slope equation.

##### 4.2 Current Field

Fig.4 shows comparison of the steady current velocity distribution between experimental results and calculated results. Fig.4(a) shows the distribution of measured steady current at upper level and Fig.4(b) at lower level. The calculated current field is also shown in

Fig. 3 Distribution of Wave Height ( $H_0=9.4\text{cm}$ ,  $T_0=1.02\text{s}$ )

Fig. 4 Steady Current Velocity Field ( $H_0=9.4\text{cm}$ ,  $T_0=1.02\text{s}$ )

Fig.4(c). According to Fig.4(a) and Fig.4(b), the experimental steady currents were generally offshore directed. In particular, strong offshore currents occurred oblique behind the cylinder, where conspicuous wave breaking were observed. On the contrary, however, calculated steady currents have a tendency to be onshore directed on behind the cylinder. The reasons for the discrepancy will be discussed below. In the experiments, it is very difficult to measure

onshore currents perfectly by using current meter. In the surf zone, generally, a mass of water at upper level is transported by breaking, bore-like waves. It causes onshore current at upper level and offshore current at lower level, that is, undertow. Therefore, it is impossible to measure steady currents above the wave trough because the current meter will be exposed to the air at the phase of trough. The steady current in the present numerical model is depth-integrated velocity calculated by assuming that the velocity is uniform over entire water depth. Therefore, undertow was not included in the model.

According to Fig.4(a) and Fig.4(b), steady current vectors direct generally from the right to the left. These longshore currents were generated by wave breaking and energy dispersion. The effect of longshore current is not included in the present model.

A cell of steady current, as shown by the dotted circle line in Fig.4(b), were observed. It indicates the existence of the vortex. In the experiments on sand bed, the bottom topography was considerably scoured in the vortex area. The vortex observed here is the separation vortex induced by the steady currents. In present experiments, however, it was impossible to investigate the vortex mechanism in detail due to the limitation of the measuring device.

#### 4.3 Bottom Topography

Fig.5 shows a comparison of the bottom topography between the laboratory experiment and numerical model. The hatched areas in the figure indicate the eroded area. Since it took approximately 5 to 6 hours for bottom topography to reach equilibrium condition, both measured result and calculated result in Fig.5 are for 6 hours after the wave generation. It can be observed that the calculated results agree qualitatively with experimental results especially near the cylinder. However, some discrepancies exist in the area at a short distance from the surface of the cylinder. The experimental bottom topography shows that the bottom was mainly scoured in the onshore area of the cylinder, conversely, the bottom in the calculation was mainly scoured in the offshore area. Furthermore, the pattern of the experimental bottom topography is not symmetrical. The reasons for the discrepancy will be discussed below.

As was stated previously, undertow and longshore current were observed around a circular cylinder in the experiments. It seems that these currents gave significant effect on the bottom topography. In the experiments, a large quantity of suspended sand, which was transported under the effect of undertow and longshore current, were observed near the cylinder and in the surf zone. For

Fig.5 Bottom Topographies  
( 6 hours after wave generation)

this reasons, bottom topography in the surf zone, that is, onshore area of the cylinder, and near the cylinder was scoured and bottom topography in the offshore area was deposited. Furthermore, bottom topography change was asymmetric. According to the experiments carried out by Saito et al.(1990), under the uniform water depth condition, no significant undertow was observed. Saito et al.(1990) concluded that the effects of mass transport velocity and standing waves are important for the sand movement. The mechanism of the sand movement under the uniform water depth condition was different from that of under uniform slope condition. Numano et al.(1989) suggested the importance of the effect of the undertow for the bottom topographical changes by using numerical model. Here also we can conclude that the effect of undertow is important for the case of sloping bottom.

According to the experimental results of the steady current field, the separation vortex due to steady current was observed oblique behind the circular cylinder. Fig.5(a) shows that bottom topography at the vortex generation area shown in Fig.4(b) was considerably scoured. It indicates that in order to estimate the bottom topography change around the cylinder, it is necessary to consider the effect of the separation vortex due to steady currents. Shibayama and Win(1992) indicated the scouring effect of the vortex under steady current field in the surf zone by using a numerical model.

Since effects of undertow, longshore current and vortex are not included in the present numerical model, it is necessary to include these important effects as a next step.

## 5. Conclusions

Investigation for the mechanism of the local scour around a large circular cylinder installed on the uniform bottom slope due to waves and currents were performed experimentally and numerically. Major conclusions are summarized as follows:

- ① Undertow, longshore current and separation vortex due to longshore current were observed in laboratory experiment around a large circular cylinder on an uniform slope in the surf zone. It appeared that these currents and vortex give strong effects on the bottom topography.
- ② A numerical model was proposed for the local scour around a large circular cylinder on an uniform slope. To improve the model prediction, it is necessary to include the effect of undertow and vortex.

## CHAPTER 215

### Vertically Varying Velocity Field in Q-3D Nearshore Circulation

A. Sánchez-Arcilla, F. Collado and A. Rodríguez<sup>1</sup>

#### Abstract

This paper presents an efficient and economic technique to obtain vertical profiles for surf-zone wave-induced currents. The current-wave bottom boundary layer is solved in a parameterized manner, while employing a power series approximation to obtain the solution in the middle layer (extending up to trough level). This "profile extraction technic" has been coupled to a 2DH surf-zone circulation model which is also concisely described. The paper ends with a brief discussion of some obtained results part of the calibration work which is a very much on going task.

#### 1. Introduction

This paper presents a solution for the vertically varying velocity field in a Q-3D modelling context. It is part of an improved version of the Quasi- 3D NEARCIR Model (S.-Arcilla et al., 1990/91) developed during the MAST-I G6M (Currents) Project. The proposed model is able to achieve a detailed simulation of nearshore flows at a reasonable cost (cheaper than a full 3D code). The model works at the current time scale and it is structured into three modules (see fig. 1):

- i) Wave Propagation Module.
- ii) Depth Uniform Current Module.
- iii) Depth Varying Current Module (including Bottom Boundary Layer).

Av. Gran Capitán s/n, 08034 Barcelona, Spain.

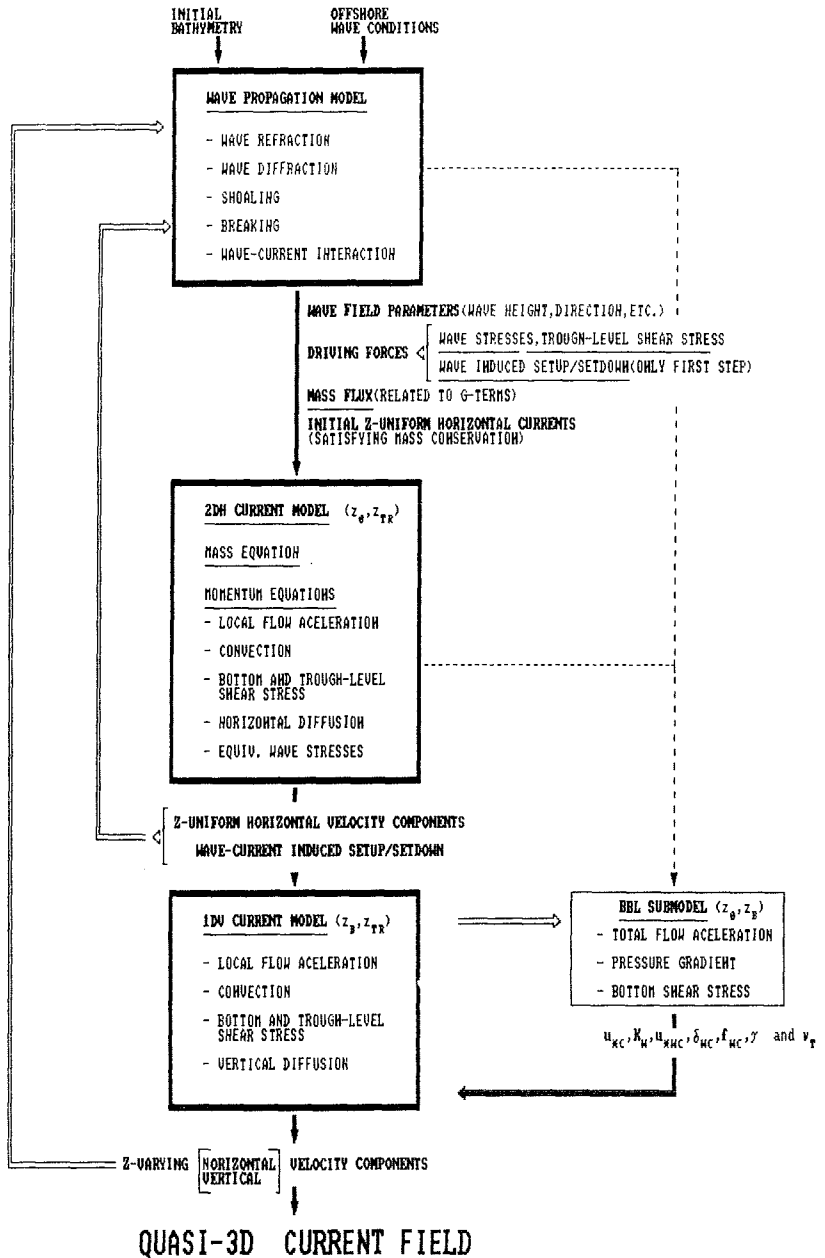

Fig. 1: NEARCIR flow chart.

The three modules operate in a sequential iterative manner (Wave—>Depth Uniform Current—>Depth Varying Current). Iterations are performed until certain prefixed convergence criteria are met. Each module is solved for a stationary solution before going on to the next one.

This paper will concentrate on the depth current module, the main new contribution being the coupling between middle and current-wave boundary layers.

2. Global Model

The model here presented considers a domain vertically splitted into three layers (figure 2). To achieve a Q-3D approach (2DH + 1DV) the total current velocity vector  $\vec{u}$ , is conveniently splitted into depth uniform,  $\vec{u}$ , and depth varying  $\vec{u}$ , components.

$$\vec{u} = \vec{u} + \vec{u} \quad , \quad (1)$$

where :

$$\int_{z_0}^{z_{tr}} \vec{u} dz = 0 \quad \text{and} \quad \int_{z_0}^{z_{tr}} \bar{v} \hat{u} dz = \bar{v} \int_{z_0}^{z_{tr}} \hat{u} dz = 0 \quad \forall \bar{v}, \hat{u} \quad (2)$$

Fig. 2: Physical domain.

The upper layer is not solved. It is considered exclusively through its effects (interaction) with the middle layer via boundary conditions at trough level  $z_{tr}$ . These boundary conditions are related to the mass and momentum fluxes in the upper layer. The formulation obtained in this manner appears to be more consistent from a physical standpoint (identical boundary conditions for  $\bar{u}$  and  $\bar{u}$ , etc...) even though it also appears to be more sensitive to the selected closure submodels.

The depth-uniform Current Module solves a set of 2DH rigid-lid mass and momentum equations in a quite general manner. The equations and solution procedure have been presented elsewhere (S.-Arcilla et al. 1990). The wave driving terms appearing in these 2DH equations are:

$$\tilde{W}_i = -\frac{1}{\rho} \frac{\partial S_{ij}}{\partial x_j} - \langle \tilde{u}_i \tilde{u}_3 \rangle \Big|_{z_o}^{z_{tr}}$$

In expanded notation the  $x$  component (similarly for  $y$ ) is:

$$\tilde{W}_x = -\frac{\partial}{\partial x} \int_{z_o}^{z_{tr}} \langle \tilde{u}^2 - \tilde{w}^2 \rangle dz - \frac{\partial}{\partial y} \int_{z_o}^{z_{tr}} \langle \tilde{u} \tilde{v} \rangle dz - \langle \tilde{u} \tilde{w} \rangle \Big|_{z_o}^{z_{tr}} \quad (3)$$

in which  $\langle \rangle$  denotes time averaging at the scale of the waves and  $(\tilde{u}, \tilde{v}, \tilde{w})$  is the wave velocity vector.

It is important to remark that this term is different from the classical radiation stress tensor due to the integration limits (actual bottom and trough level) and to the inclusion of  $(\tilde{u}, \tilde{w})$  and  $(\tilde{v}, \tilde{w})$  correlations.

The wave velocity field is given by the real part of the gradient of a velocity potential whose expression is:

$$\phi = Z(z) \epsilon(x, y) \exp(-i\omega t) \quad (4)$$

$$\epsilon(x, y) = \frac{-ig}{\sigma} A \exp(iS) \quad (5)$$

in which  $\omega$  is the observed or apparent wave frequency. The wave-number vector  $\vec{K} = (K_1, K_2)$  is given by  $\vec{K} = \vec{\nabla}_H S$  and  $Z$  is the vertical shape function.

Assuming a horizontally varying amplitude field (due to breaking effects and/or diffraction caused by, for instance, a detached breakwater) and a doppler-shifted wave frequency due to the currents, the resulting wave velocity correlations obtained are (for illustration only the correlation product of vertical and horizontal velocities is here presented):

$$\langle \vec{u}_H \vec{w} \rangle = \frac{1}{2} \frac{g^2}{\sigma^2} \frac{\partial Z}{\partial z} Z A \vec{\nabla}_H A \tag{6}$$

in which  $\sigma$  is the intrinsic frequency. Equation (6) could also be considered a generalization for a 2DH context of the expression given by Deigaard and Fredsøe (1989) for normal incidence.

The resulting wave driving terms can then be written as:

$$S_{ij} = \frac{\rho}{2} \left[ \left( \frac{1}{A^2} \frac{\partial A}{\partial x_i} \frac{\partial A}{\partial x_j} + K_i K_j \right) I_1(z_{tr}) + \delta_{ij} I_2(z_{tr}) \right] \frac{g^2}{\sigma^2} A^2 \tag{7}$$

with:

$$I_1(z) = \int_{z_o}^z Z^2 dz \quad ; \quad I_2(z) = \int_{z_o}^z \left( \frac{\partial Z}{\partial z} \right)^2 dz \tag{8}$$

A linear dispersion relation has been used to obtain  $\sigma$  in terms of  $k$  and with  $k$  satisfying a Battjes (1968) type relationship:

$$\vec{K} \cdot \vec{K} = k^2 + \frac{\Delta_H A}{A} \tag{9}$$

These expressions are similar to the classical equations for the radiation stress tensor when the upper limit of integration is equal to mean water level and the correlations of horizontal/vertical wave velocities are taken as 0 (Dingemans et al. 1987). For a more complete derivation where current variations have been considered see Rivero and S.-Arcilla (1992).

The three remaining unknowns are the wave amplitude  $A$  and the wave number vector  $\vec{K}$ , which are obtained by means of a coupled system of equations: the wave action balance equation and the kinematic conservation principle (Yoo and O'Connor 1986/88).

### 3. Depth-varying current module

An alternative treatment to solve coupledly the middle and bottom-boundary layers is here proposed. The Bottom Boundary Layer Model, strongly inspired on Fredsøe (1984), has been parameterized to be compatible with the quasi-3D cost/efficiency philosophy.

#### 3.1 Middle layer

The momentum equations in the middle layer are obtained by subtracting the depth-integrated equations from the general ones. Only a simplified version of these momentum equations for  $\vec{u}$  is presented here:

$$\frac{\partial \vec{u}}{\partial t} + A\vec{u} - \frac{\partial}{\partial z}(\nu_V \frac{\partial \vec{u}}{\partial z}) = \vec{T}(z) \quad (10)$$

With

$$\vec{T}(z) = \frac{\langle \vec{\tau}_o \rangle}{\rho e} - \frac{\langle \vec{\tau}_{tr} \rangle}{\rho e} - 2G\nabla G (P_W^2 - \bar{P}_W^2) \quad (11)$$

$$A = \begin{pmatrix} \frac{\partial \bar{u}}{\partial x} & \frac{\partial \bar{u}}{\partial y} \\ \frac{\partial \bar{v}}{\partial x} & \frac{\partial \bar{v}}{\partial y} \end{pmatrix} \quad (12)$$

$$G = \nabla_H \langle \vec{Q}_s \rangle \quad (13)$$

with  $\vec{Q}_s$  being the wave plus current volume flux in the crest-to-trough layer and  $P_W$  the vertical distribution function of the vertical current velocity,  $W$ . The thickness of the middle layer is given by  $e$  and  $\langle \vec{\tau}_{tr} \rangle$  and  $\langle \vec{\tau}_o \rangle$  are, respectively, the shear stresses at trough and bottom levels.

The main hypotheses required to derive this simplified version of the momentum equation are: i) linearization (in  $\vec{u}$ ) of convective terms, ii) neglect horizontal gradients of  $\vec{u}$ , iii) neglect Coriolis effects and iv) neglect vertical nonuniformities of wave stresses. This is the equation that has been applied in the middle layer ( $z_b, z_{tr}$ ).

#### 3.2 Bottom boundary layer

The model selected for this ( $z_o, z_b$ ) layer is similar to the one proposed by Fredsøe in 1984. It was selected based on a comparison of its numerical results with data and other numerical model results (Simons et al. 1988) and

an extensive intercomparison exercise performed during MAST-I. This model does not consider turbulence from the previous wave and assumes logarithmic velocity profiles for both waves and currents. Two matching boundary conditions are applied at the top of the boundary layer,  $z_b = \delta_m + K_N/30$ , viz. continuity of current velocity and shear-stress (in the current direction). The momentum equation perpendicular to the current velocity is used to obtain an expression of the instantaneous friction velocity,  $u_*$ , as a function of the wave phase. This equation is solved using a classic Runge-Kutta method of sixth order.

### 3.3 Boundary conditions between middle layer and bottom boundary layer

At the top of the current-wave boundary layer,  $z_b$ , the present approach assumes: i) continuity of current velocity  $u$ , ii) continuity of  $\langle \tau \rangle$  (in the current plane), iii) discontinuities of  $u_*$  (from now on shear-stress at the current time-scale),  $\frac{\partial \vec{u}}{\partial z}$ , and  $\nu_V(z_b)$ . For illustration, the current shear velocity jumps from  $u_{*wc}$  (below  $z_b$ ) to  $u_{*c}$  (above  $z_b$ ). The corresponding  $\frac{\partial \vec{u}}{\partial z}$  values are:

$$\left. \frac{\partial \vec{u}}{\partial z} \right|_{z_b}^- = \frac{u_{*wc}}{(\delta_m + K_N/30)\kappa} \tag{14}$$

$$\left. \frac{\partial \vec{u}}{\partial z} \right|_{z_b}^+ = \frac{u_{*c}^2}{\nu_V(z_b)} \tag{15}$$

in which  $\delta_m$  is the mean boundary layer thickness and  $\kappa$  von Karman's constant.

The values of  $\vec{u}$  and  $d\vec{u}/dz$  at the top of the bottom boundary layer (BBL) provided by this model are used as boundary conditions for the middle layer (ML) equations. The third boundary condition is  $d\vec{u}/dz$  at  $z_{tr}$ , obtained through the  $\nu_V$  and  $\langle \vec{\tau}_{tr} \rangle$  closure submodels. The apparent excess of a boundary condition (over stated problem) is solved by considering that the friction (wave plus current) velocity at the top of the BBL is still unknown.  $u_{*c}$  at  $z_b^+$  is in fact due to bottom-induced turbulence but should also be affected by breaking-induced turbulence. This  $u_{*c}$  can be mathematically considered as an extra degree of freedom to obtain a well defined problem that is solved using an iterative process between ML and BBL.

## 4. Numerical solution of Depth Varying Current Module

### 4.1 Numerical solution of $\vec{u}$ equations

The middle layer equations are solved using a power series approximation ( $a_i z^i$ ) to reproduce the vertical variation of the unknown  $\vec{u}$  and the right-hand-side term of the equation. Time is used as a marching variable since only

stationary currents are here considered (to be consistent with the rigid lid approximation of the 2DH equations). The semi-discrete version of equation (10) can be arranged to yield at step  $n+1$  (after discretization of the time derivative):

$$\underbrace{(I + \Delta t A)}_{A_t} \vec{u}^{n+1} - \frac{\partial}{\partial z} \left( \Delta t \nu_V(z) \frac{\partial \vec{u}^{n+1}}{\partial z} \right) = \underbrace{\vec{T}(z) \Delta t + \vec{u}^n}_{\vec{R}(z)} \quad (16)$$

After a change of variable to simplify the vertical domain of variation to the interval  $(0,1)$  and to uncouple the  $(\hat{u}, \hat{v})$  equations, the following power series are introduced into the resulting momentum equation:

$$\left. \begin{aligned} \vec{w}(\xi) &= \sum_0^M \vec{w}_i \xi^i \\ \vec{R}(\xi) &= \sum_0^M \vec{r}_i \xi^i \\ K_t(\xi) &= K_0 + K_1 \xi + K_2 \xi^2 \end{aligned} \right\} \quad (17)$$

in which  $\xi$  is a normalized vertical coordinate,  $\vec{R}$  is the right hand side term of the equation and  $K_t$  is proportional to the eddy viscosity coefficient (for which a parabolic vertical distribution has been assumed). Using equations (16) and (17) a recurrence relation for the  $w_i$  coefficients for each component is obtained:

$$w_{i+1} = \left[ -e^2 r_{i-1} + (\lambda e^2 - K_2 i(i-1) w_{i-1} - i^2 K_1 w_i) \right] \frac{1}{K_0(1+i)i} \quad (18)$$

$i = 1, \dots, M$

in which  $\lambda$  is the corresponding eigen-value coming from the uncoupling of the  $\hat{u} / \hat{v}$  equations.

The solution algorithm starts from  $\frac{d\hat{u}}{dz}(z_b)$  and  $\vec{\hat{u}}(z_b)$  values (given by the BBL model in terms of  $u_{*c}$ ,  $u_{*wc}$ ,  $\delta_m$  and the artificial wave roughness  $K_w$ ) until  $\langle \vec{r}_{tr} \rangle$  is equal to the value given by the external closure submodel. Iterations are performed using  $u_{*c}$  as a degree of freedom until a convergence condition at  $z_{tr}$  is satisfied.

#### 4.2 BBL Parameterization

The main BBL equation to be solved is the momentum equation perpendicular to  $\vec{u}$ , with gives  $u_*(t)$  as a function of  $u_{*c}$ ,  $U_m$  (wave orbital velocity),  $\theta$  (wave phase) and  $\gamma$  (wave-current angle). From the obtained numerical solution the principal BBL variables ( $\delta_m$ ,  $K_w$ ,  $u_{*wc}$  and  $u_{*c}$ ) have been parameterized by means of "simple" algebraic expressions. For illustration purposes only the  $\delta_m$  parameterization is shown here.  $\frac{\delta_m}{K_N}$  is modeled by means of:

$$\frac{\delta_m}{K_N} = \frac{\delta_{90}}{K_N}(\varphi_c, \varphi_a, \gamma = 90^\circ) + \frac{\Delta\delta_\gamma}{K_N}(\varphi_c, \varphi_a, \gamma) \tag{19}$$

$$\varphi_c = \frac{u_m}{u_{*c}}, \varphi_a = \frac{a}{K_N}$$

in which  $a$  is the amplitude of the wave orbital motion and  $K_N$  is the Nikuradse roughness parameter.  $\delta_{90}$  is the boundary layer thickness for waves perpendicular to the current and  $\Delta\delta_\gamma$  is the deviation from the perpendicular case. The resulting  $\delta_m$  is shown in figure 3. As it may be seen,  $\frac{\delta_{90}}{K_N}$  can be modeled by linear expressions at both tails and by an exponential expression in the middle. The deviation,  $\frac{\Delta\delta_\gamma}{K_N}$  is modeled by means of another exponential expression.

The maximum error (with respect to the original numerical results of Fredsøe) of the proposed fit is below 4%. The corresponding error for the parameterization of  $u_{*wc}$  is smaller than 10%.

Fig. 3:  $\delta_m$  parameterization.

5. Closure Submodels

Closure submodels have been obtained from state of art formulations, the main emphasis of this paper being on the numerical model for  $\vec{u}$ . The shear stress at  $z_{tr}$  can be modeled following (De Vriend and Stive 1987) and (Svendsen 1984/85), with an equation which includes the effects of the carrying wave, the roller and a possible free surface boundary layer. Alternatively it can also be modeled using the (Deigaard and Fredsøe 1989) and (Deigaard et al. 1991) equations adapted to a 3D case. These equations, including contributions from the wave motion, the roller and the set up, have been assumed to be valid, in the direction of the wave number vector  $\vec{K}$ , for a horizontally varying problem.

The closure submodel for  $\nu_V$  is, at present:

$$\nu_V(z, x) = \frac{\kappa u_{*c}}{z_{tr}} z (z_{tr} - z) + M \left(\frac{D}{\rho}\right)^{1/3} \frac{z^2}{z_{tr}} \tag{20}$$

With  $D$  the mean rate of wave energy dissipation per unit area and  $M$  a parameter of order  $10^{-2}$ . The first term represents the current-induced eddy viscosity and is similar to the one proposed by Coffey and Nielsen (1984). Very near the bottom this term varies approximately in a linear manner with  $z$ , which is consistent with the linear variation assumed by our BBL model.

The second term (after vertical integration) is similar to previous proposals for the breaking induced eddy viscosity (e.g. De Vriend and Stive 1987, Battjes 1983). The total  $\nu_V$  is parabolic with  $z$ , which is in accordance with the latest experimental information (see figure 4).

Fig. 4: Eddy viscosity Test A-2 Okayasu '89

The resulting expression may be formally written as:

$$\nu_V(\xi) = a + c\xi^2 \tag{21}$$

in which  $\xi$  is a normalized vertical coordinate ranging from 0 (at the actual bottom) to 1 (at the  $z_{tr}$  level).

6. Calibration

At this stage the model is being calibrated for a 2DV flume case, using a very complete set of data from Okayasu (1989) experiments. Figures 5 and 6 depict preliminary computed undertow profiles (corresponding to case A2 of Okayasu 1989 tests). These results have been obtained using measured data instead of external closure submodels, the main aim being the calibration of the numerical solution technique for  $\tilde{u}$ . The list of measured data used in the simulation is the following: wave height, wave period, water depth, trough level, mean velocity and its horizontal gradient, vertical velocity at  $z_{tr}$ , shear stress at  $z_{tr}$  and eddy viscosity values at  $z_{tr}$  and  $z_b$ . The orbital velocity and amplitude near the bottom have been estimated using linear long wave theory.

The next step of the calibration process corresponds to cases with oblique wave incidence for the following geometries: i) cylindrical beach, ii) semicircular bay and iii) longshore-uniform beach with a river mouth. All these test cases have been proposed within the G8M-MAST II Project.

Finally, it is convenient to remark the importance of continuing theoretical and experimental research to improve and "tune" the different closure submodels. The final solution appears to be strongly dependent on these closure relationships.

Fig. 5: Horizontal current velocities Test A-2 Okayasu '89

Table 1: Test case A2

The list of measured data used in the simulation of case A2 is:

type of breaking: plunging

wave height (H) : 7.36 cm , wave period (T) : 1.5 s

water depth (h) : 3.66 cm

trough level (  $z_{tr}$  ) : 2.40 cm

mean velocity (  $\bar{u}$  ) : 4.86 cm/s

horizontal gradient of  $\bar{u}$  (  $\frac{\partial \bar{u}}{\partial z}$  ) : 0.014 1/s

vertical velocity at  $z_{tr}$  (  $w(z_{tr})$  ) : 0.1 cm/s

vertical distribution of  $w(z)$

eddy viscosity at  $z_{tr}$  (  $\nu_t(z_{tr})$  ) : 3.0 cm\*\*2/s

eddy viscosity at  $z_b$  (  $\nu_t(z_b)$  ) : 1.0 cm\*\*2/s

bottom roughness (estimated) (  $K_N$  ) : 1.0 mm.

orbital amplitude (a) or max. free stream velocity (  $Um$  ) (estimated by linear long wave theory) : 24.6 cm/s

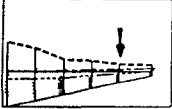

Fig. 6: Measured and computed velocities.

## 7. Discussion and Future Work

**7.1 Discussion:** An economic strategy to combine a 2DH Surf Zone circulation code with a 1DV "profile extraction" model has been established. The use of the current (in the presence of waves) friction velocity,  $u_{*c}$ , as a degree of freedom to solve the apparent over-statement of the problem works well for a  $\nu_V$  corrected by breaking effects at the top of the bottom boundary layer.

The  $\nu_V$  values given by the bottom boundary layer model are well below the experimental values of  $\nu_V$  inside the surf zone. This explains the relatively strong curvature of the  $\hat{u}$  profile right above the bottom boundary layer, which is not very consistent with the experimental data. This means that the  $\nu_V$  increment at  $z_b$  must be larger than the increase given by the bottom boundary layer relationship ( $\nu_V(z_b) = \kappa u_{*c} z_b$ ). This increment is given in the model by the addition the breaking-induced of  $\nu_V$ .

From the standpoint of the numerical solution, the  $\vec{u}$  equation becomes ill-conditioned for very small values of  $\nu_V$ . This is because there is a singularity at  $z_b$  when  $\nu_V(z_b) = 0$ . At this singularity the coefficients of the series expansion become inordinately large. Similar problems also appear with large  $\nu_V$  values near trough level.

The number of terms required in the power series development for  $\hat{u}(z)$ , inside the surf zone, depends on the type of  $z$ -dependence assumed for  $\nu_V$ . The number of terms used is determined by checking that the zero vertical-average condition for  $\vec{u}$  (mass conservation) is accurately satisfied.

The undertow profiles, considered to be more demanding from the standpoint of this model validation, were selected as the first case for calibration. For the  $\hat{v}$  equation (basically the longshore current) the double-logarithm hypothesis at  $z_b$  of the BBL model is expected to hold much more easily (the changes in vertical curvature of  $\hat{v}(z)$  are much smaller).

**7.2 Future work:** With respect to future work there are three main tasks already under way:

- To check the theoretical compatibility between the expressions for  $\langle \vec{\tau}_{ir} \rangle$  and the corresponding equations for the wave-driving terms,  $\vec{W}_i$ .
- To analyze the model sensitivity to the  $\nu_V$  value at  $z_b$  and to obtain  $\nu_V(z)$  closure sub-models which provide a better fit to the observed  $\vec{u}(z)$ .
- To test and improve all external closure sub-models.

The next step is, obviously, to run the model for a true 3D problem, to prove its quasi-3D capabilities. This in spite of the lack of reliable 3D data inside the surf zone.

## 8. Acknowledgements

This work was undertaken as part of the MAST-G6 Coastal Morphodynamics research programme. It was funded jointly by the Programa de Clima Marítimo (PCM-MOPT), Ministerio de E. y C. of Spain and by the Commission of the European Communities D.G.XIII under contract no. MAST-0035-C. Thanks are due to all research staff of LIM-UPC, particularly to Mr. F. Rivero, Mr. M. Coussirat and Mr. J. Flores. The experimental information was kindly facilitated by Dr. A. Okayasu.

## CHAPTER 216

### VERTICAL STRUCTURE OF THE NEARSHORE CURRENT AT DELILAH: MEASURED AND MODELED

Jane McKee Smith<sup>1</sup>, Ib A. Svendsen<sup>2</sup>, and Uday Putrevu<sup>3</sup>

**ABSTRACT:** Comprehensive field measurements were made of the vertical current structure on a barred beach profile at the DELILAH project during October of 1990. The current was measured with five electromagnetic current meters mounted on a mobile sled which was stationed at three to eight cross-shore positions. The incident directional wave spectra, bathymetry, tide, wind, and cross-shore wave transformation were also measured. A numerical model was developed to calculate the random wave transformation based on the model of Dally, Dean, and Dalrymple (1985) (Larson and Kraus 1991) and the local vertical current structure (Putrevu and Svendsen 1991). The model predicted the shape of the current profiles well with a root-mean-square error in velocity of 5.9 cm/sec. The model tended to underpredict the velocity over the bar crest.

### INTRODUCTION

Predicting the vertical structure of the cross-shore current is a critical step to advancing the modeling of beach evolution, especially the response of the beach profile to storms, the post-storm profile recovery, and the development and movement of bars. The cross-shore currents have also been shown to be important in describing the mixing for longshore currents (Putrevu and Svendsen 1992, Svendsen and Putrevu 1992b). The lack of high-quality field measurements of the vertical current structure has been a hinderance to the development and validation of cross-shore current models.

In October of 1990, a comprehensive field experiment was performed at the U.S. Army Engineer Waterways Experiment Station, Coastal Engineering Research Center

(CERC), Field Research Facility (FRF) in Duck, NC, to measure the wind- and wave-forced three-dimensional nearshore hydrodynamics. The DELILAH (Duck Experiment on Low-frequency and Incident-band Longshore and Across-shore Hydrodynamics) experiment was a cooperative project involving researchers from CERC, Naval Postgraduate School, Naval Research Lab, Oregon State University, Quest Integrated, Inc., Scripps Institution of Oceanography, University of California at Santa Cruz, and Washington State University.

The hydrodynamic data collected at DELILAH were used to refine and verify a numerical model developed to calculate the vertical variation of the cross-shore current. The purpose of this paper is to describe the DELILAH field measurements and to describe the application of these data to evaluate the numerical model.

### DELILAH FIELD PROJECT

The core of the DELILAH field project was a fixed array of 19 electromagnetic current meters deployed in one cross-shore array and two longshore arrays to the north of the FRF pier. The cross-shore array consisted of nine sensor positions, extending from the shoreline to 350 m offshore (4-m depth). A pressure gage was deployed along with a current meter at each position in the cross-shore array. The longshore arrays were positioned approximately on the bar crest and in the trough of the beach profile. The longshore arrays were approximately 200 m long.

The bathymetry adjacent to the current meter arrays (340 m by 600 m area) was surveyed daily during the experiment. Accurate surveying was accomplished with a special self-contained vehicle, the CRAB (Coastal Research Amphibious Buggy), that drove along survey transects (Birkemeier and Mason 1984). The position and elevation of the CRAB was determined with a Geodimeter auto-tracking electronic total station. Fig. 1 shows an example of the bathymetry surveyed on 19 October 1990. The bathymetry was generally homogeneous in the longshore direction during the cross-shore current measurements, with a linear bar approximately 100 m offshore. Offshore directional wave spectra were measured with an array of sixteen pressure gages at the 8-m depth contour. Spectra were measured every 3 hours during the experiment and provide offshore boundary conditions for wave forcing of the current model. Fig. 2 shows the two-dimensional spectrum measured on 19 October 1990 at 1300. In Fig. 2, the x-axis is the frequency,  $f$ , the y-axis is the wave direction (measured counter-clockwise from shore normal),  $\theta$ , and the z-axis is the energy density,  $S$ . Over-water winds and tidal elevation were measured at the FRF pier.

### CROSS-SHORE CURRENT MEASUREMENTS

The vertical structure of the current was measured with a vertical array of five electromagnetic current meters mounted on a mobile sled. The meters were mounted at elevations 0.35 m, 0.6 m, 1.0 m, 1.35 m, and 1.75 m above the bed on a vertically sloping beam. The beam was parallel to the shoreline, so the meters were aligned in the cross-shore. The meters were spread over a longshore distance of approximately 3.5 m. The sled was always deployed so that the lower end of the beam was in the updrift direction of the longshore current to reduce interference of the flow. A common timing pulse was used for all the current meters to reduce interference between instruments for this close proximity deployment. The meters measured the longshore and cross-shore components of the

Figure 1. Bathymetry for 19 October 1990.

Figure 2. Two-dimensional spectrum for 19 October 1990.

current. The sled was also instrumented with a pressure gage, a resistance wave staff, and an anemometer.

During the experiment, the sled was towed offshore of the breaker zone by the CRAB to a depth of approximately 3 m. The sled was then pulled back to shore with a fork lift in steps of 20 m. At each sled position, data were collected for 34 minutes. The collection period of 34 minutes was selected to balance the competing needs for long time series for stable statistics and short total time for the sled deployment to ensure stationarity of the incident waves. All current data presented are 34 minute averages. The data were telemetered to shore for real-time data quality checking. Three to eight cross-shore positions were occupied during each of eight deployments. The position and orientation of the sled were recorded using an electronic total station which sighted two prisms located on the sled mast.

The sled was deployed near the cross-shore array of current meters and pressure gages. The fixed array gages provided background data on the horizontal structure of the hydrodynamics and on the stationarity of the waves and currents. Fig. 3 shows an example of the vertical structure of the cross-shore current measured during DELILAH. The vectors in Fig. 3 represent cross-shore current magnitude and direction measured at six sled positions on 19 October 1990. The solid lines in Fig. 3 represent the survey datum and bottom profile ( $d$ ). Sled measurements were made during the final six days of the DELILAH experiment. Incident waves during these days provided a variety of conditions with wave heights of 0.5 to 1.5 m, peak spectral periods of 5 to 15 sec, wind speeds of 5 to 15 m/sec, and wave directions both north and south of shorenormal. The maximum time-averaged current velocities exceeded 0.5 m/sec during measurements with the sled.

Figure 3. Cross-shore current velocities measured during DELILAH (19 Oct 1990).

## NUMERICAL MODEL

The numerical model consists of two parts, a random wave transformation model and a model of the cross-shore flow. The wave transformation model provides the cross-shore gradient in wave height and the cross-shore variation in the mean water level which are the driving forces of the cross-shore flow. The models assume longshore homogeneity, linear wave theory, and steady-state wave forcing. Wave-current and wave-wave interactions and long wave generation are neglected.

### Wave Transformation

The random wave transformation model is based on the decay and reformation model of Dally, Dean, and Dalrymple (1985) as applied to random waves by Larson and Kraus (1991). The Dally, Dean, and Dalrymple model has been shown to be less accurate than other models for predicting wave setup (Svendsen and Putrevu 1992a), the main driving force for the undertow, but it was chosen because it includes a mechanism for breaking waves to reform in the trough shoreward of the longshore bar. The input wave parameters are the root-mean-square wave height ( $H_{rms}$ ), peak wave period, and peak wave direction measured at the linear array in a depth of 8 m. One hundred wave heights were randomly chosen from a Rayleigh distribution specified by  $H_{rms}$ . Each of the one hundred wave heights was transformed across the beach profile, assuming the same period and incident direction for each wave, according to

$$\frac{d(F \cos \theta)}{dx} = \frac{\kappa}{d} (F - F_s) \quad (1)$$

where

- $F = 0.125 \rho g H^2 C_g$ , energy flux
- $\rho$  = water density
- $g$  = gravitational acceleration
- $H$  = individual wave height
- $C_g$  = group velocity
- $\theta$  = wave direction, relative to shore normal
- $x$  = cross-shore coordinate, positive seaward
- $d$  = total water depth (still-water plus setup)
- $F_s$  = stable energy flux associated with the stable wave height,  $H_s$
- $H_s = \Gamma d$ , with  $\Gamma = 0.4$  (Dally, Dean, and Dalrymple 1985)

The parameter  $\kappa$  is zero seaward of wave breaking, with breaking specified by a height to depth ratio less than 0.78. At incipient wave breaking,  $\kappa$  is set to 0.15. Wave breaking ceases when the broken height is less than  $H_s$ , and  $\kappa$  is reset to zero. The wave directions are determined by Snell's law. The wave parameters were calculated at a 1-m cross-shore spaced grid using an explicit finite difference solution. The  $H_{rms}$  was calculated at each grid point from the 100 individual wave heights.

The wave setup,  $\bar{\eta}$ , is calculated from the time- and depth-averaged cross-shore momentum equation

$$\rho g(h + \bar{\eta}) \frac{d\bar{\eta}}{dx} = -\frac{dS_{xx}}{dx} - \rho_a C_w W W_x \quad (2)$$

where

- $h$  = still-water depth (including the tide)
- $\rho_a$  = air density
- $C_w$  = wind drag coefficient
- $W$  = wind speed
- $W_x$  = cross-shore component of the wind velocity
- $S_{xx}$  = cross-shore component of radiation stress

The two driving forces of the setup are the gradient in radiation stress and the cross-shore wind stress. The radiation stress is calculated using linear wave theory (Longuet-Higgins and Stewart 1964) based on  $H_{rms}$ . Considering the simplifying assumptions used to represent the random wave field, a more sophisticated evaluation of the radiation stress (Svendsen and Putrevu 1992a) is not justified. The wind drag coefficient given by the WAMDI Group (1988) is adopted in the model ( $C_w = .0012875$  for  $W < 7.5$  m/sec;  $C_w = 0.0008 + 0.000065 W$  for  $W > 7.5$  m/sec). The bed shear stress is known to be small and is neglected in Eq. 2. One iteration was required between the calculation of the wave height transformation and the wave setup.

### The Cross-shore Current

The vertical variation of the current is modeled with a three-layer approach (Hansen and Svendsen 1984; Stive and de Vriend 1987; Svendsen and Hansen 1988). The velocity distribution in the central layer is calculated as a local solution of the depth-dependent, cross-shore momentum equation with the surface and lower layers contributing boundary conditions. The central layer extends from the bottom boundary layer to the trough level. The lower layer, the bottom boundary layer, relates the near bottom current velocity to the mean bottom stress (Svendsen and Putrevu 1990). The upper layer contributes the mass flux which is balanced by the undertow in the central layer. In the present application, it is assumed that no net cross-shore flow exists, i.e., the mass flux above the trough balances the undertow. Forcing for the vertical variation includes gradients in radiation stress, mean current, and setup. The horizontal gradient terms in the model are calculated from the depth-integrated, one-dimensional model described above.

The vertical current structure is calculated from a double integration of the depth-dependent, cross-shore momentum equation (Putrevu and Svendsen 1991)

$$U(\zeta) = U_b + \alpha \frac{\zeta^2}{2\nu_{tz}} + \frac{\tau_{bx}\zeta}{\rho\nu_{tz}} \quad (3)$$

where

- $\zeta$  = vertical coordinate, measured positive from the bottom
- $U$  = cross-shore velocity at elevation  $\zeta$

- $\tau_{bx}$  = bottom stress (Eq. 4)
- $U_b$  = bottom velocity (Eq. 5)
- $\alpha$  = driving force for the undertow (Eq. 6)
- $\nu_z$  = eddy viscosity (Eq. 8)

In deriving Eq. 3 both  $\alpha$  and  $\nu_z$  have been assumed constant over depth. The bottom boundary condition includes the bottom stress

$$\tau_{bx} = \rho \frac{2}{\pi} f_w u_0 U_b \tag{4}$$

where

- $f_w$  = bottom friction factor
- $u_0$  = wave orbital velocity at the bottom

and the bottom velocity. The bottom velocity is determined from the depth integration of Eq. 3 with Eq. 4 substituted for the bottom stress

$$U_b = \frac{\bar{U} - \frac{\alpha d_t^2}{6 \nu_{tz}}}{1 + \frac{f_w d_t u_0}{2 \pi \nu_{tz}}} \tag{5}$$

where

- $d_t$  = depth to trough level
- $\bar{U}$  = mean undertow velocity (Eq. 7)

The driving force in Eqs. 3 and 5 is given by

$$\alpha = g \frac{d\bar{\eta}}{dx} + \bar{U} \frac{d\bar{U}}{dx} + u_w \frac{du_w}{dx} + \frac{\rho_a}{\rho} \frac{C_w W W_x}{d_t} \tag{6}$$

where  $u_w$  is the depth-averaged wave velocity and  $\rho_a$  is the density of air. The boundary condition from the upper layer is the mass transport above the trough elevation, which balances the undertow. The mass transport is proportional to  $CH^2/d$ , where  $C$  is the wave celerity, and the constant of proportionality was found to be approximately -0.3 based on the undertow measurements. The mean undertow in Eq. 5 is given by

$$\bar{U} = \frac{0.3 \sqrt{g(h + \bar{\eta})} H^2 \cos \theta}{(h + \bar{\eta})^2} \tag{7}$$

In the numerical computations we have used the same eddy viscosity at all depths, given by

$$v_{rz} = 0.05 \sim 0.01 \sqrt{g(h + \bar{\eta})_b (h + \bar{\eta})_b} \quad (8)$$

where the subscript  $b$  indicates incipient breaking conditions. In laboratory experiments on a plane beach,  $v_z$  has been found to vary as  $h\sqrt{g\bar{h}}$ . The simplification of constant  $v_z$  is chosen because the depth over the region of the DELILAH measurements varies only between 1.2 and 2.2 m, and little information is available about the variation of  $v_z$  under field conditions.

## MODEL RESULTS

The model was applied to the 8 cases of DELILAH sled data. The results from 3 cases are shown in Figs. 4 through 9. These cases were selected because they cover a variety of conditions with the largest number of sled positions. These cases are typical of the conditions and measurements during the final week of DELILAH. Table 1 summarizes the input conditions for the cases shown in Figs. 4 through 9. The wind ( $\phi$ ) and wave directions are measured counter-clockwise from shore normal. The input peak wave direction,  $\theta$ , and peak spectral period,  $T_p$ , were measured at the 8-m array. The peak wave parameters best represent the dominant wave characteristics. Fig. 2 shows considerable spread in the directional distribution of wave energy, which could strongly influence longshore currents, but has less effect on cross-shore currents. The input wave height was taken from the most seaward of the nine nearshore pressure gages (4-m depth), and the height was inversely refracted and shoaled to the 8-m depth to correspond to the wave direction and period inputs. The height measured at the 8-m array caused a 15% overprediction of the wave height at the most seaward pressure gage, which may be attributable to the use of linear refraction and shoaling in the model. The tide and wind measurements were made at the FRF pier and are averaged values over the sled deployment. For these cases, the sled was deployed spanning low tide to minimize the effect of varying tide elevation.

Table 1. Model input conditions for sample results.

Date	Time	$H_{rms}$ (m)	$\theta$ (deg)	$T_p$ (sec)	Tide (m)	$W$ (m/s)	$\phi$ (deg)
10/17	1000	0.54	-15.0	9.7	-0.47	7.8	130.5
10/18	1100	0.57	-43.0	5.6	-0.62	11.9	79.7
10/19	1200	0.65	24.0	7.0	-0.48	9.1	-51.9

The model results are compared to the field measurements in Figs. 4, 6, and 8 for the cases listed in Table 1. The figures show the measured wave height from the cross-shore array (x), calculated wave height (solid line), calculated setup (chain-dot line),

measured cross-shore current from the sled (vectors), and the calculated cross-shore current at the sled positions. Figs. 5, 7, and 9 show the calculated cross-shore current at 10-m intervals to show the cross-shore variation of the undertow profile. Offshore of the breaker zone, the profiles are fairly uniform over depth with a small increase in the offshore velocity near the wave trough level. In the region of rapid wave decay, on the bar crest, the profiles show a characteristic parabolic shape with highest velocities near the bed and smaller velocities at the wave trough. Shoreward of the bar, the waves have reformed and the current profiles are uniform over depth. The cross-shore velocities are low shoreward of the bar. The waves break again on the steep foreshore, and the velocity profiles are similar to those on the bar.

For all cases, the bottom friction factor was set to a constant value of 0.01 and the eddy viscosity to a value of 0.05. The model is relatively insensitive to value of the bottom friction factor, but the shape of the undertow profiles is sensitive to the value of eddy viscosity. Theoretically, the value of the eddy viscosity should be lower in regions of low turbulence (no wave breaking) and higher in regions of intense turbulence (breaker zone), but since the relationship between eddy viscosity and the model parameters is not well known, a constant value was applied. Although the wind speeds were significant during the measurements (8 to 12 m/sec), the wind had very little influence on the results. For the three cases listed in Table 1, the maximum difference in undertow velocity between with- and without-wind simulations was 0.005 m/sec and the root-mean-square (RMS) difference was 0.0012 m/sec.

The RMS error in the cross-shore current results for the 3 cases shown was 5.9 cm/sec. The errors were smallest offshore of the crest of the bar. In the bathymetry trough, the measured velocities were generally 0 to 5 cm/sec, and the RMS error was of the same order. This is not surprising since the low velocities are near the accuracy of the instruments and are susceptible to contamination from the longshore currents which are strong in the trough. The largest RMS errors occurred on the top of the bar (3 to 15 cm/sec), where the model tended to underpredict the measurements, although the model predicted the shape of the undertow profile well. The model results (Figs. 5, 7, and 9) show the maximum undertow velocities just seaward of the crest of the bar, while the measurements show the maximum velocities at the crest of the bar. Errors in the calculation of the wave height may contribute to the underprediction of the undertow at the bar crest (errors in wave height are magnified by squaring the wave height to calculate radiation stress). Also, previous laboratory experiments have shown a shoreward shift in the initiation of setup (the driving force in the model) in the transition region of breaking waves (Svendsen 1984; Roelvink and Stive 1989). This same effect may account for the underprediction of the undertow at the bar crest. Unfortunately, the measurements are not dense enough in the region of the bar crest to resolve this issue.

## CONCLUSIONS

Comprehensive measurements of the vertical current structure and the wave and wind forcing were made during the DELILAH field project in October of 1990 on a barred beach bathymetry. The measurements show strong offshore velocities over the bar (0.5 m/sec), and vertical structure of the current was generally parabolic. In the bathymetry trough, the offshore current was weak (0 to 0.05 m/sec) and the structure was uniform over depth. Offshore of the bar, the current was fairly uniform over depth (0.10 to 0.15 m/sec)

to 0.15 m/sec) with a small increase in velocity near the wave trough.

The numerical model developed to calculate the cross-shore (1-D) random wave transformation and vertical current structure compared well with the measurements. The RMS error in prediction of the current was 5.9 cm/sec. The model represented the shape of the vertical current structure well, but tended to underpredict the current magnitude at the bar crest.

## ACKNOWLEDGMENTS

The authors would like to acknowledge the team that designed and constructed the instrument sled for DELILAH: Messrs. Kent Hathaway, William Grogg, and Eugene Bichner (CERC) and Dr. Edward Thornton and Mr. Robert Wyland (Naval Postgraduate School). Dr. Robert Guza (Scripps Institution of Oceanography) provided useful insight on the field calibration of current meters which was greatly appreciated. The research presented in this paper was conducted under the Nearshore Waves and Currents work unit, Coastal Flooding and Storm Protection Program, by the US Army Engineer Waterways Experiment Station, Coastal Engineering Research Center. Permission to publish this paper was granted by the Office, Chief of Engineers.

## CHAPTER 217

### A REVIEW OF WAVE/CURRENT-INDUCED SCOUR AROUND PIPELINES

B.M. Sumer<sup>1</sup> and J. Fredsøe<sup>1</sup>

#### ABSTRACT

A comprehensive review is presented of scour around pipelines in the case of non-cohesive sediment. The review is organized in four main sections, namely the two-dimensional scour, the three-dimensional scour, the effect of scour on forces on and vibrations of pipelines and the mathematical modelling of scour process. Over sixty works were included in the review.

#### 1. INTRODUCTION

Marine pipelines are used for disposal of industrial and municipal wastewater into the sea, for cooling water in nuclear power plants, and for the transportation of gas and crude oil from offshore platforms. Marine cables, on the other hand, are increasingly used for communication.

Design of marine pipelines and marine cables with regard to their stability is a rather complicated problem. One of the factors which needs to be taken into consideration in the design process is the scour around the pipeline.

The scour around the pipeline is caused by the very presence of the pipeline itself. There are numerous aspects of the problem which need to be addressed during the design process, such as the formation of spans (particularly in determining the maximum extent of spans as well as timing of any remedial action), the self-burial of pipelines, the effect of self-burial on the pipeline stability, just to give a few examples.

A large volume of knowledge has been accumulated on the subject during the last decade or so, as a result of intensive research activities in countries such as Holland, Norway, U.K., U.S.A., Denmark and several others. The purpose of the present paper is to review this research work. Only the non-cohesive sediment bed is considered.

## 2. TWO-DIMENSIONAL SCOUR

### Onset of scour

Consider a pipeline which is laid on an erodible bed. Assume that the bed, soil and flow conditions are the same along the length of the pipe, i.e. the conditions are strictly two-dimensional. If the initial embedment of the pipeline is not very large and if the flow around the pipe is sufficiently strong, scour may break out underneath the pipe. The stage at which the scour breaks out is called the onset of scour.

The onset of scour is directly related to the seepage flow which occurs in the sand beneath the pipe, caused by the pressure difference between the upstream and the downstream of the pipe (Fig. 1c). When the flow velocity is gradually increased, a critical point is approached where the discharge of the seepage flow is increased more rapidly than the driving pressure difference dictates. Simultaneously the surface of the sand at the immediate downstream of the pipe rises and eventually a mixture of sand and water breaks through the space underneath the pipe. This phenomenon is called piping and is well known in soil mechanics in hydraulic structures such as dams, cofferdams etc. (Terzaghi, 1948).

The conditions under which the onset of scour occurs below pipelines have been studied by Mao (1986) and Chiew (1990) in steady currents. Mao described the role of separation vortices that form in front and at the rear of the pipe in the process of the onset of scour. Also, he discussed the seepage flow underneath the pipe in relation to the onset of scour. The latter has been further elaborated by Chiew. Chiew further linked the onset of scour to the phenomenon of piping.

In the case of waves, the piping conditions are created underneath the pipe in the same way as in steady currents. The action is immediate. However, if the conditions are such that the critical condition is not attained immediately, then the action of separation vortices will become important to create scour more early in the wave case. Sumer & Fredsøe (1991) has linked the onset of scour in waves to the latter through the Keulegan-Carpenter number and expressed the critical condition for the onset of scour by the following empirical equation

$$\frac{e_{cr}}{D} = 0.1 \ln(KC) \quad (1)$$

in which  $e_{cr}$  = the critical embedment of the pipe beyond which no scour occurs,  $D$  = the pipe diameter and  $KC$  = the Keulegan-Carpenter number defined by

$$KC = \frac{U_m T_w}{D} \quad (2)$$

in which  $U_m$  = the maximum value of the orbital velocity of water particles at the bed,  $T_w$  = the wave period. For a sinusoidal motion of water particles  $KC$  will obviously be

$$KC = \frac{2\pi a}{D} \quad (3)$$

in which  $a$  = the amplitude of the orbital motion of water particles at the bed.

### Time development of scour

The onset of scour is followed by the stage of so-called *tunnel erosion* (Leeuwenstein et al., 1985; Hansen et al., 1986). Sumer et al. (1990) present data regarding bed shear stress just under the pipe corresponding to this stage. The data indicate that the bed shear stress is

increased by a factor of 4 with respect to its undisturbed value, resulting in an increase in the sediment transport rate of a factor of 8. This explains why the scour below the pipe occurs so fast and so violently during the tunnel erosion.

The tunnel erosion is followed by the stage called *lee-wake erosion*. In this stage, the scour downstream of the pipe is governed by the lee-wake of the pipe. Sumer et al. (1988b) made an investigation of the effect of lee-wake on scour. This work demonstrates that 1) vortex shedding is present in the lee-wake from rather early stages of the scouring process, and 2) the scour downstream of the pipe is eventually governed by this organized flow.

Fig. 2 shows a typical example where the time development of scour can be seen. The mild slope of the downstream portion of the scour profile is due to the action of the pipe's lee-wake.

As seen from the figure, the scour process attains an equilibrium stage where scouring below the pipe comes to an end. When this stage is reached, the sediment transport will be the same at all sections over the reach of the scour hole, and therefore the amount of sediment which enters the scour hole will obviously be identical to that leaving the scour hole.

Fig. 3 shows the results of Jensen et al.'s (1990) velocity measurements very close to the bed at different stages of the scour process. The figure shows that, while the velocity below the pipe is increased tremendously at the initial stage of the scour process (Profile II), it eventually becomes practically identical to the undisturbed flow velocity, as the scour approaches towards its equilibrium stage (Profile V).

The depth of the scour hole is probably the most significant quantity. Normally, it is taken as the depth of the scour hole just below the pipe.

The scour depth develops towards the fully-developed equilibrium stage through a transitional period, as illustrated in Fig. 4 for a pipe rigidly placed on a bed with initially zero gap. The depth corresponding to the fully-developed stage is called the *equilibrium scour depth*. It is also seen from the figure that a certain period of time must be elapsed for a substantial amount of scour to develop. This time is called the *time scale* of scour process.

The equilibrium scour depth, as well as the time scale of the scour process, constitute two major parameters in scour studies. The remaining part of this section will focus on these two parameters.

### Equilibrium scour depth

Scour depth has been studied extensively in the case of *steady currents* (Chao & Hennessy (1972), Kjeldsen et al. (1973), Littlejohns (1977), Herbich (1981), Bijker & Leeuwenstein (1984), Lucassen (1984), Leeuwenstein et al. (1985), Herbich (1985), Herbich et al. (1984), Bijker (1986), Ibrahim & Nalluri (1986), Mao (1986), Kristiansen (1988) and Kristiansen & Tørum (1989)).

Kjeldsen et al. (1973) was the first to conduct scour experiments under controlled conditions. The experiments were done in live-bed situations. Kjeldsen et al.'s data indicated that the equilibrium scour depth can be expressed by the following relation:

$$S = 0.972 \left( \frac{V^2}{2g} \right)^{0.2} D^{0.8} \quad (4)$$

in which  $V$  = the mean flow velocity. This relation suggests that

$$\frac{S}{D} \propto \theta^{0.2} \quad (5)$$

in which  $\theta$  = the Shields parameter defined by

$$\theta = \frac{U_f^2}{g(s-1)d} \tag{6}$$

in which  $U_f$  = the bed friction velocity, corresponding to the undisturbed flow,  $g$  = the acceleration due to gravity,  $s$  = the specific gravity of sediment grains and  $d$  = the grain size.

Eq. 5 implies that the normalized scour depth  $S/D$  is only a weak function of  $\theta$ . We shall return to this point later in this section.

The exact flow picture created by the presence of the pipe depends on the following quantities: the pipe diameter  $D$ , the flow velocity  $V$ , the kinematic viscosity of the fluid  $\nu$ , the pipe roughness  $k$ , and the grain diameter  $d$  of the bed material. From these quantities, the dimensionless equilibrium scour depth can be found to depend on the following parameters:

$$\frac{S}{D} = \frac{S}{D} (k^*, R, \theta) \tag{7}$$

in which  $k^* = k/D$  is the relative roughness,  $R = VD/\nu$  is the pipe Reynolds number.

Of the three parameters that appear in Eq. 7, the influence of  $k^*$  and the Reynolds number appears through their effect on the downstream flow of the pipe. If the pipe is hydraulically rough, the wake flow is almost unaffected by the Reynolds number, while for a hydraulically smooth pipe some influence of the Reynolds number is expected in the downstream vortex-shedding pattern. Fig. 5 shows a plot of the data by Kjeldsen et al. (1973), Lucassen (1984), Mao (1986) and Kristiansen (1988) on the scour depth below smooth pipes exposed to a current. It is seen in the figure that there is some weak influence of the Reynolds number on the scour depth, because a slight decrease in  $S$  occurs for Reynolds number around  $10^5 - 3 \times 10^5$ . For a free circular cylinder, this coincides with the transition from subcritical to supercritical flow (Schewe (1983), Sumer and Fredsøe (1988)). In this transition region, the vortex shedding becomes less pronounced, which might lead to a smaller lee-wake erosion and hence less scour depth.

Fig. 5

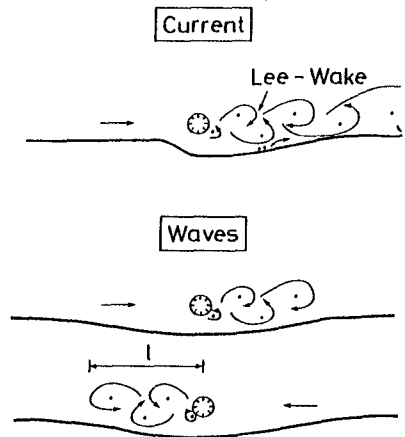

Fig. 6

As far as the influence of  $\theta$  is concerned, this must be examined in two different categories: the clear-water case, where the sediment far from the pipe is not moving ( $\theta < \theta_{cr}$ ), and the live-bed case, where sediment is transported far from the pipe ( $\theta > \theta_{cr}$ ), in which  $\theta_{cr}$  = the threshold value of  $\theta$  for sediment motion. In the clear water case, the variation in scour depth with  $\theta$  is more pronounced: as  $S/D$  increases from 0 at very small  $\theta$ -values up to values of 0.4 - 1.0 when the  $\theta$ -value approaches the live-bed case. However, when the live-bed case is obtained, very small variation in  $S/D$  is observed, as seen from Fig. 5, as has already been pointed out in conjunction with Kjeldsen et al.'s empirical equation (Eqs. 4 and 5). Ignoring this weak variation it may be suggested that, for all practical purposes, the following relation may be used as the design equation, to predict the equilibrium scour depth in steady currents

$$S/D = 0.6 \pm 0.1 \quad (8)$$

in which the first figure on the right hand side of the equation is the mean of the data plotted in Fig. 5, and the second is the standard deviation.

Regarding the scour in *tidal flows and waves*, the main difference between this case and the steady case is that the downstream-formed wake system now occurs on both sides of the pipeline. Here the strong lee-wake erosion, which gives a much more gentle downstream slope, occurs on both sides of the pipe (Fig. 6). The formation and extension of the wake pattern in oscillatory motion is governed by KC number. Therefore it must be expected that there exists a correlation between the equilibrium scour depth and KC number. Sumer & Fredsøe (1990) demonstrated that this is indeed the case. Based on their experimental data and Lucassen's (1984) data (which were recast in terms of KC number), the following empirical equation was established, relating the equilibrium scour depth to KC number for the live-bed situation ( $\theta > \theta_{cr}$ ) and for a pipe initially in contact with the bed:

$$S/D = 0.1\sqrt{KC} \quad (9)$$

The data suggests that this equation is valid in a very broad range of KC, namely from KC = 2 to about 300. This relation has been confirmed later by Gökçe & Günbak's (1991) experiments and Hansen's (1992) numerical-model results.

Sumer & Fredsøe (1990) discussed also the effect of Shields parameter as well as Re-number dependence plus the effect of the presence of ripples in the wave-flume tests.

Generally, the equations given in the preceding, namely Eqs. 4 or 8 and Eq. 9 may be used as design equations. However, there are several other factors which may influence the scour depth. Of these factors, the following may be mentioned: The pipe position in vertical (Leeuwenstein et al. (1985), Mao (1986), Sumer & Fredsøe (1990)), the roughness of pipe surface (Sumer & Fredsøe (1990)), the angle of attack of the flow (Mao (1988), Hansen (1992)), the current in combined waves and current (Hansen (1992)), the case of multiple pipelines (Westerhorstmann et al. (1992)), the armoring of bed sediment (Sidek & Ibrahim (1992)), vibrations of the pipe (Sumer et al. (1988a)) and the Shields parameter in clear-water scour (Mao (1986), Hansen (1992)).

### Time scale

As mentioned previously, the scour depth develops towards its equilibrium stage through a transitional period (Fig. 4), which can be represented by the following relation:

$$S_t = S \left( 1 - \exp\left(-\frac{t}{T}\right) \right) \quad (10)$$

The quantity T is defined as the time scale of the scour process and represents the time period during which a substantial scour develops.

Fredsøe et al. (1992) has made a study of this time scale in both steady currents and waves. They found that the time scale normalized as in the following

$$T^* = \frac{[g(s-1)d^3]^{1/2}}{D^2} T \quad (11)$$

is a function of  $\theta$ , the Shields parameter. Based on their own data as well as the data from Kjeldsen et al. (1973) and Mao (1986), they found that the relation between  $T^*$  and  $\theta$  can be represented by the following simple expression

$$T^* = \frac{1}{50} \theta^{-5/3} \quad (12)$$

for the live bed situation ( $\theta > \theta_{cr}$ ) and for a pipe with an initially zero gap. This equation was found to be valid for both steady currents and waves. Fredsøe et al. (1992) attributed this to the fact that the lee-wake scour -- the key element in the wave induced scour -- is insignificant at the initial stage of the scour process. Therefore the time scale is unable to differentiate whether the flow is a steady-current or a wave-induced flow. In Fredsøe et al. (1992) study, also the effect of change in wave climate has been investigated.

### 3. THREE-DIMENSIONAL SCOUR

#### General description

Two-dimensional scour below pipelines, as observed in two-dimensional flume test with a fixed pipe, must in the field turn to three-dimensional scour picture as sketched in Fig. 7 in order to obtain support for the pipeline. Hereby, a three-dimensional scour pattern arises as sketched in Figs. 7a and 7b: a number of scour holes is interrupted by a stretch, where the pipeline is partially or totally buried.

The scour picture in the free-span areas (Section B-B) is two-dimensional, while at other places, particularly in the neighbourhood of span shoulders (Section A-A), it is three-dimensional. See Fig. 8 for a definition sketch.

At Section A-A, the pipe sinks in the soil. This is due to the combined action of three-dimensional scour and soil failure, as will be explained in the following section.

At Section B-B, on the other hand, the scour, after it breaks out, spreads along the length of the pipeline. When the scour hole becomes sufficiently long, the pipe begins to sag into its naturally created trench hole. This may continue until the pipe comes into the neighbourhood of the bottom, which eventually brings an end to the scouring process. From this moment onwards, the backfilling process starts, and later on, the pipeline may partially or fully become covered by sand (self-burial).

#### Rate of spread of scour along the pipe

The rate of spread of the three-dimensional scour along the pipe is one of the major parameters. Research dealing with this quantity is not extensive. Gravesen & Fredsøe (1983) gave an account of how to deal with the problem when extending the results of model experiments to the nature. Also, various accounts of the spreading process have been given in Leeuwenstein (1985) and Bernetti et al. (1990). Hansen et al. (1991), on the other hand, has presented a semi-empirical model of the process, which can predict the rate of spread of scour along the pipe.

In the case when the current approaches the pipe at an oblique angle, the free span will migrate. This aspect has been investigated by Hansen et al. (1991).

Fig. 7

Fig. 8

Fig. 9

Fig. 10

Effect of pipe sagging on scour

Normally the time scale of span development,  $T_h$ , is large compared with  $T$ , the time scale of the two-dimensional scour described in the preceding section, (Eq. 10). Here  $T_h$  = the time period during which a substantial span length develops to produce some measurable deflection in the middle of the span. The time scales  $T_h$  and  $T$  may be estimated using the relations given in Hansen et al. (1991) and Fredsøe et al. (1992) (Eq. 12), respectively. While  $T_h$  may be in the order of magnitude of days,  $T$  is only in the order of magnitude of hours. This means that the pipe normally begins to sag long after the two-dimensional scour has attained its equilibrium stage. However, the sagging may influence the final scour profile and indeed the final scour depth. Effect of pipe sagging on scour has been investigated by various authors, employing two-dimensional laboratory models (Leeuwenstein et al. (1985), Fredsøe et al. (1988), Gökçe & Günbak (1991)). Backfilling and self-burial in the free-span areas has also been investigated by employing the same two-dimensional models in some of these studies.

Length of free spans

The length of free spans is also of engineering interest. Fig. 9 shows the probability density function of span length obtained by Orgill et al. (1992), based on some limited field data which,

the authors point out, is very site-specific. The figure shows that there is considerable variation in  $L/D$ , ranging from 10 to as much as 100 with the mean value of about 20.

Various authors have considered various factors with regard to the assessment of scour-induced free-span lengths (Fredsoe et al. (1988), Brushi et al. (1986), Eide et al. (1988), Bernetti et al. (1990), Bruschi et al. (1991) and Bijker et al. (1992)). In Fredsoe et al. (1988) work, the free-span length has been related to the so-called stiffness-length of the pipe.

#### Pipe sinking at span shoulders

Pipe sinking is caused by soil failure, as has already been pointed out in the preceding paragraphs. The soil failure itself may be due to a general shear failure or it may be due to liquefaction.

Sumer & Fredsoe (1993) made an investigation of sinking of pipelines at span shoulders employing a rigid pipe in the laboratory in a current flume. Sumer & Fredsoe's investigation was directed towards the understanding of the sinking process of a pipeline in the soil caused by a general shear failure. A simple formula adopted from soil mechanics regarding the bearing capacity of soil was found to give a satisfactory result in relation to the sinking of the pipe at the span shoulder.

The subject liquefaction in relation to pipelines laid on the sea-bed has been investigated by Silvis (1990). Bijker et al. (1991) gives a brief account of the liquefaction potential of seabed with regard to the presence of laid pipelines.

#### Stimulated self-burial

As has been seen in the preceding paragraphs, pipelines laid on the seabed may bury themselves in the seabed by various mechanisms. This may occur in the free-span areas where the pipe sags into its scour hole and is covered by sand upon the termination of the sagging process. It may also occur at the span shoulders where the pipe sinks in the sand.

After the discovery that a few months after a 12" pipeline (laid in 1980 on the North Sea bottom in the Dutch sector) caused the formation of a trench, 3 pipe diameter deep and then it gradually sank in this trench and buried itself with the thickness of the covering sand layer of more than 30 cm (Kroezen et al. (1982)), the Delft Hydraulic Laboratory has launched an extensive series of research to investigate the feasibility of a method, called stimulated self-burial, to exploit the self-burial potential (Hulsbergen (1984), Hulsbergen (1986), Hulsbergen & Bijker (1989)). This is particularly important in the circumstances where pipelines would not bury themselves fast enough or they would not at all bury themselves. The idea is to stimulate a controlled local scour by using fins (called spoiler) attached to the pipeline as sketched in Fig. 10. From the research carried out by the Delft Hydraulics, it was found that, firstly, the spoiler reduces the time necessary to accomplish a given embedment level by a factor of ten with respect to a plain pipe, and secondly, the final depth of burial is larger than in the case of plain pipelines. The same effects have been observed also in waves (Gökçe & Günbak (1991)).

#### 4. EFFECT OF SCOUR ON FORCES AND VIBRATIONS

Obviously forces on and vibrations of a pipe over a scoured bed will be different from those experienced when the pipe sits on a plane bed. Jensen et al. (1990) has investigated forces on a pipe at different stages of scour process in steady current, using frozen scoured-bed models. Stansby & Starr (1991) has measured forces on a pipe gradually sinking in the bed under flow action in both steady current and waves.

Effect of scour on hydroelastic vibrations of pipelines, on the other hand, has been studied

in steady currents (Sumer et al. (1988a), Kristiansen (1988) and Kristiansen & Tørum (1989)) and in waves (Sumer et al. (1989)).

Forces have been measured also on pipeline models with attached spoilers with different embedment ratios (representing different stages of the self-burial process) (Hulsbergen & Bijker (1989)).

## 5. MATHEMATICAL MODELLING

The studies concerning mathematical modelling of scouring process may broadly be divided into three categories: 1) the studies dealing with mathematical models based on potential-flow theory, 2) those dealing with  $k-\epsilon$  models and 3) those dealing with discrete-vortex models.

Regarding the potential-flow models, Chao & Hennessy (1972) was the first to apply the simple potential solution to the flow in the gap between the pipe and the bed. As a matter of fact, the potential flow around a cylinder placed near a wall was described by von Müller in as early as 1929. Müller's potential flow description was modified by Fredsøe & Hansen (1987) by taking into consideration the actual, measured velocity at the top and bottom edges of the cylinder. This modification is significant particularly in the case of very small gaps where the potential theory overpredicts the velocity in the gap. Hansen et al. (1986) later implemented the same line of thought as in Fredsøe & Hansen, and developed a potential theory for the case of a cylinder over a scoured bed. In both models, only the flow upstream of the pipe is described by the potential theory. (Clearly the downstream flow, i.e. the lee-wake, cannot be described by a potential flow model). The results of scour prediction by Hansen et al.'s (1986) potential flow description agreed satisfactorily with the experiments. Recently, Hansen (1992), with a simple representation of the lee wake, extended this model so as to cover waves. His model results give a fairly good agreement with Sumer & Fredsøe's (1990) empirical result (Eq. 9). Using the same model, he also examined the effect of Shields parameter, the effect of current in combined waves and current and the effect of angle of attack. Bernetti et al. (1990) has also developed a mathematical model of scour below pipelines. The model has two main components, namely the two-dimensional scour component and the three-dimensional scour component. The two-dimensional scour component was based on Chao & Hennessy's (1972) potential-flow description. Bernetti et al.'s model is able to predict also the development of the three-dimensional scour, the free-span length and sinking of the pipe at span shoulders. The model has been tested against simple cases where data is available (Mao (1986)). The model performance for these test cases appeared to be quite satisfactory.

The second group of mathematical modelling studies concerns the  $k-\epsilon$  simulation of the flow (Leeuwenstein & Wind (1984) and van Beek & Wind (1990)). As is well known, the  $k-\epsilon$  model is successfully used in various fields of fluid mechanics (Rodi (1984)). Regarding its application in scour below pipelines, Leeuwenstein & Wind has calculated the flow around the pipe over a scoured bed with such a model and made the morphological calculations by use of sediment continuity equation along with a sediment-transport equation. In the follow-up study, van Beek & Wind extended the model so as to cover also the suspended-load transport in the morphological calculations.

The third group of studies in mathematical modelling of scour concerns the discrete-vortex-model simulation of the flow around pipes (Sumer et al. (1988a), Jensen et al. (1990) and Jensen et al. (1989)). The particular model which has been used in these studies is the so-called cloud-in-cell method. The computational details of the method is well documented in the literature (see for example Stansby & Dixon (1983)). The method is able to predict the gross behaviour of the vortices in the lee wake of the pipe. This enabled Sumer et al. (1988b) to study the effect of lee-wake vortices on the bed shear stress downstream of the pipe over both a plane bed and a scoured bed. The method was later used by the same group to simulate flow around a pipe over a scoured bed in steady currents (Jensen et al. (1990) and in waves (Jensen et al. (1989)).

Finally, it may be mentioned that an integrated approach has been adopted recently by

the Danish Hydraulic Institute and the Delft Hydraulics in a joint study, to develop a computer model which would enable the engineer to decide on occurrence and disappearance of scour along a pipeline/cable, pipeline/cable self-burial, trench backfilling, migrating sand waves exposure and undermining of pipelines or cables. A brief account of this study has been reported by Staub & Bijker (1990).

#### ACKNOWLEDGEMENT

The study is partially supported by the research programme "Marine Techniqe" of the Danish Scientific Council (STVF).

## CHAPTER 218

### **Turbulence and mud sedimentation: A Reynolds stress model and a two-phase flow model**

**Ch. Teisson, O. Simonin, J.C. Galland and D. Laurence <sup>1</sup>**

#### **Abstract**

Two sophisticated research models, previously used and validated in internal flows, are now applied to sediment laden flows: they give a thorough insight into the vertical distribution of sediment concentration, flow-sediment interaction, stratification and inhibition of vertical mixing. The Reynolds stress model is well adapted to investigate stratification due to density effects: it gives information on turbulent fluxes of momentum and concentration, eddy diffusivity and eddy viscosity profiles, reduction of the bottom shear stress due to the presence of sediment. Results show that suspended sediments affect turbulence even at low concentrations of 1g/l. A dimensional analysis seems to indicate that these stratification effects are not well accounted for in laboratory experiments.

The two-phase flow model enables to describe the vertical profile of sediment in its continuity, from the water surface down to/through the bed, without any definition of the bed water interface. Cohesive sediment processes such as deposition, erosion or consolidation are treated as flow-particles interactions: thus, the model helps in identifying the governing parameters -floc size and density, effective stress- and does not require the classical empirical laws commonly used to describe these processes.

#### **Introduction**

State of the art for simulation of cohesive sediment transport has been considerably enhanced in the past ten years but remained tied to the knowledge of physical processes (Teisson, 1991). The sink and sources terms near the bed (Parker, 1986) and the induced repartition of sediment throughout the water column contribute to the budget of sediment, and consequently to the final output of the models. A better understanding of the complex dynamics of the vertical structure of cohesive sediment suspension (Mehta, 1989a&b) is therefore required to improve the predictability of the models.

---

<sup>1</sup> EDF- Laboratoire National d'Hydraulique, 6 Quai Watier,  
78400 Chatou, France

In that context, it is well known that turbulence is the factor responsible for maintaining in suspension very fine sediment, but is surprisingly still crudely represented in usual cohesive sediment transport models.

Turbulence in sediment laden flows has been most often studied for the case of non cohesive sediment (Lyn, 1986). The marked effects of the presence of sediment upon the flow has been highlighted by numerous laboratory experiments, as reviewed and re-analysed by Mac Lean (1991) or Villaret and Trowbridge (1991). In the experiments, discussion in general focused on the deformation of the vertical profile of velocity, whereas less attention was paid on the concentration profile by itself.

For cohesive sediment, Gust (1976) observed a turbulent drag reduction for flows over cohesive bed, even for a dilute suspension. Krone (1986) outlined the role played by aggregates, which so increase the volume concentration of suspended material that it affects the flow at even modest weight concentrations.

Field observations displayed in numeral situations that stratification effects in coastal and estuarine areas might be unrelated to thermohaline effects, but well due to the presence of sediment, since highly stratified vertical sediment concentration profiles commonly occur in otherwise vertically mixed flow regimes (Mehta, 1989a).

The way that sediment affects turbulence which in turns controls deposition or erosion is of prime importance: large deposition rate at slack waters, generation of fluid mud layers, reduction of the bottom shear stress by the presence of sediment are still unsolved problems.

Two sophisticated research models, previously used and validated in internal flows, have therefore tentatively been applied to sediment laden flows (§ 1 and 2): they give a thorough insight into the vertical distribution of sediment concentration, flow-sediment interaction, stratification and inhibition of vertical mixing.

### **1. A one dimensional second order stress flux model**

Most numerical models rely on the eddy viscosity ( $\nu_t$ ) and diffusivity ( $K_t$ ) concepts for the modelling of the turbulent stress and flux, and the influence of the sediment load on turbulence is then taken into account in various ways : this interaction can affect either only the eddy diffusivity distribution (van Rijn, 1990) or both eddy diffusivity and viscosity profiles through a (gradient) Richardson number dependency following Munk and Anderson (1948). This last approach has led to satisfactory results, most often in reproducing the behaviour of lutoclines (Wolanski et al., 1988 ; Mehta and Ross, 1989; Smith and Kirby, 1989; Costa and Mehta, 1990). Profiles for  $\nu_t$  and  $K_t$  are always derived from an assumed clear-water distribution for  $\nu_t$  (parabolic or parabolic-constant profile).

However, some discrepancies between predictions and experiments or field measurements, some shortcomings (mainly in predicting the bottom friction velocity), let investigators suspect that a stronger interaction between hydrodynamics and sediment exists. This, together with the good results obtained for the atmospheric stratified boundary layer, have pleaded for the use of higher accuracy turbulence models for sediment laden flows. Successfully were applied k- $\epsilon$  model (Celik and Rodi, 1988), algebraic stress model (Hanjalic et al., 1982 ; Sheng and Villaret, 1989) and Reynolds stress model (Teisson et al., 1991 ; Brors, 1991). Hamm et al. (1992), using Sheng and Villaret model, investigated the influence of clear or loaded water on erosion laws in laboratory experiments: they found that stratification effects were most often negligible on bottom shear stress in laboratory experiments. Brors (1991) pointed out that, for the simulation of turbidity currents, only the Reynolds stress model (RSM) appeared to be realistic, k- $\epsilon$  and algebraic stress models giving in particular wrong concentration profiles.

1.1 Scope of this study

The three essential processes involved here are the generation of an upward turbulent flux of particles, the damping of turbulence by gravity and the fluid-particle interaction. If we consider only small particles (mud and not sand), then neglecting the added-mass and other Basset forces, the problem reduces to the stratified turbulence problem. This is the well known thermal hydraulics or atmospheric boundary layer problem, for which Reynolds stress models have been developed and validated at LNH.

What can be expected from the RSM are, of course, mean concentration and velocity profiles, but also turbulent shear stress and sediment flux profiles, eddy diffusivity and viscosity distributions, Richardson numbers profiles and bottom friction velocity. In a more general meaning, the RSM could be helpful in understanding the mechanism of gravity effects and in evaluating the range of availability of the above mentioned turbulence models.

1.2. Mean equations

We consider a long free surface, flat bottom channel loaded with a volumetric concentration of sediments C, the settling velocity of the particles being  $w_s$ . The profile of mean velocity  $U(z)$  and mean concentration  $C(z)$  along the vertical in a channel flow are obtained from the following equations (capital letters represent mean values, small letters fluctuations and  $\bar{\quad}$  a statistical average) :

$$\frac{\partial U}{\partial t} = -\frac{1}{\rho_w} \frac{\partial P^*}{\partial x} - \frac{\partial \overline{uw}}{\partial z} + \nu \frac{\partial^2 U}{\partial z^2}$$

$$\frac{\partial C}{\partial t} + w_s \frac{\partial C}{\partial z} = -\frac{\partial \overline{wc}}{\partial z} + K \frac{\partial^2 C}{\partial z^2} \quad (1)$$

with  $w_s < 0$  (constant)

K : molecular sediment diffusivity

At equilibrium, the total shear stress ( $\tau = \nu \partial U / \partial z - \overline{uw}$ ) is linear so that its gradient is proportional to the pressure gradient  $\partial P^* / \partial x$  ; the settling velocity  $w_s$  induces a downward flux compensated by the gradient of turbulent concentration flux  $\overline{wc}$ .

1.3. Physical processes

When applying a Reynolds stress model, turbulence modelling assumptions are introduced only in the transport equations of the turbulent fluxes and stresses ; so the production and stratification effects, induced on these second moments by velocity and concentration gradients, are accounted for exactly. Although it is apparently complex with the 8 equations added to the mean equations (1), the Reynolds stress model allows a good understanding of the physical processes governing the turbulence-sediment interaction. Let us here concentrate on the three equations driving turbulent phenomena, that are those for the upward turbulent flux of sediments and for

the variances of the vertical and horizontal fluctuating velocities. Developing only the (exact) production terms, while the pressure-strain  $\Phi$ , diffusion  $D$  and dissipation  $\epsilon$  terms respectively are to be modelled, they read :

$$\frac{\partial \overline{wc}}{\partial t} = - \overbrace{\overline{ww} \frac{\partial C}{\partial z}}^A - g\beta \overline{c^2} + \Phi_{i,c} + D_{i,c} \tag{2}$$

$$\frac{\partial \overline{ww}}{\partial t} = \overbrace{-2g\beta \overline{wc}}^B + \Phi_{i,j} + D_{i,j} - \frac{2}{3}\epsilon \quad \text{with } \beta = -\frac{(\rho_s - \rho_w)}{\rho_w} \tag{3}$$

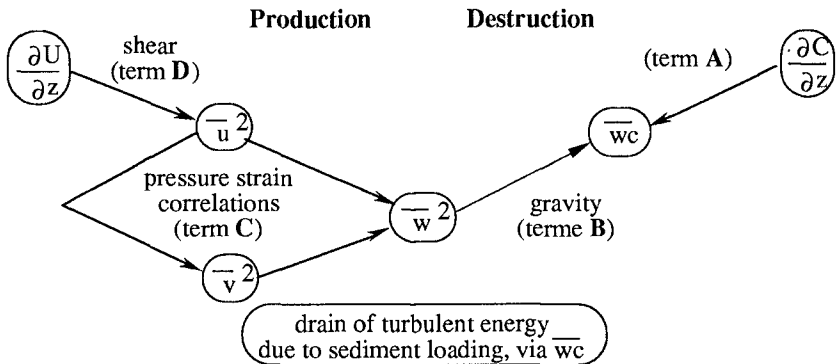

$$\frac{\partial \overline{uu}}{\partial t} = - \overbrace{2\overline{uw} \frac{\partial U}{\partial z}}^D + \overbrace{\Phi_{i,j}}^C + D_{i,j} - \frac{2}{3}\epsilon \tag{4}$$

Considering the concentration profile allows first to understand the mechanism of turbulence destruction due to the sediment load :

The concentration gradient is large, negative here. Then term A has large positive values, and (2) leads to an increase of the turbulent flux of concentration  $\overline{wc}$ . In turn, term B is negative, and (3) implies that the variance  $\overline{ww}$  decreases.

As a consequence, turbulence tends to become two-dimensional and energy is then drained from the two horizontal components  $u$  and  $v$  (eq. (4)), via the pressure-strain correlations, to feed  $w$  (eq. (3)). Finally, this mechanism leads to a decrease of the whole turbulence, which can be summarised by the following scheme :

This sketch naturally yields to the definition of the flux Richardson number  $R_{if}$  (the ratio of terms  $B/D$ ), which is the fraction of the turbulence production that can be diverted from dissipation to act against gravity.

1.4. Reynolds stress model

The second moment closure modelling adopted here is a classical one. A wall echo term is added to take into account the redistribution of energy from the vertical component of the fluctuating velocity  $w$  at the bottom, as at the free surface following the proposition by Gibson and Rodi (1989). Anisotropy affects the dissipation equation through the Launder and Tselepidakis (1991) proposition. The model has first been assessed against clear-water open channel flow data (Nakagawa et al., 1975; Komori et al., 1982).

Results are presented here for the schematic case of a steady, plane open channel flow of depth  $h = 1$  m, bulk velocity  $U_0 = 0.5$  m/s ( $Re = 500\ 000$ ), bulk sediment concentration of 1 g/l (volumetric concentration  $C_0 = 3.75 \cdot 10^{-4}$ ) and particle settling velocity  $w_s = -0.001$  m/s. Initial conditions are a homogeneous sediment concentration over the water depth and a logarithmic velocity profile, boundary condition for the concentration is a zero flux condition at both bottom and free surface.

Figures 1 to 3 show the effect of coupling the gravity (setting  $g = 0$  to  $g = 9.81$  m/s<sup>2</sup>) in the equations for the turbulent stresses on the mean velocity and concentration, and on the shear stress.

Fig. 1

Fig. 2

This effect is seen to be quite strong for the sediment concentration considered here. The concentration dies out to 0 in the 25% upper part of the water column and is multiplied by nearly a factor 3 at the bottom (fig. 1), the velocity profile significantly deviates from the logarithmic one (fig. 2) and the bottom shear stress is reduced by more than 20% at the bottom (fig. 3).

Some experimental and field investigations have already highlighted such deviations from clear-water hydrodynamics. Gust (1976) found, from experiments with cohesive sediment in sea-water, that the bottom friction velocity  $u_*$  was reduced by 20% to 40% and that the thickness of the viscous sub layer was increased by a factor varying between 2 and 5 ; furthermore, the logarithmic profile for the velocity

was shown to be no more valid in the near-wall region. Soulsby and Wainwright (1987) have also pointed out, from field measurements for non-cohesive sediments, that  $u_*$  could be over-estimated by more than 50% when using the logarithmic velocity profile, neglecting thus the suspended sediment effects.

The gradient Richardson number (fig. 4), which is usually used to introduce the influence of sediment on turbulence, is seen to be only weakly correlated to the flux Richardson number, which is the sound parameter to measure buoyancy effect according to the Reynolds stress equations. This suggests that the Reynolds analogy as well as the Munk-Anderson approach could present some shortage for this application.

Fig. 3

Fig. 4

1.5. Analytical developments

Direct comparison between numerical predictions and measurements is difficult for there are only few data available on cohesive sediment transport, even for the mean variables. Furthermore, as results of the RSM depend entirely on assumptions for modelling the turbulent second moments, validation should concern first turbulence predictions. But there is even less turbulence measurements... In this section we try to make some analytical developments that could help understanding RSM results.

As seen previously, the buoyancy level is defined by the flux Richardson number :

$$Ri_f = \frac{g\beta\overline{wc}}{\overline{uw} \frac{\partial U}{\partial z}} \tag{5}$$

Assuming a logarithmic velocity profile :  $\overline{uw} = -u_*^2(1 - \frac{z}{h})$  and  $\frac{\partial U}{\partial z} = \frac{u_*}{\kappa z}$

and when equilibrium is reached :  $\overline{wc} = -w_s C$

So that, at equilibrium and under the assumption of a logarithmic velocity profile,  $Ri_f$  becomes :

$$Ri_{f\ eq} = g\beta\kappa \frac{w_s z C_{eq}}{u_*^3 (1 - z/h)} \tag{6}$$

The maximum value for  $Ri_f$ , as measured from thermal flow investigations, is 0.25 ; turbulence being totally damped by buoyancy for higher values. We can then derive a formula giving, under the above assumptions, the maximum concentration at each location in the water column that a given flow can hold at equilibrium,  $C_{eq\ max}$  :

$$C_{eq\ max} = \frac{0.25 u_*^3}{g\beta\kappa w_s} \left( \frac{1}{z} - \frac{1}{h} \right) \tag{7}$$

Fig. 5

This analytical expression does not give an equilibrium profile and has no physical meaning, but is an upper boundary for the sediment distribution: concentration profiles should stand below the curve drawn by the formula. According to (7), a reduction of the flow velocity by a factor 2 could reduce the maximum concentration to be carried by a factor 8.

The RSM prediction agrees well with (7) in the bulk of the flow (fig. 5), which means that the drastic reduction in sediment concentration in the upper part of the channel is due to the damping of turbulence by the sediment load. Figure 5 also indicates that the flow could hold much higher concentrations at the bottom, although (5) certainly over-estimates them there because dissipation, which is important at these locations, is neglected.

Let us now make a scale analysis on the flux Richardson number, which can be expressed, under some assumptions as seen previously, by (6). Let suppose a scale model experiment and express by  $\gamma$  the similitude laws ( $\gamma = .lab / .field$ ). Then we get the following expression for the similitude law for  $Ri_f$  :

$$\hat{R}i_f = \frac{\hat{\beta} \hat{w}_s \hat{C} \hat{h}}{\hat{u}_*^3}$$

Consider now a laboratory experiment (deposition or erosion test in a flume or a carousel). Most often, the procedure is:

- to use the same mud as in the field ( $\hat{\beta} = 1$  and  $\hat{w}_s = 1$ ),
- for the same range of concentrations ( $\hat{C} = 1$ ),

- under the same hydrodynamics conditions ( $\hat{u}_* = 1$ )

to derive laws to be introduced in mathematical models for prototype applications.

This procedure leads to a scaling effect on  $Ri_f$  which reduces to the vertical scale  $\hat{h}$ . This result, obtained here from (6) under some assumptions, has also been rigorously derived from a dimensional analysis of the Reynolds stress equations (Laurence et al., 1993). This means that, in a flume with a depth of 0.20 m, stratifications effects will be 50 times less than in the field, with a water depth of 10m, for the same range of concentrations and velocities. This could explain the weak stratification effects found by Hamm et al. (1992) in laboratory, whereas a larger influence is suspected in the field (Gust, 1978). Erosion deposition laws used in modelling high turbid environment in China (Costa and Mehta, 1990) required the use of physical parameters which were significantly different from those determined in laboratory experiments performed with local mud. They concluded that erosion-depositon fluxes can be drastically modified by sediment stratification, and that typical formulations for the bottom fluxes are believed to have limited utility in such environments. The reason could be, as stated above, that, for the same hydrodynamic forcing, in heavily laden flows, stratification effects will be far more important in the field than in the laboratory.

## 2. A separated two-phase flow model

Following Wallis (1969), transport of sediment in suspension can be regarded as a two-phase flow, i.e. mixture of a continuous phase (water) and a dispersed phase (mud flocs) for the case of cohesive sediment transport. And, by writing mass and momentum balance equations separately on each phase, with appropriate momentum transfer rate between phases, the two phase formulation enables to describe how the presence of particles modifies fluid flow characteristics, and reciprocally how the instantaneous fluid flow acts on particles movements.

Mass balance :

$$\frac{\partial}{\partial t} \alpha_k \rho_k + \frac{\partial}{\partial x_i} \alpha_k \rho_k U_{k,i} = \Gamma_k \quad (8)$$

where,  $U_{k,i}$  is the mean velocity i-component for the continuous ( $k=1$ ) and dispersed phases ( $k=2$ ) respectively,  $\alpha_k$  is the volumetric fraction,  $\rho_k$  the mean density and  $\Gamma_k$  the interfacial mass transfer rate between phases. In cohesive sediment transport,  $\Gamma_k$  accounts for water capture by mud flocs during their growth or break-up (transfer of water from the water phase to the mud flocs phase), and therefore for density change of the flocs. For the applications below,  $\Gamma_k$  is set to zero, and the density of the flocs remains constant.

Momentum balance :

$$\alpha_k \rho_k \frac{\partial}{\partial t} U_{k,i} + \alpha_k \rho_k U_{k,j} \frac{\partial}{\partial x_j} U_{k,i} = - \alpha_k \frac{\partial}{\partial x_i} P_1 + \alpha_k \rho_k g_i + I_{k,i} - \Gamma_k U_{k,i} - \frac{\partial}{\partial x_j} [ \alpha_k \langle \rho u''_i u''_j \rangle_k + T_{k,ij} ] \quad (9)$$

where  $u''_i$  is the fluctuating part of the local instantaneous velocity and  $\langle . \rangle_k$  the averaging operator associated to phase k,

$$\alpha_k \rho_k U_{k,i} = \alpha_k \langle \rho u_i \rangle_k \quad \langle \rho u''_i \rangle_k = 0$$

$\langle u''_{k,i} u''_{k,j} \rangle_k$  is the turbulent Reynolds stress tensor of the liquid phase ( $k=1$ ) and the kinetic part of the particulate stress tensor ( $k=2$ ),

$T_{k,ij}$  is the molecular viscous stress tensor ( $k=1$ ) and the collisional part of the particulate stress tensor ( $k=2$ ), set to zero for this application.

$P_1$  is the mean pressure of the continuous phase,

$I_{k,i}$  is the part of the interfacial momentum transfer rate between phases which remains after subtraction of the mean pressure contribution and complies with the mean jump condition derived from the local balance of momentum at the interfaces,

$$\sum_{k=1}^2 I_{k,i} = 0$$

The closure of the averaging equations set is achieved by using :

- practical expressions in terms of the computed variables to approximate the mean interfacial transfer terms and derived from the local description of single particle transfer with the surrounding fluid ;

- second-moment modelling for the continuous phase turbulence and the kinetic (or transport) part of the particulate stress tensor ;

- constitutive relations for the mean transport properties accounting for the molecular viscous stress in the liquid phase and the collisional part of the particulate stress tensor.

Interfacial momentum transfer :

Constitutive relations for the interfacial transfer terms derive by averaging from the particulate expressions, and must be related to the mean computed variables. Neglecting the Basset force, the interfacial momentum transfer term  $I_{k,i}$  induced by the relative motion of dispersed particles, can be written:

$$I_{1,i} = - I_{2,i} = \alpha_2 \rho_1 F_D V_{r,i} - \rho_1 \langle u''_{1,i} u''_{2,j} \rangle_2 \frac{\partial}{\partial x_j} \alpha_2 + \alpha_2 \rho_1 C_A \left[ \frac{\partial V_{r,i}}{\partial t} + U_{2,j} \frac{\partial V_{r,i}}{\partial x_j} \right] + \frac{\partial}{\partial x_j} \alpha_2 \rho_1 C_A \langle u''_{2,j} v''_{r,i} \rangle_2 \tag{10}$$

The first term on the right-hand side represents the drag force, the second the correlation between instantaneous distribution of particles and fluid pressure fluctuations, and the other ones the apparent mass force. The main part of the force induced by the fluid flow is already taken into account by the expression of the pressure gradient term in the momentum equations.

$F_D$ , the average drag coefficient is written in terms of the local mean particle Reynolds number which accounts roughly for the flocs overcrowding and the non-linear dependence on the relative velocity fluctuations :

$$F_D = \frac{3 C_D \langle Re \rangle}{4 \bar{d}} \langle |\vec{v}_r| \rangle \quad \langle |\vec{v}_r| \rangle \approx \sqrt{V_{r,i} V_{r,i} + \langle v''_{r,i} v''_{r,i} \rangle}$$

$$C_D \langle Re \rangle = \frac{24}{\langle Re \rangle} \left[ 1 + 0.15 \langle Re \rangle^{0.687} \right] \alpha_1^{-1.7} \quad \langle Re \rangle = \frac{\alpha_1 \langle |\vec{v}_r| \rangle \bar{d}}{v_1} \tag{11}$$

$V_{r,i}$ , the averaged value of the local relative velocity between each particle and the surrounding fluid, can be expressed in function of the total relative mean velocity  $\Delta U_i = U_{2,i} - U_{1,i}$  and a drifting velocity  $V_{d,i}$  due to the correlation between the

instantaneous distribution of particles and the turbulent fluid motion at large scales with respect to the particle diameter :

$$V_{r,i} = [U_{2,i} - U_{1,i}] - V_{d,i} \quad V_{d,i} = \langle \tilde{u}_{1,i} \rangle_2 - U_{1,i} = \langle u''_{1,i} \rangle_2 \quad (12)$$

The drifting velocity  $V_{d,i}$  takes into account the dispersion effect due to the particles transport by the fluid turbulence and reduces to the single turbulent correlation between the concentration fluctuations and the turbulent fluid velocity when the particle diameter is tending towards zero with respect to the smallest turbulent length scales. According to the theoretical case of particles suspended in homogeneous turbulence (Deutsch and Simonin, 1991) the velocity  $V_{d,i}$  is written as follows :

$$V_{d,i} = -D_{12}^t \left[ \frac{1}{\alpha_2} \frac{\partial \alpha_2}{\partial x_i} - \frac{1}{\alpha_1} \frac{\partial \alpha_1}{\partial x_i} \right] \quad (13)$$

where the fluid-particle turbulent dispersion coefficient  $D_{12}^t$  is given in terms of the covariance between the turbulent velocity fluctuations of both phases and a fluid-particle interaction turbulent characteristic time.

The turbulence model

Turbulence is modelled through the concept of turbulent viscosity  $\nu_k^t$  prescribed by a standard k - ε model, with a different treatment of the continuous and dispersed phase (Bel F'Dhila and Simonin, 1992).

A further balance equation for the particle number :

$$\alpha_2 \rho_2 \frac{\partial}{\partial t} X_p + \alpha_2 \rho_2 U_{2,j} \frac{\partial}{\partial x_j} X_p = \frac{\partial}{\partial x_j} \alpha_2 \rho_2 D_{12}^t \frac{\partial}{\partial x_j} X_p - X_p \Gamma_2 + \Gamma_p \quad (14)$$

where  $\Gamma_p$ , the rate of change in the particle number due to breakup and agglomeration.

$N_p$ , the mean particle number by unit volume of the two-phase mixture can be expressed directly in function of the variable  $X_p$  (the mean particles number by unit of mass of the dispersed phase) :

$$N_p = \alpha_2 \rho_2 X_p$$

and leads to the general definition of the mean diameter :

$$\frac{\pi \bar{d}^3}{6} = \frac{1}{\rho_2 X_p}$$

For cohesive sediment transport, this equation would account for diameter change of the flocs due to break-up or aggregation. For the applications below, this equation is not used , and the diameter of the flocs remains constant.

Applications

The definition of the transition from water body to bed is rather vague (Parker, 1986; Mehta, 1989a) and is one of the motivations to design an approach where this definition is circumvented. In that context, the two-phase flow model appears as the most complete model of the whole process from the water surface to the rigid bed.

Once the diameter and the density of the "inclusions" have been defined as data, the fall velocity  $V_f$  of particles is not prescribed but is an output of the model, as an example of flow-sediment interaction (fig. 6).

Fig. 6. Mean relative velocity  $V_r$  (solid line) and mean velocity of the dispersed phase  $U_2$  (dash line), at low concentrations. No hindered settling ( $V_r$  constant), equilibrium conditions ( $U_2 \approx 0$ )

Fig. 7. Vertical profile of  $\alpha_2$ , volumetric fraction of the solid phase (dash line), and vertical relative velocity  $V_r$  (solid line), with strong hindering effect near the bottom for large concentration

Fig. 8. Vertical profile of concentration (solid line) and velocity (dash line)

Fig. 9. Vertical profile of concentration for the same settling velocity of 1 mm/s: for flocs of density 1070 kg/m<sup>3</sup> (solid line) and for non cohesive sediment of density 2650 kg/m<sup>3</sup> (dashed line).

Another output of the two-phase flow model is the absolute vertical velocity  $U_2$  of particles in the presence of turbulence: it can be oriented downwards (turbulence too weak to stand deposition), or be zero (equilibrium condition on fig.6) or even be orientated upwards (for instance when mixing in the water column during erosion in accelerating currents). This a fundamental result for sedimentation problem.

The capability of two phase flow approach to analyse hindered settling (fig. 7) has been pointed out by Thacker and Lavelle (1977). The counter flow of the fluid upwards through the falling sediment is included in the model, as a consequence of the mass balance equation (8). The presence of others particles is taken into account in the drag coefficient expression (11).

Results with the two-phase flow model have been obtained for the same schematic case as for the Reynolds stress model (water depth 1 m; mean velocity 0.5 m/s), but for higher concentrations. Vertical profile of flow velocity and concentration have been computed in presence of mud flocs of density  $1070 \text{ kg/m}^3$  and diameter  $160 \mu$  (settling velocity 1 mm/s after the Stokes law), with a bulk initial concentration of 0 (clear water), 4, 8 g/l.

At very low concentration (fig. 6), the profile is in equilibrium ( $U_2 \approx 0$ ) and the relative velocity  $V_r$  given by the model corresponds to the Stokes value (-1 mm/s). For the latter case (8 g/l), classical equilibrium profiles cannot be sustained, and the initial profile completely collapses, with volumetric concentration up to 0.60 near the bottom for the final profile (expressed in massic concentration on fig. 8); hindered settling is very pronounced, at such concentrations (fig. 7). Concerning the liquid phase, the classical logarithmic profile of velocity in clear water is modified by the presence of sediment, with a kink located at the level where the concentration strongly increases downwards (fig. 8). From all the tests performed, the effect of the presence of particles on the turbulence of the flow appears to be noticeable even at "low" concentrations, the order of 1 g/l.

The role of floc size and floc density, which can be taken into account only in such models, is illustrated on fig. 9: this figure presents the vertical profile of concentration, obtained with a flow of 0.5 m/s, for an initial bulk concentration of 8 g/l, for two sediments exhibiting the same settling velocity of 1 mm/s:

- non cohesive sediment (sand) of density  $2650 \text{ kg/m}^3$  and diameter  $31 \mu$ ,
- the same mud flocs as before of density  $1070 \text{ kg/m}^3$  and diameter  $160 \mu$ .

The Stokes law gives, for the two sediments a settling velocity of 1 mm/s. However, they behave completely differently: sand settles rapidly to the bed, whereas mudflocs form a mobile suspension (fig. 9). The volumetric concentration for flocs is of the order of 0.10 to 0.50, against 0.01 to 0.05 for sand, in order to have the same massic concentration: this induces hindered settling for flocs, the water has difficulty to escape between the falling flocs, as nearly half of the volume is occupied by the flocs. Thus, the two-phase flow approach points out that the floc size might play an important role in the generation of fluid mud layers; massic concentration and settling velocity are not sufficient to explain the phenomenon (they are the same for the two sediments). Floc size and density, volumetric concentration seem more appropriate than settling velocity and massic concentration.

In the near future, the two-phase flow model should offer the possibility to study aggregations and break-up of flocs as a function of the level of turbulence, through a further equation (14) on the number of flocs already included in the model, provided information is available on  $\Gamma_p$ .

Last but not least, Wallis (1969) first emphasized the analogy between two-phase flow and classical consolidation equations, by adding in the momentum balance

equation the interparticle stress, the so-called "effective stress" in consolidation theories, which appears as  $T_{k,ij}$  in (9).

Addressing the proper parameters (floc size and density, rate of aggregation and break-up, effective stress) to describe cohesive sediment processes, the two-phase flow approach should help to reduce empiricism in commonly used formulae and encourage further experimental work on these parameters

## Conclusion

Today, a new generation of models, such as Reynolds stress models and two-phase flow models has become available in the industrial domain and we have attempted to apply the most recent ideas and concepts to cohesive sediment laden flow. The philosophy was to represent the hydrodynamics, turbulence and flow sediment interaction in the most accurate way, and, if possible, to get a new understanding of the physical processes in return.

Results provided by the Reynolds stress model show a strong damping of turbulence leading to significant deformation of the mean velocity, concentration and shear stress profiles, when compared with the clear-water ones. According to (6), for a given flow, stratification directly depends on the water depth, the sediment concentration and the settling velocity. The strong effects obtained here for "macroflocs" with  $w_s = 1$  mm/s would then be reduced accordingly for settling velocities 10 or 100 times lower.

In the two-phase flow approach, the physical processes of cohesive sediment are analysed and modelled as flow sediment interaction. This model enables modelling of the vertical profile of concentration from the free surface down into the bed without any definition of the bed water interface, as cohesive sediment processes are treated internally.

Henceforth, the formalism of these turbulence models offers a rigorous framework to study in a unified way the processes of mud transport or sedimentation. Empiricism in the formula commonly used in cohesive sediment transport modelling could be reduced thanks to these better representation of flow-sediment interactions, and predictability of the models consequently increased.

## CHAPTER 219

### Mechanism of Sediment Transport around a Large Circular Cylinder

Takao Toue<sup>1</sup>

Hidehiro Katsui<sup>2</sup>

Kazuo Nadaoka<sup>3</sup>

#### ABSTRACT

Mean currents have important roles in sediment transport. The mean currents around a large circular cylinder are carefully measured. The theoretical mass transport rate is verified experimentally, and the movement of sediment on a flat and smooth bed can be numerically simulated well. On the contrary, the currents on sand ripples are quite different with the theoretical value. The currents are caused by the interaction of the return flow and the mass transport on sand ripples.

#### INTRODUCTION

Bathymetric changes and scouring around a large circular cylinder have been studied by Rance (1980), Saito et al (1990), and Katsui and Toue (1988). Fig.-1(a) and (b) are examples of the bathymetric changes around a large circular cylinder presented by Katsui (1992). The wave height is 10cm, and the wave periods are 1.0s and 2.0s and the water depth is 0.3m. In front of the circular cylinder, the feature of bathymetric change is same as that in front of a vertical structure, i.e., the scouring and accretion occur alternatively. The side of the cylinder is always accretion area irrespective to the wave period. According to Katsui et al (1990), this type of changes

fig.-1 Bathymetric Changes around a Large Circular Cylinder

is called  $N'$  type scouring. In  $N'$  type scouring, the sediment transport rate must be maximum where the gradient of shear stress is maximum. The mechanism of  $N'$  type scouring, however, is not understood well.

Saito et al (1988) simulated these particular changes numerically, but the simulation could not explain the experimental results well probably due to the poor understanding of the mean currents. In their simulation, the mean currents around a cylinder are consist of two different types of currents. One is the mass transport, and the other is the current due to the gradient of radiation stress. The calculated currents, however, are not verified experimentally.

To understand the mechanism of sediment transport around a large circular cylinder, the mean currents should be clarified first. The purposes of this study are to examine the mean current around a large cylinder and its influence on the sediment transport.

## EXPERIMENTAL PROCEDURE

Fig.-2 is the experimental set up. The length of the wave basin is 35.5 m and width is 17m. The water depth,  $h$ , is always 0.3m. The wave height,  $H$ , is 10 cm, and

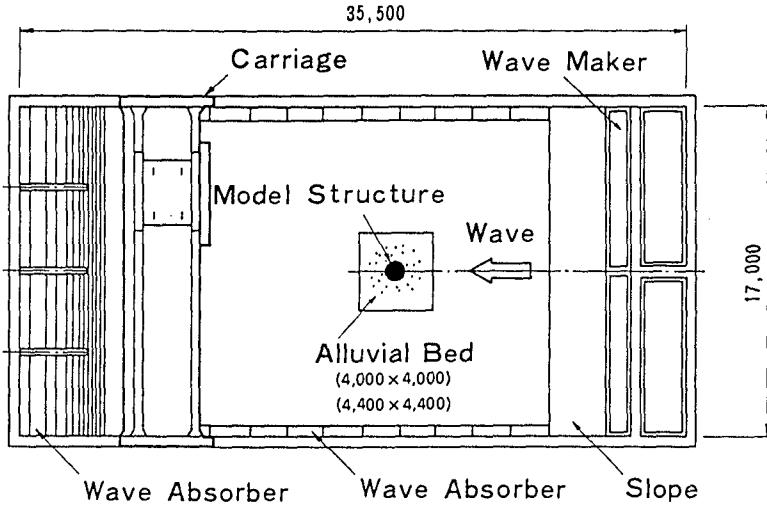

fig.-2 Experiment Set Up

wave periods,  $T$ , are 1.0s and 2.0s. The diameter of the circular cylinder,  $D$ , is 1.17m, thus the ratios of the diameter to wave length are 0.85 and 0.36. Two types of bed conditions are tested. One is a flat smooth bed and the other is the bed with sand ripples (ripple bed). In making the ripple bed, a flat movable sand layer with 5 cm thickness is formed, and then after the ripples form in the all surface by waves, the bed is fixed by cements. To measure the mean currents on the smooth bed in the boundary layer, polyethylene beads are used. Their diameter is 1 mm and the gravity ratio is 1.02. A number of beads are placed on the smooth bed, and the movements of beads are observed by the video and the photograph. The movements of sands are also observed. The sands are fine silica sands and their median diameter,  $d_{50}$ , is 0.15 mm. Mean currents are also measured by the electro-magnetic velocity meter and LASER Doppler velocity meter. The currents are measured at every 30 cm horizontally, and 20,15,10,5,3 cm above the bottom. Table -1 summarized the experiment condition and the experiment cases.

### MEAN CURRENTS ON SMOOTH BED

#### 1) Observation of Movement of Polyethylene Beads

Photo -1(a) shows the movement of polyethylene beads on the smooth beds for case 1. The beads in front of the cylinder gather in semi-circular lines which are coincide to the positions of the standing waves. The beads disappear at the side of the cylinder. All particles, however, are flown to the shore ward finally. Photo -1(b) is for case 2. The beads move more dramatically. Just after the waves reach the experimental area, all beads in front of cylinder move to the direction of waves.

Table -1 Experiment Condition and Cases

case name	wave height H(cm)	wave period T(s)	water depth h(m)	bed condition
case 1	10.0	1.0	0.3	smooth
case 2	10.0	2.0	0.3	smooth
case 3	10.0	1.0	0.3	ripple
case 4	10.0	2.0	0.3	ripple

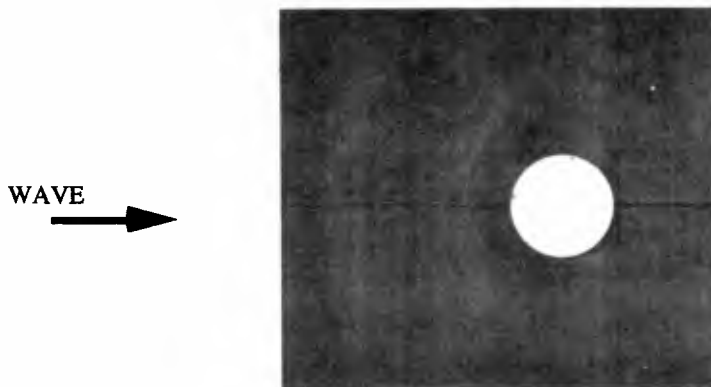

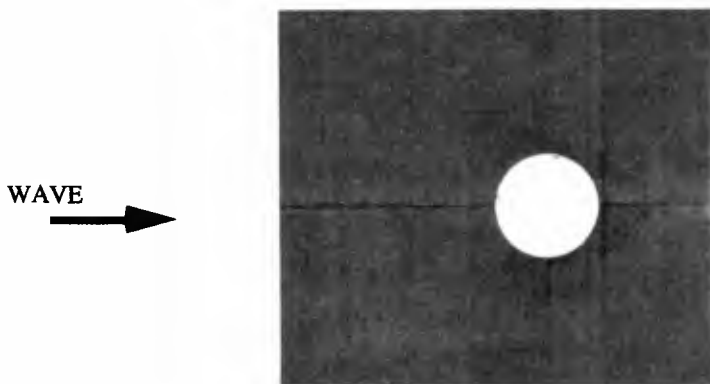

(a)  $T=1.0s$   $H=10cm$   $t=1$  min.(b)  $T=2.0s$   $H=10cm$   $t=1$  min.

Photo-1 Movement of Polyethylene Beads around a Large Circular Cylinder

Simultaneously, the beads at the side of the cylinder also disappear. The shape of the disappearance is heart like. Within 3 or 4 minutes, they disappear completely.

## 2) Mass Transport Rate around a Circular Cylinder on the Smooth Bed

According to Carter et al (1973), the mass transport rate at the outer edge of the boundary layer is given by eq. (1) and (2) in the cylindrical coordinate.

$$U = \frac{1}{4\omega} \text{Re} \left[ F_5 U_w \left( \frac{\partial U_w}{\partial r} \right)^* + F_6 \frac{V_w}{r} \left( \frac{\partial U_w}{\partial \theta} - V_w \right)^* + F_7 \frac{U_w}{r} \left( \frac{\partial V_w}{\partial \theta} + U_w \right)^* \right] \quad (1)$$

$$V = \frac{1}{4\omega} \text{Re} \left[ F_5 \frac{V_w}{r} \left( \frac{\partial V_w}{\partial \theta} + V_w \right)^* + F_6 U_w \left( \frac{\partial V_w}{\partial r} \right)^* + F_7 V_w \left( \frac{\partial U_w}{\partial r} \right)^* \right] \quad (2)$$

where  $U, V$  is the mass transport rate including *Stokes' drift* in the direction of  $r$  and  $\theta$  respectively,  $U_w$  and  $V_w$  are the velocity of wave component at the outer edge of the boundary layer and  $*$  means the complex conjugate.  $F_5, F_6$  and  $F_7$  are the complex

$$F_5 = -3 + 5i, F_6 = -1 + 2i, F_7 = -2 + 3i \quad (3)$$

constants, and given by eq. (3).

## 3) Numerical Simulation of Movements of Polyethylene Beads

If the beads are assumed to be moved by the mass transport rate, the movements of beads are simulated numerically. Fig. -3(a) and (b) are the results of the simulation for case 2. The simulations agree with the experimental results very well. In other words, this is the experimental verification of the theoretical mass transport rate.

## MOVEMENT OF SAND PARTICLES ON SMOOTH BED

### 1) Observation of Sand Particles on Smooth Bed

The mass transport rate on smooth bed is clear now. Next, the movements of sand particles are examined. The same procedure as that of the experiment for polyethylene beads is used. Photo -2 (a) and (b) is the movement of sands for case 3 and case 4. In the photos, the black part is the place where sands disappear and the white part is the place where sands deposit or do not move. In other part, sand ripples form. The photos were taken after 30 minutes wave duration.

In case 3, sands in front of the cylinder gather at the position of the loop of the standing waves, and disappear at the node of the standing waves. In case 4, however, sands gather at the loop and disappear at the node. The sands at the side of the cylinder disappear for both cases.

### 2) Numerical Simulation of Sand on Smooth Bed

The motion of sands on the smooth bed can be given by eq. (4) and (5).

(a) T=2.0s H=10cm t=10s

(b) T=2.0s H=10cm t=40s

Fig.-3 Numerical Simulation of Movement of Polyethylene Beads

$$\frac{dx_s}{dt} = u_s \tag{4}$$

$$\frac{du_s}{dt} = \frac{3C_d}{4d(s+C_m)} |u-u_s|(u-u_s) + \frac{1}{s+C_m} \frac{dU_w}{dt} + \frac{C_m}{s+C_m} \frac{du}{dt} - \frac{s-1}{s+C_m} \mu_f \tag{5}$$

where  $u_s$  is the sand particle velocity,  $u$  is the velocity of the fluid and over bar means a vector quantity.  $C_d$  is the drag coefficient,  $C_m$  is the added mass coefficient and  $\mu$  is the friction coefficient.  $C_d$  and  $C_m$  are 0.5. The friction coefficient at rest is 0.6 and

(a)  $T=1.0s$   $H=10cm$   $t=600s$ (a)  $T=1.0s$   $H=10cm$   $t=2220s$ 

#### Photo-2 Movement of Sands on Smooth Bed

changed to 0.1 when sands start to move. The height of the position  $z_0$ , which the fluid acts on the particles is the half of sands diameter, i.e., 0.075mm.  $u$  is given by eq.(6) and (7).

$$u = u_1 + u_2 \quad (6)$$

$$u_1 = \text{Re} \left[ U_w F_1(\xi) \exp(-i\omega t) \right], \xi = z_0/\delta \quad (7)$$

$$F_1(\xi) = 1 - \exp[-(1-i)\xi] \quad (8)$$

where  $u_2$  is the mean current,  $\delta$  is the thickness of the boundary layer.  $F_1$  is given by eq.(8)

Fig.-4 is the trajectory of the sand particles in the simulation. The wave height is 10cm, and wave period is 1.0s. The initial position is  $x=-0.585\text{m}$ ,  $y=0.676\text{m}$ , where the origin of the coordinates is the center of the circular cylinder.  $x$  is the positive toward the direction of the wave propagation. The sands move along the elliptic line changing the mean position toward the center of the cylinder. This movement is the same as the observation. Similar simulation was done by many researchers, such as Hino et al (1982) and Irie et al(1984) for one dimensional sands movement. In one dimensional simulation, sands stop when the velocity is very small. But, since the velocity in the both directions of  $x$  and  $y$  are not small simultaneously in three dimensional case, the sands which start to move do not stop. The simulation for all particles around a cylinder is shown in fig.-5(a) and (b). The results of the simulation agree with the experiment qualitatively. Some differences are due to the sand ripples which is not

Fig.-4 Trajectory of Sands Movement in Numerical Simulation

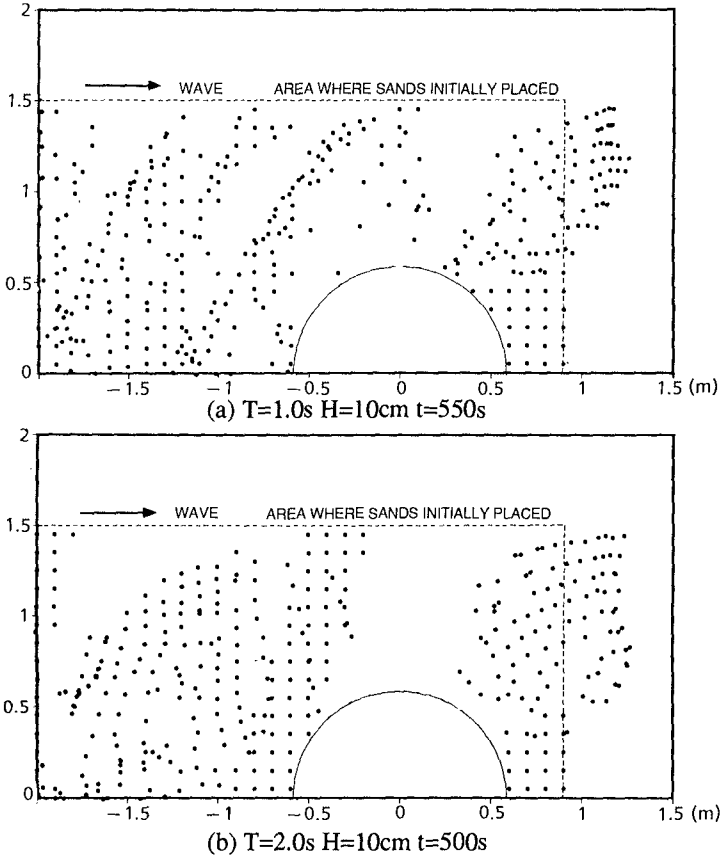

Fig.-5 Numerical Simulation of Sands Movement

included in the simulation. Important findings are the sand particles disappear at the side of the cylinder both in the simulation and the experiment. In other hand, the side of the cylinder is always accretion area in the bathymetric change experiment (see fig.-1(a) and (b)).

#### MEAN CURRENTS ON RIPPLE BED

##### 1) Observation of Movements of Polyethylene Beads

Photo-3 show the movements of polyethylene beads on the ripple bed after 30 minutes wave action. The difference between the movement on the smooth bed and the ripple bed is clear. In the case of the smooth bed, the beads are disappear within 3 or 4 minutes. On the contrary, the beads on the rippled bed remain there for more than 30 minutes. By careful observation, some particular movements of beads are found. The beads at the side of the cylinder move to the down drift side near the bed, but change the direction when the beads go up to the 3 to 5 cm above the bed. This imply the

Photo -3 Movement of Polyethylene Beads on Sand Ripple ( $T=2.0s$ ,  $H=10cm$ )

vertical distribution of the mean current might have some important role in this movement.

## 2) Mean Current around a Circular Cylinder

The mean currents measured by the electro-magnetic velocity meter is shown in fig-6. The currents in the upper layer go to the opposite direction of wave propagation. The currents in lower layer go from the rear of the cylinder to the side of the cylinder, therefore the beads would have gathered at the side of the cylinder in Photo 3.

The velocity of the currents is about 5 cm/s. As long as the wave basin is closed in the experiment, there must be a return flow. The order of the return flow is estimated to be about 5cm/s. Thus, the current in the upper layer might be a return flow. The current in the lower layer is more complicate. More detailed measurement by LASER Doppler velocity meter is carried out at the side of the cylinder. The vertical profile is illustrated in fig.-7 with theoretical value. The measured current is quite different with the theoretical current both its value and direction.

Since the theory is for the mass transport in the laminar boundary layer on the smooth flat bed, the differences are not surprising. Furthermore the theory does not consider any significant currents like a return flow outside the boundary layer. This is not so important when the boundary layer is very thin like that on smooth beds. When the boundary layer is considerably thick like that on sand ripples, the effects of the return flow must be considered. Consequently, to know the mean currents around a large circular cylinder, a theory for the mass transport on sand ripples must be developed taking into account of the effects of a return flow .

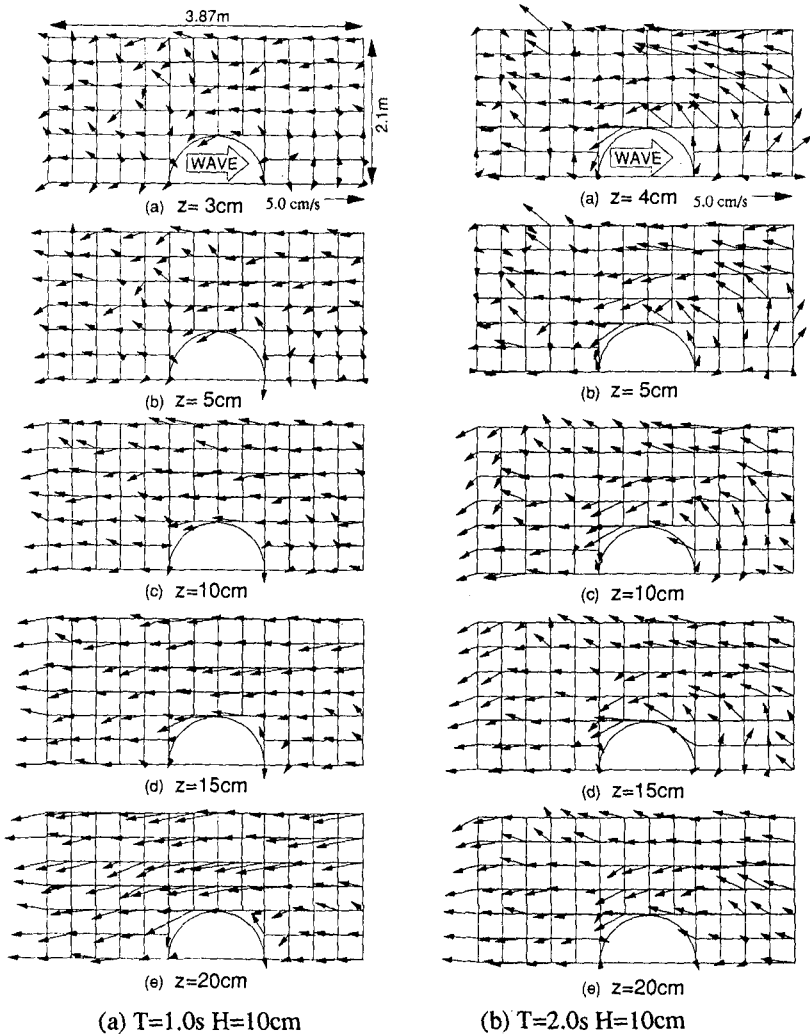

Fig.-6 Mean Currents around a Large Circular Cylinder

CONCLUDING REMARKS

The following conclusions are made;

- 1) The mass transport around a large circular cylinder on the smooth bed are verified experimentally.
- 2) The sand movements around a large circular cylinder on the smooth bed are explained by the numerical simulation well.

Fig.-7 Vertical Distribution of Mean Current

- 3) The mean current on the sand rippled are clarified by the experiment.
- 4) To know the mean current, theory for the mass transport on sand ripples must be developed taking into account of the effects of a return flow.

## CHAPTER 220

### Siltation Study in a Long Approach Channel on Large Scale Muddy Tidal Flat

Hiroichi Tsuruya<sup>1</sup>, Kazuo Murakami<sup>1</sup>,  
Isao Irie<sup>2</sup> and Kazumasa Katoh<sup>1</sup>

#### Abstract

Siltation mechanism in a 14km long approach channel on large scale muddy tidal flat is studied based on field investigations and numerical simulation. Natural conditions such as river discharge, waves, tides, tidal currents, and bed materials were measured over one year. The morphological change shows some relations with the grain size distribution of bed materials and current flow patterns. The net movement pattern of bed materials in the muddy tidal flat is given by the analysis of the field data. From the numerical simulation, it is revealed that the resuspended bed materials by waves from the surrounding tidal flat play an important role in the siltation process of the approach channel.

#### 1. Introduction

Many riverine ports in Asian countries have long approach channels which connect the river mouth with offshore through a muddy flat. The study on the transport mechanisms of fine sediments in estuaries is important to develop measures for the reduction of siltation releasing a port management body from high maintenance dredging cost. In the world, there are many estuaries and ports which suffer from siltation, and field investi-

gations have been conducted to understand the mechanism of high concentration mud movement (e.g., *Leussen and Velzen* 1989, *Costa and Mehta* 1990). Typical field investigations have been made for the siltation mechanisms in a monsoon-dominated coasts (*Terwindt et al.* 1987, *Hoekstra et al.* 1988).

In the present study, systematic field investigations were conducted in the port of Banjarmasin in South Kalimantan of the Republic of Indonesia.

The siltation mechanism on a large scale muddy tidal flat is investigated based on the field data. A numerical simulation is used to obtain detailed information on external forces which govern the siltation and the sources of materials deposited in the channel. A practical method to estimate the annual amount of deposition volume is also presented.

### 2. Natural Conditions

Field investigation was conducted from 10th September, 1988 to 10th September, 1989. Figure 1 shows the map of the

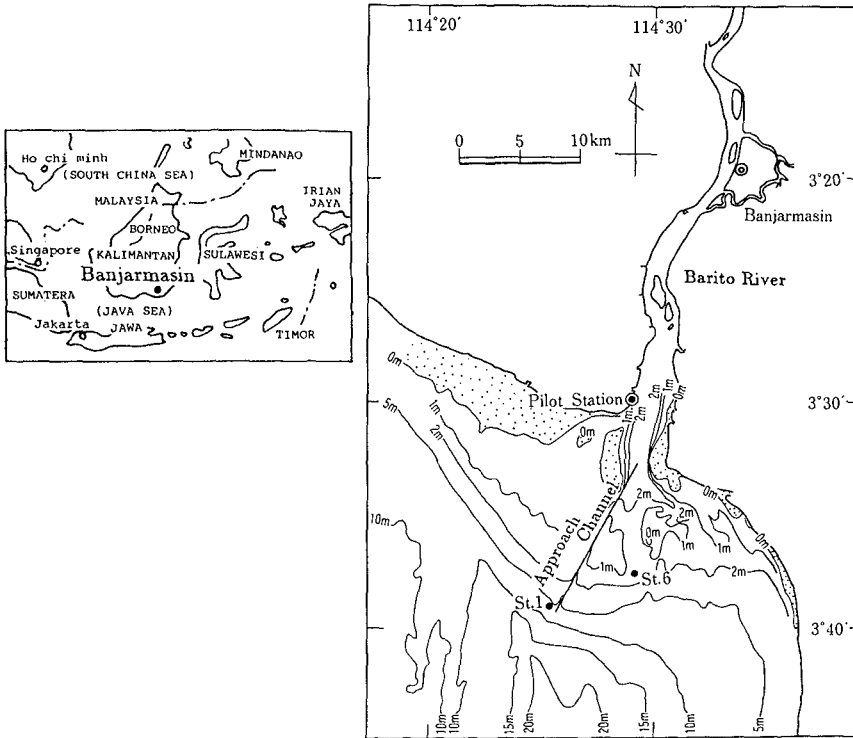

Fig.1 Map of Investigation Site

Table 1 Averaged Wave Conditions

Season	H(m)	T(s)	Direction
Rainy	0.58	4.0	S15° W
Dry	0.43	3.5	S10° W
85days	0.41	3.5	S15° W

investigation site. The port of Banjarmasin locates 26km upstream from the mouth of the Barito River. The size of the approach channel is 14km in length and 60m in width. In spite of the annual dredging (2~3 million  $m^3/y$ ), the planned water depth 6m is scarcely maintained. The river mouth is characterized by the formation of the large fine sand deposits on both sides of the approach channel. Waves, tides and winds were measured for one year. Measurements of tidal currents, saline wedge, turbidity, river discharge, etc. were also conducted.

Fig.2 Time Variation of River Discharge and Water Surface Elevation at Pilot Station

From the measurements of river discharge, it can be said that the river discharge in the dry season (from April to September) is less than  $1,000 \text{ m}^3/\text{s}$  and in the wet season (from October to March) is more than  $4,000 \text{ m}^3/\text{s}$ .

Waves were measured at St.1 near the entrance of the approach channel at the water depth of 6m for 1 year continuously at every 2 hours with an ultra-sonic wave gauge. The wave directions were determined by wind directions measured at the pilot station for wave periods less than 3 seconds, and by water particle movement directions for wave periods longer than 3 seconds. The averaged significant wave heights, wave periods and energetically weighted wave directions in each season are summarized in Table 1. In the table, the "85 days" shows the intermission period of dredging during which the actual deposition rate in the channel is estimated for the calibration of the numerical simulation of siltation.

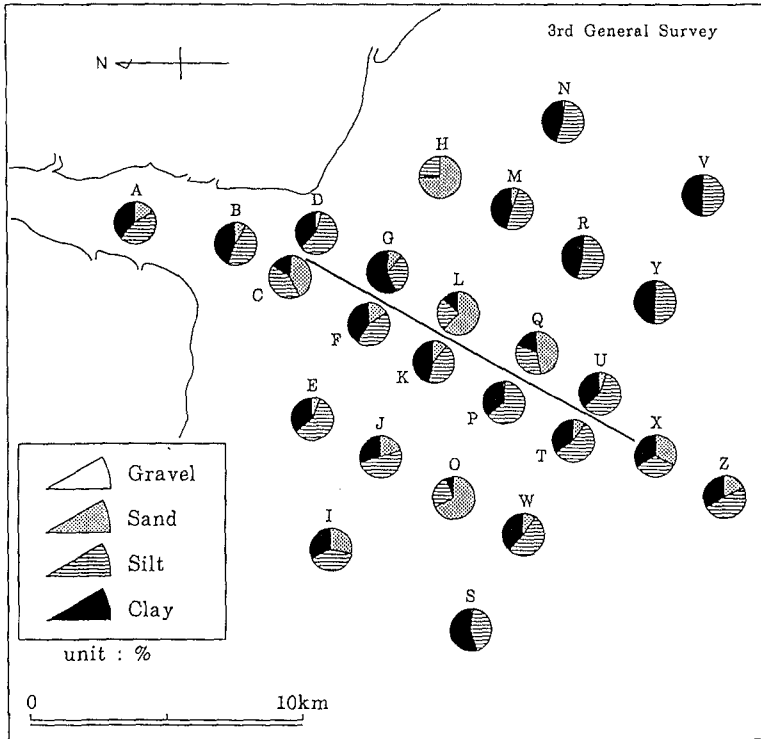

Tide is a basic factor in determining water level changes and currents in an estuary or coastal area. A tide gauge was set at the pier of the Pilot Station. According to the harmonic analysis of tides, the diurnal component  $K_1$  is the largest, and the semi-diurnal component  $M_2$  is the second largest. In the numerical simulation of deposition, the tidal level which is composed of  $K_1$  and  $M_2$  components is taken as the representative value. In the calculation, it is assumed that the periods of  $K_1$  and  $M_2$  components are just 24 hours and 12 hours, respectively. A typical time variations of the river discharge and the water surface elevation in a day is presented in Fig.2.

Tidal current observations were carried out at eleven stations with electro-magnetic current meters. The measuring stations are expressed in Fig.9 which will be shown later.

Another current observations were carried out by tracking the movement of drogues. This method is convenient to grasp the flow pattern briefly. Several drogues were released at the river mouth at high tide, then the observers follow each drogue position from the boat. The measured results will be shown in Fig.11. These current data are used for the calibration of tidal current simulation.

Bed material samplings were carried out in and around the approach channel. The total number of sampling points are 26. An example of the composition of bottom materials is shown in Fig.3. In the figure, bottom materials are classified into gravel ( $d > 2\text{mm}$ ), sand ( $0.074 < d < 2\text{mm}$ ), silt ( $0.005 < d < 0.074\text{mm}$ ), and clay ( $d < 0.005\text{mm}$ ).

At stations C, H, L, O and Q, the bottom sediments mainly

**Fig.3** Composition of Bottom Materials

consist of sand and silt, and the sand content is nearly 50% or more than 50%. At other stations, the bottom sediments mainly consist of clay and silt. From the results of field observations, bottom sediments around the approach channel are generally composed of fine silt materials, except at the tidal flat near the river mouth (Sts. C and H), and other three offshore areas beside the approach channel (Sts. L, O and Q).

### 3. Numerical Simulation

#### 3.1 Grid Arrangement

A three dimensional eight-layered level model with nested grids is used in the calculation (*Tsuruya et al., 1990*). The area for calculation is 40 km×50 km. The width of the approach channel in the present condition is 60 m. The length of it, on

the other hand, is 14 km which is about 230 times greater than the width. For the accurate estimation of the deposition rate in the approach channel, the small grid size is preferable. In the direction of the width, at least two grids must be placed in the approach channel. We can then set the transverse grid size as 30 m. As the square grid is unrealistic because of the requirement of tremendous number of grids, the longitudinal size is set to be ten times greater than the transverse grid size. Moreover, the area for calculation is divided into three areas with respect to grid sizes, that is  $270 \times 2,700\text{m}$ ,  $90 \times 900\text{m}$ , and  $30 \times 300\text{m}$  for each area from the first to the third, respectively. In the calculation the water depth is vertically divided into eight layers.

### 3.2 Tidal Currents

An example of the calculated tidal current distribution for the first layer (from  $-0.5\text{m}$  to  $1.6\text{m}$  measured from the datum level) of the second and the third area is shown in Fig.4. The time is 18 hour from the high tide as shown in Fig.2. The current vector distributions can be understood that the reproduction of current patterns in the numerical model is well in terms of the S-shaped bend of ebb currents (also see Fig.11).

### 3.3 Deposition Rate during Intermission Period of Dredging

The actual deposition rate in the approach channel can be estimated from the siltation volume measured with an echosounder. Dredging works were stopped from February 28th to May 24th 1989 for the measurement of natural mud deposition in the channel. Soundings were performed in the narrow area surrounding the approach channel. The duration of the intermission period of dredging was 85 days.

The measured volume of deposition in the channel within this period is shown in Fig.5 for both frequencies 210 kHz and 33 kHz. The Spot number 0 corresponds to the offshore side of the channel. The volume in the figure are not directly related to the substantial deposition volume to be dredged because the measured depth by echo-sounder varies considerably with the frequency adopted and density of the fluid or mud.

The substantial deposition rate in dry weight of materials per unit area is necessary in comparing the actual and calculated deposition rates. Therefore, the vertical distribution of water content of mud which was estimated by sampling is related to the echo-sounding and lead tests to get the substantial

deposition rate. **Figure 6** shows the measured and assumed vertical distribution of water content. The percentage of water content 110% corresponds to the bulk density about  $1.45\text{g}/\text{cm}^3$ . The water content near the bed which was detected by 33kHz echo-sounder was 110.3% and the level here was almost coincident with that measured by the lead. Around the level measured with the 210kHz echo-sounder, the sample showed high water content at 1,260.4%. At the end of the intermission period of dredging, the level which was detected by 33kHz echo-

**Fig.4** Current Vector Distribution (at 18:00, 1st layer)

Fig.5 Apparent Siltation Volume along Channel Axis (width ±50m)

Fig.6 Measured and Assumed Water Content of Mud

sounder increased from the initial level. This means the substantial bed shoaling. Based on the data stated above, we assume the vertical distribution of water content  $W$  (%) in the approach channel as shown in the right hand side of Fig.6. From the assumption we can estimate the substantial deposition rate. The estimated substantial amount of deposition during the intermission period of dredging (85days) is shown in Fig.7 as a histogram. The measured deposition volume is converted to that having the water content of 110%. For this value, the wet bulk density of soil is  $1.45 \text{ t/m}^3$  which is the same as that of the in

Fig.7 Observed and Calculated Deposition Rate

situ dredged soil. The total amount of deposition in 85 days thus estimated is  $733,000 \text{ m}^3$ .

To calibrate the model, the deposition rate in a day is calculated with a super-computer under the measured natural conditions such as the river discharge ( $3,500 \text{ m}^3/\text{s}$ ), concentration of suspended solids of the river water ( $50 \text{ mg/l}$ ), waves ( $H_{1/3}=41 \text{ cm}$ ,  $T_{1/3}=3.5 \text{ s}$ ), etc. The calculated deposition rate in 85 days is obtained by multiplying 85 by the calculated deposition rate in a day. It can be directly compared with the measured one as shown in Fig.7. Their distribution patterns agree well each other.

#### 4. Results and Discussion

After the calibration of the present model is completed, the deposition rates during the rainy and dry seasons can be estimated with the corresponding natural conditions. Wave direction, significant wave height and period are statistically analyzed for the rainy and dry seasons as already shown in Table 1. The river discharge is given by the field observation as  $5,000 \text{ m}^3/\text{s}$  for the rainy season and  $1,500 \text{ m}^3/\text{s}$  for the dry season. The thick line which is illustrated as "Total" in Fig.8 shows the calculated deposition rate for the rainy season of which duration is 182 days.

To investigate the source of deposited materials in the channel, the direct contribution from the river is estimated by simulation under the assumption of the fixed bed condition in the tidal flat and the approach channel, so that only the sediments from the river are the source of deposited materials. As no erosion in the approach channel is allowed in the calculation of the fixed bed condition, the deposition rate on the onshore side at 13 ~14km is larger than that of the total deposition rate. Although the rate of deposition is not a linear function of the concentration of mud for the free settling region, the difference between two curves in Fig.8 approximately correspond to the settled mud which is resuspended by waves from the surrounding tidal flat. From Fig.8, it can be concluded that the direct contribution from the river is not large except near the river mouth and the resuspended bed materials by waves from the surrounding tidal flat play an important role in the siltation process of the approach channel which is constructed in a large scale muddy tidal flat.

The hodographs of tidal currents in terms of the mean velocity and  $K_1+M_2$  components (50cm above the sea bed) are shown in Fig.9. The numbers of the hodographs correspond to the time from the high tide. The tidal current vector in the west flat (west of the main stream) rotates clockwise and the hodographs show round shapes. In the east flat, on the other hand, they rotate anticlockwise and show long and narrow

Fig.8 Calculated Deposition Rate for Rainy Season

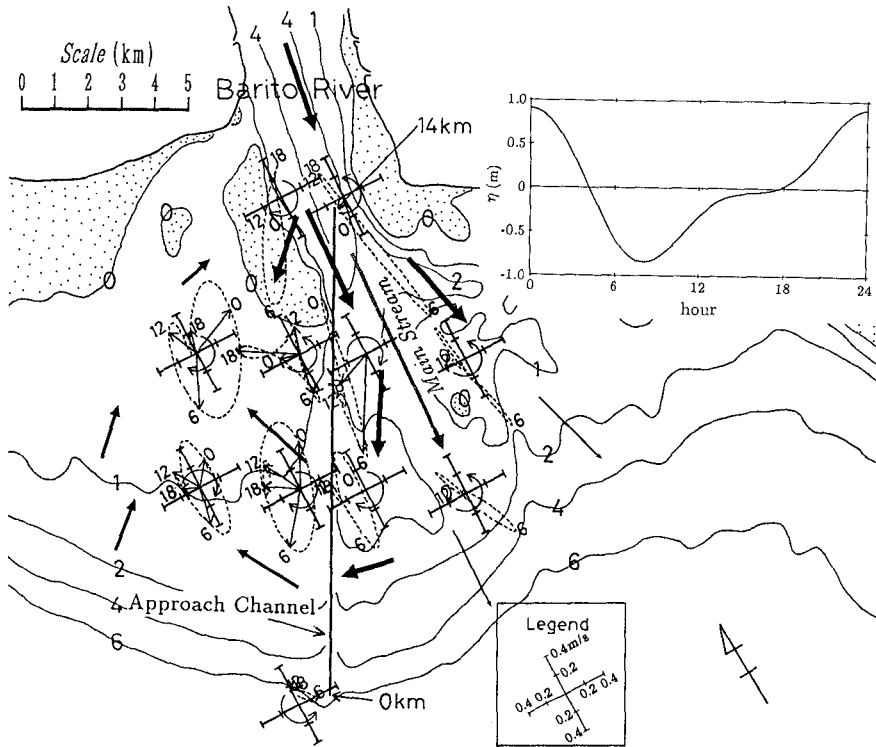

Fig.9 Hodographs of Tidal Currents and Sediment Movements

shapes. As the diurnal constituent  $K_1$  is dominant here, the surface elevation  $\eta$  varies with time as schematically shown in Fig.9. The tidal level given here is somewhat different from that in Fig.2. In general, when  $\eta$  is low or during low tide (5~18hr), the sea bed in the tidal flat is influenced considerably by waves because of the high orbital velocity and the rate of erosion from the bed is larger than that of the high tide. The tidal currents during the low tide in the west flat are dominated by westward currents, whereas during the high tide that are dominated by eastward currents as shown in Fig.9. As a result, the net transport of sediments in the middle part of the west flat is from the south-east to the north-west according to the current direction. The dominant wave direction is south-west and the sediment movement in the west flat is directed to the north-east direction because of the mass transport by waves and asymmetric characteristics of tidal currents. The directions of the net transport of bed materials expected from the above consideration are shown

in Fig.9 as the arrows with the thickness roughly showing the transport quantity.

Morphological change during 84 years is analyzed by comparing the Chart around 1905 with the surveyed sounding data in 1989. In Fig.10, accretion and erosion areas more than 60cm are shown as the thin contour lines. Near the river mouth, typical accretion can be found in the west side of the channel. In the east side near the river mouth, on the other hand, erosion is dominant. At the offshore side of the channel, erosion also can be found in the west side of the channel. In the east side near the river mouth, on the other hand, erosion is dominant. At the offshore side of the channel, erosion also can be found in the west side of the channel. The thick contour lines in the figure show the horizontal distribution of the median diameter of bed materials. There are four distinct peaks for the median diameter contours. In the west bank of the approach channel, there are two peaks and the maximum values are greater than  $1000\mu\text{m}$ . In the east bank, on the other hand, the maximum values ( $940\mu\text{m}$  and  $510\mu\text{m}$ ) are slightly smaller than that of the west bank. Figure 11 shows the loci of drogues which represent the surface current and calculated velocity distribution at the third layer (from 1 to

Fig.10 Morphological Change and Grain Size Distribution

**Fig.11** Measured Loci of Drogues and Calculated Flow Pattern

1.5m below the datum level) at an ebb tide. The loci of drogues are shown as thick solid arrows. From **Figs.10** and **11**, it can be thought that the west bank near the river mouth is formed by deposition of coarse sand which is carried from the river because of the sudden decrease of the current speed in this area and of the eastward longshore sand transport due to waves attacking from the dominant SW direction. The eroded area in the east part of the river mouth is formed by the strong current which is directed to the east direction from the river mouth, and only coarse sand which resist the strong tractive force can exist in this area. The accretion areas, therefore, are formed offshore side in the east bank. The erosion area in the west offshore side will be formed by the continuous wave attack.

## 5. Conclusions

The substantial transport direction of fine sediments on the large tidal flat was investigated based on the field data and

numerical simulations. The net transport of sediments is from the south-east to the north-west in the middle part of the west flat. Finally, the sediment movement in the west flat is directed to the north-east direction because of the mass transport by waves and asymmetric characteristics of tidal currents.

From the numerical simulation, it is revealed that the resuspended bed materials by waves from the surrounding tidal flat play an important role in the siltation process of the approach channel.

Current velocity and waves play an important role in the formation of large scale muddy tidal flat.

## CHAPTER 221

### MODELLING OCEAN WAVES IN THE COLUMBIA RIVER ENTRANCE

L.A. Verhagen<sup>1,2</sup>, L.H. Holthuijsen<sup>1</sup> and Y.S. Won<sup>1</sup>

#### Abstract

Observations by Gonzalez et al. (1984) and Gonzalez (1984) of swell penetrating the entrance of the Columbia River provide an excellent opportunity to test linear wave theory for wave - current interactions. In the present study a two-dimensional wave model for short-crested waves based on the linear wave theory is used. The model includes the propagation effects of currents and also generation and dissipation of the waves. The results agree fairly well with the wave observations in the river entrance, in spite of an uncertainty in the bathymetry and currents. Numerical experiments show that waves from westerly directions are focused in the entrance by refraction on a bar in front of the entrance and that current induced wave guide effects enhance this focusing in ebb conditions.

#### Introduction

Swell entering the Columbia River (United States west coast) may amplify considerably due to bottom and current effects. Gonzalez et al. (1984) and Gonzalez (1984) acquired observations in the river entrance which provide an excellent opportunity to study wave-current interactions. To compute the wave field, the same authors used a one-dimensional model for monochromatic, long-crested waves. Later, Rao (1990) used a two-dimensional model for random, short-crested waves. However, neither model takes the two-dimensional current structure into account nor generation and dissipation of the waves (except that the wave height or spectrum has an a priori imposed upper limit). In this study we use a model that is based on linear wave theory for short-crested waves with energy sources and sinks (in particular bottom and current induced wave breaking and bottom dissipation). It is a two-dimensional model that computes the two-dimensional wave field so that the two-dimensional structure of the wave field can be related to features in the bottom and current field. The effects of bottom and current induced refraction are addressed explicitly.

## Observations

The Columbia River entrance is located on the Pacific east rim at the west coast of the United States of America (see Fig. 1). It is a rather energetic region with high waves (in one of the observed cases the significant wave height of the swell was about 6.5 m) and an average river discharge of 10,000 m<sup>3</sup>/s and peak discharges of more than 40,000 m<sup>3</sup>/s. On the average 850 search and rescue missions are conducted and about 10 lives are lost per year (Gonzalez 1984).

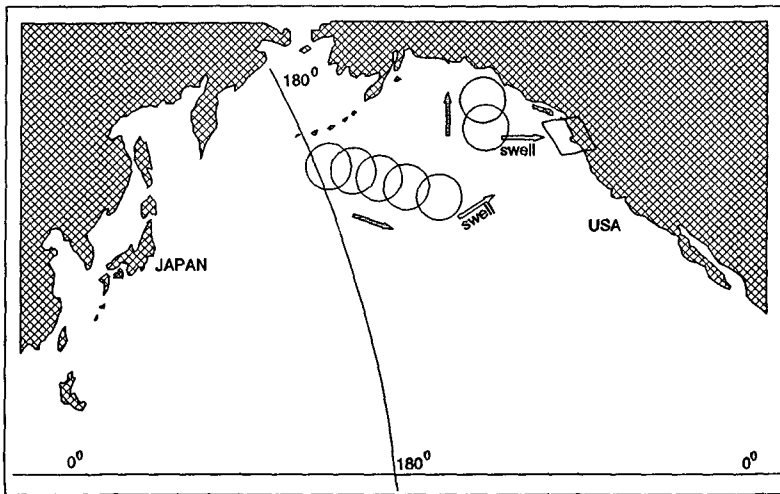

Fig. 1 The tracks of the two swell generating storms of this study. The box indicates the location of the Columbia River entrance.

Gonzalez (1984) and Gonzalez et al. (1984) observed swell that was generated in two severe storms in 1979 and 1981. From local observations at the Columbia River entrance and weather maps Gonzalez (1984) concluded that the first generating storm was a storm moving in a few days across a fair distance in the northern Pacific due west of the Columbia River entrance. The second storm was analyzed by Gonzalez et al. (1984) and they concluded from weather maps that it was a storm relatively nearby, moving from an offshore position to the Canadian coast. The tracks of these storms are schematically indicated in Fig. 1.

The bathymetry of the Columbia River entrance that we used in this study is given in Figs. 2 and 3. It is based on a map from 1983 (US Army Engineer District Portland MC-1-543) for the region seaward from the jetties (outer region) and a map from 1966 (C&GS 6151) for the region up-river from the jetties (inner region). These maps may not properly represent the bathymetry during the observations. In fact, in the outer-region we found considerable differences with the 1966 map (of more than two meters in depth near the south end of the "bar", see Figs. 3a and 3b). The map that we finally used for the outer region (the 1983 map, Fig. 3a) seems to be the closest in time to the observations that were available to us (see acknowledgements). The inner region is regularly dredged and we therefore assume that the bathymetry there has not changed dramatically over the years. To

investigate the effects of this uncertainty in bathymetry we will show results using the map from 1966 for the outer region (Fig. 3b).

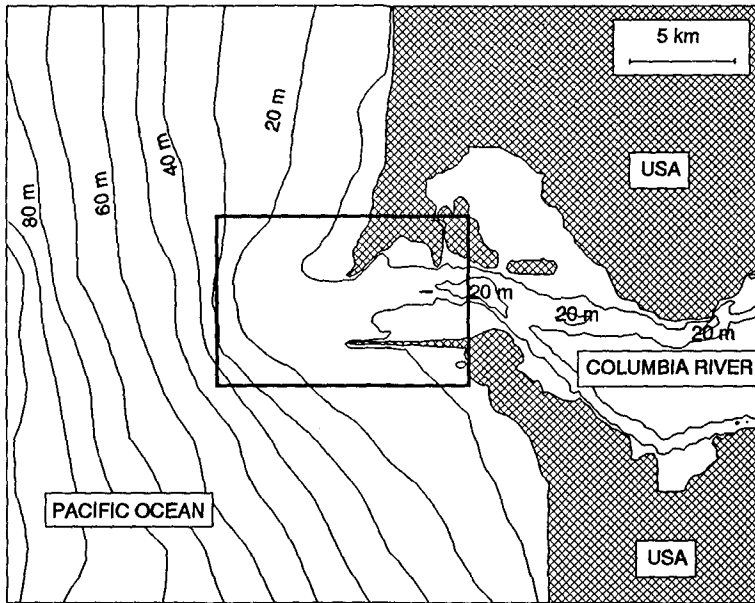

Fig. 2 The large scale bathymetry off the Columbia River entrance. The box indicates the region shown in Figs. 3 and 5.

From the observations we selected a young-swell case and an old-swell case. The young swell arrived on 12 September 1981. It had been generated in a storm moving to Canada a few hundred miles north-west from the Columbia River entrance in the period 8-10 September. The incoming significant wave height and the mean wave period were observed with a wave buoy (NOAA data buoy 46010, located about 10 km offshore) to be 2.8 m and 8.6 s (ebb case, 16:00 PST) and 7.8 s (flood case, 11:00 PST) respectively. We estimate the mean wave direction from the Side-Looking Airborne Radar (SLAR) images in Gonzalez et al. (1984) to be  $290^\circ$  true North. We estimate from the angle of view from the Columbia River entrance to the width of the generating storm area that the directional spreading of the waves was  $13^\circ$  (directional standard deviation of the directional energy distribution). In the river entrance a drifting waverider buoy measured the wave field (tracks shown in Figs. 3c and 3d). The old swell arrived at the location during the period 15 - 20 October 1979. It had been generated 9 days before in a severe storm in the northern Pacific moving from the date line towards the location. On October 19 at 16:00 PST the incoming significant wave height and the mean period were observed with a deployed waverider buoy to be 4 m and 15 s respectively. Gonzalez (1984) estimated the mean wave direction from the time development of the locally observed peak frequency and weather maps to be  $270^\circ$  true North. The directional spreading we estimate with the same technique as above to be  $6^\circ$ . The waves in the entrance were observed near buoy 8 with a waverider buoy (see Figs. 5c and 6).

Panel c) significant wave height young swell case (ebb). Panel d) significant wave height young swell case (flood). Tracks of buoy shown as centre line between A and A (parallel lines at 250 m distance).

### Wave and current models

The wave model that we used (the HISWA model, Holthuijsen et al., 1989) is based on a parameterization of the spectral balance of wave action (defined as wave energy divided by relative frequency). In the absence of a mean current it reduces to a parameterized energy balance. The parameterization is based on the presentation of the waves with a spectrum that is discrete spectral in the directions and parametric in the frequencies. This implies that the spectral representation of short-crestedness of the waves is maintained. All propagation in the model is based on linear wave theory while the sources and sinks are parametric representations of wind growth, wave breaking (whitecapping and surfing), bottom friction and blocking due to counter current. The model computes the spatial variation of this spectrum by integrating the local effects of wind, bottom and currents while propagating with the wave components on a regular grid covering the computational area (identical to the total area of Fig. 2 with 250 m resolution). Refraction is modelled as a continuous directional shifting of wave action in spectral space. For coastal regions the propagation time through the area is small compared to the time scale of wind and current variations. Time has therefore been removed as a variable. In the present study with swell in a coastal region, the only effective sources and sinks in the model are those representing wave breaking and bottom friction.

The tidal model which has been used (the DUCHESS model, Booij, 1989) to simulate the ebb and flood flow in the Columbia River entrance is based on the two-dimensional shallow water equations. It includes hydrostatic and atmospheric pressure gradients, bottom and wind stresses, Coriolis force and horizontal eddy viscosity. The inclusion of nonlinear terms such as advective acceleration, viscosity and stresses makes DUCHESS a nonlinear tidal model.

### Results

To drive the tidal model, the tidal constituents at the open ocean boundary and at Tongue Point (up-river boundary in Fig. 2) were taken from standard tide tables (Admiralty Tide Tables). In spite of choosing a relatively low frictional coefficient, we were not able to reproduce the current observations of Gonzalez et al. (1984) and Gonzalez (1984). We therefore multiplied the magnitude of all computed current vectors with a constant factor to match the observed (corrected to depth-averaged) values (factor 1.08 in the young swell case (ebb), 1.50 in the young swell case (flood) and 1.23 in the old swell case (ebb)). The current pattern for the old swell case is shown in Fig. 3a for the 1983 bathymetry (and in Fig. 3b for the 1966 bathymetry). The ocean wave boundary conditions were taken from the buoy and radar observations.

The young swell case is considered first because the wave observations in this case provide some spatial information of the wave field in the Columbia River entrance and therefore provide a good test of the fidelity of the HISWA model. The wave field is computed with HISWA for one ebb case (12 Sept. 1981, 16:00 PST) and one flood case (12 Sept. 1981, 11:00 PST). The results for the ebb case are shown in Fig. 3c where also the track of the drifting buoy is shown. The maximum significant wave in the area is approximately 4.2 m. The HISWA results along the buoy track (and 250 m north and south of this track) are compared with the drifting buoy observations in Fig. 4. For the two up-river locations, the agreement seems

Fig. 4 The computed significant wave height for the young swell case compared with the buoy observations. Upper panel is ebb case, lower panel is flood case. The track of the buoy is shown in Fig. 3.

to be fair, considering the spatial resolution of the model (250 m). For the one down-river location, there is no such agreement (observed 4 m and computed 2 m significant wave height). Considering the spatial distribution of the waves, it seems unlikely that a simple error in the location of the buoy is responsible for this discrepancy. On the other hand, a large error in the model is not very likely either considering the other results (below). The results for the flood case are shown in Fig. 3d and 4 (maximum significant wave height 3.5 m). Again, the results seem to be fair considering the uncertainty in bottom and currents.

The old swell case is rather spectacular with a significant wave height of 4 m amplifying to nearly 6.5 m on the inner bar (near buoy 8). To inspect the physical processes to some extent we first show the HISWA results without currents and without bottom refraction effects (accomplished by de-activating the refraction terms in HISWA). The results are given in Fig. 5a. It is obvious that the remaining processes in the resulting quasi-one-dimensional situation (i.e. rectilinear propagation, bottom induced shoaling and bottom friction) do not affect the wave field considerably (maximum significant wave height of 4.6 m over the bar). When we add bottom induced refraction (still without current), the results are as shown in Fig. 5b. It is obvious that the bar concentrates wave energy in front of and between the jetties, probably by a caustic type refraction pattern. The maximum significant wave height is 5.8 m at the southern edge of the bar. If we finally add ebb currents to the situation we see from Fig. 5c that the current field enhances the waves further, probably by a wave guide effect (trapping of wave components around the centre of a counter current). The maximum significant wave height is now 6.25 m at the southern edge of the bar. There is a second maximum of 6.19 m between the jetties near buoy 8 (Fig. 6). This secondary maximum differs only 4.5 % from the observed 6.48 m of swell "near buoy 8" (quote from Gonzalez, 1984). This is a surprisingly good agreement considering the uncertainty in the bottom and current fields used in the computations. To show the effect of this

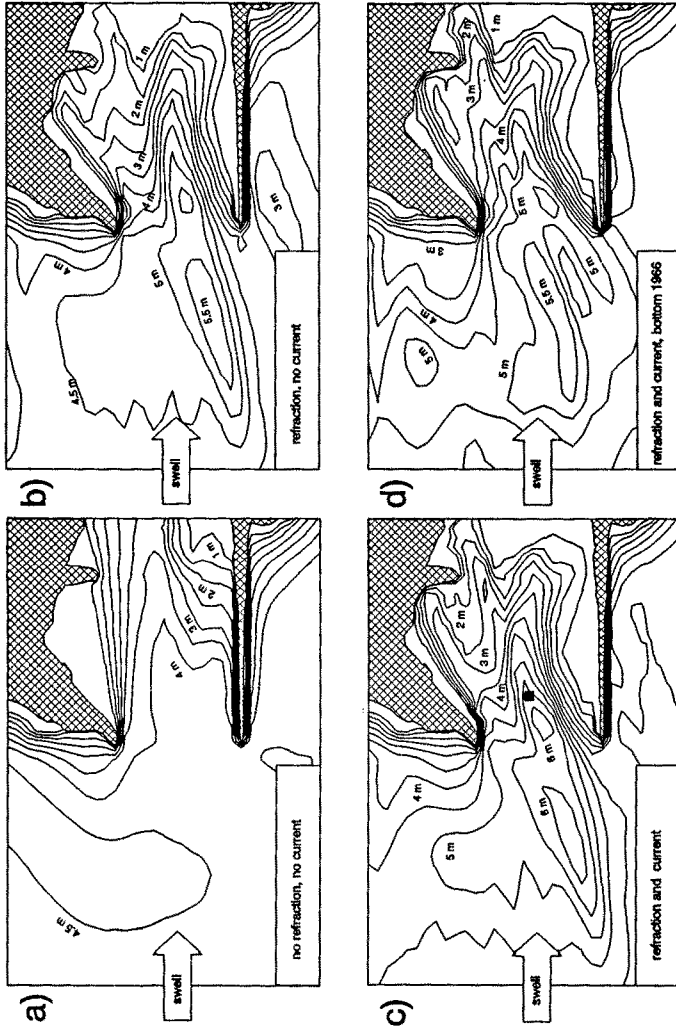

Fig. 5 The computed significant wave height in the old swell case. Panel a) without refraction and without currents (1983 bathymetry). Panel b) with refraction but without currents (1983 bathymetry). Panel c) with refraction and with currents (1983 bathymetry). Panel d) with refraction and with currents but 1966 bathymetry. Location of buoy 8 indicated in panel c) with black square.

uncertainty, we repeat the last computations with the bathymetry from the 1966 map (and corresponding current field). The results are shown in Fig. 5d where the maximum significant wave height is 5.9 m (at the southern edge of the bar).

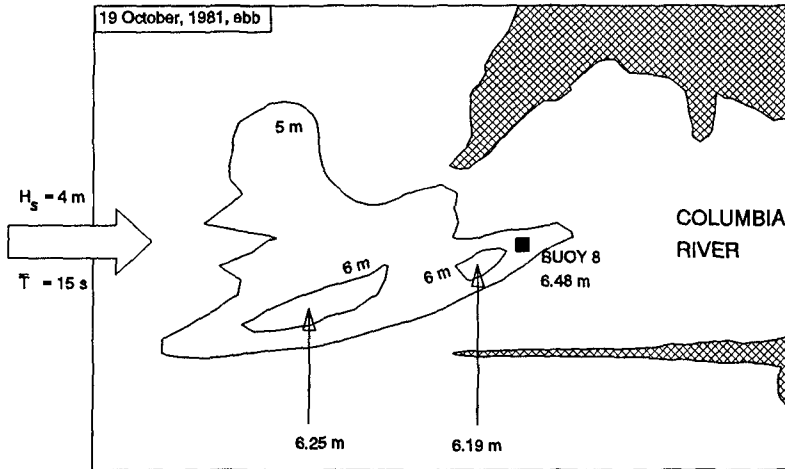

Fig. 6 The computed significant wave height for the old swell case compared with the buoy observation near buoy 8 (copied from Fig. 5c).

## Conclusions

The observations of Gonzalez et al. (1984) and Gonzalez (1984) seem to provide an excellent opportunity to test wave-current interactions within the linear wave theory. This linear wave theory is represented in the HISWA model and we find general agreement between the computational results and the observations. However, this agreement is better than one would expect considering the uncertainty in the bottom and current data used in the computations.

Independent of this uncertainty we can conclude that waves approaching the Columbia River from the west are focused into the river entrance by bottom induced refraction. This focusing is further enhanced in ebb conditions by current induced refraction.

## Acknowledgements

With pleasure we acknowledge that J. List of the U.S. Geological Survey helped us with obtaining the bathymetry in the Columbia River entrance. The work of one of the authors (Y.S.W.) was supported by the European Economic Community under contract MAST-0026-C(MB).

## CHAPTER 222

### Sediment Transport in Dredged Trenches

S. Opatha Vithana\*, MICE(Lond.), MIEAust.

#### Abstract

An attempt was made, using a 3-dimensional turbulent model coupled with a comparatively simple depth averaged sand transport model, to assess the computational feasibility of predicting sediment transport in a dredged trench, caused by a steady flow passing across the trench. A sophisticated computer software package was used to simulate 3-dimensional turbulent flow by the finite element method. A Profile Model, which discretized the transport process to enable successive computation of the flow field, was used for morphological evolution of the channel bed. A physical model was built and tested to validate the numerical models.

#### 1.0 Introduction

An attempt to set up a mathematical theory of sedimentation should take into account both the character of the fluid motion and character of the sediment motion. The K-Epsilon model is considered as the best mathematical model available at present to represent turbulent flow. Any mathematical model to represent sediment transport should take into account the movement of sediment by both suspension and bed load. Movement of sediment in suspension is considered to be best described by the diffusion-convection equation. Therefore, if K-Epsilon model is coupled with the diffusion-convection equation together with a bed load formula one can expect a very good mathematical model to represent sediment transport. However, for long term morphological computations implying the successive computation of the flow field, the use of K-Epsilon model or the diffusion-convection equation is still not attractive because of the limitations of available computer resources. To overcome this problem various mathematical models have been proposed by combining the simplified diffusion-convection equation with comparatively simple flow models.

In this paper an attempt made to assess the computational feasibility of solving this complex problem by using a

3-dimensional turbulent model coupled with a comparatively simple sand transport model is presented.

2.0 Physical Model

A physical model of the entry to a dredged navigational channel through a shelving coastline was built to simulate siltation effects. The flow and siltation conditions obtained from the physical model were used to verify the two numerical models which were under assessment.

The plan view of the inlet area considered for study is the area enclosed by broken lines in Fig. 1.0. Dimensions and isometric view of the flow domain are shown in fig.2.0.

Fig. 1.0: Area Considered for Detailed Study.

The slope of the bed in the transverse direction represents the gradient of the sea bed in the shore region.

The bed consisted of fine to medium sand of almost uniform size with the characteristic diameters of:  $d_{10} = 150 \mu\text{m}$ ,  $d_{50} = 240 \mu\text{m}$ , and  $d_{90} = 380 \mu\text{m}$ . A continuous steady flow with a mean flow velocity of about 0.3 m/sec, which was considered to be large enough to initiate movement of the sediment used in the experiment, was maintained into the model during the experiment.

Fig.2.0: Isometric View of the Flow Domain.

For validation of the flow simulation model, inlet and downstream flow velocity measurements should be carried out on a fixed bed model.

Therefore, at the first instance, the entire bed of the physical model was covered with steel sheets to maintain a fixed bed and all flow velocity measurements were carried out using Laser-Doppler velocity measuring equipment. In order to obtain input velocity boundary conditions for the flow simulation model, inlet velocity components in longshore and offshore

directions were measured on all finite element grid lines. For calibration of the flow simulation model, measurement of the longshore velocity components were carried out at four different downstream sections, at  $x = 1.75, 3.0, 4.5$  and  $7.25$  meters.

When calibration of the flow simulation model was completed, the metal sheets used to cover the bed were removed and the flow was restarted to validate the sand transport model. After 6.0 hrs. of continuous steady flow, the flow was discontinued and the bed profiles of the entire area under consideration was measured.

### 3.0 Numerical Models

#### 3.1 Flow Simulation Models

A general purpose computer software package (FIDAP) which uses the finite element method to simulate many classes of incompressible fluid flows was used to simulate turbulent flow across the channel. In FIDAP the three-dimensional, steady, turbulent flow of an incompressible viscous fluid is represented by the following equations:

$$\text{- Mass Conservation; } \frac{\partial u_j}{\partial x_j} = 0$$

$$\text{- Momentum Conservation; } u_j \frac{\partial u_i}{\partial x_j} = - \frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j} \left[ \mu \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \right]$$

where,  $u_j$  = mean fluid velocity component,  $p$  = fluid pressure,  $x_j$  = cartesian coordinates,  $i = 1,2,3$ ,  $j = 1,2,3$ ,  $\mu$  = total viscosity =  $\mu_0 + \mu_t$ ,  $\mu_0$  = laminar viscosity,  $\mu_t$  = turbulent viscosity.

Two possible turbulent models are available in FIDAP to determine the distribution of turbulent viscosity (or eddy viscosity).

##### 3.1.1 K-Epsilon Model

The three-dimensional version of the K-Epsilon model comprises three additional equations as indicated below:

$$\rho u_j \frac{\partial K}{\partial x_j} - \frac{\partial}{\partial x_j} \left( \frac{\mu_t}{\sigma_K} \frac{\partial K}{\partial x_j} \right) - \rho \epsilon$$

$$\rho u_j \frac{\partial \epsilon}{\partial x_j} - \frac{\partial}{\partial x_j} \left( \frac{\mu_t}{\sigma_\epsilon} \frac{\partial \epsilon}{\partial x_j} \right) - \rho C_2 \frac{\epsilon^2}{K}$$

$$\mu_t = \rho C_\mu \frac{K^2}{\epsilon}$$

FIDAP adopts the Galerkin form of the weighted residuals method to solve these differential equations by the finite element method.

##### 3.1.2 Mixing Length Model

In the mixing length model, the turbulent viscosity is represented by the Prandtl mixing length hypothesis.

$$\mu_t = \rho l_m^2 \left[ \left( \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \frac{\partial u_i}{\partial x_j} \right]^{1/2}$$

In FIDAP the mixing length values are computed based on Nikuradse's (Rodi W., 1980) Formula:

$$\frac{l_m}{R} = 0.14 - 0.08 \left(1 - \frac{y}{R}\right)^2 - 0.06 \left(1 - \frac{y}{R}\right)^4$$

where, R = depth of flow, y = normal distance from the wall.

### 3.1.3 Boundary Conditions for Flow Simulation Models

#### 3.1.3.1 Inlet Boundary

Mean velocities of flow in all three coordinate directions (u,v,w), turbulent kinetic energy (K), and its dissipation rate ( $\epsilon$ ) should be specified at the inlet.

##### (a). Mean Flow Velocities

Inlet velocity components in the longshore and offshore directions measured in the physical model were prescribed as input to the numerical model. Inlet velocity in the vertical direction was assumed to be zero.

##### (b). Turbulent Kinetic Energy

Time-averaged values of the fluctuating components of the fluid velocities  $\bar{u}'$  and  $\bar{v}'$  measured at the inlet by the Laser-Doppler equipment were used in calculating the turbulent kinetic energy (K) at the inlet, using the formula:

$$K = \frac{1}{2} [(\bar{u}')^2 + (\bar{v}')^2 + (\bar{w}')^2]$$

The prescribed initial values of K and  $\epsilon$  at the inlet seems to exert little influence on the predictive accuracy of the flow simulation models (Leschziner M.A., et al. 1979). Therefore, as velocity measurements were not carried out in the vertical direction it was assumed that,  $\bar{w}' = \bar{u}'$ .

##### (c). Dissipation Rate of Turbulent Kinetic Energy

Dissipation rate of turbulent kinetic energy ( $\epsilon$ ) was evaluated from the following formula (Launder B.E., et al. 1974) using the values of measured turbulent kinetic energy (K).

$$\epsilon = \frac{C_\mu^{3/4} K^{3/2}}{l_m} ; \text{ in which } l_m \text{ is a mixing length}$$

It was assumed that the value of mixing length is given by the well-known ramp function for wall boundary layers (Launder B.E., et al. 1972):

$$l_m = \lambda y_G$$

where,  $\lambda$  = a constant in mixing length model,  
 $y_G$  = effective width of shear flow.

The characteristic shear width of flow was calculated using the

measured inlet velocity profiles (Launder B.E., et al. 1972). A value of 0.125 was assumed for  $\lambda$ .

### 3.1.3.2 Wall Boundaries

The variation of the turbulent viscosity within the viscous sublayer in the near-wall region was modelled using van Driest's mixing length model with a transition to the standard high Reynolds number K-Epsilon model in flow region beyond the viscous sublayer where the turbulence is fully developed. In the van Driest mixing length approach, the eddy viscosity is defined as described in Section 3.1.2 and the van Driest mixing length is defined as,

$$l_m = k \delta (1 - e^{-y_{\text{eff}}^*/A})$$

where, A = an empirical constant, k = von Karman constant,  $\delta$  = normal distance from the wall.

In this equation  $y_{\text{eff}}$  is the dimensionless normal distance from the wall defined in terms of the turbulent kinetic energy as,

$$y_{\text{eff}}^* = \rho \delta \frac{(c_\mu^{1/2} K)^{1/2}}{\mu}$$

where,  $c_\mu$  = a turbulent constant,  $\mu$  = dynamic viscosity, K = turbulent kinetic energy.

While the computational domain for the mean flow equations encompasses the flow domain up to the solid boundary, the corresponding computational domain for the K- $\epsilon$  turbulent model only extends to near wall region. As part of near-wall implementation, FIDAP applies the following boundary conditions for K and  $\epsilon$ .

$$\frac{\partial K}{\partial n} = 0 ; \quad \epsilon = \frac{(C_\mu^{1/2} K)^{1.5}}{k \delta}$$

where, n is the direction normal to the boundary.

If no-slip boundary condition is valid at the wall, then all the velocity components assume a zero value at the wall.

### 3.1.3.3 Outlet Boundary

The outlet boundary was located far away from the area of interest so as to allow the redevelopment of fully developed flow downstream. At the outflow no velocity boundary conditions were imposed, resulting in zero normal and tangential stresses at the outflow boundary. Similarly, the turbulent kinetic energy and dissipation were not specified at the outflow boundary.

### 3.1.3.4 Water Surface

The position of the free water surface was assumed to be fixed and at the free water surface the velocity component in the vertical direction was assumed to be zero.

### 3.1.4 Creating Finite Element Mesh

The three-dimensional flow domain was first divided into a set

of 8 node brick elements. All wall boundaries were divided into quadrilaterals with 4 nodes. As the computation time needed to solve the equations is large for a finer mesh, a compromise had to be made between the accuracy and the computation time before selecting the following dimensions.

The longitudinal direction was divided into 31 elements of length 250 mm each and the transverse direction consisted of 8 elements of width 150 mm each. The vertical direction consisted of 8 elements, the dimensions of which were decreased towards the bed to provide a greater resolution in the zone where large velocity gradients exist. The solution domain thus consisted of 1984 brick elements of 8 nodes each and 2592 nodal points.

3.1.5 Fluid Properties

Following data was used as the physical properties in the flow simulation models.

fluid density,  $\gamma = 1000.0 \text{ kg/m}^3$ ; kinematic viscosity,  $\nu = 1 \times 10^{-6} \text{ m}^2/\text{sec}$ ; turbulence constant,  $c_{\mu} = 0.09$ ; empirical constants:  $c_{1E} = 1.44$ ,  $c_{2E} = 1.92$ ,  $\sigma_k = 1.00$ ,  $\sigma_\epsilon = 1.30$ ; von Karman constant,  $k = 0.41$ ; van Driest's constant,  $A = 26.00$ .

3.2 Sand Transport Model

The model considered was basically similar to what was used by Hillier and Jenkins (1976). As shown in Figure 3.0, the model zone was divided into a grid system on the horizontal plane, the longshore and offshore directions being divided into equal number of sections as used in the mesh for flow simulation models.

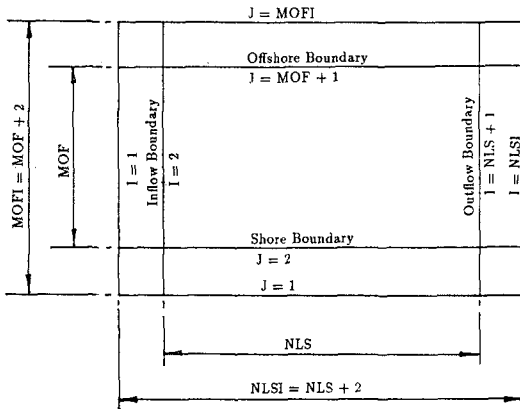

Fig. 3.0: Grid System of the Sand Transport Model

Fig. 4.0: Sediment Transport in a Cell

- MOF = number of cells in the offshore direction = 8
- NLS = number of cells in the longshore direction = 31

For the purpose of comparison, two different formulae were used to calculate the sand transport. In the first method, Shield's (1936) bedload formula and in the second method a new approach to calculate sediment transport by Ackers and White (1973) was used.

### 3.2.1 Shield's Formula

Shield's Bedload Formula for calculation of sand transport can be written as follows:

$$\frac{q_s \gamma_s}{q S \gamma} = 10 \frac{\tau_0 - (\tau_0)_{cr}}{(\gamma_s - \gamma) d}$$

where;  $q_s$ ,  $q$  = rate of bedload and liquid in volume per unit time and unit width respectively,  $S$  = slope of the energy grade line,  $\gamma$  = specific weight of liquid,  $\gamma_s$  = specific weight of sediment,  $\tau_0$  = shear stress,  $(\tau_0)_{cr}$  = critical shear stress at which sediment particles are about to move,  $d = d_{50}$  = mean particle diameter.

The rate of liquid flow can be related to the mean flow velocity as:  $q = V \times H$ ; in which,  $V$  = mean flow velocity,  $H$  = depth of flow.

The bed shear stress can be calculated from (2),  $\tau_0 = \gamma H S$ ; the critical bed shear stress, ( $\text{kg/m}^2$ ), can be related to the mean particle diameter (meters) as (Kalinske A.A.),  $(\tau_0)_{cr} = 192.65 d$ .

The slope of the energy grade line can be expressed in metric units (for manning's  $n = 0.025$ ) as (Graf W.H., 1971),

$$S = \frac{0.0006 \times V^2}{H^{4/3}}$$

Substitution of these values along with  $\gamma_s = 2650.0 \text{ kg/m}^3$  in Shield's Formula will finally yield:

$$q_s = 0.0057 \frac{V^3}{H^{1/3}} [0.59723 \frac{V^2}{H^{1/3}} - 0.04624]$$

Therefore when the values of  $V$  and  $H$  are known, the sediment transport can be calculated using the above equation.

### 3.2.2 Method Proposed by Ackers and White

Ackers and White (1973) has proposed a method to calculate transport of non-cohesive sediment by a steady uniform flow. When the physical properties of the fluid and sediments are substituted, the value of  $S$  is expressed as in Section 3.2.1, and shear velocity is defined as  $v_* = \sqrt{gHS}$ , sediment transport rate can finally be expressed in terms of  $V$  and  $H$  as follows:

$$q_s = 1.2567 \times 10^{-5} \cdot v \cdot H^{0.0936}$$

$$\left[ \frac{7.7019 v}{H^{0.0936} [\log_{10}(4.1667 \times 10^{-4} H)]^{0.4382}} - 1 \right]^{2.9343}$$

Therefore, when the values of the mean velocity ( $V$ ) and the mean

depth of flow (H) are known the sediment transport can be calculated using the above equation.

### 3.2.3 Calculation of Sediment Transport Rate

For calculation of sediment transport rate, depth averaged velocities were used in the sand transport formula. Therefore, the nodal velocities obtained from the flow simulation model were first converted to depth averaged nodal velocities. These depth averaged nodal velocities were then converted to cell velocities in the longitudinal and transverse directions. Using the Sand transport formula, the rate of sediment transport was calculated in longitudinal and transverse directions for each cell.

With reference to Figure 4.0, SANDX(I,J) and SANDY(I,J) are defined as rates of sand transport in Cell (I,J) in x & y directions respectively. If just one cell is considered its sediment transport components can be averaged with those of the surrounding cells to obtain the boundary flow.

$$\begin{aligned} \text{Boundary flow in longitudinal direction} &= \text{BDX}(I,J) \\ &= 1/2.[\text{SANDX}(I,J) + \text{SANDX}(I+1,J)] \\ \text{Boundary flow in transverse direction} &= \text{BDY}(I,J) \\ &= 1/2.[\text{SANDY}(I,J) + \text{SANDY}(I,J+1)] \end{aligned}$$

The sand movement within the cell is then the difference between the transport rates into the cell and the transport rates out of the cell.

$$\begin{aligned} \text{Net longitudinal sand transport in cell}(I,J) &= \text{XMOVE}(I,J) \\ &= \text{BDX}(I-1,J) - \text{BDX}(I,J) \\ \text{Net transverse sand transport in cell}(I,J) &= \text{YMOVE}(I,J) \\ &= \text{BDY}(I,J-1) - \text{BDY}(I,J) \end{aligned}$$

The sediment movement is actually a volume rate per unit time per unit width. Therefore, multiplication by the cell width and an appropriate time interval will yield the volume change of sand. Then simply dividing by the cell area will give the change in depth of the cell.

$$\begin{aligned} \text{The amount of Erosion or Deposition in cell}(I,J) &= \text{RISE} \\ &= [\text{M.XMOVE}(I,J) + \text{N.YMOVE}(I,J)].\text{MTA}/\text{AREA} \end{aligned}$$

where, M,N = width of cell(I,J) in transverse and longitudinal directions respectively, AREA = M x N, MTA = time period for which the sand transport is calculated.

$$\text{New Depth of Cell}(I,J) = H(I,J) - \text{RISE}$$

### 3.2.4 Boundary Conditions for the Sand Transport Model

Following boundary conditions were used in the Sand Transport model.

#### 3.2.4.1 Inflow Boundary

At the inflow boundary it was assumed that the rate of sediment transport in longitudinal direction was equal to the rate of sediment

transport in the first cell in the same direction, figure 3.0.

$SANDX(I,J) = SANDX(2,J)$  and  $H(1,J) = H(2,J)$ ; where,  $J = 2$  to  $MOF+1$

#### 3.2.4.2 Outflow Boundary

At the outflow boundary the rate of sediment transport in longitudinal direction was assumed to be equal to the rate of sediment transport in the last cell in the same direction.

$SANDX(NLSI,J) = SANDX(NLS+1,J)$  ,  $H(NLSI,J) = H(NLS+1,J)$   
where,  $J = 2$  to  $MOF+1$

#### 3.2.4.3 Shore Boundary

At the shore boundary, the rate of sediment transport in the transverse direction was assumed to be zero.

$SANDY(I,1) = 0.0$  and  $H(I,1) = H(I,2)$ ; where,  $I = 2$  to  $NLS+1$

#### 3.2.4.4 Offshore Boundary

Similar to the shore boundary, the rate of sediment transport in the transverse direction was assumed to be zero.

$SANDY(I,MOFI) = 0.0$  and  
 $H(I,MOFI) = H(I,MOF+1)$  where,  
 $I = 2$  to  $NLS+1$

### 3.3 Profile Model

Using a flow simulation model described in Section 3.1 and a sand transport model described in Section 3.2 a Profile Model, as shown in the Flow Chart in Figure 5.0, was developed for morphological evolution of the shore area.

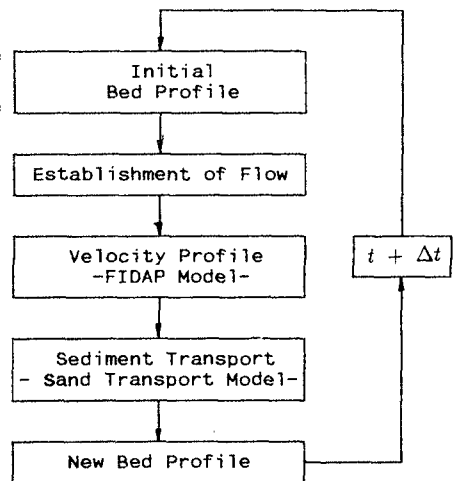

Figure 5.0: Flow Chart of the Profile Model

The constituents of the Profile Model are as follows:

- The initial bed profile of the area under consideration is decided.
- A known flow field is established over the area under consideration.
- The velocity field in the computation domain is numerically simulated using Mixing Length Model.
- Rate of transport of sediment due to known velocity field is calculated using the Sand Transport Model.
- Change of bed profile due to transport of sediment for a time period  $\Delta t$  is calculated and the new bed profile is obtained.

The new bed profile obtained after time  $\Delta t$  was used as the initial profile for the next cycle. This procedure was continued until

sufficient number of cycles are completed over the required time period for which morphological evolution of the shore area is to be determined.

4.0 Results and Discussion

4.1 Flow Simulation Models

Computed velocity profiles using the K-Epsilon and Mixing Length models have been compared against the measured velocities, at four different sections, in Figure 6.0.

It was observed that the K-Epsilon model, in general, predicted velocities closer to the measured values when compared to the Mixing Length Model. Specially, in the flow velocity measuring stations downstream of the dredged channel, ie. at  $x = 4.5$  and  $x = 7.5$  m, the K-Epsilon Model predicted velocities to a fairly good accuracy.

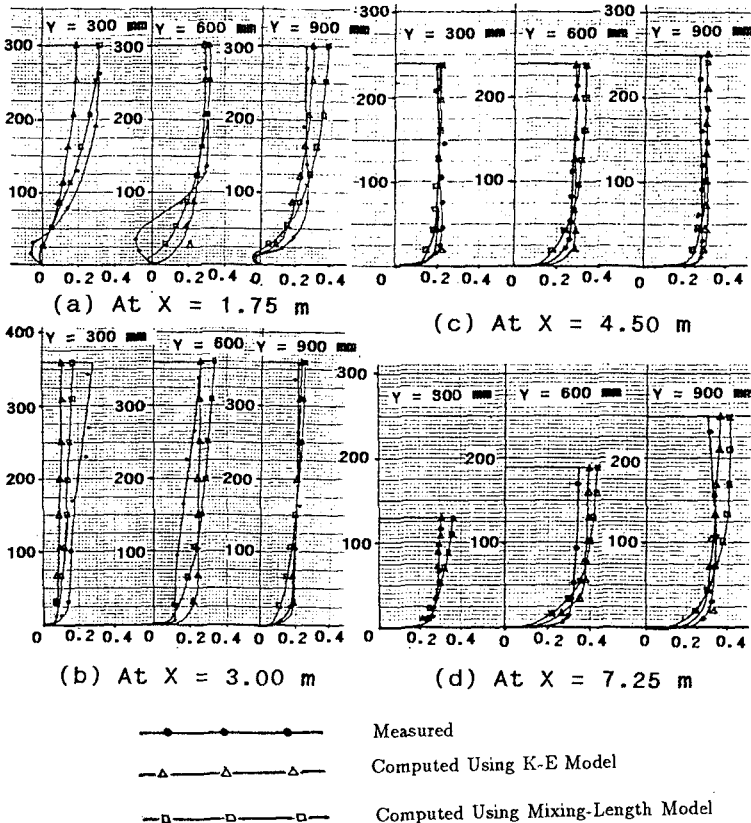

Figure 6.0: Measured and Computed Velocities

However, it was observed that the computed velocities deviated

from the measured velocities in the region from the inlet upto the dredged channel. When the cause for this situation was examined it was observed that selected inlet section was too close to the dredged channel. However, limited space available in the Hydraulic Laboratory did not allow shifting of the inlet section further upstream of the dredged channel.

The following assumptions made in making the numerical models would also have affected the accuracy of the predicted results.

- \* All wall boundaries, including the bed boundary, have been assumed to be fully rough (no-slip boundary condition.)
- \* For specification of normal and tangential boundary condition, the bed boundary has been assumed to be horizontal.

It is also expected that accuracy of computed velocities could be increased by having a finer mesh discretization, specially in the recirculation region.

Therefore, it can be concluded that under assumed conditions flow simulation models gave reasonable to good accuracy except for a few sections in the recirculation and inlet regions which in retrospect would have been expected.

## 4.2 Sand Transport Models

### 4.2.1 Shield's Formula

Shield's formula which is essentially a bed load formula is based on the assumption that shear stress is the main parameter defining sediment transporting power. Transport of sediment by suspension at higher shear velocities has not been taken into account and at all velocities sediment is assumed to be transported as bed load. Further, the resistance to sand movement caused by the bed forms on the deformed bed has not been considered in the formula.

The velocity field existing at the granular surface determines the shear stress on the grains. Therefore, it is more realistic to relate the bed shear velocity to the flow velocity at the bed level. But in this experiment, the bed shear stress, hence the bed shear velocity, in the Shield's formula has been related to the depth averaged mean flow velocity which could be higher than the near bed velocity.

Due to these reasons and also since the sand transport is a function to the fifth power of the mean fluid velocity (Section 3.2.1) exaggerated sand movement can be expected in areas where the velocity is high relative to the depth.

Examination of bed profiles at the inlet region showed that predicted higher velocities have caused exaggerated erosion and deposition of the cells in the region and the model became unstable after few iterations.

As Shield's formula is purely a bed load formula, errors in predicted results can be expected at higher shear velocities relative to the critical shear velocity. Therefore, Shield's formula was not considered as suitable for long term morphological computations.

#### 4.2.2 Ackers and White Method

This method predicts the total load and not the bed-load transport only. In this method average stream velocity has been used in preference to shear stress as the basis of sediment transport function. The grain roughness has been taken into account by relating it to the median sediment diameter. As such this method can be expected to perform better than the Shield's formula.

The following observations can be made when the bed contours, as shown in Fig.8 and bed profiles shown in Fig. 7, are reviewed.

1. A prominent movement of sand in the longshore direction was seen throughout the flow domain; a clear overprediction compared to the Physical Model.

2. In the area downstream of the dredged channel where the computed and measured flow velocities had a better match, measured and computed bed profiles and contours have similar shapes and are almost parallel.

3. The movement of sand in the offshore direction observed in the Physical Model was not seen in the numerical model. This can not be explained in terms of flow velocities as both measured and computed flow velocities in offshore direction were small compared to the longitudinal

velocities. It should be noted here that the effect of gravity has not been taken into consideration in the numerical model. As such it will be interesting to examine whether the gravity has played a role in the movement of sand along the steep gradient in the transverse direction.

4. In the upstream region of the dredged channel where the computed

Fig. 7.0: Measured and Computed Bed Profiles

(Mixing Length Model) velocities did not show a good agreement with the measured velocities, the computed bed profiles deviated from the measured profiles as would be expected.

Fig. 8.0: Measured and Computed Bed Contours

An important factor that would have affected the predictions of the sand transport model is the changing bed profile and hence the flow velocities at the inlet which has not been taken into consideration. It was assumed that the prescribed inlet velocities remain unchanged throughout the experiment even though the bed profile was allowed to vary. As the computed flow velocities upstream of the dredged channel were found to be very sensitive specially to the direction and the magnitude of transverse velocities, this would have had a direct effect on the model predictions.

#### 4.3 Conclusions

The sand transport model which used the Ackers and White method performed reasonably well in the areas where the computed velocities were in agreement with the measured velocities. As the sand transport is a function to the fourth power of the mean velocity, (Section 3.2.2), a small error in the predicted flow velocities could accumulate to create a major error in the predictions of the sand transport model when a simulation is carried out over a large number of cycles for long term morphological computations. Thus, the accuracy of predictions of such a long term model will depend critically upon the accuracy of the predicted velocities in the flow simulation model.

It can be concluded that, once calibrated and validated using measured data, an advanced flow simulation model coupled with a simple sand transport model, as used in this experiment, appears feasible at this stage to predict long term morphological computations to a reasonable accuracy.

#### 4.4 Future Work

Since the numerical models performed reasonably well even without improvement, it would be worthwhile to investigate the influence of the factors such as; proximity of the inlet section to the dredged channel, change of cross-section at the inlet, a refined mesh, and influence of gravity, etc. on the performance of the models.

The sand transport model used looks crude compared to the advanced flow models used. However, as this is only the first developmental model better sand transport models can be coupled with the flow model to improve the predictions.

## CHAPTER 223

### MOTION OF MOBILE BEDS AT HIGH SHEAR STRESS

Kenneth C. Wilson<sup>1</sup> and Fidelia N. Nnadi<sup>2</sup>

#### 1. INTRODUCTION

Beds of granular material show various types of behaviour as the dimensionless shear stress or Shields ordinate,  $Y$ , is increased. This quantity is defined as  $\tau/\rho g(S-1)d$ , where  $\tau$  is boundary shear stress,  $\rho$  is fluid density,  $g$  is gravitational acceleration,  $S$  is the ratio of solids density to fluid density and  $d$  is particle diameter. Following the zone of no particle movement at low  $Y$ , there is a range at which sand waves are found, and finally, in the high shear-stress region where  $Y$  exceeds 0.8, the bed tends to become plane.

This high-stress or upper-plane-bed condition may be encountered in rivers in flood, large flows in estuaries, and closures or breaches of cofferdams or dykes. Because of the very high rates of sediment transport associated with this type of flow, it has a disproportionate effect on both natural topographic features and engineering works. The investigation of such behaviour by traditional flume experiments is not easy, but testing in enclosed pressurised conduits can eliminate many of the difficulties (Wilson, 1966; Nnadi and Wilson, 1992).

Nnadi (1992) has described an experimental program carried out recently using a recirculating system located at Queen's University. The test section was a square conduit with side dimension 98 mm, and series of runs were made with three sizes of sand ( $S = 2.67$ ), two sizes

---

of bakelite ( $S = 1.56$ ) and one size of nylon particles ( $S = 1.14$ ).

## 2. ANALYSIS AND EXPERIMENTAL RESULTS

Analysis based on the experimental findings shows that at high shear stress the bed load moves in a shear layer (the sheet-flow layer) with thickness which is proportional to the shear stress applied by the flow to the mobile boundary. Within this layer, the submerged weight of the grains comprising the bed load (also called the contact load) is counteracted by intergranular contacts, which may be either continuous or sporadic. The thickness of the shear layer,  $\delta_s$ , can be an order of magnitude larger than the particle diameter. For this high-shear-stress configuration, the equivalent roughness of the boundary is not proportional to the size of the individual particles (as had been assumed in the past for the upper-plane-bed regime), but instead varies directly with the shear-layer thickness,  $\delta_s$ , and hence is proportional to the applied shear stress.

The resulting value of the equivalent roughness,  $k$ , is about  $0.5 \delta_s$ . It follows that the value of  $k/d$  is not constant (as for the rough-boundary relation) but increases with  $Y$  in what is essentially a direct proportionality. Wilson and Nnadi (1990) produced a plot of the ratio of equivalent roughness to particle diameter ( $k/d$ ) versus the dimensionless shear stress. This plot is reproduced here as Figure 1. It clearly shows that  $k/d$  is far from constant, but instead increases with  $Y$  in accord with the analytical prediction, which can be approximated (Wilson, 1989) by the simple relation

$$\frac{k}{d} = 5Y \quad [1]$$

More detailed analysis is given by Nnadi and Wilson (1992), but the basic points to be noted is that the effective roughness for sheet flow is no longer proportional to particle diameter, but is strongly affected by increasing shear stress. As seen from the figure, a broad range of the variables is represented, the trend is clear, and the scatter band is less than that usually displayed by moveable-boundary data.

Both the experimental work mentioned above and the associated analysis have been concerned with essentially horizontal flows. It was realized that for certain cases of practical importance, such as wave uprush on beaches or bars, the flow is inclined, and the effect of this

Figure 1 Effective Roughness Ratio for Horizontal Flow

inclination can be important. In order to investigate this effect, it was arranged that the closed-conduit test section could be inclined to the horizontal. Several series of runs in the upper-plane-bed regime were made at inclination angle  $\theta$  (elevation increasing in the direction of flow) of  $10^\circ$ ,  $20^\circ$  and  $30^\circ$ . The values of manometric gradient, mean flow velocity and bed-associated hydraulic radius were obtained for each run, and used to calculate  $k/d$  and  $Y$  in the same fashion employed previously for the horizontal tests. The results for  $10^\circ$ ,  $20^\circ$  and  $30^\circ$  inclination are shown on Figures 2, 3 and 4, respectively. The general trends are very similar to that of the plot for horizontal flows but it is worth noting that for the inclined flows the range of the variables is larger than for the horizontal case, and  $k/d$  has a somewhat larger rate of increase with  $Y$ . The data for the various inclinations indicate that, in the range investigated, the rate of increase of  $k/d$  with  $Y$  is monotonically related to the inclination angle.

Analysis of particle motion in inclined flows showed that a positive inclination introduces a submerged-weight force component which acts opposite to the direction of motion. The resulting behaviour is equivalent to a horizontal flow with a larger effective value of

Figure 2 Effective Roughness Ratio for  $\theta = 10^\circ$

Figure 3 Effective Roughness Ratio for  $\theta = 20^\circ$

Figure 4 Effective Roughness Ratio for  $\theta = 30^\circ$

submerged relative density, equivalent to multiplying (S-1) by the factor  $\cos\theta(1+\tan\theta/\tan\phi')$ , where  $\phi'$  is the dynamic friction angle of the solids. On this basis it is predicted that the solids transport rate will diminish with increasing inclination  $\theta$  (for given values of hydraulic gradient and bed-associated hydraulic radius).

This effect can be expressed by applying a suitable adjustment to the dimensionless bed-load transport coefficient  $G_s$ , defined by the equation

$$q_s = \frac{G_s}{(S-1)g} \left( \frac{\tau}{\rho} \right)^{1.5} \quad [2]$$

Here  $q_s$  is the volumetric discharge of bed-load solids per unit breadth, and the other symbols have been defined previously. In the high-shear-stress range (where the critical shear stress for the beginning of particle motion is a negligibly small fraction of the applied shear stress) Equation 2 is compatible in form to the equation of Meyer-Peter and Müller. That equation produces a  $G_s$  value of 8.0 for near-horizontal flow. However, as proposed earlier (Wilson, 1966 and 1987),  $G_s \approx 12$  gives a better fit both to sand data at high shear stress and to the theoretical expectations for

horizontal flow in the upper-plane-bed region. The present analysis indicates that  $G_s$  will vary with both  $i/(S-1)$  and the inclination angle  $\theta$ . Figure 5 shows calculated curves for various inclinations up to  $30^\circ$ . Each curve displays an essentially flat initial section, followed by a downturn at higher values of  $i/(S-1)$ . The series of curves shows the expected decrease of  $G_s$  with increasing  $\theta$ .

The experimental data for inclination angles of  $0^\circ$  to  $30^\circ$  were found to be in good accord with the trends shown by the predicted curves. Figures 6, 7, 8 and 9 show the data for  $\theta$  values of  $0^\circ$ ,  $10^\circ$ ,  $20^\circ$  and  $30^\circ$ , respectively.

Although there is a fair degree of scatter in the experimental results for  $G_s$ , each data set clusters about the predicted line. The droop in  $G_s$  at high  $i/(S-1)$ , which is particularly clear from the nylon data, occurs for each of the inclination angles. Comparison of the four data sets clearly shows the downward trend of  $G_s$  with increasing  $\theta$  that follows the general trend of the predicted curves.

### 3. CONCLUSION

At high shear stress, beds of granular materials tend to become plane, with bed-load particles forming a sheet-flow layer of thickness proportional to the applied shear stress. Results from both experiments and analysis have shown that this region is characterised by large friction factors and high rates of bed-load transport.

The study of horizontal sheet flow has now been extended to inclined flows, which are significant for beach morphology. The effect of an inclination angle (with bed elevation increasing in the direction of flow) is to increase friction and to diminish bed-load transport rate. Once again, experimental and analytical results are found to be in good accord.

## CHAPTER 224

### Port Site Selection on Coast with Radial Sandbanks

Yixin Yan and Kai Yen

#### Abstract

Along the silty coast of the Jiangsu Province, it was found that on the coast stretch which we call the "Radial Sandbanks" coast stretch, deepwater port sites could be created if suitable tidal inlets were selected and provisions were made to maintain the required deepwater areas for port development.

#### Introduction

The Jiangsu Province, facing the Yellow Sea and the East China Sea, is one of the most developed provinces of China in industrial and agricultural production. China's policy of reform and opening to the outside world has greatly enhanced the economic development of this province. It is therefore urgently needed to build deepwater ports to meet the demand of increasing sea-going traffic. For a long time, the difficulty was to find suitable port sites, because along the entire 1000km coastline of this province, most of the coast stretches are silty coast with very gentle beach slope composed of fine sand and silt, very susceptible to changes under the action of waves and currents. Therefore it was considered impracticable to construct deepwater

- 
- (1) Asso. Professor, Hohai University, Nanjing 210024, China  
(2) Professor, Hohai University, Nanjing 210024, China

ports on such coast. However, during the Nationwide Comprehensive Assessment of Coastal Zone Resources which was carried out from 1980 to 1985 along the entire 18,000 km coastline of China's mainland it was found that there is a coast stretch in the Jiangsu Province where the early and late deposited submarine sediments were disturbed and scoured by waves and currents, sorted, coarsened and redeposited. At last, an extensive area of well sorted fine sand and all kinds of sediments are radially extended towards the sea, thus forming the coast with radial sandbanks. Between the sandbanks are tidal inlets leading to the coastline, and deepwater port sites could be created if suitable tidal inlets were selected and provisions were made to maintain the required water depth for port development.

### Morphological and Hydrological Features of the Radial Sandbanks

The Radial Sandbanks, extending from northwest to southeast along the coast of North Jiangsu, cover an area of the South Yellow Sea from the mouth of Sheyang River to the Yangtze River Estuary and to the east up to 25 m water depth, nearly 20,000 km<sup>2</sup>. About 70 sandbanks lie radially from Jianggang towards the sea, of which 8 are above the Abandoned Yellow River Datum, with total area of 1268 km<sup>2</sup>, the biggest one called Dongsha is 694 km<sup>2</sup> (Fig.1). The rest are underwater sandbanks. Between the sandbanks are tidal channels, the largest one, called Huangsha Yang, is located at the middle of the Radial Sandbanks and extends from the sea westward to the coast near Jianggang. The second large tidal channel, Xi Yang, is located at the west and the third one, Xiaomiao Hong, at the south of the Radial Sandbanks. All these three tidal channels ended in the proximity of the coastline and could therefore be utilized as approach channels for port development.

The Radial Sandbanks were essentially the ancient submarine delta of the Yangtze River. The formation of such typical topography may be attributed to the existence of two tidal systems, one comes from southeast, being a progressive tidal wave from the Pacific, and the other from northwest, being a reflected tidal wave from the Shandong Peninsula. The concurrence of these two tidal systems gives rise to a rotary standing tidal wave with the node point somewhere 80 km beyond the

Abandoned Yellow River Mouth, where the tidal range is nearly zero. Figure 2 shows the  $M_2$  constituent of the tide in harmonic

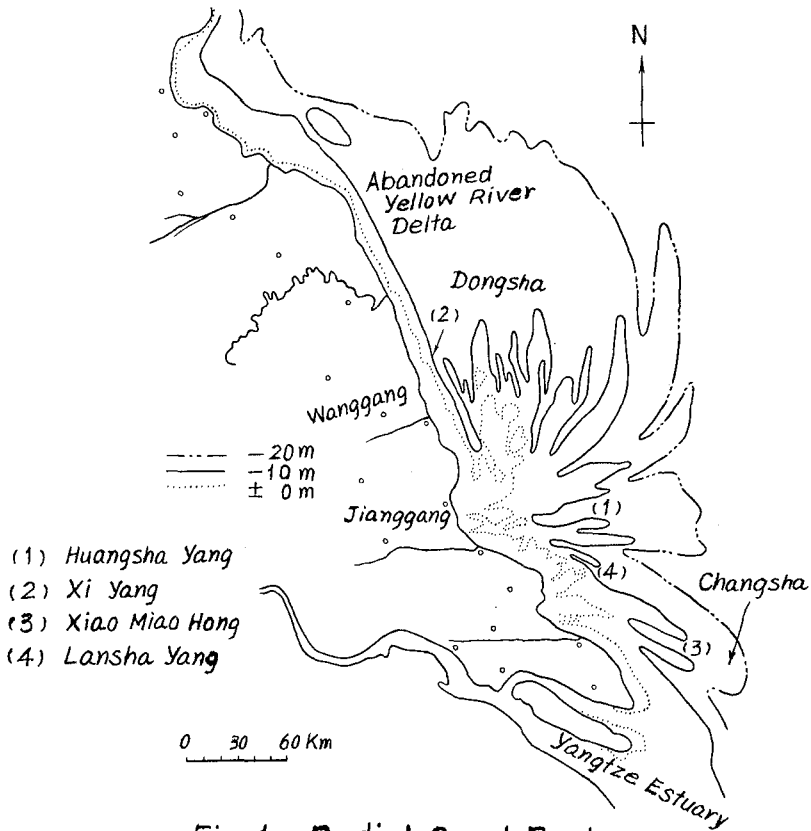

Fig. 1. Radial Sand Banks

analysis. The converging point of the two tidal waves is in the vicinity of Jianggang. Here we find a region of strong tide, the mean tidal range at Jianggang is 3.9 m. It increases to 4.9 m at Yangkou, the end of the main channel of Huangsa Yang, here a max. tidal range of 9.28 m was observed in 1981, which also ranks first along the entire coast of China. The mean tidal ranges in the other two large tidal channels, Xi Yang and Xiaomiao Hong

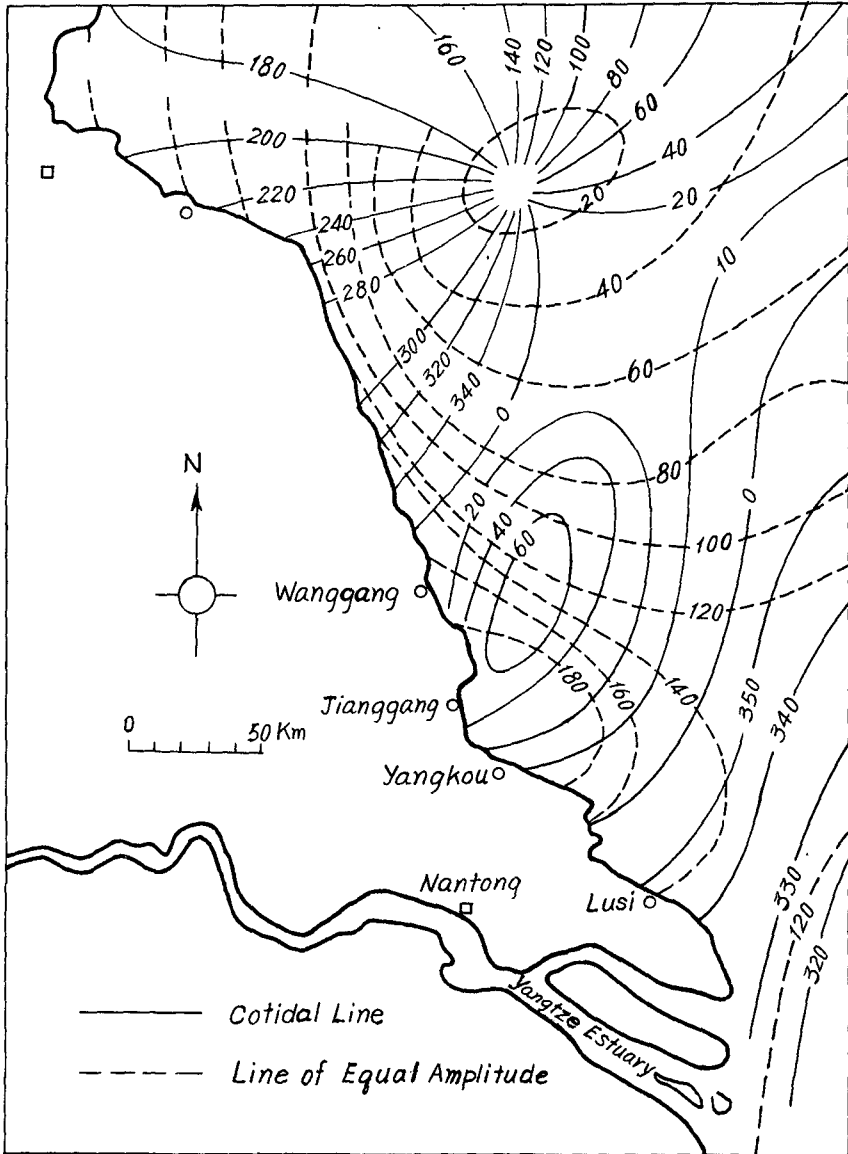

Fig.2.  $M_2$  Constituent in Harmonic Analysis

are respectively **2.64** at Wanggang and **3.68** m at Lusi, with a max. of **5.46** m and **6.87** m respectively (Fig.3). The tidal current in this region is also strong. In Huangsa Yang and Xi Yang, the flood current velocity is higher than that of ebb tide, attaining a max. of **2.5** m/s and **2.0** m/s respectively, while in Xiaomiao Hong the ebb current is stronger, having a max. of over **1.5**m/s.

Waves exercise also significant influence on the Radial Sandbanks. Waves generated by prevailing wind come from NEE and the storm waves come mostly from NW and N. Under the action of waves and currents the Abandoned Yellow River delta is continually under erosion and large amount of the eroded materials are transported to the Radial Sandbanks. The sediments from the Yangtze River, which amounts to ca. **500**×**10<sup>6</sup>**t yearly, are also partly transported to the Radial Sandbanks by flood tides, particularly during the flood season of the Yangtze.

Investigation shows that in the summer the dominant sediment transport is landwards from the sea through the tidal inlets, converging in the vicinity of Jianggang, and in the winter the sediment flow is spreading seawards and to the Yangtze Estuary. It has been found that the littoral drift in the Xi Yang tidal channel is directed southwards, in the Huangsa Yang it is westwards and in the Xiaomiao Hong eastwards. The sediment concentration in the winter is **1.5** to **2** times higher than that in the summer, and it increases from the sea landwards, a max. concentration of **1.2** kg/m<sup>3</sup> has been observed in the vicinity of Jianggang. The sediments are composed mainly of fine sand, sandy silt and silt. The mean sediment diameter of the sediments on the sandbanks ranges from **0.125**~**0.5** mm, in the tidal channels it is **0.07**~**0.18** mm and on tidal flats, **0.03**~**0.09** mm.

As a rough estimate, the yearly sediment transport into the area of Radial Sandbanks is **109**×**10<sup>6</sup>** t from the north, **203**×**10<sup>6</sup>**t from the east and **36**×**10<sup>6</sup>** t from the west, totalling **348**×**10<sup>6</sup>** t, and sediments flowing out of this area is **102**×**10<sup>6</sup>** t. Thus there is a net sediment inflow of **246**×**10<sup>6</sup>** t, and the area of the Radial Sandbanks is continually increasing. Nevertheless, the change is rather slow, as can be also seen by comparing the topographic maps of **1964** and **1979**, as well as from the satellite pictures. It has also been found that the entire Radial Sandbanks including the tidal inlets are relatively stable, and in

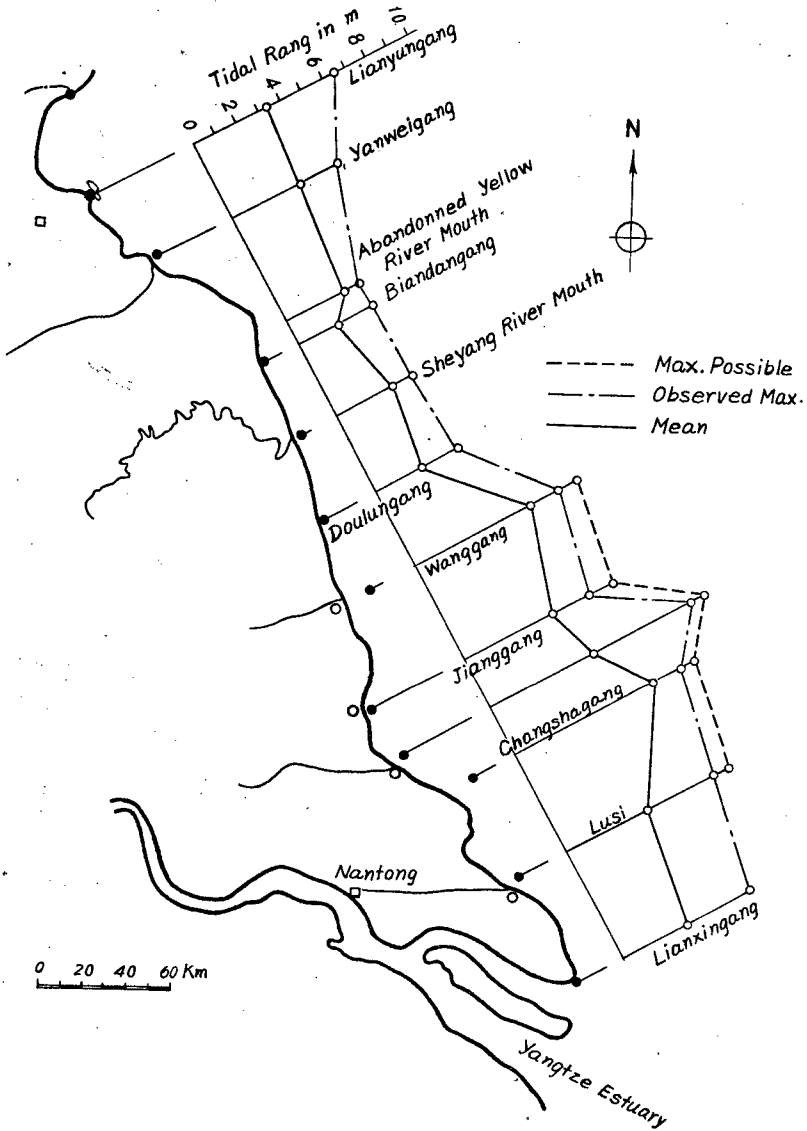

Fig. 3 Tidal Range Along Jiangsu Coast

the above mentioned three tidal inlets deepwater channels underwent little change. Only at the ends of these channels erosion and accretion occurred frequently and this is sometimes aggravated by wanton reclamation of the adjacent tidal flats.

### Selection of Port Sites

A comprehensive investigation had been carried out since early 1980's along the coast of Jiangsu Province, which includes the field survey, laboratory work and theoretical study. One of the main problems to be solved was the stability of the tidal inlets. It has been found that the inlets are relatively stable due to the existence of the strong tidal action. For instance, at Wanggang the depth contours of  $-5$  m and  $-10$  m had been moving seaward at a rate of 100 m and 68 m per year from 1979 to 1990, respectively, but the depth contour of  $-12$  m had been kept basically unchanged. Meanwhile the Xi Yang tidal inlet was enlarged to correspond with the increased tidal discharge, the inlet became deeper and the shore slope turned steeper.

As compared with port on open sea coast or in an estuary, port located inside a tidal inlet has neither the problem of protection against storm waves, which usually needs the building of costly breakwaters, nor the bar forming at the mouth of the estuarine channels, which as a rule gives hindrance to navigation. So the three large tidal inlets of the Radial Sandbanks provide favorable conditions for port development. In these tidal inlets the water areas are well sheltered, the sediment concentration is low and channels are relatively stable. The drawbacks are, however, the large tidal range and wide tidal flat, which bring inconvenience to navigation and difficulties in port layout. Therefore these should be taken into full consideration in the development of ports inside such tidal inlets.

In the selection of deepwater port site along the coast of Jiangsu, we have to bear in mind that the Yangtze River, which flows through the Jiangsu Province and is an important waterway for sea-going traffic, can only allow vessels of under 25,000 t to pass the estuarine channel due to the bar forming at the mouth, and it is a very difficult task to increase its water depth. Hence it is necessary to explore deepwater port sites along the open coast. Moreover, coastal harbours have the

advantage of more direct access to the hinterland of North Jiangsu than ports in the Yangtze Estuary, since for the former there is a network of inland waterways facilitating the connection with the hinterland. In view of the fact that Jiangsu Province is badly short of energy resources, the import of coal and the development of petroleum industry have become of ever increasing importance in the economic construction. For this purpose the creation of deepwater port along the coast with berths of **50,000 to 100,000 t** and over is needed. It has been planned to build deepwater ports in all the above mentioned three large tidal inlets, namely Huangsha Yang, Xi Yang and Xiaomiao Hong, taking due consideration into the rational geographical distribution of ports. We have then in the south a port group with Port Yangkou in the Huangsha Yang tidal inlet, Port Lusi in the Xiaomiao Hong tidal inlet and Port Nantong in the Yangtze Estuary as the major ports; in the middle a port group with Port Wanggang in the Xi Yang tidal inlet as the major port; and in the north a port group with Port Lianyungang as the major port, as shown in Fig.1. The Port Lianyungang is an existing port built in the thirties. It has been rehabilitated, extended and modernized since the founding of the People's Republic, and is now one of the major ports of China, capable of berthing vessels of **50,000 t**.

Except port Nantong and Port Liangyungang all the above mentioned ports are situated in the tidal inlets of the Radial Sandbanks. It is rather unique to built deepwater port under such conditions. In the following a typical example is given for the layout of the Port Yangkou in the Huangsa Yang tidal inlet.

### Preliminary Layout of Port Yangkou

Full use is made of the Huangsa Yang tidal channel in the layout of the Port Yangkou. The water depth of this tidal channel varies from **10 m to 30 m** with channel width of **0.7 km to 2 km**. The channel ends at Yangkou, the selected port site. Here a well sheltered water area is available for port development. The port will mainly serve for oil and coal transportation and to some extent container and general cargo traffic. The layout is shown in Fig.4. As can be seen from the figure, there is **20 m** deepwater area of **2.4 km<sup>2</sup>** at a distance of about **10 km** from the coastline and within this area we find an area **700 m × 2000 m** where the water

depth is 22 m. This can be used to berth the 100,000 t tankers which requires a water depth of 21.5 m. Underwater pipeline will be used to deliver the oil to the oil depot on the bank. It has also been contemplated to provide berths for supertankers of 200,000 t in the future at the location 20 km to the east of Yangkou, called Changsa, where the tidal inlet Lansha Yang joins Huangsha Yang. Here 25 m deepwater area of 4.7 km<sup>2</sup> is available for mooring such supertankers, only that the under water pipeline will be longer, i.e. >16 km.

For coal import, 10,000 t berths will be provided at the -10 m water area and navigation channel should be built for coal transfer. The coal will be transferred by barges of 100 t to 300 t or by highways to the neighboring areas. Container berths will be located at the deepwater area west of the tanker berths, with a connecting trestle leading to the container terminal or transferred by shipment. Trestle for berthing ships of 3,000 t is also provided west of Yangkou for general cargo handling.

Serving as an approach channel to the sea, the Huangsa Yang tidal inlet has a length of 50 km from Port Yangkou to -20m depth in the sea. In order to create a navigable channel for 100,000 t tankers it is estimated that the amount of dredging would be 260,000 m<sup>3</sup>. If the berthing of supertankers of 200,000 t were contemplated, the tidal inlet Lansha Yang - Huangsha Yang should be used as approach channel to the berthing area Changsa, which has a length of about 30 km, and the amount of dredging would be 1,000,000 m<sup>3</sup> to 3,000,000 m<sup>3</sup>.

## 5. Conclusions

Sea port construction is essential to the economic development of the Jiangsu Province and opening to the outside. The aforementioned three port groups along the Jiangsu coast all have good connection with the hinterland. The intercontinental railway connecting Port Lianyungang to Rotterdam, the waterways of the Huai River system and Yangtze River system, together with the Grand Canal and other waterways and highway systems, form a transportation network very convenient to the gathering, distribution and transfer of cargo. The utilization of tidal inlets of the Radial Sandbanks for port construction is technically possible and economically feasible as the preliminary

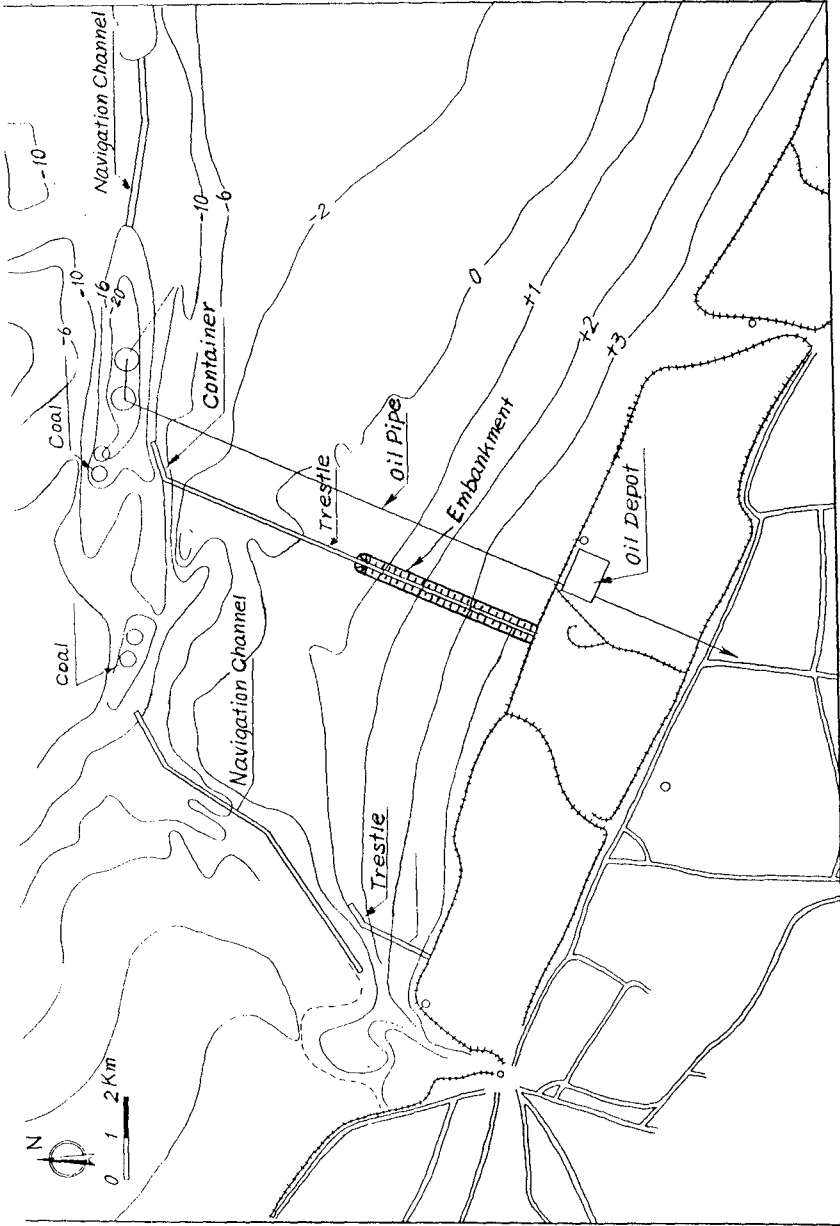

Fig. 4. Layout of Port Yangkou

study of the morphological and hydrological features of this region and the economic assessment have shown. Numerical modelling has been undertaken to study the channel condition of the Huangsha Yang tidal channel. It was found that the channel would be relatively stable and the tidal currents are favorable to maintenance of a stable channel.

## CHAPTER 225

### Liquefaction and erosion of China Clay due to waves and current

P.J. de Wit<sup>1</sup> and C. Kranenburg<sup>2</sup>

#### Abstract

A research project was started to study the behaviour of cohesive sediments at the Delft University of Technology in 1989. An existing flume was modified to study the liquefaction and erosion of China Clay due to waves and current. China Clay is an artificial mud, mainly consisting of kaolinite. Among other things, the experimental results showed that fluid mud was generated by wave action if the wave height exceeded a threshold value; the threshold value increases as the consolidation period increases. Waves were significantly damped when a fluid mud layer was present and the damping was only little influenced by a current. Furthermore, the fluid mud is transported very easily by a current and hardly any mud was entrained into the water layer during this process. The pore pressure showed a transient decrease when the mud started to liquefy, succeeded by a gradual build-up of an excess pore pressure to compensate for the vanishing effective stress. Finally, it was found that observations or measurements made at a sidewall during an experiment only give a rough indication of the physical processes away from the sidewall; measurements carried out far from a wall have to be used for a quantitative description of the bulk processes in the bed.

#### Introduction

In several coastal and estuarine areas across the world the bed mainly consists of

---

<sup>1</sup> PhD-student, Delft University of Technology, Department of Civil Engineering, P.O. Box 5048, 2600 GA Delft, The Netherlands.

<sup>2</sup> Senior Research Scientist, same address.

cohesive sediment, often referred to as mud. The influence of these beds on the coastal environment is usually very large due to the specific properties and transport processes of cohesive sediments such as flocculation, settling, deposition, consolidation, liquefaction and erosion.

Two main hydrodynamic forces drive the transport processes of cohesive sediments in these regions: tidal currents and wind waves. Many researchers have studied the erosion or deposition of mud by currents, because of practical reasons as the maintenance of harbours, for instance. Various empirical relationships were derived from experiments and adopted to simulate the transport of mud (Partheniades, 1984).

However, in shallow waters wind waves dominate the hydrodynamic forcing of the cohesive sediment. The erosion of mud due to waves has also been studied experimentally by several researchers (Maa & Mehta, 1987, 1990). In some of the experiments a layer of fluid mud was formed under the influence of waves (Lindenberg et al., 1989). This phenomenon, which has also been observed in coastal areas, is caused by the varying wave loading. The fluid-mud layer may be transported very easily by a tidal current, for instance, yielding in a relatively large transport of sediment material close to the bed.

A striking observation which can be made at a muddy coastline is the marked wave damping as a result of the dissipation of wave energy in the bed. The energy dissipation depends on the rheological properties of the bed. Such damping phenomenon plays an important role in the protection of these coastlines.

The interaction between both waves and currents and a muddy bed has hardly been studied and is not well understood. In particular the liquefaction mechanism, the near-bed turbulence structure and the influence on wave damping require further study. Therefore a research project was started at the Delft University of Technology some three years ago. A set-up was built to study experimentally the influence of waves on the liquefaction process and the influence of both waves and current on the transport and erosion processes of mud. In the present paper only a brief account of the experimental results will be presented. A full description of the experimental results is given by De Wit (1992).

## **Sediment**

China Clay, an artificial mud mainly consisting of kaolinite, was used as sediment. The main reason for using this artificial mud is to get reproducible measurements. An additional reason is that the small-scale waves in the experiments require a less cohesive mud, which kaolinite is. Furthermore, using natural mud in experiments would involve the use of the natural water. The costs of temperature and light controlled transport and storage of the natural sediment with the accompanying fluid were prohibitive. Several properties characterising this clay were determined and some of them are listed in Table I.

**Table 1** *Properties of China Clay used.*

particle size distribution	> 10 $\mu\text{m}$	14 %
	< 2 $\mu\text{m}$	41 %
C.E.C.		5.0 meq/100g
density		2593 $\text{kg}\cdot\text{m}^{-3}$
specific surface area		29.9 $\text{m}^2\cdot\text{g}^{-1}$
mineralogical composition		mainly kaolinite

There was no free gas in the sediment, and sodium chloride was dissolved in the tap water used (salinity: 5 ‰) to increase the flocculation of kaolinite and to eliminate the possible influence of small quantities of other chemicals on the characteristics of the mud, as for instance the settling velocity. According to Van Leussen (1988) the settling velocity of kaolinite is maximal for chloride concentrations ranging from 2 to 18 ‰.

The rheological behaviour of the China Clay used was determined with a Haake viscometer; model Rotovisco RV100 and measuring system CV100. It is a viscometer capable of testing materials under either steady rotation, or dynamic oscillation with a frequency range from 0.01 to 9.9 cycles per second. The oscillating strain can be superimposed on a steady shear as well. This device is provided with several sample holders, the so-called sensor systems, such as a

**Figure 1** *Rheological behaviour of suspensions of China Clay in saline tap-water (salinity 5 ‰, sensor type: Q30).*

cone-plate and a plate-plate system. Each sensor system is designed to provide a specific range of shear rate, shear stress and viscosity.

Several suspensions of China Clay and saline tap-water were tested with suspended sediment concentrations ranging from 100 to 600 kg·m<sup>-3</sup>. In the tests the shear rate increased from zero to a maximum value of 125 s<sup>-1</sup> in 3 minutes and then decreased in the same period to zero again. Several sensor types were used depending on the concentration. The samples were thoroughly mixed and ultrasonically treated during 5 minutes before they were inserted in the sample holder. The temperature of the samples was 20 ± 0.5°C.

Some results are presented in Figure 1. The dynamic viscosity and the yield strength of a suspension can be estimated using these results. Furthermore, dynamic oscillation experiments were made on various clay samples at different concentrations (De Wit, 1992).

## Experimental set-up

A flume, length about 40 m, width 0.8 m and height 0.8 m, in the Hydro-mechanics Laboratory was modified for the purpose (see Figure 2). A simple mechanical wave maker was mounted at one end of the flume in order to generate regular waves, with a maximum wave amplitude of 0.11 m and a period ranging from 1 to 4 s. At the other end a stainless steel wave damper was mounted in such a way that it reduces wave reflection and would not interfere with generating a current. A recirculation pipe and a centrifugal pump were installed below the flume, which makes it possible to generate a steady current. The maximum flow rate is about 0.05 m<sup>3</sup>·s<sup>-1</sup>. The fluid is withdrawn below the wave damper at the end of the flume and it re-enters the flume via a smooth stainless steel duct installed below the wave maker. Wooden parts were used originally but these were replaced by stainless steel ones, because it was found that after a while fungi, algae and other micro organisms were growing on them. In this way the influence of organic material on the measurements is kept as small as possible.

The test section which holds the sediment is 8.0 m long. The vertical endwalls

Figure 2 Experimental set-up.

of the test section are 0.2 m high and are formed by stacking four beams of which three can be removed during an experiment. The downstream and upstream endwalls are connected to the bottom and the upstream cement false bottom, respectively, by 2 m long asbestos-cement plates which were made adjustable by means of hinges. In this way the height of the test section can be adjusted during an experiment by removing a beam and lowering the free side of the plate.

## Experimental procedure

Prior to the experiments some tests were carried out to measure the wave decay, the wave reflection and the velocity distribution in the flume without sediment. For this purpose a temporary false bottom, made of cement, was placed over the test section. Measurements were also made in this configuration when both waves and current were present. The results showed that there was no significant wave reflection and no significant wave decay above the closed test section. Furthermore, the velocity distribution for a steady current was almost uniform.

The false bottom over the test section was removed and preparations were made for the experiments with China Clay. The China Clay was thoroughly mixed with saline tap-water (salinity 5‰) in a mixing tank. The tank, in which a continuously revolving grid was installed, contained about 3 m<sup>3</sup> of suspension with a concentration of about 250 kg·m<sup>-3</sup>. The suspension was regularly circulated in the tank; the suspension was withdrawn at the bottom and re-entered the tank at the top. After the suspension had been mixed for at least one week, it was pumped to the test section which was separated from the rest of the flume. Then the suspension was mixed again and finally it was allowed to consolidate. After consolidation the mud layer in the test section was approximately 0.2 m thick.

Prior to the preparation of the mud bed, four miniature pore-pressure transducers (Druck PDCR 81) were fixed in a cross-section in the middle of the test section. The measured accuracy of the devices is  $\pm 5$  Pa. Furthermore, six wave height meters and three electromagnetic velocity meters were installed in the test section. The sensor of the electromagnetic velocity meter has an ellipsoidal shape (11 × 33 mm) and the sensing area is a cylinder just below the sensor with diameter 33 mm and height 5 mm. Concentrations of mud in the supernatant water layer were measured by an optical method and by taking samples. The concentration in the bed was measured using a conductivity probe. The data were recorded on a personal computer and video recordings were made.

Three experiments with China Clay were made. The composition of the China Clay used in experiment III differed very little from the China Clay used in experiments I and II. In all experiments the behaviour and the processes in the mud were studied and measurements were made for different settings of the wave height ( $\leq 0.1$  m) and water velocity ( $\leq 0.2$  m·s<sup>-1</sup>). The wave period was 1.5 s and the depth of the tap-water above the initial bed was 0.30 m. For a detailed

overview of the experimental programmes of the three experiments see De Wit (1992).

During the first, preliminary experiment the configuration was different from the one described above. A description of the configuration used in experiment I is given by De Wit and Kranenburg (1991). In Table 2 the initial heights of the beds and the consolidation periods are listed for the three experiments.

**Table 2** *Consolidation periods and initial heights of the bed.*

Experiment No.	date	initial height of the bed [cm]	consolidation period [days]
I	June 1991	18.5	22
II	December 1991	19.8	9
III	June 1992	18.5	6

## Results

When waves were generated, it was observed that a layer of fluid mud was formed for wave heights exceeding a threshold value. This value increased with the consolidation period. The consolidation periods for the different experiments are listed in Table 2. The mud in experiment I started to liquefy when the wave height was about 7 cm. In experiments II and III liquefaction occurred when the wave height was about 3.0 cm.

Prior to the experiment the concentration profile of the initial mud bed was measured. In Figure 3 concentration profiles are shown measured at two different places in the test section prior to the experiment and when a layer of fluid mud was present. The latter profile was measured at the down-stream end of the test section. The thickness of the mud layer near the downstream endwall did not decrease very much during an experiment, because fluid mud was transported in the downstream direction by the waves. It can be seen that the bed was quite uniform.

Although sometimes overlooked, the shear stresses caused by the streamwise variation in wave-induced pressures seem to play an important role in the liquefaction process of cohesive sediments (Suhayda, 1984). A rough estimation of these pressure-induced shear stresses is made in the appendix assuming an ideal elastic behaviour of the mud. It is shown that the maximum shear stress increases almost linearly with depth. Using the characteristic values of experiment III it was

Figure 3 Concentration profiles of the bed at two locations in the test section during experiment III.

found that the maximum shear stress at 1 cm below the water-clay interface, for instance, is approximately 3 Pa for a wave height of 3 cm. The initial concentration of the upper part of the bed was about  $400 \text{ kg}\cdot\text{m}^{-3}$ , see Figure 3. In Figure 1 it is shown that the yield stress of mud with a concentration of  $400 \text{ kg}\cdot\text{m}^{-3}$  is approximately 3.5 Pa, which is of the same order of magnitude as the stress generated by the pressure oscillations. At 15 cm below the water-clay interface, the maximum pressure-induced shear stress is about 30 Pa, which is an order of magnitude greater than the yield stress of the sediment at this level in the bed. Only just below the water-clay interface the pressure-induced shear stress is smaller than the yield stress of the sediment. Consequently, the bed will be liquefied immediately after the generation of waves with a wave height of 3 cm, which corresponds with our observations.

As soon as a layer of fluid mud had been generated, the waves were significantly damped and the damping increased with the thickness of the fluid-mud layer. The damping was only little influenced by a current (see Figure 4).

Visual observations of dye injected near the bed surface seemed to indicate that the turbulence intensities in the overlaying water decreased when fluid mud was present. Furthermore, the fluid mud was easily transported by a current and hardly any mud was entrained into the water during this process.

In a later phase of experiment I erosion prevented the fluid mud to leave the test section, which then was just a trench in the false bottom. Instead a large circulation zone was generated in the fluid mud. This was the main reason for changing the test section into the present configuration. In experiments II and III this problem did not occur.

Figure 4 Average wave heights measured above the test section when waves and both waves and current ( $10 \text{ cm}\cdot\text{s}^{-1}$ ) were generated. (Experiment II, fluid-mud layer present)

Figure 5 Wave-averaged velocity amplitudes in and above a partly liquefied bed. (standard deviation:  $0.5 \text{ cm}\cdot\text{s}^{-1}$ )

When a significant layer of fluid mud had been generated due to wave action, an electromagnetic velocity meter was used to measure velocity amplitudes just above and in the bed during experiment III. Although the flow of the fluid mud was disturbed significantly by the velocity meter, it was still possible to measure velocities. The calibration of the electromagnetic velocity meter was checked in towing tests prior to the experiment. According to visual observations at that moment, the bed was approximately 17.5 cm thick; the thickness of the fluid mud layer was when judged at the glass sidewall 4 cm. However, the measured wave-averaged velocity amplitudes shown in Figure 5, indicate that in the centre of the flume the whole mud layer had been liquefied.

In experiments II and III, four miniature pore-pressure transducers were installed. Three of them were fixed at several levels in the bed and one was fixed just above the bed as a reference. Wave-averaged water pressure changes measured just above and in the mud layer after the onset of liquefaction are shown in Figure 6. The pressure above the bed hardly changed during liquefaction. The pore pressure, however, showed a transient decrease which was probably caused by the break down of the aggregate structure. Then a gradual build-up of an excess pore

Figure 6 Wave-averaged pressure changes during liquefaction; a pressure at about 23 mm above the bed, b pore pressure 21 mm below the bed surface.

pressure was observed. Due to the low permeability of the mud layer the excess pore pressure did not dissipate, but rose to a final value corresponding with a zero effective stress.

## Discussion and conclusions

In each experiment a layer of fluid mud was generated due to wave action. However, the threshold value of the wave height at which liquefaction occurred depends on the consolidation period of the mud; the threshold value increased as the consolidation period increased.

Although the assumption made in the appendix of cohesive sediment being an elastic material is not quite appropriate, the estimate of the maximum pressure-induced shear stress given shows these stresses play an important role in the liquefaction process of mud.

The wave height was damped significantly as soon as a layer of fluid mud was generated and the damping was only little influenced by a current. Furthermore, dye injections seemed to indicate that the turbulence intensities decreased when a fluid mud was present. However, measurements using laser doppler anemometers or electromagnetic velocity meters are necessary to validate this observation.

The fluid mud was transported very easily by a current and hardly any mud was entrained into the water layer.

Usually visual observations and pressure measurements are made at a transparent wall of a set-up. However, from the measurements made with an electromagnetic velocity meter in the experiments carried out so far it is found that observations or measurements made at a sidewall are not representative of the actual physical processes away from the sidewalls. Only measurements carried out far from a wall give a quantitative description of the bulk processes inside the bed.

Pore-pressure measurements showed a transient decrease possibly caused by the break down of the aggregate structure, succeeded by gradual build up of an excess pore pressure so as to compensate for the vanishing effective stress.

This work will be continued by examining the liquefaction of sediments composed of other clay minerals. Furthermore, mathematical models relating the wave damping to the rheological properties of the bed are being tested.

## Acknowledgements

The authors wish to thank Delft Hydraulics for making available their Haake viscometer. This project was partly funded by the Commission of the European Communities, Directorate General for Science, Research and Development under MAST Contract no. 0035 (G6 Morphodynamics research programme).

### Appendix

#### Wave induced shear stresses in the bed

Waves are capable of generating shear stresses in the bed. The total shear stress is a superposition of the shear stress caused by the oscillating flow and the shear stress caused by the streamwise variation in the pressure on the bed. The shear stress imposed upon the upper bed surface by the oscillating flow can be calculated from viscous flow theory for laminar flow or an empirical equation for turbulent flow. The pressure-induced shear stress is sometimes overlooked, but seems to play an important role in the liquefaction process of cohesive sediments (Suhayda, 1984). This shear stress can be estimated in the following way.

Consider a two-dimensional semi-infinite isotropic linear-elastic solid in the domain  $z \geq 0$ . The  $x$ -axis of the cartesian coordinate system is in the streamwise direction. In the origin of this coordinate system a vertical point force is applied. Boussinesq derived a solution for the resulting stress components at any point in the solid in 1885 (Timoshenko, 1951). Using the principle of superposition the maximum value  $\sigma_{\max}$  of the shear stress  $\sigma_{zx}$  can be calculated for a sinusoidal pressure distribution  $p = \hat{p} \sin(kx)$ , where  $k$  is the wave number. It is thus found that

$$\sigma_{\max} = \hat{p} k z e^{-kz} \quad (1)$$

The maximum shear stress is found for  $kz = 1$ , but liquefaction may start at higher level in the bed because usually the strength of the bed increases with depth. Approximating for small  $kz$ , equation 1 gives  $\sigma_{\max} \approx \hat{p} kz$  which was also found by Maa & Mehta (1990).

The pressure amplitude  $\hat{p}$  at the upper bed surface generated by progressive waves with amplitude  $a$  as calculated using linear short-wave theory is

$$\hat{p} = \frac{\rho g a}{\cosh kD} \quad (2)$$

where  $\rho$  is the density of the fluid,  $g$  the gravitational acceleration and  $D$  the water depth.

## CHAPTER 226

### CONSOLIDATION OF SOFT MARINE SOILS: UNIFYING THEORIES, NUMERICAL MODELLING AND *IN SITU* EXPERIMENTS

Alain Alexis<sup>1</sup>, Philippe Bassoullet<sup>2</sup>, Pierre Le Hir<sup>2</sup>  
and Charles Teisson<sup>3</sup>

#### ABSTRACT

This paper first presents a literature review of consolidation theories. A link between sedimentation and consolidation models is pointed out and a more general formulation is suggested. The constitutive relationships between the void ratio and the effective stress or the permeability are discussed from experimental data available in literature. Then a numerical modelling is used to simulate settling column tests. At last field measurements of mud characteristics are presented.

#### 1 INTRODUCTION

Cohesive sediments are often at the core of coastal problems, either by their undesirable accumulation in estuaries and sheltered areas as harbours, or by their active pollutant role as a carrier of heavy metals or radionuclides. Thus, various numerical models have been developed over the past decade to reproduce cohesive sediment transport, through the well known advection-diffusion equation, with deposition and erosion acting as sink and source terms. But few industrial models do take into account consolidation. Its representation, when it exists, is often empirical and loosely linked with

consolidation theories (HAYTER, 1986; TEISSON and LATTEUX, 1986; LE HIR et al., 1989). Recent approaches try to take into account consolidation by including effective stress as a parameter of the settling velocity (TOORMAN, 1992). However, consolidation is a very important parameter which governs sediment dynamics at a fortnight tidal scale: part of the sediment, which deposits during neap conditions, will have time to consolidate and will not be resuspended during spring conditions, because of its higher critical shear stress. A good prediction of the amount of resuspended sediment and consequently definitive deposit therefore depends on a good simulation of consolidation.

**2 LITERATURE REVIEW**

As soft soils are at the boundary between water and soil, consolidation has been investigated by hydraulicians and geotechnicians, with separate approaches. We use an original tree method, shown in fig.1, to analyse the historical background and study the convergence of the different points of view.

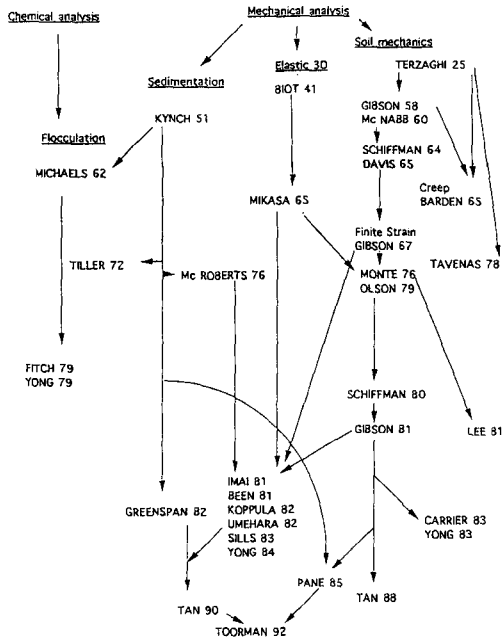

Fig.1: Soft soil consolidation historical tree of theoretical studies.

During the past ten years, some theories have been brought closer, but there is still no real inclusive approach, notably concerning the link between sedimentation and consolidation.

The study of previous theoretical works show that TERZAGHI (1925), KYNCH (1952) and GIBSON et al.. (1967) have been the key papers of this theoretical background. As TERZAGHI's formulation is only valid with small deformations and KYNCH's formulation does not take into account the effective stress, they reveal to be too restrictive. GIBSON's model is more general, but is limited to constitutive relationship only depending on the void ratio, and to incompressible phases.

In order to simulate the behaviour of a very soft marine soil, a relevant model should take into account large deformations, increasing or decreasing effective stresses due to the load history (deposition and erosion), variable or cyclical pore pressure (waves, tide), compressible fluid and grains (unsaturated, organic matter) and long term deformations (creeping).

### 3 TOWARDS A UNIFYING THEORY

As they appear different, models of consolidation have been rewritten using a unique notation system which allows their comparison.

GIBSON's law (1967) appears to be the most general of the previous studies. This formulation needs the use of a Lagrangian coordinate, the material coordinate  $z$ , which is constant for a given slice of sediment and corresponds to the height of solids above the slice. Stresses acting on sediment are studied separately, as effective stress on grains on the one hand, and pore pressure on fluid on the other:

$$\sigma = \sigma' + u_w$$

Mass balance,

$$\frac{\partial v_m}{\partial z} + \frac{\partial e}{\partial t} = 0$$

stresses equilibrium,

$$\frac{\partial \sigma}{\partial z} = \gamma(1+e) \quad \frac{\partial u_0}{\partial z} = \gamma_w(1+e)$$

extended Darcy's law,

$$v_m = -\frac{k_r}{\gamma_w} \frac{\partial u}{\partial z}$$

and constitutive relationships,

$$\sigma' = \sigma'(e) \quad k = k(e)$$

are written to get the Gibson's equation:

$$\frac{\partial e}{\partial t} - \frac{\gamma'_s}{\gamma_w} \frac{dk_r}{de} \frac{\partial e}{\partial z} + \frac{1}{\gamma_w} \frac{\partial}{\partial z} \left( k_r \frac{d\sigma'}{de} \frac{\partial e}{\partial z} \right) = 0 \quad (1)$$

where:  $e$  void ratio,  $k_r$  reduced permeability ( $k/(1+e)$ ),  $\gamma_w$  and  $\gamma'_s$  unit weights of water and of

immersed solids.

When self weight is ignored and small deformations are considered, it follows:

$$\frac{\partial e}{\partial t} = \frac{k E'}{\gamma_w(1+e_0)} \frac{\partial^2 e}{\partial z^2} \quad (2)$$

When effective stress is ignored, it follows:

$$\frac{\partial e}{\partial t} - \frac{\gamma'_s}{\gamma_w} \frac{dk_r}{de} \frac{\partial e}{\partial z} = 0 \quad (3)$$

SCHIFFMAN *et al.* (1985) have shown that the GIBSON'S equation (1) includes TERZAGHI'S equation (1925) (2) used in geotechnics for terrestrial soil and KYNCH'S equation (1952) (3) used in sedimentation as simplified and particular cases, when they are written in the same system of notations.

Moreover, the relation with the two-phase flow approach (TEISSON *et al.*, 1992) can be pointed out.

The usual condition of zero effective stress during the sedimentation phase induces the existence of a boundary void ratio. But a slightly decreasing effective stress down to very small but non zero values, with increasing void ratio, could allow to link sedimentation and consolidation as a continuous process.

We propose a new and extended formulation to take into account the compressibility of fluid and grains and non pure Darcinian flow:

$$\frac{\partial}{\partial z} \left( \gamma_f v_m \left( e, \frac{1}{1+e} \left( \gamma'_s - \frac{\partial \sigma'}{\partial z} \right) \right) \right) = \gamma_s \frac{\partial}{\partial t} \left( e \frac{\gamma_f}{\gamma_s} \right) \quad (4)$$

where the mean relative flow velocity  $v_m$  depends on  $e$  and the excess pore pressure gradient, but not necessarily according to the Darcy's law. It can be easily shown that the simultaneous use of the assumption of incompressibility for solid and fluid phases and of Darcy's law will make Gibson's equation 1 a restrictive case of equation 4.

Let us notice that the grain size distribution remains uniform, because of the use a material coordinate, but that creeping and the history of loading could be taken into account using a relevant effective stress evolution.

#### 4 CONSTITUTIVE RELATIONSHIPS

In order to solve (1) or (4) the representative constitutive laws  $\sigma'(e)$  and  $k(e)$  are definitely needed, which is the most difficult part of the task as these parameters can only be obtained through experimental ways for a given mud. This is all the most difficult as we deal with cohesive sediment and a very large range of concentration (BERLAMONT, 1992).

These two specificities also put the stress upon the necessary link between hydraulics and soil mechanics with a mutual benefit.

We have brought together experimental data issued from a hundred tests available in litterature. Our will was to mix the results of available experiments, in order to point out common trends although the experimental conditions and the soil composition were different in these various tests.

Void ratio was chosen as the main parameter, consistently with geotechnicians' habit. Bibliographic data were harmonized by transforming the other parameters (water content, density, dry density, weight concentration, volumetric concentration). When needed, the average value of 2,65 was taken for the density of solid particules.

For the effective stress, 48 experimental curves from IMAI (1981), UMEHARA and ZEN (1982), PANE et al.(1982), YONG et al.(1983), TAN et al.(1988) have been used.

A random distribution could have been expected, but in spite of the scattered dots, fig.2 shows a trend of the effective stress. This trend is in agreement with the effective stress shape introduced to link sedimentation and consolidation in part 3.

The next stage will consist of separating dots in different families by taking into account their plasticity as the main parameter of their nature.

Fig.2: Gathering of effective stress literature experimental data.

A similar diagram has been drawn for the relationship between void ratio and permeability. We have used here 10 experimental curves from PANE et al.(1982), YONG et al.(1983), TAN et al.(1988), TAN et al.(1990) and TOORMAN (1992). Permeability or consolidation tests data are shown in fig.3a, down to a concentration of 300 g/l. In order to represent (fig.3b) very low concentration data, down to 50 g/l, settling velocity data (white squares in fig.3b) were transformed in permeability, using the correspondence:

$$v_s = \frac{k}{\gamma_w} (\gamma' - \frac{\partial \sigma'}{\partial x})$$

with a zero effective stress.

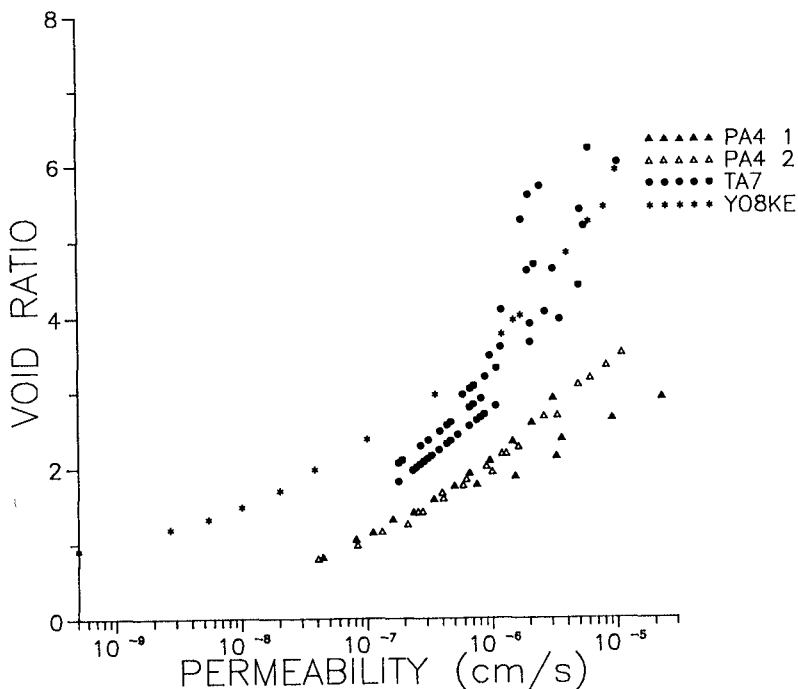

Fig.3a: Gathering of permeability literature experimental data (without settling velocity data).

The trend seems to be of the same nature on these diagrams, except for the fact that higher effect of the

soil composition or structure may lead us to imagine several curves.

Fig.3b: Gathering of permeability literature experimental data (including settling velocity data).

## 5 NUMERICAL MODELLING

Gibson's equation expresses time and vertical evolution of the void ratio  $e$ , and can be easily modelled as a 1 D vertical advection-diffusion equation, except for the cost of computing due to the required fine vertical discretization. The equation is formulated in finite differences and solved with a semi-implicit numerical scheme. But the main problems lie in the appropriate formulation of the boundary condition at the interface between water and consolidating bed, and in the determination of the constitutive relationships  $k(e)$  and  $\sigma'(e)$ , i.e. permeability and effective stress as a function of the void ratio. Experimental settling tests of BEEN and SILLS (1981) have been satisfactorily reproduced with our model. The simulated height of the sediment column

is in good agreement with the experimental one (fig.4). Density at bottom is well represented but little discrepancies appear in the middle of the column (fig.5). They are probably due to the rather high sensitivity of the model to the constitutive relationships.

Fig. 4: Time evolution of total height of deposit.

Fig. 5: Comparison of simulation with experiment profiles of BEEN and SILLS (1981).

## 6 IN SITU EXPERIMENTS

Some specific characterization tests are essential to evaluate fine cohesive sediments properties in muddy intertidal environments, in order to determine the relevant parameters for modelling mud erosion and deposition processes and to confront the results of previous theories and simulations with real situations. The involved parameters are naturally the concentration (or dry density) of the surficial sediment but also its shear strength which is assumed to be correlated with the "rigidity" of the mud.

In a same cross-section of the Elorn estuary (Brittany), small cores have been sampled in three locations of the intertidal area, according to three different mud levels, at several moments of the tidal cycle, during spring or neap tides, in winter and summer (december 1990 - june 1991 - january 1992). From these cores, vertical profiles of water content, dry density and yield stress have been measured every two centimeters, just after sampling. Yield stress measurements are made with vane testers which are specifically fitted to soft muds. A short synthesis from some of these cores is presented here. The resulting profiles show classical increases of concentration and shear strength over the first ten centimeters. The gradients can vary according to the tidal amplitude, the season and the location along the cross-section.

### Tidal variations

The effect of the tidal amplitude is more noticeable in the lower part of the mud bank where large irregular variations of dry density appear on spring tides, probably due either to stronger flows or to drainage processes in the cross-section of the mud.

As for the variation during the tidal amplitude, measurements show larger concentrations as well as higher yield stresses before the covering by the flood than just after the uncovering during the ebb, but the differences are only perceptible for the 2-3 upper centimeters. This phenomenon can lead to a variation of mud erodibility within the tidal cycle.

### Seasonal variations

The comparison between winter and summer data, at the same level of the intertidal flat (fig.6 and fig.7), points out more extended gradients in winter, when the surficial mud is less concentrated and less stiff.

These seasonal variations can be attributed to modifications of the deposit rate - due either to erosion elsewhere (L'YAVANC and BASSOULET, 1991) or to temperature effects or more probably to biological processes; several past studies have pointed out the role of biota seasonal variations and, in addition, some positive correlation

between the organic content and the shear strength of the mud (see for example MONTAGUE, 1986).

Fig. 6: Concentration profiles at a same location. Winter and summer measurements. Spring tide.

From all these results, it appears that the state of the surficial mud can change according to various processes which are not presently included in theories and models. On the other hand, a rather good correlation between concentrations and yield stress has been obtained and if we assume an additional correlation between yield stress and erosion processes, the previous direct *in situ* measurements can give information on the erodability of natural mud in an intertidal environment.

#### 7 CONCLUSION

The purpose of our survey was first to make a scanning of previous theories with the attempt to bring the light on the implied assumptions and to classify them.

In order to make a skimming of their most representative qualities we have attempted to develop an original formulation with less restrictive assumptions than before.

Gathering experimental literature data has allowed us to distinguish general trends of effective stress and permeability evolution for a large range of void ratios.

In spite of the usual difficulty to obtain relevant constitutive relationships (effective stress and

permeability), we have tried to simulate numerically a sediment settling in a laboratory column with a pair of experimental constitutive laws and have obtained a positive result.

But in situ experiments have shown that our theories still have to be improved, taking into account many other parameters, not considered up to now.

These complementary approaches should lead to a better description, understanding and modelling of consolidation processes, which will benefit to models of cohesive sediment transport.

#### ACKNOWLEDGEMENTS

This work has been undertaken as part of the MAST G6 Coastal Morphodynamics Programme. It was funded partly by the Commission of European Communities, Directorate General for Science, Research and Development under MAST Contract n°0035-C and partly by the French Sea State Secretary (STCPMVN).

## CHAPTER 227

### EFFECTIVE STRESSES AND PERMEABILITY IN CONSOLIDATING MUD

Jean Berlamont, Lut Van den Bosch and Erik Toorman<sup>1</sup>

#### Abstract

Measurements of density and pore pressures for consolidation experiments on estuarine mud are analyzed. Results for bulk permeability, local permeability and effective stress are presented and simple relationships between each of these parameters and the density are proposed. The problems associated with the accuracy of the measurements and their consequences on the determination of closure equations for consolidation models are discussed.

#### 1. Introduction

The study of erosion, deposition and transport of sediments is of major importance for the operation of harbours, the planning of maintenance dredging, the spreading of pollutants and the stability of coastal structures. Therefore, many efforts have been devoted during the past few years to develop mathematical models for simulating the movement and deposition of sediments in coastal regions and estuaries. Although various commercially available models are capable of predicting fairly well the behaviour of non-cohesive material (sand), they do hardly better than producing qualitative results when cohesive sediments (mud) are involved. This, unfortunately, is very often the case in harbours and estuaries. The reason is that the basic physical processes involved are not yet fully understood, and thus cannot be modelled adequately.

---

<sup>1</sup>Hydraulics Laboratory, Katholieke Universiteit Leuven, De Croylaan 2, B-3001 Heverlee, Belgium

The actual erosion rates and whether or not a muddy bed will be eroded by currents or wave action depend on the degree of consolidation of the bed. Each cohesive sediment transport model should therefore include the modelling of the time history of the bed and its consolidation. A review of consolidation models can be found in (Shiffman *et al.*, 1985) and (Alexis, 1991). More recent approaches, taking into account hindered settling as well, are due to (Tan *et al.*, 1990) and (Toorman, 1992).

The consolidation of a cohesive sediment bed depends on: (1) the expulsion of water through the pores between the solid particles, i.e. on the permeability  $k$  of the mud layer; (2) the deformation of the card-house-like structure of mud flocs, i.e. on the effective stresses  $\sigma' = \sigma - p$ , in which  $\sigma$  is the total stress and  $p$  is the pore water pressure. Therefore, there is a great need for general constitutive equations for the effective stress and for the permeability of a mud layer. Both are still largely unknown.

In the first part of this paper the results of experiments in settling columns will be described and discussed. Experiments were carried out both with drained and undrained mud layers. In the second part an attempt is made to determine permeability and effective stress as a function of bulk density.

**Fig.1:** Settling column: experimental set-up.

## **2. Settling column experiments**

In the Hydraulics Laboratory of the K.U.Leuven several series of consolidation experiments on drained and undrained mud layers were carried out in order to investigate the effect of drainage on the consolidation rate.

### 2.1 Experimental set-up.

Figure 1 shows the experimental set-up of the settling column. The transparent column has a diameter of 0.10 m and is equipped with water pressure gauges. Where the piezometers are connected to the column, a cigarette filter is inserted to prevent mud particles from entering the tubes. The bottom of the column is closed for undrained experiments. In the case of drainage it is replaced by a filter, about 10 cm thick, consisting of a gradation of sand and gravel. The bottom of the filter is connected to a small reservoir of which the level can be changed in order to allow a variation of the imposed head difference over the mud layer. The percolating discharge is measured by regular weighing of the measuring cup. Density profiles can be measured with a nuclear density probe with an accuracy of  $10 \text{ kg/m}^3$  (MAST-G6M Report, 1992).

### 2.2 Experiments

In this paper three sets of experiments are discussed. Table 1 gives an overview of test conditions. In all cases mud from the River Scheldt was used.

Exper. nr.	$H_0$ (m)	$\rho_0$ ( $\text{kg/m}^3$ )	Drainage	$\Delta h$ (m)	Duration (days)
KO1	1.600	1095	drained	0.0	119
KO2	1.600	1095	undrained	-	97
KO3	1.602	1095	drained	0.8	126
KO4	1.600	1095	drained	1.6	119
KO5	1.604	1095	undrained	-	92
KO6	1.602	1095	drained	variable	92
KO7	1.983	1060	undrained	-	41
KO8	1.993	1095	undrained	-	22
KO9	1.983	1098	undrained	-	26

**Table 1: Experimental conditions**

The first set of experiments (KO1, KO2, KO3, KO4) were ordered by IMDC (International Marine & Dredging Consultants) and fit within the study program for the design and optimization of a mud basin and capture reservoir (Mengé *et al.*, 1991). Afterwards, a second series of experiments (KO5 and KO6) were carried out to investigate optimal compaction through controlled drainage. The initial density in each case was  $1095 \text{ kg/m}^3$ . Interface level, pore pressures, density profiles and percolating discharge were measured. The columns were filled from the top. The columns were cooled at the surface with tap-water to keep them at a constant

temperature ( $\pm 13^{\circ}\text{C}$ ) in order to reduce gas production by organic matter.

In order to evaluate the results of permeability and effective stress values as a function of density, a third set of undrained consolidation experiments has been carried out. The general set-up for the settling columns was the same as for the previous ones except for a larger number of piezometers, which allows better estimation of local permeabilities. Cooling was now obtained by placing the columns in a constant temperature room. Tests are carried out at a temperature of  $8^{\circ}\text{C}$ , which is a more realistic value for in-situ conditions of underwater disposals and almost eliminates gas production. The columns were now filled by sucking up the slurry into the column by creating vacuum, which has the additional advantage of de-airing the mud.

**Fig.2:** Settling curves for experiments KO1-KO4.

2.3 Discussion of observations

From the settling curves of KO1-KO4 it can be concluded that the descend of the water-mud interface starts earlier when the column is drained. During the first hours the consolidation rate of the undrained column KO2 is much lower than that of the drained column (Fig.2). The consolidation rate of KO1 (head difference  $\Delta h = 0.0$  m) is even larger than that of KO4 ( $\Delta h = 1.6$  m). After 100 hours the mud-water interface of both columns has reached the same level. This means that

consolidation rate of the drained column with head difference 0.0 m has decreased.

The smaller the head difference during the first hours the higher the consolidation rate at that moment. Afterwards the consolidation rate of the columns with a lower head difference decreases. At the end of the experiments (after 3 months) drainage gives a better compaction. The compaction increases for greater head difference. The compaction of KO1 and KO3 after 3 months is more or less the same. The compaction of KO4 is much higher than the others (i.e. 21 % better than for the undrained column KO2).

Density profiles for drained columns show that there is an upper layer of approximately constant density and a lower zone where the density increases with depth (Fig.3), which is clearly indicated by a distinct inflection point. The zone of constant density is similar to an undrained mud layer. Comparison of the density profiles of KO1-KO4 shows that the height of the zone with high densities increases with the imposed head difference (Fig.3).

**Fig.3:** Density profiles for experiments KO1-KO4 after two months.

In order to combine both effects to maximize compaction, two new experiments (KO5 and KO6) were started. In experiment KO6 the imposed head difference was stepwise varied during the experiment from 0 to nearly the initial column height (Fig.4). The experiment KO5 (undrained) was used as reference.

**Fig.4:** Consolidation curves for columns KO5 (undrained) and KO6 (drained).

As in the first experiments (KO1-KO4), the lowering of the interface starts earlier for the drained column (KO6) than for the undrained column (KO5) (Fig.4). However, although the geometric head difference during the first 2 days was zero, there is a small head difference over the mud sample caused by a difference in density between the fluid mud (initially the mud has no structure) and the water in the tube connecting the filter with the downstream reservoir. Therefore water can migrate downwards through the filter pushed by a small head difference. After a few hours a structure is formed and the head difference disappears. After 2 days the head difference was increased by lowering the reference reservoir level, resulting in an increased consolidation rate. After 4 days the head difference is 1.47 m. After 3 months the compaction in the drained column is 23 % higher than in the reference undrained column KO5. The density profile of KO6 (Fig.5) shows that the bottom zone of high densities is even thicker than in the tests KO1-KO4.

**3. Permeability and effective stress**

**3.1 Mean bulk permeability**

Data of the above discussed experiments have been used to estimate the permeability. For a closed (undrained) column the global permeability of the layer is calculated as a function of the average bulk density  $\rho$  using Darcy's law:

$$\frac{Q}{A} = k \frac{\Delta h}{L} \tag{1}$$

Fig.5: Density profiles for columns KO5 (undrained) and KO6 (drained).

where:  $\Delta h$  = difference over a certain time interval ( $\Delta t = t_{i+1} - t_i$ ) of pressure head above hydrostatic at the bottom of the column;  $L_i$  = mud layer thickness at time  $t_i$ ;  $A$  = cross sectional area of the column;  $Q = A (L_i L_{i+1}) / 2\Delta t$  = average pore water flow rate;  $L = (L_{i+1} + L_i) / 2$  = mean layer thickness.

Fig.6: Global permeability as a function of average bulk density for columns KO5 (undrained) and KO6 (drained).

Fig.6 shows the results for columns KO5 and KO6. The relation between  $k$  and  $\rho$  can be approximated (for  $1130 < \rho < 1210 \text{ kg/m}^3$ ) by:

$$\log k = a\rho + b$$

[2]

where:  $a$  and  $b$  are empirical constants.

The inflection point in the density profiles was found to correspond with the level where the water head above hydrostatic reaches its maximum value (Fig.7). Hence, the excess pore water pressure gradient changes sign here, which implies that the pore water flows downward through the filter for the layer under the inflection point and upward for the zone above it. For the drained column the permeability of the upper zone is calculated as above for the undrained columns, whereas for the bottom layer the measured percolated discharge is used in Darcy's law. Hence, in drained columns permeabilities of mud layers of much higher density can be obtained. The obtained values of  $k$  are close to those obtained with Eq.[2] (Fig.6).

Fig.7: Density profiles and pore pressures above hydrostatic for the drained column KO6.

### 3.2 Effective stress

The total stress  $\sigma$  at a certain level is obtained by integration of the density profile from the surface down to that level. When the pore pressure  $p$  is measured at that point, the local effective stress  $\sigma'$  can be computed as  $\sigma - p$ . Fig.8 shows the total pressure, the pore pressure and the effective stress as a function of the depth for an undrained (KO2) and a drained column (KO4). It can be seen that the effective stresses in the drained mud layer are greater than in the undrained case.

Fig.8: Stresses in the undrained column KO2 and the drained column KO4.

It was found that the dimensionless parameter  $\sigma^* = \sigma'/\rho k^2$  (where  $k$  is calculated with Eq.[2]) gives a rather good linear correlation with  $\rho$  on a semi-logarithmic scale, i.e.:

$$\log \sigma^* = a' \rho + b' \quad [3]$$

Substitution of Eq.[2] in [3] results in:

$$\log(\sigma'/\rho) = a'' \rho + b'' \quad [4]$$

where:  $a'' = a' + 2a$  and  $b'' = b' + 2b$ . Hence a plot of  $\sigma'/\rho$  as a function of  $\rho$  should directly give a linear correlation on a semi-logarithmic scale. The results for an undrained (KO5) and drained (KO6) column can be seen in Fig.9. The large scatter for small  $\sigma'$  values is due to the low accuracy of measuring effective stresses (especially at low  $\rho$ ), because  $\sigma'$  is obtained as the small difference of two parameters ( $\sigma$  and  $p$ ) which are of the same order of magnitude (see *MAST-G6M* Report, 1992).

To check the relationship [4] a new set of consolidation tests (KO7-KO9, Table 1) were carried out. The experimental results for the relationship between

effective stress and local density are shown in Fig.9. The effective stresses during the first two days are not plotted because of the low accuracy of these values. To extend the relationship for low values of effective stress a more accurate measuring method for effective stress is needed. In general it can be concluded that for the range  $1100 < \rho < 1350 \text{ kg/m}^3$  the relationship in a semi-log scale is linear.

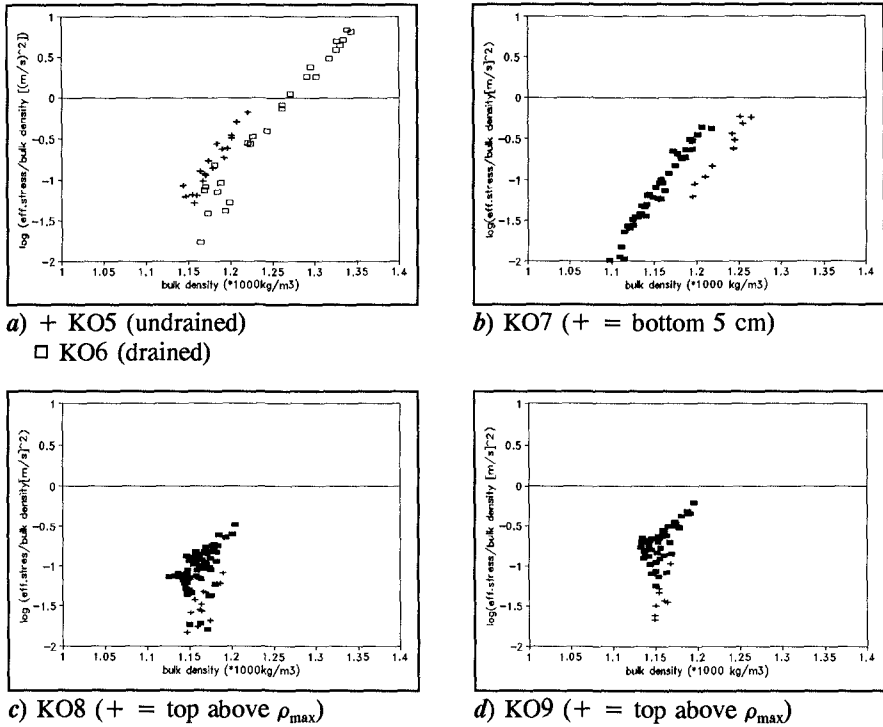

Fig.9: Effective stress as a function of bulk density for columns KO5-KO9.

Looking at the results of the columns KO7-KO9 separately, it can be seen that for KO7 in fact two lines can be distinguished, i.e. for points in the bottom 5 cm of the column and for those above. Possibly, because the initial density ( $1060 \text{ kg/m}^3$ ) of this experiment (KO7) was below the gel-point (the critical concentration for structure formation) of this mud, sand may have migrated to the bottom during the first hours of the experiment, causing a difference in composition of the mud for the points of the two lines. Moreover, the density measurements are biased close to the bottom of the column. A comparison of the results of KO7 with those of KO6 and KO5, shows that the data for the bottom layer of KO7 are comparable to those of the drained column KO6, while the values for the top layer of KO7 are on the same line as for the undrained column KO5, even though the mud in both sets of

experiments originated from different locations in the Scheldt.

The shape of the density profiles of KO8 is not as expected, showing a large zone of decreasing density with depth (Fig.10). Similar density profiles have also been found by *Bowden* (1988). At first sight, the results of effective stress for KO8 do not show a clear linear correlation (Fig.9c). It can be seen that there are two clouds of points. Possibly the relationship depends on the shape of the density profiles. For KO9 similar observations were made as for KO8.

**Fig.10:** Density profiles for column KO8.

### 3.3 Local permeability

For the experiments KO7-KO9 an attempt was made to determine the local permeability by using the following form of Darcy's law, which is only valid for undrained tests (*Bowden*, 1988):

$$k = \frac{w_s'}{i} \quad [5]$$

where:  $w_s$  = local settling rate (average solids velocity),  $k$  = permeability,  $i$  = local hydraulic gradient. The settling rate can be estimated from successive density profiles, by following levels in the mud layer below which a certain constant fraction

of the total mass of the sediment is found. The hydraulic gradient can be estimated by the difference in excess hydraulic head between two neighbouring pressure taps divided by the distance between them.

The local permeabilities as a function of local density were calculated for KO7, KO8, KO9 (Fig.11a-c). Again the experimental results can be approximated by a linear relationship between  $\log(k)$  and  $\rho$ . For column KO7 the linear approximation is very good in the range from  $1050 \text{ kg/m}^3 < \rho < 1200 \text{ kg/m}^3$ . For higher densities there is a lot of scatter. For this range the calculation of  $k$  by Eq.[5] is very inaccurate, because the settling rate is determined from two successive density profiles, measured with limited accuracy (§2.1), which hardly change any more at this stage of the consolidation process.

a) KO7

b) KO8

c) KO9

Fig.11: Local permeability as a function of density for columns KO7-KO9.

For KO8 and KO9 a linear relationship between  $\log(k)$  and  $\rho$  is a good approximation. The scatter is larger than for KO7 because the initial density was higher, which reduces the accuracy of the calculation of  $w_s$ . The inaccuracy is largest for the 80% mass level, because the density profiles are integrated all the way from the top down. The values of  $k$  for KO8 and KO9 are a factor 5 to 10 smaller than the permeabilities of KO7. Because the density profiles are used for calculation of

$k$ , a possible explanation can also here be found in the shape of the density profiles, which is influenced by the initial density of the slurry.

### 3.4 A theoretical consideration

Darcy's equation for undrained consolidation, Eq. [5], can more explicitly be written as a relationship between effective stress, permeability and settling rate (Toorman, 1992):

$$\frac{1}{g} \frac{\partial \sigma'}{\partial z} \approx \rho_w \frac{w_s}{k} - \Delta \rho \quad [6]$$

where:  $g$  = gravity constant;  $\Delta \rho = \rho - \rho_{w(\text{atcr})}$ . When the density is below the critical concentration where no structure exists, hindered settling takes place instead of consolidation and thus there is no effective stress. Hence, Eq. [6] reduces to:

$$k = w_s \frac{\rho_w}{\Delta \rho} \quad [7]$$

This was first pointed out by *Been* (1980). Therefore, for low densities Eq. [2] can no longer be valid, because in the limit where  $\Delta \rho$  goes to zero, the permeability becomes infinite since  $w_s$  then equals the (finite) Stokes fall velocity of a sediment particle.

## 4. Conclusions

The settling curves of the drained and the undrained mud layers show that drainage fastens the settling and the consolidation rates. The compaction can be maximized by applying a variable, i.e. increasing, head difference over the mud sample. Higher densities than in undrained conditions are then obtained in a thick layer above the bottom. Hence it is possible to obtain values of permeability and effective stress at higher densities using drained columns.

The presented results suggest linear correlations between  $\log(k)$  and  $\rho$  and between  $\log(\sigma'/\rho)$  and  $\rho$  within the range  $1100 < \rho < 1200 \text{ kg/m}^3$ . Because there is often significant stratification in the mud layer, it is unlikely that the global permeability can be used to calibrate a closure law for  $k$  needed in numerical modelling, since local values are required. Local permeabilities however are harder to measure. Nevertheless, the magnitude of local and bulk permeabilities were found to be comparable. More experimental work is required to get more accurate data for the ranges of low and high densities, as well as to investigate the effect of parameters, such as initial density, structural history, shape of the density profiles, initial height, depth from the interface, etc.

### Acknowledgements

This work has been undertaken as part of the MAST G6 Coastal Morphodynamics Programme. It was funded partly by the Commission of European Communities, Directorate General for Science, Research and Development under MAST Contract No.0035-C and partly by national funding. Part of the settling column experiments (KO1-KO4) were financially supported by IMDC (Int. Marine & Dredging Consultants, Antwerp, Belgium). The last author received a grant from the Belgian National Fund for Scientific Research.

## CHAPTER 228

### Cohesive Profile Erosion by Waves

Craig Bishop<sup>1</sup>, Michael Skafel<sup>1</sup> and Rob Nairn<sup>2</sup>

#### Abstract

Hydraulic tests of the erosion by waves of a shore profile made from intact samples of till, a cohesive material comprising a large part of the Great Lakes shorelines, have been completed. Over 1000 h of testing in a laboratory flume with random depth-limited breaking waves, varying conditions of sand cover, and varying mean water levels have been run. The vertical erosion rates of the till were measured along the centreline of the 8 m long, 0.35 m wide and 0.25 m thick till profile; its initial shape was the equilibrium form  $y = Ax^{2/3}$  common on sandy beaches. Some of the important findings are that this type of hydraulic test is viable, the role of sand in the erosion process is similar to its role in unidirectional flow model tests but the thickness and volatility of the sand layer are also factors, the main effect of varying water levels is to shift the zone of erosion activity up and down the profile, and that erosion can occur in the absence of sand if the rate of wave energy dissipation is high enough (plunging breakers, steep slopes).

#### Introduction

A large part of the Laurentian Great Lakes shoreline consists of cohesive materials, especially till. Similarly, much of the Black Sea coast, England's North Sea coast and others consist of cohesive materials. These shorelines are typically characterized by an eroding backshore bluff and a small, thin beach; cohesive material underlays the beach of cohesionless (sandy) materials. A shore can be defined as cohesive when a cohesive sediment substratum occupies the dominant role in the change in the shoreline shape (i.e. through erosion). It has been recognized that there are fundamental differences in the erosion process between sandy and cohesive shores. Cohesive shores are often glacial in origin, and they derive their strength from the cohesion of the clay as well as their consolidation from the period of glacia-

tion. Once the material is eroded, it cannot reconstitute itself; it's cohesive nature is lost and the fine particles are advected away from the nearshore zone. Therefore, unlike sandy shores, erosion on cohesive shores is irreversible. The recession of cohesive bluffs is now understood to be controlled by the vertical erosion (downcutting) of the nearshore profile (Kamphuis 1987). Typically, the beach of cohesionless material in front of a cohesive bluff plays a complex role in the erosion process; it can provide some protection or can serve as an abrasion agent depending on its volume and the wave energy. Only when the volume of cohesionless material overlying a cohesive layer is large (of the order  $200 \text{ m}^3/\text{m}$  for the Great Lakes), as can occur at a large obstruction such as a harbour jetty or a headland, does the erosion process return to being the same as that on a sandy shore (Nairn 1992).

The erosion process on a cohesive coast can be demonstrated by a comparison of two cross-sections of a bluff and nearshore profile at a site in Lake Ontario (Nairn 1992). Figure 1 shows the estimate of the underlying cohesive profile and the sand cover in 1952 and again in 1989. The bluff face has receded about 30 m over this 37 year period for an average recession rate of 0.8 m/yr. In order for this to occur, the nearshore lake bed had to be downcut considerably. Furthermore, the profile shape in 1952 is very similar to that in 1989; it has simply shifted shoreward by 30 m. In a review of many field data sets throughout the Great Lakes, profiles were generally found to retain their shape as they receded (Nairn 1992). There appears to be an equilibrium or preferred cohesive profile shape.

Fig. 1 Lake bottom and till profiles in 1952 and 1989 at Scarborough Bluffs, Lake Ontario (after Nairn, 1992).

In the present work, the processes important in the erosion by waves of a nearshore profile made from intact samples of till are examined by means of hydraulic tests.

### Field Work

A vital component of this study was the collection of intact till samples in the field. Remoulded clays are known to have much reduced resistance to erosion compared with the undisturbed or intact clay (Lefebvre and Rohan 1986). After several field reconnaissance visits to the Lake Erie shoreline, a suitable site located about 200 m from the northshore bluff of Lake Erie was found. The site, Shanks' Gravel Pit #1, is located just west of Port Alma on Highway 3, where, after stripping off the overburden, a sand-gravel layer which overlies Port Stanley till is mined using a dragline. The bluffs and lake bottom over a large part of northwestern Lake Erie consist of Port Stanley till, a relatively homogeneous, cohesive material laid down by glaciers over 10,000 years ago.

Open-ended steel boxes were manufactured using 1/8 inch (3.2 mm) thick steel. The box dimensions are 1.0 m long, 0.35 m wide and 0.45 m high. The front (cutting) end of each box has a bevelled edge and sloped back at an angle of 2, 3 or 7 degrees; these slopes were intended to minimize the surface gaps between blocks when installed in the flume.

2a Backhoe clearing face of till

2b Cutter frame with till sample

2c Till sample in steel box

2d Field site after removing 25 samples

Fig. 2 Photographs of field site

On October 9, 1990 Shanks removed the overburden and sand-gravel layer, prepared a work area and scraped the till surface smooth using a mid-sized bulldozer and a 25-ton crane with a dragline. On October 10, after pumping out accumulated rainwater, the till surface was trimmed by another 30 cm. Then a trencher was used

to cut a smooth vertical face in the till. A backhoe and bulldozer were used to clear the working face of the till (Fig. 2a).

A custom made aluminum cutter frame was positioned and levelled in front of the prepared vertical till face; it was held in place by the trencher and bulldozer. A portable diesel hydraulic unit was used to power a 20-ton hydraulic ram. The ram slowly pushed an empty steel box guided by the cutter frame into the till (Fig. 2b). The end of the box in the till was cut away using a chainsaw with a trenching chain. The box was then lifted (Fig. 2c) and transported to a flatbed truck using the crane. The tops of the samples were covered with cheesecloth, sprayed with water, then the whole till-filled steel box was wrapped in plastic. By repeating this procedure, 25 till blocks were collected on October 10-11 by 8 people (Fig. 2d). When the samples arrived at NWRI, each block was misted again with water, and then put into 2 plastic bags which were then taped shut. Later, on May 23, 1991 all unused till blocks were stored under water until needed.

Size analysis and geotechnical tests on samples of the till gave the following average properties: 21% sand and gravel, 33% silt, 46% clay, mean grain size  $D_{50} = 0.0052$  mm, liquid limit 27, plastic limit 17, plasticity index 10, and vane shear strength 86 kPa.

### Laboratory Flume Setup

Tests were conducted in the 100 m long wind-wave flume at the NWRI Hydraulics Laboratory. An existing smooth plywood beach at a slope of 1:20 was modified to incorporate a 0.37 m wide channel along its centeline. Fig. 3 shows the test setup. A motorized carriage, equipped with a variable speed motor, traversed the working length of the test channel. Its position was monitored using an electronic synchro transmitter with horizontal accuracy of about  $\pm 3$  mm. Profile data were collected at horizontal speeds of the order of 10 mm/s. Vertical profile data were measured with an optical bedplotter device mounted on a bracket attached to the carriage. Light from a light emitting diode is sent through a probe of fibre optic cables; a servo system raises or lowers the probe so as to maintain a preset voltage, corresponding to a vertical gap of about 15 mm, from the light signal reflected from the bed. The accuracy of the system is about  $\pm 1$  mm. A bedplotter reading was taken on a fixed reference plate before and after each profile. Typically, variations between before and after readings were about 0.5 mm.

### Waves

Waves were generated by a piston-type wavemaker using GEDAP (Funke and Mansard 1984) software. One random wave voltage sequence was used to drive the wavemaker for all tests. It was developed for a mean water depth of 100.0 cm, a peak frequency of 0.4 Hertz, a duration of 500 s (200 waves), unspecified groupiness, and a ratio of mean wind speed to wave phase speed ( $U/c_p$ ) of 1.3. Waves were measured by 3 capacitance wave gauges. The spacing between gauges 1 and 2 was 0.706 m, and between 1 and 3 was 1.696 m. Incident and reflected wave spectra were separated using the method of Mansard and Funke (1980). The characteristic wave height ( $H_{m0}$ ) of the incident waves was 0.31 m at a water depth of 1.00 m, 0.29 m at 0.95 m, 0.26 m at 0.85 m, and 0.26 m at 0.75 m. The corresponding values

of peak frequency ( $f_p$ ) varied between 0.33 and 0.39 Hertz.

Since the laboratory tests used intact samples of prototype till and depth-limited breaking waves over most of the profile, these tests can be considered as full scale of the nearshore zone to a water depth of 0.5 to 0.75 m. There may be some model effects due to the peak frequency of the waves being higher than typical storm values of 0.1 to 0.2 Hz in the field.

Fig. 3 Test setup in laboratory flume

**Initial Profile**

According to Kamphuis (1987), nearshore profiles on cohesive coasts in wave-dominated environments have a long term, stable shape similar to the so-called "equilibrium" shape of sandy beaches described by Dean (1977). This shape is of the form  $y = Ax^{2/3}$  where  $y$  is the vertical distance measured downward from the mean water level,  $x$  is the horizontal distance measured from the mean water line, and  $A$  is a shape factor. This equation is for the mean profile and inherently ignores sand bars. Moore (1982) relates the shape factor to the mean grain size present on the beach. A medium sand, with  $D_{50} = 0.51$  mm, available in the laboratory, was put in the testing part of the flume and subjected to about 20 h of the test wave spectra. The sand profile reached a stable shape and was measured. Ignoring the bars, the shape corresponds well with the predicted shape using the value of  $A$  given in Moore (1982) for the 0.51 mm sand (Fig. 4).

Based on these preliminary tests with sand, the starting profile for the till was designed to be of the form  $y = 0.18x^{2/3}$ . Eight till blocks, trimmed to a height of 0.25 m, were installed in their steel boxes in the flume; loose till was packed into the seams and then the profile was measured under water. The initial till profile is compared to the design profile in Figure 4. Only a brief summary of results of several different test categories are given here; for a detailed description of tests and results, refer to Bishop and Skafel (1992).

Fig. 4 Equilibrium sand profile (---), design profile (ooo), and initial till profile (—). Water depth = 1 m.

### Scour Hole Formation

The first (exploratory) test series (TS1) was run with a mean water level of 100.0 cm; the most striking observation was the formation of a significant scour hole at the plunge point for a majority of the breaking waves, located in the top till block just below the mean water level. The test began with a large supply (est. 100 L) of 0.51 mm sand on the profile above the top till block. This acted as a sand dune and provided unlimited sand to the till profile for the first few hours of testing. After only 2.08 h of waves, the beginning of the formation of a scour hole from the mean water line to a depth of about 0.18 m was observed. Then, to restrict the sand supply, the sand dune was flattened and then covered with fibrous matting; however, sand was still available by leaking out from under the matting. Sand was being lost from the till surface through gaps at the seams between till blocks; this implies that sand was moving across the till surface. Fig. 5 shows the till profile and rate of change in elevation (erosion rate) at  $t = 8.33$  h at which time only a few sand ripples were left at the bottom of the profile. (In Figures 5 to 13 the solid and dashed lines are the initial and final profiles respectively for the test sequence under discussion; they refer to the left hand vertical axis. The dot-dash line is the erosion rate (right hand vertical axis) and the dotted line is the zero erosion rate.) The scour hole continued to erode rapidly. Over the first 8.33 h the peak erosion rate at the scour hole averaged 13 mm/h; this was the highest rate measured over the entire test program.

The seams were repaired by excavating a narrow trench at each seam, grouting the bottom of the trench, and then backfilling and compacting the seam with remoulded till. A variety of tests were run with and without sand. After 140 h, the till profile is shown in Fig. 6. The scour hole continued to grow in size but the rate of change decreased dramatically.

Fig. 5 Till profile and erosion rate after 8.33 h of testing at  $d = 1$  m.

Fig. 6 Till profile and erosion rate after 140 h at  $d = 1$  m.

The second test series (TS2) began with an initial profile that was the eroded profile after 145 h from TS1. In order to avoid effects due to the scour hole, the mean water level was lowered to 85.0 cm. In this and subsequent test series, the test conditions were varied in systematic fashion and the response of the till was measured. At the end of TS1, somewhat less than 8 L sand was left on the profile. This sand moved quickly from  $4 < x < 5$  m to  $5 < x < 6$  m, the latter being the stable sand bar position for the lower water level of TS2. For the first 15 h of TS2, no new sand was added.

The most striking feature of TS2 was that a large scour hole did not form below the MWL as had occurred in TS1. The dominant zone of plunging breakers moved offshore from the scour hole area of TS1 to the region around  $x = 4$  m. In TS1 the scour hole formed where plunging breakers struck an initially steep (1:5.5) till slope. In contrast, for TS2, at the lower water level, the breakers struck a flatter (1:10) initial till slope and were not plunging as intensely.

### No Sand

From the results of unidirectional flow lab tests by Kamphuis (1990), it is known that the erosion rate of till is strongly dependent on the presence of sand in the water. As part of the present study, Kamphuis carried out erosion tests on till samples from Shanks pit in a manner identical to earlier tests of Kamphuis (1988).

When clear water was used to erode the samples, the "critical shear stress" required to begin erosion was about 7 Pa. When sand was introduced into the flow, erosion began at a much lower shear stress of about 0.8 Pa, which corresponds to the threshold for movement of the sand. This indicates that erosion of a cohesive layer subjected to a flow containing some sand begins when the sand becomes mobile as discussed in Kamphuis (1990).

A "no sand" scenario was investigated by draining the flume, washing the till surface, and then running 62.5 h of waves; the only cohesionless material on the profile was that which had been missed in the washing and that which eroded from the till surface during the test. Fig. 7 shows that the erosion rate (note the change in erosion rate scale) is very small (less than 0.2 mm/h); the higher rate around  $x = 4.8$  m is due to some protruding grout having been manually removed. The results agree with the findings of Kamphuis (1990).

Fig. 7 Till profile and erosion rate after 62.5 h,  $d = 0.85$  m, no sand.

Fig. 8 Till profile and erosion rate after 37.5 h,  $d = 0.85$  m, stationary sand bar.

### Stationary Bar

A stationary bar scenario was investigated by placing 24 L of sand evenly on the profile at  $5 < x < 7$  m; the waves caused a bar to form at the location indicated by the short horizontal line in Fig. 8. Waves were run for 12.5 h, the sand was scraped from the bed and then, after profiling, the sand was placed evenly at  $5 < x < 7$  m again. This sequence was repeated two more times. Over this time Fig. 8 shows virtually no erosion beneath the bar, but some erosion both onshore and offshore; the small accretion rate indicated under the bar is due to some sand being missed when cleaning the till surface. From the results of this and other tests, it has been shown that the presence of a stationary sand layer of 10 mm or more thickness is sufficient to prevent erosion of the underlying till for the wave conditions and grain size characteristics associated with these tests.

### Sparse Sand Cover

A sparse sand cover environment was created by leaving an estimated 2-3 L of sand on the bed after it had been scraped, adding no new sand and running 37.5 h of waves. After this test, the flume was drained, the profile was washed and about 1.5 L of sandy gravel was recovered from the profile and another 0.5 L may have been washed away or missed. Grain size analysis of the recovered material gave  $D_{50} = 1.3$  mm. The profiles and erosion rate for this period are shown in Fig. 9. Clearly, the erosion rate is higher than the case of a stationary bar and the zone of erosion extends across most of the profile, including the former bar location; the null spot around  $x = 4.8$  m is at a hardened seam.

Fig. 9 Till profile and erosion rate after 37.5 h,  $d = 0.85$  m, sparse sand cover.

Fig. 10 Till profile and erosion rate after 40 h,  $d = 0.85$  m, recycled bar.

### Recycled Bar

An artificially recycled bar environment was created by adding about 20 L sand at the scour hole, letting it move to the bar location, then scraping it off the bar and placing it in the scour hole again at intervals of 1.25 h. Earlier tests had determined that all the sand moved to its stable bar position within 1.25 h. Fig. 10 shows the erosion rate over this 40 h period. There are null spots around  $x = 3.8$  m and 6.8 m, both at hardened seams, and relatively high erosion rates (up to 0.5 mm/h) out as far as  $x = 8$  m. This scenario is probably fairly representative of three-dimensional conditions in that sand is moving over the profile out to a least  $x = 6$  m and all parts of the profile are fully exposed for some of the time. From the results of this and other tests, the exposure of the till to moving sand, or, expressed another way, the volatility of the sand cover, is an important factor in the erosion process.

**Varying Water Levels**

The objective of this test series (TS4) was to investigate the influence of changing mean water levels on the erosion of the till profile. Tests were conducted at water levels 85, 95, 75 and back to 95 cm. The 8 till blocks used for the first tests were removed and replaced with new till blocks plus an extra one, the ninth, above block 1. The shape of the profile was the same as before, i.e.  $y = 0.18x^{2/3}$ , except that the slope of the top two blocks was reduced to 1:9.4 so as to be the same as the third block, formerly the second block. A sealed wood beach with fibrous matting on top was installed above block 1 at the same 1:9.4 slope.

After 140 h of tests at a mean water level of 85 cm, the mean water level was raised to 95 cm. For the next 60 h waves attacked the profile without any supplementary sand. However, it was observed that quite a lot of gravel eroded from the till and collected over  $3.7 < x < 4.6$  m; gravel filled in any low spots, especially a runnel along the centreline. At 30 h the profile was washed and about 5 L sandy gravel was recovered. For the subsequent 30 h, a recycled bar environment was created again by adding 2 L sand at the mean water level at 3.33 h intervals and scraping the bed underwater at 10 h intervals. After washing the bed, about 5 L sandy gravel was recovered. Fig. 11 shows the profiles at the start and end of the 90 h test with a depth of 95 cm and the corresponding erosion rates. Clearly, the major zone of activity is the upper part of the profile near the mean water line. A distinct scour hole again formed at the upper (steep) part of the profile at the zone of dominant breaking.

Fig. 11 Till profile and erosion rate after 90 h,  $d = 0.95$  m. Fig. 12 Till profile and erosion rate after 120 h,  $d = 0.75$  m.

After lowering the mean water level to 75 cm, 70 h of waves were run without adding any sand. About 0.5 L of sandy gravel was eroded from the till, and removed by scraping, during each 10 h period. After 70 h the flume was drained and the bed was washed. For the next 50 h, a recycled bar environment was created by

adding 2 L sand just below the mean water line at 3.33 h intervals and scraping the bed underwater at 10 h intervals. Fig. 12 shows the profiles at the start and end of the tests at 75 cm. The major zone of erosion has shifted offshore to the zone of dominant breaking corresponding to the lower water level. The main effect of a change in mean water level is to shift the location on the profile that experiences the breaking waves; for high water, the zone of erosion is further onshore, while for lower water, the zone moves offshore.

The mean water level was raised again to 95 cm and 50 h of waves were run without adding any sand. Fig. 13 shows the beginning and end profiles, and the erosion rate, for TS4 after 400 h (of the series of four water levels). The profile has shifted shoreward and has steepened slightly at its top end. The erosion rate starts near zero around the highest mean water level, quickly reaches a maximum near the dominant plunge point of the breakers at the highest mean water level, then decreases quite uniformly in the offshore direction. These trends agree with the field results depicted in Figure 1.

Fig. 13 Till profile and erosion rate after 400 h,  $d = 0.85, 0.95, 0.75$  and  $0.95$  m.

### Numerical Model

A numerical model has been developed to simulate the processes on a cohesive shore profile. The downcutting process of a cohesive profile is more complicated and less well understood than the transport of the overlying sand. The model, first presented by Nairn et al (1986), empirically relates downcutting to two processes: (1) the shear stresses on the bed due to the wave orbital velocities; and (2) the intensity of wave breaking (as indicated by the local gradients in wave energy dissipation across the surf zone) and associated turbulence and jets (due to plunging breakers) impinging on the bottom. The former is dominant outside the surf zone, while the latter is dominant in the surf zone. These concepts are in agreement with the observations that the degree of downcutting increases towards the shore, a result that

cannot be sustained by a model based only on shear due to orbital velocity. Two empirical coefficients are used to relate the downcutting to these processes. The presence of sand overlying the cohesive layer has two distinctly different roles, depending on its thickness. A thin veneer acts as an abrasive agent, increasing the downcutting. A thicker layer, typically greater than 5 to 10 mm in these tests, protects the underlying cohesive material. An updated version of the original model (Nairn 1990) is able to predict the movement of the sand layer over a fixed surface, and so the resultant effects on the cohesive layer can be predicted in the short term. The model upgrade includes the consideration of supply limitation to sediment transport predictions. This type of short term modelling is helpful in developing a better understanding of the erosion processes through an extension of the physical experiments. For long term predictions heavy computational demands of the model and cumulative errors in simulating the sand movement require the use of the model without explicitly accounting for the sand cover, with appropriate coefficients.

Results of the calibration runs for the two types of simulation are shown in Fig. 14 in which the dashed line is the initial profile, the solid line is the experimental erosion rate and the dot-dash line is the numerical model erosion rate. In Fig. 14a, sand cover was explicitly considered in the case of the recycled bar: the relatively high downcutting rates are well represented over most of the surf zone except the very top part. Under the influence of the sparse sand cover the downcutting was reproduced equally well (Fig. 14b) with coefficients that did not take the presence of sand into account. For the sparse sand cover case, the ratio of the values of the coefficients from the two types of simulation indicate that, at any one point, the profile was subjected to downcutting for only 10 to 20% of the time. These numerical model calibration runs provided valuable guidance in extending the numerical work to prediction of the evolution of various cohesive shore types in the Laurentian Great Lakes (Nairn 1992).

## Conclusions

Hydraulic tests of the erosion by waves of a shore profile made of intact till samples have been conducted successfully and have helped to advance our understanding of coastal processes on cohesive shores. The role of sand in the erosion process is very important: in the absence of sand, there is virtually no erosion except where turbulence and/or hydraulic jets reach the cohesive bed; a stationary sand layer of 10 mm thickness or more is sufficient to protect the underlying cohesive material from erosion due to waves tested in this study ( $H_{m0} = 0.3$  m,  $T_p = 0.35$  Hz); and, other factors being equal, the greater the volatility of the sand cover, the greater the erosion rate will be. Long term erosion rates measured inside the surfzone for the wave and water level conditions of this study are of the order of 0.5 mm/h, peaking at the zone of dominant breaking, and decreasing monotonically in the offshore direction. The main effect of varying mean water levels is to shift the zone of dominant breaking up or down the profile: for higher levels, the zone of highest erosion rates shifts onshore, while for lower levels, the zone of highest erosion rates shifts further offshore so that, in the long term, the whole profile tends to maintain an equilibrium shape.

## CHAPTER 229

### The Kinematics of Wave Induced Flows Around Near-Bed Pipelines

T.Bruce<sup>1</sup>, W.J.Easson<sup>2</sup>

#### ABSTRACT

Particle Image Velocimetry (PIV) has been applied successfully to give quantitative, full field measurements of instantaneous velocity fields for oscillatory flows past a model of a pipeline above a plane bed. The application of PIV to this problem is discussed, and results for the case of  $KC = 20$  with gap ratios 1.0 and 0.1 are presented in the form of velocity vector maps, and contour plots of vorticity distribution.

#### INTRODUCTION

There is extensive coverage in the literature of research into the fluid loadings experienced by cylindrical structures in a wide variety of flow regimes [eg. Sarpkaya, Isaacson, 1980]. Many studies have focussed on the cyclic variation of drag and lift forces on a horizontal cylinder exposed to wave action. Some of these studies have been extended to investigate the effect of the proximity of a plane bed on cylinder loadings.

Recently, qualitative flow visualisation studies have improved the understanding of loading cycles through wave periods. Williamson [1985] performed simultaneous visualisations and force measurements for a cylinder being oscillated at  $KC$  numbers up to 60, and was able to relate the form of the loading-time curve to the vortex shedding process in a number of distinct shedding regimes. Sumer et al [1991] have extended this work to investigate the influence of a plane boundary close to the cylinder.

The objective of the work reported here was to obtain quantitative, full-field measurements of the kinematics of oscillatory flows past a cylinder near a plane boundary. These flows are unsteady, so building up a quantitative map of the kinematics using a single point measurement technique would be impossible. Attention must therefore be turned to techniques which can measure velocities over

a complete, two-dimensional measurement zone. Established methods such as streak photography which readily give qualitative flow visualisations can be made to yield quantitative data, but the analysis can be laborious and the errors involved are in general large. A technique which suffers none of the above drawback is Particle Image Velocimetry (PIV), and it is this technique's application to oscillatory flows past near-bed cylinders which is described here.

The numerical modelling of unsteady flows past cylinders is becoming increasingly successful. The discrete vortex model has been applied to the flow past a cylinder above a plane boundary [Penoyre and Stansby, 1988] with promising results. However, in order to assess the validity of these models, accurate, full-field quantitative data for the flow kinematics is required. Also, quantitative data of this kind may find use in the modelling of sediment transport and the scour process in the vicinity of a seabed pipeline.

## METHOD

PIV is a relatively new technique which gives a quantitative map of instantaneous flow velocities over a large area. Additionally, the velocities obtained are of high accuracy and high resolution. The basis of PIV is to stroboscopically illuminate a two-dimensional plane through the flow, which has been *seeded* with tiny reflective particles which are assumed to follow the flow accurately. The illuminated plane is then photographed, the shutter being held open long enough to record at least two illuminations. Thus each seeding particle gives rise to at least two particle images. The local flow can then be determined from the separation of these images. A fully automated system is used to *interrogate* the photograph over an array of points to build up a flow velocity map. A detailed description and appraisal of PIV is presented elsewhere in the proceeding of this conference [Greated et al, 1992].

A purpose-built facility has been constructed for these studies, consisting of a rectangular 6m by 1m tank with a water depth of 0.5m, above which runs a computer controlled trolley (figure 1). This trolley tows objects through initially stationary water, and may be programmed to execute complex motion sequences. For the experiments reported here, a horizontal test cylinder (of diameter 50mm) and a false bed were rigidly attached to the trolley and were towed through the tank to give a sinusoidal motion. In general, the flow kinematics resulting from moving an object sinusoidally through initially stationary fluid are identical to those generated by a sinusoidal fluid flow past a fixed object [Garrison, 1980]. However, in the case being studied, it was important that the influence of the bed on the kinematics was correctly included in the tests: In order that the finite length of the false bed did not affect the flows observed, the false bed was more than twice the length of the largest amplitude oscillations.

A two-dimensional plane in the flow is illuminated stroboscopically through the glass bottom of the tank by a 15W Argon Ion continuous wave laser and a *scanning beam* system [Greated et al, 1992, Gray et al, 1991]. The flow is seeded

Figure 1: Experimental facility

with conifer pollen and photographed using a Hasselblad *EL/M* medium (55mm) format camera. For these experiments, the camera was triggered electronically from the trolley control system, so that a precise phase of the flow could be selected and captured. Additionally, the camera was panned across the measurement field as the photograph was taken. The reason that it was necessary to pan the camera is as follows:

PIV in its basic form gets velocity information from the separations of double particle images on a photograph. In general there is no way to tell which image is the first, and thus there exists an inherent ambiguity in the sense of the velocity measurement obtained at any given point. In many, indeed most cases, this does not cause a problem; eg in the case of a breaking wave, it is known *a priori* all the motion is in one  $180^\circ$  arc. However, in this application, there are both forward and reverse flows present. Also, PIV in its basic form cannot positively measure a region of zero flow velocity — it relies on measuring the separation of correlated particle images, and if the first and second images overlap, then no correlated separation will be visible and thus no velocity measurable.

Panning the camera as the photograph is taken solves both these problems: As it is being panned, the camera sees the whole flow field as if a large *shift*

velocity had been imposed on the true flow field. The velocities recorded will have this large offset superposed on the true flow. If this *shift* velocity is made sufficiently large, the first particle image will always be to the same side of the second, and particle images which would have been coincident in areas of very low or zero flow velocity are now separated. The shift can be subsequently subtracted from the measured field to give the true flow field. (This *image shifting* technique is analogous to *frequency shifting* in LDA).

## EXPERIMENTAL PARAMETERS

The formation of vortices at the pipeline, and the subsequent motion of these vortices (particularly when they are *swept back* over the pipeline) strongly affect the drag and lift forces on the pipeline. Naturally, the pattern of vortex formation and movement varies a great deal for different flow regimes. The structure of these flows past a smooth pipeline is governed by three dimensionless parameters:

The Keulegan Carpenter number (KC) is defined as

$$KC = \frac{U_m \tau}{D}$$

where  $U_m$  is the magnitude of the maximum velocity of the oscillatory flow,  $\tau$  is the period of the oscillation and  $D$  is the characteristic dimension of the flow; here, the cylinder diameter. Thus the larger KC, the larger the motion of *fluid particles* relative to the size of the cylinder.

The second important parameter is the *gap ratio*,  $e/D$ .

$$e/D = \frac{\text{size of gap between cylinder and bed}}{\text{cylinder diameter}}$$

Finally, the Reynolds number ( $R_e$ )

$$R_e = \frac{U_m D}{\nu}$$

where  $\nu$  is the kinematic viscosity.

The structure of the flow is strongly affected by the combination of KC and  $e/D$ . However, the dependence on  $R_e$  is only weak — all the flows studied here are sub-critical, and the form of the flow is largely independent of  $R_e$  within the sub-critical range of  $R_e$ .

Williamson [1985] studied oscillatory flows past a cylinder in free stream (ie, without a plane boundary) and identified distinct ranges of KC values over which a particular pattern of vortex formation and motion was observed. Sumer et al [1991] reviewed the flow patterns in these regimes for various values of the gap

ratio  $e/D$ . He presents visualisations and loading measurements for  $KC = 4, 10, 20, 30$  and  $e/D$  over the range from 0 to 3.5.

This paper presents results of the first experiments in this study. As such, the work of Sumer et al was considered an excellent starting point. The cases of  $KC = 20$  with  $e/D = 1.0$  and  $e/D = 0.1$  were the first to be studied, and it is these tests that are reported here.

Figure 2: Velocity vectors,  $KC = 20$ ,  $e/D = 1.0$ , phase =  $0^\circ$

## RESULTS

Once the process of obtaining good PIV images has been established for a given application, it is possible to obtain large quantities of data in a short time. Here, there are a large number of flow regimes of interest, each characterised by  $KC$  and  $e/D$  parameters. For each regime, there are a number of interesting events (eg vortex separation) which should be recorded. The results presented here have been chosen to be illustrative of the sort of data obtained. The data is presented in two forms: as velocity vector maps, and as contour plots of the vorticity distribution.

Figure 2 is an example of a velocity vector map. Each of the vectors corresponds to one analysed point on the PIV photograph, so the flow has been measured at around 1000 points from the PIV photograph. No interpolation has been carried out on the data. The map shows the measured flow at the end of one

Figure 3: Vorticity,  $KC = 20$ ,  $e/D = 1.0$ , phase =  $0^\circ$

half-cycle for the case  $KC = 20$ ,  $e/D = 1.0$ . The model pipe is instantaneously at rest having moved from right to left over the previous half cycle.

Some interesting features of the flow stand out immediately. There are two vortices clearly visible. The vortex just to the right of the pipe has just been shed. Its rotation is counter-clockwise, so before it was shed, it developed on the side of the pipe adjacent to the wall. In addition to this *wall-side* vortex, there is a second vortex rotating clockwise near the bed whose origin is not clear from this map alone.

An alternative way to present the data is in the form of a map of vorticity distribution. Figure 3 shows the vorticity distribution derived from the same data as shown in figure 2.

The vorticity ( $\Omega$ ) at a point  $(x,y)$  in the field was calculated from

$$\Omega(x, y) = \frac{v_x(x, y + \delta y) - v_x(x, y - \delta y)}{2\delta y} - \frac{v_y(x + \delta x, y) - v_y(x - \delta x, y)}{2\delta x}$$

where the  $v_x(x, y)$  and  $v_y(x, y)$  are the x and y components of the measured velocity at  $(x,y)$ , and  $\delta x$ ,  $\delta y$  is the separation in space between neighbouring ve-

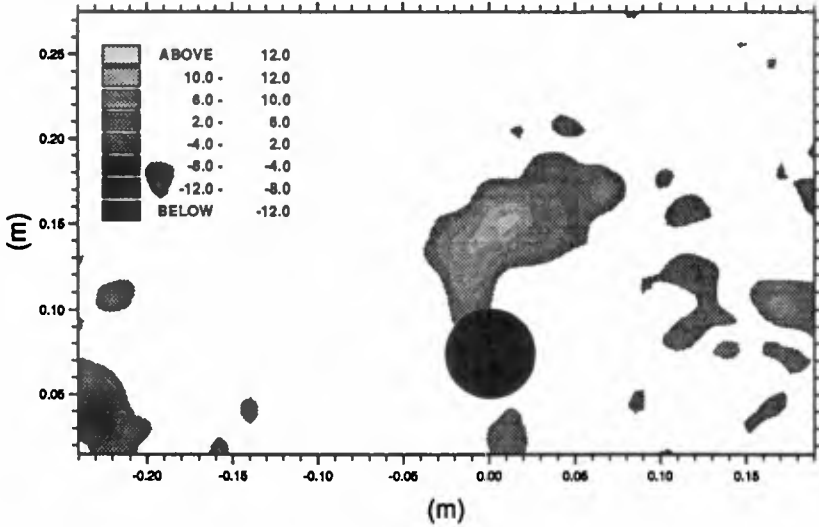

Figure 4: Vorticity,  $KC = 20$ ,  $e/D = 1.0$ , phase =  $270^\circ$

locity points. Such numerical differentiation is very susceptible to errors, but the smoothness of the resulting distribution indicates that these errors are acceptably small.

The white background indicates areas where there is little or no vorticity (or rotation) in the flow. The contoured areas leading to a light centre indicate positive vorticity (clockwise rotation), and the areas leading to a dark centre indicate negative (counter-clockwise rotation). In this case, the structure of the flow is clearly visible on both vector and vorticity maps. However, when there is an area of weak vorticity, this structure often only becomes clearly visible when the vorticity is calculated.

Figure 4 shows the vorticity distribution a quarter cycle ( $90^\circ$ ) before that shown in figure 3, and helps clarify the origin of the large region of positive vorticity visible near the bed in the middle of the previous plots. Here, the pipe is moving from right to left at its maximum velocity of  $200\text{mms}^{-1}$ . It shows clearly a positive vortex being washed over the pipe. It is this vortex which subsequently appears as the rightmost vortex in figure 3. This vortex was the wall-side vortex shed during the previous half-cycle.

When the gap ratio  $e/D$  is reduced from 1.0 to 0.1, the structure of the flow is quite different. Only one vortex (the wall-side vortex) of any size develops

Figure 5: Vorticity,  $KC = 20$ ,  $e/D = 0.1$ , phase =  $165^\circ$

during a half-cycle, and this happens quite near the end of the half-cycle. As the pipe comes to rest and begins to move back on the next half cycle, this vortex is promptly washed back across the pipe. Figure 5 shows the flow as measured at a phase of  $165^\circ$ , just before the end of the left to right half cycle. The wall-side vortex is quite well developed and clearly visible. Also visible is a small area of negative vorticity, lower left of the map. This area is the remnant of the wall-side vortex from the previous half-cycle which was washed over the pipe during the current half-cycle.

## CONCLUDING REMARKS

PIV has been successfully applied to a model of a pipeline above a plane seabed. The quality of the first velocity maps and vorticity contour maps is most encouraging, and detailed comparison with numerically modelled flows should be possible.

In the immediate future, this study will be extended to survey a number of other  $KC$  and  $e/D$  combinations which are representative of the various different flow regimes. It is hoped to place particular emphasis on those flow regimes most relevant to the real coastal environment.

Following the studies of the plane bed, it is intended to move on to investigate

the new kinematics in the case of a scoured bed below the pipeline, and also the case of interaction between cylindrical structures.

## CHAPTER 230

### MIXING BY SHEAR INSTABILITIES OF THE LONGSHORE CURRENT

J.C. Church<sup>†</sup>, E.B. Thornton<sup>†</sup>, and J. Oltman-Shay<sup>‡</sup>

#### ABSTRACT

Shear instabilities of the longshore current are examined as a possible source of non-zero  $\overline{u'v'}$  values (mixing) within the surfzone. This term is calculated using model generated stream functions whose amplitudes are calibrated with the observed turbulent kinetic energy spectrum. Data from the DELILAH experiment, conducted at the barred beach at Duck, North Carolina is used. Excellent agreement is found between the predicted range of shear instabilities and observations as seen in frequency-wavenumber plots. Maximum predicted values for  $\overline{u'^2}$ ,  $\overline{v'^2}$  and  $\overline{u'v'}$  are .04, .20, and .03 m<sup>2</sup>/s<sup>2</sup>.

#### INTRODUCTION

During 1986 SUPERDUCK, Oltman-Shay *et al.* (1989) observed low frequency oscillations (<0.01 Hz), with wavelengths less than 300m. Free surface gravity waves below 0.05 Hz consist of two classes of waves: edge waves which are trapped by refraction along the beach face, and those which escape seaward as "leaky" waves; these waves have been observed in great detail and are considered "infragravity" waves because of their low frequencies relative to the sea-swell band. The uniqueness of the oscillations observed lies in the fact that the wavelengths observed were an order of magnitude shorter than the shortest infragravity wave under applicable conditions (a function of frequency and beach slope). These oscillations were considered to be kinematically distinct based upon their frequency / wavenumber range.

Energy density distributions represented by gray shading in wavenumber-frequency space for 10 October during the DELILAH experiment are shown in fig. 1. The theoretical dispersion curves for trapped edge waves, modes 0, 1, and 2 are shown for the appropriate beach slope. Significant energy is seen outside of these edge wave curves; this energy is linear in f-K space (where K, cyclic wavenumber, is equal to  $k/2\pi$ ), indicating that these oscillations (considered to be alongshore progressive waves) are non-dispersive. The relationship between the phase speed of these oscillations, given by the wavenumber-frequency slope, and the magnitude

Fig. 1 Frequency-cyclic wavenumber spectrum for 10 Oct. with shading representing log-variance density.  $\Delta f=0.00098$ ,  $\Delta K=0.0005$ . Theoretical edge-wave dispersion curves (modes 0-2) are plotted.

of the mean longshore current, together with the lack of any such oscillations in the absence of mean longshore currents, indicates that the longshore current, and its associated kinetic energy, may be the driving force behind these waves.

Bowan and Holman (1989) formulated a theoretical framework to explain these observations as shear instabilities, deriving a conservation of potential vorticity equation in which the vorticity of the longshore current shear functioned as the restoring force. They also related a phase shift in the stream functions produced by the instabilities to non-zero  $\overline{u'v'}$  values which were suggested as possible sources of significant mixing in the nearshore.

Standard longshore current models (based on an alongshore balance between the radiation stress gradient and bottom shear stress) applied to barred topography predict two current maxima in the form of "jets", the first over the bar, and the second at the beach face. Conversely, observations routinely show a single longshore current maximum, found in the vicinity of the trough. Typically,

longshore current models employ some sort of horizontal mixing term to try to eliminate this disparity. This mixing term is a parameterization of the turbulent radiation stress gradient and is usually described in terms of eddy viscosity. Turbulence is present in the surf zone over a wide range of frequency and spatial scales; in the present work the turbulence (or perturbations) associated with shear instabilities is studied with the specific objective of calculation of the  $\overline{u'v'}$  term, thus avoiding the need for parameterization.

Putrevu and Svendsen (1992) carried out a numerical study of shear instabilities over various topography and using an order of magnitude analysis, concluded that even a weak shear in the longshore current could be capable of producing significant mixing. To quantify this possibility requires calculation of the  $\overline{u'v'}$  associated with the shear instabilities. Unlike non-linear models such as Dodd (1992), which may be used to predict stream function amplitudes, linear models utilize stream functions which are of arbitrary amplitude; thus the predicted velocities, which are based on the gradients of the stream functions, are likewise arbitrary. Calibration of the stream function amplitudes requires one of two approaches. The first, followed in Dodd *et al.* (1992), assumes that the growth rates predicted by the model may be taken as an indication of the ultimate distribution of energy across the wavenumber spectrum. For example, should wavenumber  $k_1$  have a predicted growth rate twice that of wavenumber  $k_2$ , it would be assumed that the steady state energy of  $k_1$  will be twice as great also. Linear theory is then used to relate energy to amplitude squared. This method allows for the inter-comparison of different wavenumbers, but still lacks an absolute reference.

The second method is to measure observed energy at the wavenumbers/frequencies of interest and then scale the stream function amplitudes such that the predicted and observed energies match. This approach does produce an absolute reference and will be used in the current work. The combined  $u$  and  $v$  energies (i.e.  $\overline{u'^2} + \overline{v'^2}$ ) have been used for calibration, being invariant with orientation. Once the stream function amplitudes have been so calibrated, the result is an alongshore averaged profile of  $\overline{u'v'}(x)$  for each wavenumber for which growth is predicted. Integrating these produces a profile which represents the net radiation stress associated with the shear instabilities. Data obtained during the 1990 DELILAH experiment are used to evaluate the magnitude and structure of this term across a barred beach.

## SHEAR INSTABILITY THEORY

### A. Assumptions

Linear wave theory is utilized, with the  $x$ -axis perpendicular to the bathymetry (positive seaward). Both mean and perturbation current velocities are vertically integrated and the mean current is assumed steady state. The longshore current and bathymetry are assumed uniform in the alongshore direction.

### B. Shear Instabilities of the Longshore Current

In the companion paper to Oltman-Shay *et al.* (1989), Bowen and Holman (1989) offered a theoretical basis for shear instabilities. Using conservation of potential vorticity as the restoring force, they were able to relate the mean longshore current shear to observed oscillations.

The momentum equations, with the velocity consisting of perturbations ( $u'$ ,  $v'$ ) and a mean longshore current ( $V$ ) are:

$$1) \quad \frac{\partial u'}{\partial t} + V \frac{\partial u'}{\partial y} = -g \frac{\partial \eta}{\partial x}$$

$$2) \quad \frac{\partial v'}{\partial t} + u' \frac{\partial V}{\partial x} + V \frac{\partial v'}{\partial y} = -g \frac{\partial \eta}{\partial y}$$

where  $\eta$  is surface elevation. These equations are linearized and a non-divergent (rigid lid) approximation is applied allowing the use of a stream function to represent the flow, such that:

$$3) \quad u' = -\frac{1}{h} \frac{\partial \Psi}{\partial y} \quad v' = \frac{1}{h} \frac{\partial \Psi}{\partial x}$$

Cross differentiating to combine equations and eliminate  $\eta$ , the result is:

$$4) \quad \overset{1}{\left(\frac{\partial}{\partial t} + V \frac{\partial}{\partial y}\right)} \overset{2}{\left(\frac{\Psi_{yy}}{h} + \left(\frac{\Psi_x}{h}\right)_x\right)} = \overset{3}{\Psi_y} \overset{4}{\left(\frac{V_x}{h}\right)_x}$$

where the subscripts denote differentiation. Term 1 represents the local rate of change. Term 2 is the advection by the mean longshore current. Term 3 is the relative potential vorticity of the perturbations. Term 4 represents the advection by the perturbations of the potential vorticity of the mean longshore current. This potential vorticity equation is comparable to the barotropic Rossby equation used for planetary scale flow with the exception that the background vorticity of the current shear is substituted in place of the Coriolis parameter.

A solution is then assumed of the form:

$$5) \quad \Psi = \text{Re}\{\phi(x)e^{i(ky - \omega t)}\}$$

where  $\phi$  is the cross-shore structure function. The alongshore wavenumber,  $k$ , is taken to be real, but  $\omega$ , the angular frequency, and  $\phi$  may be complex. The form of the solution which allows growth with time is then:

$$6) \quad \Psi = \exp(\omega_{im} t) \text{Re}\{\phi(x) \exp[i(ky - \omega_{re} t)]\}$$

Inserting this solution in the previous equation yields:

$$7) \quad (V - c)(\phi_{xx} - k^2 \phi - \frac{\phi_x h_x}{h}) - h \phi \left(\frac{V_x}{h}\right)_x = 0$$

where  $c$  is the phase speed of the shear wave, equal to  $\omega/k$ . Dodd *et al.* (1992)

include the dissipative effects of bottom friction through a parameterization,  $\mu=2c_r U_b/\pi$ . The resulting modification of the basic equation produces:

$$8) \quad \left(V - \frac{i\mu}{kh} - c\right) (\phi_{xx} - k^2\phi - \frac{\phi_x h_x}{h}) - h \left(\frac{V_x}{h}\right) \phi + \frac{i\mu}{kh} \left(\frac{\phi_x h_x}{h}\right) = 0$$

The principle result of the inclusion of dissipation is a dampening effect on instabilities as indicated through the model by the reduced range over which growth is predicted. This equation, with  $c_r=0.003$ , is the essence of the shear instability model employed in this study.

After inserting known topography and an *a priori* longshore current profile, this equation takes the form of a quadratic equation in  $\omega$ . This may be written in matrix form as  $[A] \{\phi\} = c [B] \{\phi\}$  which produces the eigenvalues,  $c$ , for each wavenumber. Using  $c=\omega/k$  the real and imaginary parts (should  $\omega$  be complex) may be found. It is the cases when  $\omega_{im}$  is positive that growth is predicted for an instability of that particular wavenumber.

For any instability to grow, (i.e. to have a positive  $\omega_{im}$ ) there must be some source of energy, be it either potential (baroclinic instability) or kinetic (barotropic instability). A mechanism must then exist to transfer this energy from its source, here the longshore current, to the growing perturbation. Dodd and Thornton (1990) derive a set of energy equations to further study this transfer, yielding:

$$9) \quad \frac{\partial}{\partial t} (KE) = - \int_0^\infty \overline{u'v'} V_x dx - g \int_0^\infty \frac{h_x}{h} \overline{u'\eta} dx$$

where KE denotes the kinetic energy of the perturbations and the averaging has been done over the  $y$  direction. The first term on the right hand side represents the role of the Reynolds stresses ( $\overline{u'v'}$ ) in transferring energy and the second term the work done by the surface pressure gradients. This second term can be expected to be small as a result of the ratio of the depth,  $h$ , to the bottom slope in the  $x$  direction. Thus simplified, the required condition for a growing instability is that there must be a negative correlation between  $\overline{u'v'}$  and the shear of the longshore current.

## EXPERIMENT

The 1990 DELILAH experiment, the data from which is the basis of this paper, was conducted at the U.S. Army Corps of Engineers Field Research Facility at Duck, North Carolina, (same site as SUPERDUCK), and was designed specifically to measure shear instabilities. Two alongshore arrays, the first of 5 current meters and located in approximately 1.5 meters of water, monitored conditions in the trough, while the second longshore array, located in approximately 3 meters of water, was positioned on the seaward face of the bar. It is these two arrays which were used in obtaining the normalized, spatially lagged, cross-spectral matrix used with the Iterative Maximum Likelihood Estimator (Pawka 1982) to produce the  $f$ -K spectra. An autonomous Coastal Research Amphibious Buggy (CRAB), which was designed to provide a stable platform for operations within the surf zone, was used for daily bathymetric measurements. A cross-shore array of 9 current meters and wave sensors extending across the surf zone was deployed to define the longshore current. These three principle arrays, shown in figure 2, were

Fig. 2 Meter/gage placement

used to acquire data near-continuously throughout the experiment with a sampling rate of 8 Hz. A wide variety of wave conditions occurred during the one month experiment, including a northeaster which drove broad banded waves and a hurricane which generated narrow banded swell, each resulting in strong longshore currents and concomitant shear instabilities.

#### MODEL/DATA COMPARISON

Required as input to the shear instability model is the longshore current profile. In the present work this is obtained through application of a cubic spline to the nine observations. The resulting profile and the measured bathymetry are shown in figure 3 together with the calculated background vorticity (term 4 in eq. (4)). This background vorticity exhibits a relative minima approximately 75 meters offshore. This relative minima corresponds to an elimination of the restoring force and so is the location of the predicted instabilities, an example of which (cyclic wavenumber = .0065) is shown in figure 4. The longshore current profile is overlaid on figure 4 and demonstrates the transfer of energy described by equation (9), (i.e. that the axis of the instabilities are generally opposite to the local current shear).

Predicted growth rate,  $\omega_i$ , and frequency,  $\omega_r$ , (which is linear and therefore non-dispersive) versus cyclic wavenumber are shown in figure 5. Overlaying this predicted dispersion relation on the observed f-K spectra shown in figure 6. demonstrates excellent agreement.

To calibrate the amplitude of the model produced stream functions, the energy density spectra ( $u'^2 + v'^2$ ) were calculated for each of the nine cross-shore current meters. Two hour time series were used with sampling at 8 Hz. The total record length was broken up into 8 sub-records based on the required time interval necessary to produce frequency resolution comparable to that used in the model. An unfortunate result is that the degrees of freedom available remain fairly small and the confidence intervals are therefore excessively large. As an alternative test

**Fig. 3** Splined longshore current velocity profile, measured depth, and calculated background vorticity.

**Fig. 4** Model predicted stream functions and superimposed longshore current profile showing opposing tilt of system as required for energy transfer.

Fig 5. Model predicted frequency ( $\omega_r$ ) and growth rate ( $\omega_m$ ) versus cyclic wavenumber.

of the statistical strength of the data, the consistency over the nine current meters is offered, shown in figure 7. The observed  $u'^2 + v'^2$  as a function of frequency is thus obtained for each of the nine current meters of the cross shore array.

To calculate  $u'^2 + v'^2$  for the model, an analytical solution was obtained by substituting an amplitude variable, A, into eq.(6). The modeled  $u'^2 + v'^2$ , averaged over one wavelength in the alongshore direction can be written then as:

$$10) \quad \overline{u'^2} = \frac{A^2 k^2}{2h^2} (\phi_r^2 + \phi_i^2) \quad \overline{v'^2} = \frac{A^2}{2h^2} \left[ \left( \frac{\partial \phi_r(x)}{\partial x} \right)^2 + \left( \frac{\partial \phi_i(x)}{\partial x} \right)^2 \right]$$

These are combined, providing the modeled  $u'^2 + v'^2$  as a function of cross-shore distance for each of the wavenumbers for which growth was predicted (in this particular case 22). Since the predictions are in wavenumber space, while the observations are in frequency space, the model predicted dispersion relation is used to translate the output into frequency space for comparison.

The observed and predicted  $u'^2 + v'^2$  spectra may each be thought of as an energy surface in two dimensional x-f space. In the case of the observations there are 9 lines of E(f) spread across x, and in the case of the model output, there are 22 lines of E(x) spread across k. The surface given by the model output may be adjusted based upon the values of A(f) and so the two surfaces are matched in a best fit manner. These values of A(f) are then applied to the calculation of  $u'v'$  based on the analytical form (again averaged over the alongshore wavelength) given by:

$$11) \quad \overline{u'v'} = -\frac{A^2 k}{2h^2} \left( \phi_r \frac{\partial \phi_i}{\partial x} - \phi_i \frac{\partial \phi_r}{\partial x} \right)$$

This produces a  $\overline{u'v'}(x)$  profile for each of the modeled wavenumbers. Finally, these are integrated to provide a single  $\overline{u'v'}(x)$  profile representing the net effect of the predicted range of shear instabilities (shown together with  $u'^2$  and  $v'^2$  in figure 8).

### Summary

The magnitude and cross-shore structure of the turbulent radiation stress associated with shear instabilities of the longshore current has been examined. Through calibration of the model-generated stream function amplitudes, an absolute reference has been incorporated such that dimensional values of  $\overline{u'v'}(x)$  have been obtained. The cross-shore gradients of the radiation stresses due to both waves (calculated through a Thornton and Guza (1983) model) and shear instability turbulence are compared in fig. 9. The model suggests that the turbulence term may well exceed the wave forcing term for this data. Further study will examine additional data from DELILAH and attempt to link the longshore current model predicted "two-jet base state" to the single maximum observed profile, through a series of progressive steps.

### Acknowledgements

The authors wish to express their appreciation to all those who participated in the DELILAH experiment and in particular the staff of the Coastal Engineering Research Center's Field Research Facility, under the direction of Mr. William Birkemeier. Nick Dodd of the Institute for Marine and Atmospheric Research, Utrecht University, is thanked for his initial development of the shear instability model code while formerly associated with the Naval Postgraduate School. In addition, special appreciation is expressed to Rob Wyland, Naval Postgraduate School, and Katie Scott, Univ. of Calif. Santa Cruz, for their roles in acquisition of wave and current data, and to Mary Bristow, Naval Postgraduate School, for

initial processing of the data. EBT was funded by Office of Naval Research Coastal Sciences Grant N00014-92-AF-0002 and JCC is an ONR fellow.

## CHAPTER 231

### BOTTOM STRESS MODIFICATION BY BREAKING WAVES WITHIN A LONGSHORE CURRENT MODEL

J.C. Church and E.B. Thornton †

#### Introduction

Early radiation stress models of longshore current generation (Bowen 1969, Longuet-Higgins 1970a, 1970b, Thornton 1970) employing monochromatic wave models produced reasonable cross-shore current distributions over planar beaches, but relied heavily on horizontal mixing for smoothing of the velocity profile. Such mixing is required because the radiation stress associated with the alongshore component of the wave-induced momentum flux,  $S_{yx}$ , is, in theory, conserved outside the surf zone, but at the singular location of breaking predicted for monochromatic waves experiences instantaneous decay, and so an infinite gradient in radiation stress.

Waves observed in nature are seldom monochromatic and so more recent models of wave height transformation employ random wave height descriptions. This randomness is normally invoked through use of a representative statistic, such as  $H_{rms}$ , via either a probabilistic (eg. Thornton and Guza (1983)) or a deterministic/Monte Carlo (eg. Dally *et al.* (1985)) approach. Thornton and Guza (1986) found that for the near-planar beach at Santa Barbara, the distribution of breaker locations produced through such randomness, and the resulting smoothing of the rms-wave height decay, yielded a satisfactory velocity profile without the inclusion of a horizontal mixing term.

The random wave height model is not, however, able to explain longshore currents on barred beaches. The same radiation stress approach which performs well on a planar beach now predicts two maxima in forcing (over the bar and at the shore) and, if mixing is omitted, two maxima in longshore current velocity. This is in direct conflict with observations from the DELILAH experiment, (an acronym for *Duck Experiment on Low-frequency and Incident-band Longshore and Across-shore Hydrodynamics*), which generally show a single maximum in longshore current over the trough, where the radiation stress gradient is near zero.

Most longshore current models assume a spatially constant bottom friction coefficient ( $c_f$ ), which is solved for empirically. Considerable range in the values is found in the literature. Given the extreme variation of fluid flow characteristics across the surf-zone, this assumption of constancy seems perhaps unrealistic. In general, while theories exist relating  $c_f$  to physical parameters such as bottom

---

† Department of Oceanography, Naval Postgraduate School, Monterey, Ca. 93943

roughness and wave steepness (e.g. Jonsson 1967), data suitable to test these theories are extremely sparse.

The present study utilizes non-linear bottom stress in which  $c_f$  is likewise used to relate the free stream velocity to the bottom stress (i.e. the law of the wall), but incorporates the effects of breaking-wave produced turbulence, in that  $c_f = c_{fl} + c_{fr}$ , where  $l$  and  $r$  denote local (bottom boundary layer) and remote (breaking-wave) turbulence effects. In regions of breaking waves, the remotely generated turbulence is hypothesized to be a significant source of vertical mixing of the mean longshore flow and is thus essential to relating the free stream velocity to the bottom stress. Whereas the locally generated (boundary layer) turbulence is limited in magnitude by the restriction of equilibrium between the mixing it induces and the shear which produces it, the mixing potential of the remotely generated turbulence is essentially limitless. The result of this breaking-wave induced mixing is that for a given bottom stress, free stream velocity is decreased (Fig. 1). This modification of the longshore current's vertical profile by the breaking-wave induced turbulence is the essence of the present study. The cross-shore distribution of turbulent kinetic energy (modeled by a simple vertically integrated balance between breaking-wave production and dissipation), combined with a penetration parameter, is proposed to describe the intensity of near bottom breaking-wave induced turbulence, and thereby the modification of the relationship between bottom stress and free stream velocity. Model comparison with data from a barred beach (the DELILAH experiment at Duck, North Carolina) and data from a planar beach (NSTS data from Leadbetter Beach, Santa Barbara, California) yields improved agreement.

Fig. 1 Schematic of breaking-wave induced turbulence effects on vertical profile of longshore current.

## Longshore Current Formulation

### Assumptions

Linear wave theory is utilized, with x-axis perpendicular to the assumed straight and parallel, but arbitrary, bathymetry. Mean currents are assumed steady state, and are vertically integrated. All quantities are assumed uniform in the alongshore direction. Current shear is assumed sufficiently small that refractive interaction may be neglected. Narrowbandedness is assumed for both direction and frequency of the incident wave field.

### Equations

The time averaged, depth integrated momentum equation in the alongshore direction produces a simple balance between the gradient of the radiation stress and the bottom stress, e.g. Phillips (1966):

$$1) \quad \frac{\partial \overline{S}_{yx}}{\partial x} = \frac{\partial \overline{S}_{yx}}{\partial x} + \frac{\partial S'_{yx}}{\partial x} = \overline{R}_y$$

The radiation stress has been separated into two terms, one associated with the wave motion ( $\overline{S}$ ) and the other due to turbulence ( $S'$ ). It is assumed the wave motion and turbulence are statistically independent of each other. The turbulent radiation stress, typically parameterized as a horizontal mixing term, is neglected. Although mixing is likely to be occurring on numerous scales, driven by numerous mechanisms, the purpose of this study is simply to examine the proposed modification of the bottom stress term. All subsequent references to "radiation stress" will pertain to wave associated radiation stress and the tilde will be omitted.

### *Radiation Stress Forcing*

After applying Snells law for wave refraction based on the assumption of straight and parallel contours, the gradient of the alongshore momentum flux given by linear wave theory may be written as:

$$2) \quad \frac{\partial \overline{S}_{yx}}{\partial x} = \frac{\sin \alpha_0}{c_0} \frac{\partial}{\partial x} (E C_g \cos \alpha)$$

in which energy is given by  $E = \frac{1}{2} \rho g H_{rms}^2$ , with  $H_{rms}$  denoting rms-wave height.  $C_g$  is group velocity and  $\alpha$  is incident wave angle. The subscript o indicates values at some initial point well seaward of breaking. The wave height transformation model of Thornton and Guza (1983) is applied. Two parameters are included in the model;  $\gamma$ , which describes the saturation conditions given by  $\gamma = H_{rms}/h$ , at which all waves are consider to be breaking, and B, a measure of the intensity of breaking as indicated by the portion of the foam region on the breaker face.

### *Bottom Stress*

Neglecting molecular viscosity and surface wind stress, equation (1) becomes a simple balance between the radiation stress gradient and the bottom friction stress.

$$3) \quad \frac{\partial \overline{S}_{yx}}{\partial x} = \tau_y^b$$

The general form of the component of the bottom stress in the alongshore direction is given by:

$$4) \quad \overline{\tau_y^b} = c_f \rho \overline{|\vec{U}|(V+\bar{v})}$$

where the overbar denotes time averaging and  $V$  is the mean longshore current velocity. The magnitude of  $\vec{U}$ , which represents the vector sum of the steady and wave-induced flow is obtained from

$$5) \quad |\vec{U}| = (\bar{u}^2 + 2\bar{u}V\sin\alpha + V^2)^{\frac{1}{2}}$$

where the depth integrated cross-shore mean velocity,  $\bar{U}$ , is assumed equal to zero through conservation of mass. The result is then:

$$6) \quad \overline{\tau_y^b} = \frac{1}{T} \int_T \rho c_f (\bar{u}^2 + 2\bar{u}V\sin\alpha + V^2)^{\frac{1}{2}} (V + \bar{u}\sin\alpha) dt$$

In considering the non-linear form of the bottom stress for the case of random wave heights, specific treatment is required to maintain the ensemble-averaged nature of the radiation stress approach. Specifically,  $\bar{u}$  cannot be solved for based directly on  $H_{rms}$ , but instead the bottom stress for each wave height will be calculated and then ensemble averaged as given by:

$$7) \quad \overline{(\tau_y^b)} = \int_0^\infty \tau_y^b(H) p(H) dH$$

An iterative method described in Thornton and Guza (1986) is used to calculate the longshore current velocity.

Bottom Stress and Free Stream Velocity:

The exact vertical profile of the longshore current within the boundary layer is not required, but it is inherently assumed, in accordance with Prandtl's mixing length hypothesis, that a state of equilibrium exists between the vertical mixing effect of the mechanically generated turbulence and the shear generated through the no-slip condition. In this manner, the friction coefficient,  $c_f$ , not only relates the free stream velocity,  $V$ , to the bottom stress,  $\tau_y^b$ , but also to the characteristic turbulence/friction velocity,  $u_*$ , through:

$$8) \quad \overline{\tau_y^b} = \rho u_*^2 = c_f \rho \overline{|\vec{U}|(V+\bar{v})}$$

In most instances, for homogeneous fluids, the only source of turbulence (as represented by  $u_*$ ) is local mechanical generation linked to the near-bottom current shear. Within the surf-zone, where breaking-wave generated turbulence is present, there are clearly two distinct sources. The intensity of the remotely generated turbulence is not limited by the equilibrium condition and so must be solved for separately. In regions where sufficient remotely produced turbulence is present, its vertical mixing effect may significantly alter the vertical profile of the longshore current. This modification to the relationship between bottom stress and free stream

velocity is included in the proposed model through recognition of distinct components,  $c_n$  and  $c_{fr}$ , producing:

$$9) \quad \overline{\tau_y^b} = (c_n + c_{fr})\rho \overline{|\vec{U}|(V+\vec{v})}$$

Conceptually, for the same free stream longshore velocity, enhanced vertical mixing would increase the velocity near the bed and increase the bottom stress, or conversely, the same bottom stress would be associated with a reduced free stream velocity (see again Fig. 1).

In regions of high breaking-wave induced turbulence penetration,  $c_{fr}$  is expected to dominate, while away from breaking-wave induced turbulence, bottom stress is again governed by the local generation through  $c_n$ . In the present work  $c_n$  will be arbitrarily set to 0.0005.  $c_{fr}$  will be formulated based upon a suggested model of horizontal and vertical distributions of turbulent kinetic energy (tke), a turbulence penetration parameter,  $\chi$ , and a fitting coefficient,  $\Lambda$ .

#### Horizontal Distribution of Turbulent Kinetic Energy:

A one-dimensional turbulent kinetic energy equation (tke- $\epsilon$ ) (see for example Launder and Spalding (1972)) is used to solve for the temporally and vertically averaged breaking-wave induced tke, based on local balance of dissipation and production. Horizontal (cross-shore) advection of the turbulence has been neglected, as in Deigaard *et al.* (1986), based on the small cross-shore net particle velocities considered over the column. Vertical distribution is assumed to be through turbulent vortices injected from the surface, as concluded by Svendsen (1987) in his analysis of experimental data.

The resulting equation is then:

$$10) \quad \frac{\partial(Ec_{gx})}{\partial x} = \rho \int_{-h}^0 c_d \left( \frac{tke}{l_v} \right)^{\frac{3}{2}} dz$$

where the left hand side represents production of tke, and the right hand side, dissipation. Here  $c_d$  is a coefficient taken as 0.08 following Launder and Spalding (1972), and  $l_v$  is the length scale of the vortices estimated as  $0.07h$ , with  $h$  representing depth, following Deigaard *et al.* (1986). Assuming vertically uniform tke and the combining of  $c_d/l_v \approx 1.0/h$ , as done by Roelvink and Stive (1989), integration of (13) yields:

$$11) \quad tke = \left[ \frac{1}{\rho} \frac{\partial Ec_{gx}}{\partial x} \right]^{2/3}$$

#### Vertical Distribution of Turbulent Kinetic Energy:

The vertical distribution of breaking-wave induced turbulence is quite likely non-uniform, but at present is unresolved. Deigaard *et al.* (1991) presents a theoretical model with significant vertical variation, while Svendsen (1987), summarizing a number of field and laboratory studies, found the turbulence to be surprisingly uniform. Different assumptions regarding advection and diffusion are made and the subject appears far from resolved.

The present work reflects this uncertainty in the magnitude of near-bottom breaking-wave induced turbulence through the use of a fitting coefficient,  $\Lambda$ , and a penetration parameter,  $\chi$ , which scales the vertically averaged, wave induced turbulent kinetic energy contribution. This rather crude approach seeks the computational advantage of the assumption of vertically uniform tke, while recognizing that physically there must be some decay in tke close to the bed, ultimately going to zero. Intuitively, one might expect the turbulent penetration to be related to breaker type, with increasing penetration going from spilling, to plunging, to collapsing breakers. A new parameter,

$$12) \quad \chi = \frac{\tan\beta(x)}{gH_{rms0}}$$

is employed. When the product is taken of  $\chi$  and the vertically averaged tke the result is non-dimensional and is proposed to be parameterization of the near bottom mixing effect of the breaking-wave induced turbulence.

The wave height transformation model (Thornton and Guza 1983), which stresses an ensemble view of wave breaking, assumes the wave heights are described by the Rayleigh distribution. Waves may break at any location throughout the surf zone with the likelihood at any given point being some weighted portion of the Rayleigh distribution. Thus, some small portion of the waves might break on the shore side of the bar, a region in which the bottom slope,  $\tan\beta$ , is negative, producing a negative value of  $\chi$ ; use of this parameter in predicting the turbulence penetration would yield non-physical negative values over the shoreward side of the bar. To eliminate this problem with the least disturbance to the relative nature of the parameter  $\chi$ ,  $(\tan\beta+.03)$  was universally inserted in place of  $\tan\beta$ . In all of the cases studied, this was sufficient to ensure positive values throughout the surf zone, (i.e. the shoreward sloping faces do not exceed -0.03). In the planar beach case presented, this is of course unnecessary, but for comparison of the fitting parameter, results with and without this adjustment have been included.

An important point regarding the calculation of either  $\chi$  over barred topography is that near the beach face, where the newly reformed wave rises up to break again, no history of the original wave height is maintained and so the utility of the original  $H_{rms0}$  in such a parameter as  $\chi$  is limited. Instead, it is suggested that a new value of  $H_{rms0}^1$ , i.e. that found over the trough, is used when considering breaking at the beach face. This implies (assumes) that surf characteristics are locally determined and cannot be represented by characteristics measured seaward of some previous breaking region. Values of  $\chi(x)$  at the beach face are significantly increased through inclusion of the trough defined  $H_{rms0}^1$  (175%). Recognition of the relevance of the trough region's  $H_{rms0}^1$  to beach-face breaking is not only significant in the present penetration parameterization, but likewise in any application of a surf parameter on a barred beach. The proposed modification of bottom stress due to the near bottom mixing effect of the breaking-wave produced turbulence is completed by defining:

$$13) \quad c_{fr} = \Lambda \chi(x) tke(x)$$

### Solution Method

A Thornton and Guza (1983) wave height transformation model using bore dissipation theory is used to predict the gradient of cross-shore wave energy flux, used in eq(2) to calculate the radiation stress gradient (which serves as the forcing term in equation eq(3)). Additionally, the penetration parameter (used in eq(13)) is similarly given by the model. The cross-shore distribution of  $tke$  is solved for through eq(11) and is then used in eq(13) to estimate the vertical mixing effect of the breaking-wave induced turbulence. The modification of the bottom stress due to the breaking-wave induced turbulence is then modeled through eq(9). Balancing the radiation stress gradient with the bottom stress in eq(3) allows solution for the longshore current velocity.

### DELILAH Experiment Description

The DELILAH experiment was conducted between October 1 and 21, 1990 at the US Army Corps of Engineers' Field Research Facility (FRF) at Duck, North Carolina, a barred beach which was the site of the previous experiments DUCK 85 and SUPERDUCK. Site selection was based upon the presence of the FRF and its infrastructure, including the permanent directional wave array which the FRF maintains in 8 meters of water, and the relative isolation of the beach. The cross-shore array consisted of 9 current meter/pressure gage stations deployed from the beach face to just beyond the 4 meter contour (Fig. 2). An autonomous Coastal Research Amphibious Buggy (CRAB), was used for daily bathymetric measurements.

Fig. 2 Meter/gage locations.

Wave conditions on Oct. 10, chosen for model comparisons in the present consisted of an rms wave height of .77m arriving at 16.7 deg. and peak wave frequency of .094. Reasonable narrowbandedness in both frequency and direction can be seen in the two-dimensional energy density spectra (Fig. 3). Measured bathymetry is shown in Fig. 4. Bathymetry for Santa Barbara on 4 Feb is described in Thornton and Guza (1983) and is near planar with a slope of .038.

DELILAH 10 October, 1990

Fig. 3 Frequency/directional energy density spectrum.

Fig. 4 Measured bathymetry for 10 Oct DELILAH.

## Comparison with Data

Model results are presented in Fig. 5 for Feb. 4 Santa Barbara NSTS data and Fig. 6 for Oct. 10 DELILAH. Each wave height plot contains measured rms-wave height and bathymetry together with predicted rms-wave height and the distributions. Agreement between observed and predicted  $H_{rms}$  is for both days generally good. Values for the two coefficients contained in the wave height transformation model, obtained by fitting the model to the data in a least square sense, are  $\gamma=0.41$  for both days, and  $B=1.28$  for Santa Barbara and 1.30 for DELILAH. Each longshore current plot contains bathymetry and 3 longshore current profiles (one for a linear bottom stress term, one for a non-linear term, and one for the proposed term which is also non-linear, but includes the effects of breaking-wave induced turbulence).

### Longshore Current Modeling

Fitting of the Santa Barbara velocity profiles (Fig. 5), for the two spatially constant  $c_r$  cases, linear and non-linear (without breaking-wave induced turbulence), produces  $c_r$  values of 0.008 and 0.006. The proposed model with  $\Lambda=4.0$  and  $c_n=0.0005$  produces a broader profile with increased velocity on the seaward extreme (where  $c_n$  dominates). The overall result is slightly better agreement with observations. It should be remembered that the adjustment of  $\tan\beta$  necessitated by the bar has been included strictly for comparison and is not physically necessary. Without this adjustment a value of  $\Lambda=7.5$  is found (the resulting velocity profile has been omitted as it is essentially identical to that shown).

In the case of the barred beach (Fig. 6), longshore current profiles for the linear and non-linear (without breaking-wave induced turbulence) cases show maxima at the seaward face of the bar and at the beach face. These are offered for comparison, without fitting, using the values of 0.008 and 0.006 (those found for the Santa Barbara data). Again, none of the velocity profiles include horizontal mixing. For the case of the proposed bottom stress form, fitting of the predicted profiles in the high turbulence regions (the vicinity of the bar and beach face), where  $c_{fr}$  dominates, yields  $\Lambda$  values of 3.0.  $c_n$ , which is important away from the breaking-wave induced turbulence, has been set at 0.0005 arbitrarily in order to demonstrate that significantly lower values may in fact be plausible.

$c_{fr}$  and its two spatially variable components,  $\chi$  and  $k_e$ , are shown in Fig. 7. Sensitivity tests on  $\Lambda$  and  $c_n$  are shown for in Fig. 8. The three profiles of  $V$  shown represent three values of  $\Lambda$  (2.5, 3.0, and 3.5) with  $c_n$  held constant at .0005. It can be seen that the profiles are not overly sensitive to  $\Lambda$  with approximately a 40% change in  $\Lambda$  producing only a 15% change in  $V_{max}$ . The converse situation is also shown where  $\Lambda$  is held constant (3.0) and  $c_n$  is varied. As expected, the changes are found in the trough and seaward of the bar, regions away from the domination of breaking-wave induced turbulence.

## Discussion and Conclusions

The assumption that the relationship between the free stream longshore current velocity and the bottom stress is constant across the surf zone has been brought into question. Field data from DELILAH have been used to demonstrate that inclusion of breaking-wave induced turbulent effects reduces reliance on horizontal mixing for all regions except the trough of a barred beach. In the cases of the two spatially constant  $c_r$ 's (linear and non-linear without wave induced turbulence), current velocities outside the breaking region are greatly under-predicted. Improved agreement with observations is obtained using the proposed form with  $c_n=0.0005$ . Data

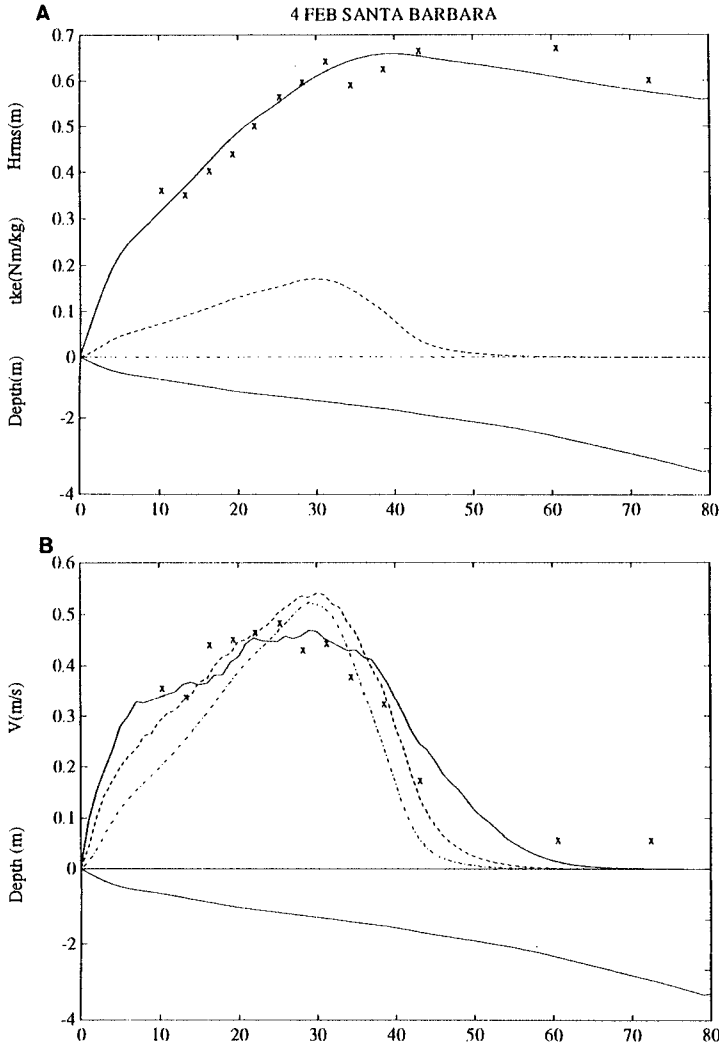

Fig. 5 a) Hrms model prediction (solid), tke (dashed), and measured bathymetry. b) Longshore current model predictions with linear bottom stress (dot-dash,  $C_f=0.008$ ), non-linear (dashed,  $C_f=0.006$ ), and non-linear with wave induced turb. effects (solid,  $\Lambda=4.0$ ,  $C_{fl}=0.0005$ ).

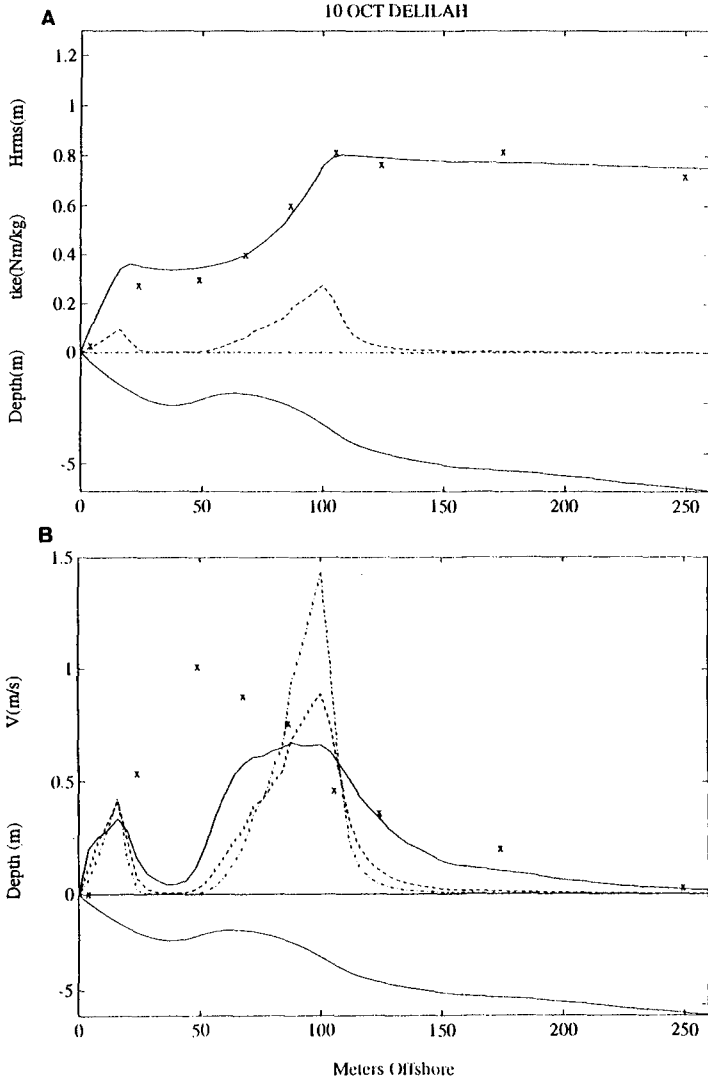

Fig. 6 a) Hrms model prediction (solid), tke (dashed), and measured bathymetry. b) Longshore current model predictions with linear bottom stress (dot-dash,  $C_f=0.008$ ), non-linear (dashed,  $C_f=0.006$ ), and non-linear with wave induced turb. effects (solid,  $\Lambda=3.0$ ,  $C_{fl}=0.0005$ ).

from NSTS Santa Barbara have shown that the proposed model is similarly applicable to planar beaches. Although the calculated value of  $c_n=.0005$ , used throughout this study, is significantly lower than  $c_f$  values used in previous studies, it should be noted that cross-shore mean of  $c_f=c_{fr}+c_n$ , calculated from the shore out to 200m, is .0023 which is more comparable to the spatially constant values found in the literature.

As was noted earlier, horizontal momentum mixing, which has been omitted from the proposed model, does occur to some extent in nature and the contributing roles of mean cross-shore flow and shear instabilities are being explored. Certainly, such mixing would be likely to transfer some longshore momentum into the trough region. It is worthy of note that generation of a velocity maximum between two predicted maxima, via horizontal mixing length theory, requires up-gradient momentum transfer, and therefore does not appear appropriate.

Fig. 7 Bottom friction coefficient associated with breaking-wave turbulence modification ( $C_{fr}$ ) with its principle components  $tke$  and the penetration parameter  $\chi$ .

*Summary:* A spatially variable bottom stress is proposed through the inclusion of the effects of breaking-wave induced turbulence. Employing reasonable assumptions regarding the horizontal and vertical distributions of this turbulence, it is shown that inclusion of breaking-wave induced turbulence effects improves agreement between predicted and observed longshore current velocities for both a planar and barred beach. It is suggested that disparities between predicted and observed velocities over the trough are most likely due to a failure to identify a significant alteration of the forcing mechanism in this particular region.

## CHAPTER 232

### HYDRODYNAMICS AND SEDIMENT CONCENTRATIONS AT WALKER BAY

R C COPPOOLSE, J S SCHOONEES, G G SMITH AND G P MOCKE

#### Abstract

A novel and cost-effective technique for measuring sediment concentrations in high energy surf zones, using a helicopter, was developed and applied at Walker Bay, South Africa. Using this technique, which involved an innovatively operated suspended sediment sampler (TASSS), 280 sediment samples and hours of continuous sediment concentration measurements (with a transmissometer) were acquired at several levels. Currents and waves were also measured at several positions along a cross-shore section. The helicopter was also used to successfully survey the nearshore area using a new method. Spectral analysis of wave and concentration data show responses of the sediment concentration to incident and infragravity waves beyond the surf zone, while suspension is seen to be more intermittent in the surf zone. The concentration profiles beyond the surf zone exhibited typical exponential distributions. Reasonable correlation between the TASSS and the transmissometer was found.

#### Introduction

Knowledge about sediment transport in the nearshore zone is of vital importance for the design of harbours and for the understanding of the processes causing beach erosion and the factors controlling the stability of estuaries. It is against this background that the CSIR undertakes field exercises as part of a research programme. The aims of these exercises (Schoonees, 1990) are to develop low-cost measuring techniques that are capable of measuring in high energy surf zones and to obtain accurate data under South African conditions against which to check the accuracy of predictive techniques.

During a previous exercise in November 1987 (Schoonees, 1990), field measurement techniques were developed to determine suspended sediment concentrations in the inner surf zone. From 12 to 15 and from 19 to 23 February 1990 a fourth field exercise (CAESAR 4) was held at Walker Bay on the Cape South Coast of South Africa (Figure 1) to measure sediment concentrations in the outer surf zone. One of the specific aims of this exercise was to test newly-developed equipment and its deployment procedures, thereby

---

Research Engineers, CSIR, P O Box 320, Stellenbosch, 7599, South Africa

ensuring the capability of measuring sediment concentrations in the outer part of high energy surf zones.

Previous researchers tackled the problem of measuring in the outer surf zone by either deploying instruments from a permanent or temporary pier (e.g. Watts, 1953, Fairchild, 1977, Derks and Stive, 1984 and Antsyferov and Kos'yan, 1990), by using a helicopter (Kilner, 1976) or using a sampler attached to a rope between the shoreline and an offshore anchor (Kilner, 1976). At sites with large tidal variations like in the United Kingdom, it is also possible to deploy instruments in the dry during low tide and then to sample during high tide (Soulsby *et al.* 1990). In South Africa, however, the tidal variations are too small to do this.

It was decided to make use of a helicopter because a pier was not available and would be expensive to construct. In addition, a helicopter is very versatile for other applications during the exercise, (e.g. aerial photographs and survey work) and is useful at remote sites. The helicopter was also used to develop a new technique to measure nearshore profiles.

This paper describes the field exercise, with emphasis on the sediment concentration measurement. Environmental conditions, instrumentation, measuring techniques and finally some results are presented.

### Site Description

Walker Bay, situated about 120 km south-east of Cape Town (Figure 1), is a large sandy bay of about 20 km length, which is completely exposed to the dominant incident southerly to south-westerly deep-sea waves (Schoonees, 1990). The 1 in 1 year and 1 in 100 years deep-sea significant wave heights are 7,6 m and 11,1 m respectively (Rossouw, 1989). Peak wave periods ranged between 5 s and 22 s with a median value of about 12 s. Surf zone widths of up to 500 m are not uncommon.

During the February 1990 exercise, the median grain size of the bed material was 0,30 mm. The slope of the beach face was about 1/16 while the nearshore slope was about 1/90.

Strong longshore currents (often 0,5 m/s) occur regularly. The mean spring tidal range is 1,44 m. The main wind directions are south to east in summer (December to February) and west to north-west in winter (De Decker, 1989).

The layout of the test site is shown in Figure 2. A temporary camp was established just behind the frontal dune where measuring equipment was stored, the helicopter refuelled, water/sediment samples were removed and data from the instrumentation transferred.

### Instrumentation

#### General

Instruments were deployed on a line perpendicular to the shore (Figure 2), in order to measure the cross-shore variation of the wave height, longshore current velocity and the suspended sediment concentration in the

outer surf zone. Outside the surf zone in 20 m of water an Endeco directional wave buoy and a pressure transducer was anchored. A pressure transducer and an array of electro-magnetic current meters (Colbrook meters with discus heads) attached to an H-frame, were jetted into the sandy sea bed by divers at 5 m and 10 m depths .

In the inner surf zone a single current meter was manually installed on a fixed frame. In addition, a helicopter was used to place two frames at different places in the surf zone. One frame contained a pressure transducer and current meter while the second frame contained a "remote controlled" Time Averaged Suspended Sediment Sampler (TASSS), a sub-frame with an array of transmissometers (called Brutus) and a pressure transducer.

Although different sensors have been used to measure instantaneous concentrations (see e.g. Huntley, 1982, Brenninkmeyer, 1974 and Beach and Sternberg, 1988), a transmissometer was chosen for this purposes due to its availability. The Kilner suction sampler (Kilner, 1976) was not used to obtain time-averaged concentrations because it is bulky and as such will disturb the flow and limit the number of samples that could be taken per day.

Because of its reliability and simplicity, it was decided to modify the suction sampler of Nielsen (1984) for deployment with a helicopter.

#### Time-Averaged Suspended Sediment Sampler (TASSS)

The purpose of this sampler was to extract undisturbed water/sand samples at different elevations at a predetermined position so that time-averaged sediment concentrations can be obtained. The actual starting time of sampling was important to correlate the result with the transmissometer at a later stage. The principle of pressure difference between the suction inlet and the air outlet of the sample jars was used to suck in the samples (Nielsen, 1984). The intake velocities (about 1,5 m/s) were checked to give a well-defined relation between measured and real concentrations under field conditions (Bosman, 1982). The sampler was placed landwards of the transmissometer position at the side of the deployment frame in order to minimise the disturbance to the other instrumentation (Figures 3 and 4). In addition, a thin cantilever arm was used from which samples were sucked about a metre away from the main frame (Figure 4). Careful placing of the frame by the helicopter was therefore critical in order to avoid damage to the fragile cantilever arm.

A reliable triggering mechanism was required to initiate sampling as soon as the frame was properly placed on the sea bed and the disturbance to the sediment during placing had subsided. A system of pressurising the sample jars by means of compressed air which is released from a seven litre scuba tank on impact with the water surface was used. Figure 5 shows the pressurising principle in more detail. One common air outlet was used. The triggering mechanism consisted of a float which was attached to a valve on the scuba tank. A lock mechanism was attached to prevent opening and closing of the valve due to wave action after initial triggering. The delay in operation was in the order

of 2 to 3,5 minutes depending on initial pressure in the scuba tank. Considering the relevant settling velocities, this was deemed to be adequate for disturbed bottom sediment to re-settle. The delay in relation to the pressure in the scuba tank was calibrated in the laboratory in 1,3 to 1,5 m tanks and also in a 4,5 m deep pool.

The system was designed so that air bubbles do not disturb the flow regime near the intakes during pressurisation and so that the intake lines are cleared prior to sampling. Special care was also taken in the design to prevent overfilling and subsequent mixing of samples as well as to prevent loss of the samples when retrieving the frame by helicopter.

### Transmissometer

The transmissometer is used to measure sediment concentration continuously, based on the principle of the attenuation of a light beam by suspended sediment. The seven beam transmitter/sensor pairs and the data logger are shown in Figures 3 and 4. These were manufactured at the CSIR. The transmitter housing consists of a PVC tube containing a lens and a light source with its driving circuit. The light shines through a glass window at one end. The receiver housing is similar but slightly longer than that of the transmitter, in order to prevent direct ambient light from reaching a phototransistor and causing erroneous readings. The instrument was operated at a frequency response of 2 Hz.

Since the instrument is sensitive to grain size, it is necessary to calibrate it with the sediment from the site of measurement. The calibration was carried out in a tank in which sand is suspended by the rapid oscillation of a grid. With the use of a pump, the sediment concentrations corresponding to transmissometer readings are obtained, yielding an exponential calibration curve.

The transmissometer is very sensitive to water turbidity due to fine particles. This "background" turbidity had to be removed from the measurements. In addition, the instrument is strongly sensitive to bubbles. Nevertheless, accuracy was sufficient to obtain some useful results.

### Field Procedure

In the inner surf zone a combined pressure transducer and electromagnetic current meter was installed on the sea bed at low tide. Two frames were designed for helicopter deployment. The frames were manufactured from galvanised steel tubing and had overall dimensions of 5 m x 2 m. One frame contained an electromagnetic current meter while the other frame contained the TASSS, transmissometer and a pressure transducer (Figures 3 and 4). Problems that had to be overcome using deployment by helicopter (a small Jet Ranger with a maximum lifting capacity of 450 kg) were:

#### *Placing the frame in a predetermined position*

A series of prisms was connected to the skid of the helicopter and by means of a theodolite and electronic distance meter (EDM) and radio contact

between surveyor and pilot, the pilot could be guided to the correct position. The frame was attached to the quick release hook of the helicopter by means of a rope and swivel connectors. The frame was therefore rotating continuously. The rope was connected to an off-centre arm on the frames (Figures 3 and 4) causing the frame to hang slightly forward (Figures 6 and 7). Before the frame was lowered it was allowed to rotate to the correct position. Thereafter it was dropped on its "back legs" and pushed forward by the waves and the helicopter (Figure 7). Although at this stage the frame was more or less in its correct position, it could still be adjusted by the helicopter. The hoist rope was left in the water with a buoy. This was retrieved with a grip (hook) attached to a thin line by which the rope attached to the frame was pulled up and then reconnected to the helicopter.

### *Stability and strength*

In order to withstand wave impact the frame was given the dimension (in plan) of 5 m x 2 m (5 m perpendicular to the wave crests). The length of five metres was chosen because when lowering the frame in five metres of water (about the maximum placing depth) it was still visible when its "back legs" touched the sea bed. At that stage it could be observed whether the frame was in the correct position and if it would possibly overturn. The 2 m width was chosen as a practical width for stability and for overland transport purposes. The layout of the frame is shown in Figures 3 and 4. To prevent the frame from sinking too deeply into the sand, galvanised steel tubing was used, because this has a relatively large surface area. This also provided the necessary structural strength and caused the least local turbulence. Flat bars were welded on underneath the tubing (Figure 3) to limit the sliding of the frame during deployment. Diving inspections revealed that the frame sank into the sand up to the centre of the bottom tubing.

Weep holes of about 20 mm diameter, were made near the ends of the tubing of the frame. These were covered with permeable cloth preventing sand from entering the tubing but allowing air to escape, thereby improving the stability of the frame. At the same time, these holes allowed the water to run out again when the frame was retrieved so that it was not necessary for the helicopter to have to pick up the added mass of the water.

Five to six deployments were performed over the turn (3 h) of each tide (during which the water level stayed virtually constant). The electromagnetic current meter was first deployed and remained at the same position during the measuring cycle of three hours. The sampler frame was first deployed beyond the surf zone and then subsequently at different positions in the surf zone. Measurements were taken for 20 minutes each time after which the frame was retrieved and sample jars were replaced. The turn around time was about 30 min. Measurements were taken on seven days and 56 helicopter deployments were undertaken in total.

Beach surveys were performed before and after each series of tests. The beach sections were taken by theodolite, EDM and staff with prism. For the nearshore measurements use was made of a 6 m high stand on which three

prisms were attached at the top. This stand was placed in the surf zone by helicopter (Figure 8). Communication between surveyor and pilot was maintained by means of radios. Very accurate surveys were obtained in this way.

## Results

### *Hydrodynamics*

Figure 9 illustrates the prediction of wave height with distance offshore, using the wave transformation model of Battjes and Janssen (1978) and Battjes and Stive (1985) (called the Battjes model hereafter). As can be seen, the model provides a good prediction of the measured values. Furthermore, accurate predictions of wave height and direction, using the refraction model RCPWAVE (Ebersole *et al.*, 1986), were found to compare very well with measurements obtained from the pressure sensors at the 20 m, 10 m and 5 m depths.

### *TASSS*

In total, 280 samples were successfully collected during the 56 deployments. All samples were accurately weighed (to determine the volume) and sediment was separated from the samples. The concentrations were calculated and adapted using the results from calibration tests as presented by Bosman (1982), whereby the measured concentrations were multiplied by a factor of 1,37. The concentrations were subsequently plotted and some typical results are shown in Figure 10.

It can be seen that an exponential distribution exists over the first metre above the sea bed. The samples collected at the highest intake showed relatively high concentrations for that particular day. The reason for this is that the top intakes were sampling only when large waves were passing by, while during lower waves the inlet was exposed to the air. It was often found that the sample jar connected to the top intake was only partly filled.

### *Transmissometer*

Figure 11 illustrates a typical concentration record from the transmissometer in the shoaling region, together with the wave record. Truncation of the concentration record of the lower sensor can be seen; this occurred at high concentrations and in the presence of bubbles. Careful observation shows that the peaks in the sediment concentration record correspond to peaks and troughs in the wave record, indicating a response to wave orbital motion. In addition, an increase in the mean concentration in response to wave groups is evident.

Figure 12a illustrates wave energy spectra and spectra of the sediment concentration in the shoaling region (outside the surf zone) and in the surf zone (measured less than one hour later). In the shoaling region (Figure 12a) a clear peak is evident in the wave energy spectrum at about 0,08 Hz. A second peak can be seen at 0,017 Hz, apparently representing the group-bound infragravity

wave energy. Corresponding to these, clear peaks are evident in the sediment concentration spectrum.

A different situation is, however, evident in the surf zone (Figure 12b). Although an energy peak in the sediment concentration spectrum is evident in response to the incident wave frequency (although somewhat shifted), no clear response occurs at the infragravity wave energy. Rather, an increase in the spectral energy of the concentration with decreasing frequency in the infragravity region towards 0,0 Hz can be seen. Experimentation showed that this type of spectral shape is indicative of intermittent (i.e. non-periodic) sand suspension events.

It is worthwhile to point out that linear spectral analysis of sediment concentrations does have limitations, since the non-linear "spiky" nature of sediment concentration records can cause erroneous energies in the spectrum. This is recognized in the above analysis, which is taken in the context of comparative results between the shoaling region and the surf zone.

Figure 13 illustrates the simultaneously sampled results of the transmissometer and TASSS, averaged over five deployments in the shoaling region under similar wave conditions (depth about 3 m and a significant wave height of about 1 m). The lowest transmissometer result is eliminated from this analysis due to frequent truncation of the record at higher concentrations. As can be seen (excluding the sensor at 1,046 m elevation, which was found to be erratic) the exponential distribution is found from the transmissometer results as is expected beyond the breakers (Nielson, 1984). In the case of the TASSS, an exponential distribution with a similar slope and of the same order of magnitude is found.

Figure 14 illustrates the results of comparisons between concentrations obtained from the TASSS with concentrations measured with the transmissometer. The comparison is limited to cases where the transmissometer record was not truncated due to bubbles or high concentrations. A tendency of the transmissometer to give relatively lower readings at high concentrations is apparent. Over 75 % of the concentrations agree within a factor of four. This type of result is to be expected since the two instruments are approximately 2 m apart, and the timing of their sampling is not perfectly correlated. Huntley (1982) confirms this; he considered that a 50 % agreement between an *in situ* calibration and a laboratory calibration would be a "good match". In a similar comparison, sand flux measured with a streamer trap sampler is compared with measurements from an optical backscatter sensor, OBS (with flow measured with a current meter). Agreement is found within a factor of 3,5 with 68% certainty (Rosati *et al.*, 1991).

#### *Beach and nearshore surveys*

During the exercise seven beach and nearshore surveys were undertaken. The results are shown in Figure 15. It is shown that the largest variation occurred at -0,5 m mean sea level (MSL) to -2 m MSL. A maximum vertical variation of 0,75 m occurred within the seven days. Also clearly shown are the

two offshore bars. These were situated at -3 m MSL and at -1 m MSL. The outer bar was fairly stable while the nearshore bar was highly dynamic.

Reasonable to good correlation was obtained between the helicopter survey and the conventional theodolite and staff method in the regions where the profiles overlapped (Figure 15). It has to be taken into account that the measurements were not done simultaneously nor at exactly the same positions.

### Conclusions

Techniques for measuring in high energy surf zones have been successfully developed. Particularly successful was the use of the helicopter, allowing extreme flexibility and accurate positioning of instrumentation and proving to be cost-effective. In addition, a time-averaged suspended sediment sampler, operating on simple and reliable principles, allowed a large number of samples to be collected in a short time.

Measured wave heights compared favourably with predictions using the Battjes model. Despite some serious limitations, due primarily to truncation of the record and the influence of bubbles, useful recordings were obtained with a transmissometer array, especially with regard to almost instantaneous concentration phenomena. In the shoaling region, sediment suspension due to wave orbital motion and due to wave groups was evident. However, although suspension does occur at the incident wave frequency in the surf zone, it mostly occurs in the form of intermittent events. A further result was the occurrence of exponential distributions of sediment concentrations beyond the breakers. Comparisons of the transmissometer with the TASSS showed that over 75% of the concentrations agree within a factor of four. This type of result is typical of previous, similar studies. Finally a simple yet accurate method was devised to measure the nearshore bathymetry (up to 6 m depth) by means of a helicopter.

### Acknowledgement

The field exercise was a team effort. We would like to thank Messrs J P Möller, F van Dulm, L van der Merwe, A K Theron, C Roux, E Mabile, J de V Serdyn, W Daniels, H J A Davids, Miss J B Crowley and Dr J W Gonsalves for their contribution. A special word of thanks is due to the pilot Mr K Wittle and the flight engineer Mr S Harbottle for excellent flying.

## CHAPTER 233

# Water Wave Propagation in Jettied Channels

Robert A. Dalrymple<sup>1</sup>, F., ASCE

### Abstract

Navigational channels are frequently maintained by the use of jetties. These stabilized channels often form long straight waterways which permit the passage of tidal flows and waves into harbors, lagoons, or rivers. This paper concerns the decay of the waves down the channel due to energy losses within jetties. The analysis involves the use of an impedance boundary conditions at the channel side walls to model the wave dissipation there. The wave motion is described by an eigenfunction expansion for the velocity potential within the channel, with and without tidal currents.

For the case that the water wave length is long with respect to the channel width and no currents are present, the wave height decay down the channel can be described by an exponential decay,  $H = H_0 e^{-\Gamma x}$ , where  $\Gamma = \gamma x / (2kb)$ ,  $\gamma$  is a (real) damping factor,  $k$  is the wave number, and  $2b$  is the width of the channel. For the case of a mean current in the channel, the same expression results, but for a different form of the wave number, (Eq. 24).

### Introduction

Stabilized entrance channels often form long straight waterways which permit the passage of tidal flows and water waves into harbors or lagoons. This paper concerns the interaction of water waves with rubble mound jetties, including the significant energy loss into the jetties, due to turbulent energy dissipation.

The energy decay down a channel may be calculated if the rates of energy loss are known at the bottom and the sides of the channel. The conservation of energy flux down the channel is

$$\frac{d\mathcal{F}}{dx} = -\mathcal{D} \quad (1)$$

---

<sup>1</sup>Professor and Director, Center for Applied Research, Department of Civil Engineering, Univ. Delaware, Newark, DE 19716

where the wave energy flux is  $\mathcal{F} = EC_g(2b) = \frac{1}{4}\rho g H^2 C_g b$ , where  $\rho$  is the fluid density,  $g$  is the acceleration of gravity,  $H$ , the wave height in the channel,  $C_g$  is the group velocity of the waves, and  $b$  is the half-width of the channel.  $\mathcal{D}$  is the energy dissipation per unit length of channel. This expression can be rewritten as

$$\frac{dH}{dx} = -\frac{2\mathcal{D}}{\rho g H C_g b} \quad (2)$$

Hunt (1952) examined the decay of wave height due to laminar boundary layers at the sides and the bottom of a rectangular impermeable channel. In this case,  $\mathcal{D}$  is proportional to  $H^2$ , and therefore Eq. 2 can be written as

$$\frac{dH}{dx} = -\Gamma H \quad (3)$$

which leads to the following expression for wave height down the channel,

$$H(x) = H_o e^{-\Gamma x} \quad (4)$$

where  $\Gamma$  depends on the viscosity of the fluid as well as the other factors.

Battjes (1965) studied the damping of waves in a rectangular wave channel with roughness strips attached to the sidewalls along the length of the channel. The strips were mounted vertically over the depth on the sides of the channel with a fixed spacing. Vortices shed by the wave-induced flow past the strips resulted in a decrease in wave height down the channel. Battjes examined a 'turbulent damping' such that the dissipation as the side walls was assumed to be proportional to  $H^3$ ,

$$\frac{dH}{dx} = -\beta H^2 \quad (5)$$

leading to

$$H = \frac{H_o}{(1 + \beta H_o x)} \quad (6)$$

The experiments were conducted in an approximately 27.5 m long, 3.0 m wide test section of the channel. To get an adequate decay distance, the wave height at the end of the test section after one run, was used as the input to another test. By coupling experiments in this fashion, data on wave height versus distance was generated for an equivalent tank, 6 to 7 times longer. However, since the phenomenon he discusses is nonlinear and cross-tank oscillations occur, it is not likely that this is a valid experimental approach.

Isaacson (1978) applied the same formula as Battjes for the wave height down a prismatic trapezoidal entrance channel laboratory model lined with stone, varying the side slopes. He found that there was a strong dependency of  $\beta$  on wave period, with  $\beta$  increasing with period.

Melo and Guza (1991a,b) in an interesting computational and field study showed that the wave height down the centerline of an entrance channel decreased rapidly, mostly due to the diffraction of the waves into the absorbing jetty structures. They also point out that the diffraction through a breakwater gap of the same width as the entrance channel gives similar damping behavior down the centerline. If the channel is narrow with respect to the wave length of the incident waves, then the diffractive damping is more severe, as discussed by Losada *et al.* (1990). The computational analysis of Melo and Guza consisted of two coupled parabolic models of wave propagation, one in the channel and another within the porous structure, with matching conditions on the jetty face for velocity and pressure.

The intent of this paper is to develop a new methodology for computing the wave field within navigational channels without having to use coupled parabolic wave models (as in Melo and Guza) through the use of the impedance boundary condition.

### Theory

The wave motion will be described within the jetty section, assuming that the wave height is specified across the mouth of the channel. Figure 1 shows the channel and the coordinate system to be used in the analysis. The channel is assumed here to be constant in depth, which simplifies the analysis.

Between the jetties, which are located at  $y = \pm b$ , the wave motion is assumed to be described by linear wave theory which results from the assumption of small amplitude irrotational wave motion within an incompressible fluid. The associated governing equation is the Laplace equation for a velocity potential  $\phi(x, y, z, t)$ ,

$$\nabla^2 \phi = 0 \quad (7)$$

from which the velocities in the fluid can be determined,  $\mathbf{u} = (u, v, w) = -\nabla \phi$ . At the bottom boundary, no flow is permitted,

Figure 1: Schematic of Channel

$$-\frac{\partial\phi}{\partial z} = 0 \quad \text{on } z=0. \tag{8}$$

At the jetties, an impedance boundary condition is assumed,

$$\frac{\partial\phi}{\partial y} = i\gamma\phi = ik\beta\phi \quad \text{on } y = |b| \tag{9}$$

where  $\gamma$  is  $k$  (the wave number) times the *specific admittance*,  $\beta$ , of the jetties. This assumption follows from acoustics, where it is used to determine the damping of acoustic waves due to absorbent duct boundaries (e.g. Morse and Ingard, 1968, §6.3). If  $\gamma$  is real, then wave energy is absorbed by the jetties; for  $\gamma$  purely imaginary, this boundary condition leads to 100% reflection with a phase shift. The value of  $\gamma$  (or equivalently the dimensionless  $\beta$ ) will strongly dictate the nature of the solution and its value will be specified later.

The impedance boundary condition on the jetties can be compared to a transmitting condition for plane waves, usually imposed on an open coast model (e.g., Kirby, 1985), which is taken as

$$\frac{\partial\phi}{\partial y} = ik \sin \theta\phi \tag{10}$$

where  $\theta$  is the angle of the wave direction to the  $x$  axis. Comparing to (9), the specific admittance for a transmitting boundary is  $\beta = \sin \theta$ , which varies from 0 to 1. The value of  $\gamma$  then must be less than the wave number,  $k$ , as it implies that waves are normally incident on the jetties and fully transmitting through them.

For the general case, an equivalent admittance will be defined as  $\sin \theta$  when  $\beta$  is real.

Eigenfunction Expansion

The velocity potential in the channel will be similar to that used by Dalrymple (1989), studying ‘designer waves’ for directional wavemakers. In general, the total potential will consist of even and odd eigenfunction components, across the channel, but here we will restrict ourselves to normally incident wave trains, so that only the even modes will be utilized. The potential (in the absence of a mean flow in the channel) is therefore assumed to be

$$\phi(x, y, z, t) = \sum_{n=1}^{\infty} C_n \cos \lambda_n y \frac{\cosh k(h+z)}{\cosh kh} e^{i(\sqrt{k^2-\lambda_n^2}x-\sigma t)} \tag{11}$$

where the set  $\{\cos \lambda_n y\}$  is an anharmonic (orthogonal) Fourier series in  $y$ , and the usual linear wave theory dispersion relationship holds:

$$\sigma^2 = gk \tanh kh, \tag{12}$$

which relates the wave number  $k$  and the water depth and wave angular frequency,  $\sigma = 2\pi/T$ , where  $T$  is the wave period.

The lateral boundary conditions (9) place the following constraints on the  $\lambda_n$  in the Fourier series,

$$-\lambda_n \tan \lambda_n b = i\gamma \quad n = 1, 2, \dots \quad (13)$$

which is a transcendental equation to determine the wave numbers  $\lambda_n$  in the lateral direction. (Note that if  $\gamma$  is zero, then the  $\lambda_n = n\pi/b$ .) This boundary condition leads to the orthogonality of the Fourier series:

$$\int_{-b}^b \cos \lambda_n y \cos \lambda_m y \, dy = \begin{cases} 0, & \text{for } n \neq m, \\ \frac{2\lambda_n b + \sin 2\lambda_n b}{2\lambda_n}, & \text{for } n = m. \end{cases} \quad (14)$$

The velocity potential (11) is composed of an infinite number of wave trains, consisting of wave trains which are 'standing' in the cross-channel direction and either propagating or decaying in the down-channel direction. In fact, only a few terms in  $\phi$  represent propagating wave trains as, for large values of  $n$ , the real part of  $\sqrt{k^2 - \lambda_n^2}$  becomes negative and results in a strongly damped motion in the  $x$  direction. In fact, for incident wave trains with wave lengths larger than  $2b$  (the channel width), or  $kb < \pi$ , then only one wave mode ( $n = 1$ ) propagates down the channel (this is strictly true for  $\gamma = 0$ ; but it serves as a guide).

The values of  $C_n$  are determined by the initial value of  $\phi(0, y, t)$ . By orthogonality of the set  $\{\cos \lambda_n y\}$  over  $-b < y < b$ , we find

$$C_n = \frac{2\lambda_n \int_{-b}^b \phi(0, y, t) \cos \lambda_n y \, dy}{2\lambda_n b + \sin 2\lambda_n b} \quad (15)$$

For a given incident wave train of frequency  $\sigma$ ,  $\phi(0, y, t)$  is taken as unity across the mouth of the channel, and the  $C_n$  can be reduced to

$$C_n = \frac{4 \sin \lambda_n b}{2\lambda_n b + \sin 2\lambda_n b} \quad (16)$$

This initial condition imposes phases on the various wave modes (more on this later).

Examining narrow channels, ( $\gamma b \ll 1$ ) and  $kb < \pi$ , the lateral boundary condition (13) can be approximated for  $\lambda_1$ ,

$$\lambda_1^2 = -i\gamma/b \quad (17)$$

The leading term of  $\phi$  is

$$C_1 \cos \lambda_1 y \frac{\cosh k(h+z)}{\cosh kh} e^{i(\sqrt{k^2 - \lambda_1^2} x - \sigma t)} \quad (18)$$

Introducing the approximation for  $\lambda_1$  yields for the approximate wave decay

$$e^{-\left(\frac{\gamma_r}{2bk}\right)x} = e^{-\left(\frac{\beta_r}{2b}\right)x} \tag{19}$$

as  $C_1$  asymptotically goes to unity. Here, the subscript  $r$  denotes the real part. Comparing with the linear damping formula, (4),  $\Gamma = \gamma_r x / 2bk$ . Therefore, the wave height in a channel decreases exponentially down the channel according to this theory. Further, the damping is inversely proportional to  $b$ , the channel half-width.

Alternatively, since  $\lambda_1^2 \ll k^2$ , the exponential term in  $x$  can be approximated as

$$e^{i\sqrt{k^2 - \lambda_1^2}x} \rightarrow e^{ikx} e^{(\lambda_1)_r(\lambda_1)_i x/k}$$

Thus, given the real and (negative) imaginary parts of  $\lambda_1$ , found from (13), the decay of the first wave mode with  $x$  can be found as

$$e^{(\lambda_1)_r(\lambda_1)_i x/k} \tag{20}$$

Since this expression is based on the lateral boundary condition, rather than an approximation, it is more accurate than that provided in (19).

Effects of Tidal Currents

The previous results were obtained for the case of no currents in the channel. However, it is likely for a majority of the tidal cycle there will be a slowly varying flow in the channel or a current due to a river discharge. Therefore the effects of the currents on the wave field and the damping in the channel must be determined.

To include the current (with uniform speed  $U$ , with  $U \gg |\nabla\phi|$ ), the velocity potential is changed to

$$\phi(x, y, z, t) = \phi_c + \phi_w = -Ux + \sum_{n=1}^{\infty} C_n \cos \lambda_n y \frac{\cosh k_n(h+z)}{\cosh k_n h} e^{i(\sqrt{k_n^2 - \lambda_n^2}x - \sigma t)} \tag{21}$$

where the  $\lambda_n$  satisfy the same impedance relationship (9) as before; however,  $\gamma$  may be different than for the no-current case. Also, the dispersion relationship for the wave number results in a different wave number for each wave mode, due to the wave-current interaction, which depends on the wave direction,

$$\left(\sigma - U\sqrt{k_n^2 - \lambda_n^2}\right)^2 = gk_n \tanh k_n h, \quad n = 1, 2, 3, \dots \tag{22}$$

due to the effects of the current on the linear combined free surface boundary condition (e.g., Dean and Dalrymple, 1991, § 3.4.5)

$$\frac{\partial^2 \phi_w}{\partial t^2} + 2U \frac{\partial^2 \phi_w}{\partial x \partial t} + U^2 \frac{\partial^2 \phi_w}{\partial x^2} + g \frac{\partial \phi_w}{\partial z} = 0 \quad \text{on } z = 0 \tag{23}$$

where  $\phi_w$  is the portion of the velocity potential describing the wave motion. The resulting wave numbers ( $k_n$ ,  $n = 1, 2, 3, \dots, \infty$  from 22) are all complex.

For narrow channels, a similar approximation to (19) can be made for the case of waves on currents. This leads to the following relationship for wave height decay down a channel (for normal wave incidence)

$$e^{-\left(\frac{\gamma_r}{2bk_1}\right)x} \quad (24)$$

where  $k_1$  is given by (22).

### Results and Comparisons to Field and Laboratory Data

Figure 2a shows the instantaneous wave field ( $\eta(x, y) = -(i\sigma/g)\phi(x, y, 0)$ ) and the absolute value of  $\eta$  in a channel with the following characteristics:  $b = 120$  m,  $T = 12$  s,  $h = 8$  m, and specific admittance is 0.156, which is  $\gamma = 0.012$  m<sup>-1</sup>. For this case, the curvature of the wave crests is clear with the waves turning into the jetties by diffraction. For this example, the equivalent transmission angle is 8°.

The absolute value of the water surface is contoured in Fig. 2b, with the contours spaced by 0.1. The initial condition of normally incident waves with unit amplitude leads to a forced phasing of all the modes which comprise the wave field (11), such that as the waves propagate down the channel there is a focussing after two wavelengths, for this wave period (the largest contourline corresponds to 1.1; the smallest, to the far right, is 0.3).

Fig. 3 shows the decay of the absolute magnitude of each of the largest five wave modes down the channel centerline for this example; clearly the higher modes (greater than, say, the third) decay rapidly (note one wavelength corresponds to 102 m) and, after long distances, only the first mode is important.

Melo and Guza (1991b) carried out a field experiment at Mission Bay, CA. The entrance channel is 1200 m long, 250 m wide, with a depth of 8 m. The jetties are sand tight, prohibiting the propagation of waves through the jetties. Pressure sensors were deployed at five locations along the centerline of the jetties as shown in Figure 4. Data was obtained during the period March 2 to April 8, 1985. Using data and parabolic model predictions, Melo and Guza determined that the effects of wave height and bottom friction on the wave height reduction along the channel were small. There was no wave breaking observed in the channel.

The effects of currents were observed to have only a small effect on the damping down the channel. The model given in the section Effects of Tidal Currents can predict the damping factor exactly;  $\Gamma$  is the imaginary part of  $\left(\sqrt{k_1^2 - \lambda_1^2}\right)$ . A variation in  $U$  of  $\pm 1$  m/s had nearly no effect on the value of  $\Gamma$ ; the variation was less than 0.3%.

Figure 6: Wave Spectra at the Different Channel Locations (28 March, 1985; adapted from Melo and Guza, 1991b)

The wave spectra observed at the five locations in the channel by Melo and Guza on April 1, 13:31–14:40 hs, 1985 and March 28, 12:24–13:32 hs, 1985 are shown in Figures 5 and 6. Thirty three different frequencies are represented from 0.05 Hz to 0.3 Hz ( $\Delta f = 0.078$  Hz). A comparison of this model to the field data was undertaken by calculating the wave field associated with each of the 33 frequency bands (with unit amplitudes at the channel mouth). The energy densities at the first interior gage, *P2*, were then scaled to match the field data at that location. The wave heights at the other 4 gage locations were then computed from Eq. 11. These heights were then converted into energy densities and plotted. The results for each of the 33 frequency bands are shown in Figure 8 for the 1 April case. By best fit matching of the data, a smoothly varying impedance was chosen, corresponding to an impedance angle linearly varying from  $6.3^\circ$  to  $57.3^\circ$  at the highest frequency (giving  $0.004 \text{ m}^{-1} > \gamma < .04 \text{ m}^{-1}$ , from lowest to the highest frequency). The agreement between model and field data is reasonably good, giving confidence in the model for low frequencies (0.05 to 0.1 Hz; or for a range of dimensionless channel widths,  $4 < kb < 9$ ).

For the spectrum with sea and swell, March 28, the specific admittance was taken the same as for the previous case for the 10 lowest frequencies, but the higher frequencies could not be computed reasonably. The higher frequency wave in the range of 0.15 Hz to 0.30 Hz were predicted to grow down the channel.

Figure 7: Computed Wave Spectra at the Different Channel Locations, April 1.

The reason for this 'growth' is the location of the focussing region shown in Fig. 2b. For the higher frequencies, this focussing region migrates down the channel, giving an apparent amplification, which is not seen in the field data. These waves (roughly  $14 < kb < 44$ ) are seriously affected by the phases imposed by the initial condition. For the lower frequency waves this was not a problem as the focussing occurred before any of the measurement points. For a realistic case, the phasing of the wave modes will be far different. In Fig. 8,  $\gamma$  was taken somewhat arbitrarily taken as  $0.007(1 - i)$  for the higher frequencies, as it was found by trial and error that the use of a complex value would reduce the amount of focussing.

As an alternative and a simpler approach to this problem, a pure exponential decay (according to Eq. 19) was tried. The wave energy density at P2 was multiplied by

$$e^{-\left(\frac{2\gamma}{2bk}\right)x} = e^{-\frac{\beta}{b}x} \quad (25)$$

where the introduction of the 2 comes about by the energy being proportional to the square of the wave height. Using the specific admittance ( $\beta$ ) of 0.139 (apparent angle of  $8^\circ$  and  $\gamma = k\beta$  ranging from  $0.005 \text{ m}^{-1}$  for the low frequency waves to  $.05 \text{ m}^{-1}$  for the highest frequency) for April 1 and 0.190 (apparent angle of  $11^\circ$ ) for March 28, gives the results in Figs. 9 and 10. For the case of the narrow banded sea state, there is almost no difference between the complete

Figure 8: Computed Wave Spectra at the Different Channel Locations, March 28.

model (Fig. 7) and the exponentially decaying model. For the wide-banded seas, the frequency dependency of  $\gamma$  causes the low frequencies to decay too rapidly when compared to the field data. This can of course be improved by varying  $\gamma$  in the model. The exponential model result here is better than the complete model shown in Fig. 8, because only a single wave mode is used and the focussing can not occur.

### Conclusions

The behavior of water waves in straight channels with energy absorbing side walls, such as rubble mound jetties, can be reasonably predicted with a simple eigenfunction expansion model. For the case of Mission Bay, CA, only a very few wave modes are needed to provide an adequate description of the wave field, except for the case of the high frequencies. The absorbing sidewalls are modelled by a simple impedance boundary condition (Eq. 10), where the specific admittance  $\beta$  can be expressed as an equivalent transmission angle,  $\theta$  from  $\beta = \sin \theta$ . The values of  $\theta$  found here are between 8 and 11°.

The complete model predicts the decay of wave spectra at Mission Bay, CA reasonably well for the low frequencies, with problems associated with focussing and the phasing of the initial condition at the higher frequencies. A simple model based on purely exponential decay (Eqs. 19 and 20) provides a useful tool for preliminary estimates of wave decay.

## CHAPTER 234

### DISPERSION MODEL OF DREDGE SPOIL DUMPED IN COASTAL WATERS

G. Drapeau<sup>1</sup>, D. Lavallée<sup>1</sup>, J.F. Dumais<sup>1</sup> and G. Walsh<sup>2</sup>

#### Abstract

This model is specifically conceived to work in estuarine environments characterized by strong tidal currents. It operates on a microcomputer and it is conceived to work with minimal input. The model determines the velocity and radius of the dense sediment cloud, formed by the release of sediments from a scow, during its downfall in the water column. These parameters are used to determine the proportion of sediments settling at the point of impact. Sediments maintained in suspension by the high level of turbulence following impact on the bottom form a density current that spreads out radially. The performance of the model was verified by a series of experiments carried out in the St Lawrence Estuary to monitor the disposal of dredged spoil from a 400 m<sup>3</sup> scow.

#### 1. INTRODUCTION

The present model was initially developed for the Canadian Ministry of Fisheries and Oceans to evaluate the impact of dredged sediments dumped from a scow in different marine biotopes. Prerequisites were that the model works with minimal input and runs on a microcomputer. Another requirement was that the model would be efficient in estuarine environments characterized by strong tidal currents.

---

<sup>1</sup> Centre océanographique de Rimouski, Université du Québec, Rimouski, Québec, Canada, G5L 3A1

<sup>2</sup> Institut Maurice-Lamontagne, Pêches et Océans Canada, Mont-Joli, Québec Canada, G5H 3Z4

The bulk of sediments released from a scow reach the sea floor at the dumping site and only a small percentage remains in the water column. Gordon (1974) estimates that more than 95 per cent of sediments released from a scow reach the sea floor and observations by Tavolaro (1984) lead to similar conclusions. The present model describes the behavior of the dredged sediments that reach the sea floor at the dump site and a companion model is used to determine the fate of sediments dispersed in the water column.

Different mathematical models have been developed to describe the dispersal of dredged sediments. A model was developed by Edge and Dysart (1972), in which the dumped material is assumed to behave as a dense liquid moving in a lighter one. Koh and Chang (1973) used similar concepts to develop a model that deals with each of the three phases of dredged material dispersal and can handle continuous discharge of sediments as well as dumps from a scow. However, this model is not particularly suited for coastal environments and it is much more complex than the model described in this paper. Bokuniewicz et al. (1978) developed a mathematical model that determines potential and kinetic energy of dumped sediments. Based on the energy budget of the dumped sediments, the authors determine the maximum distance reached by the density current that spreads on the sea floor after the dumped sediments impact on the bottom.

Field measurements to develop this model were carried out in in Canada, in the Lower St. Lawrence Estuary. Measurements took place at Rivière-du-Loup and Rimouski where the tidal range varies between 5 and 6 m. and the dump sites are located in 10 m. and 20 m. water depth respectively.

## **2. MODEL DESCRIPTION**

The dispersal of dredged sediments released from a scow follows three stages (Fig. 1). Upon release, the dredged material descends rapidly through the water column as a well-developed high density jet; subsequently, when the dredged material hits the bottom, part of the sediment load settles at the site of impact; and finally, the high level of turbulence generated by the impact maintains a cloud of sediments in suspension that forms a density current which spreads out radially.

### **2.1 Descent of sediments through the water column**

A series of flume experiments conducted by Krishnappan (1975) have shown that the fall of dumped sediments can be treated in two distinct phases, an entrainment phase when sediments leave the scow followed by a settling phase that develops only when the water depth is sufficient (which is not the case in coastal waters) for the vertical downward velocity to become the same as the settling velocity of sediment particles. During the entrainment phase, the size of the

**Figure 1.** A) The dump load leaves the scow as a massive cloud of sediments that expands during its fall as water is incorporated.

B) At impact on sea floor a portion of the dumped sediments settle on the sea floor and the remainder is maintained in suspension by the high level of turbulence generated by the impact and forms a density current.

C) The density current expands radially taking the shape of a torus. For modeling purposes, the initial radius of the torus is taken to be that of the falling sediment cloud at the moment of impact.

sediment cloud, that forms when the scow opens, grows owing to the incorporation of external fluid while the vertical downward velocity diminishes (Fig. 1a). Flume measurements and dimensional analysis have lead Krishnappan to formulate the downward velocity ( $W_f$ ) as well as the radius ( $R_f$ ) of the sediment cloud as a function of water depth:

$$R_f = \alpha_k Z \quad (1)$$

$$W_f = \beta_k F^{1/2} / Z \quad (2)$$

where  $Z$  is the water depth,  $F$  is the negative buoyancy of sediments and  $\alpha_k$  and  $\beta_k$  are variables whose values are functions of the sediment grain size determined experimentally by Krishnappan.

## 2.2 Settling of sediments at point of impact

No systematic formulation is presently available to determine the exact proportion of the total sediment load that settles on sea floor at the point of impact. The parameters that determine the settling of dumped sediments at the point of

impact are: 1) the sediment grain size and 2) the impact velocity on the sea floor, which is related to water depth. It stands to reason that coarser sediments will have a greater tendency to settle at the point of impact than finer ones. Velocity of the mass of dumped sediments at the moment of impact provides the energy necessary to generate a level of turbulence sufficiently high to bring sediments into suspension. For instance, if the water depth is sufficient to allow sediments to reach their inherent settling velocity, all sediments would settle naturally on the sea floor without further movement, no energy being left to generate turbulence and maintain sediments in suspension.

The proportion of sediments settling directly at the point of impact is defined as follows in the present model:

$$S = 1 - C(W_{fi} - W_s)/W_{fi} \quad (3)$$

where  $W_{fi}$  is the downfall velocity of the mass of dumped sediments at the moment of impact and  $W_s$  is the natural settling velocity of sediment particles (Fig. 1b).  $C$  is a constant; its present value is set at 0.5. This equation determines the "excess energy" available to generate a density current. As explained above, if  $W_{fi}$  diminishes to the point that  $W_{fi} = W_s$ , Then  $S = 1$  and no sediments are left to form a density current.

According to field measurements carried out by Gordon (1974), 80 per cent of the dumped sediment load settles within a 30 m. radius from the point of impact. Other workers (Bokuniewicz et al., 1978; Tavolaro, 1984; Truitt, 1986) observed that a large proportion of dumped sediments settle at the point of impact, but no specific correlation is established with sediment grain size and water depth.

### 2.3 Formation of a density current

Truitt (1988) summarized observations of many workers explaining that dredged sediments form density currents that spread on the sea floor following impact on bottom. Profiles of dredged sediment dispersion, measured by Gordon (1974) and also by Malherbe (1990), on a larger scale, outline this phenomenon.

The principle of conservation of mass is used to determine the transfer from a massive sediment fall before impact on the bottom to the formation of a density current (Fig. 1). The cloud of sediments formed by the content of the scow falling through the water column has a radius  $R_{fm}$  (cf. eq. 1) and a downward velocity  $W_{fm}$  (cf. eq. 2) when it hits the sea floor. The vertical flux is defined as:

$$\text{Flux} = \pi R_{fm}^2 W_{fm} \quad (4)$$

The density current generated by the impact on the sea floor expands radially and it takes the shape of a tore (Bokuniewicz et al., 1978). If  $R_{ti}$  is the initial radius of the tore,  $H_{ti}$  is the initial height, and  $V_{ti}$  is the initial velocity, the initial flux of the density current expanding radially on the sea floor is:

$$\text{Flux} = 2\pi R_{ti} H_{ti} V_{ti} \quad (5)$$

The initial radius  $R_{ti}$  of the density current is that of the sediment cloud when it impacts on the sea floor (Fig. 1b and 1c):

$$R_{ti} = R_{fm} \quad (6)$$

Using the principle of conservation of mass to equate equations 4 and 5, we can write:

$$\pi R_{fm}^2 W_{fm} = 2\pi R_{ti} H_{ti} V_{ti} \quad (7)$$

and:

$$R_{fm} W_{fm} = 2H_{ti} V_{ti} \quad (8)$$

This equation contains two unknowns; the initial height ( $H_{ti}$ ) and the initial velocity ( $V_{ti}$ ) of the density current.

### 2.3.1 Velocity of the density current

Density currents are studied principally to interpret sedimentary facies (Middleton and Southard, 1984). For instance, Keulegan (1957) and Middleton (1966a,b) produced density currents experimentally by releasing brines and suspensions of spherical beads into horizontal channels. Experimental results agree to define the velocity of the density current as follows. The difference density  $D_t$  of the density current is defined as:

$$D_t = p_s/p \quad (9)$$

where  $p_s$  is the excess density of the density current and  $p$  is the density of water; and:

$$V_t = Fr(D_t g H_t)^{1/2} \quad (10)$$

where  $V_t$  is the velocity of the density current,  $Fr$  is the densimetric Froude number,  $D_t$  is the difference density of the density current, and  $H_t$  is the height of the density current. Middleton (1966a) has found experimentally that the densimetric Froude number for density currents generated by sediments into suspension flowing on a horizontal bottom has a constant value of 0.75. The velocity of the density current is then a function of the density difference and the height of the density current. The density difference is determined by the quantity

of sediments brought into suspension following the impact of sediments on the sea floor. This quantity is known from equation 3.

### 2.3.2 Height of the density current

Equation 10 shows that  $V_t$  is a function of  $H_t$  and it is then possible to determine the initial height ( $H_{ti}$ ) of the density current. Equation 10 is introduced in equation 8 and  $H_{ti}$  is defined explicitly as:

$$H_{ti} = [(R_{ti}W_{fi})^2/(4Fr^2gD_{ti})]^{1/3} \quad (11)$$

This algorithm effectively sets the initial height ( $H_{ti}$ ) of the density current in such a way that the conservation of flux is respected, as defined by equations 4 and 5.

### 2.3.3 Evolution of the density current

The following initial conditions are assumed to define the evolution of the density current: 1) the density current forms a torus that expands radially (Bokuniewicz *et al.*, 1978), 2) the volume of the torus is constant, and 3) the width ( $L$ ) of the torus is constant. Consequently, in order to maintain the volume constant, the height of the torus ( $H_t$ ) diminishes as the torus spreads radially. It implies that  $H_t$  is a time dependent variable.

Sediments suspended in the density current are settling on the sea floor according to their nominal settling velocity ( $W_s$ ) and, consequently, the density of the density current diminishes as the settling of sediments on the sea floor progresses. The concentration of sediments in the density current can be defined by the following differential equation:

$$dP_t/dt = -(P_t/M_t)W_sA_t \quad (12)$$

where  $P_t$  is the quantity of sediments in the density current,  $M_t$  is the volume of the density current,  $W_s$  is the settling velocity of sediment particles and  $A_t$  is the surface area of the density current. As:

$$M_t/A_t = H_t \quad (13)$$

where  $H_t$  is the height of the density current. Equation 13 can be rewritten as follows:

$$dP_t/dt = -P_tW_s/H_t \quad (14)$$

As mentioned above,  $H_t$  is itself time dependent. This equation is solved numerically; initially using a Runge-Kutta algorithm, but it is handled more efficiently by linear iteration.

The rate of deposition on the sea floor of sediments contained in the density current is proportional to the sediment concentration in the density current. That rate of deposition is also inversely proportional to the velocity at which the density current is moving on the the sea floor; for example, when the density current is moving faster, the sediments settling on the sea floor are spread over a larger area.

#### 2.4 Advection by tidal currents

Tidal currents play an important role in estuarine environments. At the present stage of development of the model, tidal currents are simply advecting the density current (Fig. 2). In theory, advection should have an influence on the densimetric Froude number but, in practice, it is not significant within the context of the present model.

**Figure 2.** Three-dimensional mesh of sediment accumulation on the sea floor resulting from the simulation of 125 dumps totaling  $50,000 \text{ m}^3$  of dredged sediments at a water depth of 20 m. and tidal currents reaching  $.4 \text{ ms}^{-1}$ . The bulk of sediments is deposited within a 150 m. radius and the remainder is transported by density currents advected in different directions depending on the phase of the tide.

## **2.5 Sedimentation grid**

The present model is designed to describe the cumulative effect of dredging operations resulting from many dumps at a given site. The cumulative sedimentation resulting from successive dumps is handled by implementing a grid system that works as follows. The spatial and temporal scales to calculate the amount of sedimentation on the sea floor are set to obtain sedimentation measurements spaced approximately 10 m. apart. A 2x2 kilometer grid, using a 10 m. mesh size, is established and each sedimentation calculation is attributed to the corresponding mesh. This procedure permits to record sedimentation from successive dumps even if they do not originate from the same location on the dumpsite (Fig. 2). This feature is important to allow for the possibility to simulate inherent navigation errors and also to take into account that scows are not necessarily completely stopped during dumping operations.

## **2.6 Drifting during dumping**

Most operators prefer not to stop completely during dumping operations. This situation is simulated by spreading sediments settling at the point of impact over a 50x50 m. area instead of a single point. Other dimensions can be chosen at will, depending on the speed of the scow and the time taken to unload.

## **2.7 Positioning error**

The positioning of a scow over a dump site is more or less precise depending on the navigation system used. This inherent error is dealt with by choosing at random a position within a circle corresponding to the positioning uncertainty, typically 150 m. in the St. Lawrence Estuary.

# **3. INPUT / OUTPUT**

## **3.1 Input**

The following parameters are used as input: 1) volume of sediments dumped, 2) number of dumps, 3) water depth, 4) sediment grain size, 5) radius of navigation error, 6) currents (current-meter records or tidal- current ellipses).

Three sediment grain sizes with corresponding percentages are used to describe the texture of dredged sediments. Two options are offered to input current data: current-meter data files or keyboard input of tidal current ellipses. When a current-meter data file is used as input, the data sampling from the file is organized to correspond as closely as possible to the dredging operations. For example, data sampling from the file starts to coincide with the beginning of the dredging operations and sampled data are averaged to correspond to the dumping routine (e.g.

one dump every hour). Furthermore, if dumping operations are not continuous, the idle periods (night time) are not sampled. When current meter data are not available, tidal currents are simulated by the model on the basis of tidal current ellipses. Speeds and directions of tidal current ellipses are input from the keyboard to simulate estuarine conditions prevailing at the studied dump site.

### 3.2 Output

Data produced as output are: a) three files: 1) sedimentation matrix file, 2) N-S cross-section file, 3) W-E cross-section file and b) four graphics: 1) Contours of dredged sediment deposit (Fig. 2 and 5), 2) 3-D mesh of sediment deposit (Fig. 2), 3) N-S sediment deposit cross-sections, and 4) W-E sediment deposit cross-section. Graphics displays are produced by the software package "Surfer" (Golden Software, Boulder, U.S.A.).

## 4. FIELD MEASUREMENTS

### 4.1 Location and dredging equipment

Field experiments were carried out at two locations in the St. Lawrence Estuary to verify the present model. At Rivière-du-Loup the dump site was located in 10 m. water depth and tidal currents reached  $1.5 \text{ ms}^{-1}$ . At Rimouski, the water depth was 20 m. at the dump site and tidal currents reached  $1.0 \text{ ms}^{-1}$ . The dredging equipment operating at both locations was a clamshell dredge loading  $400 \text{ m}^3$  scows.

### 4.2 Sediment types

The operations monitored were maintenance dredging at both sites. The sediments dredged were poorly sorted very fine sands mixed with silty muds, the grain size ranging between 0.015 and 0.250 mm.

### 4.3 Field measurement equipment

Echosounder: A 200 kHz echosounder was used to track the dispersal of dredged sediments. That frequency is very effective to trace sediment clouds in the water column (Fig. 3).

Transmissometer: Transmissometer measurements could confirm the presence of density currents but more in a qualitative than a quantitative way.

Water samples: Water samples were taken to calibrate transmissometer data.

**Sediment traps:** Sediment traps were very useful to calibrate the model, because they provide factual measurements of sedimentation rates. The traps were made of 30 cm. high by 10 cm. wide plastic cylinders. The cylinders were mounted in lead containers, that were heavy enough to be placed directly on the sea floor.

**Figure 3.** Example of density current observed using a 200 kHz echosounder from a boat anchored in 10 m. water depth. The sharp front of the density current appears on the left side of the recording and the more diffuse tail is recorded in the right portion of the echogram.

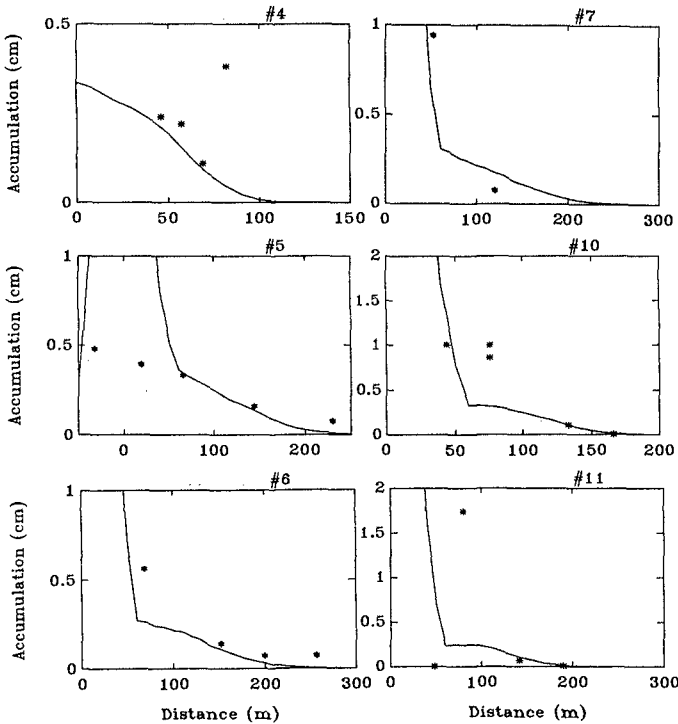

## 5. RESULTS

Model estimates of dredged material accumulation on the sea floor are compared with field measurements obtained from sediment trap deployments. The model is run to simulate the dumps that were monitored with sediment traps and results from the model are compared with sediment trap measurements in figures 4 and 5. The dots on the six diagrams shown in figure 4 are the sediment trap measurements and the full lines show the results of model estimates of sedimentation corresponding to specific dumps monitored at Rivière-du-Loup. The sharp breaks in model estimates result from the fact that sediment accumulation is much higher near the point of impact, where a large proportion of the dumped sediments are settling.

Figure 5 shows the monitoring settings for dumps #4 and #11. Contours of sediment accumulation on the sea floor predicted by the model are plotted on a grid. The location of sediment traps is indicated by dots. Model estimates corresponding to sediment trap measurements are outlined in the upper right corner of each diagram.

### 6. DISCUSSION AND CONCLUSIONS

The dumping of dredged sediments from a scow is an operation which is difficult to monitor, particularly when tidal currents are strong. Sediment traps have to be deployed ahead of time before dumping takes place. The success of the operation depends on the ability to foresee the direction and intensity of tidal currents at the very moment the dumping of dredged sediments will take place. Because of tidal currents and winds, dumps do not always take place at the exact location where they had been planned, with the consequence that the alignment of sediment traps is not always optimal. In addition, sediments dredged with a clamshell remain clumsy and scows are equipped with doors that do not open instantly. The result is that dumped sediment loads are not always as uniform as one would like from an experimental point of view.

**Figure 4.** Comparison of model estimates and sediment trap measurements. The full lines on these six diagrams show the model estimates and the dots are the sediment trap measurements. The sharp breaks in model estimates result from the fact that sediment accumulation is much higher near the point of impact, where a large proportion of the dumped sediments settle out.

Despite the problems inherent with the monitoring of dispersal of dredged sediments, the monitoring carried out at Rivière-du-Loup and Rimouski was successful enough to warrant that the concepts used to develop the present model are realistic. As it can be seen in figure 4, dump #4 shows a good agreement between measurements and model except for the fourth sediment trap for which there is no explanation. Dump #5 is one of the most interesting, because it shows that the sedimentation rate as a function of distance from the point of impact is well predicted by the model, although the point of impact of the model (coordinates 0,0) does not coincide with the location where the dump effectively took place. The other diagrams show a relatively good agreement between measurements and estimates. An exact fit between model and field measurements is beyond expectations. However, the overall trends and rates of sedimentation as a function of distance from the point of impact estimated by the model are realistic.

The correlation between model estimates and sediment trap measurements is outlined more explicitly in figure 5. Dump #4 took place when tidal currents were weak,  $.1 \text{ ms}^{-1}$ , and dump #11 was carried out when tidal currents reached  $.7 \text{ ms}^{-1}$ .

**Figure 5.** Examples of sediment distribution for different tidal conditions. Results obtained from the model are compared with accumulation in sediment traps. The quantity of sediments dumped is 400 cubic meters and the water depth is 10 m. Tidal currents are  $.1 \text{ ms}^{-1}$  for the plot on the left and  $.7 \text{ ms}^{-1}$  for the plot on the right. Dots on the plot show the location of the sediment traps. The diagrams on the upper right corner of each plot compare the simulation from the model (the full line) with the measurements from the sediment traps.

In both cases the agreement is good between the model estimates and field measurements. Comparison of these two experiments outlines the importance of tidal currents as well as the capacity of the model to cope with it. The principal effect of tidal currents is to advect dumped sediments. The distance reached by sediments when tidal currents are strong ( $.7 \text{ ms}^{-1}$ , dump #11) is 200 m., which is twice the distance reached under weak tidal currents ( $.1 \text{ ms}^{-1}$ , dump #4).

At the present stage of development, the quantity of sediments settling at the point of impact versus the quantity entrained in a density current is based on approximate qualitative observations. We can only say that the formulation used in the present model seems acceptable because the sediment trap measurements obtained for specific dumps are adequately estimated by the present model configuration. The evaluation of settling of sediments at the point of impact would need to be investigated further. One difficulty is that it is not possible to place sampling instruments directly under the scow, because they would be buried by the sediment load settling at the point of impact. One avenue is to experiment in flume tanks to gain a better understanding of the physics of this phenomenon. An other approach would be to survey the dumping operations with a multi-beam echosounding system. The present experiments were carried out using a single echo-sounder aboard a ship at anchor, which is equivalent to carrying out eulerian measurements at a single point of observation. A stationary multi-beam system would provide a two-dimensional perspective of the phenomenon. Furthermore, if positioning were precise enough and the ship could move rapidly by comparison with the cloud of dumped sediments, a three-dimensional perspective of dumped sediment dispersal could be obtained.

## ACKNOWLEDGMENTS

This publication is a contribution of the Oceanographic Centre of Rimouski - a partnership of INRS (Institut National de la Recherche Scientifique) and UQAR (Université du Québec à Rimouski) operating under the auspices of University of Quebec. The research presented in this paper was sponsored by Fisheries and Oceans Canada, contract No FP707-9-4296/01-XSK. The authors are grateful to Dr. A. Walton for reading the manuscript and they also acknowledge the collaboration of Captain P. Tremblay.

#### Abstract

In order to solve water circulation and solute transport-diffusion problems in two-dimensional hydrodynamical systems a comprehensive simulator, composed by two finite element models, has been developed. In particular the first model, which is of semi-implicit kind, solves hydrodynamical shallow water equations whereas the second, which is an Eulerian-Lagrangian method (ELM), is based on the Modified Method of Characteristics (MMOC) combined with Galerkin finite element method. Semi-implicit procedures for hydrodynamical models are sometimes used with finite differences but are quite rare with finite elements. Nevertheless they have a lot of advantages compared to the others, principally linked to a considerable time saving. This is determined by the fact that the systems of equations in the unknown levels and velocities are uncoupled and the time step is not constrained by Courant-Friedrichs-Levy stability criterion. It can be demonstrated that in the linear case the hydrodynamic model is indefinitely stable and good accuracy can be achieved for velocity field. On the other side, the proposed transport-dispersion model presents interesting features, among which the possibility to obtain good results in mass conservation and minimum numerical oscillations or grid orientation problems even under sharp front conditions. In these papers we shall discuss only the approximation method of transport-dispersion model, showing the theoretical fundamentals and some of its applications.

#### Introduction

The transport-dispersion equation constitutes one of the most difficult problem to solve by numerical methods, since the equation ranges from a parabolic to almost hyperbolic form, depending on the ratio of advection to dispersion, the Peclet number. In particular, when advection terms of the equation are dominant and concentration gradients very steep, using standard finite element many difficulties in the numerical solution arise, such as numerical dispersion, numerical oscillations, grid orientation influences and, even, mass conservation.

To treat this problem many approximations have been developed, but, nevertheless, three broad classes of methods can be identified.

The first group, based on using optimal test functions, is referred to as Optimal Spatial Methods (OMS). Examples of these approximations include the Quadratic Petrov-Galerkin Method (Christie et al., 1976; Bouloutas et al., 1988), the Optimal Test Function Method (OTF) (Celia et al., 1989). The limits of all these schemes consist in the variably upwinded nature of test functions which restrict the range of Peclet numbers allowable without numerical diffusion.

A second broad class is constituted by the Eulerian-Lagrangian methods (ELM), which appear to overcome the problems inherent to advection-dominated transport conditions. The approximations in this class of schemes have, as their common element, a Lagrangian treatment of advection processes. Again there are many examples from literature, including Operator Splitting Method (Baptista, 1987;

Wheeler et al., 1988), Eulerian-Lagrangian Method with the Method of Characteristics (Pinder et al., 1977), Eulerian-Lagrangian Method with the Modified Method of Characteristics (Ewing et al. 1984; Russel, 1985; Chiang et al., 1988). These methods can obtain significant reduction in numerical oscillations and in numerical diffusion even in presence of large Courant numbers. The principal drawbacks of ELM are, in some case, difficulty to conserve mass and to formulate general boundary conditions. However, material balance mass errors can be greatly reduced when an accurate velocity field from the solution of hydrodynamical equations is derived.

The third broad class (ELLAM) combines the ideas of OTF and ELM, by using space-time test functions satisfying a local adjoint condition that introduces a Lagrangian frame of reference (Celia et al., 1989; Zisman, 1988; Russel, 1990). Among other things, ELLAM schemes allow the solution of transport-dispersion equation in the conservative form unlike, for example, ELM methods where the obtained solution concerns the non-conservative form of the same equation. For this reason sometimes ELLAM approximations can achieve a better result in mass conservation than ELM themselves, even if at the expense of a non-irrelevant increase of computational effort.

Taking into account all these considerations, these papers present a comprehensive analysis of a numerical method adopting a Eulerian-Lagrangian Method with the Modified Method of Characteristics (MMOC), with interesting proceedings to evaluate the advection term of diffusion equation. Furthermore two brief reports, regarding a numerical validation and a real case application, are presented.

### Governing equation

The general solute diffusion equation in a non-conservative form has been derived as follows:

$$\frac{\partial c}{\partial t} + \bar{v} \cdot \nabla c - \frac{1}{h} \nabla \cdot (hD \cdot \nabla c) = s \quad (1)$$

where

- c solute concentration, [kg/m<sup>3</sup>];
- D dispersion tensor, [m<sup>2</sup>/s];
- $\bar{v}$  velocity vector, [m/s];
- h water depth, [m] ( $h = Z - Z_f$  where  $Z$ ,  $Z_f$  are surface and bottom levels, relative to a reference plane);
- s solute source or sink, [(kg/m<sup>3</sup>)/s].

The dispersion tensor D in two-dimensional flow fields is defined as (Peaceman, 1966):

$$D = \begin{pmatrix} D_{xx} & D_{xy} \\ D_{yx} & D_{yy} \end{pmatrix} = D_m I + \frac{hg^{1/2}}{C|\bar{v}|} \left\{ \alpha_l \begin{pmatrix} u^2 & uv \\ uv & v^2 \end{pmatrix} + \alpha_t \begin{pmatrix} v^2 & -vu \\ -vu & u^2 \end{pmatrix} \right\} \quad (2)$$

where

- $D_m$  molecular isotropic diffusion coefficient, [m<sup>2</sup>/s];
- I unit tensor, dimensionless;
- $\alpha_l$  longitudinal dispersion coefficient, dimensionless;
- $\alpha_t$  transversal dispersion coefficient, dimensionless;
- u, v velocity components along coordinate axes, [m/s];
- g gravitational constant, [m/s<sup>2</sup>];
- C Chézy coefficient, [m<sup>1/2</sup>/s].

The factors which determine diffusion processes are mainly two: the first, of advection kind, characterized by transport for the fluid base motion; the second, of dispersive nature, linked to whirling motions of turbulent origin internal to fluid masses.

Indeed equation (1) would range from a hyperbolic-type, if the hydrodynamic dispersion were null, to a parabolic-type, if the process were purely dispersive. Numerical proceedings which permit to solve suitably hyperbolic differential equations differ deeply from those applied in case of parabolic-type equations. It is well known that solution for hyperbolic-type equations can be represented from the initial data propagating over well-defined paths, called characteristics, over the surface in direction of flow. The solution of the overall equation (1) can be viewed as spreading or dispersion away from these characteristic curves, along which solute concentration is a smooth function (Douglas and Russel, 1982).

With regard to this, consider a domain  $\Omega$  delimited by a boundary  $\Gamma$  where Dirichlet or null-flux boundary conditions are applied.

Defined the unit vector  $\bar{v}(\bar{x}, t)$  in the characteristic direction, the directional derivative along a characteristic curve in  $\bar{x}$  at time  $t$  can be evaluated through the expression:

$$\frac{\partial}{\partial \tau} = \frac{1}{(|\bar{v}|^2 + 1)^{1/2}} \left( \frac{\partial}{\partial t} + \bar{v} \cdot \nabla \right) \quad (3)$$

where  $\bar{v}$  is the local velocity vector.

If we substitute expression (3) in equation (1), we will obtain:

$$(|\bar{v}|^2 + 1)^{1/2} \frac{\partial c}{\partial \tau} - \frac{1}{h} \nabla \cdot (h D \cdot \nabla c) = s \quad (4)$$

which constitutes the non-divergence form of diffusion equation.

### Time discretization of diffusion equation

Many methods, based on characteristics, fix a point at the current time level and evaluate the final position at the advanced time level. MMOC method takes the opposite view, fixing a point at the advanced time level  $t^{n+1}$  and asking where it came from at the current time level  $t^n$ . Thus the solution grid at the advanced time level is controlled by the method, not the flow, so allowing a fixed finite element mesh to use.

In the mathematical model the derivative along characteristic curves can be approximated by a back-ward finite difference procedure, obtaining in this way:

$$(|\bar{v}|^2 + 1)^{1/2} \frac{\partial c}{\partial \tau} = (|\bar{v}|^2 + 1)^{1/2} \cdot \frac{c(\bar{x}, t^{n+1}) - c(\bar{x}^*, t^n)}{[(\bar{x} - \bar{x}^*)^2 + (t^{n+1} - t^n)^2]^{1/2}} + O(\Delta \tau) \quad (5)$$

If we would assign a precise physical meaning to the problem,  $\bar{x}^*$  might be interpreted as the initial position at time  $t^n$  where a particle, following the flow line, will arrive at time  $t^{n+1}$  from. During the time interval  $\Delta t$  within  $t^n$  and  $t^{n+1}$ , the relation linking  $\bar{x}, \bar{x}^*$  can be achieved, as first approximation, through the following cinematic expression:

$$\bar{x}^* = \bar{x} - \bar{v} \cdot \Delta t + O(\Delta t^2) \tag{6}$$

The backward difference in time makes the procedure implicit in nature and (5) becomes:

$$\left(|\bar{v}|^2 + 1\right)^{1/2} \frac{\partial c}{\partial \tau} = \frac{c(\bar{x}, t^{n+1}) - c(\bar{x}^*, t^n)}{\Delta t} + O(\Delta \tau) \tag{7}$$

The final form of the diffusion equation to solve, by using Galerkin weighted residual method, is thus the following (Neuman, 1981; 1983):

$$\frac{c(\bar{x}, t^{n+1}) - c(\bar{x}^*, t^n)}{\Delta t} - \frac{1}{h} \nabla \cdot (hD \cdot \nabla c^{n+1}) = s' \tag{8}$$

Considering equation (8), it can be noted that, in order to avoid the appearance of an artificial numerical diffusion mainly connected to large time steps often utilized in numerical simulations, the dispersion term is computed at advanced time level  $t^{n+1}$ .

Before proceeding to the mathematical formulation of the finite element method, it is necessary to define some notations. First of all denote the following surface and line integrals:

$$(u, v) = \int_{\Omega} (u \cdot v) d\Omega$$

$$\langle u, v \rangle = \int_{\Gamma} (u \cdot v) d\Gamma$$

where center dot is the inner product. Let  $H^n(\Omega)$  be the Hilbert space of n-order defined in  $\Omega$ . Let also  $H_{\Gamma_1}^n(\Omega)$  be the Hilbert subspace of n-order defined in  $\Omega$  of functions  $u \in H^n(\Omega)$  which vanish on boundary  $\Gamma_1$  where Dirichlet boundary conditions are applied.

The variational problem corresponding to differential equation (8), subject to boundary conditions just pointed out, is then the following:

$$\left( \frac{c(\bar{x}, t^{n+1}) - c(\bar{x}^*, t^n)}{\Delta t} - \frac{1}{h} \nabla \cdot (hD \cdot \nabla c^{n+1}) - s', \psi \right) = 0 \quad (\forall \psi \in H_{\Gamma_1}(\Omega)) \tag{9}$$

Integrating by parts against weight function  $\psi$  with Green formulas, we will obtain the Galerkin form of variational problem:

$$\left( \frac{c(\bar{x}, t^{n+1}) - c(\bar{x}^*, t^n)}{\Delta t}, \psi \right) + \frac{1}{h} (hD \cdot \nabla c^{n+1}, \nabla \psi) - (s', \psi) - \langle D \nabla c \cdot \bar{n}, \psi \rangle = 0 \quad (\forall \psi \in H_{\Gamma_1}(\Omega)) \tag{10}$$

Consider now a base  $\varphi_i$  ( $i = 1, 2, \dots, N$ ) of a subspace  $K_N \subset H_{\Gamma_1}^1(\Omega)$  and suppose unknown concentration  $c$  and weight function  $\psi$  to be approximated by  $C$  and  $\varphi_i$  respectively, belonging to such subspace  $K_N$ ; then equation (10) provides the following  $N$  linear equations in the unknown concentration  $C^{n+1} = C(\bar{x}, t^{n+1})$ :

$$\left( \frac{C^{n+1} - C(\bar{x}^*, t^n)}{\Delta t}, \varphi_i \right) + \frac{1}{h} (hD \cdot \nabla C^{n+1}, \nabla \varphi_i) - (S', \varphi_i) - \langle \frac{q_d^{n+1}}{h}, \varphi_i \rangle = 0 \quad (i=1, 2, \dots, N) \tag{11}$$

where  $q_d$  is the flux on the boundary, for unit length, of only dispersive nature.

Since, for hypothesis, boundary flux is null, developing equation (11) in its full form we will

obtain after all:

$$\begin{aligned} & (C^{n+1}, \varphi_i) + \frac{\Delta t}{h} \left\{ h \left[ D_{xx} \frac{\partial C^{n+1}}{\partial x} + D_{xy} \frac{\partial C^{n+1}}{\partial y} \right] \frac{\partial \varphi_i}{\partial x} \right. \\ & \left. + \left[ h \left[ D_{xy} \frac{\partial C^{n+1}}{\partial x} + D_{yy} \frac{\partial C^{n+1}}{\partial y} \right] \frac{\partial \varphi_i}{\partial y} \right] \right\} = (C(\bar{x}^*, t^n), \varphi_i) + (S', \varphi_i) \Delta t \quad (i=1,2,\dots,N) \end{aligned} \quad (12)$$

Equation (12) completes the procedure which combines the modified method of characteristics with finite element Galerkin method for the simulation of solute transport-dispersion equation. The integral relative to the function  $C(\bar{x}^*, t^n)$  is computed through the well known quadrature formulas in a approximated way, since  $\bar{x}^*$  may belong to several elements as  $\bar{x}$  runs over a single element. Finally note that, being advection term  $C(\bar{x}^*, t^n)$  moved to the right side of (12), the system of linear equations is symmetric and positive definite.

**Backtracking algorithm**

The integrals in (12) are standard in finite element schemes except for the inner product relative to  $C(\bar{x}^*, t^n)$ . The point  $\bar{x}^*$  does not lie, in general, at a precise node of the mesh, since it becomes necessary to utilize some particular procedure for its determination. In particular the integration involving  $C(\bar{x}^*, t^n)$  is calculated by means of Gauss quadrature formulas, with a number of integration points in each element variable from three to twelve, in function of concentration front steepness and relative required solution precision. Consider then a point  $P(\bar{x}_i, t^{n+1})$  within a finite element  $T_S$  at time  $t^{n+1}$  (fig. 1). Actually, even if particle path joining points  $P(\bar{x}_i, t^{n+1})$  and  $P(\bar{x}_i^*, t^n)$  could be determined, as first approximation, from equation (6) using the same time step considered for integration of overall diffusion equation, mainly for increasing method's precision particle path is calculated with a time step  $\Delta t'$  shorter.

Fig. 1 - Path of a particle along a characteristic curve in the hydrodynamic system during a integration time  $\Delta t$  of dif-fusion equation. Integration time step  $\Delta t'$  of characteristics is often much less than  $\Delta t$ , with the aim to increase method accuracy.

The particular attention reserved to the evaluation of corresponding points  $P(\bar{x}_i, t^{n+1})$ ,  $P(\bar{x}_i^*, t^n)$

resides fundamentally in the aim to evaluate correctly the advection term of transport-dispersion equation, fraction certainly of crucial importance especially in coastal and lagoon problems.

The cinematic differential equations governing particle motion are the following:

$$\frac{dx}{dt}=u(\bar{x},t) \quad , \quad \frac{dy}{dt}=v(\bar{x},t) \quad (13)$$

with initial conditions  $\bar{x}=\bar{x}_i$  at  $t=t^{n+1}$ . The velocities  $u(\bar{x},t)$ ,  $v(\bar{x},t)$  inside a generic  $m$ -node finite element  $T_S$  will be calculated through the expressions:

$$\begin{cases} u(\bar{x},t)=\sum_1^m u_j(t;T_S)\cdot\phi_j(\bar{x};T_S) \\ v(\bar{x},t)=\sum_1^m v_j(t;T_S)\cdot\phi_j(\bar{x};T_S) \end{cases} \quad (14)$$

where  $u_j, v_j$  are  $j$ -th node velocities and  $\phi_j$   $j$ -th node shape function within an element  $T_S$ .

Generally nodal velocities  $u_j, v_j$  from hydrodynamical simulation are stored only at discreet regular intervals, so that it is necessary some type of interpolation to determine velocity values at each time, as required by integration of (13). In this case, to interpolate velocities, linear, quadratic and cubic polynomials are used, depending on number of velocity values available for such node in that particular phase of hydrodynamical simulation.

### Boundary conditions

As we pointed out, one of the principal drawbacks of ELM procedures is the difficulty of formulating them for general boundary conditions. Indeed, during the early development of modified method of characteristics, a no-flow boundary condition was assumed for all boundaries (Neuman, 1981). Actually these schemes are suitable to reproduce both Dirichlet conditions at open boundaries  $\Gamma_1$  ( $I^\circ$  type) and no-flow conditions at closed boundaries  $\Gamma_3$  ( $III^\circ$  type).

For what concerns  $I^\circ$  type conditions, it is necessary to distinguish, first of all, between inflow and outflow at open boundary  $\Gamma_1$ . During inflow boundary conditions are imposed upon the system from the outside, so being sufficient to assign directly the concentration values on boundary nodes. The situation at an outflow boundary is altogether different, since boundary conditions are no longer influenced from the outside. In this case, neglecting dispersion and so making an approximation quite often reasonable in this kind of problems, the concentration value corresponds with that of the particle arriving in a boundary node from inside the system. Therefore it needs only to determine initial position of the particle by the backtracking procedure.

At last in the case of  $III^\circ$  type condition, when  $\bar{x}$  reaches across the boundary, the hydrodynamical velocity field is used to reflect back the particle, implicitly imposing a no-flow boundary condition.

### Model verification

The following presents an analysis of numerical results of the model. It is important to emphasize that, mainly in order to avoid completely the presence of negative concentrations, has been developed a particular procedure able to eliminate negative values and to conserve exactly solute masses without introducing any significant numerical diffusion, as it will be proved later in the numerical tests.

The model has been applied to cases from low to high Peclet numbers, in order to observe model's ability in handling steep concentration gradients. The diffusion equation was solved with a 2-D grid consisting of right isosceles 3-node elements of small legs  $\Delta x$ , where  $\Delta x$  was nodal spacing. Independent parameters include Peclet number  $Pe = u \Delta x / D$ , Courant number  $Cu = u \Delta t / \Delta x$  and the number of elements  $N$  which the source is distributed in flow direction over.

It was analysed the following two sets, whose analytical solutions are known, having assumed in all cases seven integration points for each triangular element, utilized in Gauss quadrature formulas for integration of advection terms.

#### Instantaneous source in a uniform flow

The base one-dimensional equation is the following :

$$\frac{\partial c}{\partial t} + u \frac{\partial c}{\partial x} - D \frac{\partial^2 c}{\partial x^2} = 0$$

with initial condition  $c(x) = C_0 \cdot \exp(-\sigma |x - x_0| / N \Delta x)$  for  $t=0$ .

From numerous tests, mass and phase appear exact for all runs and numerical diffusion, even with a very concentrated source and high  $Pe$ , is quite negligible. In the case of a particularly steep gradient ( $N=2$ ), with parameters  $Cu = 0.48$  and  $Pe = \infty$ , results are shown in Fig.2 for different time steps (0,10,20,30,40 and 50  $\Delta t$ ).

#### Breakthrough distribution in a uniform flow

The same analysis was carried for the case of a breakthrough distribution in a uniform flow.

The graphics in Fig.3 still show the case of a particularly steep gradient ( $N=3$ ),  $Cu = 0.48$  and  $Pe = \infty$  for different time steps (0,10,20,30,40 and 50  $\Delta t$ ). It is possible to note only small oscillations in numerical results, however quickly damped in space, on either edges of the breakthrough curve. However, by numerical experiences, their maximum value and influence tends to decrease with increasing  $N$  and decreasing  $Pe$ .

### Model application to Barbamarco lagoon (Rovigo - ITALY)

Among other things, the model has been set-up and applied to examine diffusion phenomena on Barbamarco lagoon, which is a small coastal lagoon on Delta Po. The hydrodynamical model has been verified on the base of tidal level measurements, caught in four gages all around the lagoon, and contemporary discharges, flowing through the two mouths and a controlled gate dug into Po river.

Because, unfortunately, there were no data measurements relating to diffusion phenomena in the lagoon, to evaluate the effectiveness of the projected canal network to dredge the results of the model were compared with those referring to real situation supposing a instantaneous source release of a conservative solute in different zones of hydrodynamical system, especially where water exchange is

particularly difficult.

The most interesting result is relative to a solute released near West Mouth (fig. 4). In fig. 4a the finite element mesh of Barbamarco lagoon and the Zoom of the zone interested to conservative solute diffusion are represented, while in fig. 4b the initial concentration distribution is shown. The following two pictures (fig. 4c, 4d) illustrate the distribution evolution during the first 12 hours, with 6 hours' time between representations. Finally the last four pictures (fig. 5a, 5b, 5c, 5d), which report the distribution isolines relative to four days from the beginning of hydrodynamical simulation, show the effects of slow plume migration towards East Mouth, so confirming the results obtained with hydrodynamical model where a residual current in the same direction, equal to roughly 10% of total volume exchanged during a tidal cycle, was noted.

## Conclusion

A comprehensive simulator composed by two finite element models, the first solving hydrodynamical shallow water equations whereas the second the diffusion equation, has been developed. However, in this report only the diffusion model, based on the Modified Method of Characteristics (MMOC), is presented.

The important feature of the MMOC procedure is tracking the solution backward in time along the characteristics, in contrast to the forward front tracking or moving point methods. Thus the solution grid at the advanced time is controlled by the method, not the flow, and therefore a fixed grid system can be used for mathematical simulations. Among other advantages algebraic system is symmetric and positive definite.

Since diffusion equation is solved in a non-divergence form, it is required a very accurate velocity field to maintain good numerical material balance. On its hand, the two levels semi-implicit hydrodynamical model seems to furnish a solution accurate enough to assure overall mass conservation.

The accuracy of the model is analyzed through a comparison with analytical solutions. Good agreement between model results and analytical solutions is demonstrated. Furthermore the experiments demonstrate that large time steps can be taken without sacrificing much of MMOC model's solution accuracy. However, the model does require to consider a sufficient number of Gauss points in each finite element to resolve sharp concentration gradients increasing, in this case, computational effort.

## CHAPTER 236

### SEDIMENTATION AND EROSION PROBLEMS OF YAKAKENT FISHERY HARBOR

A.Rıza GÜNBAK <sup>1</sup>, K. Tunç GÖKÇE <sup>2</sup>, Işıkhan GÜLER <sup>3</sup>

#### **Abstract**

This paper summarises the studies carried out about sedimentation and erosion problems of Yakakent Fishery Harbor. Since the start of the construction of the harbor, accretion in the west coast and erosion in the east coast occurs. Additionally, the entrance of the harbor shoals. As a result of accretion at the west coast shoreline moved towards sea and about 300meters of the breakwater was on land. Erosion at the east coast of the harbor caused collapse of two houses which were about 20meters inside the original shoreline. After identifying the causes, precautions for sedimentation and erosion problems are again studied using one-line model and a series of precautions are recommended.

#### **Introduction**

Yakakent Fishery Harbor is located at the Black Sea coast of Türkiye as shown in figure 1.

Construction of the harbor was started in 1972. Initially the harbor was protected by a 350meters long main breakwater and a secondary breakwater of 230m. length. Then in 1988 the main breakwater was extended to 475m. Figure 2 shows the plan of the harbor after this stage.

Figure 1 ... Location of Yakakent Fishery Harbor

Figure 2 ... Plan View of Yakakent Harbor

Since the start of the construction of the harbor, accretion in the west coast and erosion in the east coasts resulted with considerable change in the shoreline. Additionally the entrance of the harbor which is situated towards east suffered from sedimentation and shoaling. Due to shoaling, depth of entrance of the harbor is about 0.7m. Just after the harbor entrance, depth increases suddenly inside the harbor (~3.0 meter water depth). Consequently continuous dredging was necessary to keep the entrance open even for the small fishing boats. This was tried to overcome by extending the main breakwater to 720m, but problem remained same.

As a result of accretion at the west coast shoreline moved towards the sea and about 300 meters of the breakwater was on land and just behind the secondary breakwater shoreline progressed about 80 meters towards the sea. At the further east coast of the harbor, severe erosion caused collapse of two houses which were about 20 meters inside the original shoreline. Then a seawall having 600 meters length was considered mainly aiming to protect the houses in the vicinity. Although seawall was observed to be functional in this aspect, it also enhanced the erosion down at the east coast. Seawall was further extended, this time to prevent erosion, but the result was same increased erosion at further east.

### Wave Climate

Long term wave analysis were made using hourly average wind records, for a duration of 3 years (Pierson, 1964). Probability distribution of deep water significant wave height,  $(H_{1/3})_0$  are shown on figure 3 and 4. Long term wave statistics showed that dominant wave direction is from NW to NE with 1703 hours per year above 1 meter significant wave height.

Figure 3 - Longterm Probability Distribution of Deep Water Wave Height

Figure 4 - Longterm Probability Distribution of Deep Water Significant Wave Height

From the long term wave statistics, the mean wave height, period and their occurrence of duration in a year are given in Table 1.

Table 1. For Yakakent Harbor region, mean wave height and their occurrence of duration, t(hr) in a year.

DIRECTION	WAVE HEIGHT(m)	PERIOD	t(hours)
WNW	0.79	3.36	70.1
NW	1.1	4.01	2133.2
NNW	1.32	4.34	794.0
N	1.37	4.44	167.5
NNE	1.33	4.37	127.2
NE	1.14	4.04	154.5
ENE	1.19	4.13	118.7
E	0.88	3.56	129.4

The sea bottom is sand with mean diameter of  $D_{50}=0.16\text{mm}$ . Using Shields Criteria for incipient motion it is found that at the -8 meter water depth, initiation of sediment motion will start with 6 second period and 0.20 meter wave height. Sediment in suspension will occur with 0.52 meter wave height.

### Methodology

Topographic field measurements available through the years were solely not sufficient, but together with the wave hindcast studies and further measurements, they formed guidelines for erosion and sedimentation patterns.

To investigate the variation of shoreline and the bottom topography and their reasons, the harbor region may be divided by six areas. (figure 5)

These are,

1. West Coast of the main breakwater
2. Entrance of the harbor.
- 3-Harbor basin
- 4-East of the secondary breakwater
- 5-Existing seawall at the east coast
- 6-East coast extending after the seawall

Figure 5 \_ The Regions for Sediment Transport Pattern

Main breakwater protruding from shoreline, presents a littoral barrier and blockage of longshore sediment transport is the main cause of accumulation at the west coast. As normally expected significant erosion is experienced at the east coast. The seawall constructed to prevent erosion was not functional and erosion was enhanced.

Figure 6 gives a schematic explanation of the wave action and current circulation patterns around the breakwater. Based on this figure the sedimentation at the harbor is explained below.

Figure 6 - Mechanism of Sediment Transport

Wave diffraction around the main breakwater resulted in settlement of suspended load as wave diminish in height could not carry suspended sediment any more. This sediment spreads out on a wide area shadowed by the main breakwater which may further be carried towards harbor entrance either by clockwise circulation waves or longshore current created by low frequency NE waves. The suspended sediment is also carried towards the harbor entrance by the diffracted NW waves and settles at the harbor entrance due to sudden drop of wave height in the harbor.

Figure 7 shows the diffractions coefficients ( $K_D$  values) at the various points in the harbor for the NW waves.

The wave height at the head of main breakwater is 2.02 meters as seen from figure 7,  $K_D$  value at the entrance of the harbor is 0.2. At this point, wave height will be 0.40 meters. Just after entrance of the harbor  $K_D$  value drops to 0.09. This means that wave height decreases up to 0.18 meters. Due to this sudden drop of wave height, suspended sediment could not be carried by the waves any more and sediment in suspension will settle. Then entrance of the harbor shoals. Rivers in the adjacent coast discharge huge amounts of the material which considerably increases the suspended sediment.

Figure 7 - Diffraction Coefficients for NW waves

**Application of one-line Model**

The hindcasted deep water wave characteristics were transformed up to breaking point by a computer program using Goda's approach (figure 8 and 9). This program calculates breaking wave height distributions and breaking angles along the shore. Breaking wave heights, angles duration of storms, wave period, location of the coastal structures are used in the one-line shore evaluation model (Hanson, 1986). Model is calibrated by existing field measurements.

Figure 8 - Wave Refraction Diagram NNW Direction T=6 sec.

Figure 9 - Wave Refraction Diagram NE Direction  $T = 6$  sec.

For the simulation, a series run were done. Figure 10 shows shoreline variation at the west coast by the effect of NNW waves. For the same waves seawall enhanced the erosion down at the east coast (figure 11) and figure 12 shows the accretion caused by NE waves just behind the secondary breakwater.

Figure 10 - Shoreline Changes Due To NNW Waves

Figure 11 - Effect of Seawall On The Shoreline under NNW Direction waves

Figure 12 - Accretion The Behind Secondary Breakwater Due To NE Waves

Simulation with the one-line model are found to be satisfactory in the adjacent coast. Since the shoreline cannot reach equilibrium condition at the west coast, it will progress to the breakwater head and depth at the breakwater head will be -3 meter or less (figure 13).

Figure 13. - Shoreline Change by One Line Model Due To NNW Waves

Figure 13 shows the output of the model for the simulation of shoreline change in the close vicinity of the harbor. However, for the entrance as this model is inadequate, sedimentation pattern is studied analytically. Based on these studies the main reason for the siltation at the harbor entrance is found to be due to the settling of suspended sediment as explained above.

**Conclusion and Recommendation**

After identifying the causes, precautions for the sedimentation and erosion problems are again studied using the same one-line model. The effect of one groin on shoreline change at the east coast by the various direction waves is studied and shown in figure 14 and 15.

Figure 14. - The Effect of One Groin At The East Coast Due To NW Waves

Figure 15 - The Effect of One Groin At The East Coast To NE Waves

A series of precautions shown in figure 16 are recommended which include;

- i. Extension of the main breakwater with a more perpendicular direction to the shore. This aims to cross the west-east directed sediment from sedimentation.
- ii. A new secondary breakwater to provide a relatively more exposed entrance and to reduce circulation area which carries suspended load towards harbor entrance.
- iii. Groin field at the east coast which will start from the existing beach. Sand by passing from west of breakwater to the East and artificial nourishment is recommended for the groinfield.
- iv. Sand by-passing of accreted sediment from west coast to east coast periodically (When necessary)

The following symbols are used in this paper:

$(H_{1/3})_0$  = Deepwater significant wave height;

NW = North-West;

NE = North-East;

NNW = North-North-East;

$D_{50}$  = mean sediment diameter;

$K_d$  = Diffraction coefficients;

## CHAPTER 237

# A Study on Mud Mass Transport under Waves Based on an Empirical Rheology Model

Masahiko Isobe<sup>1</sup> Trien N. Huynh<sup>2</sup> and Akira Watanabe<sup>1</sup>

### Abstract

The rheological properties of mud play an important role in the motion of bed mud due to waves, currents, or combined waves and currents. In this paper, a dynamic rotary shear meter is developed to measure the shear stress in the mud under an arbitrary time history of the shear rate. Kaolinite is tested as an example of bed material and its rheology model is proposed. Another experiment is performed to confirm the predominance of the mud mass transport mode over the suspended mud transport mode in the wave-induced transport. Further experiments examine the role of pressure as an external force of the motion of the bed mud and measure some characteristics of waves on the mud bed. Finally, based on the empirical rheology model, a numerical model is developed to predict the motion of the bed mud, and resulting mud mass transport and wave damping. The calculated mud mass transport velocity and wave height change agree well with measurement.

## 1 Introduction

Muddy coasts represent a type of coastline where the bed material is mainly consists of fine grained, cohesive sediment. Typical muddy coasts are found in China, Vietnam, Indonesia, Bangladesh, Surinam, Brasil, and the United States. Siltation is a problem proper to muddy coasts where the transport mechanism of bed material is quite different from that on sandy coasts. Therefore, it is of great importance to study the transport phenomenon of mud.

The mud transport by waves and currents is separated into two modes: suspended mud transport in the water layer and mud mass transport in the bed. It is expected that the latter mode is quantitatively predominant under a wave action (Shibayama, *et al.*, 1990), but further experimental verification is still needed.

To predict the motion of bed mud and resulting mud mass transport velocity and wave damping, the rheological properties of mud should be given. Rheological models used so far are, for example, elastic, viscous, visco-elastic, visco-plastic, visco-elastic-plastic models (for example, Mei and Liu, 1987; Tsuruya *et al.*, 1987; Sakakiyama and Bijker, 1989; Shibayama *et al.*, 1990). On assuming one of the rheology models, the parameters in the model are determined by using a rotary or oscillatory viscometer, or other similar apparatuses. However, it is necessary to study the relationship between the stress and strain rate under various patterns of motion.

<sup>1</sup>Dept. of Civil Eng., Univ. of Tokyo, Tokyo 113, Japan.

<sup>2</sup>Civil Eng. Div., The Ho Chi Minh Polytechnic Univ., Ho Chi Minh City, Vietnam.

The pressure gradient and bottom friction can be external forces for the motion of bed mud. To develop a numerical model, it is necessary to investigate the dominant external force and to select an appropriate theory to estimate it.

In the following, a series of experiments performed in relation to the above issues are described. Especially in the experiment of the rheological properties of mud, a dynamic rotary shear meter is developed. Based on an empirical rheology model, a one-dimensional numerical model of the motion of bed mud is developed. Calculated mud mass transport velocity and wave height change are compared with measurements.

## 2 Rheological Properties of Mud

In the previous studies, either unidirectional rotary viscometers (Tsuruya *et al.*, 1986; Otsubo and Muraoka, 1988) or oscillatory viscometers (Mehta and Maa, 1986) were used to determine the parameters included in the assumed rheology models. However, it is necessary to examine the general behavior of mud for an arbitrary shear strain or shear rate. For this purpose, a dynamic rotary shear meter is developed in this study.

### 2.1 Dynamic, rotary shear meter

Since muds are tested at mean and high water content ratios, samples cannot stand by themselves. A new apparatus was designed and made as shown in Fig. 1. It consists of two coaxial cylinders of which the outer one is fixed and the inner one can be set in predetermined motions by controlling a stepping motor from a personal computer. The torque which results from the motion of the inner cylinder is measured by strain gages which are attached on an acrylic column supporting the outer cylinder. The gap between two cylinders is made small to ensure a uniform shear stress and the clearance below the inner cylinder is made large to minimize the end effect of the cylinder.

The calibration was performed before each test by static and dynamic loadings. The dynamic loading is performed by a sinusoidal oscillation of a mass and spring system. It was seen that a linear relation is acceptable without a significant error. To check the

Figure 1: Sketch of the dynamic rotary shear meter.

end effect, a series of tests were done for various depths of mud filled in the gap. By a linear extrapolation of the immersed depth for a null torque, the end effect was found to be equivalent to 1.5 to 2.5 mm which is negligible compared to 70 to 80 mm of the immersed depth.

## 2.2 Experimental condition

### 2.2.1 Patterns of motion

Tests were done for the following patterns of motion.

- 1 ) Pattern S: sinusoidal oscillation which represents wave loading. The amplitude is 0.5 to 8 deg. and the period 1 to 40 s.
- 2 ) Pattern A: linearly varying shear rate in a short duration as shown in Fig. 2. This examines mainly the effect of the shear rate on the shear stress. In the figure,  $T = 10$  to 200 s,  $T_s = 0$  to 20 s, and the rate of change of the shear rate is 0.05 to 1.0 deg./s<sup>2</sup>.
- 3 ) Pattern V: linearly varying shear stress in a long duration. Pattern V is similar to Pattern A but the vertical axis in Fig. 2 is the position in stead of the velocity. The parameter  $T = 100$  to 500 s,  $T_s = 10$  to 200 s, and the rate of change of the position, *i.e.*, the velocity, is 0.01 to 0.2 deg./s.
- 4 ) Pattern SV: combination of constant velocity and oscillation as shown in Fig. 3. This represents the action of combined waves and a current. The velocity is 0.5 to 2 deg./s, the amplitude 1 to 2 deg., and the wave period 1 to 20 s.
- 5 ) Pattern SC: combination of initial shear stress and oscillation as shown in Fig. 4. This examines the effect of creeping.

Figure 2: Motion of the inner cylinder (Pattern A).

Figure 3: Motion of the inner cylinder (Pattern SV).

Figure 4: Motion of the inner cylinder (Pattern SC).

### 2.2.2 Mud sample

Commercial kaolinite mixed with tap water was used in the experiments. The water content ratio was 126 to 310 %. By the combination of the motion of the shear meter and the water content ratio, the total number of experiments is more than 100.

## 2.3 Experimental result

### 1) Pattern S

Figure 5 shows the relationship between the shear stress and shear rate for sinusoidal oscillations with various wave periods and a fixed amplitude. Curves are not so smooth because the shear rate is obtained by differentiating the displacement numerically. For long wave periods, the stress increases while the shear rate is positive, which implies that the increase of shear strain results in the increase of the shear stress for small shear rates. On the other hand, for short wave periods and therefore for large shear rates, the stress tends to increase with the shear rate but hysteresis loops are formed.

### 2) Pattern A

Figure 6 shows the results for linearly varying shear rates. A hysteresis loop is formed around the origin and linear relations are found for larger magnitudes of shear rates. The path from the maximum to zero shear rate agrees with that for the Bingham fluid. This result is considered to represent general characteristics, while the results for Patterns S and SV represent parts of this path.

### 3) Pattern V

For Pattern V, after the shear rate changes its direction, the shear stress changes abruptly and then gradually approaches to a constant value.

### 4) Pattern SV

Figures 7(a) to (c) represent the results for Pattern SV in which the constant component of shear rate is smaller than, comparative to, and larger than the oscillatory component, respectively. These results can be understood as parts of Figure 6.

### 5) Pattern SC

For Pattern SC, the average stress in one wave period, which is made positive by the initial shear strain, tends to disappear because of the creeping.

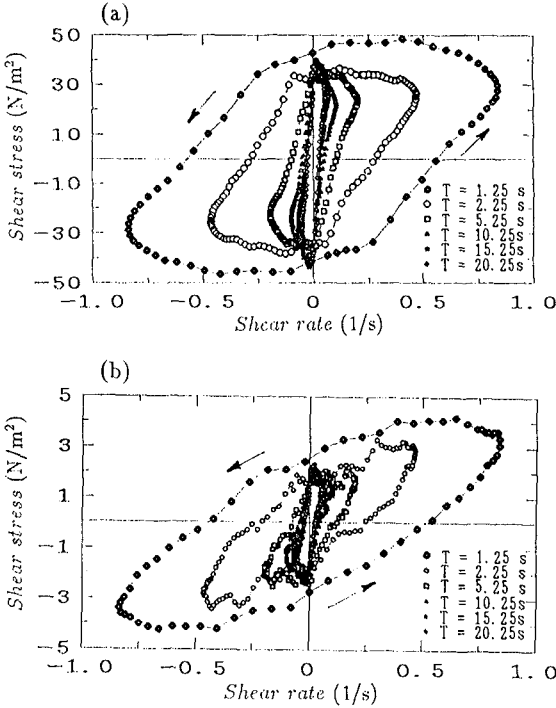

Figure 5: Relationship between shear rate and shear stress (Pattern S).

Figure 6: Relationship between shear rate and shear stress (Pattern A).

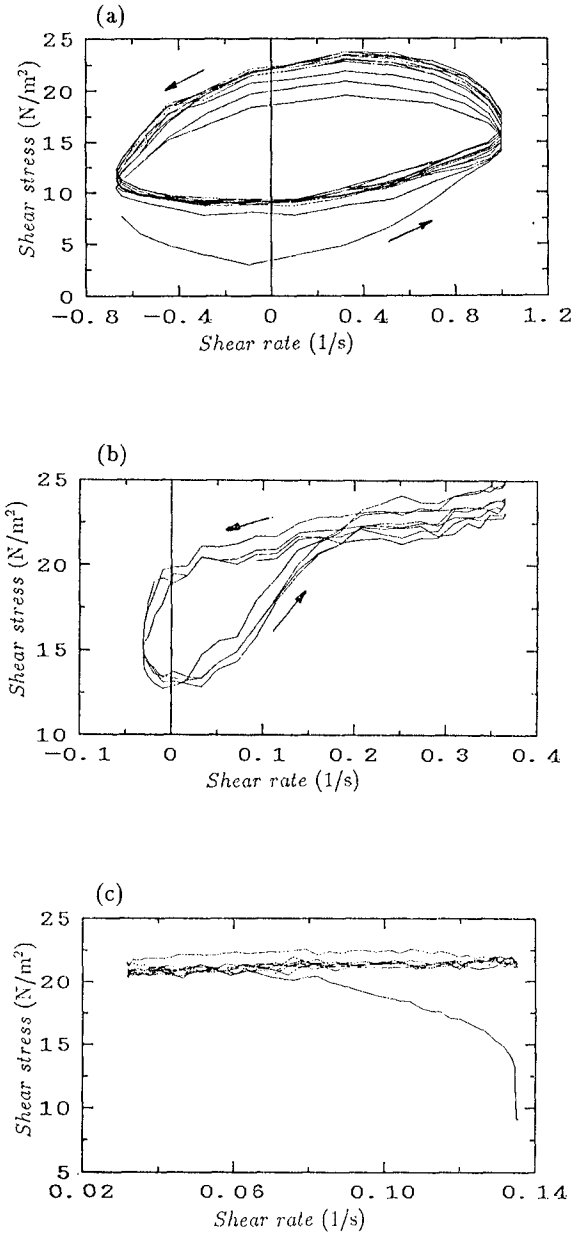

Figure 7: Relationship between shear rate and shear stress (Pattern SV).

2.4 An empirical rheology model

Based on the above experimental results, the following rheology model can be proposed. A backbone curve in Fig. 8 is first introduced:

$$\tau = \begin{cases} \text{sign}(\gamma)\tau_1(|\gamma|/\gamma_c)^n & (|\gamma| \leq \gamma_c) \\ \text{sign}(\gamma)\tau_0 + \mu_1\gamma & (|\gamma| > \gamma_c) \end{cases} \quad (1)$$

When the amplitude of the shear rate is larger than  $\gamma_c$ , the outer path in Fig. 8 is applied:

$$\tau = \begin{cases} \text{sign}(\gamma)\tau_0 + \mu_1\gamma & (|\gamma| \leq \gamma_c, \gamma(d\gamma/dt) \leq 0 \text{ or } |\gamma| > \gamma_c) \\ -\text{sign}(\gamma)\tau_0 + \mu_2\gamma & (|\gamma| \leq \gamma_c, \gamma(d\gamma/dt) > 0) \end{cases} \quad (2)$$

where  $\gamma_c$  is the critical shear rate, and  $\mu_1$  and  $\mu_2$  are viscosities when the magnitude of shear rate is decreasing and increasing, respectively. When the amplitude is smaller than or equal to  $\gamma_c$ , the inner path is applied:

$$\tau = \begin{cases} \text{sign}(\gamma)\tau_{m0} + \mu_1\gamma & (\gamma(d\gamma/dt) \leq 0) \\ -\text{sign}(\gamma)\tau_{m0} + \mu_{m2}\gamma & (\gamma(d\gamma/dt) > 0) \end{cases} \quad (3)$$

where

$$\tau_{m1} = \tau_1(\gamma_{mc}/\gamma_c)^n \quad (4)$$

$$\tau_{m0} = \tau_{m1} - \mu_1\gamma_{mc} \quad (5)$$

$$\mu_{m2} = (\tau_{m1} + \tau_{m0})/\gamma_{mc} \quad (6)$$

Figure 8: Empirical rheology model.

### 3 Mechanism of Mud Transport

Experiments are done to confirm the predominance of the mud mass transport mode, to measure some properties of waves on mud bed, and to check the importance of the pressure as an external force of the mud mass transport. A wave flume which is 1 m deep, 80 cm wide and 21 m long was used. As shown in Fig. 9, the mud bed was made 12 cm deep and 8 m long.

#### 3.1 Contribution of mud mass transport

A trench of a trapezoidal shape was made at the center of the mud bed and both sides were separated by two walls which prevent the mud mass transport and allow the suspended mud transport. Figure 10 shows the change of bottom configuration due to wave action. As can be seen, the suspended mud transport across the walls is negligible compared to the mud mass transport occurred on seaward and shoreward sides of the walls.

Figure 9: Wave flume and mud bed.

Figure 10: Transformation of trench profile.

### 3.2 Wave properties on the mud bed

#### 3.2.1 wavelength

Figure 11 compares the measured and calculated wavelengths of waves on mud bed. Curves are obtained by the small amplitude wave theory for the depth,  $d_1$ , of the water layer and the total depth,  $d$ , including the depth of mud bed. It is seen that the effect of mud bed on the wavelength is negligible and it is calculated simply from the depth of water.

#### 3.2.2 Pressure in the bed mud

Tsuruya *et al.* (1987) measured the pore pressure in the mud bed. Figure 12 compares the measured and calculated pore pressure. Curves which represent the amplitude of the bottom pressure calculated by the small amplitude wave theory agree well with the measured pore pressure.

### 3.3 Role of pressure as an external force

The gradient of the pressure and shear stress on the bed can be external forces for the bed mud motion. Comparative experiments were done to check the predominance of the pressure. In one experiment, the bed is covered with a nylon sheet which transmits the pressure and at least modifies the shear stress on the bed although it may not cut off completely. The other experiment was done without the cover. Figure 13 compares the wave height decay due to the motion of mud bed with and without the nylon cover. For a wide variety of the incident wave height, the wave height distributions are almost the same, which implies that the pressure gradient due to the wave motion is the dominant external force for the mud motion.

Figure 11: Wavelength of waves on mud bed.

Figure 12: Pore pressure in mud bed.

Figure 13: Effect of nylon cover on wave damping.

#### 4 Numerical Model of Mud Mass Transport

##### 4.1 Oscillatory motion of mud

A numerical model was developed based on the rheology model proposed above.

On assuming that the horizontal length scale is much longer than the vertical scale, the horizontal motion of the bed mud is analyzed as a one-dimensional problem in which the gradient of the pressure is given as the external force. The equation of motion for the velocity,  $u = u(z, t)$ , of the mud is

$$\rho_m \frac{\partial u}{\partial t} = -\frac{\partial p}{\partial x} + \frac{\partial \tau}{\partial z} \quad (7)$$

where  $p$  is the pressure,  $\tau$  the shear stress,  $\rho_m$  the density of the mud,  $x$  and  $z$  the horizontal and vertical coordinates, and  $t$  the time. The pressure is given as the bottom pressure predicted by the small amplitude wave theory. By substituting the shear rate,  $\gamma = \partial u / \partial z$ , into the empirical rheology model proposed above, the shear stress is expressed in terms of  $u$ . Thus, the above equation becomes a closed governing equation for  $u$ . The boundary conditions are the non-slip condition at the bottom of the mud bed and zero shear stress on the bed:

$$u(0, t) = 0 \quad (8)$$

$$\tau(d, t) = 0 \quad (9)$$

Considering the above boundary conditions, the mud layer is divided into  $(N+1/2)$  equal-distance sublayers in discretizing the governing equation. The quantity  $u$  is defined at 0 to  $N$  levels, while  $\tau$  at  $1/2$  to  $N+1/2$  levels. The numerical calculation is continued until a periodic solution is obtained.

## 4.2 Wave damping

The wave damping occurs due to the work done through the shear stress in the mud. The equation of the wave energy is

$$\frac{d}{dx}(EC_g) = -D \quad (10)$$

where  $E = \rho g H^2 / 8$  ( $\rho$ : the density of water,  $g$ : the gravitational acceleration,  $H$ : the wave height) is the wave energy density,  $C_g$  the group velocity, and  $D$  the energy dissipation rate which is estimated by

$$D = \int_0^d \tau \frac{\partial u}{\partial z} dz \quad (11)$$

From Eq. (11), the coefficient,  $D_H$ , of the wave height damping is expressed as

$$D_H \equiv -\frac{1}{H} \frac{dH}{dx} = \frac{1}{2} \frac{D}{EC_g} \quad (12)$$

## 4.3 Mud mass transport

The total mud mass transport velocity,  $U$ , is obtained as the sum of the Eulerian mass transport velocity,  $U_E$ , and the Stokes drift,  $U_S$ :

$$U = U_E + U_S \quad (13)$$

By introducing the average viscosity,  $\mu_{ave}$ , in one wave period, the Eulerian mass transport velocity is calculated from the average momentum equation:

$$\mu_{ave} \frac{\partial^2 U_E}{\partial z^2} = \frac{\partial \overline{\rho_m u^2}}{\partial x} = -2D_H \overline{\rho_m u^2} \tag{14}$$

for which the boundary conditions are

$$U_E = 0 \quad (z = 0) \tag{15}$$

$$\frac{\partial U_E}{\partial z} = 0 \quad (z = d) \tag{16}$$

The Stokes drift can be calculated by

$$U_S = \frac{\partial u}{\partial x} \int u dt = \overline{\left( -\frac{1}{C} \frac{\partial u}{\partial t} - u D_H \right) \int u dt} \tag{17}$$

**4.4 Comparison between calculation and experiment**

Four series of experiments were done for the water content ratios of 132, 171, 223 and 379 %. In each series, the mud mass transport velocity was measured for one case and the wave height distribution was measured for various incident wave periods and heights. The mud mass transport was measured by the same procedure as Sakakiyama and Bijker (1989). Figure 14 and 15 show examples of comparison between the calculated and measured wave height distribution and vertical profile of the mud mass transport velocity, respectively. Figure 16 compares the calculated and measured damping coefficients as a function of the wave period (frequency). The agreements are generally good.

Figure 14: Comparison between calculated and measured wave damping.

Figure 15: Comparison between calculated and measured vertical profiles of the mud mass transport velocity.

Figure 16: Comparison between calculated and measured damping coefficients.

## 5 Conclusion

The rheological properties of mud are studied by a dynamic rotary shear meter which was designed and made to measure the shear stress under an arbitrary change of shear rate. Experiments are done to confirm the predominance of the mud mass transport mode, the validity of the small amplitude wave theory for predicting wave characteristics and the predominance of the pressure as an external force of the mud motion. Based on the proposed empirical rheology model, a numerical model is developed to simulate the motion of bed mud due to wave action. Comparisons with the measurements show good agreement both for the vertical profile of the mud mass transport velocity and for the wave height damping.

In the future study, the parameters used in the rheology model should be formulated as a function of the water content ratio. In addition, bed materials other than kaolinite should be tested. In the present study, the pressure is assumed to be uniform vertically throughout the bed since its thickness is small enough. However, the vertical motion and consolidation process should be taken into account for analyzing the motion of the bed mud of a large depth.

## CHAPTER 238

### SETTLING PROPERTIES OF COHESIVE SEDIMENTS IN A COOLING WATER INTAKE BASIN

Susumu Kanayama <sup>1</sup>, Takuzo Shimizu <sup>1</sup> and Kazuhiro Ueki <sup>2</sup>

#### ABSTRACT

In the present study, with the ultimate objective of developing a numerical model of siltation in a cooling water intake basin of a power plant, the settling velocities of non-uniform sediments are investigated using the settling tube tests. The critical shear stress for deposition of suspended silt and the vertical concentration profile of suspended sediments are investigated on the basis of field data. The deposition rate as well as the grain size distribution of deposited sediments were reproduced satisfactorily by a one-dimensional model.

#### INTRODUCTION

In a power plant basin used for both the intake of cooling water and the navigation channel, siltation usually occurs and a silty area is created inside the harbor, even if the basin is sited in a sandy coast. Cohesive fine sediments are suspended by the wave action outside the harbor under the severe wave conditions and transported by the intake flows through the entrance into the harbor. Most of the inflow fine sediments are settled and deposited on the bottom in a tranquil area inside the harbor.

Figure 1 shows the location map and the layout of the investigation site. The

investigation site is the harbor basin of Fukushima No.2 Nuclear Power Plant and is located in Fukushima Prefecture, Japan, facing directly the Pacific Ocean. The spatial distribution of the median grain diameters of deposited sediments in the basin is also shown in this figure. A large portion of the basin is occupied by fine sediments with the median diameter below  $100\ \mu\text{m}$ , although the surrounding coast consists of fine sands with the median diameter of approximately  $200\ \mu\text{m}$ . The median grain diameters decrease along the streamline of the intake flow. In the course of transportation and deposition, sediment sorting due to difference of settling velocities occurs because the suspended fine sediments are composed of a wide range of grain sizes approximately from  $1$  to  $100\ \mu\text{m}$ . Consequently, the median grain sizes of deposited sediments show a wide range of spatial distribution from about  $200\ \mu\text{m}$  in the sandy area around the entrance to  $20\ \mu\text{m}$  in the tranquil area near the intake channel.

In developing a numerical model for simulating siltation in such a cooling water intake basin, detail understanding of the depositional properties of non-uniform cohesive sediments is the first subject to be solved. In this study, we aim to discuss about a proper method for estimating the deposition rate by taking into account the effects of flocculation and nonuniformity of the grain size on the basis of the laboratory experimental data and the field measurement data.

## DEPOSITION RATE

One of the well-known expressions for the deposition rate  $D$  is described as follows (e.g. Nicholson and O'Conner, 1987) :

$$D = C_b w_b \left( 1 - \frac{\tau}{\tau_d} \right), \quad \text{for } \tau < \tau_d \quad (1)$$

where  $C_b$  is the near bottom concentration,  $w_b$  the near bottom settling velocity,  $\tau$  the bottom shear stress, and  $\tau_d$  the critical shear stress for deposition. According to this expression, the deposition rate is regarded as the product of three factors; 1)the suspended sediment concentration near the bottom, 2)its settling velocity and 3)the probability of particles sticking to the bed which is described as  $( 1 - \tau/\tau_d )$  in eq. (1).

It is well recognized that the settling velocity of cohesive fine sediments is influenced sensitively by the suspended sediment concentration owing to the effect of flocculation. In the present study, the laboratory experiments in a settling tube were carried out in still water to examine the influence of concentration on the settling velocity of non-uniform sediments.

In depth-integrated models which are widely used for simulating the behavior of suspended particles, the near bottom concentration is to be evaluated from the depth-averaged concentration. Therefore, the vertical concentration profile should be determined for numerical calculation. Also the critical shear stress for deposition  $\tau_d$  is a very important parameter for estimating the depositional rate. In this study, the vertical concentration profiles for different grain sizes and the critical depositional shear stress are evaluated through comparisons between the calculated results and the field data.

## SETTLING VELOCITY

The settling velocities of non-uniform sediments were investigated by the settling tube tests. The sediments used in the tests were sampled from the seabed in the tranquil area of the investigation site. The median grain diameter was 23  $\mu\text{m}$  after passing through a sieve with 106  $\mu\text{m}$  openings. The cation exchange capacity was 27 (meq/100g), and a large portion of absorbed cation was occupied by  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ .

The inner diameter of the settling tube was 27 cm, and the available water depth was 95 cm. Saline water with a temperature of 20°C was used as the settling medium. Sediments were initially stirred to create a state of homogeneous suspended sediment concentration in the tube. The water samplings and the

concentration measurements were conducted six times after 3, 8, 25, 90, 180 and 420 minutes from the start of the test, and the sampling mouth was set at the water depth of 60 cm.

The time series of concentration were transformed to the settling velocity curve. The grain-size distributions were also analyzed by the laser diffraction method after breaking the flocs. Then, the settling velocity curves were obtained for every grain-size class.

Figure 2 shows the relationships between the median settling velocity  $w_{50}$  of each grain-size class and the initial total concentration. It is recognized that in the case of low concentration,  $C < 200$  mg/l, the settling velocity is independent of concentration and can be evaluated by the Stokes law. In the case of  $200 \leq C \leq 2000$  mg/l, the settling velocity increases exponentially with concentration and the following general formula can be used:  $w = kC^m$  ( $k$ : empirical constant,  $m$ : empirical exponent). The settling velocity reaches the equilibrium value of 0.19 (cm/s) for each grain-size class at a concentration of approximately 2000 mg/l.

These tendencies are observed only for the grain-size classes with the median diameter below 48  $\mu\text{m}$ . For the larger grain-size classes, dependence of settling velocities on concentration can not be observed. According to these results, the settling velocity of suspended sediments is formulated as a function of grain size and total concentration as shown in Figure 3. The critical median diameter, 48  $\mu\text{m}$ , above which flocculation is negligible, corresponds to the equilibrium settling velocity of 0.19 cm/s. It should be noticed that these quantities are regarded as local factors which are inherent in the sediment properties of the investigation site. The range of concentration for flocculated settling obtained in this study corresponds to the results of the previous studies (e.g. Ross and Mehta, 1989).

## VERTICAL CONCENTRATION PROFILE AND PROBABILITY OF DEPOSITION

The vertical concentration profile and the probability of deposition were investigated on the basis of field data. The critical shear stress for deposition and the reference level at which the near bottom concentration was defined were evaluated through comparisons between the cumulated depositional fluxes calculated from the measured time histories of concentration and the measured weights of the deposited sediments in the traps.

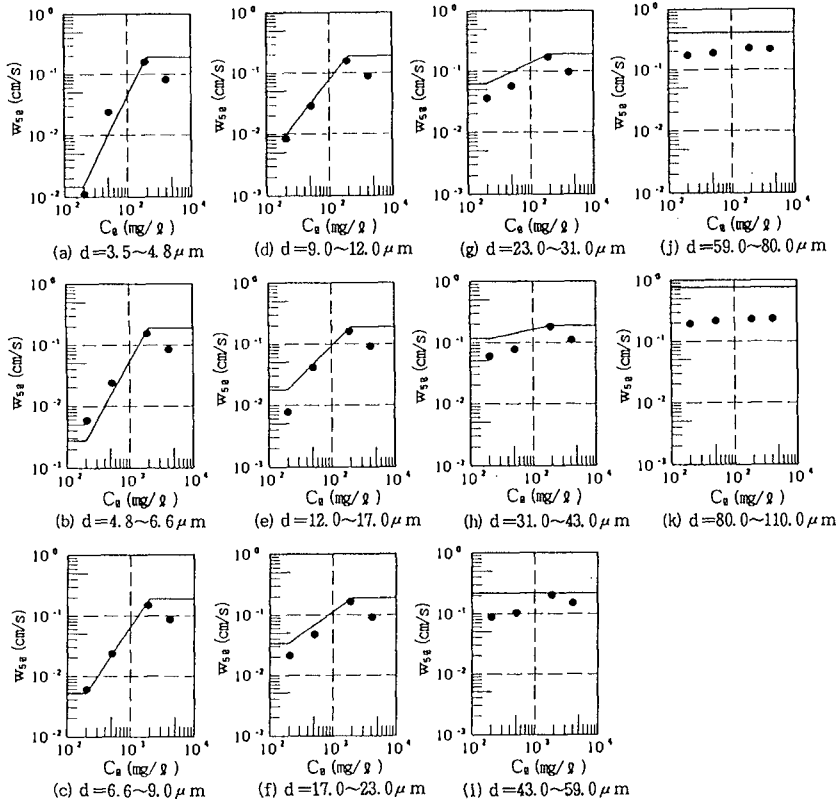

Fig. 2. Relationships between settling velocity of each grain-size class and concentration.

**Outline of Field Data**

An intensive field investigation was carried out in the harbor basin of Fukushima No.2 Nuclear Power Plant over a period of approximately two months from July to September in 1989 (Shimizu et al., 1990). Figure 4 shows the arrangement of observation points. Among them, three points are concerned in the discussion here. They are point A-2 in the sandy area at the harbor entrance with a median grain diameter of about  $150 \mu\text{m}$ , point A-6 in sand-silt coexisting area with a median grain diameter slightly below  $100 \mu\text{m}$  and point A-8 in the silty area with a median grain diameter of approximately  $50 \mu\text{m}$ .

A synchronized combination of an ultrasonic wave gauge and an electro-magnetic current meter with a pressure gauge and a turbidity meter were placed at each of the above three observation points. Hourly time histories of suspended sediment concentration at 1.5 m above the bottom together with the wave height and near-bottom flow velocity were measured simultaneously. At point A-8, another turbidity meter was set at 3.0 m above the bottom in addition to the one at 1.5 m, so that the ratio of concentrations measured at these two elevations could provide the information about the vertical concentration profile.

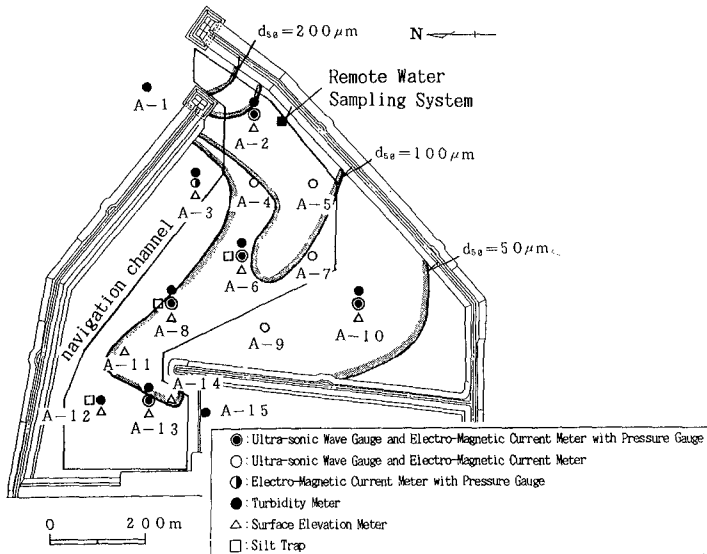

Fig. 4. Location of observation points.

Two types of silt traps were set at points A-6 and A-8, to obtain direct measurements of the weight and the grain-size distribution of newly deposited silt. The photograph of silt traps are shown in Figure 5. Type-A has a trapping mouth at almost the same elevation as the sea bottom, and Type-B has its mouth at 0.3 m above the bottom. The traps were set in pipe lattices so as to trap only the suspended silt falling down into the bed.

Fig. 5. Photograph of silt traps ( Type A and Type B ).

Fig. 6. Photograph of remote water sampling system.

At point A-2, remote water samplings were conducted during severe wave conditions by a newly developed apparatus shown in Figure 6. Figure 7 shows the grain size distribution of suspended silt measured at point A-2 by this apparatus. This will be used as the boundary condition for simulation of grain size sorting, to be discussed later.

Fig. 7. Grain size distribution of suspended silt at harbor entrance.

### Vertical Concentration Profile

The vertical concentration profile should be determined in order to evaluate the bottom concentration  $C_b$  from the measured concentration at 1.5 m above the bed. In the present study, the vertical concentration profile is assumed to have an exponential form as shown in Figure 8:

$$C(z) = C_\delta \exp\left(-\frac{w}{u_* \kappa \delta}(z - \delta)\right) \quad (2)$$

where  $C(z)$  is the concentration at elevation  $z$  above the bed,  $C_\delta$  is the concentration at the reference level  $\delta$ ,  $w$  the settling velocity of suspended sediment corresponding to the depth averaged concentration, and  $\kappa$  the Karman constant. The bottom concentration is assumed to be equal to  $C_\delta$ . In this expression, the eddy viscosity  $u_* \kappa \delta$  is regarded as vertically constant and proportional to the friction velocity.

By assuming this profile, the concentration related to each grain-size class at 1.5 m above the bed can be estimated using the corresponding settling velocity, and the total concentration at this elevation can be also estimated as the sum of the contributing components. Then,  $C_\delta$  can be determined by comparing the estimated total concentration with the measured one at 1.5 m elevation. However, in estimating the total concentration, the information is needed about the grain size distribution of the suspended sediments at the point of interest.

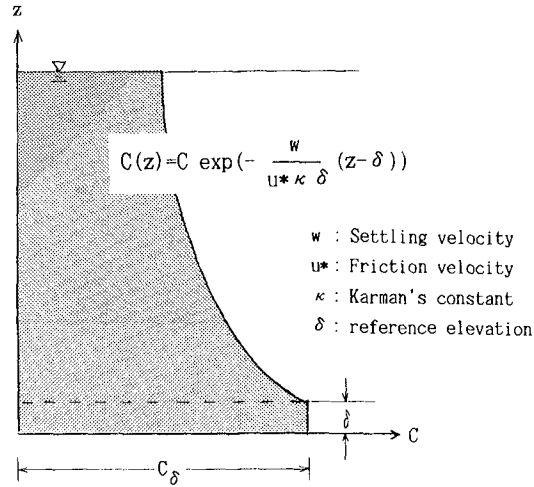

Fig. 8. Assumption of vertical concentration profile.

In the present study, the grain size distributions at points A-6 and A-8 were estimated by a simple numerical model of sediment sorting along the streamline as introduced in the following section. It should be mentioned that in the above calculations, the measured concentration at 1.5 m above the bed has been used as the depth-averaged concentration for estimating the settling velocity in eq.2).

**Sediment Sorting Simulation by One-dimensional Model**

In this study, a one-dimensional depth-integrated model is employed for calculation of sediment sorting. The harbor is regarded as a simple channel along the streamline of intake flow as shown in Figure 9. The channel is divided into 23 grids with an interval of 50 m on the main streamline. Assuming the quasi-equilibrium state and neglecting the diffusion term, the mass conservation of suspended silt for a certain grain-size class is described as follows.

$$u \frac{\partial C}{\partial x} = -\frac{w_b C_{\delta}}{h} \left(1 - \frac{\tau}{\tau_d}\right) \tag{3}$$

where  $C$  is the depth-averaged concentration,  $h$  is the water depth and  $u$  is the current velocity.

Fig. 9. One-dimnsional modelling of harbor along streamline.

The near bottom concentration  $C_\delta$  is evaluated from the depth-averaged concentration  $C$  by using eq. (2). At each grid, the value of  $C_\delta$  calculated for its preceding grid is used. The settling velocity  $w_b$  on the bottom ( exactly at the elevation  $\delta$  ) is evaluated by the relationship between the diameter of each grain-size class and the total concentration as indicated in Figure 3.

The wave height at each grid is computed by multiplying the diffraction coefficient, calculated in advance, by the measured incident wave height at the harbor entrance. The depth-averaged current velocity is estimated by dividing the intake discharge by the cross-sectional area of each grid. The bottom shear stress at each grid is then evaluated by the friction law for the wave-current coexistent field proposed by Tanaka and Shuto(1981). The measured time history of concentration is given as the boundary condition at the grid No. 3 which corresponds to point A-2. The concentration for each grain-size class at the boundary is given according to its ratio based on the grain size distribution measured at point A-2 during the severe wave conditions as shown in Figure 7.

### Determination of Critical Shear Stress and Reference Level

According to the above procedure, the deposited weights and their grain size distributions at points A-6 and A-8 can be estimated by using the assumed values of  $\tau_c$  and  $\delta$ . The objective here is to find the appropriate values for these parameters which provide the best agreement between calculations and measurements.

However, the effects of these parameters on calculation results are not so simple. The increase of  $\tau_d$  has both effects of increasing the deposition rate owing to the increase in probability of deposition and of decreasing it because of the increase in the deposition rate in the upstream region. The decrease of  $\delta$  has the same effects as those caused by the increase of  $\tau_d$ .

Table 1 shows the measured and the calculated results of deposited weights in the traps at points A-6 and A-8. Three couples of  $\tau_d$  and  $\delta$  listed in the table were selected in order to reproduce the deposited weight at point A-8. By using two of these couples, the deposited weight at point A-6 could also be well reproduced at point A-6.

Figure 10 shows the comparisons between the measured and calculated grain size distributions of trapped silt at points A-6 and A-8. The grain size distribution at point A-6 is reproduced well by setting  $\tau_d$  and  $\delta$  equal 0.4 (Pa) and 3.0 (cm), respectively. At point A-8, on the other hand, the grain size distribution could not be reproduced satisfactorily. In general, judging from these results, it is concluded that the most appropriate values for  $\tau_d$  and  $\delta$  are respectively 0.4 (Pa) and 3.0 (cm).

Figure 11 shows the time histories of the measured significant wave height, the estimated bottom shear stress, the measured concentration, the vertical ratio of concentration, the calculated mean grain diameter and the calculated weights of trapped silt at points A-6 and A-8 with  $\tau_d = 0.4$  (Pa) and  $\delta = 3$  (cm). During the observation period, storm waves attacked twice, with the peak significant wave heights of 5.0 m and 3.8 m, respectively. During these stormy periods, considerable deposition occurred. As shown in this figure, the trapped weight of Type-B which has the mouth at 0.3m above the bed could be also reproduced by considering the concentration at 0.3 m above the bottom as the bottom concentration. It is also observed that the calculated time history of the ratio of concentration at 3m above the bottom to that of 1.5 m at point A-8 agrees reasonably well with the measurements.

Table 1. Comparison between measured and calculated weights of trapped silt.

$\tau_d$ (Pa)	$\delta$ (cm)	Trapped Weight (kg)	
		A-6	A-8
0.7	2.0	2.6	4.0
0.4	3.0	3.5	4.3
0.2	2.5	5.4	4.0
Measurement		3.0	4.2

CONCLUDING REMARKS

The settling process of nonuniform cohesive sediments in a cooling water intake basin was investigated on the basis of laboratory experiments and field measurements. The settling velocity was formulated empirically as a function of the grain-size and the total concentration by taking into account the effect of flocculation. The critical shear stress for deposition and the vertical concentration profile were also evaluated through comparisons with field measurements. A numerical model was developed to simulate the transportation and deposition of nonuniform sediments in the basin. The deposition rate as well as the grain size distribution of deposited sediments were reproduced satisfactorily by this model.

## ACKNOWLEDGEMENTS

We would like to express our deep appreciation to Prof. Horikawa, president of Saitama Univ. , Prof. Watanabe and Prof. Isobe, Univ. of Tokyo and Associate Prof. Mimura, Ibaragi University. Our thanks are extended to Mr. Kajima and Mr. Sakakiyama of the Central Research Institute of Electric Power Industries for their useful discussions.

## CHAPTER 239

### **Sediment Transport Modelling in a Macrotidal Estuary : do we need to account for Consolidation Processes ?**

Pierre Le Hir and Nancy Karlikow<sup>1</sup>

#### **Abstract**

In order to investigate the role of consolidation processes on the sediment transport in a macrotidal estuary, a simple vertical model of fluid mud consolidation has been coupled to a cross-averaged sediment transport model in the Loire estuary. Simulations show that sediment patterns (turbidity maximum and fluid mud location) are few dependent on consolidation. On the other hand, the consolidation influences the residual deposition after a spring/neap tidal cycle and thus the net transport of sediment through the estuary. It is pointed out that consolidation is in competition with turbulence damping so that both processes have to be considered when predictive simulations are wanted.

#### **Introduction**

The transport of cohesive suspended sediment in a macrotidal estuary is dominated by the occurrence of a turbidity maximum, either due to tidal asymmetry or to density gradients, which partly traps material flowing through the estuary (Allen *et al.*, 1980 ; Nichols and Biggs, 1985).

Besides, many large estuaries are known for their patterns of fluid mud constituted by the deposition of suspended sediment after spring tides, where the turbidity maximum lies. This fluid mud consolidates more or less and then can either be resuspended during the increasing tidal

---

<sup>1</sup> Ifremer, Centre de Brest, B.P. 70, 29280 Plouzané, France.

amplitude or remain as consolidated mud until a larger hydrodynamical forcing occurs. Even if the process is well known, it has rarely been quantified and/or modelled.

The aim of this study is to see how consolidation processes affect the results of suspended sediment transport in order to get tracks of whether and how much one should account for it. More precisely, by means of a mathematical model, we would try to answer the following questions :

- Are the sediment patterns (turbidity maximum and fluid mud) affected by consolidation processes ?
- Is the (long term) sediment transport dependent on consolidation ?
- How accurate should be the consolidation modelling, when computing the transport of cohesive sediment in a macrotidal estuary ?

### **Consolidation modelling**

Many factors can influence the erosive behaviour of a sediment and its consolidation. In particular, the role of biological processes as bioturbation or surficial protection by mucilage have been pointed out (Montague, 1986 ; Paterson *et al.* 1990). Also waves can induce some fluidization of the mud, and thus modify its erodibility without changing its concentration. But in the area of a turbidity maximum within an estuary, these processes are weak : waves are small if compared with the water depth and biota are poor, due to high turbidities. Thus the sediment concentration remains a good parameter to represent the degree of consolidation providing an empirical relationship with the shear strength  $\tau_c$ , the usual parameter for mud erosion (see Mehta *et al.*, 1989).

### **Brief review**

Previous mathematical models for consolidation were mostly empirical when coupled with sediment transport models, for saving computing costs. In first models (Ariathurai and Krone, 1976 ; Onishi, 1982) the soil was discretized in layers of given thicknesses, with

characteristic shear strengths. The exchanges between layers were forced by the deposition rate.

For Teisson and Latteux (1986) the layers were characterized by a given residence time of sediment and naturally a specific shear strength. Hayter (1986) developed a more sophisticated model and considered the time variations of bed density and shear strength according to typical measured profiles. Le Hir *et al.* (1989) introduced a differential law for the bed density variations, allowing any empirical formulation.

All these models could not directly fit the consolidation theories because of the discretization in thick layers. But the performance of new computing facilities allows the required refinement to account for these theories.

### *Consolidation theories*

Two types of conceptual models have been developed (see Alexis *et al.*, 1992).

- The "sedimentation" models express the mass conservation of the solid particles, with vertical exchanges represented by the settling fluxes. A common assumption of this approach is the unique dependence of the settling velocity  $v_s$  on the local suspension density (Kynch, 1952). The usual state variable of these models is the dry density or concentration  $c$ , and the equation can be written :

$$\frac{\partial c}{\partial t} + V(c) \frac{\partial c}{\partial \zeta} = 0 \quad (1)$$

$$\text{where } V(c) = v_s + c \frac{dv_s}{dc}$$

$\zeta$  : vertical coordinate

$t$  : time

- The so-called "consolidation" models account for the mass conservation of pore water and relate its expulsion between particles to the pressure vertical gradient by means of the permeability  $k$ , assuming Darcy's law. From the dynamics point of view, the stress within the soil

can be split into the effective stress ( $\sigma'$ ) on the grains and the pore pressure on the fluid: only the latter forces the water movement. This concept is the basis of geotechnicians' approach for which the void ratio  $e$  is the state variable. When combined with water mass conservation, it leads to Gibson's equation (Gibson *et al.*, 1967), assuming constitutive relationships for permeability and effective stress as a function of the void ratio:

$$\frac{\partial e}{\partial t} - \frac{\gamma'_s}{\gamma_w} \frac{dk_r}{de} \frac{\partial e}{\partial z} + \frac{1}{\gamma_w} \frac{\partial}{\partial z} \left( k_r \frac{d\sigma'}{de} \frac{\partial e}{\partial z} \right) = 0 \quad (2)$$

where  $k_r = k / (1 + e)$  : relative permeability  
 $\gamma'_s$ : immersed unit weight of particles  
 $\gamma_w$ : unit weight of pore water  
 $z$ : material coordinate, representing the thickness of solid particles.

Recently, several authors (Been, 1980, Tan *et al.*, 1990 in Alexis *et al.*, 1992; Toorman and Berlamont, 1991) have pointed out the analogy of these models and proposed unifying theories where the settling velocity can be expressed as a function of the permeability and the effective stress.

The main problem of these theories is the validation of the involved constitutive relationships ( $v_s(c)$ ,  $k(e)$  or  $\sigma'(e)$ ), to which models are very sensitive (see Alexis *et al.*, 1992). Besides, in the present study, the role of effective stresses has a minor importance, as we are mainly dealing with fluid mud and fresh deposit. Thus we choose the sedimentation concept, with the formalism of consolidation models, that is material coordinate  $z$  and void ratio  $e$ . The continuity equation, which can be deduced from (2) with  $\sigma' = 0$ , is written :

$$\frac{\partial e}{\partial t} + \frac{dv_s}{de} \frac{\partial e}{\partial z} = 0 \quad (3)$$

The use of discretized material coordinates prevents the exchanges of material between layers during the consolidation, which is interesting to avoid spurious numerical diffusion, especially when we look for the becoming of marked fractions of sediment.

The fundamental assumption of this simple model is the dependence of the settling velocity on the void ratio, which is equivalent to the Kynch's hypothesis. Nevertheless, such a model can fit rather well many settling tests after appropriate calibrations. In particular it can reproduce steps in density profiles (lutoclines) just by means of strong variations of the derivative  $dv_s/de$ , which are likely to correspond to changes of the soil structure.

### Modelling the Loire estuary

The summer configuration of the Loire estuary, on the Atlantic coast of France has been chosen to test the effects of consolidation. This estuary is about 100 km long (fig. 1), with a tidal range of 5 m on spring tides and a fresh water flow varying from 80 to 5 000  $m^3.s^{-1}$  (average : 800  $m^3.s^{-1}$ ). In the case of low river flow (100-400  $m^3.s^{-1}$ ) a 1-D cross-averaged advection/dispersion model has proved its efficiency in simulating a realistic turbidity maximum, induced by tidal propagation only (Le Hir and Karlikow, 1991). In particular the settling of the turbidity maximum as fluid mud on neap tides and the resuspension of this fluid mud when the tidal range increases was quite well reproduced.

Figure 1: Location of the Loire estuary.

However, consolidation was very crudely accounted for : only two sediment classes (a little concentrated "fluid" mud and a more concentrated mud) were considered, and consolidation was represented as periodic exchanges between these classes.

In the present study, consolidation is computed by means of the previously described sedimentation model, coupled with the horizontal transport model through the deposition and erosion terms. The latter is empirically related to a shear strength which is deduced from the surficial mud concentration according to a power law (Owen in Mehta *et al.*, 1989) :

$$\tau_{ce} = \alpha C_s^\beta \quad (4)$$

$\tau_{ce}$  : critical shear stress for erosion ( $N.m^{-2}$ ).

$C_s$  : surficial sediment concentration, computed by the sedimentation model ( $kg.m^{-3}$ ).

$\alpha, \beta$  : coefficients to be calibrated.

Actually the results are very sensitive to this relationship which is part of the consolidation modelling ; moreover, there can be some compensation between the uncertainty on the computed concentration (however easier to validate) and the lack of knowledge related to the shear strength, especially for fluid mud. Last but not least, the bottom shear stress itself is poorly determined, as the effects of turbulence damping by high suspensions (Teisson *et al.*, 1992) are not accounted for.

Figure 2: Evolution of sediment density profiles  
(initial height : 2 m ; initial concentration : 20 g/l)  
a) laboratory settling tests with sediment from Loire  
(after Gallenne, 1974).  
b) Simulation with a sedimentation model.

Nevertheless, the sedimentation model has been briefly calibrated with laboratory settling tests made by Gallenne (1974) on the Loire sediment. Although the observations proved the dependence of the sedimentation on the salinity, which is not accounted for by the model, the simulated results are in relative agreement with the experiments (fig. 2). Settling velocities at the beginning of the settling tests have been reduced, in order to maintain low densities (very fluid mud) during the neap tide in the simulations of the Loire system. The resulting relationship  $v_s$  (e or c) is plotted on figure 3 : one can see some continuity with known values of settling velocities for flocculated suspensions (e.g. in Metha *et al.*, 1989).

**settling velocity (m.s<sup>-1</sup>)**

Figure 3 : relationship  $v_s$  (e) used in the sedimentation model of the Loire estuary. The relation between e and c is based on a grain density of 2,65.

In the following, four runs will be compared to show the effect of consolidation on sediment transport in the Loire estuary.

- Run 1 : no consolidation, any deposited sediment has a fixed low shear strength (0,8 N.m<sup>-2</sup>).

- Run 2 : schematic consolidation : two sediment classes with low and high shear strengthes (respectively 0,8 and 1,6 N.m<sup>-2</sup>).

- Run 3 and 4 : full consolidation modelling, as previously described.

The difference between run 3 and run 4 is a change in the relationship

- $\tau_{ce}(C_S)$  : - run 3 :  $\tau_{ce} = 0,14 C_S^{0,4}$  for which resuspension is easy.

- run 4 :  $\tau_{ce} = 0,2 C_S^{0,4}$  leading to hard resuspension .

For each run the tide conditions and river flow are identical, and presented on figure 4.

Figure 4 : Tidal forcing and riverflow regime during the simulation of sediment transport in the Loire estuary.

**Note :** a test with no shear strength of the (fluid !) mud has been run. In this case the turbidity patterns are completely unrealistic, with a turbidity maximum at the sea boundary and no stable mud deposit on neap tide. In fact such a result can be induced by the absence of turbulence damping in the model. In reality the latter process could maintain a fluid mud in the estuary. This comment has little impact on the following tests : in fact we are dealing with the consolidation process, that is a change in space and time of sediment characteristics, rather than the rheological behaviour of the mud. Besides, the low value of the exponent in the relation (4) partly accounts for the turbulence damping, as it reduces the large resuspension that would occur for low surficial sediment densities.

### Effects of consolidation processes on the sediment transport in the Loire estuary

On figure 5, the average distribution of suspended sediment during a spring tide for a low river flow is presented for each run. The analogy between the simulated turbidity maxima is obvious. Differences only appear in the extension of the turbidity structure which is more spread when consolidation is badly accounted for, especially in the upper part of the estuary ; this is due to the fact that in such cases, just after deposition, the sediment get instantaneously some shear strength, whereas in a more

realistic scenario, it should not have time to consolidate before the flow is strong enough to resuspend it. The same observation can be made for the total deposited mud (fluid mud and partially consolidated mud) on the following neap tide (fig. 6) : locations are similar but the deposition in the upper estuary is higher for run 4 (consolidation is more effective).

Figure 5 : Computed turbidity maximum (tidally averaged) after 46 days simulation (spring tide ; low river flow =  $200 \text{ m}^3 \cdot \text{s}^{-1}$ ).

Figure 6 : Computed mud deposits (tidally averaged) after 52 days simulation (neap tide ; low river flow).

Considering the time variation of suspended particulate matter (SPM) and mud deposit in the middle of the estuary during a fortnightly tidal cycle (fig. 7), we still notice a similitude between the four runs, but the phase of resuspension is strongly dependent on the consolidation modelling. In particular, in run 4, consolidation is quick enough to prevent the total resuspension, and a net deposition after the neap/spring tidal cycle is observed. However the range of mud deposition as well as

suspended particulate matter are very similar. It should be noticed that the maximum of SPM does not occur on spring tide but during the mean tides, when exchanges with bottom are maximum. The differences between the minima of SPM at high water during spring tides can be related to the variations of turbidity spreading we mentioned before, as the observation is located on the upstream edge of the turbidity maximum at high water.

Figure 7 : Time evolution of suspended particulate matter and mud deposit, computed at station "Le Pellerin" (low river flow).

When the river flow is increased, all sediment patterns are shifted downstream (fig. 8 ; Le Hir and Karlikow, 1991). Turbidity maxima still

look like each other, but the ranges can differ, due to possible previous consolidation. This is pointed out on figure 9 : when consolidation effects are more effective (run 4) some sediment previously deposited during the period of low river flow remains in the upper estuary, which notably reduces the seaward transport of material, at least for mean river flow. Thus the consolidation can affect the residual flux of sediment within the estuary during the seasonal changes.

Figure 8 :  
 Computed turbidity maximum (tidally averaged) after 104 days simulation (spring tide ; mean river flow =  $500 \text{ m}^3 \cdot \text{s}^{-1}$ )

Figure 9 :  
 Computed mud deposits (tidally averaged) after 110 days simulation (neap tide ; mean river flow).

## **Discussion and conclusions**

The simulation of sediment transport in the Loire estuary shows that both turbidity maximum and fluid mud patterns are few dependent on consolidation processes.

However the consolidation influences the time lags between hydrodynamical forcings and sediment processes : for instance within the fortnightly cycle, for the sediment resuspension by tidal currents, or within the seasonal cycle, for the longitudinal transport through the estuary. Thus the consolidation forces the residual deposition or erosion of mud. Naturally these results are specific to a macrotidal estuary and should not be generalized to all cohesive sediment areas.

But this study has also pointed out the sensitivity of simulations to the relationship between the sediment density and its erodibility : our knowledge on this subject is so poor that a sophisticated model for the prediction of mud density would be useless. In addition the required constitutive relationships that any consolidation model involves are still hypothetical. For these reasons we should recommend to use simple consolidation models until the knowledge on soil behaviour progresses substantially.

Lastly, we mentioned the competition between the strengthening of sediment by consolidation and the bottom stress reduction related to the turbulence damping in highly concentrated suspensions. This means that the use of any sophisticated - and presumed realistic - consolidation model should be completed by a bottom stress computation with the same accuracy. Many field validation measurements are required to manage it.

## **Acknowledgements**

The study of the Loire estuary is financed by the "Association pour la Protection des Eaux de l'Estuaire de la Loire" and by IFREMER. The work on consolidation is partly funded by the Commission of European Communities, Directorate General for Science, Research and Development under MAST Contract n° 0035-C. The authors thank Dr. P. Bassoullet for his fruitful comments and D. Guillerm for her help.

## CHAPTER 240

### WAVE-INDUCED PORE PRESSURE ACTING ON A BURIED SUBMARINE PIPELINE

Waldemar MAGDA \*

#### ABSTRACT

The response of a sandy seabed to surface water waves, with a special emphasis to wave-induced excess pore water pressure oscillations is studied here in relation to the vertical stability of submarine buried pipelines. The main object of the paper is to present a study of the distribution pattern of the pore water pressure acting around the pipeline, and to calculate the seepage force, the up-lift force particularly, affecting the pipeline stability, under the assumption of compressible both the pore fluid and soil skeleton, for the case of an arbitrary seabed depth as well as for the infinite thickness of the subsoil.

#### INTRODUCTION

Generally, the problem associated with buried submarine pipelines depends, on the water and wave conditions. The wave climate plays a very important role and can influence the interaction between the submarine buried pipeline and the surrounding soil significantly. In practice, pipeline located in water depths up to 60 m are buried, whilst the cover must have a thickness ranging from 0.5 to 1.0 m, depending upon the water depth and the covering material.

Submarine pipelines buried in a seabed are an engineering means of transport for crude oil and natural gas from "off-shore" oil fields onto a land. When waves pass over a permeable sandy seabed, pore water pressure is continuously

---

\* *Ph.D., Research Engr.*

*University of Hannover, Sonderforschungsbereich 205, Appelstr. 9A, 3000 Hannover 1, Germany (on leave from the Marine Civil Engineering Department, Hydroengineering Faculty, Technical University of Gdańsk, Poland)*

induced within it. Among all environmental loads usually considered in "off-shore" pipelines design, the wave-induced pore water pressure plays one of the most important role. The most critical problem in determining the stability of a pipeline buried in permeable soils under wave loading is the prediction of the pore water pressures in the soil in a vicinity of a pipeline (Dursthoff and Mazurkiewicz, 1985). An excess of the pore water pressure can cause instability of a seabed, liquefaction of the upper sand layer and then floatation which can even lead to a failure of a submarine pipeline. The wave-induced excess pore water pressure developed in a vicinity of a buried pipeline is considered as a one of the main parts in a design procedure. The wave-induced uplift force acting on the pipeline is comparable to the displaced water weight if the pipeline is located in the pore water pressure boundary layer and an inadequate design can cause floatation of pipeline and, subsequently, can lead to costly failures. Therefore, it is essential to improve our knowledge on the interaction among waves, seabed and a submarine pipeline.

**Figure 1** Definition sketch for the uplift force analysis.

It is a very complex and challenging task to define properly the wave-induced excess pore water pressure field around a submarine pipeline buried in a porous seabed. Many researches simplified the problem assuming both the porous medium and pore water incompressible. Under this assumption Lai *et al.* (1974), Liu and O'Donnell (1979) and Lennon (1985) investigated this

problem using a numerical analysis. Liu and O'Donnell (1979) considered two different types of waves acting on the seabed, namely, monochromatic and solitary, and introduced the integral equation method to solve the resulting integral equation. In a numerical solution procedure developed by Lennon (1985) the pressure distribution on the pipeline was calculated using also the boundary integral equation method (BIEM). Employing conformal mapping techniques, MacPherson (1978) and McDougal *et al.* (1988) presented analytical solutions for the case of an infinite depth of the seabed, whereas Monkmeyer *et al.* (1983) developed a solution using so-called 'image pipe' method which, comparing to the former, can be applicable also to a soil layer of a finite thickness.

The common feature in the studies mentioned above is that the effect of compressibility of both the pore water and porous medium was neglected. Moreover, some researchers showed that there is a difference between theoretically computed values of pore water pressure and those observed in experiments. In laboratory studies on the stability of buried pipelines, Philips *et al.* (1979) concluded that potential theory did not generally give an accurate representation of the transmission of wave-induced pressures through the sand, when comparing to the test results.

Reported differences between theoretical and experimental results can have three main reasons, namely:

- the theories are based on the Darcy model and therefore they do not contain all important soil/water parameters (incompressible pore water and nondeformable soil skeleton are assumed),
- boundary conditions applied into computation are not realistic, specially when comparing with laboratory tests environment (seabed layer of a finite thickness),
- values of parameters used in calculations are not exactly the same like these 'in-situ' which accompany laboratory investigations.

The proposed method of calculation is based on:

- the pore water pressure theory where the main soil and pore fluid parameters are considered and a finite sand bed layer system is taken into account,
- the 'image pipe' theory which is able to solve both the upper (at the sea bottom) and the lower (at finite depth of the seabed layer) boundary conditions, and also the boundary condition induced by presence of a pipeline (perturbation or scattering effect).

An implementation of certain soil and pore water parameters, *e.g.* compressibility and permeability, leads not to the Laplace equation, which depends only on a geometry of the problem, but to the storage equation, which is much more complex in form. Using Madsen's (1978) general solution of this equation, an analytical solution for a finite thickness of the seabed layer has been derived and verified qualitatively in numerous large-scale laboratory experiments in a big wave-flume, and quantitatively in small-scale laboratory tests (Magda, 1989,

1991). These tests enabled to study influences of single soil/water parameter changes on the character of the pore water pressure damping within a porous medium. A great attention has been put to modelling and controlling different degrees of saturation which is of a special interest for coastal and tidal areas where, because of a continuous water table movement and wave-breaking zones, the sediment is not and cannot be treated as a saturated medium.

### MATHEMATICAL FORMULATION OF THE PROBLEM

Introducing a pipeline-like structure into a soil body, it is not so easy to derive a solution to the governing equation for flow of a compressible pore fluid in a compressible porous medium (*e.g.* given by: Madsen, 1978; Yamamoto *et al.*, 1978). Therefore, after some mathematical manipulations, and presenting the solution in terms of the pore-water pressure and effective stresses, a new form of the governing equation can be obtained (Okusa, 1985):

$$\nabla^2 \left( \nabla^2 - \frac{1}{c_v} \frac{\partial}{\partial t} \right) p = 0 \quad (1)$$

where  $p$  is the wave-induced excess pore water pressure,  $c_v$  is the coefficient of consolidation,  $t$  is the time, and  $\nabla$  is the Laplacian operator. The coefficient of consolidation,  $c_v$ , can be defined for the unsaturated soil as

$$\frac{1}{c_v} = \frac{\gamma}{k} \left[ \frac{n}{K} + \frac{1 - 2\mu}{2G(1 - \mu)} \right] \quad (2)$$

where  $\gamma$  is the unit weight of the pore fluid,  $k$  is the isotropic coefficient of soil permeability,  $n$  is the porosity of the porous bed,  $\mu$  is the Poisson's ratio,  $K$ , is the bulk modulus of water, and  $G$  is the shear modulus of soil. From this it is easily seen that the solution of Eq. (1) can be formulated as a mixed solution of both the Laplace equation

$$\nabla^2 p = 0 \quad (3)$$

and the consolidation (diffusion) equation

$$\nabla^2 p - \frac{1}{c_v} \frac{\partial p}{\partial t} = 0 \quad (4)$$

in two dimensions. It has to be pointed that sometimes (*e.g.* Qiu and Sun, 1987) the simplification of the solution to the governing flow equation is going too far and, due to the total elimination of the soil displacements, the problem is reduced only to the consolidation equation. However, the correct solution has to be treated as a sum of the general solutions to the last two differential equations of the second order.

SOLUTION METHOD

Assuming that the wave-induced hydrodynamic pressure at the seabed is described by the periodic function

$$p = P_0 \exp[i(ax - \omega t)] \quad (5)$$

where  $a = 2\pi/L$  is the wave number,  $L$  is the wave length,  $\omega = 2\pi/T$  is the angular velocity,  $T$  is the wave period, and  $P_0$  is the pressure amplitude at the seabed, and due to linearity of the above mentioned component equations, all the unknowns in the problem considered (among others: the wave-induced pore pressure) are periodic with  $a$  and  $\omega$ . Then, the wave-induced pore pressure  $p$  is represented by

$$p = f(z) \exp[i(ax - \omega t)] \quad (6)$$

where  $f(z)$  is a function of  $z$  only. Introducing this into Eqs. (3) and (4), the general solution is represented by the sum of the solutions from the two following differential equations

$$\frac{d^2 f}{dz^2} - a^2 f = 0 \quad (7)$$

$$\frac{d^2 f}{dz^2} - \left( a^2 - \frac{\omega}{c_v} i \right) f = 0 \quad (8)$$

Because the governing equations are linear, the wave-induced stresses can be obtained by superposing, as previously indicated by Yamamoto (1981) and Okusa (1985a). The general solutions  $f_1$  of Eq. (7) and  $f_2$  of Eq. (8) are

$$f_1 = C_L \exp(az) + D_L \exp(-az) \quad (9)$$

$$f_2 = C_C \exp(\kappa z) + D_C \exp(-\kappa z) \quad (10)$$

where  $C_L, C_C, D_L, D_C$  are integral constants depending on the boundary conditions and

$$\kappa = \sqrt{a^2 - \frac{\omega}{c_v} i} \quad (11)$$

For the case of infinitely thick homogeneous sediment, the wave-induced pore pressures, stresses, and displacements must tend to zero as  $z \rightarrow \infty$ . Therefore (Okusa, 1985):

$$C_L + C_C = 1 \quad (12)$$

$$C_L = \frac{2(1 + \mu)B}{3 + 2\mu B - B} \quad C_C = \frac{3(1 - B)}{3 + 2\mu B - B} \quad (13)$$

where the Skempton's pore pressure coefficient  $B$  is defined as

$$\frac{1}{B} = 1 + \frac{n\beta}{\alpha} \quad (14)$$

where  $\alpha$  is the volume compressibility of the sediment,  $\beta$  is the volume compressibility of the pore fluid.

Now, using a complementary wave loading method, *i.e.* two waves having the same phase and different amplitudes ( $C_L$  and  $C_C$ ) are assumed for solving the Laplace equation and consolidation equation separately, one can write

$$p = C_L \times \mathbf{L} + C_C \times \mathbf{C} \quad (15)$$

where  $\mathbf{L}$  and  $\mathbf{C}$  denote values obtained from the solutions of Laplace equation and consolidation (diffusion) equation, respectively, assuming for both of them a unit amplitude of the inducing hydrodynamic pressure wave at the seabed.

A contribution of the particular components, supplied by the solutions of Laplace equation and consolidation equation, to the total solution of the problem is illustrated in Tab. 1.

Degree of Saturation	$C_L$	$C_C$
$S = 1.00$	0.998	0.002
$S = 0.99$	0.855	0.145
$S = 0.98$	0.748	0.252
$S = 0.97$	0.665	0.335
$S = 0.96$	0.598	0.402
$S = 0.95$	0.544	0.456

**Table 1** Contribution of single components (from the Laplace equation and consolidation equation) in the total solution, with regard to different saturation conditions.

It has to be stressed once more that the influence of partly saturated seabed conditions is predominant for the investigated case of the uplift force acting on a buried submarine pipeline. Therefore, the both solutions to the Laplace equation and consolidation equation have to be always taken into account simultaneously. To confirm an existence of partly saturated conditions in a natural environment, a measuring campaign was conducted on Norderney Island (Germany). After sampling and statistical analysis of the measured and calculated

results, the mean value of the degree of saturation was found to be 0.975 (Magda and Davidov, 1990).

Fig. 2 shows a set of pore pressure profiles with depth calculated for the singular solutions, *e.g.* the Laplace and consolidation problems, considered separately, comparing them with a solution for the compounded problem of the compressible fluid flow through compressible media.

**Figure 2** Comparison of different solutions for the pore pressure distribution with depth.

A similar analysis can also be performed for the case of a finite thickness of the seabed layer. The formulas describing coefficients  $C_L, C_D, D_L, D_D$  are, however, much more complicated.

The solution to the Laplace equation, Eq. (3), for the boundary conditions problem created by a finite thickness of the seabed layer and a pipe-like structure embedded in the soil sediment, is not trivial but does not bring any troubles. As documented in the introduction, it is possible to obtain this solution using, for example, one of the reported conformal mapping techniques.

It is not an easy task to solve the consolidation partial differential equation, Eq. (4), in the Cartesian coordinate system for the identical to the above mentioned boundary conditions problem. Therefore, to overcome the difficulties, the solution method presented below is based on the cylindrical (circular-cylinder) coordinate system.

The consolidation equation, also known as diffusion or heat conduction equation, is considered. It can be presented in general form as

$$\nabla^2 \varphi = \frac{1}{h^2} \frac{\partial \varphi}{\partial t} \quad (16)$$

The solution of any of the scalar equations like: the Laplace equation, the Poisson equation, the diffusion equation, the wave equation, the damped wave equation, transmission line equation, and the vector wave equation may be reduced to a solution of the scalar Helmholtz equation, or its special case – the Laplace equation (Moon and Spencer, 1971). For the consolidation equation (16), let

$$U(u_i)T(t) \quad (17)$$

where  $U$  is a function of the space coordinates and  $T$  is a function of time only. Substitution into the consolidation equation allows the separation of the time part, giving

$$\nabla^2 U + \kappa U = 0 \quad (18a)$$

$$\frac{dT}{dt} + \kappa^2 h^2 T = 0 \quad (18b)$$

where  $\kappa$  is the separation constant.

The solution of the Helmholtz equation (18a) depends on the space variables and the boundary conditions, and will be different for each problem. The equation in time (18b), however, is independent of the coordinate system. Thus the solution of the consolidation equation is always

$$\varphi = U(u_1, u_2, u_3) e^{-\kappa^2 h^2 t} \quad (19)$$

Geometry of the problem, *i.e.* circular pipe buried in a seabed (see Fig. 1), advises to use the circular-cylinder coordinates

$$\begin{cases} u_1 = r & 0 \leq r < \infty \\ u_2 = \theta & 0 \leq \theta < 2\pi \\ u_3 = z & -\infty < z < +\infty \end{cases} \quad \begin{cases} x = r \cos \theta \\ y = r \sin \theta \\ z = z \end{cases} \quad (20)$$

Rewriting the Helmholtz equation (18a),  $U$  must satisfy, in polar coordinates,

$$\nabla^2 U + \kappa^2 U = \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial U}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 U}{\partial \theta^2} + \kappa^2 U = 0 \quad (21)$$

Separation of the Helmholtz equation (21), in two-dimensional polar coordinate system (in a plane problem  $\theta$  is independent of  $z$  and the circular-cylinder coordinate system is simplified and becomes the polar coordinate system), leads to (Moon and Spencer, 1971):

$$\frac{d^2 R}{dr^2} + \frac{1}{r} \frac{dR}{dr} + \left(\kappa^2 - \frac{\lambda^2}{r^2}\right) R = 0 \quad (22a)$$

$$\frac{d^2 \Theta}{d\theta^2} + \lambda^2 \Theta = 0 \quad (22b)$$

where  $R$ ,  $\theta$  are functions of  $r$ ,  $\theta$ , respectively, and  $\lambda$  and  $c$  are separation constants. These equations are solved for  $R$  and  $\Theta$ , and the solution of the Helmholtz equation has a following form

$$U(r, \theta) = R(r) \Theta(\theta) \quad (23)$$

Differential equation (22b) has a following general solution

$$\Theta(\theta) = \alpha \cos \lambda \theta + \beta \sin \lambda \theta \quad (24)$$

For the governing problem,  $U$  is a harmonic function of  $\theta$  with a period  $2\pi$ , therefore,  $\Theta$  must have the same feature. It is possible only when  $\lambda$  is represented by an integer number. By limiting the range of values of  $\lambda$  only to positive ones ( $\lambda = 0, 1, 2, \dots, n, \dots$ ) both functions  $\Theta(\theta)$  and  $R(r)$  can be written accordingly as

$$\Theta_0(\theta), \Theta_1(\theta), \Theta_2(\theta), \dots, \Theta_n(\theta), \dots \quad ; \quad R_0(r), R_1(r), R_2(r), \dots, R_n(r), \dots \quad (25)$$

In this way, an infinite system of solutions for Eq. (23) is obtained which now can be written as

$$U(r, \theta) = \sum_{n=0}^{\infty} [\alpha_n \cos n\theta + \beta_n \sin n\theta] R_n(r) \quad (26)$$

Eq. (22a) can be considered as the Bessel equation which in general form can be written

$$\frac{d^2 W}{dw^2} + \frac{1}{w} \frac{dW}{dw} + (\mu^2 w^2 + q^2 - s^2/w^2) W = 0 \quad (27)$$

The general series solution of Eq. (27) may be written, for  $s \neq$  integer,

$$W = A \mathcal{J}_s(\mu, q, w) + B \mathcal{J}_{-s}(\mu, q, w) \quad (28)$$

These series are valid everywhere in the finite complex plane. If  $s = n$ , an integer,  $\mathcal{J}_{-s}$  is no longer independent of  $\mathcal{J}_s$  and the general solution of Eq. (27) is

$$W = A \mathcal{J}_n(\mu, q, w) + B \mathcal{Y}_n(\mu, q, w) \quad (29)$$

where  $\mathcal{J}_n$  and  $\mathcal{Y}_n$  are the Bessel wave functions of the first and second kind (also called the Weber function), respectively. If  $\mu = 0$  (this is the case) it can be concluded that the Bessel functions degenerate and Eq. (29) becomes

$$W = A\mathcal{J}_n(qw) + B\mathcal{Y}_n(qw) \quad (30)$$

Introducing the Hankel functions (*i.e.* the Bessel functions of the third kind, which are linear combinations of the Bessel functions of the first and second kinds)

$$\mathcal{H}_n^{(1)}(qw) = \mathcal{J}_n(qw) + i\mathcal{Y}_n(qw) \quad (31)$$

$$\mathcal{H}_n^{(2)}(qw) = \mathcal{J}_n(qw) - i\mathcal{Y}_n(qw) \quad (32)$$

where:  $\mathcal{H}_n^{(1)}$ ,  $\mathcal{H}_n^{(2)}$  are the Hankel functions of the first and second kind, respectively, and of order  $n$ , the general solution of Eq. (27) may be also written (Moon and Spencer, 1971):

$$W = A\mathcal{H}_n^{(1)}(qw) + B\mathcal{H}_n^{(2)}(qw) \quad (33)$$

Comparing now Eq. (22a) and Eq. (27), and replacing  $W$  by  $R$  and  $qw$  by  $\kappa r$ , one has

$$R = A\mathcal{H}_n^{(1)}(\kappa r) + B\mathcal{H}_n^{(2)}(\kappa r) \quad (34)$$

Two-dimensional Helmholtz equation (18a), describing diffraction, after transformation into the polar coordinates system gets a form which is known as the Bessel equation, the solution of which, in two-dimensional scattering by localized objects in a sea of constant depth can be constructed by superposition of the following terms (Mei, 1989):

$$\left\{ \begin{array}{l} \mathcal{H}_n^{(1)}(\kappa r) \\ \mathcal{H}_n^{(2)}(\kappa r) \end{array} \right\} \left\{ \begin{array}{l} \sin n\theta \\ \cos n\theta \end{array} \right\} \quad (35)$$

Because of the asymptotic behaviour of the Hankel functions

$$\left\{ \begin{array}{l} \mathcal{H}_n^{(1)}(\kappa r) \\ \mathcal{H}_n^{(2)}(\kappa r) \end{array} \right\} \simeq \left( \frac{2}{\pi\kappa r} \right)^{1/2} \exp \left[ \pm i \left( \kappa r - \frac{\pi}{4} - \frac{n\pi}{2} \right) \right] \quad (36)$$

$\mathcal{H}_n^{(2)}$  must be discarded when  $\kappa$  is complex with a positive real part (Mei, 1989).

Assuming the hydrodynamic bottom pressure oscillations of a unit amplitude, expressed by harmonic solution

$$p = e^{-i\omega t} \quad (37)$$

where  $i$  denotes the imaginary unit, and comparing it with Eq. (6), the separation constant can be expressed by

$$\kappa = \sqrt{\frac{i\omega}{c_v}} \quad (38)$$

In fact,  $\kappa$  is a complex number and can be presented in a general form as

$$\kappa = \sqrt{a + ib} \quad \text{where} \quad a = 0 \quad \text{and} \quad b \equiv \frac{\omega}{c_v} > 0 \quad (39)$$

This can also be written

$$\kappa = a' + ib' \quad (40)$$

Comparison of the last two expressions shows that

$$a', b' \geq 1 \quad \text{when} \quad b \geq 1 \quad \text{and} \quad 0 \leq a', b' < 1 \quad \text{when} \quad 0 \leq b < 1 \quad (41)$$

So,  $b'$  is always positive without any respect to the positive value of  $b$  ( $b \geq 0$ ).

And thus, the general solution for the scattered (radiated) waves, also pore water pressure waves, may be written as

$$U = \sum_{n=0}^{\infty} (\alpha_n \cos n\theta + \beta_n \sin n\theta) H_n^{(1)}(kr) \quad (42)$$

An implementation of the "image pipe" theory (Monkmeyer *et al.*, 1983) allowed to fulfil all requirements concerning the boundary conditions of the problem.

## RESULTS OF CALCULATION

An application of the method is illustrated by some calculation examples where the meaning of the seabed saturation problem is specially emphasized. For a certain geometry (depth of burial, pipeline outside diameter) the pipeline uplift force is computed, taking into account values of the degree of saturation from the range between 0.85 and 1.00, for which the soil can be considered as a saturated soil but with the pore fluid having some degree of compressibility (higher than a pure water) due to the presence of the air bubbles (Esrig and Kirby, 1977).

The solution to Eq. (1) enables to investigate the problem of pore pressure gradient, especially in a vicinity of the seabed surface. Performing series of calculation, the most unfavourable (from the pressure gradient point of view) phase of the pore pressure oscillations can be detected and then, it becomes feasible to calculate the most critical value of the pipeline uplift force. And

**Figure 3** Definition sketch for the uplift force analysis (influence of different saturation conditions).

**Figure 4** Pipeline uplift force versus different saturation conditions of seabed sediments.

thus, Fig. 3 shows the governing problem and Fig. 4 illustrates the results of calculations for a certain set of data where the uplift force is influenced by different values of the degree of saturation.

It can be easily recognized that the pipeline uplift force depends very strongly on the degree of saturation and has a maximum value for the degree of saturation very close to 1.00.

Changing a value of the degree of saturation with a step of 0.01 (*i.e.*, 1%), for example, the most critical situation can be easily omitted. Therefore, looking for an absolute maximum value of the pipeline uplift force, it is required to apply even smaller increment of the degree of saturation when performing a parameter study by means of numerical calculations to obtain a precise picture of possible variations in the pipeline uplift force.

The elaborated method seems to be very useful in a optimization design procedure and gives the result which reflects, among others, the most inconvenient case for the pipeline stability with respect to saturation conditions of the seabed which are, on the other hand, extremely difficult and almost impossible to determine 'in-situ', using engineering methods of testing, with the exactness which is comparable to the necessary step of calculation.

The calculation procedure, presented in the paper and based on the advanced pore water pressure theory, make it feasible to incorporate important soil/water parameters into the pipeline uplift force analysis. Obtained values of the uplift force appear to be greater than these computed from the potential theory; this finding is in accordance with some observations from laboratory tests reported in the literature.

## CHAPTER 241

### Hydraulic Approach to Determining Optimum Interval of Discharge Sites of Barge in Constructing Rubble Foundation of Deep Water breakwater

Yoshiharu Matsumi <sup>1</sup> Akira Kimura <sup>2</sup>

#### Abstract

This study aims to establish the effective and economical construction scheme of the rubble mounds which are constructed by discharging a large amount of rubble from hopper barge. Since the plane scatter of the landing rubble on the sea floor directly depends on the random drift force exerted on the settling rubble, the statistical properties for the scattering range of the settling rubble in the still water are fully investigated in experiments. On the basis of the experiments and the discrete block method which equipped to cope with the steeper slope of rubble mound than the angle of repose for rubble, a numerical technique to simulate the spatial geometry of the discharged rubble on the sea floor taking the angle of repose for the rubble into account is developed. An optimum interval of the discharge sites of the barge which makes the uneven property of the mound's surface minimum is discussed in connection with the change in the the design water depth of breakwater and the discharge times.

#### 1 Introduction

Caisson type breakwater is usually placed on a rubble mound foundation. In general the foundations are constructed by discharging a large amount of rubble from hopper barges. An advantage of this construction method exists in its rapid "executability", since barges can carry a large volume of rubble at one time. However the mounds by individual discharge from the barge tend to form uneven surface, since the rubble landing on sea floor distributes widely. This is a drawback of this construction method. Since the design water depth of breakwaters has become deeper and the size of the rubble mound has become greater,

<sup>2</sup>Professor, Dept. of Social Systems Engg., Faculty of Engg., Tottori University.

Figure 1: Definition of the fluctuation of the settling rubble.

the portion of the rubble foundation work to the total process of breakwater construction has been increasing. Therefore, the technique to construct a mound for breakwaters effectively and economically has become very important. This study aims to establish the effective construction scheme of the rubble mound by using a hopper barge, firstly the statistical properties of the landing rubble distributions on the sea floor are investigated with the experiments, secondly a numerical technique to simulate the spatial geometry of the discharged rubble mound from hopper barges by taking the angle of repose for the rubble into account is developed. Finally, the effective interval of the discharge points of the barges which minimizes the uneven property of the mound's surface is discussed in connection with the spatial geometry of the rubble mound by multi-discharge and the water depth.

## 2 Stochastic properties for scattering position of settling rubble in still water

In the experiments, the representative sizes of rubble  $d = 2.8 \text{ cm}$ ,  $3.7 \text{ cm}$  and  $4.3 \text{ cm}$  are employed. Experiments have been carried out in a laboratory settling tank with  $2 \text{ m}$  depth and  $1.1 \text{ m} \times 1.1 \text{ m}$  cross-section. Every piece of rubble is dropped from same position on the water surface. The total amount of settled rubbles is 3000 for each rubble diameter. At six different water depths, the  $x$  and  $y$  positions of the settling rubble are measured by two video cameras (Figure 1,  $x$ ,  $y$ ; horizontal axes,  $z$ ; vertical axis).  $O$  is the discharge point of rubble,  $dx$  and  $dy$  are the displacements between specified depths in  $x$  and  $y$  direction. The stochastic properties for  $dx$  and  $dy$  at every water depth are investigated.

Figure 2 shows the distributions for  $dx$  and  $dy$  at six different water depths. These experiments are the case for the average diameter  $d = 2.8 \text{ cm}$ . The shapes of distributions are similar to each other except for the case of  $z/d = 7.1$ . The

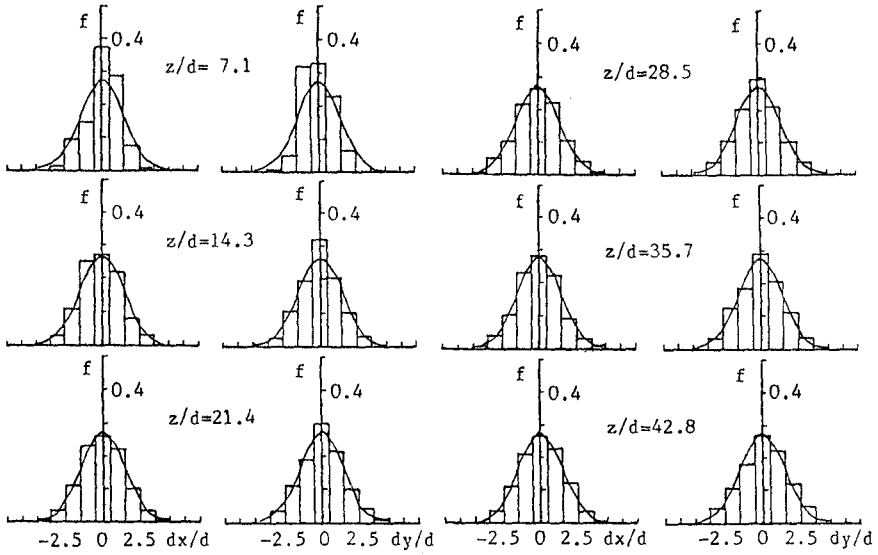

Figure 2: Distributions for  $dx/d$  and  $dy/d$  at six different water depth.

cases for other diameters are the same properties to this case. Therefore, it may be considered that the stochastic property for the displacement of the settling rubble at every section is identical.

Figure 3 shows the change in the mean values ( $dx_m/d, dy_m/d$ ) and the standard deviations ( $\sigma_x, \sigma_y$ ) with respect to the relative water depth from the still water surface. Though the values of  $dx_m/d$  and  $dy_m/d$  at every section show a random fluctuation with changing  $z/d$ , the fluctuation range is less than about 10% of rubble diameter. On the other hand, no practical difference in standard deviations  $\sigma_x$  and  $\sigma_y$  at every section except for  $z/d = 7.1$  is observed. From these investigations, the stochastic properties for the displacement of the settling rubble at every section may be assumed to be identical. In this study, the means for  $dx$  and  $dy$  at every section are assumed to be zero,  $\sigma_x$  and  $\sigma_y$  are assumed to be equal at every section.

### 3 Stochastic simulation technique for spatial geometry of rubble mound discharged from hopper barge

#### 3.1 Probability distribution for settling position of rubble

In this study, the distribution for the displacement of the settling rubble at every section is assumed to be estimated by the Gaussian distribution with zero mean

Figure 3: Change in the mean values and the standard deviations for  $dx/d$  and  $dy/d$  with changing water depth.

value as following:

$$f(x^*) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left\{-\frac{1}{2}\left(\frac{x^*}{\sigma}\right)^2\right\} \tag{1}$$

$$f(y^*) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left\{-\frac{1}{2}\left(\frac{y^*}{\sigma}\right)^2\right\} \tag{2}$$

where  $\sigma = (\sigma_x + \sigma_y)/2$ ,  $x^* = x/d$ ,  $y^* = y/d$ . In Figure 2, the solid lines are the calculations of Eq. (1), (2). The calculations and the experiments except for  $z/d = 7.1$  agree reasonably well. The other cases for the rubble diameter were same results also. From these investigations, it may be considered that the stochastic properties for the displacement of the settling rubble at every section are identical and stationary process. Therefore, applying the Markov chain theory to the stochastic process for the displacement of the settling rubble, the stochastic model to estimate the distribution for the settling position of rubble is developed In this study.

The situation space vector  $S$  for the settling position of one piece of rubble in this stochastic model is defined as

$$S = \{-r, -r + 1, \dots, 0, \dots, r - 1, r\} \tag{3}$$

where  $r(= x/d = y/d)$  is the relative longest distance of the plane scatter of the landing rubble on the sea floor in the  $x$  and  $y$  direction, and  $r$  is the positive integral constant. Then, the transition probability matrix  $P$  is given by

$$P = [ p(i, j) ] \quad i = -r \sim r, j = -r \sim r \tag{4}$$

where

Figure 4: Probability distribution for the settling position of rubble at different water depth.

$$\begin{array}{ll}
 i - j = 0 & p(i, j) = p_0 \\
 i - j = -k & p(i, j) = p_k^+ \\
 i - j = k & p(i, j) = p_k^- \\
 |i - j| > k & p(i, j) = 0 \\
 & (k = 1, 2, \dots, 6)
 \end{array}$$

in which  $p(i, j)$  is a transition probability that the rubble settles from the  $i$ -th position at the  $m$ -th section to the  $j$ -th position at the  $m+1$ -th section,  $p_0$  and  $p_k$  are the probabilities for the cases in which the displacement of the settling rubble at a section is 0 and  $k$  respectively, these values can be calculated from Eq. (1) and (2). Then the probability distribution for the settling position of rubble is given by

$$\begin{aligned}
 \Pi(m) &= \Pi(m - 1) \cdot P \\
 \Pi(0) &= [ \underbrace{0, \dots, 0}_r, 1, \underbrace{0, \dots, 0}_r ]
 \end{aligned}
 \tag{5}$$

where  $\Pi(0)$  is the probability vector for the initial position of rubble at dropping. Figure 4 shows examples of the experimental distributions and the calculated results for the settling position of rubble (solid line). The present stochastic model can simulate the shape of distributions regardless of the relative water depth with sufficient accuracy.

Table 1 shows the correlation coefficient of  $dx/d$  and  $dy/d$  at every sections. The values of correlation coefficient except for  $z/d = 7.1$  may be approximately zero

Table 1: Correlation coefficient between  $dx/d$  and  $dy/d$ .

Section	$d = 2.8 \text{ cm}$	$d = 3.7 \text{ cm}$	$d = 4.3 \text{ cm}$
$z/d = 7.1$	0.176	0.129	0.136
$z/d = 14.3$	0.019	0.006	-0.012
$z/d = 21.4$	-0.002	0.013	-0.021
$z/d = 28.5$	0.017	0.003	-0.047
$z/d = 35.7$	-0.008	0.025	-0.044
$z/d = 42.8$	0.032	0.023	-0.058

regardless of the sections and the case. Therefore, it may be considered that the stochastic properties for the displacements of the settling rubble in the  $x$  and  $y$  direction are independent. Then the probability distribution of the plane scatter for the settling position of rubble is given by

$$p_r(x^*, y^*) = \Pi_x \cdot \Pi_y \quad (6)$$

where  $\Pi_x$  and  $\Pi_y$  can be calculated from Eq. (6).

### 3.2 Spatial geometry of rubble mound discharged from hopper barge

The spatial geometry of individual rubble mound discharged from a hopper barge can be evaluated by combining the volume of rubble at discharge with a probability distribution of the plane scatter for the landing rubble on the sea floor. This probability distribution of can be evaluated as

$$P_r(j) = \left\{ \sum_{i=1}^N p_{ri}(j) \right\} / N \quad (7)$$

where  $N$  is the number of the panels which divid the hopper mouth into the  $d \times d$  plane size in the numerical calculations (Matsumi Y.;1990),  $p_{ri}(j)$  is a probability that the rubble which is fallen from the  $i$ -th discrete portion in the hopper mouth lands to the  $j$ -th discrete portion on the sea floor. The probability  $p_{ri}(j)$  can be calculated from the probability distribution for the settling position of rubble (Eq. (6)). Finally, the spatial geometry of rubble mound which is discharged from a barge can be simulated by

$$H(j) = V \cdot P_r(j) / d^2 \quad (8)$$

where  $H(j)$  is the mound height in the  $j$ -th discrete portion on the sea floor,  $V$  is the volume of rubble at discharge.

Figure 5 shows the comparison of heights of the calculated rubble mounds by the present stochastic simulation technique and experimental data by Okude et al.

Figure 5: Comparison between height of calculated rubble mounds and experiments.

(1982), in case for the rubble mound which is formed by an single discharge. In the experiments of Okude et al., a 1/20 scale model hopper barge with  $100 \text{ m}^3$  hopper volume was employed. It may be concluded that the spatial geometry of rubble mounds formed by an single discharge can be evaluated with sufficient accuracy by the present stochastic simulation technique.

#### 4 Simulation technique for rubble mound at multi-discharge

In the case for rubble mound formed by multi-times discharge from the same position, the slope of rubble mound approaches the angle of repose for the rubble with increasing discharge times. Then, the rolling rubbles and the sliding those on the slope may occur. The present stochastic simulation technique cannot cope with those phenomena which are recognized in the experiments. Therefore, to cope with the steeper slope of rubble mound than the angle of repose for rubble, the correctional model for the stochastic technique is investigated through the experiments and the numerical calculations.

Experiments have been carried out in a laboratory settling tank with  $1.5 \text{ m}$  depth and  $2 \text{ m} \times 2 \text{ m}$  cross-section. The hopper barge model used was a 1/20 scale model with  $100 \text{ m}^3$  hopper volume. The representative sizes of rubble  $d = 2.8 \text{ cm}$ ,  $3.7 \text{ cm}$  and  $4.3 \text{ cm}$  are employed in the experiments. The height and width of the rubble mound formed by multi-times discharge from the same position were measured by two video cameras which were allocated in the directions of barge width and length. Furthermore, the change in the shape of cross section of the discharged mound with respect to the discharge time was investigated. From the experiments, it has been found that the shape of cross section of the rubble mound formed by multi-times discharge can be classified into three patterns, namely, as the discharge time increases, the sectional shape of rubble mound

Figure 6: Correctional model for cross section of simulated rubble mound.

Figure 7: Comparison of calculations for width and height of mound with experiments

transforms from a trapezoidal shape into a pentagonal shape and further into a triangular shape with slope of the angle of repose for the rubble.

From these shape properties of cross section of the rubble mound, a correctional model for the shape of cross section of the simulated mound by the present stochastic technique is devised as shown in Figure 6. In this figure, the dotted line is the cross section of the simulated mound, the solid line is the corrected shape,  $H_n$  and  $B_n$  are the height and width of the corrected mound respectively,  $\theta$  is the angle of repose for rubble. In the case for  $H_n \geq L_n \cdot \sin \theta$ , the shape of cross section of the simulated mound is corrected to the trapezoidal shape or the pentagonal shape such that the areas of shadowed portions A and B become equal. On the other hand, in the case for  $H_n \leq L_n \cdot \sin \theta$ , the shape of cross section of the simulated mound is corrected to the triangular shape with the angle of repose for rubble.

Figure 8: Change in measured  $\theta$  with respect to  $n$ .

The values of  $H_n$  and  $B_n$  in Figure 6 have been given by comparing the calculations for the height and width of the mound at every time discharge with the experiments as shown in Figure 7, in which the abscissa  $n$  is the number of discharge time.  $B_{nx}$  and  $B_{ny}$  are the measured width in the barge length and width directions respectively,  $B_{mnx}$  and  $B_{mny}$  are the calculated those,  $H_n$  and  $H_{mn}$  are the measured height and the calculated that. This Figure is the case for the water depth  $h = 60$  cm. It is found that the calculations for the width of the mound at every time discharge agree with the experiments reasonably well. However, since the present stochastic simulation technique cannot cope with the sliding rubbles and the rolling those on the slope of mound, the calculations for the height and the experiments markedly become to disagree with increasing the discharge time. Then, from the investigation on the relationship between the simulated heights of the mound at every discharge and the measurements, it has been found that a linear relationship between  $H_{mn}$  and  $H_n$  is established and  $H_n$  is given by

$$H_n = 0.6H_{mn} \quad (9)$$

Figure 8 shows the change in the angle of slope of the measured mound with respect to the number of discharge time  $n$ . The values of  $\theta$  show a tendency to approach to about  $40^\circ$  with increasing  $n$ . However, since the measured data vary widely, when reading a value of the angle of repose for the rubble from these results, the error of reading becomes very large. Then, the discrete block method (Cundall P.A., 1971, 1976) are applied to analyze the angle of repose for rubble numerically.

In the discrete block method, the rubble is approximately replaced by a circular element as shown in Figure 9. The elastic and inelastic characteristics of rubble are modeled by an elastic spring (spring coefficient;  $K$ ), a viscous dashpot (vis-

Figure 9: Dynamic system in the discrete block method.

cous coefficient;  $\eta$ ) and a frictional slider (friction coefficient;  $\mu$ ). The behaviours of the rolling and sliding rubbles on the slope of mound can be numerically simulated by solving the simultaneous common differential equations which are set up for the translational and rotational motions for every rubble element. The equations of the translational and rotational motion for every rubble element are given as following difference equations including unknown variables  $u, v$  and  $\phi$  explicitly.

$$\begin{aligned}
 (m + C_M \rho_W V_S) [\ddot{u}]_t &= \\
 & - \eta [\dot{u}]_{t-\Delta t} - K [u]_{t-\Delta t} - 0.5 \rho_W C_D d [|\dot{u}]_{t-\Delta t}| [\dot{u}]_{t-\Delta t} \\
 & + (\rho_S - \rho_W) V g \\
 (m + C_M \rho_W V_S) [\ddot{v}]_t &= \\
 & - \eta [\dot{v}]_{t-\Delta t} - K [v]_{t-\Delta t} - 0.5 \rho_W C_D d [|\dot{v}]_{t-\Delta t}| [\dot{v}]_{t-\Delta t} \\
 I [\ddot{\phi}]_t &= - (\eta [\dot{\phi}]_{t-\Delta t} + K [\phi]_{t-\Delta t}) d^2 / 4
 \end{aligned}
 \tag{10}$$

where  $u$  and  $v$  are the displacements of rubble element in the vertical and horizontal motions,  $\phi$  is the angle of element in the rotational motion,  $m$  and  $V_S$  are the mass and volume of it,  $I$  is the inertia moment of it,  $\rho_S$  and  $\rho_W$  are the density of rubble and fluid,  $C_D$  and  $C_M$  are the drag coefficient ( $= 1.0$ ) and the added-mass coefficient ( $= 2.0$ ) of rubble and  $\Delta t$  is the time interval of numerical calculation. Since the rubble is modeled by a circular element in this study, to prevent the modeled rubble after landing on the sea floor from the rolling motion in the horizontal direction, the sea floor is replaced by the ripples with the diameter of rubble element. In the numerical calculations, the spring coefficients ( $K_n, K_s$ ), the viscous coefficients ( $\eta_n, \eta_s$ ) and the frictional slider coefficient ( $\mu$ ) adopt values listed in Table 2 which contains both cases for the rubble to rubble and the rubble to sea floor respectively. The difference between the values of

Table 2: Values of  $K, \eta, \mu$  and  $\Delta t$ .

Coefficient	Rubble to rubble	Rubble to sea floor
$K_n/\rho_s g$ (cm)	$3.64 \times 10^4$	$(1/5)3.64 \times 10^4$
$K_s/\rho_s g$ (cm)	$9.48 \times 10^3$	$(1/5)9.48 \times 10^3$
$\eta_n/\rho_s g$ (cm/s)	$2.18 \times 10$	$(1/5)2.18 \times 10$
$\eta_s/\rho_s g$ (cm/s)	$2.18 \times 10$	$(1/5)2.18 \times 10$
$\mu$	$\tan 30^\circ$	$\tan 10^\circ$

Figure 10: Simulated cross section of rubble mound formed by 1, 3 and 8 times discharge.

coefficients in the case for rubble to rubble and those for rubble to sea floor is to deal successfully with a buffer action effect due to the sand bed in the sea floor. The time interval of the numerical calculation  $\Delta t$  is  $1.0 \times 10^{-4}$ s. The initial positions of rubble elements in the numerical calculations are densely arranged in the simulated cross section by the present stochastic simulation technique. The initial settling velocity of every element in the vertical direction adopts the sinking velocity of rubble (60 cm/s) which has been clarified from the experiments. The calculations in the case for the multi-times discharge were carried out by such method that the rubble elements at the following discharge are fallen on the simulated mound at the previous discharge.

Figure 10 shows the simulated cross section of rubble mound formed by one, three and eight times discharge from the same discharge point. As the number of discharge time increases, the shape of the cross section of rubble mound trans-

Figure 11: Change in calculated  $\theta$  with respect to  $n$ .

forms from the trapezoidal shape into the pentagonal shape and further into the triangular shape. Therefore, it can be concluded that the present technique simulates the dominant features which are recognized in the experiments with reasonable well. The angles of the slope of mound at every discharge which are read from the cross section of the rubble mound calculated through the discrete block method are shown in Figure 11. It is found that  $\theta$  approaches to about  $40^\circ$  with increasing  $n$ . Therefore, the angle of repose for the rubble is estimated to be  $40^\circ$  in this study, this value is adopted in the present correctional model.

To investigate the application of the present correctional technique, the width and height of the corrected cross section of rubble mound are compared with the experiments in the case for  $h = 120\text{ cm}$  as shown in Figure 12, in which the white and black symbols indicate the experiments and the calculations respectively. Firstly, though the calculated width  $B_{nxc}/d$  of the mound in the barge length direction can evaluate the change in the experiments  $B_{nx}/d$  with respect to  $n$ , the calculations overestimate the experiments. Secondly, in the case for the mound width in the barge width direction,  $B_{ny}/d$  and  $B_{nyc}/d$  agree with sufficient accuracy. Finally, the calculations  $H_{nc}/d$  for the height of the mound agree well with the experiments  $H_n/d$ . Therefore, it may be concluded that the shape of the cross section of rubble mound formed by multi-times discharge from the same point can be evaluated by combining the stochastic simulation technique with the present correctional technique. However, the applicable limitation of this correctional technique for the case of the barge length direction is not sufficiently made clear in this study.

Figure 12: Comparison of calculations for width and height of mound with experiments.

### 5 Optimal Interval of Discharge Sites of Barge

In this study, the optimal interval of discharge sites of barge is defined as a distance between discharge points from barges which minimizes the uneven property of the mound’s surface. Figure 13 shows the change in the size of the gap between mounds with respect to the relative interval of the discharge sites of the barge, in which  $\delta$  is the gap size between individual mounds,  $H$  is the representative height of mound and  $a$  is the distance between the discharge sites of barges. These calculations are the case for 2, 6 and 10 times discharge at two kinds of relative water depths  $h/d = 42.8$  and  $71.4$ . The effective interval of the discharge sites of the barge can be determined by this figure. Comparing the case for  $h/d = 42.8$  with  $h/d = 71.4$ , when the water depth is deeper, the interval of the discharge points of the barge which makes the uneven property of the mound’s surface minimum becomes longer. Therefore, it may be concluded that when deciding the interval of the discharge sites of the barge, the design water depth of breakwater becomes the important parameter.

### 6 Conclusion

Concluding remarks are as follows:

- (1) The stochastic properties for the displacement of the settling rubble at every section are identical and the stationary process. The stochastic simulation technique which is developed by applying the Markov chain model can estimate the distribution for the settling position of rubble regardless of the relative water with sufficient accuracy.

Figure 13: Change in the gap size between mounds with respect to the relative interval of discharge point of barges.

(2) The angle of repose for the rubble can be numerically calculated by applying the discrete block method. The spatial geometry of the multi-times discharged rubble mound from the same point can be successfully simulated by combining the present stochastic technique with the present correctional technique. However, applying this combined simulation technique for the case of the barge length direction, the problem of how to deal with the width of the mound remains still.

(3) The effective interval of the discharge points from barges which makes the uneven property of the mound's surface minimum in the case for the barge width direction is clarified in connection with the design water depth of breakwater and the number of discharge times.

## CHAPTER 242

# Vortex Train in an Offshore Zone

Nobuhiro Matsunaga<sup>1</sup> and Kosei Takehara<sup>2</sup>

### Abstract

A row of vortices forms in an offshore zone when two-dimensional regular surface waves run up on a sloping flat bed. It is called the offshore vortex train. The vortices begin to appear near a breaking point. Moving in the offshore direction, they develop and increase their horizontal length scale through the vortex merging. The vortex train forms due to the shear instability between onshore and offshore drift-currents. After reaching a location of the offshore side, however, they decay rapidly because of the decrease of shear strain rate between the drift-currents. The formation region has been investigated on the basis of visual experiments for three bed slopes. The formation does not depend on the type of wave breaking but is observed when the steepness of deep water waves is smaller than  $4.2 \times 10^{-2}$ . The horizontal length scale of the vortices and the velocity of the vortex movement have also been evaluated empirically.

### Introduction

A coastal region has attracted considerable research attention because of the central role which it plays in the budget of sediment, the generation of nearshore currents, the diffusion of pollutant, etc. This region is usually divided into the

- 2 Research Associate, Department of Civil Engineering, Kinki University, Osaka 577, Japan.

nearshore zone and the offshore zone (e. g. Komar 1976). Typical features of the nearshore zone are breaking waves and turbulent fluid motion. Miller (1976) pointed out the formation of breaker vortices from the behavior of air bubbles entrained due to wave breaking. Since his work, the turbulence structure in this zone has been investigated vigorously through field observations and laboratory experiments. Most of these studies, which have been reviewed in detail by Peregrine (1983) and Battjes (1988), are mainly concerned with coherent structures near the free surface. Matsunaga & Honji (1980) and Matsunaga et. al. (1988) showed that the Stokes layer separates periodically near a breaking point when two-dimensional regular waves climb up a sloping flat bed, and that the separated flow forms a vortical pattern and lifts up a large amount of sediment.

On the other hand, the fluid motion is considered usually to be irrotational in the offshore zone. The Lagrangian mass transport of fluid in waves is one of interesting problems in this zone. Bagnold (1947) carried out the experiments in which two-dimensional, regular waves propagated on a horizontal smooth bed. He found a strong, forward drift-current along the bed, and a weak, backward one induced under the water surface. The difference between Bagnold's observation and the well-known 'Stokes drift' created a sensation. Longuet-Higgins (1953) solved it theoretically by taking into account the existence of the Stokes layer. Russell & Osorio (1958) measured the velocities of the forward drift-currents at the outside edge of the Stokes layer for horizontal, up-sloping and down-sloping beds. Their data collapse well on the theoretical curve obtained by Longuet-Higgins. The authors (1988) also carried out laboratory experiments to investigate the drift-currents for the case when two-dimensional regular waves climb up a sloping

Figure 1. Offshore vortex train.

bed. At that time, they found a row of vortices forming under the waves. As mentioned previously, the fluid motion in the offshore zone has been treated generally as irrotational one. Therefore, this is a fresh phenomenon in the fluid dynamics as well as the coastal engineering. It was called the offshore vortex train. Figure 1 shows one example of the offshore vortices visualized by using dye of aniline blue. The arrow indicates the direction of wave propagation. The interval between B and C was 0.5 m. The mean water depth was 14.0 cm at position B. The bed slope was  $1/23.5$  and the breaking point was 2.68 m shoreward from position C. The vortices with the clockwise rotation are seen obviously. They move slowly in the offshore direction along the water surface and increase their intervals by the vortex merging. After reaching a location of the offshore side, however, they decay rapidly.

In this paper, universal expressions about the formation region of the offshore vortices, the horizontal length scale of the vortices and the velocity of the vortex movement are given through visual experiments for three bed slopes.

### Experimental set-up and procedure

Figure 2 shows schematically an experimental apparatus. The wave tank was 12 m long, 0.4 m deep and 0.15 m wide. It was made of transparent acrylic plates and equipped with a sloping flat bed. The grades of  $\tan \theta = 1/37.0$ ,  $1/23.5$  and  $1/12.3$  were used as a bed slope. Two-dimensional regular waves were made by oscillating a flap. The wave period  $T$  was varied from 0.517 s to 2.59 s. The wavelength in deep water  $L_0$ , being calculated from  $gT^2/2\pi$ , was in the range from 0.417 m to 10.5 m, where  $g$  is the gravitational acceleration. The local wave height  $H$  was measured by using a capacitance-type wave gauge, and the local wave velocity  $C$  by putting a measuring point between two wave gauges. The wave height in deep

Figure 2. Schematic diagram of experimental set-up (dimensions in m). (a) water tank; (b) wave generator; (c) sloping bed; (d) wave gauges.

water  $H_0$  was evaluated by dividing the shoaling coefficient into  $H$ . The value of  $H_0$  ranged from 0.93 cm to 6.58 cm. The local wavelength  $L$  was calculated from  $L = C T$ .

Drift-currents induced in the offshore side from the breaking point were investigated by means of flow visualization. Dye of water-soluble aniline blue was used as a tracer. Granules of the dye were scattered on the water surface of the offshore zone. Whether the vortex train formed or not was confirmed through visual experiments. The behavior of vortices was videotaped to evaluate their characteristic quantities, i. e., the horizontal length scale of the vortices  $l$  and the velocity of vortex movement  $u$ . The length scale, which is defined by the horizontal distance from center to center, was determined by sampling some dozen of pictures in which the vortices arrange well over a distance of 0.5 m, and by averaging the read vortex intervals over the number of the samples. About ten sampled pictures were used for the evaluation of each value of  $u$ . The value of  $u$  was obtained by dividing a given distance by the time elapsed while a vortex moved through the distance, and by averaging the velocities measured in this way over the sampling number.

### Universal expression for vortex formation

Figure 3 shows a relation between the formation of the offshore vortex train and the types of breaking waves. The open circles and solid ones indicate its formation and non-formation, respectively. The two solid lines arc border lines between three types of breakers, which are given by Gaughan and Komar (1975). It is seen from this figure that the division of the formation region is given by the dash-dot line, i. e.,  $H_0/L_0 = 4.2 \times 10^{-2}$ , and that it is independent of the breaker types.

The formation conditions for the offshore vortices can be determined by using the variables of  $h$ ,  $L$ ,  $H$ ,  $T$ ,  $C$ ,  $g$  and  $\tan\theta$ , where  $h$  is the mean water depth. Two variables can be eliminated by considering into account the dispersion relation of water waves and the relation of  $C = L/T$ . If  $C$  and  $g$  are chosen as the two variables and the dimensional consideration is performed, a non-dimensional expression for the formation region is given by

$$f ( H/L, h/L, \tan\theta ). \quad (1)$$

In figures 4(a) to (c), the regions of the vortex formation and

Figure 3. Relation between the formation of offshore vortex train and the types of breaking waves.

non-formation are indicated by the open circles and solid ones, respectively. The solid curves mean the limiting wave steepness. These figures make it clear that the offshore vortices form in a shallow region offshoreward from the breaking point in the case when the wave steepness is relatively small.

Let us try to represent the three formation regions shown in figures 4(a) to (c) universally. For this purpose, at least, a coordinate system should be chosen to give an universal expression for the limiting wave steepness. Various empirical relations between the wavelength  $L_b$ , wave height  $H_b$  and water depth  $h_b$  at the breaking point have been proposed by many researchers (e.g. McCowan 1894 and Miche 1944). Galvin (1972) gives a relation including the bed slope,

$$H_b/L_b = 0.72 (1 + 6.4 \tan\theta) h_b/L_b . \tag{2}$$

In figure 5, the data obtained in this study are plotted to confirm the validity of Galvin's relation. The measured values for  $\tan\theta = 1/10$  are also included in this figure. The linear line shows Galvin's relation and the curved line is obtained by applying the

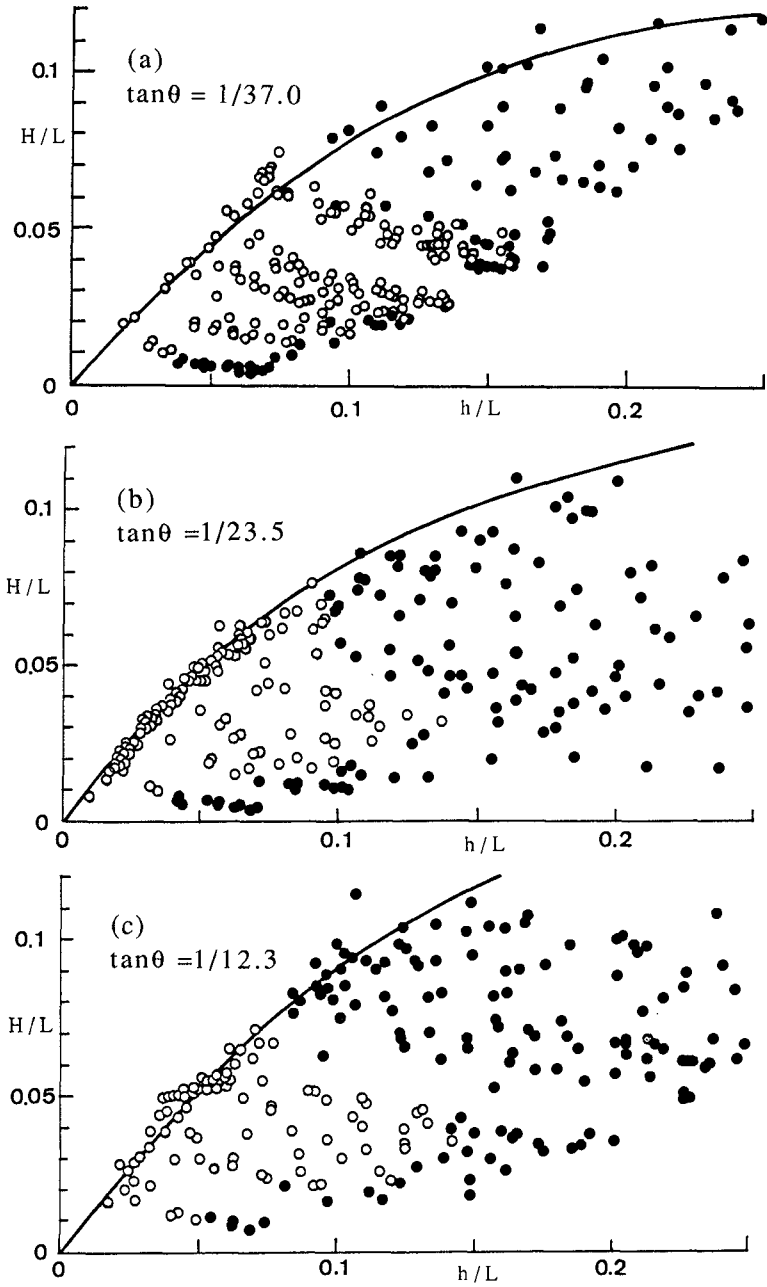

Figure 4. Formation regions of vortices for three bed slopes.

Figure 5. Universal expression for characteristic quantities of breaking waves on various bed slopes.

Figure 6. Universal expression for the vortex formation.

least squares method to these data. Though the data agree well with relation (2) at  $H_b/L_b \leq 0.05$ , the disagreement between them becomes remarkable in the range of  $H_b/L_b > 0.05$ . However, it is seen that the use of this coordinate system can express universally the limit of wave steepness over the wide range of  $H_b/L_b$ .

In figure 6, the data shown in figure 4 are rearranged in Galvin's coordinate system. The three formation regions are unified in the region bounded by three solid lines (a), (b) and (c). The offshore vortices form when waves with  $H_0/L_0 \leq 4.2 \times 10^{-2}$  propagate on a sloping bed. The condition is expressed by the region under line (b). The onshore border of the vortex formation is the breaking point, and that of the offshore side is given by line (c).

## Quantitative properties

### 1. Horizontal length scale of offshore vortices

The horizontal interval between offshore vortices  $l$  can be described completely by using the seven characteristic quantities of  $h$ ,  $L$ ,  $H$ ,  $C$ ,  $T$ ,  $g$  and  $\tan\theta$ . As discussed in the previous section, however, two dimensional quantities can be removed from these seven quantities. If  $C$  and  $g$  are eliminated, a dimensionless form of  $l$  is given by

$$l/h = f(H/L, h/L, \tan\theta). \quad (3)$$

Figures 7(a) to (c) show relations between  $l/h$  and  $H/L$  for each value of  $\tan\theta$ . It is seen that  $l/h$  is proportional to  $(H/L)^{-1}$ . Though the value of  $h/L$  was varied from 0.015 to 0.15 in this study, no systematic dependence of  $l/h$  on  $h/L$  was recognized. By approximating these data with the solid lines and plotting the values of  $(l/h) / (H/L)^{-1}$  against  $\tan\theta$ , the relation

$$l/h = 1.2 \times 10^{-2} (\tan\theta)^{-1/3} (H/L)^{-1} \quad (4)$$

is obtained empirically from figure 8. The comparison of the experimental data and equation (4) is shown by figure 9. It gives a good agreement. Another important thing is that  $l/h$  is of order unity. This means that the length scale of the offshore vortices is controlled mainly by the local water depth.

Figure 7. Relations between  $l/h$  and  $H/L$ .

Figure 8. Dependence of  $l/h$  on  $\tan\theta$ .

Figure 9. Universal expression for vortex intervals.

2. Velocity of vortex movement

The offshore vortices move slowly in the offshore direction. As discussed above, their velocities  $u$  also depend on  $h$ ,  $L$ ,  $H$ ,  $T$  and  $\tan\theta$ . The dimensional consideration deduces

$$u/(L/T) = f(h/L, H/L, \tan\theta). \tag{5}$$

Since  $u$  and  $L/T$  are of order  $10^{-1}$  cm/s and  $10^2$  cm/s, respectively, the value of  $u/(L/T)$  becomes extremely small. Therefore,  $L/T$  seems to be unsuitable as a quantity to non-dimensionalize  $u$ .

Another representative quantity is the velocity of offshore drift-current in the offshore zone. Longuet-Higgins derived its velocity profile induced by the wave propagation on a horizontal bed, i. e.,

Figure 10. Longuet-Higgins' solution at  $kh = 0.5$

Figure 11. Dependence of  $F_{max}$  on  $kh$ .

$$U(z) = (\pi H/L)^2 C F(z/h), \quad (6)$$

where

$$F(\mu) = \frac{1}{4 \sinh^2 kh} \left[ 2 \cosh \{2 kh(\mu - 1)\} + 3 + kh \sinh \{2 kh (3\mu^2 - 4\mu + 1)\} \right. \\ \left. + 3 \left( \frac{\sinh 2kh}{2 kh} + \frac{3}{2} \right) (\mu^2 - 1) \right], \quad (7)$$

z-axis is taken in the direction downward from the mean water level and  $k$  is the wave number. Figure 10 shows the profile of  $F(\mu)$  at  $kh = 0.5$ . The positive value of  $F(\mu)$  means that  $U(z)$  has the velocity in the offshore direction. The profile given by equation (7) takes a positive maximum value  $F_{\max}$  as shown in figure 10. Figure 11 shows the relation between  $F_{\max}$  and  $kh$  which was obtained numerically. Here, let us use the maximum offshore velocity calculated from

$$U_{\max} = (\pi H/L)^2 C F_{\max} \quad (8)$$

as a characteristic quantity controlling  $u$ , though it is obtained for a horizontal flat bed. In this case, a dimensionless form is given by

$$u/U_{\max} = f(h/L, H/L, \tan\theta). \quad (9)$$

Figures 12 (a) to (c) show the relations between  $u/U_{\max}$  and  $h/L$  for three bed slopes. The tendency that  $u/U_{\max}$  increases in proportion to  $h/L$  is recognized from these figures, but no systematic dependence of  $u/U_{\max}$  on  $H/L$  is seen. The relation between the proportional factors, which are obtained by approximating the data with the solid lines, and  $\tan\theta$  is shown in figure 13. It is seen that the proportional factors depend on  $(\tan\theta)^{2/3}$ . From these results, an empirical relation for the velocity of vortex movement,

$$u/U_{\max} = 3.6 \times 10^1 (\tan\theta)^{2/3} (h/L) \quad (10)$$

is obtained. The comparison of the experimental data and equation (10) is made in figure 14. A good agreement is recognized.

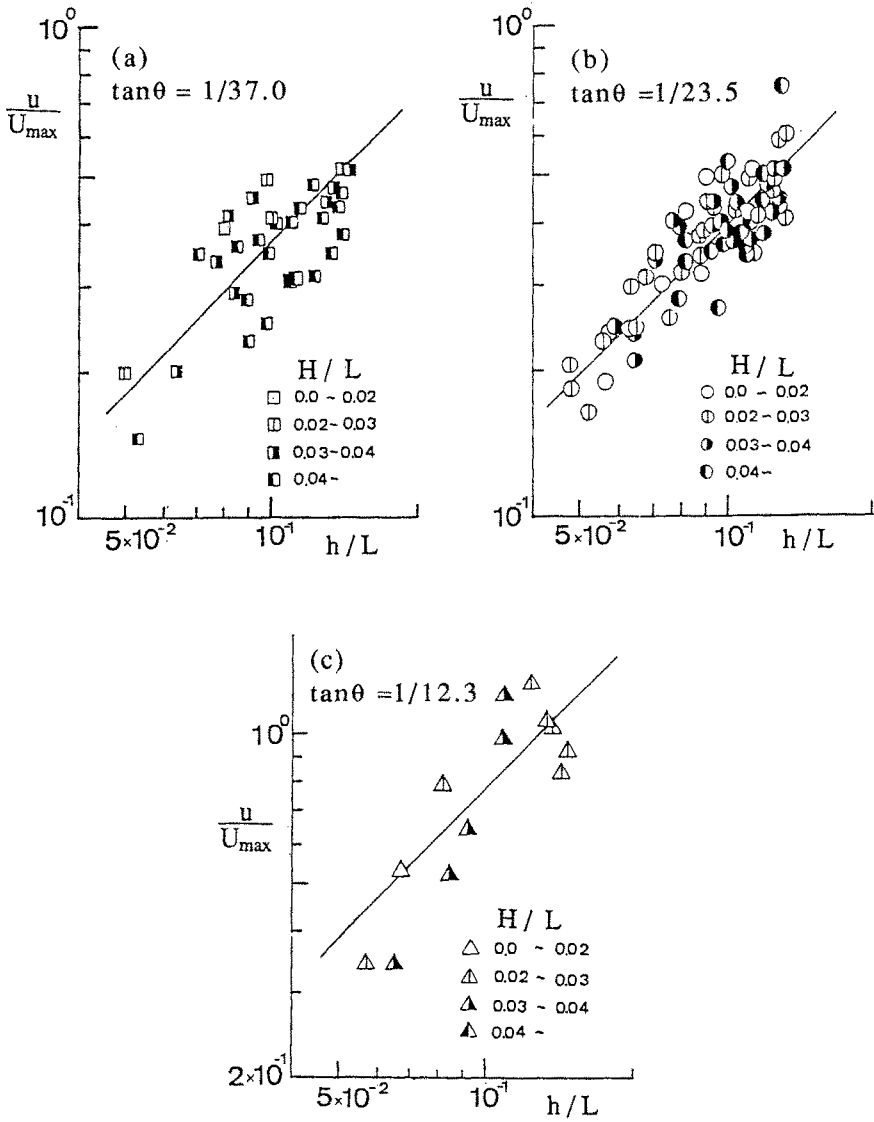

Figure 12. Relations between  $u/U_{max}$  and  $h/L$ .

Figure 13. Dependence of  $u/U_{max}$  on  $\tan\theta$ .

Figure 14. Universal expression for vortex velocities.

## Conclusions

It was found that a row of vortices, which was called the offshore vortex train, forms along the water surface of an offshore zone when two-dimensional regular waves whose steepness in deep water is smaller than  $4.2 \times 10^{-2}$  run up on a sloping bed. It seems to occur owing to the shear instability between the onshore drift-current and the offshore one. The instability starts near the breaking point. Moving in the offshore direction, the vortices merge each other and increase their intervals in the size of water depth. After reaching a location of the offshore side, they begin to decay because of the decrease of the strain rate between the two drift-currents. The universal expressions were also obtained empirically for the formation of the offshore vortices, their horizontal length scales and the velocities of vortex movement.

## CHAPTER 243

The Variation of Floc sizes within a turbidity maximum  
at spring and neap tides

J C McCabe<sup>1</sup>, K R Dyer<sup>2</sup>, D A Huntley<sup>2</sup>, A J Bale<sup>3</sup>

### Abstract

The variation of floc size has been measured during spring and neap tides at a height of 0.5 m above the bed in the turbidity maximum of the Tamar Estuary, UK. Two size populations were present. Small flocs were eroded from the bed during spring flood tides and were transported up estuary. Large flocs were dominant at other times, particularly just after high water when differential settling concentrated large flocs near the tip of the salt intrusion.

### Introduction

Many studies have shown that the size of flocs of cohesive sediment are functions of salinity, temperature, concentration (Owen, 1970), turbulent shearing (Burban et al, 1989) and other factors, such as surface ionic charge (Hunter & Liss, 1982). Most of these studies have been carried out in the laboratory, and the results interpreted in terms of known field situations. However, many of the flocs are fragile and floc sizes and size distributions obtained from samples are not good representations of those present in-situ (Gibbs & Konwar, 1983). There have been few studies where the undisturbed floc sizes have been measured in-situ. Gibbs et al (1989), Eisma et al (1990), Wells (1989), have used an underwater camera; Bale and Morris (1987) a marinized Malvern laser particle sizer, and van Leussen & Cornelisse (1992) an underwater video system.

<sup>3</sup> Plymouth Marine Laboratory, Plymouth, UK

Despite use of these techniques, it is still not clear what is the spatial and temporal distribution of floc sizes within a turbidity maximum, and what are the controlling processes.

This paper describes an in-situ study of the floc size distribution in the turbidity maximum of a partially mixed estuary carried out over spring and neap tides. The objectives were to consider the question of whether turbulence affects floc sizes in estuaries, but initially a description of the tidal variation of floc size was necessary.

### Methods

A Malvern laser sizer was mounted on a bed frame at a height of 50 cm above the bed. This instrument, described by Bale & Morris (1987), measures the diffraction of a laser beam by suspended particles in a sampling volume of approximately 1 cm<sup>3</sup>. The sizer produces a percentage size distribution in sixteen bands for diameters from 564  $\mu\text{m}$  to less than 5.8  $\mu\text{m}$ . Two distribution samples were recorded every 20 minutes.

Also mounted at a height of 50 cm were two Valeport annular electromagnetic flowmeters. These were mounted orthogonally at 45° to the flow direction so that the longitudinal and lateral components of the flow could be resolved, together with two estimates of the vertical component. Downing Optical Backscatter Gauges (OBS) were mounted at 23 and 50 cm height.

Through depth profiles were carried out every 20 mins to obtain profiles of salinity, temperature, velocity and suspended solids. This paper will concentrate on the results from the vertical profiles and the floc sizer.

Measurements were carried out over two spring tides (4, 5 July 1989) when the tidal range was 4.3 to 4.2 m, and two neap tidal cycles (28, 29 June 1989) with tidal range of 2.9 to 3.0 m at a position near Calstock on the Tamar Estuary (Fig 1). This position, 8 km from the head of the estuary, was within the tidal trajectory of the turbidity maximum and in the area where significant variations of concentration were likely during the tide, together with erosion and settling.

### Results

#### General Structure

During the neap tide (Fig 2) the rig was located within

the river water at low water, with the turbidity maximum to seaward. As the tide flooded, the turbidity maximum was pushed landwards, with concentrations of  $500 \text{ mg l}^{-1}$  being measured near the bed. Maximum velocities at this point coincided with the peak of the concentrations in the turbidity maximum. Once the peak of the turbidity maximum had passed, the saline intrusion appeared as a well mixed water column, rather like a piston pushing up the estuary. At HW there was a period of almost 2 hours of low velocities and salinities of  $>12\text{‰}$  near the bed. The surface outflow started before high water and the almost stationary salt intrusion was gradually eroded down to the bed over a period of about 2 hours with intense shearing at a rate of about  $0.2 \text{ s}^{-1}$  at the interface. Once the salt intrusion had been eroded, and the ebb current penetrated to the bed, the turbidity maximum was carried back on the ebb tide, but with peak concentrations about half and peak velocities about two-thirds those on the flood.

The pattern of change over a spring tidal cycle was remarkably similar, but with somewhat enhanced velocities and concentrations (Figure 3). On the flood tide concentrations in the turbidity maximum reached  $1000 \text{ mg l}^{-1}$  with velocities of  $1 \text{ ms}^{-1}$ . On the ebb tide concentrations were again about half that on the flood, but with velocities the same as that on neaps. The other two tidal cycles gave almost identical information for spring and neap tides.

### Floc Sizes

The size distributions show that there were two predominant modes in the floc distribution, flocs of less than  $5.8 \text{ }\mu\text{m}$  and flocs of  $100 \text{ }\mu\text{m}$  and larger. The relative proportions of these varied consistently through the tide. The smallest particles are thought to be individual grains and microflocs with small settling velocities and with stable structure. The largest flocs are likely to have been prone to break-up during shearing, and to rapid settling at times of low currents. Consequently their relative numbers were related to current speed.

During the first part of the flood tide in the water upstream of the turbidity maximum, the flocs were predominantly in the fine sizes. Within the turbidity maximum on the flood tide, there was a significant difference between spring and neap tides (Fig 4). On neap tides there was a broad peak of large flocs centred at about  $200 \text{ }\mu\text{m}$ , and with very few small flocs. During spring tides, however, there was a predominance

of fine flocs, with no large flocs. There were more flocs in the size range 10-100  $\mu\text{m}$  at spring tides, and these may be the result of turbulent breakup of the larger flocs present at neap tides.

At the seaward end of the turbidity maximum, encountered a little later in the flood tide the proportion of fine flocs diminished rapidly, and large flocs predominated. This period extended over high water and into the beginning of the ebb tide. The peak of the distribution became more and more sharp (better sorted), until during the time when the salt intrusion was being eroded, there were relatively few flocs of less than 100  $\mu\text{m}$  (Figure 5). There is a remarkable similarity between the size distributions at this phase of the tide between neap and spring tides. It is also likely at this time that there were larger flocs still within the water that were beyond the resolution of the instrument.

Within the turbidity maximum on the ebb the proportion of large flocs diminished and the proportion of flocs in the size range 30-200  $\mu\text{m}$  increased (Figure 6). The differences between spring and neap tides in the fraction greater than 10  $\mu\text{m}$  in the ebb turbidity maximum is small in comparison with those in the turbidity maximum on the flood tide. This may reflect the similarity in current velocities and in concentrations on neap and spring ebb tides, and the contrast on the respective flood tides.

Consequently there appears to be a significant variation in floc sizes through the turbidity maximum, with large flocs predominating at the downstream end of the maximum. The fine sizes are present at spring tides and particularly during the maximum flood current.

### Discussion

The most striking feature is that the spring flood turbidity maximum consisted almost entirely of particles less than 6  $\mu\text{m}$  in diameter. The neap flood turbidity maximum consisted mostly of larger particles. The active event seemed to be the spring flood tide when new primary particles were eroded off the bed. These were carried upstream past the rig, but did not all return on the ebb. The distribution of larger particles remained remarkably similar on each ebb and was also similar to that of the neap flood. These observations suggest that there are two populations of particles present, with different characteristics.

It is surprising that the two populations of flocs can be so distinctive especially in the energetic spring

tide situation. The dramatic change in the floc size distribution was associated with the erosion and retreat of the salt intrusion prior to the passage of the main part of the turbidity maximum on the ebb tide. As the salt intrusion was entrained into the upper layer and the interface was eroded down to the height of the instrument, the particle size became steadily larger and better sorted. When the interface was below the level of the sensors, and they were in the upper seaward flowing brackish layer, the sizes abruptly decreased. The size variation during this period may be explained by comparing the rate of entrainment with the particle settling velocity. The entrainment rate of  $\sim 1.5 \text{ m hr}^{-1}$  or the rate of descent of the interface, is comparable with the settling velocity, measured in-situ, of about  $200 \mu\text{m}$  (Fennessy, pers comm). Thus flocs of this size would tend through settling to accumulate at the interface. Larger particles would settle through into the lower layer and reach the bed, though the larger flocs may have an effective density low enough to become neutrally buoyant at the interface. Fine particles would be sheared off downstream in the brackish water layer. Thus, as the thickness of the lower layer reduced, the larger particles became concentrated at the tip of the salt intrusion. This process will enhance the effects of differential settling which will cause larger particles to accumulate near the bed. Differential settling will also take place throughout the turbidity maxima, but redispersion will occur during the maximum currents. In this case some breakup of the flocs is likely to broaden the peak of large flocs and reduce the modal diameter. Thus largest flocs are retained at the downstream end of the turbidity maximum. Gibbs et al (1989) have found in the Gironde Estuary that the maximum of floc size is 30 km seaward of the turbidity maximum, and there are indications of similar floc size distributions within the turbidity maximum of other estuaries (Eisma et al, 1991).

On the flood the maximum is advected upriver picking up any large flocs that settled out during the ebb. On spring tides primary particles are also eroded from the bed to form the bulk of the flocs. The turbidity maximum passes upstream and, since less particulate matter is carried downstream on the ebb, deposition occurs. Differential settling takes place and those settling into the salt intrusion are separated by the velocity shear from the finer flocs. The larger flocs are then re-eroded on the following flood tide.

## CHAPTER 244

### DISPERSION OF HEAVY SUSPENSIONS IN WAVE BOUNDARY LAYERS

Chiang C. Mei & Chimin Chian  
Department of Civil Engineering  
Massachusetts Institute of Technology

#### 1. Introduction

The transport of suspended particles is of interest to the coastal engineer because it affects the distribution of sediments and the evolution of shorelines. It is also important to pollutant disposal in the sea, and to the transport of nutrients needed for sustaining marine life. Planktonic larvae depend on waves and currents to carry them from offshore to the rock stratum for reproduction and growth. External fertilization of sperms and eggs of marine organisms are further affected by the convection and diffusion processes in the sea.

Taylor's pioneer work in a steady flow through a tube has shown that diffusion, whether molecular or turbulent, is greatly enhanced by transverse shear in the flow. Since in the sea the bottom boundary layer is the zone where shear is the strongest, dispersion must be the most prominent there. For wave-induced boundary layers only the flow field has been studied extensively. For example Stokes laminar boundary layer theory has been extended to turbulent boundary layers by Kajiura(1968), Jonnson & Carlsen(1976), Grant & Madsen(1979) and others. The mean circulation induced in the oscillating boundary layer by Reynolds stresses has been studied under pseudo-laminar model by Longuet-Higgins(1958), Hunt & Johns(1963), Carter, Liu & Mei(1973) etc. Trowbridge & Madsen(1984a,b) further extended it to turbulent flows. So far there has been little theoretical work for predicting dispersion in wave boundary layers.

What is needed is a theory for diffusion of particles in such a transient and nonuniform field of shear. In this paper we outline our recent work obtained by employing the theory of homogenization, which is a systematic technique of taking averages over the period of microscale to obtain the slow variations

over the microscale. The central tool is the method of multiple scales which has been recently applied to dispersion through spatially periodic porous media. The same technique is shown here to be effective for wave problems where there is periodicity in time. Specifically we consider here the dispersion of a cloud of suspension with a prescribed initial distribution in the boundary layer. Attention will be focussed on small amplitude waves without ambient current so that the flow field including the first order oscillations and second order mean can be worked out by a perturbation method, and use will be made of the fact that the boundary layer is much thinner than the horizontal length scale so that the vertical variation can be decoupled from the horizontal problem. Starting with a convective diffusion equation for a heavy suspension for one particle size, we expand the concentration as a perturbation series in powers of the wave steepness. At the leading order the concentration is expected to vary only slowly in time and does not oscillate with the wave because of its weak velocity field. The vertical distribution is due to the balance between vertical diffusion and gravity, but the horizontal distribution is undetermined. The corresponding mathematical problem is a homogeneous boundary value problem in the vertical direction. At the next two orders the fluctuation from the mean is caused by the oscillatory velocity field and consists of both oscillating and slowly varying parts. Their time averages over a wave period are governed by two inhomogeneous boundary value problems in the vertical direction. The solvability condition which imposes constraints on the horizontal and temporal variation of the leading order concentration, leads to the effective diffusion equation. The effective horizontal velocity of convection is shown to be a weighted average of the induced streaming velocity in the boundary layer. For the special model of constant eddy viscosity, the convective velocity and dispersivity tensors are found explicitly in terms of the oscillatory velocity field outside the boundary layer. Specific initial value problems for a prescribed initial concentration cloud will be solved for the following cases, with emphasis on the effects of the initial position of the cloud on its final destiny.

## 2. Perturbation analysis of diffusion in the boundary layer

We assume that the particles are so small that its velocity is nearly equal to the mean velocity of the local fluid, and that the volume concentration is so small that the suspension cloud does not alter the dynamics of the fluid motion.

Let  $C$  denote the volume concentration,  $-w_o$  the fall velocity of the suspended particles, and  $D_H, D_V$  the eddy mass diffusivities. The diffusion equation for the concentration  $C$  of a very dilute sediment cloud can be approximated by

$$\frac{\partial C}{\partial t} + \frac{\partial u_j C}{\partial x_j} + \frac{\partial}{\partial z} [(-w_o + w) C] = \frac{\partial}{\partial x_j} \left( D_H \frac{\partial C}{\partial x_j} \right) + \frac{\partial}{\partial z} \left( D_V \frac{\partial C}{\partial z} \right), \quad (2.4)$$

where  $j = 1, 2$  and  $u_j$  represent the horizontal components of the fluid velocity and  $w$  the vertical component. The crucial boundary condition on the seabed is a matter of considerable uncertainty. For example in steady uniform flows there should not be any net exchange of particles, hence

$$D_V \frac{\partial C}{\partial z} + w_o C = 0, \quad (2.5)$$

This leads to the profile of  $C(z)/C(0)$  but leaves the value of  $C(0)$  undetermined. For spatially nonuniform flows Sayre (1969) proposed the following empirical relation

$$D_v \frac{\partial C}{\partial z} + (1 - \alpha)w_o C + W = 0,$$

where  $\alpha$  is the bed absorbcency coefficient representing the probability that a particle settling to the bed is deposited there,  $W$  the average rate of local entrainment. Direct measurements of  $\alpha$  and  $W$  are obviously difficult and none is known to have been made. To simulate resuspension in wave boundary layers it has been proposed that the rate of concentration flux is an empirical function of time. Others have suggested that the bed concentration is proportional to the excess shear stress over the critical stress to initiate the bed load movement. These empirical consideration are necessary practical measures when local scour is an integral part of the sediment process. However, there are situations where the sediments or contaminants are dumped from ships, or released from a sewage outfall, and not supplied locally from the seabed. Then as long as they can be kept in suspension, the no-flux condition is still appropriate. We shall confine our attention to such cases where the bed is non-erodible bed and particles so small that they are kept in suspension for almost any bed shear. It is reasonable to take  $\alpha = W = 0$  so that

$$D_V \frac{\partial C}{\partial z} + w_o C = 0, \quad z = 0 \quad (2.6)$$

suffices.

At the upper edge of the boundary layer we assume

$$C = 0, \quad z \rightarrow \infty. \quad (2.8)$$

In addition, the initial horizontal distribution of the depth averaged concentration is prescribed in some source area. Thus the physical problem is to seek the long-time diffusion of a sediment cloud from a localized source.

In oceanic flows, momentum eddy diffusivities in horizontal and vertical directions may be quite different (see *e.g.*, Pedlosky, 1979), but the value of the horizontal diffusivity is difficult to estimate reliably. In past theories on dispersion, two assumptions are common. One is the equality of momentum and

mass diffusivities (Reynolds analogy, Taylor, 1953). The second is the equality of the longitudinal and transverse diffusivities (Taylor, 1953; Sayre, 1969 and Sumer, 1974). In wave boundary layers, there is the added complexity that the eddy viscosity may depend on time. However, for coastal applications, most models of eddy viscosity are time-independent (see Sleath 1992 for survey); this simplifying assumption is also adopted here.

In the present problem there are several characteristic length scales in the vertical direction. The first is the thickness of a steady concentration layer due to the balance of downward sedimentation by gravity and vertical diffusion,  $d \sim D_V/w_o$ . Associated with fluid oscillations there are two additional vertical length scales, i.e., the oscillatory boundary layer thicknesses  $\delta \sim \sqrt{2\nu_e/\omega}$  and  $\delta_D \sim \sqrt{2D_V/\omega}$ . For generality, all three scales are assumed to be comparable, i.e., implying that

$$Sc = \frac{\nu_e}{D} \sim \left( \frac{\delta}{\delta_D} \right)^2 = O(1), \quad (2.9)$$

where  $Sc$  is the Schmidt number.

We now consider small amplitude oscillations of high enough frequency so that both the wave steepness,  $kA$ , and the ratio of the oscillatory boundary layer thickness to the wave length,  $k\delta$ , are small, i.e.

$$\epsilon = kA \ll 1, \quad (2.10a)$$

$$\beta = k\delta \sqrt{\frac{D_H}{D_V}} \ll 1. \quad (2.10b)$$

Let us expand the velocity field  $(u_i, w)$  in powers of  $\epsilon$ ,

$$u_i = u_i^{(1)} + u_i^{(2)} + \dots, \quad i = 1, 2; \quad w = w^{(1)} + w^{(2)} + \dots, \quad (2.11)$$

where the superscripts indicate the order in powers of  $\epsilon$ , i.e.,  $u_i^{(n)}, w^{(n)} = O(\epsilon^n)$ . Clearly there are two distinct time scales in the diffusion process, one for the vertical diffusion across the boundary layer,  $O(\delta^2/D_V)$ , and the other for the horizontal diffusion across a wave length,  $O(1/k^2 D_H)$ . The ratio between the two is  $O(k^2 \delta^2 D_H/D_V) = O(\beta^2)$ . It is therefore natural to introduce multiple scale coordinates for time,  $t$  and  $t' = \beta^2 t$ . Assume for generality  $\epsilon = O(\beta)$  so that we may use

$$T = \epsilon^2 t \quad (2.12)$$

instead of  $t'$ , and expand  $C$  as a perturbation series

$$C = C^{(0)} + C^{(1)} + C^{(2)} + \dots, \quad (2.13)$$

where  $C^{(0)}$  is independent of the fast time scale and  $C^{(n)}, n = 1, 2, \dots$  dependent on  $t$  and  $T$ . At the leading order in  $\epsilon$ ,  $C^{(0)}$  satisfies the homogeneous ordinary differential equation

$$-w_o \frac{\partial C^{(0)}}{\partial z} = \frac{\partial}{\partial z} \left( D_V \frac{\partial C^{(0)}}{\partial z} \right), \quad 0 < z < \infty, \tag{2.14}$$

with the homogeneous boundary conditions

$$w_o C^{(0)} + D_V \frac{\partial C^{(0)}}{\partial z} = 0, \quad z = 0; \tag{2.15}$$

$$C^{(0)} = 0, \quad z \rightarrow \infty. \tag{2.16}$$

The nontrivial solution is

$$C^{(0)} = \widehat{C}F, \tag{2.17a}$$

where

$$F = \exp \left( - \int \frac{w_o}{D_V} dz \right) \tag{2.17b}$$

gives the vertical structure and

$$\widehat{C} = \widehat{C}(x_i, T), \quad i = 1, 2 \tag{2.17c}$$

gives the horizontal variation of  $C^{(0)}$ . As in the steady uniform flow  $C^{(0)}$  is so far unknown. At  $O(\epsilon)$ , the period-average of  $C^{(1)}(x, y, t, T)$  can be shown to be zero. Assuming the first order fluid velocity in the boundary layer to be simple harmonic, the time-harmonic part of  $C^{(0)}$  is forced by various products of  $u^{(1)}$  and  $C^{(0)}$  and their derivatives. Therefore  $C^{(1)}$  can be solved in terms of  $C^{(0)}$  and its horizontal gradient. At  $O(\epsilon^2)$ , the period-average of  $C^{(2)}$  satisfies an inhomogeneous differential equation similar to (2.6). Its solution implies that the depth average of the forcing terms must vanish. This leads to

$$\frac{\partial \widehat{C}}{\partial T} \langle F \rangle + \frac{\partial}{\partial x_i} \left[ \langle \bar{u}_i^{(2)} F \rangle \widehat{C} \right] = - \frac{\partial}{\partial x_i} \langle \bar{u}_i^{(1)} C^{(1)} \rangle + \frac{\partial}{\partial x_j} \langle D_H \frac{\partial}{\partial x_j} (\widehat{C}F) \rangle. \tag{2.18}$$

Once a specific choice of  $D_V$  and  $D_H$  is made, the right hand side of (2.18) can be found in terms of  $C^{(0)}$ , hence  $\widehat{C}$ . This then gives the effective convection-diffusion equation for  $\widehat{C}$ . As will be identified later,  $\bar{u}_i^{(2)}$  on the left is Eulerian streaming in the boundary layer. The first term on the right represents the dispersion due to oscillatory shear in the boundary layer and the last term the horizontal turbulent diffusion.

Though the form is entirely expected, every term in (2.18) has been deduced here without *additional* closure hypotheses.

In the rest of the paper the simplifying assumption  $D_H = D_V = D =$  constant will be made to enable explicit analytical results.

**3. The Stokes effective coefficients**

For constant eddy diffusivities the first order velocity is the well known solution of Stokes the second order mean is the Eulerian streaming inferable from Hunt and Johns (see Mei 1983). Details of  $C^{(1)}$  is described elsewhere. After considerable algebra we get the effective diffusion equation for  $\hat{C}$ :

$$\frac{\partial \hat{C}}{\partial T} + \frac{\partial}{\partial x_i} (u_i \hat{C}) = D \frac{\partial^2 \hat{C}}{\partial x_j \partial x_j} + \frac{\partial}{\partial x_i} \left( \mathcal{D}_{ij} \frac{\partial \hat{C}}{\partial x_j} \right), \tag{3.1}$$

where

$$u = \frac{1}{\omega} \Re \left( H_1 U_o \frac{\partial U_o^*}{\partial x} + H_2 V_o \frac{\partial U_o^*}{\partial y} + H_3 U_o \frac{\partial V_o^*}{\partial y} \right), \tag{3.2}$$

$$v = \frac{1}{\omega} \Re \left( H_1 V_o \frac{\partial V_o^*}{\partial y} + H_2 U_o \frac{\partial V_o^*}{\partial x} + H_3 V_o \frac{\partial U_o^*}{\partial x} \right),$$

$$\begin{aligned} \mathcal{D}_{xx} &= \Re \left[ \frac{H_4}{\omega} |U_o|^2 \right], & \mathcal{D}_{xy} &= \Re \left[ \frac{H_4}{\omega} (U_o^* V_o) \right], \\ \mathcal{D}_{yx} &= \Re \left[ \frac{H_4}{\omega} (U_o V_o^*) \right], & \mathcal{D}_{yy} &= \Re \left[ \frac{H_4}{\omega} |V_o|^2 \right]. \end{aligned} \tag{3.3}$$

The coefficients  $H_1, H_2, H_3$  and  $H_4$  are functions of  $M$  and  $Sc$ .

Equation (3.1) may be normalized by defining  $\bar{U}_o$  to be the maximum of the first order velocity  $(U_o^2 + V_o^2)^{1/2}$  and letting

$$U'_{oi} = \frac{U_{oi}}{\bar{U}_o}, \quad x'_i = kx_i, \quad t' = \frac{k^2 \bar{U}_o^2}{\omega} T, \tag{3.4}$$

where primes denote dimensionless quantities. Then

$$\frac{\partial \hat{C}}{\partial t'} + \frac{\partial}{\partial x'_i} (u'_i \hat{C}) = \frac{\partial}{\partial x'_i} \left( K'_{ij} \frac{\partial \hat{C}}{\partial x'_j} \right), \tag{3.5}$$

where

$$u' = \Re \left( H_1 U'_o \frac{\partial U'^*_{o'}}{\partial x'} + H_2 V'_o \frac{\partial U'^*_{o'}}{\partial y'} + H_3 U'_o \frac{\partial V'^*_{o'}}{\partial y'} \right),$$

$$v' = \Re \left( H_1 V'_o \frac{\partial V'^*_{o'}}{\partial y'} + H_2 U'_o \frac{\partial V'^*_{o'}}{\partial x'} + H_3 V'_o \frac{\partial U'^*_{o'}}{\partial x'} \right),$$

$$K'_{xx} = \mathcal{D}'_{xx} + D' = \Re(H_4) |U'_o|^2 + D',$$

$$K'_{xy} = \mathcal{D}'_{xy} = \Re(H_4 U'^*_o V'_o),$$

$$K'_{yx} = \mathcal{D}'_{yx} = \Re(H_4 U'_o V'^*_o),$$

$$K'_{yy} = \mathcal{D}'_{yy} + D' = \Re(H_4) |V'_o|^2 + D',$$

$$D' = D / (\bar{U}_o^2 / \omega),$$

in which  $K'_{ij}$  are components of the total dispersivity tensor.

In steady flows in a channel or a tube the longitudinal dispersion coefficient is usually much greater than diffusivity (molecular or eddy). It can be shown that the shear-enhanced dispersion can be much greater than the eddy diffusivity if the ambient oscillation is sufficiently intense or the frequency sufficiently low. Otherwise the two can be comparable.

We now examine the spatial variations of the dispersion phenomenon by specific examples. For brevity, primes on dimensionless quantities will be dropped for convenience in later discussions. The values of  $H_1, H_2, H_3, H_4$  are for  $M = Sc = 1$ .

**4. Two-dimensional diffusion of a localized cloud in bidirectional waves**

We consider a system of short-crested waves whose inviscid velocity amplitudes near the seabed are described in dimensional variables by

$$\begin{aligned} U_o &= 2i\bar{U}_o \cos \theta \sin(kx \cos \theta) e^{iky \sin \theta}, \\ V_o &= 2\bar{U}_o \sin \theta \cos(kx \cos \theta) e^{iky \sin \theta}. \end{aligned} \tag{4.1}$$

This corresponds to a plane wave incident towards and reflected by a sea wall along the  $y$  axis. The angle of incidence is  $\theta$ . In normalized variables (with primes omitted), we have

$$\begin{aligned} U_o &= 2i \cos \theta \sin(x \cos \theta) e^{iy \sin \theta}, \\ V_o &= 2 \sin \theta \cos(x \cos \theta) e^{iy \sin \theta}. \end{aligned} \tag{4.2}$$

It is easy to calculate the following dimensionless coefficients,

$$\begin{aligned} \mathcal{U} &= [2\Re(H_1) \cos^3 \theta + (\Re(H_3) - \Re(H_2)) \sin \theta \sin 2\theta] \sin(2x \cos \theta), \\ \mathcal{V} &= [2\Im(H_1) \sin^3 \theta + \Im(H_3) \cos \theta \sin 2\theta] 2 \cos^2(x \cos \theta), \\ K_{xx} &= 4\Re(H_4) \cos^2 \theta \sin^2(x \cos \theta) + D, \\ K_{yy} &= 4\Re(H_4) \sin^2 \theta \cos^2(x \cos \theta) + D, \\ K_{xy} &= -K_{yx} = \Im(H_4) \sin 2\theta \sin(2x \cos \theta). \end{aligned} \tag{4.3}$$

Note that the tensor  $\{K_{ij}\}$  is not symmetric.

Let us examine the diffusion due to the impulsive release from a localized Gaussian cloud

$$\hat{C}(x, y, 0) = C_o \exp \left\{ - [(x - x_c)^2 + (y - y_c)^2] / L^2 \right\}. \tag{4.4}$$

The assumption of  $Sc = M = 1$  is still kept, for which  $\Re(H_1) = -0.122$ ,  $\Im(H_1) = \Im(H_3) = 0.659$ ,  $\Re(H_2) = 0.033$ ,  $\Re(H_3) = -0.155$ ,  $\Re(H_4) = 0.024$  and  $\Im(H_4) = 0.234$ . Choosing  $D = 10^{-3}$  and  $L^2 = 0.1$ , the initial value problem is solved numerically by a Peaceman-Rachford ADI (alternating-direction) finite difference method. Three angles of incidence and various positions of the initial source center have been considered.

As a sample we consider oblique incidence  $\theta = \pi/4$ , then

$$\begin{aligned} \mathcal{U} &= \frac{1}{\sqrt{2}} \Re(H_1 + H_3 - H_2) \sin \sqrt{2}x = -0.219 \sin \sqrt{2}x, \\ \mathcal{V} &= \sqrt{2} \Im(H_1 + H_3) \cos^2 \frac{x}{\sqrt{2}} = 1.864 \cos^2 \frac{x}{\sqrt{2}}, \end{aligned} \quad (4.5)$$

and

$$\begin{aligned} K_{xx} &= 2\Re(H_4) \sin^2 \frac{x}{\sqrt{2}} + D = 0.048 \sin^2 \frac{x}{\sqrt{2}} + D, \\ K_{yy} &= 2\Re(H_4) \cos^2 \frac{x}{\sqrt{2}} + D = 0.048 \cos^2 \frac{x}{\sqrt{2}} + D, \\ K_{xy} &= -K_{yx} = \Im(H_4) \sin(\sqrt{2}x) = 0.234 \sin(\sqrt{2}x). \end{aligned} \quad (4.6)$$

Thus for  $x_c = 0$ ,  $\mathcal{V}$  is dominant; the cloud is convected along the line  $x = 0$  and diffused faster in the  $y$  than in  $x$  as shown in figure 1. For  $x_c \cos \theta = x_c/\sqrt{2} = \pi/2$ ,  $K_{xx} > K_{yy}$ , the nonuniform convection velocity causes the cloud to bifurcate towards the lines  $x_c/\sqrt{2} = 0, \pi$  where  $K_{yy} > K_{xx}$ , as in figure 2. For  $x_c \cos \theta = \pi/4$ , most of the pulse is convected to the left, with the front leading the rest in the shape of an eel, as shown in figure 3.

We have also considered a sustained source and solved the inhomogeneous diffusion equation

$$\frac{\partial \hat{C}}{\partial t} + \frac{\partial}{\partial x_i} (u_i \hat{C}) = \frac{\partial}{\partial x_j} \left( K_{ij} \frac{\partial \hat{C}}{\partial x_j} \right) + S(x_i), \quad t > 0. \quad (4.7)$$

The source function  $S$  is chosen to be a cosine-shaped distribution centered around  $(x_c, y_c)$  and maintained at a steady rate after  $t = 0$ . A plume is formed with the front evolving in the same way as the impulsively released cloud, but the plume is always connected back to the steady source. We shall, therefore, omit the results here.

## 5. Concluding remarks

In this paper we have given general formulas for convections and diffusion in a wave boundary layer. As an example we have examined a localized cloud in a bidirectional wave system which may represent an obliquely incident and reflected wave system near a sea wall. The cloud drifts to the nodal line close

to its initial position. When the particle cloud is initially midway between two nodal lines along the  $y$  axis. The cloud then bifurcates towards the two nodal lines on each side while the peaks diminish.

Future improvements must include better models of turbulence, deposition and resuspension. For fine cohesive sediments possible coagulation is worth studying. Finally it is interesting to examine dispersion in the surf zone where breaking waves induce longshore currents.

## CHAPTER 245

### COMBINED CONVECTION-DIFFUSION MODELLING OF SEDIMENT ENTRAINMENT

by

Peter Nielsen

#### Abstract

A new, quantitative framework is presented for the modelling of suspended sediment concentration distributions. It accounts for large scale mixing (convection) as well as small scale mixing. The small scale mixing is modelled in terms of gradient diffusion as usual. It is shown how the new, combined convection-diffusion model can explain the different  $\bar{c}(z)$ -distributions of different sediment sizes in the same flow. Also, the dependence of the  $\bar{c}(z)$ -distribution shape on wave period and sediment settling velocity is explained for oscillatory flow over ripples. It is shown that individual Fourier components of  $c_n(z,t)$  behave differently in diffusion dominated and in convection dominated flows. This makes it possible to determine the dominant entrainment mechanism (convection or diffusion) on the basis of concentration time series taken simultaneously at different levels.

#### 1. Introduction

Experimental data calls for a new description of the distribution of suspended sediment. That is, the traditional gradient diffusion model is inadequate as a description of many natural suspension processes.

Gradient diffusion is suited only as a description for processes where the mixing length  $l_m$  is small compared to the overall scale. It cannot describe details on a scale comparable or smaller than  $l_m$ , see Figure 1.

Some of the natural processes which involve large scale mixing mechanisms are: Entrainment of sand from rippled beds, lifting of sand straight from the bed to the surface behind plunging breakers, entrainment by turbulent bursts in sheet flow, entrainment by the obliquely descending vortices of Nadaoka et al (1988), and from steady streams, entrainment by the vortices which are formed behind dunes and subsequently carry sand to the surface.

Australia 4072, fax +61 7 365 4599.

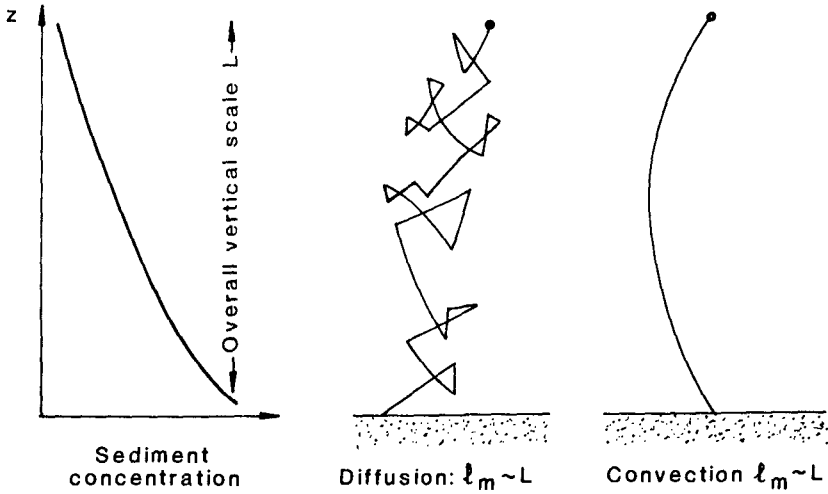

Figure 1: A concentration profile with overall scale  $L$  may be generated by either gradient diffusion ( $l_m < L$ ) or convective entrainment ( $l_m \sim L$ ), but usually it will be due to a mixture of both.

These processes require a different modelling framework than gradient diffusion.

The quantitative framework for the combined convection-diffusion process is briefly derived in Sections 3 and 4. The main new ingredient here is the expression for the convective upward flux proposed by Nielsen (1991).

Section 5 then discusses the shape of the distributions of time-averaged concentrations  $\bar{c}(z)$ . A single shape parameter  $S$  is defined with which variation in shape of the  $\bar{c}(z)$ -profiles with wave period and sediment settling velocity can be explained.

The behaviour of the time dependent (harmonic) components  $c_n(z,t)$  of the concentration is discussed in Section 6. It is shown how the relative importance of convective versus diffusive mixing is indicated by simultaneous concentration time series from different elevations.

### 3. Quantification of the convective entrainment flux

Most natural suspension processes involve mixing on different scales, see Figure 1, and mechanisms with large mixing lengths  $l_m$  compared with the overall scale, require a different mathematical framework than gradient diffusion. A quantitative description for the large scale ( $l_m \sim L$ ) mixing mechanisms is suggested as outlined in Figure 2.

Figure 2: Sand which is entrained from the bed at time  $t_0$  is assumed to travel upwards with speed  $w_c$ . Not all of the sand will reach the same level. The distribution of entrainment levels  $z_e$  is given by  $F(z) = P\{z_e > z\}$ . After reaching its entrainment level  $z_e$  at time  $t_0 + z_e/w_c$ , a sand particle is assumed to settle out with its still water settling velocity  $w_o$ . During the settling process it may be affected by small scale mixing (diffusion).

A quantitative description of the convective, upward sediment flux  $q_c(z,t)$  in accordance with Figure 2, has been derived by Nielsen (1991,1992). He suggested the form

$$q_c(z,t) = p\left(t - \frac{z}{w_c}\right) F(z) \quad (1)$$

where  $p(t)$  is the amount of sand which is picked up from the bed at time  $t$ .

#### 4. Continuity equation for the combined process

The continuity equation for the combined process, i.e., the equation which expresses the conservation of sand in the combined convection diffusion process is

$$\frac{\partial c}{\partial t} = w_o \frac{\partial c}{\partial z} - \frac{\partial q_c}{\partial z} - \frac{\partial q_D}{\partial z} \quad (2)$$

which with the expression (1) inserted for the convective upward flux, and with

the upward diffusive flux  $q_D = -\epsilon_s \frac{\partial c}{\partial z}$  becomes

$$\frac{\partial c}{\partial t} = w_o \frac{\partial c}{\partial z} + \frac{1}{w_c} p'(t - \frac{z}{w_c}) F(z) - p(t - \frac{z}{w_c}) F'(z) + \frac{\partial}{\partial z} (\epsilon_s \frac{\partial c}{\partial z}) \quad (3)$$

or

$$\frac{\partial c}{\partial t} - w_o \frac{\partial c}{\partial z} - \frac{\partial}{\partial z} (\epsilon_s \frac{\partial c}{\partial z}) = \frac{1}{w_c} p'(t - \frac{z}{w_c}) F(z) - p(t - \frac{z}{w_c}) F'(z) \quad (4)$$

from which we see that the homogeneous equation is the usual diffusion equation, while the convective flux enters only through the forcing terms.

#### 4. The shape of the $\bar{c}(z)$ -profiles

The inadequacy of pure gradient diffusion as a universal model for sediment suspension becomes particularly evident when one considers the distributions of different grain sizes in the same flow. An example is shown in Figure 3.

Figure 3: Normalised distributions of different sand sizes in the same flow (oscillatory flow over ripples). The data was obtained by sieving suction samples from each elevation. Data from Nielsen (1983).

The interesting thing about these profiles is that they do not have the same shape. In this case, the fine sand shows typically upward convex profiles while the coarse sand shows upward concave profiles. Such differences between different sand sizes (different settling velocities  $w_o$ ) cannot be explained within the gradient diffusion framework. If the concentration profiles had been a result of pure gradient diffusion with diffusivity  $\epsilon_s(z)$ , they would have had the mathematical form

$$\ln \frac{\bar{c}}{C_o} = -w_o \int_0^z \frac{dz}{\epsilon_s} \quad (5)$$

where  $C_o = \bar{c}(o)$ .

This shows that the profiles for different sand sizes would have similar shapes when plotted as in Figure 3, the role of the settling velocity  $w_o$  would be only to tilt the profiles towards the left.

The same picture as Figure 3 was presented by the natural-ripple-data from a subsequent laboratory study of McFetridge & Nielsen (1985).

Another observation which underlines the need for a new distribution model is that time averaged concentration profiles over rippled beds under waves tend to change shape from upward convex to upward concave with increasing wave period. Examples of this are shown in Figure 4.

Figure 4: Time averaged concentration profiles over rippled beds in an oscillating water tunnel. For the shortest periods, the  $\bar{c}$ -profiles are upward convex (at least for the first 4 ripple heights). With increasing  $T$ , they become more and more upward concave.  $d_{50}=0.21mm$  in all of the experiments.  $\blacksquare$  :  $T=1s$ ,  $U_{max}=0.5m/s$ ,  $+$  :  $T=2s$ ,  $U_{max}=0.5m/s$ ,  $*$  :  $T=4s$ ,  $U_{max}=0.3m/s$ ,  $\times$  :  $T=10s$ ,  $U_{max}=0.3m/s$ . Data from Bosman (1982) and Ribberink & Al-Salem (1989).

This change of shape of the  $\bar{c}(z)$ -profiles with wave period is difficult to explain within the gradient diffusion framework. The different shapes for  $\bar{c}(z)$  would, in that framework, indicate different distributions of the diffusivity  $\epsilon_s(z)$ . That is however an unlikely explanation, in so far as  $\epsilon_s(z)$  should be closely related to the eddy viscosity and hence similar from experiment to experiment, because the flow conditions were rather similar.

Furthermore, a similar set of concentration profiles measured over flat beds (Horikawa et al 1982) show the same gradual change of shape with increasing period, see Nielsen (1992) p271.

We shall see that both the change from upward convex to upward concave for sediments with increasing settling velocity in the same flow and the analogous change for the same sand in flows with increasing periods can be modelled by the combined convection diffusion model. The shape differences are shown to be consequences of different relative importance of diffusive (small scale) and convective (large scale) mixing, and this is quantified in terms of the shape parameter  $S$ . The shape parameter is found to follow the rough, general rule

$$S \sim \frac{w_o T}{\sqrt{A} r} \tag{6}$$

where  $A$  is the wave induced particle semi excursion just above the boundary layer and  $r$  is the bed roughness.

When  $S$  is small, the  $\bar{c}$ -profiles tend to be upward convex, for large  $S$  they tend to be upward concave.

The derivation of the form of the shape parameter (Nielsen 1992, p 249) is based on the solution to the time-averaged version

$$w_o \bar{c} + \epsilon_s \frac{d\bar{c}}{dz} = \bar{p} F(z) \tag{7}$$

of the continuity equation (3) in the simple case where  $\epsilon_s$  is a constant and  $F(z) = \exp[-z/L]$ . In that case the time averaged concentration is given by

$$\bar{c}(z) = \frac{\bar{p}}{w_o} \left\{ \frac{1}{1 - \epsilon_s/w_o L} e^{-z/L} + \left(1 - \frac{1}{1 - \epsilon_s/w_o L}\right) e^{-w_o z/\epsilon_s} \right\}, \quad \epsilon_s/w_o L \neq 1. \tag{8}$$

This solution shows that the relative importance of the diffusion solution (the last term) and the convection solution (the first term) is measured by the ratio  $\epsilon_s/w_o L$  which may be seen as the ratio between the vertical scale  $\epsilon_s/w_o$  of the pure diffusion solution and that ( $L$ ) of the pure convection solution. The inverse of this ratio is the shape parameter :

$$S = \frac{w_o L}{\epsilon_s} \quad (9)$$

To express the shape parameter in terms of basic flow parameters it is then noted that oscillatory boundary layers over rippled beds usually have a structure which is analogous to that of laminar oscillatory flow over a flat plate. That is, the eddy viscosity is constant, and its value is  $\nu_t = 0.5 \omega z_1^2$  where  $z_1 = 0.09 \sqrt{rA}$ , cf Nielsen (1992) p 40. Hence, assuming that  $\epsilon_s$  is proportional to  $\nu_t$  and that the convective length scale  $L$  is proportional to  $z_1$  we are lead to the formula (6) which agrees with the observations in Figures 3 and 4. That is, in both cases, the transition from upward convex to upward concave profiles happens with increasing values of  $S$ .

It is interesting to note that experiments with suspensions of limited amounts of sand over artificial, fixed ripples give less pronounced  $\bar{c}(z)$ -shape differences between coarse and fine sand fractions. Such experiments were reported by McFetridge & Nielsen (1985) and by van de Graff (1988). In the fixed-ripple-experiments, the  $\bar{c}(z)$ -profiles agree more closely with the gradient diffusion model in the sense of Equation (5). It is believed to be due to the fact that when the sand supply at the bed is limited, the convective entrainment mechanism is less important. Most of the sand stays in suspension rather than being continually picked up and resuspended by the travelling lee vortices. The limiting case in this respect is pure wash load which is hence expected to obey the diffusion equation very closely.

### 5. Time dependent concentrations in pure diffusion

The time dependent diffusion equation

$$\frac{\partial c}{\partial t} - w_o \frac{\partial c}{\partial z} - \frac{\partial}{\partial z} (\epsilon_s \frac{\partial c}{\partial z}) = 0 \quad (10)$$

which emerges from Equation (4) when the convective entrainment flux is zero, with the boundary conditions

$$\begin{aligned} -\epsilon_s \frac{\partial c}{\partial z} &= p(t) \quad \text{for } z = 0 \\ c(z,t) &\rightarrow 0 \quad \text{for } z \rightarrow \infty \end{aligned} \quad (11)$$

was solved by Nielsen et al (1978). The solution is in the form of a Fourier series and based on separation of the variables. Each concentration component  $c_n(z,t)$  which is generated by the corresponding component  $p_n(t) = P_n e^{in\omega t}$  of the pickup function was found to have the form

$$c_n(z,t) = \frac{P_n}{w_o \alpha_n} e^{-\alpha_n \frac{w_o z}{\epsilon_s}} e^{in\omega t} \quad (12)$$

where

$$\alpha_n = \frac{1}{2} + \sqrt{\frac{1}{4} + i \frac{n\omega \epsilon_s}{w_o^2}} \tag{13}$$

Alternatively Equation (12) may be written

$$c_n(z,t) = \frac{P_n}{w_o |\alpha_n|} e^{-Re\{\alpha_n\} \frac{w_o z}{\epsilon_s}} \cos(n\omega t - Arg\{\alpha_n\} - Im\{\alpha_n\} \frac{w_o z}{\epsilon_s}) \tag{14}$$

or with a slight rearrangement of the phase of the cosine function

$$c_n(z,t) = \frac{P_n}{w_o |\alpha_n|} e^{-Re\{\alpha_n\} \frac{w_o z}{\epsilon_s}} \cos [n\omega (t - \frac{Im\{\alpha_n\} w_o}{n \omega \epsilon_s} z) - Arg\{\alpha_n\}]$$

which shows that in a diffusion process with constant diffusivity, a concentration wave with radian frequency  $n\omega$  travels upwards with speed  $w_n = \frac{n \omega \epsilon_s}{w_o Im\{\alpha_n\}}$ . The behaviour of the solution (14) is illustrated in Figure 5 for the case of  $p(t) \sim w_o \cos^6(\omega t/2)$ .

Figure 5: Sediment concentrations at different levels ( $0, \frac{\epsilon_s}{2w_o}$  and  $\frac{\epsilon_s}{w_o}$ ) generated by the shown, periodic pickup function and pure gradient diffusion with constant diffusivity and  $\omega \epsilon_s / w_o^2 = 1$

**6. Time dependent concentrations in pure convection**

For the case of purely convective entrainment we set  $\epsilon_s = 0$  in Equation (4) and get

$$\frac{\partial c}{\partial t} - w_o \frac{\partial c}{\partial z} = \frac{1}{w_c} p'(t - \frac{z}{w_c}) F(z) - p(t - \frac{z}{w_c}) F'(z) \quad (15)$$

For the simple case of  $F(z) = \exp(-z/L)$  this equation has a Fourier series solution, which corresponds to (12), with

$$c_n(z,t) = C_n e^{-\beta_n z/L} e^{in\omega t} \quad (16)$$

where

$$C_n = \frac{P_n}{w_o} \frac{\beta_n}{\beta_n + i \frac{n\omega L}{w_o}} \quad \text{and} \quad \beta_n = 1 + i \frac{n\omega L}{w_c} \quad (17)$$

cf Nielsen (1992) p 240. In analogy with (14) this solution can be written as

$$c_n(z,t) = |C_n| e^{-z/L} \cos[n\omega(t - z/w_c) + \text{Arg}\{C_n\}] \quad (18)$$

Figure 6: Sediment concentrations at different levels generated by the shown pickup function and purely convective entrainment.  $F(z) = \exp(-z/L)$  and  $\omega L/w_c = 1$ .

This expression illustrates that all the harmonics of the pure convection solution decay at the same rate (as  $F(z)$  in general, and as  $\exp(-z/L)$  in this particular case), and that all time lags grow at the same rate with  $z$ . Compared with the diffusion case, this corresponds to a greater shape similarity between time series at different elevations for the convective case. The nature of the convection solution is illustrated in Figure 6 for the case of  $p(t) \sim w_o \cos^6(\omega t/2)$  (same as for the diffusion solution in Figure 5).

7. Comparison with measured time series

Consider the situation where simultaneous time series  $c(z_i,t)$  have been measured at a number of levels, and one wishes to infer the nature of the sediment entrainment process.

Before such an analysis is undertaken using the framework above one should note, that what has been measured by a point (or line) sensor and what is modelled above as  $c(z_i,t)$  are not conceptually identical. The model assumes horizontal uniformity while the sensor samples from a spotted carpet of concentrations  $c(x,y,z_i,t)$  which move back and forth with the waves. Thus, some of the time variation seen by the sensor is not modelled, and is indeed, not a feature of the horizontally averaged concentration  $c(z_i,t)$ . If the measurements have been taken close to a bed with strong topographical features the difference may be very significant. The problem may be amended (at least in part) by averaging over several sensors in the same horizontal plane or by using line sensors which average over one or more bedform lengths.

Assume now that concentration time series  $c(z_i,t)$  have been measured by such an array of sensors that the abovementioned "spotted carpet effect" is neutralised, and that that the corresponding Fourier series have been obtained

$$\begin{aligned}
 c(z_i,t) &= \sum_0^\infty c_n(z_i,t) = \bar{c}(z_i) + \sum_{n=1}^\infty A_{i,n} \cos n\omega t + B_{i,n} \sin n\omega t \\
 &= \bar{c}(z_i) + \sum_1^\infty R_{i,n} \cos(n\omega t - \varphi_{i,n})
 \end{aligned}
 \tag{19}$$

where  $R_{i,n} = \sqrt{A_{i,n}^2 + B_{i,n}^2}$  and  $\varphi_{i,n} = \tan^{-1} \left( \frac{B_{i,n}}{A_{i,n}} \right)$ .

First consider the possibilities of deriving information about  $\epsilon_s$ ,  $\bar{p}$  and  $F(z)$  from the time averaged concentrations. The time-averaged continuity equation (7) can, if  $\bar{c}(z)$  and  $w_o$  are known, be seen as having two unknowns namely  $\epsilon_s(z)$  and  $\bar{p}F(z)$ . Thus,  $\epsilon_s(z)$  and  $\bar{p}F(z)$  cannot be determined from this equation alone. Additional information is needed. Such information can be sought along different lines.

Firstly, it may be that  $\epsilon_s(z)$  can be inferred from knowledge about the

eddy viscosity  $\nu_t$ . Indeed, one of the benefits of the combined convection diffusion model is that one should be able to assume identity between diffusivity and eddy viscosity.

Alternatively, if concentration profiles  $\bar{c}_1(z)$  and  $\bar{c}_2(z)$  of two different sand sizes with settling velocities  $w_1$  and  $w_2$  are known, we have at each level two equations (two versions of (7)) for finding the two unknowns  $\epsilon_s(z)$  and  $\bar{p}F(z)$ . Unfortunately, such detailed datasets are rare at present.

Thirdly, as pointed out by Nielsen (1992) p 248,  $\bar{p}F(z)$  may be inferred from the shape of  $\bar{c}(z)$  alone for very coarse sand fractions. This is done simply by neglecting the second term in Equation (7).

Most of the available data on suspended sediment concentrations contain too little detail for the analysis outlined above. Usually, the measured concentrations are compounded by a fairly wide distribution of grain sizes and no information is available about the contributions from individual, narrow size fractions. Furthermore, much of the time series data obtained with optical or acoustical instruments suffer from uncertainty about the absolute magnitude of the concentrations.

However, some information can be extracted about the nature of the entrainment process even from such data. Assume that Fourier series of the form (19) have been obtained from at least two different levels and that the settling velocity distribution of the suspended material is narrow. Then the phase shifts and magnitudes of different Fourier components will show quite different developments in the two cases of pure gradient diffusion and purely convective entrainment.

It may be seen from the expressions (12) and (13) that the magnitudes of different Fourier components decay at different rates in a pure diffusion process with constant diffusivity. The decay rates are given by

$$\frac{d \ln|c_n|}{dz} = -\text{Re}\{\alpha_n\} \frac{w_0}{\epsilon_s} \quad (20)$$

which is an increasing function of the frequency  $n\omega$ . In contrast, in the case of purely convective entrainment, all components decay at the same rate, namely as  $F(z)$ . For  $F(z) = \exp(-z/L)$  this means

$$\frac{d \ln|c_n|}{dz} = -1/L \quad \text{for all } n \quad (21)$$

The growth of the phase lags  $\varphi_n(z)$  are also different for the two types of processes. For the gradient diffusion process with constant diffusivity, Equation (14) tells us that

$$\frac{d \varphi_n}{dz} = -\text{Im}\{\alpha_n\} \frac{w_0}{\epsilon_s} \quad (22)$$

while Equation (16) for the convection process with  $F(z) = \exp(-z/L)$  gives

$$\frac{d \varphi_n}{dz} = - \operatorname{Im}\{\beta_n\} \frac{1}{L} = - \frac{n\omega}{w_c} \tag{23}$$

corresponding to the same time lag for all components as was also indicated by Equation (18).

If relative increments

$$Y = \frac{\varphi_n(z_i) - \varphi_n(z_j)}{\ln \bar{c}(z_j) - \ln \bar{c}(z_i)} \tag{24}$$

of the phase shifts  $\varphi_n$  are plotted against the relative increments

$$X = \frac{\ln |c_n(z_j)| - \ln |c_n(z_i)|}{\ln \bar{c}(z_j) - \ln \bar{c}(z_i)} = \frac{\ln R_{j,n} - \ln R_{i,n}}{\ln \bar{c}(z_j) - \ln \bar{c}(z_i)} \tag{25}$$

of  $\ln |c_n|$  as in Figure 7, the result for a pure diffusion process will trace the hyperbola branch  $Y = \sqrt{X^2 - 1}$ ,  $x > 0$  which is the locus for  $\alpha_n$  in the complex plane. For the pure convection case, the points will trace the vertical line  $X = 1$ ,  $Y > 0$ , which is the locus of  $\beta_n$ .

Figure 7: The relative decay rates (X) and phase lag increments (Y) defined by (25) and (24) correspond respectively to the parameters  $\alpha_n$  in pure diffusion with constant  $\varepsilon_s$  and, to  $\beta_n$  for purely convective entrainment with  $F(z) = \exp(-z/L)$ . For details about  $\alpha_n$  see Nielsen (1979), p 131.

Finally, we note that information about the convective entrainment velocity  $w_c$  may be found simply by considering the time difference between the occurrence of identifiable peaks at different levels, cf Equation (18). If a peak arrives at  $z_i$  at time  $t_i$  and at  $z_j$  at time  $t_j$ , the corresponding  $w_c$  in a purely convective entrainment process is given by

$$w_c = \frac{z_j - z_i}{t_j - t_i} \tag{26}$$

In contrast to the convective entrainment process considered above, the upward propagation speed of a concentration wave in a diffusive medium is frequency dependent as mentioned in connection with Equation (14). For constant diffusivity, the speed  $w_n$  of a concentration wave with frequency  $n\omega$  is given by

$$w_n = \frac{n\omega\epsilon_s/w_0}{\text{Im}\{\alpha_n\}} \tag{27}$$

or

$$\frac{w_n}{w_0} = \frac{n\omega\epsilon_s/w_0^2}{\text{Im}\{\alpha_n\}} = \frac{n\omega\epsilon_s/w_0^2}{\text{Im}\left\{\frac{1}{2} + \sqrt{\frac{1}{4} + i\frac{n\omega\epsilon_s}{w_0^2}}\right\}} \tag{28}$$

the behaviour of which is illustrated in Figure 8. In the limit of  $w_0 \rightarrow 0$  i.e. for neutrally buoyant sediments or momentum, the value of  $w_n$  is simply  $\sqrt{2 n \omega \epsilon_s}$ .

Figure 8: Dependence of  $w_n$  on  $n\omega\epsilon_s/w_0^2$  in a pure gradient diffusion process with constant diffusivity.

## CHAPTER 246

### MOVEMENTS OF MOORED SHIPS IN HARBOURS

Th. Elzinga<sup>1</sup>, J.R. Iribarren<sup>2</sup>, O.J. Jensen<sup>3</sup>

#### ABSTRACT

The paper discusses criteria for safe working and safe mooring conditions for various types of seagoing vessels. These criteria are based on acceptable movements for moored ships in harbours and have been established by a working group under the Permanent International Association of Navigation Congresses (PIANC).

#### INTRODUCTION

Modern maritime transport requires minimum time for loading and unloading in ports and at maritime terminals, a requirement often restricted by ship movements at quays. If the ship movements experienced are too large, cargo handling operations will slow down or even cease and ultimately damage to the ship and port installations may occur. In recent years changes in cargo handling methods have resulted in changes of both ship and port installations, changes which may have large economic consequences. Requirements for fast cargo handling operations without delays due to ship motions are increasing.

<sup>2</sup> Centro de Estudios y Experimentación de Obras Públicas (CEDEX), Alfonso XII, 3-280014, Madrid, Spain

<sup>3</sup> Danish Hydraulic Institute (DHI), Agern Allé, Hørsholm, Denmark.

The Permanent International Association of Navigation Congresses (PIANC) therefore commissioned a special Working Group to study the movements of moored ships in harbours with the aim to establish new criteria for acceptable ship motions in safe working conditions (i.e. when cargo handling operations have to be reduced or even ceased), as well as for safe mooring conditions (i.e. when ships have to leave the berths). Further, it was the aim to assess measures for improving safe working and safe mooring conditions. The main objective in establishing criteria was to provide guidelines for port designers and port operators to minimize downtime for ships in harbours.

The Working Group comprised 14 international members (see Appendix A) and commenced in June 1990. The final report will be published by PIANC in spring 1993. This paper summarises the main findings and conclusions of the Working Group.

### **METHODOLOGY**

The world fleet of ships is divided into the following categories, each category having its own typical characteristics in view of ship motions and cargo handling operations and safe mooring conditions:

- Small craft and pleasure boats.
- Fishing vessels.
- Freighters and coasters.
- Ferries and RO-RO vessels.
- General cargo vessels.
- Container vessels.
- Bulk carriers.
- Oil tankers.
- Gas tankers

For each category the following aspects have been assessed by the Working Group:

- i. Description of the vessels, typical sizes, composition of world fleet, future trends and provisions for mooring outfits on board (positions of winches and fairleads, composition of mooring lines: number, type, diameter).
- ii. Description of typical berths and cargo handling equipment (e.g. types of cranes, ramps, loading arms).

- iii. Description of governing parameters for ship motions, cargo handling operations, efficiency and safety.
- iv. Review and assessment of available literature, including recent test results and prototype measurements.
- v. Recommendations for acceptable ship motions, mooring and fender line forces at berths in safe working and safe mooring conditions, taking into account a reduced efficiency in cargo handling in case of worsening weather.
- vi. Recommendations for improvement of operation and efficiency with respect to berth location and orientation, application of operational criteria for wind and waves, implementation of dedicated berths and modification of mooring arrangements.

## **SHIP MOVEMENTS**

Movements of moored ships can be caused by various external influences such as: winds, currents, waves, seiches, tides, passing ships and cargo handling operations. The report of the Working Group addresses the effects of these parameters on the behaviour of a moored ship. One chapter in particular deals with the physics of ships moored in waves and discusses the use of mathematical and physical models in this respect.

The movements of a moored ship at a berth can be either horizontal (surge, sway and yaw) or vertical (roll, pitch and heave). Vertical ship motions are almost independent of the mooring system, but horizontal motions are typically dependent on the loading conditions of a ship, the mooring arrangements, i.e. geometry and stiffness of mooring lines and fenders, and the type of berth.

When ship movements are too large safe working limits and ultimately safe mooring limits are exceeded. This is illustrated in Figure 1 where the cargo handling efficiency is plotted against the ship motions. When ship motions are between A and B the cargo handling efficiency is 100%. Between B and C cargo handling rates are reduced due to increased ship motions. When the motions exceed level C cargo handling operations are stopped: the safe working limits are reached. Between C and D the vessel can still stay at the berth. Once ship motions exceed level D the vessel has to leave the berth in order to prevent damage to ship and/or quay: safe mooring limits are exceeded.

Figure 1. Relation Cargo Handling Efficiency and Ship Motions.

It should be noted that ship motion is one parameter affecting the efficiency of cargo handling operations. Other parameters are, amongst others, cargo handling equipment, skill of crane operators, and operational conditions such as wind, rain, ice, day- and nighttime (light conditions).

### MOORING ARRANGEMENTS

The mooring arrangements for ships moored at berths may comprise the following elements:

- Mooring lines connecting ships to berths
- Bollards and storm bits on shore.
- Mooring hooks or quick release mooring hooks on mooring and breasting dolphins.
- Fenders between ship and berth.
- Mooring winches and bollards on board the ships.

The report of the Working Group contains a brief description of type and characteristics of mooring lines and fenders, mooring arrangement principles and operational considerations for mooring lines. Further, the report discusses the guidelines as issued by various classification societies concerning the number and type of mooring lines to be carried on board. It was felt that an update of these guidelines would be useful. Such new guidelines should reflect that a moored ship is a dynamic system having special requirements with respect to safe working as well as safe mooring conditions.

### **SMALL CRAFT AND PLEASURE BOATS**

Small craft and pleasure boats may be defined as boats with lengths up to 20m. Moored boats are particularly sensitive to short period waves coming from abeam or quartering directions. Their berths require a sheltered location to prevent damage to ships and quays as well as to increase the comfort of passengers on board. In designing harbours for pleasure boats and small craft due attention should be given to the effect of locally generated wind waves having short fetch lengths.

The Working Group has defined acceptable ship motion criteria in terms of wave height and period, because it was felt that these parameters would reflect sufficiently the comfortability criteria for these boats. The criteria are reported in Table 1 and correspond to an acceptable exceedance frequency of once to a few times per year.

### **FISHING VESSELS**

Fishing vessels range from small ships of 10-100 GRT up to large trawlers liners and net boats of 3,000 GRT. These vessels are mainly berthing in their home ports and the berths and mooring arrangements should meet the criteria for safe working as well as safe mooring conditions.

Fishing vessels are typically moored with polypropylene lines against truck tire fenders or rubber fenders. Cranes, elevators and suction pumps are used for unloading the fish. Acceptable ship motion criteria for safe working conditions are determined by sizes of hatches and the dimensions of boxes and tubs handled.

Table 1: Recommended wave criteria small craft and pleasure boats.

Ship Length (m)	Beam/Quartering Seas		Head Seas	
	Period (s)	Height $H_s$ (m)	Period (s)	Height $H_s$ (m)
4 - 10	< 2	0.20	< 2.5	0.20
	2 - 4	0.10	2.5 - 4	0.15
	> 4	0.15	> 4	0.20
10 - 16	< 3	0.25	< 3.5	0.30
	3 - 5	0.15	3.5 - 5.5	0.20
	> 5	0.20	> 5.5	0.30
20 m	< 4	0.30	< 4.5	0.30
	4 - 6	0.15	4.5 - 7.0	0.25
	> 6	0.25	> 7.0	0.30

An extensive research program was carried out by the Nordic countries to establish acceptable criteria of moored fishing vessels. Motions of moored ships were measured at a number of ports for various ships being unloaded by different gear. Acceptable motions were determined based on interviews with ship crews and port operators ( Jensen et al, 1990) and are shown in Table 2.

Requirements for safe mooring conditions for these home port fleets are rather high. In many cases there is no other alternative than to stay in the port once a storm has reached the site. The recommended criteria comprise ship motions as well as velocities and are presented in Table 3 for various ship sizes. Velocities and ship sizes represent the dynamic impact of a moored ship on a berth and are considered adequate parameters regarding safe mooring conditions.

Table 2. Recommended motion criteria<sup>1</sup> for safe working conditions.

Ship Type	Cargo Handling Equipment	Surge (m)	Sway (m)	Heave (m)	Yaw (°)	Pitch (°)	Roll (°)
Fishing vessels	Elevator crane	0.15	0.15				
	Lift-on-Lift-off	1.0	1.0	0.4	3	3	3
	Suction pump	2.0	1.0				
Freighters, coasters	Ship's gear	1.0	1.2	0.6	1	1	2
	Quay Cranes	1.0	1.2	0.8	2	1	3
Ferries, RO-RO	Side ramp <sup>2</sup>	0.6	0.6	0.6	1	1	2
	Bow/stern ramp	0.8	0.6	0.8	1	1	4
	Linkspan	0.4	0.6	0.8	3	2	4
	Rail ramp	0.1	0.1	0.4	-	1	1
General cargo	--	2.0	1.5	1.0	3	2	5
Container vessels	100% efficiency	1.0	0.6	0.8	1	1	3
	50% efficiency	2.0	1.2	1.2	1.5	2	6
Bulk carriers	Cranes	2.0	1.0	1.0	2	2	6
	Elevator/bucket-wheel	1.0	0.5	1.0	2	2	2
	Conveyor belt	5.0	2.5		3		
Oil tankers	Loading arms	3.0 <sup>3</sup>	3.0				
Gas tankers	Loading arms	2.0	2.0		2	2	2

- Remarks:
- <sup>1</sup> Motions refer to peak-peak values (except for sway: zero - peak).
  - <sup>2</sup> Ramps equipped with rollers.
  - <sup>3</sup> For exposed locations 5.0 m (regular loading arms allow large movements).

Table 3. Recommended velocity criteria<sup>1</sup> for safe mooring conditions.

Ship size (DWT)	Surge (m/s)	Sway (m/s)	Heave (m/s)	Yaw (°/s)	Pitch (°/s)	Roll (°/s)
1,000	0.6	0.6	-	2.0	-	2.0
2,000	0.4	0.4	-	1.5	-	1.5
8,000	0.3	0.3	-	1.0	-	1.0

<sup>1</sup> These criteria are applicable for fishing vessels, coasters, freighters, ferries and RO-RO vessels.

A unique system of berth and port classifications has been developed in Iceland, which is based on various exceedance frequencies for critical ship motions as presented in Table 2.

### **COASTERS AND FREIGHTERS**

Coasters and freighters are ships of less than 10,000 DWT sailing on short sea and domestic routes. These vessels are generally moored with polypropylene lines against rubber fenders.

Cargoes can be handled by quay cranes or ship's own gear. Safe working conditions are determined by hatch openings and cargo parcel sizes. The criteria recommended by the Working Group are based on the studies carried out by the Nordic countries as discussed earlier and are shown in Table 2.

### **FERRIES AND RO-RO VESSELS**

Vessel types considered comprise car and rail ferries, and RO-RO vessels. These vessels are characterised by loading and unloading operations taking place horizontally via ramps and walkways. Ramps may be shore ramps, bridge ramps (including link-spans) and ship ramps.

The main function of the mooring arrangements for these ships is to reduce the horizontal ship motions as much as possible, in particular at the position of the ramps or walkways. This can be achieved by tensioning the mooring lines, sometimes up to 40 tonnes.

Recommended criteria for allowable ship motions for safe working conditions are presented in Table 2. In addition, for movable rail ramps and for walkways, the vertical velocity is recommended not to exceed 0.2 m/s and the vertical accelerations should be less than 0.5 m/s<sup>2</sup>.

The governing parameter for safe mooring conditions, defined as the limiting conditions for damage to ship and/or quay, is the kinetic energy, which is characterised by the ship size and velocities. The recommended velocity criteria are presented in Table 3.

### **GENERAL CARGO VESSELS**

General cargo vessels range typically from 5,000 to 10,000 DWT and may carry a wide variety of cargo. Ships are most often moored with polypropylene lines, while large vessels are equipped with nylon ropes and/or steel wires. Generally these vessels are moored with 8 to 10 lines.

The cargo is handled by ship's gear or quay cranes. Acceptable ship motions in safe working conditions are determined by the sizes of the hatches, sizes of boxes and units handled, and by the type of unloading gear. The criteria recommended by the Working Group are based on an extensive Japanese research program (Ueda, 1987; Ueda and Shiraishi, 1988). These criteria have been established based on interviews with port and ship operators in various ports along the Japanese coast. Numerical simulations were applied to correlate identified critical wind speeds and wave heights with acceptable ship motion limits. Provisional limits were then discussed with various operators and authorities to arrive at the final criteria for safe working conditions as presented in Table 2.

In situations where large general cargo ships are exposed to long period waves, it is recommended to use soft mooring systems, i.e. synthetic lines or steel wires with nylon tails and soft fenders. Smaller vessels should preferably be moored in protected port basins (inner harbour) to reduce wave influences on moored ships.

### **CONTAINER VESSELS**

The world fleet of container vessels has increased considerably during the last decades and comprises nowadays small feeders, second and third generation container vessels as well as Post Panamax vessels, which came into operation recently.

Container vessels are generally moored with steel spring lines, to reduce surge motions, and polypropylene mooring lines. All lines are connected to bollards positioned at the front side of the quay wall. Rails for container cranes extend along the whole quay and prevent the use of typical breasting lines.

Containers are handled by shore based gantry cranes and ship motions should be kept to a minimum to provide uninterrupted container handling conditions. Positioning and picking-up of containers for example are hampered and containers can become stuck in their guides in the case of strong roll motions. Maximum container handling rates are an essential requirement for these ships sailing on tight time schedules.

Two levels of safe-working criteria are established by the Working Group for this special category of ships. One level is representing an uninterrupted container handling at an efficiency rate of 90 to 100%, whereas the second level reflects a 50% handling efficiency rate (see Table 2). It should be noted that besides ship motions the skill of the container crane drivers plays an important role for the overall efficiency of handling containers in a port.

### **DRY BULK CARRIERS**

Dry bulk carriers have been developed to transport cargoes such as ore, coal, grain and fertilizer in bulk and mostly in large quantities. Some typical sizes for bulk carriers are the Handy size (30,000-40,000 DWT), Panamax size (70,000-80,000 DWT) and CAPE size (120,000-150,000 DWT).

Bulk carriers are mainly moored with 8 to 10 synthetic lines and 4 steel spring lines. Mooring lines are attached to bollards located at the front side of the quay walls for the same reasons as for the container vessels. Loading operations are generally carried out using conveyors and hoses (grains). For unloading operations cranes, bucket-wheel unloaders, elevators and suction devices are used. A special category of bulk carriers is nowadays the so-called self-unloading bulk carrier. Horizontal ship motions are mainly induced by low frequency waves (and winds). Vertical ship motions are mainly caused by first order wave effects.

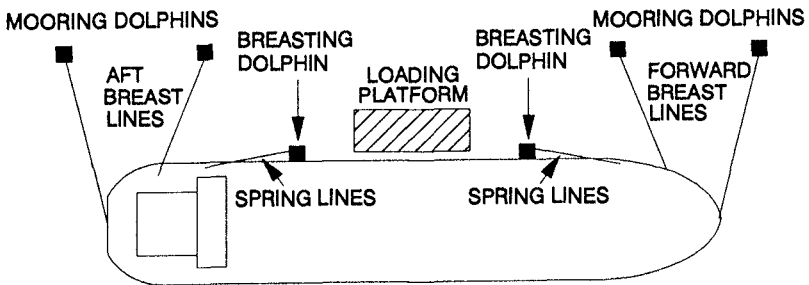

Operational criteria for cargo handling are determined by the risk of cargo handling equipment hitting the hatches or ship's bottom. This is of particular importance for unloading operations. The safe working criteria for bulk carriers recommended by the Working Group are based on practical experiences of port and ship operators (Bruun 1987, Moes 1992), supported by numerical simulations (Ueda and Shiraishi 1988). These criteria are presented in Table 2. Safe mooring conditions are determined by acceptable mooring line and fender forces (BSRA 1969 and OCIMF 1978).

Cargo handling operations may be improved by the application of softer springs and by the use of shore based mooring equipment, particularly when moored ships are exposed to long period wave actions. Further, pretensioning of mooring lines will result in an increase of fender friction and will contribute in reducing surge motions. Particular attention should be paid to the resonance of long waves in harbours (seiches) when designing basins for dry bulk vessels.

**OIL TANKERS**

Oil tankers are used to transport oil and oil products. Oil products are generally transported in tankers under 70,000 DWT, while crude oil is transported in high capacity tankers up to 420,000 DWT. Tankers are loaded and unloaded through the manifold located in the middle and close to the side of the ships. The manifold is connected to the pipelines onshore by loading arms and sometimes by flexible hoses.

A typical berth lay-out for an oil tanker is shown in Figure 2 and comprises breasting and mooring dolphins, and a loading platform. Tankers are moored with spring lines, breast lines and (optionally) head and stern lines. The mooring lines for large tankers are in general steel wires and steel wires with nylon tails. The OCIMF (OCIMF, 1978) has issued guidelines for jetties and mooring arrangements of oil tankers, as well as for the design and operation of loading arms (OCIMF, 1980).

**FIGURE 2. TYPICAL BERTH LAY-OUT FOR TANKERS**

The motions of moored tankers are characterised by low frequency horizontal motions (with typical periods of 1 to 2 minutes) caused by long period wave effects, and relative high frequency vertical motions with periods ranging from 5 to 20 s.

Operational cargo handling criteria are determined by the allowable reach of the loading arms in the surge (longitudinal) and sway (transversal) direction. Other tanker motions are generally well within the design motion envelopes of the loading arms. The criteria recommended for safe working conditions are shown in Table 2.

Berths for large tankers are generally located in deep water and at more exposed locations. Due attention should be given to align a berth with predominant wave and current conditions. Tanker motions may be reduced by pretensioning the breast lines in order to maintain sufficient friction between the ship's hull and fenders.

### **GAS TANKERS**

Gas tankers may range from refrigerated ships of over 100,000 m<sup>3</sup> for the transportation of LNG and LPG to small tankers of up to 5,000 m<sup>3</sup> for the shipment of propane, butane and chemical gases in pressure tankers. The number of gastankers in the world fleet is relatively small; some 780 in 1991.

Berths for LNG and LPG tankers are generally designed for dedicated ships and trades, whereas berths of small gas tankers are multi-functional. The berths and mooring arrangements for gastankers are similar to the ones for oil tankers (Figure 2). Comprehensive guidelines for berths and gas tanker moorings are issued by OCIMF/SIGTTO (1985).

Motions of moored gastankers are in particular induced by currents and low frequency wind and wave effects. Wind effects on gastankers are more important compared to oil tankers because of higher freeboard and the presence of spherical tanks. Acceptable motions are determined by restrictions in the cargo handling systems (i.e. loading arms) and mooring line and fender forces (hull pressure). Recommended values for tanker motions are presented in Table 2.

Particularly for gas and oil tanker berths it is important to establish Operational Manuals including, amongst others, guidelines for mooring arrangements and safety operations as well as checklists to improve the safety of cargo handling operations.

### **ACKNOWLEDGEMENTS**

The authors are very grateful for the permission of the members of the Working Group "Movements of Moored Ships at Berths" as listed in Appendix A to prepare this paper. Without their work and enthusiasm the Working Group would not have completed its task and the data necessary for this paper would not have been collected.

## CHAPTER 247

### WAVE AGITATION CRITERIA FOR FISHING HARBOURS IN ATLANTIC CANADA

Charles P. Fournier<sup>1</sup>, Michael W. Mulcahy<sup>2</sup>, K. Ander Chow<sup>1</sup>, Otavio J. Sayao<sup>1</sup>, M.ASCE

**ABSTRACT:** The existing criteria for defining allowable levels of wave agitation in Canadian harbours are outlined in the Guidelines of Harbour Accommodation (Fisheries and Oceans). These criteria were developed based on a previous study which concentrated primarily on recreational harbours. However, it was realized that fishing vessels, when berthed or moored, may be able to tolerate a greater degree of wave agitation than pleasure craft because of the different characteristics and functions of the two types of vessels. Furthermore, fishermen tend to have more liberal tolerance limits to wave agitation than pleasure craft owners, and have more rugged craft. To develop new allowable wave agitation criteria for commercial fishing harbours in Atlantic Canada, a field measurement programme was conducted in selected harbours. The objective was to determine the threshold values at which the wave climate at both the service/offloading area and mooring area creates either dangerous, difficult or unacceptable working conditions. This was determined to be the point at which operations must cease or the vessel had to be removed to a more protected area. Wave measurement gauges were installed at two locations within two study harbours, and a wave rider buoy was used to measure nearshore waves for each harbour site. A procedure was also developed whereby daily field observations were taken and recorded by the harbour master. Particular emphasis was given to the wave climate events which rendered the facilities less than adequate, unsafe or unusable. By correlating the harbour masters field observations with the measured wave data, the threshold values for unacceptable wave agitation were determined, and new wave agitation criteria for fishing harbours recommended.

#### INTRODUCTION

The criteria (and practice) for defining allowable levels of wave agitation in Canadian harbours prior to 1991 were developed by the Small Craft Harbours Directorate (SCHD), and are

outlined in the Guidelines of Harbour Accommodation by Fisheries and Oceans (F&O, 1985). These criteria were applicable to harbours which fall under the administration of the SCHD and it was customary to follow these criteria for all work undertaken on behalf of the SCHD.

This study (Atria, 1991) was developed with the objective to revise the acceptable wave agitation criteria that have been used by engineers when engaging in the planning and design of fishing harbours. The criteria (F&O, 1985) which specify the agitation requirements within fishing harbours were developed based on a previous study (NHCL, 1980). The 1980 study to determine acceptable wave climates in small craft harbours concentrated primarily on recreational harbours. It was realized that fishing vessels, when berthed or moored, may accept greater degrees of wave activity than pleasure crafts because of the different characteristics and functions of the two types of vessels. Furthermore, fishermen tend to have more liberal tolerance limits to wave agitation than pleasure craft owners. Also, as a rule fishermen have more rugged craft. A reduction in wave agitation criteria could yield optimized protective structures and hence significant savings in capital costs.

The purpose of the present study was to develop new allowable wave agitation criteria for fishing harbours. The scope of the work consisted of: 1) reviewing existing wave agitation criteria for fishing harbours within Canada and abroad; 2) undertaking a field measurement programme in conjunction with the Marine Environment Data Service (MEDS) at two fishing harbours with the aim of establishing the point at which unacceptable wave conditions occur; and 3) recommending new guidelines of accommodation specifically for allowable wave agitation in fishing harbours.

#### EXISTING WAVE AGITATION CRITERIA

The existing wave agitation criteria were obtained by means of a literature review and a questionnaire survey. The questionnaire was sent to various organizations in Canada and foreign countries such as U.S.A., England, Japan, Denmark, Holland and others. Each organization was asked for information regarding guidelines for fishing harbour design in their country as well as the description of the fishing fleet for which their guidelines apply.

Canada: The Guidelines of Harbour Accommodation, developed by the SCHD (F&O, 1985), outline the criteria (and practice) for defining allowable levels of wave agitation in Canadian harbours. These criteria were based on NHCL (1980). Since this study was restricted to recreational craft, directly applying the results of their findings to fishing harbours likely resulted in conservative allowable agitation levels for fishing harbours. Therefore the criteria that were developed and proposed for all harbours (including fishing harbours) are more stringent when applied to fishing harbours than if the study considered fishing harbours alone. It is customary at Public Works Canada and with consulting engineers when undertaking SCHD projects to design the facility such that the agitation levels within the harbour meet the requirements of the guidelines.

The recommended allowable wave agitation criteria (Tables 1 and 2) were determined by classifying harbours by vessel-metres usage. Class A harbour is defined as over 800 vessel-metres, Class B as between 300 and 900 vessel-metres, and Class C between 0 and 400 vessel-metres. The existing guidelines specify that for Class A, B and C harbours, the hours of significant waves which exceed 0.25 m in height at the service/offloading (i.e. berthing) area cannot be greater than 0.17%, 0.87% and 1.74% of the time respectively. For a 6 month season, these % yield 0.3, 1.6 and 3.2 days (respectively) of wave activity in excess of 0.25 m.

Previous to the NHCL study, the widely accepted rule of practice for the design of wave protection for small craft harbours was that the wave height within the harbour should not exceed 0.3 m (1 ft). Of course, if one waits long enough, a storm will occur and will create waves in excess of this limit. Therefore, wave protection is a function not only of a given acceptable value, but also the probability of occurrence (or exceedance) of the value. The NHCL study examined this "one foot" rule and the many variables affecting wave agitation in marinas, and made recommendations towards an improved set of criteria to define acceptability of wave climates within small craft harbours.

**Table 1 Allowable Maximum Significant Wave Height (from F&O, 1985)**

Location	All Recreational Boats	
	Fishing Boats < 15 m	Fishing Boats > 15 m
Within Harbour Entrance	1.00 m	1.00 m
Mooring Basin	0.50 m	1.00 m
Berthing Area	0.25 m	0.50 m

**Table 2 Classification of Harbours (from F&O, 1985)**

Class of Harbour	Percentage of Time when the Wave Height Criteria May Be Exceeded
A	0.17
B	0.87
C	1.74
D	No Limit

In general, their findings revealed that there has been remarkably little research work performed or reported in the literature with respect to wave agitation criteria for small craft harbours or marinas and on response of moored small craft to waves. However, the available literature related to the general subject of marina design, all made reference to wave criteria which came reasonably close to specifying a 0.3 m significant wave height.

United States of America: The ASCE Task Committee on Small Craft Harbours (1969) published a manual on small craft harbours and they recommended simply "in general, wave heights in the mooring basin should be reduced to a maximum of approximately 0.5 ft (0.15 m) to 1 ft (0.3 m)". These criteria were defined with reference to sport and pleasure craft. They stated that: "harbours for commercial fishing boats may be considered a special type of installation. This is due largely to the type of usage, the characteristics and habits of commercial fishermen, and equipment requirements. Usually utility supersedes appearance, because a fishing boat is a work boat and the operator's work in port is essentially preparation for the next trip".

United Kingdom: In England, guidance for wave agitation in harbours is available in the British Standard Code BS6349 (Part 1, 1984). The acceptable wave conditions for moored boats in fishing harbours are given as follows: "since fishing craft are normally larger and more strongly built than pleasure craft the maximum wave height considered as acceptable for boats

up to 30 m in length is 0.8 m. Typically, this makes the maximum acceptable significant wave height 0.4 m. As in the case of pleasure craft, inner harbours or basins are frequently provided for accommodating fishing boats safely."

**Japan:** Japanese fishery ports are administered by the Ministry of Agriculture and Fishery. This Ministry's report "Guide to Planning of Fishery Ports" outlined the range of wave heights available for mooring and water area facilities (Table 3). The wave heights for mooring and water area facilities varies between 0.3 m to 1.2 m (maximum significant). It also stated that the probability of exceedance of these wave heights was not determined. In general, it recommended that ports should be constructed such that the probability of wave heights less than the permitted level becomes more than 97.5% in a year.

Previous to this criteria, the Overseas Coastal Area Development Institute of Japan (1980) recommended that wave agitation was addressed as basin calmness. It stated that a basin in front of a pier (i.e. service/offloading facility) should be calm to allow mooring for 90 to 95 % or more days per year (or each season, when the seasonal variation of calmness is extreme). Calmness was defined as significant wave heights being less than the defined critical wave height. The critical significant wave height for cargo handling in a basin in front of berthing facilities was defined as  $H_s = 0.3$  m for small craft harbours and  $H_s = 0.5$  m to 0.7 m for other craft. It was noted that these criteria may not apply when the frequency of mooring is low such as would be the case with fishing harbours during the fishing season. However, more work on wave agitation in fishing harbours is presently underway in the National Research Institute of Fisheries Engineering (these new publications are in Japanese).

**Table 3 Maximum Significant Wave Height for Mooring and Water Area Facilities**

Water Depth in Anchorage Area	Less than 3 m	More than 3 m
1. anchoring and mooring in a port is possible	0.60 m	0.70 m
2. water way is available	0.90 m	1.20 m
3. loading and unloading is possible	0.30 m	0.40 m
4. quay for rest is available	0.40 m	0.50 m

Source: "Guide to Planning of Fishery Ports, report by the Ministry of Agriculture and Fishery of Japan.

**Nordic Countries:** The Nordic Council (1986) published a research report which established criteria for acceptable ship movements in harbours. When considering wave agitation, they found that loading / unloading methods, pattern of the vessel, mooring and fender system, and the ability of the vessel to escape the harbour during a storm, were important factors.

For fishing vessels, the type of loading / unloading method used was of concern. When unloading trash fish they considered the elevator crane. With this method problems arise due to the size of the hatch. Small movements can cause damage to both the ship and the crane. Vertical ship movements can also cause damage to the ship bottom and to the crane. Another problem arises when the ship collides with the fenders causing fish to slide within the hold, causing danger to people within the hold.

Safe mooring conditions was another topic considered in the Nordic Council (1986) report.

Acceptable mooring conditions were considered to be where no damage occurred to the ship or to the quay. Also, they outlined for taut mooring of fishing vessels different values than the ones given in Table 4. Thus, criteria for safe mooring conditions at berth are given in Table 5. In determining the final criteria for vessel movement when moored at berth, it was assumed that she was well moored and that the quay was well equipped with fenders.

Other Countries: No official guidelines were available from other countries contacted by questionnaires. Some answers mentioned "empirical, often subjective rules" and most European countries quoted the Nordic Council (1986) study. In Holland, no specific guidance on wave agitation for fishing harbours were obtained. Reference was made to the Nordic Council (1986) study. Vlemmix et al. (1987) set out criteria for bulk carriers and outlined the limiting deep water wave heights. In Spain, the only available document on fishing harbours dates back to the 1960's. Marine Trust Ltd. of Israel follows in house rules as criteria for wave agitation. A significant wave height of 80 cm may not be exceeded for more than two days per year. Their experience comes from harbours for small fishing vessels with few trawlers. Other references related to the design of Small Craft harbours using physical models may be found in literature, for example Rosen and Kit (1984) which report on limiting criteria regarding maximum allowable values of vessel movements and fender forces.

In general it appears that the F&O (1985) guidelines may be considered too stringent. It has the lowest acceptable wave height and the lowest frequency of occurrence. This is understandable since the values were determined from a study for recreational craft and then adapted to fishing vessels.

In the NHCL (1980) study, from which the SCHD guidelines were developed, much emphasis was placed on the one foot (0.3 m) criterion since it is widely accepted by most authorities. Although it provides satisfactory results in marinas, it neglects the fact that fishing vessels unlike recreational craft can tolerate more agitation. They do point out however, that it is important to consider the wave direction, as beam seas are more distressing than head seas. They also point out that boat response depends greatly on the wave period relative to the boat length.

In the Nordic Council (1986) report, they agree with the F&O (1985) guidelines on the wave height criteria for small vessels. They present their conclusions for larger fishing vessels (25 m to 60 m long) with respect to method of loading/unloading, and ship movements. This data are the result of an investigation on 11 harbours. The Nordic report gives extensive information on acceptable movements for large fishing vessels, but does not provide as much information for smaller fishing vessels.

It is difficult to compare wave height criteria since each report bases its findings on different criteria. F&O (1985) presented its guidelines for frequency of occurrence based on vessel-metres usage. The study done by NHCL (1980) referred to significant wave height with respect to direction and period, as did the Vlemmix et al. (1987) study. Japanese criteria was based on the depth of the harbour. In the case of large fishing vessels the criteria were also presented as a function of ship movements.

#### WAVE AGITATION STUDY

To develop new allowable wave agitation criteria for commercial fishing harbour, a field measurement programme, managed by Atria and executed by MEDS, was conducted to

determine (in the field) the threshold values at which the wave climate at the service/offloading area and mooring area created either difficult, dangerous or unacceptable working conditions.

Wave measurement gauges were installed at two locations within two study harbours. Also, a wave rider buoy was used to measure nearshore waves for each harbour site. Wave data were collected during two fishing seasons to ensure that the majority of extreme wave events (events of unacceptable wave agitation) were well defined.

A procedure was developed and established by Atria and the local harbour masters by which daily field observations were taken and recorded by the harbour master. Particular emphasis was given to the wave climate events which rendered the facilities less than adequate, unsafe or unusable. By correlating the harbour masters field observations with the measured wave data inside the harbour, the threshold values for unacceptable wave agitation were determined.

A synthesized wave climate was developed for the study sites using a parametric wave hindcast model (Atria, 1991). First, waves were hindcasted for the wave measurement period and were calibrated with measured wave data obtained from the offshore wave riders. Subsequently, 20 years of hindcast waves were produced at each fishing harbour and analyzed to define a magnitude-duration-frequency relationship, which was assumed to be representative of the wave climate for the study harbours. By correlating the magnitude of unacceptable wave agitation levels determined from the field programme with the 20 year hindcast, the allowable duration and frequency of unacceptable wave agitation levels were obtained.

**Table 4 Criteria for Fishing Vessel Movements during Working Conditions**  
(Nordic Council, 1986)

Type of Vessel	Surge (m)	Sway (m)	Yaw (°)	Heave (m)	Pitch (°)	Roll (°)
Lift on/Lift off	1.0-1.5	1.0-1.5	3.5	0.4-0.6	3	3-5
Elevator crane	0.15	0.15				
Suction pump	2.0-3.0	1.0-2.0				

Note: The movements are maximum peak-peak. Frequency of occurrence of these movements should be less than is 1 week per year (2 % of the time).

**Table 5 Criteria for Fishing Vessel Movements Moored at Berth**  
(Nordic Council, 1986)

Type of Vessel	Surge (m)	Sway (m)	Yaw (°)	Heave (m)	Pitch (°)	Roll (°)
Fishing Vessel (25 m to 60 m length)	1.2-1.5	1.0-2.0	6	0.6-1.0	4	8

Note: The movements are peak-peak values. For the berth to be acceptable, the frequency of the movements should be less than 3 h/year.

Wave Data Acquisition Programme: The field measurement programme was initiated in December 1989 with the installation of the wave gauges and wave riders at their designated locations in Sandford and Stoney Island harbours, in Nova Scotia, Atlantic Canada. The locations of the inner and outer gauges for each harbour (Figure 1), were designed to record wave agitation data at the service/offloading area and at the harbour entrance respectively. The acquisition of data began in January 1990.

The harbour master field observations covered two field measurement seasons, the first period from December 1989 to end of May 1990 and the second season period from October 1990 to end of January 1990 for both locations. The harbour masters were responsible to visually record wind, wave and harbour conditions on a daily basis. The harbour conditions that were of interest for the present study were those events that could not be tolerated by the fishermen at the service/offloading wharf (i.e. unacceptable harbour conditions) and those events when the wave conditions were severe, but the harbour conditions could be tolerated (i.e. acceptable harbour conditions). The unacceptable conditions provide an indication of the lower bound of wave agitation that is unacceptable, while the acceptable conditions provide the upper bound of wave agitation that is tolerable. Summaries were compiled from the harbour masters field notebooks by condensing the information into categories of weather, waves, and harbour conditions recorded on each day.

The magnitude of the threshold wave height for unacceptable wave agitation at the service/offloading area was determined by simply identifying the measured wave height at the inner wave gauge for each unacceptable event as observed by the harbour master. This process was followed for both harbours. A sample time series plot for Stoney Island was shown in Figure 2 where the occurrences of unacceptable wave conditions were shown as a solid dot at the time of occurrence. Visual inspection of this plot shows a good coherency of measured (by the wave riders) and observed wave data (by the harbour masters) for the unacceptable events.

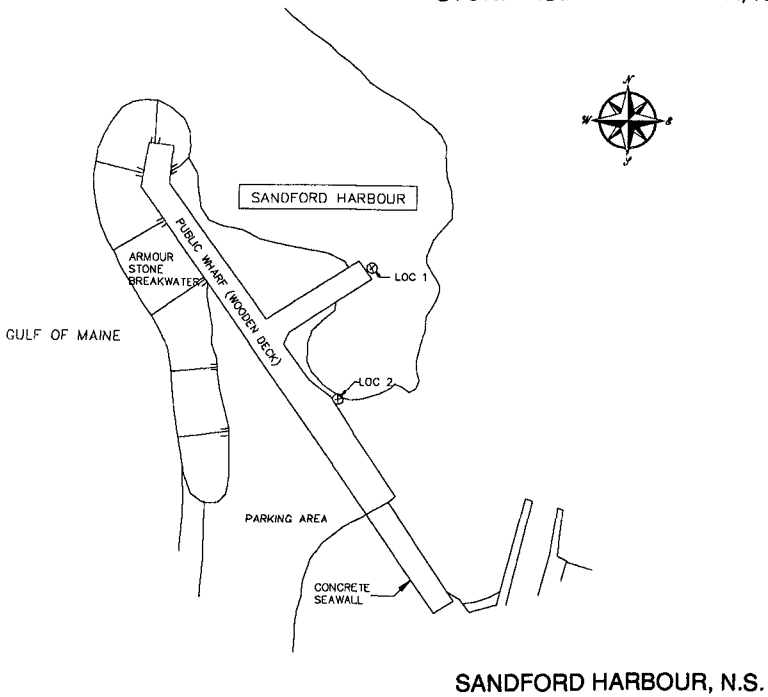

Similarly, acceptable harbour condition occurrences were also indicated on this time series plot as hollow dots. It is interesting to note that for these dates of acceptable (but severe) conditions, the inner gauge at Stoney Island showed a maximum value of 0.39 m and a minimum value of 0.15 m. This indicated that the harbour condition became unacceptable when the significant wave height exceeded 0.4 m.

Wave Hindcast: A 20 year wave hindcast was conducted to simulate the wave climate for each study harbour at the location of the wave riders. A parametric hindcast model based on the SMB equations (Atria, 1991) was used. The hindcast analysis used wind data from Yarmouth, N. S. as primary input to the model. The model was calibrated to the measured wave data at each wave rider, and subsequently, the long term hindcast was conducted for the 20 year data set using the calibration factors determined from the calibration process.

For both harbours, the hindcast model was calibrated by comparing the MEDS wave data measured at the wave riders with the hindcast waves using Yarmouth winds. In the calibration procedure, the original (smoothed) wind data were first used to hindcast waves in 8 and 16 point sectors. The initial hindcast used the original (unfactored) Yarmouth wind data and resulted in the hindcast waves being generally smaller than the measured values. The hindcast waves were then calibrated with the measured MEDS data by adjusting the wind scale factors until a reasonable match was achieved. Procedures to modify the (Yarmouth) wind data using overwater/overland speed ratios were applied and were presented in Atria (1991).

STONEY ISLAND HARBOUR, N.S.

SANFORD HARBOUR, N.S.

FIGURE 1 Location of selected harbours, Nova Scotia, Canada

FIGURE 2 Time series plot of wave data for Stoney Island Harbour, November 1990

To establish the directional relationship between the wave conditions inside the harbours and those at the wave riders, the wave heights at inner and outer wave gauges were plotted against those measured at the wave riders for both sites. The fitted equations obtained using linear regression were shown in the plots of Figure 3, for Stoney Island harbour. For this, hindcasted wave directions were used when in concurrence with the wave directions observed by the harbour masters. Otherwise, the observed wave directions were used. Further, a 20 year hindcast representative for the two wave rider locations was performed using the wind data and calibration factors discussed above.

The results of the hindcast were presented in frequency of occurrence tables of the hourly significant wave height and wave period. The 20 year wave climates for both Sandford and Stoney Island, at the harbour wave gauges, were developed using the 20 year wave hindcast and applying the transfer functions given in Figure 3. These transfer functions modify the waves from the wave rider locations to the wave gauge locations. A summary of the wave statistics for all directions for both harbours inner wave gauges was presented in Atria (1991).

Discussion: The threshold value for unacceptable wave agitation (magnitude of wave height which renders the service/offloading area unusable) was determined by linking the harbour master's field observation of harbour agitation conditions to the MEDS measured wave data. The data for Stoney Island is shown in Figure 4. This figure shows a summary plot for all events of unacceptable harbour agitation conditions and the measured wave parameters. Using the Stoney Island inner wave gauge to represent the wave climate at the service/offloading area, the acceptable wave heights range from 0.27 m to 0.43 m and the value of 0.27 m could be considered as the threshold value. Figure 4 also presented a summary plot for the acceptable (but severe) harbour agitation condition. Inspection of the inner wave gauge for Stoney Island indicated that all data for acceptable harbour agitation conditions were under 0.4 m but greater than 0.27 m. This upper bound value could also be considered as the threshold value for unacceptable conditions. These conflicting information may be attributed to measuring errors or other factors such as freezing rain or strong wind conditions, which made the harbour masters feel that the harbour conditions were unacceptable. Closer examination of these two plots indicated that if the data point of 0.27 m wave height is ignored then the unacceptable threshold is about 0.4 m. Considering this, a value of 0.4 m was proposed here as the threshold wave height for unacceptable harbour agitation conditions. Also, this proposed threshold value agrees with the British Standard Code BS6349 that the maximum acceptable significant wave height is 0.4 m for boats up to 30 m. Wave agitation levels greater than this value would induce undesirable vessel motions which could result in vessel damage.

Allowable wave agitation criteria are incomplete without specifications for the frequency of occurrence of the defined threshold value. Determination of the allowable frequency of a specified wave agitation level is basically an economical/policy decision. The scatter diagram for the predicted wave climate for the inner gauge at Stoney Island (Atria, 1991) indicated that the exceedance probability of a wave height greater than 0.4 m is 1.04% and the exceedance probability of a wave height greater than 0.25 m is 4.89%.

According to the SCHD inventory of fishing harbours, both Sandford and Stoney Island harbours are Class B harbours. Under the existing Guidelines of Harbour Accommodation (F&O, 1985), the required allowable maximum wave agitation at the service/offloading area is 0.25 m and its exceedance probability cannot be greater than 0.87%. Based on the existing guideline, Stoney Island harbour would be considered as a problem harbour. However, on average for 15 times per year the fleet at Stoney Island have to abandon the harbour and seek

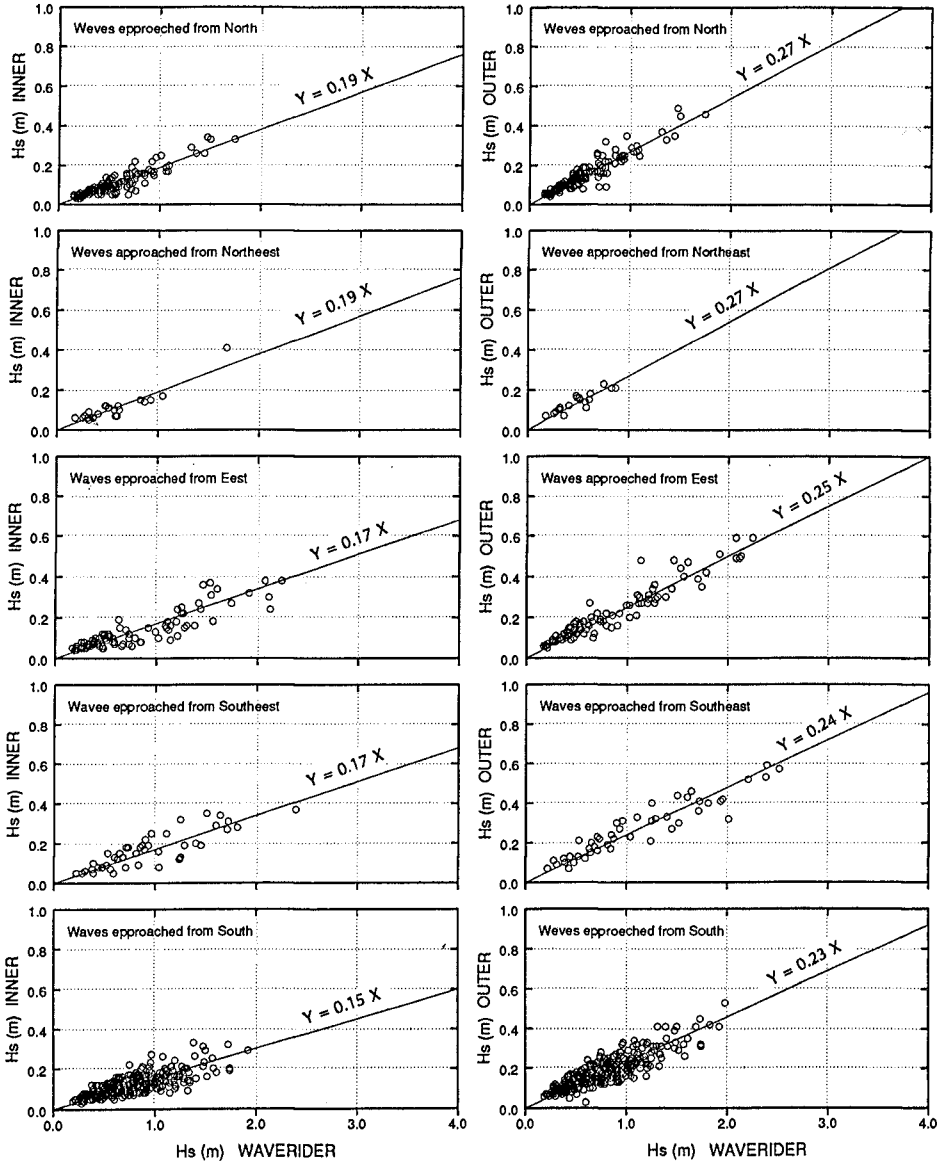

FIGURE 3 Fitted equations for different wave directions, Stoney Island Harbour

refuge at other harbours (J. Ross, SCH, pers. comm., 1991). If this occurrence of refuge seeking is considered acceptable to SCHD, the Stoney Island harbour would be considered as functional and the frequency of wave agitation found in this study could be accepted and applied to other harbours in a generic manner. On the other hand, if SCHD considers this frequency of refuge seeking to be unacceptable, then frequency of 1% may be considered high. When compared to the exceedance probability of 2.5% suggested by the Japanese Ministry of Agriculture and Fisheries for allowable wave heights of 0.4 m, it does not seem unreasonable that the wave height of 0.4 m cannot be exceeded 1% of the time in a year.

The vessels which operate at Sandford and Stoney Island harbours are known as Cape Islanders which fall into the STACAC (Statistical Coordinating Committee for Atlantic Canada) class 2 (35 to 45 ft) category. The wave measurement programme at Sandford and Stoney Island (and resulting recommended allowable levels of wave agitation) applies to STACAC class 2 vessels. The recommended guidelines proposed here towards allowable levels of wave agitation apply to STACAC class 2 and 3 (45 to 60 ft) fishing vessels in Atlantic Canada.

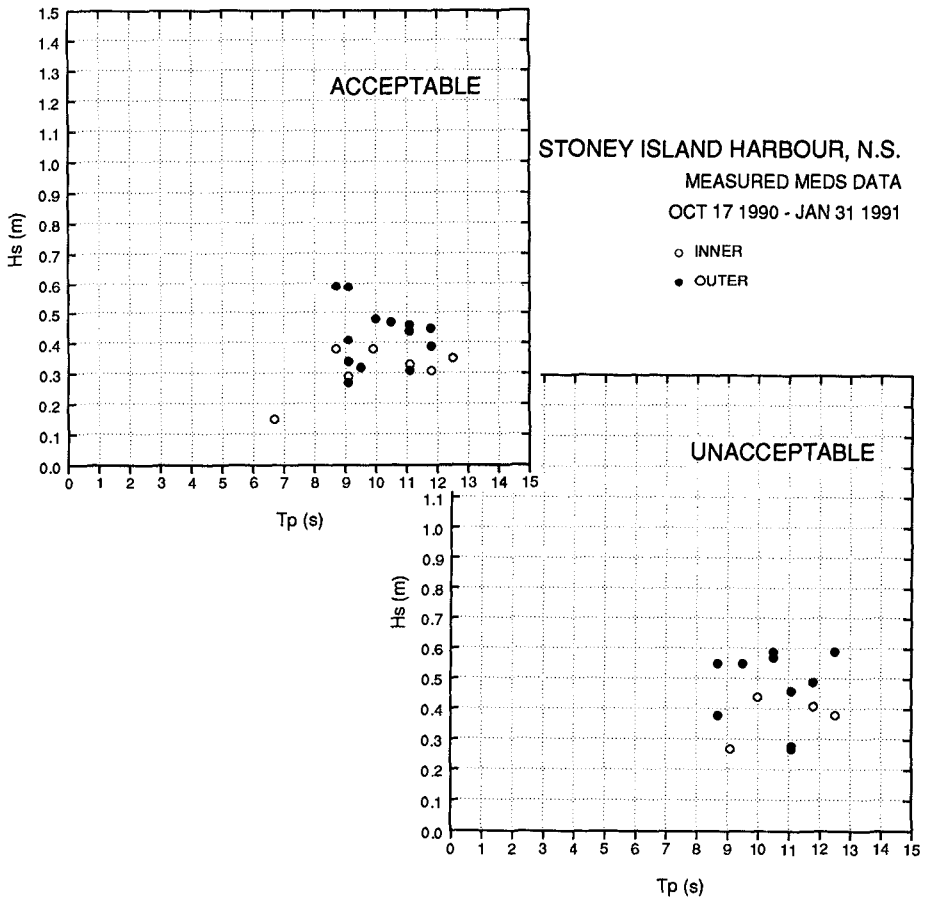

FIGURE 4 Stoney Island Harbour - acceptable and unacceptable harbour conditions

## CONCLUSIONS

It is proposed that harbour classification should not be a parameter governing allowable wave agitation criteria, rather vessel classification should be considered as a governing parameter. The rationale for this can be explained as follows: a given vessel at berth experiencing beam seas, undergoes the same discomfort from the incoming wave attack as ten of the same vessels moored bow to stern under the same wave conditions. On the other hand, fishing vessels of different class will not respond in (exactly) the same manner under the same wave disturbances and therefore experience different levels of discomfort. Therefore the allowable wave agitation level and its frequency of occurrence should depend on the dominant type of vessel in a harbour, rather than the total vessel meters in that harbour.

The associated frequency of occurrences allow for some down time at the service/offloading wharf at which point in time alternate action will have to be sought by the local fishermen. This alternate action may consist of mooring the vessel in a mooring field, removing the vessel from the harbour by a slip or departing from the harbour altogether and seeking refuge in a nearby harbour (which is the case at Stoney Island harbour). Therefore, the alternate action is a function of the facilities available at each site specific harbour.

Measuring waves in a harbour with an organized harbour monitoring programme proved to be an effective means of determining the threshold point of unacceptable wave agitation as applied to fishing vessels on the Canadian east coast. During the planning and design of commercial fishing harbours, the associated frequency of wave agitation recommended in this document apply to wave events which occur during the fishing season alone.

It was concluded that the results of this study, which were based on wave measurements with peak wave periods in the order of 10 to 13 s, may be safely applied to sites with shorter peak wave periods. Inland waters typically have wave climates which have shorter periods than wave climates in Atlantic Canada. Considering this, it is recommended that the above criteria for wave agitation may be safely applied to inland water commercial fishing harbours.

For planning purposes of Canadian east coast commercial fishing harbours which have predominantly STACAC class 2 or class 3 fishing vessels, it is recommended to use the threshold significant wave height with the associated frequency of occurrence listed in Tables 6 and 7 for the service/offloading wharf and for the mooring basin respectively.

**Table 6 Recommended Allowable Wave Agitation Criteria for the Service/Offloading Wharf for STACAC Class 2 and Class 3 Fishing Vessels**

Threshold Significant Wave Height	Frequency of Occurrence
0.40 m	1.0 % - 2.5 %

**Table 7 Recommended Allowable Wave Agitation Criteria for the Mooring Basin for STACAC Class 2 and Class 3 Fishing Vessels**

Threshold Significant Wave Height	Frequency of Occurrence
0.50 m	1.0 % - 2.5 %

Threshold value for unacceptable wave agitation (magnitude of wave height which renders the service/offloading area unusable) for a STACAC class 2 fishing vessel was determined to be 0.4 m. The scatter diagram for the predicted wave climate for the inner gauge at Stoney Island indicated that the exceedance probability of a wave height greater than 0.4 m is 1.04% and the exceedance probability of a wave height greater than 0.25 m is 4.89%. The results of the present study indicated that the frequency of occurrence for wave agitation should be 5 to 6 times greater than the current guidelines values (F&O, 1985).

Allowable wave agitation criteria are incomplete without specifications for the frequency of occurrence of the defined threshold value. Determination of the allowable frequency of a specified wave agitation level is basically an economical/policy decision. A 1% to 2.5% frequency of occurrence of the threshold wave height is recommended.

It is proposed that the results of this study, which apply to STACAC class 2 vessels, may be safely applied to STACAC class 3 vessels. Also, these criteria could possibly be reduced for STACAC class 1 (up to 35 ft) vessels. Atria Engineering Hydraulics Inc. is currently (1992) undertaking a similar field monitoring programme in Newfoundland to determine the threshold values of wave agitation criteria for STACAC class 1 vessels.

#### ACKNOWLEDGEMENTS

The authors would like to express their appreciation to Small Craft Harbours Branch, Fisheries & Oceans Canada, for financial support of the study.

## CHAPTER 248

# Erosion of the Damietta Promontory, the Nile Delta

A. M. Fanos\*, A. A. Khafagy\* and P. D. Komar\*\*

### Abstract

The Damietta sediment-formed promontory is located on the eastern half of the Nile Delta, about 40 km west of the Suez Canal breakwaters at Port Said. Following a long period of accretion, the promontory began to erode early this century with shoreline recession rates reaching a maximum of 38 m/yr. This paper documents the shoreline changes, the coastal processes responsible for those changes, and the protective measures that have been erected to control the erosion.

### Introduction

During historical times, the Nile Delta shoreline was built out by sediments delivered to the coast through seven or more distributaries. Since the 9th century, most of the Nile River water and sediment delivered to the coast have passed through the Rosetta and Damietta branches, and these have built out the pronounced promontories apparent in the modern outline of the delta shoreline. The shapes of these promontories reflect the quantities of sediments delivered to the coast versus the effectiveness of the waves and nearshore currents in redistributing the beach sands along the delta shoreline.

About the turn of the century, the general accretion of the Rosetta and Damietta promontories reverted to erosion

---

\*\*College of Oceanography, Oregon State University, Corvallis, Oregon 97331

characterized by rapid rates of shoreline retreat. Inducement of this erosion is generally attributed to construction of barrages along the Nile River as part of water-control activities, and in particular to the construction of the Aswan Low Dam in 1902 and the Aswan High Dam in 1964 (Orlova and Zenkovitch, 1974; Inman and Jenkins, 1984; Frihy et al., 1991). Completion of the Aswan High Dam has cut off almost all water discharge from the river and the delivery of sediments to the delta coast.

The focus of this study is on the Damietta promontory which is located about 40 km west of the Suez Canal breakwaters at Port Said. The objectives of this paper are to: (1) illustrate the patterns of shoreline changes from analyses of old maps and recent surveys; (2) to summarize the measurements of waves, longshore currents and beach profiles; (3) to evaluate the longshore sediment transport rates through various techniques; and (4) to highlight the shoreline protective works that have been completed or are being proposed.

### **Patterns of Shoreline Changes**

The shoreline changes, as revealed in old maps and recent surveys, are summarized in Figure 1. There was an overall accretion from the 1800 survey until about the beginning of the 20th century, the maximum seaward growth appearing in the 1912 mapped shoreline. After that date the successive surveys show a rapid retreat of the shoreline to the immediate east of the Damietta river mouth, that long-term maximum erosion averaging 38 m/yr between the 1912 and 1983 shorelines. Development in this erosion area to the east of the river was minimal, with the main impacts being the necessity of moving the coastal highway inland and the recent replacement of the light house which is in danger of being lost.

It is apparent in Figure 1 that the shoreline retreat and the rates of erosion have varied considerably along the length of the promontory shoreline, and actually revert to a zone of accretion to the east of a nodal area, reflected in the progressive seaward advance of the shorelines. Part of this accretion has been the development of a sand spit on the eastern flank of the Damietta promontory, seen in the 1973 and 1983 shorelines (Fig. 1).

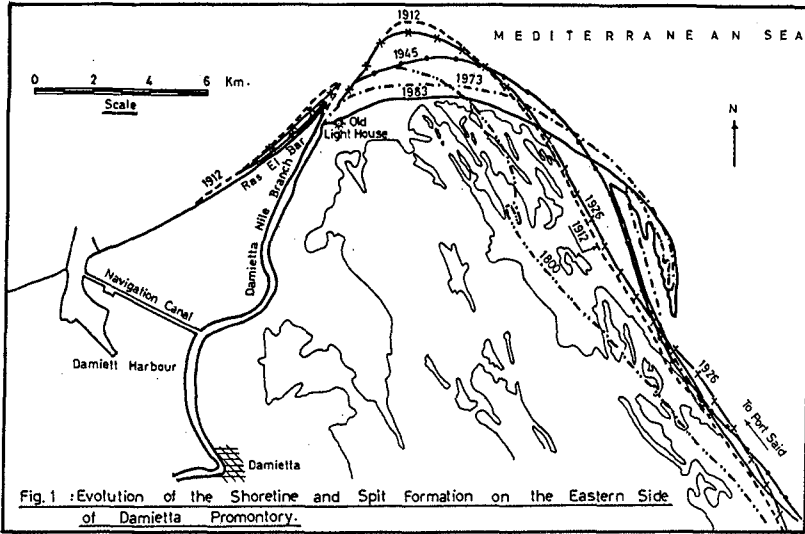

Fig.1 :Evolution of the Shoreline and Spit Formation on the Eastern Side of Damietta Promontory.

The shoreline changes to the west of the river mouth have been particularly critical due to the erosion of the resort community of Ras El Bar. The study of old maps has shown that the Ras El Bar tongue of land grew in length to about 500 meters and widened during the period from 1800 to 1900, corresponding to the time of general growth of the Damietta promontory. Since the turn of the century, the pattern has been primarily one of erosion, during which the Ras El Bar tongue eroded back following the overall shoreline retreat of the promontory. The erosion has been partly stabilized by the placement of a series of groins and a seawall.

It is seen that there have been substantial changes in the shoreline positions along the Damietta promontory since about the turn of the century. The main impact has been one of erosion, with the point of the promontory having retreated by some 3 to 4 km and continuing at a rapid rate. However, beach accretion, partly in the form of a sand spit, has taken place along the eastern flank of the promontory. The inducement of these shoreline changes is undoubtedly a response to the cut-off of sand delivery to the coast through the Damietta branch of

the Nile River. The continued action of waves, longshore currents and sediment transport has acted to displace sediments toward the east, resulting in the observed patterns of shoreline changes.

### **Processes Affecting the Damietta Promontory**

The normal wind regime along the Mediterranean coast of Egypt is controlled by various atmospheric conditions which occur on a seasonal basis. The annual wind rose for the area offshore of Damietta indicates that the winds blow predominantly from the NW and WNW directions. These directions correspond to the maximum fetch distance along the length of the Mediterranean Sea, and account for the observed patterns of wave heights and directions along the Nile Delta coastline.

A program for collecting wave data in the study area began as early as 1964-1966 and has been continuous from 1972 onwards (Fanos et al., 1989; Nafaa et al., 1991). The earliest measurements were collected with pressure gauges termed the Offshore Pressure Operated Suspended System, installed in about 6 meters water depth directly seaward of the point of the Damietta promontory. Its records have been analyzed manually by the zero up-crossing method and/or the Tucker and Drapper method (Tucker, 1963; Drapper, 1966) to obtain significant wave heights and periods, while the wave direction was determined from wind data. In order to obtain a more complete description of the wave climate, a directional wave recording system termed the Cassette Acquisition System has been used since it became fully operational in 1985. It was installed in 7 meters water depth, about 1 km offshore from the Damietta Promontory. Measurements for 34 minutes every 6 hours are recorded on cassettes, and are computer analyzed to yield spectra, significant wave heights, periods, and wave directions (Lowe and Inman, 1984; Elwany et al., 1988; Nafaa et al., 1991).

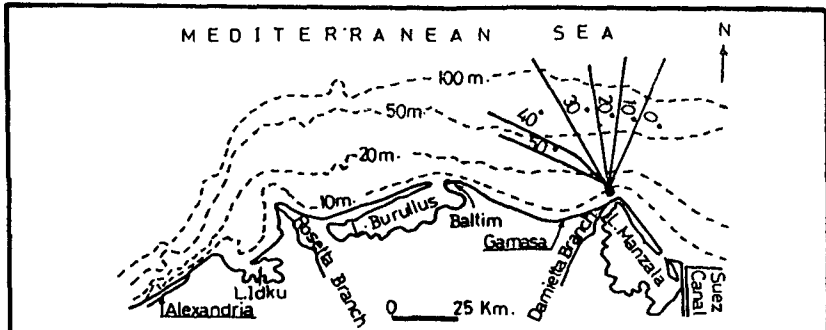

Wave action on the Nile Delta is seasonal, with the intensity and direction following the seasonal patterns of winds. The maximum significant wave height recorded during 1985 to 1990 was 4.3 m. The predominant wave directions are from the WNW, NNW, N and W; a small portion of waves arrived

from the NNE and NE, especially in March through April and possibly in November, due to easterly winds during those months. It is noticeable that wave characteristics vary from season to season and from year to year. These variations cause the changes in wave energy flux which are responsible for the nearshore coastal changes.

All of the wave records are from one point in shallow water, and in order to obtain the deep-water wave characteristics and to determine the wave climate along the length of the promontory shoreline, back and forward refraction calculations have been carried out. Figure 2 shows the back refracted rays of the recorded data (Elwany et al., 1989), and examples of forward refraction of waves from the NNW and WNW (CRI/UNESCO/UNDP, 1978). This figure illustrates the concentration of wave energy on the promontory, and in part explains the severe erosion that has occurred.

Longshore currents have been measured within the surf zone at three stations on each side of the mouth of the Damietta Nile branch. The collected data during 1990 and 1991 have been subjected to monthly, seasonal and yearly statistical analyses to determine the probability distributions of the longshore currents. The predominant current direction on both sides of the river mouth was found to be from west to east, except during the months of March, April, May and November when the current periodically reverses and its direction depends on the daily wind and wave directions.

The shift from erosion to accretion along the eastern flank of the Damietta promontory, Figure 1, reflects the longshore variations in the quantities of sand being transported. As one moves east from the river mouth, the erosion contributes more and more sand to the littoral transport toward the east, so that the total quantity must be progressively increasing. The maximum longshore sediment transport is positioned at the nodal point between the areas of erosion versus accretion. With the change to beach accretion, there is progressively less and less sand being carried as littoral drift. By this interpretation, the longshore sediment transport is everywhere to the east, but its varying quantities account for the shifts from erosion to

A - Backrefraction for Waves Near Damietta Promontory.

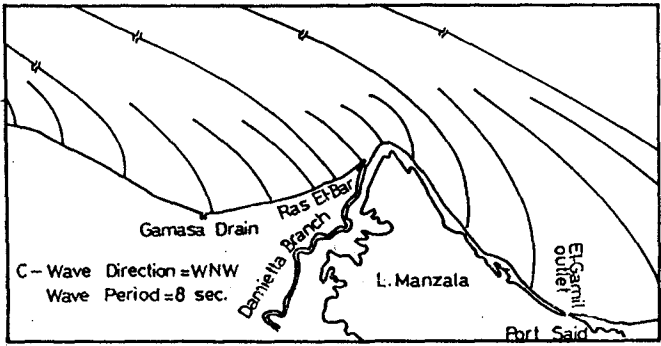

Fig. 2 : Backrefraction and Forward Refraction.

deposition.

This pattern of sediment transport has been quantitatively assessed for the stretch of shoreline east of the Damietta river mouth, similar to the analyses of Frihy et al. (1991) for the Rosetta promontory. The rate of shoreline retreat or advance is related to the longshore gradient of the sand transport rate, rather than to the absolute quantities of that transport. If  $y$  is the shoreline position so that  $dy/dt$  is its time-rate of change ( $dy/dt = -$  signifies erosion,  $dy/dt = +$  represents accretion), then a consideration of sediment continuity yields  $Z(dy/dt) = -dQ_s/dx$  where  $Q_s$  is the local sediment transport rate and  $x$  is in the longshore direction.  $Z$  is an elevation factor that converts the  $dy/dt$  shoreline change into a volume of sand eroded or deposited per unit shoreline length. According to beach profiles from the area, this elevation change is approximately  $Z = 4$  meters. Therefore, there is a simple proportionality between  $dy/dt$  and  $dQ_s/dx$ .

The average rates of shoreline erosion or accretion ( $dy/dt$ ) between the years 1912 and 1983 have been determined from Figure 1. The corresponding  $dQ_s/dx$  local gradients calculated from the continuity equation have been integrated in the longshore direction from west to east, to yield the graph of  $Q_s$  in Figure 3. It has been assumed that  $Q_s = 0$  at the river mouth, that is, there is presently no exchange of sand with the area to the west, either with the river channel or with the western flank of the promontory. If there is in fact some net exchange, then the  $Q_s$  curve of Figure 3 would simply shift up or down by that amount, while retaining its overall shape. It is seen that  $Q_s$  progressively increases with longshore distance from the river, reaches a maximum of approximately  $0.41 \times 10^6 \text{ m}^3/\text{yr}$ , and then decreases. According to the computations of Figure 3, the transport is reduced to essentially zero due to deposition on the sand spit along the eastern flank of the promontory, indicating that there is an approximate balance between the quantities of sand eroded and subsequently deposited. The varying quantities of longshore sediment transport rates found in this analysis are due to systematic changes in breaker angles and wave energies

along this stretch of shore, in turn caused by the refraction of the predominant NW-NNW waves around the shallow offshore of the promontory.

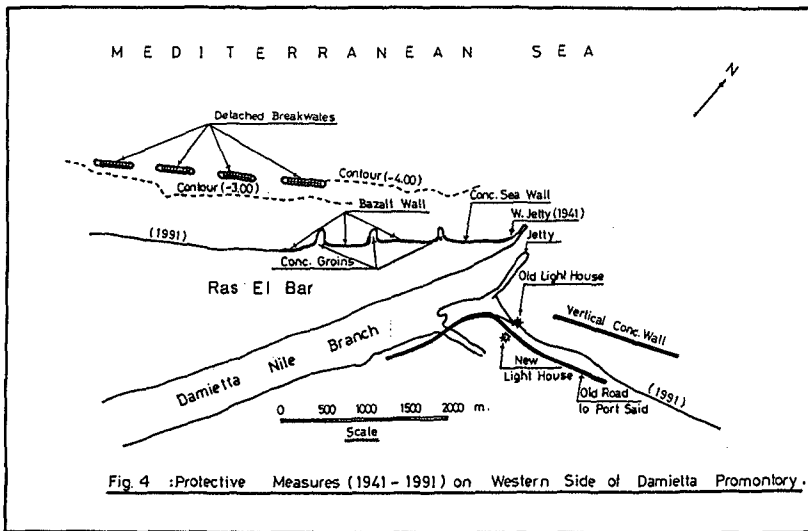

Measurements and/or computations of the littoral drift have been carried out by various investigations along different stretches of the Damietta promontory. Kadib (1969) measured the transport at Ras El Bar using fluorescent tracers, and reported a value of  $1.15 \times 10^6 \text{ m}^3/\text{yr}$  for the net transport toward the east. More recently, experiments by El Fishawi et al. (1992) have been carried out using tracers to determine sand transport rates at two locations, 0.80 km east and 3.0 km west of the Damietta mouth, every month during the period from January to December 1991. The results are graphed in Figure 3, labeled as CRI-1991. To the east of the river the evaluated net littoral drift is  $0.8 \times 10^6 \text{ m}^3/\text{yr}$ , which is substantially greater than determined by the other techniques. To the west of the river along the Ras El Bar shoreline, the net littoral drift is evaluated to be  $0.26 \times 10^6 \text{ m}^3/\text{yr}$  toward the east, a value that is smaller than obtained by the other techniques and studies.

Tetra Tech (1984) estimated the net littoral drift at Ras El Bar to be  $0.8 \times 10^6 \text{ m}^3/\text{yr}$  to the east. Using the CERC equation, Sogreah (1982) evaluated the transport rates along an extended length of shoreline to the west of the river mouth, including the beach along Ras El Bar. The results are graphed in Figure 3. These calculations indicate that the net littoral drift is everywhere toward the east, progressively decreasing from  $0.6 \times 10^6 \text{ m}^3/\text{yr}$  to essentially zero ( $0.03 \times 10^6 \text{ m}^3/\text{yr}$ ) near the Ras El Bar jetty. The calculated values using the CERC equation are very approximate because they depend on the accuracy of measuring the shoreline orientations, the breaker angles, and breaker heights.

Longshore sediment transport rates can be computed from the daily measurements of wave heights ( $H_b$ ) and longshore currents ( $v$ ) with the modified Bagnold equation  $Q_s = 0.026(H_b)^2 v$  as established by Komar (1990). This formula is particularly applicable to analyses of sediment transport rates on the Nile Delta due to the accumulated long-term measurements of waves and longshore currents, and eliminates the requirement of accurate assessments of breaker angles needed in the CERC equation. Applying this relationship with the available wave and current measurements, the average annual eastward and westward littoral drifts on the western side of the river mouth were computed to be  $0.64 \times 10^6 \text{ m}^3/\text{yr}$  and  $0.2 \times 10^6 \text{ m}^3/\text{yr}$  respectively, the net to the east being  $0.4 \times 10^6 \text{ m}^3/\text{yr}$ . These values are graphed in Figure 3 at the position corresponding to the location where the longshore currents were measured to the west of the Ras El Bar jetty. Similar calculations for a position to the east of the river mouth yielded eastward and westward transports of  $0.72 \times 10^6 \text{ m}^3/\text{yr}$  and  $0.23 \times 10^6 \text{ m}^3/\text{yr}$ , with a net  $0.49 \times 10^6 \text{ m}^3/\text{yr}$  toward the east. This is approximately the maximum transport rate as evaluated above from shoreline changes and continuity considerations, but the measurement location is closer to the jetty where the calculated transport from continuity considerations is roughly half that value (Fig. 3). Therefore, the agreement is good only to a factor of 2.

### Shoreline Protection Measures

The protective works on the Damietta promontory began in 1936 in order to defend the Ras El Bar summer resort from the erosion, and also to prevent siltation of the estuary. A 200-m long concrete jetty was constructed during the period 1936-41 at the NE extremity of Ras El Bar (Figure 4). In 1965 a concrete protective sea wall was built along the first 400 m of shoreline to the west of the jetty, fronted by riprap and doloes. Three 150-m long concrete groins were added in 1970 to protect the beach to the southwest of the sea wall, and in 1982 a basalt riprap revetment was constructed between the groins and to the west of the groin field. Presently, four detached breakwaters are under construction to the west of the groins, Figure 4, and the beach behind the breakwaters is being nourished. These combined projects will offer protection to nearly the full length of the Ras El Bar shoreline.

The jetty on the eastern bank of the river mouth was constructed in 1979. However, the earliest shoreline structure to the east of the river mouth was a seawall several kilometers in length, Figure 4, constructed in 1971 to protect the very old

coastal road between Damietta and Port Said. Most of this wall has become submerged in the offshore during the continued retreat of the shoreline. Recent erosion has threatened the lighthouse to the immediate east of the river, and necessitated the placement of a protective riprap wall surrounding the structure and extending to the east. This old lighthouse has become unstable due to the erosion, and has been replaced by a new lighthouse in an inland position. Tetra Tech (1984) has suggested the construction of a revetment having a 6 km length along the coast, using the old road to Port Said as part of the structure. However, erosion would continue at its eastern end as the promontory shoreline continues to retreat. We have suggested that the revetment instead extend for about 1.5 km parallel to the old road, and then turn inland to the south to offer protection from the erosion that will continue further to the east.

### **Summary and Conclusions**

Erosion of the Damietta promontory has been continuous since about the turn of the century, with very high rates of shoreline retreat. This erosion is confined to the central portion of the promontory closest to the river mouth. To the east of the river the rate of shoreline retreat progressively decreases along the flank of the promontory, and beyond a nodal area reverts to accretion and shoreline advance, in part involving the formation of a large sand spit. This reorientation of the shoreline is in response to the continued wave action and longshore sediment transport, while at the same time the sediment delivered to the coast has been cut off due largely to the construction of dams on the Nile River. A program of data collection, including the measurement of waves, beach profiles, longshore currents and sand transport rates, has documented the main processes responsible for the shoreline changes. The measurements of longshore currents and sand transport show a dominant movement toward the east, and this corresponds to the prevailing winds and waves arriving from the NW and WNW directions. Although the net longshore sediment transport is everywhere toward the east, the rates vary due to systematic

longshore variations in wave breaker heights and breaker angles along the length of the promontory shoreline. This variation in rates of eastward transport is responsible for the patterns of shoreline erosion near the river mouth versus accretion at greater distances, the zone of erosion corresponding to the shoreline where the transport is progressively increasing while the accretion is in the zone of decreasing littoral drift.

The promontory erosion has threatened developed areas, in particular the resort community of Ras El Bar to the west of the river. The response to this erosion has been the construction of a jetty, followed by the placement of a seawall and series of groins along the eroding shoreline. Most recent is the placement of four detached breakwaters and nourishment of the sheltered beach. There is less development to the east of the river, but the erosion has destroyed the coastal road to Port Said, requiring its rerouting to a more landward position. The old lighthouse has been undermined by the erosion, necessitating its replacement. Riprap has recently been installed to protect the old lighthouse and extended eastward to offer some protection to the replacement Port Said highway. Plans are being formulated for the construction of a large seawall that will extend for several kilometers to offer additional protection to the eastern shore of the Damietta promontory.

## CHAPTER 249

### NEARSHORE COASTAL CHANGES ALONG THE NILE DELTA SHORES

A.A. Khafagy<sup>1</sup>, M.G. Naffaa<sup>1</sup>, A.M. Fanos<sup>1</sup> and R.G. Dean<sup>2</sup>

#### ABSTRACT

The Nile Delta coast is a dynamic system formed by the Nile River sediments discharged into the Mediterranean Sea through the historic seven branches of the Nile. The central headland at Burullus began to erode around the 10th century upon abandonment of the old Nile branch which had been providing sediment to this area. Commencing in the early 20th century the nine barrages along the main river were constructed which initiated a general erosional trend along the Nile Delta with concentrations around the Rosetta and Damietta promontories. This alarming erosion has been aggravated since the erection of the Aswan High Dam in 1964, which trapped essentially all of the flood sediments in its storage basin.

Eighty beach profiles, covering the Delta coast, have been surveyed twice per year since 1976 and surveying is continuing to the present. A computer program was developed to analyze the collected profile data. This program calculates the accretion/erosion quantities and the movement of various contour lines up to 6 meters depth. The results have shown that the changes do not follow a clear pattern except at the Rosetta and Damietta promontories and around the El Burullus area where consistent erosion is evident.

#### INTRODUCTION

The Nile Delta coast consists of sandy beaches approximately 240 km in length (Figure 1). This coastline has two promontories at Rosetta and Damietta and one "bulge" at Burullus with concave shorelines in between. Six outlets exist in this coastal segment, listed from west to east as: Idku Lake Outlet, Rosetta Exit, Burullus Outlet, Gamasa Drain Outlet, Damietta Exit, and El Gamil Outlet. The

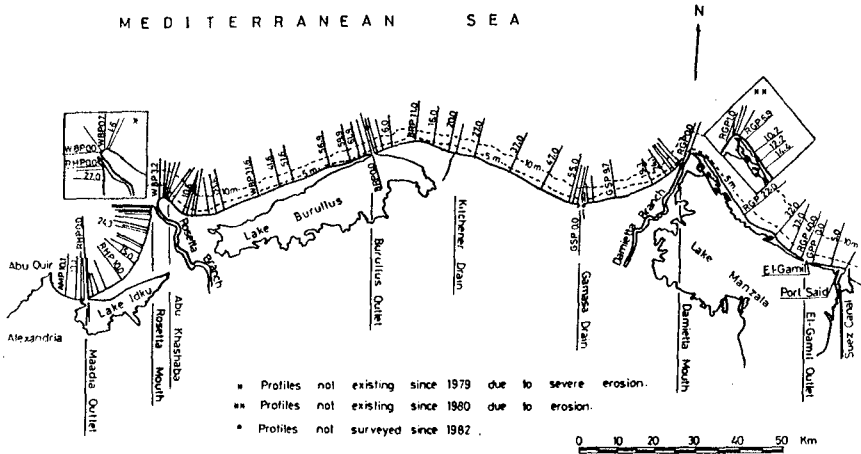

Figure 1. General Layout of Main Profiles along the Nile Delta Coast.

instability of the Nile Delta coastal zone in terms of erosion and accretion has been documented since the beginning of the present century. Local severe erosion has destroyed roads and caused losses of buildings and resort beaches while shoaling due to siltation in lake outlets and estuaries has resulted in navigation hazards and reductions in fish productivity. There has been considerable interest over the last two decades in the marked coastal changes observed along the Nile Delta coast, leading to studies of: coastal geomorphology (Sestini, 1976; Frihy et al., 1988); analysis of beach profiles up to the 6 m depth (Manohar, 1976 a & b); aerial photography analysis (Frihy, 1988); satellite image analysis (Klemas and Abdel Kader, 1982; Smith and Abdel Kader, 1988; Blodge et al., 1991); shoreline changes (Sestini, 1976; Misdorp, 1977); dynamic factors (Khafagy and Manohar, 1979; Manohar, 1981; Fanos, 1986; Elwany et al., 1988; Naffaa et al., 1991) sediment transport (Inman and Jenkins, 1984; Frihy et al., 1991) and sediments (El Askary and Lotfy, 1980).

The erosion and accretion patterns along the Nile Delta coast in general are a result of: 1) a decrease of sediment supply after the construction of the Aswan High Dam and other impoundment structures built on the Nile which have reduced the sediment supply from more than 120 million tons per year to almost zero at present (Orlova and Zenkovitch, 1974; Sharaf El Din, 1974; Smith and Abdel Kader, 1988; Frihy, 1988), 2) rise of sea level in the Mediterranean over the last 40 years at an average rate of about 1.63 mm/yr (Sharaf El Din et al., 1989), 3) subsidence of the land at a rate of 3.5 to 5.0 mm/yr in the northern part of the Delta based on carbon-dated core sections (Stanley, 1988), and 4) dynamic factors including waves and currents which are the principal driving forces for the transport

of sediments and hence the chief agent in beach erosion. Wave action along the Nile Delta coast is seasonal in nature. The energy supplied by severe Winter storms contributes significantly to the total annual energy budget. The maximum wave height recorded is 4.0 m in Winter at Abu Quir Bay. The predominant direction of the waves is WNW-NW with less wave energy from the NNE-NE sector (Naffaa et al., 1991). The predominant littoral current is toward the east with velocities ranging from 20 to 50 cm/sec (Fanos, 1986).

This paper describes the nearshore coastal changes, including the sediment quantities, shoreline changes, bar formation and physiographic nearshore units from the profile data collected during the last ten years, i.e., from 1981 to 1990.

### DATA COLLECTION

The data base for this study has been established from repeated surveys of 80 hydrographic profiles along the Nile Delta coast and simultaneous collection of sediment samples. The most westerly profile is located 6 km west of Maadia Outlet and the most easterly profile 5 km east of El-Gamil Outlet (about 7 km west of Port Said western breakwater). The spacing between adjacent profiles depends on the nature of the coastline and varies from 0.5 km to 10 km with the exception of one 17 km spacing between two profiles west of Rosetta (Figure 1). More detail is provided in Khafagy, Fanos and Naffaa (1992).

The profiles are referred to a permanent baseline which extends, more or less, parallel to the local shoreline. The monument for each profile is a steel angle iron imbedded in a barrel filled with concrete. The hydrographic survey of the coastal profiles extends from the monument to the closer distance of a 6 meter water depth or 1000 m offshore. The surveys have been conducted twice per year since 1976; once during September/October termed "Autumn profiles" which represent the results of the Summer season swell waves and the other during April/May termed "Spring profiles" representing the results of the Winter season storm waves.

The surveys along the profiles are carried out by taking a measurement every 10 meters along the first 250 m from the baseline (surf zone) and then every 50 meters. A surface bottom sediment sample is taken every 100 meters with a grab sampler. The measurements are corrected to the zero Survey Authority datum.

### ANALYSIS OF PROFILE DATA

The profile data have been analyzed in terms of their spatial and temporal variations (Khafagy, Fanos and Naffaa, 1992). Samples are given in Figure 2. Two methods have been used in the analysis of the beach profiles namely: the Eigen-function method (Winant et al., 1975) and the erosion/accretion method (CRI/UNESCO/UNDP, 1978). The first considers the spatial and temporal characteristics of the profiles by computing the first three eigen-functions, representing the mean,

Figure 2. Typical Accretional, Erosional and Equilibrium Profiles.

bar/berm and terrace functions, respectively. The results from this method are beyond the scope of the present paper. Some results for the Burullus area are presented in Khafagy and Fanos (1981). The accretion/erosion method was used to interpret the nearshore changes and the coastal processes of the Nile Delta coast. This method seeks to calculate the nearshore morphology characteristics of the profiles such as the position of the shoreline, depth contours, underwater bars, bed slopes and the volumetric transport rates of the sediments by erosional and/or accretion processes.

A computer program was developed to calculate the accretion/erosion quantities between adjacent profiles. Also computed are the bed slope, bar characteristics and the distances of the 0, 2, 4 and 6 m contours from the original baseline. The surface bottom samples were analyzed mechanically and the mean grain size ( $D_{50}$ ) was computed for each sample.

RESULTS AND DISCUSSIONS

Nearshore Profiles

Based on examination of the 80 profiles along the Egyptian coast, over the period 1981 to 1990, three profile types were identified:

- i. Undernourished profiles characterized by a rapid recession of the beach. These profiles act as sediment sources; the Rosetta Promontory profiles (Figure 2) provide examples.

- ii. Overnourished profiles which are generally accreting and act as sediment sinks, e.g. profiles at Abu Khashaba about 10 km east of Rosetta Branch, and in Abu Quir Bay from Maadia Outlet to 6 km south of Rosetta Exit (Figure 2).
- iii. Dynamically stable profiles which keep their forms at a maximum steepness, and unlike the undernourished profiles which erode continuously, they alter between erosion and accretion. Profiles of this type exist between Kitchener Drain and New Damietta Harbor and west of the Burullus Outlet (Figure 2). Figure 3 gives the seasonal changes for each profile type.

Shoreline and Bed Contour Changes

Measured shoreline and depth contour changes, i.e. 0 m, 2 m, 4 m and 6 m contours during the 10 year period (1981 to 1990) are shown in Figure 4. It is clear that the shoreline is retreating along almost the entire coast except in some short regions between Maadia and west of Rosetta, at Abu-Khasaba, between Kitchener Drain and west of New Damietta Harbor and to the west of Port Said breakwater. Maximum retreat of the shoreline is documented at Rosetta Promontory to be about 70 m/y, while it is about 5 m/y at both of Burullus Headland and Ras El Bar sea resort and about 8 m/y to the east of Damietta branch. There are three regions which are subject to erosion from the shoreline to the 6 m contour. They are Rosetta and Damietta promontories and Baltim Sea resort area which is located about 10 km to the east of Burullus Outlet. This is due to the wave and current action and the absence of the sediment supply from the Nile itself which was balancing some of these losses before the completion of the High Aswan Dam. Also Figure 4 shows that there is accretion for the contours 2, 4 and 6 m along some other areas of the Delta.

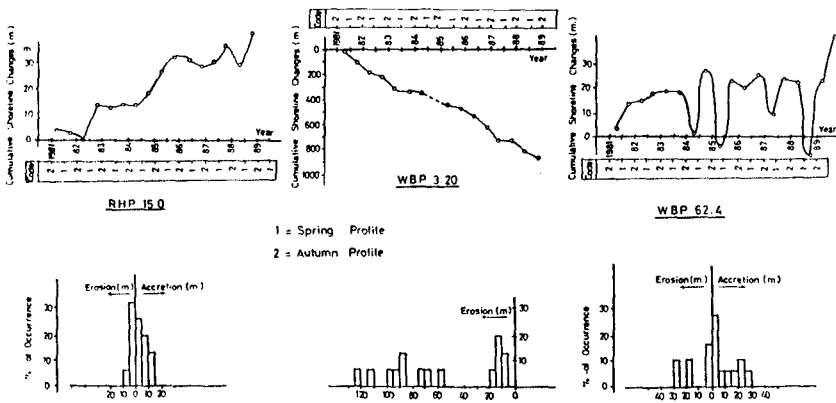

Figure 3. Seasonal Shoreline Variations.

Figure 4. Changes of Contour Lines along the Nile Delta Coast.

### Bed Slope Changes

Based on the profile data it is evident that the Nile coastal beaches have two or three ranges of gradients, with the steeper gradients located in the surf or breaker zone (ranging from 1:76 to 1:140); followed by a seaward transitional milder slope ranging from 1:35 to 1:350 and a still flatter seaward slope ranging from 1:90 to 1:435. The slopes steepen just west of the outlets within and beyond the breaker zone. This is true for all the outlets except those which are provided with protective structures ( Maadia, Burullus and El-Gamil) such as jetties where they are flatter in the breaker zone only due to sedimentation processes. However, for the Damietta Outlet, the slopes are steeper due to the formation of a large eddy west of the jetty which prevents any sediment deposition. East of the outlets, the slopes are steeper than those on the west side, especially in the breaker zone. They gradually flatten for some distance to the east and then steepen again both in and beyond the breaker zone. The very steep slopes (1:5) at the eastern part of the Damietta Promontory are the result of active scour in front of the vertical wall existing in the area and not due to natural causes. The changes in bed slopes during the 1981-1990 period were relatively small.

Grain Size Changes

The size characteristics of the surface bottom samples along the Nile Delta coast during the 1982 to 1989 period show insignificant changes. Some decrease in sediment size was evident from 1982 to 1989, primarily in the zone of maximum wave energy and strong longshore current, namely the breaker zone; from the shoreline to a distance of 300 m offshore. The data showed a clear trend of size reduction in the seaward direction. Coarser sands were also found near Maadia, near Burullus and at Damietta Outlet. These may be a "lag" product resulting from erosion concentrated at the old Nile branches.

Relation between median grain size and bottom slope

It is well known that grain size is an important parameter in determining the profile slopes under water or above water. Figure 5 shows the variation in slope as a function of median grain size  $D_{50}$ , for the beach face and beyond the breaker zone for the entire coast. It is clear that: (i) the slope increases as grain size increases, (ii) the effect of grain size on slopes is greater in the beach zone area than beyond the breaker zone, and (iii) exposure to different wave conditions such as breaking waves modifies the slopes and grain sizes.

Figure 5. Bottom Slope Versus Medium Grain Size.

### Underwater bars

One characteristic feature of a beach in a relatively enclosed sea with small tidal range such as the Mediterranean Sea is a series of submarine bars (Manohar, 1979). Along most of the Nile Delta coast there are three underwater bars, one in the breaker zone in depths of 0-2 m (summer bar) formed by the short waves and swells, one or two storm bars in water depth ranging from 3-4 m and/or from 5-6 m formed by the largest storm waves. The convex shape of the bars has been interpreted as an index of the existence of more than one predominant wave direction, i.e. waves from NE and NW directions (Khafagy, Fanos, Naffaa, 1992). The bar heights range from 0.30 m to 1.00 m and in some cases are very flat and low in height. Their heights increase in areas of accretion and flatter slopes, whereas in erosional areas their base is large and their heights low. The formation and migration of these bars is a complex phenomenon which is difficult to study in a natural environment.

### Volumetric Changes and Trends in Erosion and Accretion

Coastal processes can be interpreted in terms of changes of profiles and volumes. These types of results were developed from the 1981-1990 profile data and are presented in Figure 6. Figure 6b presents the mass curve (cumulative volume along the baseline). In the mass curve, a steeper upward slope indicates accelerated accretion and a flatter slope means the accretion is less than in the previous zone. A downward slope signifies erosion. Figure 6c presents the total volume of sediments moving on the Nile Delta coast within the zone between the baseline and the 6 meter contour. These figures indicate the following:

1. Volumetric change rates appear to depend on time, for example the volume change during a particular period is not equal to volume change per year multiplied by the number of years.
2. The gross volume change (accretion + erosion) which amounted to  $235 \times 10^6$  cu.m. in the ten year period is by far larger than the net volume change (accretion - erosion) which amounted to  $13 \times 10^6$  cu.m. in the same period.
3. In the breaker zone, erosion predominates over accretion, with a few areas of accretion such as Abu Khashaba east of Rosetta Exit, to the west of Gamasa Drain and near Port Said. The accretion in the Baltim Sea resort area is due in part to the artificial nourishment of the beach.
4. The net volume change over the full length of the coast is sometimes accretion (up to 6 m depth) and sometimes it is erosion. This means that sediments are coming from or lost to depths beyond 6 m. This stresses the importance of extending the profile surveys offshore beyond 6 m to the closure depth.
5. The changes of the profiles do not follow a certain pattern except at Rosetta and Damietta promontories and to the east of Burullus Outlet where they erode progressively.

Figure 6. Mass Curve of Total Sediment Volume Determined from Profile Data Along the Nile Delta Coast during the Period from 1981 to 1990.

6. The analysis of the spring profiles shows recession along the coast due to the high waves of the winter season while autumn profiles show redistribution of the sediments and shoreline advancement due to the lower swells of the summer season.

#### Physiographic Nearshore Units

According to the seasonal analysis of the beach profiles many independent physiographic units could be proposed as described below and shown in Figure 7:

1. Abu Quir Bay from Madiaa Outlet to 6 km south of Rosetta Exit is an independent unit although its northern end acts as a sink for the erosional products from the Rosetta Promontory.
2. The Rosetta Promontory, for about 15 km on both sides of the Rosetta Exit behaves as a separate unit acting as sources for adjacent areas.
3. Abu Khashaba zone acts as a sink for erosional material from the Rosetta Promontory.
4. The 40 km east of Abu Khashaba to Burullus Outlet appears to be a unit by itself where the shore is shifting back and forth.
5. The reach from Burullus Outlet to Kitchener Drain is an erosion area with cusp formation at Baltim sea resort.
6. From Kitchener Drain to the western breakwater of New Damietta Harbor is almost stable area with some accretional and erosional pockets.
7. Damietta Promontory on both sides of the Nile estuary is a separate unit similar to the Rosetta unit.
8. The reach from the beginning of the spit and up to 15 km to the east acts as a sink for the promontory erosion and to some extent as a source for the 10 km stretch located immediately eastwards.
9. The remaining stretch appears to be an independent unit and acts as the major source for the Port Said breakwater and its entrance channel.

#### SUMMARY AND CONCLUSIONS

The coastal processes and changes along the Nile Delta shoreline are a result of the dominantly westerly wave incidence, the historic changes in location of the Nile tributaries ( $\approx$  1000 years before present) and the more recent (this century) dramatic reduction in sediment supply due to barrage construction along the Nile River. An effective means of studying the current processes is through analysis of repetitive beach profiles extending a sufficient distance seaward to encompass the active profile.

This study has identified the dominant erosional areas as those characterized by convex outward shorelines as a result of historical sediment supply by the Nile River tributaries. These erosional zones serve as sources of sediment for the accretional areas which are dominantly concave in planform. Consistent with theory

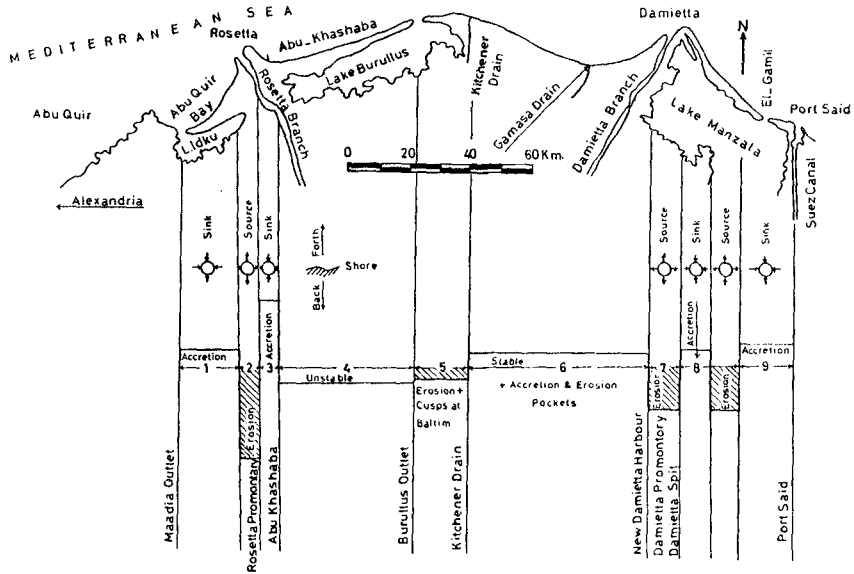

Figure 7. Physiographic Units Identified.

of planform change, it is expected that the erosional zones will broaden with time. The profile and sediment characteristics are qualitatively in agreement with the findings of previous investigators, namely that there is a correlation between local slope and local sediment size. The profile analysis indicates a complex pattern of erosion/accretion both in the longshore and cross-shore directions.

Continued profile measurements will provide a valuable data base which will provide additional understanding of the complex and dynamic coastal processes along the Nile River Delta and will assist in the critical future management decisions relating to this resource.

## CHAPTER 250

### NILE DELTA PROFILES AND MIGRATING SAND BLANKETS

Douglas L. Inman<sup>1</sup>, M. Hany S. Elwany<sup>2</sup> (M.ASCE),  
Ahmed A. Khafagy<sup>3</sup> and Abraham Golik<sup>4</sup>

#### ABSTRACT

Before construction of the various Nile River dams, the position of the Nile Delta shoreline was in equilibrium between the sediment supplied by the river and the transport of sediment along the coast. Following dam construction sediment yield from the river has virtually ceased. In the absence of sediment from the river, currents, waves and winds are actively eroding the delta. Extensive beach profiling shows that the primary locus of erosion, in excess of  $10 \times 10^6 \text{ m}^3 \text{ yr}$ , is from the Rosetta promontory. This material is carried eastward in part by wave action but predominantly by currents of the east Mediterranean gyre which sweep across the shallow delta shelf with speeds up to 100 cm/sec. Divergence of the current downcoast from Rosetta and Burullus promontories results in formation of accretionary blankets of sand that episodically impinge on the shoreline. Individual blankets of sand form 1.5 m thick covers over the residual profile in depths of 6 to 4 m, and extend for 2 to 4 km along the shore. The sand blankets move progressively downcoast at rates of 0.5 to 1 km/yr, generating series of accretion/erosion waves along the shoreline.

The erosion/accretion/erosion shoreline change is commonly 50 to 100 m and has a periodicity of 3 to 8 years. When the accretionary phase of the wave has passed downcoast, the shoreline returns to its previous form and exhibits a "residual" equilibrium profile. In its residual form, the beach profile goes through characteristic adjustments to seasonal wave climate, exhibiting an equilibrium winter profile with a pronounced bar and a summer profile when the bar tends to migrate onshore. When the nearshore is blanketed with sand during the accretionary part of the cycle, the profile is in disequilibrium with wave forcing and frequently shows several, irregularly spaced bars and troughs. Although the year to year shoreline changes associated with the accretion/erosion waves are large, 0(50 m/yr), the long-term (decadal) changes based on successive residual profiles from the erosion portion of the cycle are relatively moderate, say 0(2 m/yr).

<sup>4</sup>National Institute of Oceanography, IOLR, Haifa 31080, Israel

Findings from this study suggest that the coastal current augmented by waves may transport 10 - 20 million  $m^3/yr$  of sandy sediment, while the longshore sand transport near the shore is about 1 million  $m^3/yr$ . Thus it appears that the blankets of moving sand that episodically impinge on these relatively shallow (6 m deep) profiles are only revealing the "toe of the elephant." Additional study is needed at depths of 20 m or more to resolve this problem.

## INTRODUCTION

The shoreline of the Nile Delta extends along the Mediterranean coast from near Alexandria for 200 km to the east (Figure 1). The Nile River has been the sole source of the sediment for the delta as well as for the entire Nile littoral cell that extends an additional 500 km to Akko, Israel (e.g., Inman and Jenkins 1984; Carmel et al. 1985). The sediment load from the Nile River was deposited along the submerged portion of the delta where it was sorted and transported to the east by the prevailing waves and by currents of the counterclockwise east Mediterranean gyre that commonly flows at about 50 cm/sec over the delta. Prior to 1964, the turbid plume of the flood waters of the Nile River could be traced along the Mediterranean coast for over 700 km to the shores of Lebanon (Orin 1952; Hecht 1964).

Until 1964, the major sediment source of the littoral cell was the Nile River. Construction of the High Aswan Dam, which began filling in 1964, has resulted in a near absence of Nile River flow into the Mediterranean and a corresponding complete loss of the Nile River as a source of nutrients to coastal waters and as an active sediment source for the delta and the coastline of the Nile littoral cell. As a result, the Nile Delta is now subject to severe erosion in a number of localities.

Previous studies have shown that the Nile Delta shoreline is bordered by a ribbon of sand, approximately 10 km-wide, extending from Rosetta promontory to near Damietta promontory (e.g., Fishawi et al. 1976; Misdorp 1977). Curiously, just west of Damietta promontory, this ribbon of sand diverges in a northeasterly direction from the coast, arching seaward from the promontory, leaving a mostly muddy offshore area from Damietta to Port Said (Figure 1). More recent studies by Murray et al. (1980; 1981) show that the Damietta promontory interacts with the east Mediterranean gyre to form a large, stationary eddy that begins at Damietta, extends offshore for up to 35 km and eastward along the coast for about 70 km. The seaward portion of the eddy is a high-speed jet over 5 km wide that forms off the promontory and flows northeasterly and then easterly with measured surface-to-bottom velocities of over 60 cm/sec. The eddy drives a field of actively migrating sand ridges easterly over a smooth mud plain. The sand belt begins in depths of 10 m, flows northeasterly, turns easterly and finally arcs southeasterly towards the coast between Port Said and Bardawil Lagoon (Coleman et al. 1981). This appears to be a major transport path and a partial sink for Nile sand.

The formation of the eddy down-current from Damietta is associated with the abrupt bend to the southeast in coastal orientation at that point. This area, including Manzala Lagoon and its barrier beaches, appears to have subsided at rates up to 0.5 cm/yr during the past 7500 years. Stanley (1988) suggests that the subsidence is associated with the Pelusium Line, a northeast-trending compressional zone bordering the Levant Basin and entering Africa along the axis of the ancient Pelusium Branch of the Nile between Port Said and Bardawil Lagoon (Neev et al. 1976).

## PRESENT STUDY

This report is part of a study of the budget of sediment of the Nile littoral cell sponsored by the U.S. Agency for International Development. It is based on extensive

Figure 1. Bathymetry and sediment transport paths on the Nile Delta. Sandy sediment (stippled) after Fishawi et al. (1976), dunes after Sestini (1976) and Stanley et al. (1992), prevailing 25–75 cm/sec currents (central arrows) from hydrographic charts, and 50–75 cm/sec Damietta eddy current (arrows) after Murray et al. (1980).

beach profiling, sediment analysis and wave measurements. The profiling includes 70 ranges extending over the 200 km of Nile Delta shoreline (see Khafagy et al. this proceeding), about 80 % of which were measured twice annually. Measurements during the early winter quarter of the year (October-December) were initiated under a previous UNDP/UNESCO study and, as used in this study, extended over the 18-year period from 1971 to 1988. Measurements during the spring quarter (April - June) extended from 1976 to 1988. These profiles were surveyed to depths of 6 m or distances of 1 km, whichever occurred first.

Sediment sampling accompanied the profile surveying. Samples from the beach face at MSL show a mean grain size of about 250  $\mu\text{m}$  from Rosetta east, coarsening to 340  $\mu\text{m}$  off Burullus and returning to 250  $\mu\text{m}$  in the Baltim segment. Much finer sand, 150  $\mu\text{m}$ , occurs on the Manzala barrier beaches, suggesting that the longshore transport coupling between the Manzala barriers and the Burullus-Baltim area is far from direct.

Wave arrays are located on an oil platform off Abu Quir Bay and in depths of 6 m off Ras el Bar on Damietta promontory. Both are three element arrays that provide wave directional-frequency spectra (Lowe et al. 1972). The Abu Quir array became operational in 1982/83 and the Ras el Bar array in 1985 (Lowe and Inman 1984; Elwany et al. 1988). The arrays show that the predominant waves are from the northwest to west-northwest and the wave climate is characterized by  $1/2 \leq H_s(m) \leq 3$  and  $3 \leq T_p(s) \leq 8$ , where  $H_s$  is the significant wave height and  $T_p$  is the peak spectral period.

## SHORELINE CHANGES

Analysis of the 18 years of profiling along the 70 Nile Delta ranges shows that there are some sections of long-term erosion and accretion while, in other sections, the shoreline exhibits large cyclic changes with periods of 3 - 8 years, but undergoes little net long-term change. An "end-point" analysis of shoreline change over the 18 years is shown in Figure 2 together with the standard deviation of change. The end-point procedure gives

Figure 2. Mean shoreline change rate along the Nile Delta for the survey period 1971-1988 (below) and the standard deviation of the data set (above).

Figure 3. Shoreline retreat of 90 m/yr shown by successive surveys on Rosetta promontory.

valid information where the change in shoreline follows a continuous trend as in Figure 3, but can give biased results when there are cyclic changes in trend, as shown in Figure 4 (e.g., Dolan et al. 1991).

Inspection of Figure 2 shows that the primary locus of erosion is from Rosetta promontory. Volume changes down to the 6 m depths surveyed give the erosion rate as 5 million  $m^3/yr$ . Since the erosion clearly extends to greater depth, and the profile is steepening as it recedes (Figure 3), a conservative estimate is about 10 million  $m^3/yr$ . This material is transported easterly along the delta coast by waves and currents. The strong currents, which may reach their near-bottom velocity maximum in depths of 10 to 30 m, are also likely eroding sediments from these deeper portions of the shelf.

## SAND TRANSPORT

There appear to be two interrelated sand transport mechanisms with somewhat different paths along the Nile Delta coast: a *longshore* and a *coastal current* transport path. The classical longshore sand transport is most intense in and near the surf zone, and is driven by the waves and wave-induced longshore currents. Along the Nile shoreline the longshore sand transport is eastward at rates of about 1 million  $m^3/yr$  (Inman and Jenkins 1984).

A coastal current transport path of sand appears to be primarily driven by the easterly-flowing east Mediterranean gyre that attains velocities of up to 100 cm/sec over the shallow shelf. This transport is undoubtedly enhanced by wave action, particularly during storms when 3-m-high, 8-sec-period waves can move sand in depths of 40 m. However, the sediment distribution and coastal current measurements (e.g., U.S. Hydrographic Chart 56100) suggest that this transport occurs in a band about 5 to 10 km wide centered around depths of 10 to 15 m. Clearly this transport path is carried to much greater depths by the trapped jet off Damietta promontory (Figure 1). Consideration of the overall budget of sediment suggests that the coastal current system may transport sand at rates of 10 to 20 million  $m^3/yr$  along the coast. The coastal transport of sand along the southern California coast, which is largely wave-driven, appears to be about 10% of the longshore transport rate (Inman and Masters 1991). Along the Nile Coast, the coastal current transport is likely an order of magnitude larger than the longshore transport rate.

Pronounced changes in downcoast orientation, as at Damietta promontory, produce large, standing eddies. However, more gradual changes in orientation, as off Burullus, appear to result in a downcoast current divergence or spreading out and a decrease in velocity. This divergence results in a local decrease in the coastal sediment transport rate and the accretion of sand. This may, in part, explain the formation of the Damietta Banks west of Damietta promontory and the formation of the extensive Baltim dune field (Figure 1). This zone of sand accretion also appears to be a contributing factor in the formation of accretion and erosion waves along the shoreline east of Burullus Inlet.

### *Accretion and Erosion Waves*

Divergence of the current downcoast from Rosetta and Burullus promontories results in formation of accretionary blankets of sand that episodically impinge on the shoreline. Downcoast from Burullus promontory, individual blankets of sand from 1 to 2 m thick covers over the residual beach profiles in depths of 4 to 6 m (Figure 5), and extend for 2 to 4 km along the shore. The sand blankets move progressively downcoast at rates of 0.5 to 1 km/yr, generating series of accretion/erosion waves that travel along the shoreline (Inman 1987). These rhythmic features are clearly visible in satellite imagery which shows the turbid plumes in their nearshore circulation pattern (Inman et al. 1976). Their overall shoreline accretion to erosion patterns are shown in Figure 4 and their

Figure 4. Accretion and erosion waves at ranges 16 and 20 km east of inlet to Burullus Lagoon. Vertical bars show initial impingement of sand blanket on profile. Compare with Figure 5.

temporal and spatial statistics listed in Table 1. The individual sand blankets impinging on the beach profile have volumes of about 2 to 5 million  $m^3$ .

The impingement of the sand blanket on the beach profile is relatively rapid, always appearing in its full thickness ( $\sim 1.5m$ ) between two annual surveys (Figure 5). The initial time of impingement is shown by the vertical bars in Figure 4. Thereafter the blanket gradually thins while the shoreline accretes. After several years the blanket migrates downcoast, and the shoreline erodes back to its former width.

#### *The Residual Equilibrium Profile*

When the accretionary phase of the wave has passed downcoast, the shoreline returns to its previous form and exhibits a "residual" profile. In its residual form, the beach profile goes through characteristic adjustments to seasonal wave climate, exhibiting an equilibrium winter profile with a pronounced bar and a summer profile when the bar tends to migrate onshore (Figure 6a,b). When the nearshore is blanketed with sand during the accretionary part of the cycle, the profile is in disequilibrium with wave forcing and frequently shows several, irregularly spaced bars and troughs. Although the year to year shoreline changes associated with the accretion/erosion waves are large,  $O(50 \text{ m/yr})$ , the long-term (decadal) changes based on successive residual profiles from the erosion portion of the cycle are relatively moderate, say  $O(2 \text{ m/yr})$ .

The best-fit form for the equilibrium profile follows that suggested by Inman et al. (in press). Their model consists of two contiguous curves, an offshore (shorerise) portion joined at the breakpoint bar with the onshore (bar-berm) portion (Figure 6). Both portions of the profile are well-fitted by parabolic curves of the form  $h = Ax^n$  where  $h$  is positive

Figure 6. Profiles and definition sketch for compound parabolic curve fitting. Parameters are listed in Table 2.

downward and  $x$  is the positive offshore coordinate (Table 2). It was found that the compound parabolic curves gave the best fit, especially when there was a longshore bar present as in Figure 6a. However, when the bars migrate onshore leaving a reasonably "smooth" profile as in Figure 6b, then a single-fit parabolic curve gives reasonable good fit as shown in Figure 7 and Table 2.

## CHAPTER 251

### DESIGN AND CONSTRUCTION OF THE BOSTON OUTFALL

Y. Eisenberg, F.ASCE  
P. Brooks, MIE (Aust.)

#### ABSTRACT

The Boston Outfall, presently under construction in Massachusetts, U.S.A., is the world's largest tunnel outfall. The outfall represents the latest in tunnel outfall technology and when completed will discharge up to 1300 million gallons per day of secondary treated effluent through a system of seabed diffusers, nine and a half miles off the coast of Boston. Installation of the 55 diffusers and risers are nearing completion, with the construction of the outfall tunnel just commencing. The Outfall is a major component of the Boston Harbor Clean-up Project.

This paper presents a description of the design and construction of the deepwater Boston Outfall.

#### INTRODUCTION

In 1985 the Massachusetts Water Resources Authority (MWRA) was created with an objective to construct a new secondary wastewater treatment plant in order to end the pollution of Boston Harbor. The Boston Harbor Project is an 11 year \$6.1 billion effort, making it the largest wastewater treatment project in the U.S.A. The new facilities, with a capacity to treat more than one billion gallons per day, will replace two antiquated and over-burdened primary sewage treatment plants on Boston's Deer and Nut Islands. In addition to the new treatment plants, the Project also includes a new headworks facility, a five mile hard rock tunnel between the two islands and a nine and a half mile long effluent outfall tunnel from Deer Island. A Site Plan of the Project is shown on Figure 1. Construction on the project began in 1988 and will be completed by 1999. The Boston Harbor Project is being carried out under a "fast track" schedule due to Federal Court mandated milestones.

The outfall construction was bid in July 1990 for a total of \$279 million and is scheduled for completion in April 1995.

## OUTFALL CONFIGURATION

During initial investigations for the Outfall design, concepts were evaluated for both a seabed pipeline and a tunnel for transport of the effluent. Some of the factors that dictated the selection of a tunnel were:

- Preliminary investigations indicated that the dredging of Boston Harbor for the construction of a large diameter pipeline would not be permitted because of environmental reasons.
- The required internal diameter of the Outfall (24.25 feet) would require massive pipe sections and create enormous logistics, handling and connection problems if a seabed pipe was selected.
- Construction of a large diameter pipeline, nine and a half miles out into the Atlantic Ocean presented significant construction risk in terms of both operations and schedule delays.
- Costs for large diameter tunnels become more competitive against pipelines over longer distances.
- Tunnels have reduced operation and maintenance costs, and provide a longer service life in comparison to a pipeline.

Based on the decision to construct a tunnel in preference to a pipeline, an outfall system was developed which consists of the following principal components and features: (Refer to Figure 2.)

- A vertical dropshaft, 30 feet in diameter to a depth of 420 feet below Deer Island. The tunnel depth was dictated by the requirement to have a minimum of four tunnel diameters of competent rock between the tunnel crown and the surface of the rock.
- A submarine outfall tunnel, 24.25 feet in finished diameter, approximately 43,000 feet long to the start of the diffuser zone. The tunnel has an upward grade to allow ground water to drain back to the shaft.
- A tunnel venturi immediately upstream of the diffuser zone to assist in tunnel purging and prevention of seawater intrusion into the tunnel.
- Tapered tunnel in the diffuser zone, 6600 feet long. Tunnel cross section reduces gradually in area to maintain relatively constant effluent velocity.
- 55 riser offtakes connecting the diffuser tunnel to the seabed risers.
- 55 riser pipes, 30 inches in diameter and 250 feet long to carry the effluent from the tunnel up to the seabed diffuser heads.
- 55 diffuser heads, each comprising eight radial ports with conical nozzles attached. The diffusers are spaced 125 feet apart and disperse the effluent in 110 feet of water.

## OUTFALL DESIGN CRITERIA

A prerequisite to the design of the outfall was the establishment of realistic criteria on which to base the design. The key issues influencing the design of any outfall system are:

- Existing and ultimate dry and wet weather flows.
- Internal and external hydraulic performance

- Operational life
- Structural integrity
- Regulatory requirements
- Constructability
- Operations and maintenance (O&M)

Specific quantitative design criteria were developed to meet the site constraints and the regulations of numerous government agencies and local authorities. They reflect multi-disciplinary considerations including oceanography, geology, technical, hydraulics and hydrodynamics, water quality, biology, and empirical observations of existing outfalls.

A summary of the general design criteria assumed by the designers is as follows:

- A design life of 100 years was specified.
- The design water depth took into consideration the greenhouse effect, combined with maximum tide and storm surge.
- The design flows of the system were determined to be 1270 mgd peak to 320 mgd minimum.
- The Outfall was to be designed to allow full seawater purging of the tunnel. Purging flows are 80% of the peak design flows with the specified seawater and effluent densities.
- Minimize sea water intrusion into the tunnel.
- Outfall dewatering. It was a requirement that the outfall be able to withstand being fully dewatered at least 4 times over the 100 year life of the system.
- Maximum surface and seabed currents.
- Design wave height and period typically taken on the 100 year return wave.
- Assessment of accidental impact loads due to anchors, chains or trawling equipment.
- Bedrock and seabed overburden properties.
- Corrosion allowance for steel seabed structures and the elimination of metals as far as possible to reduce the potential for galvanic corrosion.
- Assumed construction guidelines such as installing the riser shafts and diffusers prior to the tunnel construction reaching the diffuser zone.

## **SITE INVESTIGATIONS**

The geotechnical conditions along the outfall alignment presented the design engineers with some challenges. The bedrock is a very competent sedimentary argyllite material of approximately 25,000 psi comprehensive strength, with presence of diabase dikes and fracture zones. Overlying the bedrock, particularly in the diffuser zone are sediments and clays (Boston Blue Clay) in layers up to 100 feet deep. Underlying the clays are bands of glacial till characterized by cobbles and boulders. By any standards, the geology of the area is judged very complex and thus difficult to define precisely.

To assist in the outfall design process, a comprehensive geotechnical and geophysical exploration program was carried out for the Project. In 1988, the

MWRA contracted for the drilling of 25 exploratory borings, geophysical surveys, surface mapping, laboratory tests and other exploratory work in the general vicinity of the alignment. Explorations were also carried out on Deer Island. Based on this information, suitable diffuser sites were selected and a preferred general alignment was established.

In 1989, additional exploration was carried out for the MWRA as part of the outfall design program. These explorations concentrated in a narrower strip along the preferred alignment and included 31 borings, 15 piezocone borings, 96 vibracores, seismic reflection and refraction profiling, a deep digital survey, side scan sonar, and magnetometer profiling, as well as field and laboratory testing. The program represented one of the most intensive geotechnical and marine investigations undertaken for an outfall project.

## **OUTFALL DESIGN**

### **Shaft**

Various methods of ground support were considered for the section of the 30 feet diameter shaft through the glacial till from ground level to -110 feet below Mean Sea Level. These included precast concrete segments, soldier piles and lagging, the New Austrian Tunneling Method (N.A.T.M.) and diaphragm walls. Diaphragm walls were selected by the designers as the most reliable means of support that would meet design criteria and ensure safety during construction operations.

The second section of the shaft, from -110 feet to -365 feet consists of three sections of shaft supported by rock bolts, mesh and a skin of reinforced shotcrete.

The third and lowest portion of the tunnel shaft consists of a back tunnel (Figure 4), a shaft invert and pumping sump and a TBM erection chamber. The final lining for the shaft and the initial length of tunnel up to the point where the main tunnel lining commences is to be unreinforced cast-in-place concrete. This 12 inch thick lining was designed to withstand full external hydrostatic pressure in the temporary condition and full internal hydrostatic pressure in the operational condition. The construction of the shaft commenced in late 1990 and was completed in early 1992.

### **Tunnel**

The 43,000 feet long main outfall tunnel has a 24 feet, 3 inch inside diameter. Approximately 90% of the tunnel was determined to be in competent sedimentary argyllite material, with an approximate compressive strength of 25,000 psi. For the few areas where blocky and seamy rock were encountered, the engineers provided suggested grouting layouts for the Contractor as shown in Figure 5.

Two designs for tunnel lining were provided in the bidding documents:

- 1) Precast segmental liner erected under a shield;
- 2) Cast-in-place liner using a precast invert segment.

Both liners were designed to resist full hydrostatic pressure. The Contractor was permitted in the specifications to offer his own liner design subject to the approval of the engineer. The "as bid" precast liner consisted of six segments per each 5 feet deep ring: an invert segment, four side segments and a "keystone wedge" trapezoidal shaped top segment. The longitudinal joints were "ship-lap" type and the transverse ones were "knuckle" joints. The Contractor submitted his own design for a variation of the precast liner. After passing physical testing and analysis, this liner system was accepted for use. The Contractor's design utilizes equal and interchangeable trapezoidal shaped segments held together longitudinally with pins and held together transversely with guiding rods (see Figures 6 & 7). The precast units are presently being manufactured in Hudson, New Hampshire approximately 50 miles from the outfall site.

### **Diffuser and Riser**

Like all large marine construction projects, the installation method has a major bearing on the design. Because of the high operating spread cost of the equipment involved, the designers sought a configuration that would lend itself to a "production line" installation method. This was especially relevant considering the large number of repetitive tasks involved. Construction issues considered during design included:

- All component makeup was to be performed on shore or on the barge in controlled conditions.
- Critical inspection and QA activities were able to be performed by ROV or by electronic survey instruments.
- Critical path downtime, e.g., such as that typically occurring while waiting on concrete curing, was reduced to a minimum.
- Diver intervention (a major cause of downtime) would be minimized.
- Potential downtime scenarios for several construction methods were analyzed, and allowances made in the design to mitigate their occurrence.
- Installation tolerances were set at achievable levels based on recent historical precedent.

The designers were fortunate in that they had just been involved in the design and construction of the Sydney Ocean Outfalls, which involved the fabrication and installation of 96 diffusers in 250 feet of water off Sydney, Australia, and were then able to take advantage of the experience gained from that project.

Conditions Affecting Design. The combination of site conditions (thick sediment of overlying clay) and loads resulting from external conditions (storm activity, shipping activity) has determined the overall diffuser and riser design from the bedrock to the seabed. Because of the proximity of the diffuser zone to the US Coast Guard Navigation Buoy 'B' and hence the high likelihood of shipping activity in the area, the risk of high impact loads from anchors as well as anchor drag has been taken into account. Another factor that has been considered is the storm activity in the area and the effect of the resulting environmental action (e.g., scour) upon the structure.

The internal and external hydraulic requirements of the outfall have determined the configuration required for the diffuser, while the internal hydraulics (purging and anti-intrusion) have determined the elevation of the diffuser above the seabed.

**Casing.** A steel casing was selected to support the weight of the diffuser and to resist the lateral loads predicted by the anchor risk analysis. The casing also serves various functions during the installation process. These include:

- a) Stabilizes the upper seabed formation and any weathered or fractured bedrock;
- b) Supports the installed riser and diffuser assembly while the riser cement is curing;
- c) Provides vertical restraint against riser buoyancy forces during the riser cementing and cement curing processes;
- d) Provides an installation reference datum to ensure that the diffusers are at the same elevation relative to seabed. Port elevations are fixed with regard to casing height.

Because the casing is a structural component and is required for the full design life, allowances have been included in the form of increased wall thickness and internal and external coatings in the upper section.

**Riser Assembly.** The riser functions as a conduit for the effluent. It has been designed to be strong enough to withstand the external hydrostatic pressures both in the long-term (over 100 years) and in the initial dewatered conditions. The riser was also analyzed for installation loads from wave action, offshore transport and hydrostatic loads from the 250 feet grout column. Fiberglass reinforced plastic (FRP) was chosen for the riser material for its ease of handling, durability, non-corrosive properties and to provide a hydraulically smooth conduit. A riser unit length of 40 feet was selected as a standard length for ease of handling onshore during road transport and offshore on the installation vessels. The riser is to be supported in the drilled hole by a fully grouted annulus of cement.

**Diffuser Head.** The diffuser head has been designed in four components: base, cap, ringwall and protective dome. Concrete has been selected as the main structural element of the base and cap. For durability, the concrete mix is designed for high strength, high density and low permeability. The components are held together by Inconel high nickel alloy rods. These fasteners also double as lifting attachment points for installation purposes.

**Diffuser Base.** The base acts as a foundation for the diffuser cap and transmits all vertical and lateral impact loads to the drilled and grouted casing. To prevent the diffuser head and riser from being "pumped" out of the hole by hydrostatic forces during cementing, the base incorporates a latching mechanism that positively locks and anchors the base to the casing.

**Diffuser Cap.** The cap accommodates the FRP manifold, which is the primary dispersion structure for the effluent. The cap is replaceable in the unlikely event it needs recovery and repair through damage, and it also

incorporates a manhole cover to facilitate future inspection. The manifold consists of eight ports with detachable nozzles and sealing caps to be removed upon commissioning. The material used for the nozzles, cast nylon, has been selected for its high durability and machinable properties, abrasion resistance and low magnitude of roughness.

To assist in installation and commissioning, each diffuser has a pressure gauge to monitor the internal pressure and an internal air bleed-off assembly to equalize pressure prior to removing port caps. The cap and base are locked together with tie rods prior to installation.

Diffuser Dome. The primary concern for the designers with the diffuser structure was the potential for vertical and horizontal impact loads. To accommodate these concerns, the designers developed a durable, flexible, energy-absorbing shell. The principal material requirement of the dome shell is good ductility, corrosion resistance and high impact resistance. Cross-linked high density polyethylene (HDPEX) was selected as the most suitable material for the intended application.

Ringwall. The ringwall provides protection to the nozzles, as well as support for the HDPEX dome. Its design as a separate component allows the manifold and/or dome to be replaced without requiring the removal of the permanently grouted base. The ringwall is made of reinforced concrete. Extra protection to the exterior concrete is provided by a coating of urethane which displays excellent abrasion resistance as well as a low friction coefficient. The diffuser base is similarly coated on all surfaces likely to experience ground tackle or trawl board contact.

The entire diffuser assembly including dome ringwall and base is designed to present as smooth a profile as possible to minimize snagging by anchors, mooring lines or fishing equipment. In the event that anchors or anchor chains do snag or wrap around the diffuser structures, the riser casing and diffuser system has been designed to resist a lateral load of up to 200 tons.

Rock Armor and Filter Layer. The surrounding rock protection is provided to guard against potential scour and undermining of the diffuser cap and dome, and thereby eliminates the possibility of an anchor chain snagging under the diffuser. The rock protection also provides a smooth seabed profile in the vicinity of each diffuser. To prevent migration between the rock armor and the natural sediments, a 1.5/feet minimum sand/gravel filter layer was specified.

Riser Offtake. The riser offtakes provide the link between the pre-installed risers and the outfall tunnel. As this is essentially a horizontal extension of the riser pipe, FRP was the logical choice for material.

Of major importance in the design of any tunnel which is to connect with seabed structures (e.g., power station cooling water intakes, outfalls and ship loading facilities), is the protection of the tunnel worker from accidental flooding through the riser shafts. There are several devices designed to ensure sealing of the risers from the ocean. They are:

- a) Manifold Port Caps - installed with the riser and diffuser. These employ an O-ring fitting to effect a seal. Each port cap and nozzle is individually pressure tested to twice working pressure prior to installation.
- b) Riser Plug and Sealing Mechanism - a secondary sealing mechanism designed to prevent flooding due to loss of a seal at the port caps during initial stages of offtake installation. It is installed with the riser assembly and removed immediately prior to offtake installation.
- c) Offtake Elbow Sealing Plug - this plug fits into a recessed groove in the offtake elbow pipe and guards against flooding in the event of a loss of seal at the port caps after the riser plug is removed.

## **OUTFALL CONSTRUCTION**

### **Contract Package**

The construction contract packages for the tunnel and seabed diffuser work were issued for bid in two ways:

- 1) A contractor could bid for all of the work in both packages.
- 2) A contractor could bid for just one of the packages, diffusers or tunnel.

The reasoning behind this was that it was thought that bidding all the work in one package would reduce the competition among bidders as only very large construction companies would have the resources to undertake all of the work. On the other hand, the designers recognized the potential savings involved if the contractor was to coordinate all of the work, and hence, this option was left open. As expected, the second option (separate contracts) was pursued by the Client upon bid opening. The tunnel contract was awarded to a joint venture of Kiewit Construction Company, Guy F. Atkinson Construction Co., and Kenny Construction Company for \$202 million and the diffuser fabrication and installation contract to a joint venture of J.M. Cashman of Boston and Interbetton of the Netherlands for \$77 million.

### **Tunnel Construction**

The Robbins tunnel boring machine (TBM) purchased for this project is a double shield hard rock rotary machine. The TBM was refurbished by Robbins at their Chicago site and arrived by barge at Deer Island in October 1991. The machine has high thrust capability for hard rock application and a shield to support poor ground while tunnel supports are installed. (For the TBM's Technical Specifications, see Table 1.)

The cutterhead provides basic face stability while cutting. The two piece shield provides full ground support back to the rear of the lining installation area. A forward shield surrounds the cutterhead support structure providing ground support immediately behind the gauge cutters. A large area gripper system provides low unit ground loading for reacting machine thrust, torque

and steering forces. All the major machine structure pieces can be disassembled for removal from a lined tunnel. Included with the TBM is the machine conveyor which terminates approximately 90 feet from the face. The conveyor is supported in the rear on a trailing gantry. Also included is a wheel mounted gantry approximately 30 feet long, a rotary segment erector, segment transport hoist, segment car platform, and the hydraulic and electric power modules for the machine. These modules are mounted on the conveyor structure and trailing gantry.

The TBM has now been fully assembled at the bottom of the shaft and tunneling has begun. The average rate of advance of the TBM including lining is expected to be about 100 feet per day using two 10 hour shifts.

To ensure accurate positional control over the 9 mile length of the drive, the tunneling contractor has elected to use a 3 second gyroscope for tunnel surveying. This instrument is the most accurate available, with a claimed accuracy of 3 seconds of arc. A second system, yet to be determined, will be used to provide an independent parallel check on the gyroscope survey system.

Tunneling in the diffuser zone, which will start at about 43,000 feet east of the shaft, will offer the Contractor special challenges, mainly because of the requirement for the finished tunnel to reduce in cross section. The Contractor has not yet specified what method of construction will be used to form this 6600 feet long tapered section of tunnel. Several options are available including, precast concrete segments, cast in place concrete or concrete pipe segments of reducing diameter. Options for excavation in this zone include continuation of the TBM or use of drill and blast methods to excavate a smaller diameter tunnel. The use of cast in place concrete will require special concrete mixes, including retardants and accelerators because of the long transportation distance. When the tunnel is complete, the off-take adits will be excavated from the main tunnel to the previously drilled and capped risers, the connecting pipes and elbows installed and the off-take adits backfilled. (Figure 8 shows the tunnel and offtake section in the diffuser zone.)

### **Tunnel Offtakes**

The final operation which connects the underground work to offshore work is the installation of the tunnel offtakes.

Probe holes are drilled from the tunnel to ascertain the riser location and to tap and drain the risers of ballast water. (The risers have been installed and filled with fresh water containing green dye - this provides positive proof that the probe drill has intersected the riser and not a ground fault or cement void.) The offtake adits are then excavated horizontally from the tunnel to the pre-installed risers which will be exposed. The risers are then cut and an elbow section installed followed by the offtake pipework linking the riser to the tunnel. The void surrounding the pipework and exposed riser is to be backfilled with concrete (see Figure 8).

### **Diffuser and Riser.**

The contractor chose as his principal construction vessel a 4 leg jackup vessel assisted by a dredge barge, specially equipped grout barge, supply/anchor handling tugs and material barges. The jackup barge is equipped with 2 Wirth pile top shaft drilling rigs, a Manitowoc 4100 ringer crane, a smaller all terrain crane, helideck and construction offices. The grout barge was fitted out with bulk cement and water tanks, mixing equipment and oil field style high pressure cement pumps.

Prior to the jackup commencing installation, the sediment in the immediate vicinity of the riser is excavated by the dredge barge. Typical dredge depths are 6 feet below seabed over a 30 feet radius. Once dredging is complete at a riser site, the dredge continues along the Outfall while the jackup is floated into position using its mooring lines and jacked up over location. To expedite operations, two riser holes are drilled concurrently from the one site. Two sided mounted drilling templates, able to be moved along opposite sides of the barge, are accurately positioned to ensure the risers are within the alignment tolerance and at the correct spacing.

After positioning, a temporary casing is driven into the sediment and restrained laterally at barge level by the drilling templates. The casing is used to support the drilling and stabilize the upper sediments to prevent hole collapse. A 67 inch hole is drilled by reverse circulation air-lift methods and the 61 inch permanent casing is installed. Permanent casing lengths were specified to be a minimum length of 40 feet and 10 feet into solid rock. To date most casings have been 40 feet with several 60 feet and even 100 feet long casings installed to cope with the deeper sediments along the alignment. The casing elevation is checked by lead line, then grouted in stages via four grout lines attached to and lowered with the casing. The first stage forms a neat cement plug at the toe of the casing; this grout is allowed to set up and then the remainder of the annulus is grouted up to the top of the casing. The Designers provided a suggested float shoe design in the bid package, however, the Contractor selected to use a two-stage method.

The next phase comprises the installation of the diffuser and riser. A smaller (53") drill bit is used to drill a hole approximately 250 feet down from the seabed. The hole is surveyed by wire-line tools to ascertain bottom hole coordinates. The Bottom Hole Assembly (BHA) and drill string are now removed from the hole and laid down on the deck of the barge. The pile top rig is removed from the conductor casing, which is now cut off just above the (dredged) seabed and removed. The contractor chose to assemble the FRP riser joints into 120 feet lengths at the onshore staging area to reduce the offshore installation time, hence only two field joints were necessary to make up the 240 feet string. The riser, diffuser base, manifold and ringwall are made up on the drilling template, lowered into the drilled hole and latched into the permanent casing as one unit. Pressure gauges on the diffuser port caps record the internal pressure of the riser, thus detecting any leaks between the sealing caps or between FRP joints. The annulus between the riser and drilled hole is then grouted through two grout lines installed with the riser assembly. A cement slurry of equal parts cement, sand and slag is used to reduce heat of hydration temperatures of the curing cement to less

than 160 degrees Fahrenheit and thus avoid heat induced damage to the FRP. A downhole nuclear density gauge installed in the riser/casing annulus provides real time recording of in situ grout densities, while specially designed overflow ports located in the diffuser base allow for visual observation of cement returns. The entire operation of riser installation is observed using an ROV and recorded on video.

With the riser installed and grouted, the jackup moves onto the next two risers and all that remains is for the installation of the HDPEX protective dome and placement of the sand/gravel and rock armor. These activities are performed from the dredge barge, with divers assisting in dome placement and any topping up of cement levels which have dropped due to slump.

One of the most critical offshore operations is the positioning survey of the seabed diffusers and corresponding riser shafts. The tunnelers will be required to locate the toe of these risers more than nine miles out along the tunnel alignment and 30 feet from the tunnel center line. To minimize the amount of probe drilling that must be performed and to align the tunnel to ensure the correct riser offtake distances can be achieved, it is imperative that the bottom hole coordinates of all risers are within a specified tolerance of one riser diameter, 34 inches.

The offshore surveying is carried out in two stages:

- a) High accuracy survey of the jackup rig position and drilling templates to the baseline coordinates.
- b) Separate downhole surveys providing relative position of the bottom hole coordinates to the drilling platform.

Because the jackup rig was essentially stationary, the contractor was able to employ differential G.P.S. backed up by conventional geodetic survey methods (E.D.M.'s and theodolites) to tie in the rig position to the base line coordinates. As the drilling templates were moved slightly on every riser site, these were surveyed relative to the jackup survey control points on each location.

The bottom hole coordinates of the drilled riser hole were obtained using a two axis wireline deployed gyroscope. Such tools were developed and are commonly used for steering and navigation of directionally drilled oil and gas wells. This survey also had a backup by means of an inverted pendulum shaft survey tool. This method, developed for surveying the verticality of mine ventilation and access shafts, relies on the plumb-bob effect of a suspended mass to move a surface float. The surface float assumes the same horizontal coordinates as the drill bit. Vertical measurements, although not as critical as horizontal accuracy, are obtained by lead line and drill string length.

Because of the number of surveys performed in each loop from the bottom hole survey to positioning the tunnel probe drilling equipment, it is imperative that the same baseline network is used for both tunneling and the diffuser installation. A separate high precision baseline network has been established for use by both contractors.

At the time of writing, the Contractor had installed all 55 of the risers from the jackup barge. The dredge barge will remain on site to finalize dome and rock placement on those sites not completed.

### **Material Fabrication**

There are very few structures built anywhere in the world where the expected service life and environmental conditions are as demanding as for ocean outfalls. With the exception of some parts of the diffuser structure, the riser and diffuser assembly are permanent installations and must remain serviceable for the design life of the system, in this case, 100 years.

Because of this, it is considered essential that a fairly stringent series of quality control tests are specified by the engineer to ensure that the materials selected for the outfall components are of the highest standard and meet specification design requirements. Evaluation of components made from plastics and exotic alloys as opposed to steel and concrete requires specialized testing methods.

For the Boston Outfall Project, specific items in the manufacture of the components were strictly controlled. These include:

- FRP Riser Pipes and Manifolds. Riser bend tests and diffuser cap (External) pressure tests were conducted while specimens were monitored by acoustic emission tests. Barcol Hardness and cube strength tests were performed on the glass and resin samples respectively.
- Cast Nylon Nozzles and Port Caps. Mechanical strength tests on specimens were performed to confirm physical properties with respect to tensile and impact loads.
- HDPEX Dome. Low temperature impact, tensile and density tests were performed on specimens cut from this component.
- Inconel Fasteners. Accelerated corrosion tests were performed to evaluate the resistance of these components to pitting and crevice corrosion.
- Riser Clamps. Tensile and chemical composition tests were performed on samples and radiographic tests were performed on completed cast steel items.

### **CONCLUSION**

The designers of the Boston Outfall sought a configuration that allowed for a rapid installation cycle while exposing the Contractor to as minimum risk as possible. Proof of the success of this approach was borne out by the recent completion of diffuser installation almost a year ahead of schedule, despite the Contractor electing to shut down in the winter months to reduce weather risk to equipment and personnel.

The successful low bid for the offshore construction was \$70 million below the independent engineers estimate; with the construction bids ranging from \$77 to \$173 million dollars. The large spread of bids can be explained by the

uncertainty of method in offshore construction and the wider variety of unknowns for this type of project. Other factors contributing to this effect are:

- increased risk to the Contractor from the marine environment.
- differing construction methods assumed during the bidding process.
- the unique nature of the project, with few contractors having experience and few similar projects for the engineer to base comparisons on.

Tunneling bids, by comparison, were much closer together despite the greater cost magnitude (low bid \$202 million, engineers estimate \$216 million, high bid \$246 million). This reflects a greater familiarity and precedent of this type of work amongst contractors. The tunnel completion date is scheduled for mid-1995, while the entire offshore installation will be complete in September 1992.

Deepwater tunnelled outfalls are proving to be increasingly cost effective when compared to conventional large diameter cut-and-cover pipeline outfalls. Not only is it possible to keep all but a small portion of the system from being exposed to the marine environment and thus achieve the specified longer design life, but per unit costs of recent tunneled outfalls have been lower than an equivalent sized seabed pipeline systems. In this case, the designers ought to achieve a low maintenance system that will still be operational in the year 2100 while keeping costs and construction durations below that of more conventional systems.

#### **ACKNOWLEDGEMENTS**

The owner of the facility is the Massachusetts Water Resources Authority. Parsons Brinckerhoff Quade & Douglas, Inc. was the Project Design Engineer and the senior author was the Design Manager (Project Engineer). Wholohan Grill and Partners, whose USA subsidiary is WGP Engineering, was the sub-consultant to Parsons Brinckerhoff for diffusers and risers and the co-author was the Manager for that effort. Mott Hay Inc. designed the tunnel shaft.

## CHAPTER 252

### MODELLING AND MONITORING OF A PERCHED BEACH AT LIDO DI OSTIA (ROME)

Andrea Ferrante<sup>1</sup>, Leopoldo Franco<sup>2</sup>, Sander Boer<sup>3</sup>

#### Abstract

A description is given of a new large project of artificial beach nourishment protected by a submerged sill carried out at Lido di Ostia near Rome in 1989-1991. After a review of the main aspects of the design (supported by model tests) and construction, details are given of the ongoing field monitoring program. Collected data has been used to verify the predictions of numerical models of cross-shore and longshore evolution of the perched beach. Useful preliminary lessons have been drawn from this unconventional experience of coastal protection.

#### Introduction

The sandy beaches of Lido di Ostia stretch along the southern delta cusp of the river Tiber, some 25 km from Rome on the Tyrrhenian Sea, and represent long since a very popular holiday resort for the Roman community (Fig.1). The cusped delta was formed by alluvial sediments carried by the river, producing a progressive coastline advance of more than 4 km from the Roman age until this century (Fig.2). Then, particularly in the last 25 years, a severe erosion process has been taking place reverting the evolution trend to a recession rate of 1.7 m/year. The main cause has been the strong reduction of river sediment supply (due to upstream dams and extraction of building material from the river bed) with a consequent deficit in the coastal sand budget and a trend towards the cusp straightening and smoothing out.

Fig.1. Location map of Ostia Lido and nearshore wave climate recorded in 1990-91

The local tidal range is very small (below 0.5 m), but deepwater waves may exceed a significant height of 5 m and a period of 10 s. Recent coastal protection works have been partially successful, such as the system of detached breakwaters constructed near the river mouth: erosion was shifted downdrift, mainly affecting the southern beach between the Vittoria Pier and the Pescatori Canal, causing damage to the beach clubs and even to the littoral road during storm periods.

An innovative beach nourishment project was then designed in 1988 by the competent Authority, the Office of Civil Engineers ("Genio Civile") for Maritime Works - Rome of the Italian Ministry of Public Works. A preliminary description of the project was given by Toti et al. (1990).

### Project objectives and constraints

The aim of the project was to re-create a wide protective beach with an efficient technical defence solution complying with the economical, managing, political and environmental requirements. In fact the local community rejected any traditional emerging coastal structure to favour tourism, aesthetics and ecology. Indeed the project represents a new approach of the Administration toward a global view in coastal defence, also taking into account the environmental aspects. Financial constraints restricted the project area to the most vulnerable 3 km stretch of coast.

Given the existing high deficit of the littoral sand budget, the proposed beach nourishment needed to be protected by some coastal structure able to dissipate part of the wave energy and reduce the littoral transport, and to retain the new fill material. The most suitable solution then included an offshore underwater rock barrier "fixing" the natural dynamic sandy bar, as a "perched beach" scheme. The submerged bar should hold the artificial beach at a shallower slope, reducing both offshore sand losses and longshore transport, enhancing the development of marine fauna, without endangering bathing and leisure navigation.

Important constraints were also resulting from the scarcity of marine sand for nourishment. The native beach sediments at a depth of MSL-10 m (on a 1% slope) have a too fine grain size with  $D_{50} = 0.1$  mm. Fill material needed to be quarried inland on the alluvial Tiber delta at 20 km distance from the beach: the available material is a poorly sorted mix of well rounded sands and gravels.

### Design scheme and problems to be studied

The protection scheme covers a beach length of 3 km (Figs.3-4) and basically consists of:

a) a sill made with a submerged rubble mound parallel to the shoreline at a distance of some 150 m, with toe level at MSL -4.0/-5.0 m, a 15 m wide crest berm at -1.5 m, seaward slope of 1:5, a multilayer rock mound (maximum stone weight of 1 t) placed above a geotextile and a 5 m wide rock toe protection in a 1 m deep trench;

Fig.2. Historical evolution of the river Tiber delta from year 110 a.C. (Segre,1950)

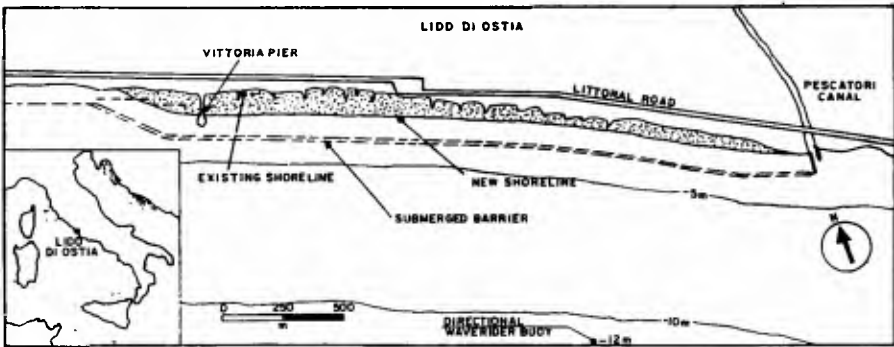

Fig.3. Design plan of the nourishment project

b) a fill with a double layer of quarry material: a lower layer of mixed sandy gravel with a wide grading of 0.08-120 mm, and a 1.0 m thick upper layer of sand with grading 0.3-1.3 mm; the underlayer also acts as a 5 m thick filter between the sand and the rock bar; the beach equilibrium slope is 2.5% and the berm crest located at MSL +1.0 m. The average design shoreline advance is about 60 m.

The main problems to be studied were related to the prediction of: the average losses of beach material due to longshore and cross-shore transport; the effects on the adjacent beaches; and the profile deformation during storms (which should not expose the underlayer). The sill hydraulic stability also needed to be verified.

### Model tests

The above design problems were solved with the support of physical and mathematical model studies carried out by Delft Hydraulics (1989). The one-line mathematical model simulated the long term evolution of the whole shoreline planshape, finding a dynamic equilibrium position just 5 years after construction. A cross-shore numerical model was also used to check the morphological changes of the beach profile. Annual sediment volume losses were estimated in 4-10 m<sup>3</sup>/m for the first year (depending on wave climate severity), reducing by 50% within three years. A minor erosion effect along the initial 700 m of downdrift beach was predicted. A 2-D mobile-bed hydraulic model at a scale 1:15 showed a remarkable stability of both the rock barrier and the artificial beach profile. A maximum 0.3 m vertical erosion was observed, together with an expected steepening of the beach slope at the shoreline and a horizontal recession of 5 m.

### Construction features

The execution of the works was carried out by Condracos, a consortium of specialized Italian contractors. The works started in May 1989 with a 3-month stop in the tourist summer season; in June 1990 a 2150 m beach portion was built, while the final 850 m were completed in the following spring, for a total construction period of only 14 months. The works progressed from the Pescatori Canal to the north against the net littoral drift direction with the following sequence:

- a) construction of longshore and cross-shore causeways to provide access for land-based equipment to build up the offshore barrier (initially emerging);
- b) dumping and shaping of beach granular material with both land-based and marine equipment; some native dark beach sand (iron-rich) was temporarily stockpiled to be mixed with the yellow quarry sand as toplayer .

The construction equipment consisted of one hopper suction dredger, three 600 m<sup>3</sup> capacity barges, one tug, one pontoon, four dumpers, two bulldozers, three excavators and many trucks for material transport from the quarry. The total material quantities were about 1,360,000 m<sup>3</sup> of sand and selected mixed sandy-gravel and about 300,000 m<sup>3</sup> of rock (basalt and limestone from different quarries).

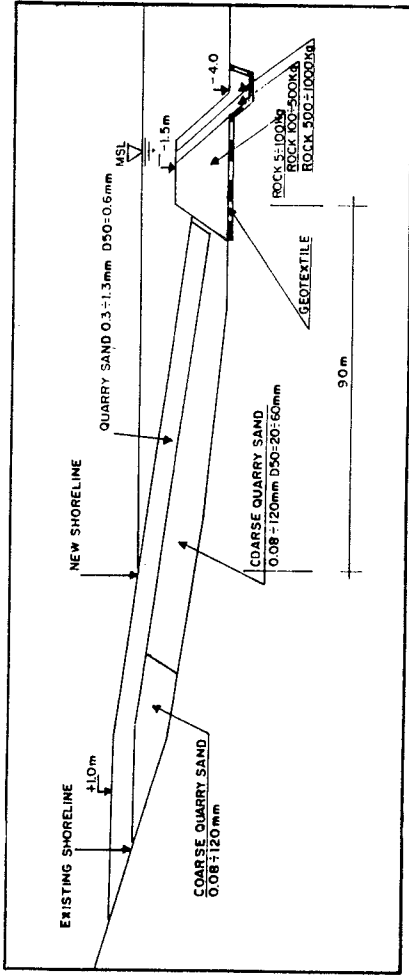

Fig. 4. Design cross section of the perched beach

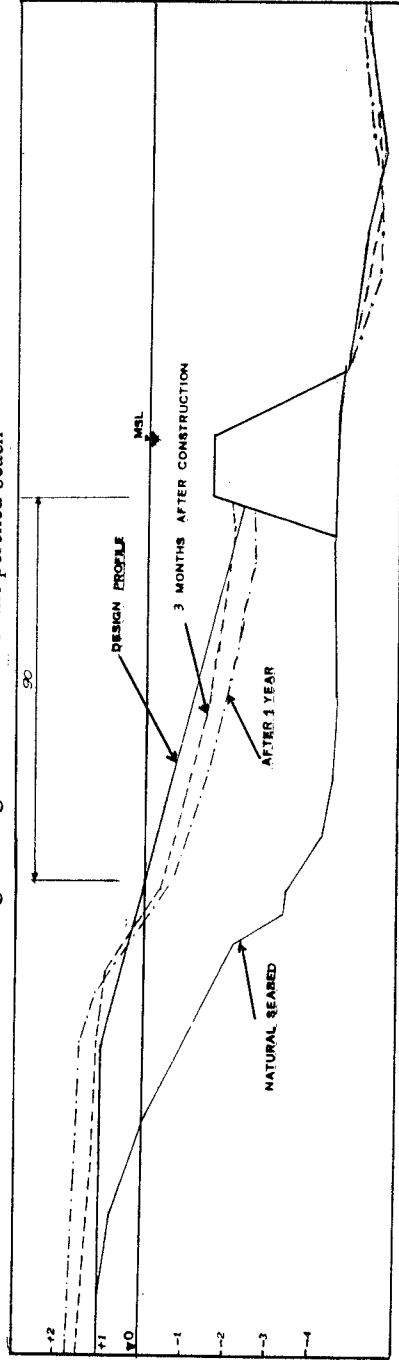

Fig. 5. Measured average perched beach profiles

### Monitoring program and analysis of field observations

Given the innovation of this technical solution and the unusual length of nourished beach without groynes, the Supreme Council of the Ministry of Public Works attributed an experimental character to the works and imposed the setup of a monitoring program since the construction start in mid 1989.

The periodic acquisition of field data includes: aerial photographs (twice a year), beach profile surveys (four per year), sediment sample analysis and directional wave recordings (starting on 3 Jan 1990). Beach profiles are surveyed up to MSL -7.0m at 100 m intervals, while 5 samples are collected across sections spaced 250 m. Local wave activity is recorded by a directional Datawell Waverider buoy moored in a depth of 12 m at 2 km distance from the coast, where a station easily receives the radio signals, supplying wave data in real time. Eight samples of 200 s (26.6 minutes) are processed with FFT and spectral results displayed every half hour. Records are stored every 3 hours unless a threshold of 2.5 m significant wave height is exceeded. Site surveys and underwater inspections were carried out also by the Authors.

The analysis of the topographical surveys has shown a general stability of the new beach with predicted maximum 20-30 m shoreline advance (at southern end) and retreat (at northern end), due to the southbound littoral drift. This sediment transport is reduced by the presence of coarser material and of the fixed bar in the surfzone. Dredging volumes smaller than before were in fact required to open the inlet of Pescatori Canal. No adverse effects have been observed on the adjacent beaches.

Photo 1 shows the original dark beach before the intervention and photos 2,3,4 the new large artificial beach, with gravel ridges typically forming near the cusped shoreline (which also shows an active 3-D inshore circulation).

The elevation of the emerged beach has increased up to MSL+1.5/+2.0 m, while the submerged beach profile generally deepened, as shown in fig. 5. In the first months after construction stagnant water ponds formed on the upper beach due to poor drainage of wave uprush, caused by this shoreline ridge and by the initial impermeability of the mixed surface layers (also compacted by truck transit). However natural wind and wave action later redistributed the sediment avoiding this problem.

Minor scour has been observed at the barrier seaward toe, but some deposition in deeper water may indicate small offshore sand losses. Some fine material has penetrated into the rock sill, thus reducing its permeability, but not the stability.

As far as wave measurements are concerned, the local climate of two years is shown in fig.1. It shows a typical bimodal distribution and the resultant of the wave energy vector is just directed from 225 N, still quite angled to the coastline normal oriented at 210 N, thus confirming the southbound littoral drift. These nearshore wave records have also been correlated with those taken at the deepwater directional station off Ponza island, finding a good correspondance. The main wave direction is typically

refracted inshore with a rotation of 25-30 degrees and the directional spread reduced from 30 to 10 degrees. An annual average of 7 storms with a peak significant wave height  $H_s > 2.5$  m was recorded, with a maximum  $H_s$  of 4.4 m. The corresponding offshore significant wave height of 5.8 m has an estimated return period of 10 years. This was indeed a severe positive test for the just completed perched beach.

#### Post-construction computation of beach deformation

The field data collected during the monitoring program has been used for hindcast computations of beach plan evolution and beach profile deformation, which have been performed with the "Unibest" software suite of Delft Hydraulics.

##### a) Profile development

Hindcast computations of the beach profile developments have been performed with "Unibest-TC". In this program the principal processes (wave asymmetry, undertow, gravity) underlying the cross-shore sediment transport are taken into account. The surfzone dynamics are computed by a built-in random wave propagation and decay module (Battjes and Stive, 1984). It includes the wave energy changes due to bottom refraction, shoaling and dissipation due to bottom friction and wave breaking. The secondary currents due to the vertical non-uniformity of the driving forces in the nearshore zone are modelled according to the formulations of Stive and De Vriend (1987). The cross-shore sediment transport along the coastal profile is calculated according to the formulations given by Bailard (1981), which include the transport due to the combined actions of steady current, wave orbital motion and bottom slope effect. The related bottom level changes of the cross-shore profile are computed from the mass balance.

For the computation of the perched beach profile morphodynamics at Ostia the local wave data from the directional Datawell Waverider buoy has been used in chronological sequence. The original wave data has been averaged per day on the basis of wave energy. The computation has been performed for the typical measured cross-shore profile as shown in Fig.5, but only the upper fill layer consisting of 0.3 - 1.3 mm was taken into account. The effect of coarsening of the beach material at the surface due to mixing of the upper and lower fill layer was just considered by increasing the  $D_{50}$  from 0.6 to 0.8 mm. In Figure 6 the computed beach profile developments after 3, 6 and 12 months are shown together with the distribution of the cross-shore transport  $S_y$  at the time step of 3 months. For the computed profile situated below MSL a similar erosion pattern can be observed in comparison with the profile developments which have been measured in nature (see Fig.5), although the calculated erosion seems to be slightly underestimated. Near the waterline the computation also show the formation of a ridge similar to the natural development. However, above MSL, at the emerged beach face, a large difference between calculated and natural development can be observed. In the model the accretion of the upper beach profile does not occur. One explanation for this may be the poor description in "Unibest" of the effect of wave up-rush on ridge formation at the

Cross-shore transport  $S_y$

$t = 90$  days

Profile developments

- $t = 0$  days
- -  $t = 90$  days
- $t = 180$  days
- -  $t = 360$  days

Fig. 6. Cross-shore transport and profile developments computed with UNIBEST-TC (Delft Hydraulics)

waterline. Possibly, aeolic transport along the dry beach face may be another explanation for this difference.

#### b) Beach planshape evolution

Computation of the beach planform shape have been performed with the program "Unibest-CL". This program computes the coastline changes due to longshore sediment transport gradients and cross-shore sediment losses/ gains on the basis of the one-line schematization. The model is based on the well known single line theory, which was first presented by Pelnard-Considère (1956). The profile characterizing the beach is assumed to move horizontally over its entire active height as a result of accretion or erosion. The beach slope therefore does not change. An equation of motion and a continuity equation are used together with specified initial and boundary conditions.

The basic input data for the module "Unibest-CL" is generated with the module "Unibest-LT" which computes tide- and wave-induced longshore currents and sediment transports on a beach of arbitrary profile. The surfzone dynamics are derived from the same built-in random wave propagation and decay model as used in the model "Unibest-TC". The distribution of the longshore current is computed from the momentum equation alongshore taking into account the radiation stress gradient, the bottom friction under combined current and wave action and the tidal surface slope alongshore.

The longshore transport computations have been carried out for the design profile of the beach nourishment with the same grading assumptions. The computations are based on a statistical description of the local directional wave recordings. The longshore transport computation are carried out with the Bijker formula (Bijker, 1971).

For the computation of beach planform development it has been assumed that the active profile extends down to the toe of the submerged rubble mound barrier. At the updrift boundary of the coastline model a zero transport has been imposed; at the downdrift boundary of the model the current transport has been modelled.

Figure 7 shows the results of the coastline computation after approximately 1 year. The initial coastline in January 1991 is also shown. The results display a retreat of the beach in the area south of Pontile della Vittoria due to the southward directed longshore transport and a small accretion in the area north of Canale dei Pescatori. From the computational results it can be noticed that the beach-line fluctuations which are present in the initial situation are slightly smoothed by the model. The reason for this is that longshore transport has been computed in the model for only one typical cross-shore profile. In nature, however, local deviations of the beach profile and nearshore area may cause small differences in beach response. In Figure 7 the corresponding net sediment transport distribution alongshore is shown as well. The sediment transport rate varies between 5,000 and 15,000 m<sup>3</sup>/year.

### Lessons from field experience and conclusions

After nearly three years of monitoring and the occurrence of many severe storms, the behaviour of the new perched beach at Lido di Ostia has been satisfactory. The observed alongshore and cross-shore redistribution of sediments are in good agreement with the design predictions. Volume losses appear to be small and correspond fairly well with the model predictions for a relatively bad wave climate. Negligible effects are observed on the downdrift and offshore beach morphology. Therefore the design choice to avoid groyne construction seems to be correct.

Ecological and aesthetical impacts are also acceptable: the quality of beach sediments and of seawater is satisfactory, as confirmed by the large tourist crowds in summer. The submerged rubble sill is stable and does not affect the beach recreational activities (a part from surfing). It is easily seen as a dark blue strip in the sea, marked with buoys. The rock barrier has favoured the development of marine fauna, being now fully covered with mussels and stimulating leisure fishing.

The experience gained so far from this innovative large-scale project can give some useful technical indications for the design of other perched beaches in similar hydro-morphological conditions.

The rock bar could be composed by a reduced number of gradations and the stone toe protection enlarged and laid directly on the geotextile above the seabed, thus saving the trench dredging. A proper filter layer of small stones should separate the fill toe from the barrier to avoid intrusion of fines into the sill.

The natural beach profile reshaping can be favoured and the construction eased by dumping the fill material on a steeper slope and keeping the cheaper coarse sediments on the submerged profile and the blanket of precious fine sand on the emerged beach face, which can be designed with a higher crest level.

However, final conclusions will be drawn after a longer monitoring period.

Field data has also been used to perform an interesting hindcasting of the beach profile and shoreline development with advanced mathematical models. The models could also be further calibrated to achieve more reliable predictions for the future evolution of the perched beach.

### Acknowledgements

The Authors wish to thank Mr Patrizio Cuccioletta, chief design engineer of the project, and Mr Osvaldo Mazzola, project manager of the consortium of contractors Contracos, for their major efforts in the project finalization and for the supply of useful data. Support and suggestions from prof.A.Noli (University of Rome) are also gratefully acknowledged.

## CHAPTER 253

### The Restoration of Bate Bay, Australia - Plugging the Sink

Angus D Gordon<sup>1</sup>

#### Abstract

For more than 200 years aeolian processes have removed sand from the Bate Bay coastal compartment. This ongoing loss resulted in long term recession of the 5.5km beach. By the mid 1970's the recession threatened both public and private assets. A detailed coastal process study was undertaken to develop a management plan aimed at halting the recessional trend. The plan was progressively implemented over a period of 14 years. The result is that the foreshores of Bate Bay are now stable. The management strategy adopted has not only protected the public and private assets but has also enhanced the recreational amenity of the area. Throughout the project monitoring was undertaken of both the coastal process and the management options. These monitoring programs have provided useful information on the pragmatic application of traditional study techniques and on the effectiveness of the selected management options.

#### Introduction

Kurnell Peninsula is located some 25km south of Sydney Heads. The Peninsula is a coast parallel sandy isthmus linking the rock outcrop of Kurnell Headland to the mainland bedrock at Cronulla. It is the sandy barrier which forms the eastern boundary of Botany Bay. On its seaward side, to the east, lies the 5.5km, crescent shaped embayment of Bate Bay. The embayment includes the following beaches (from south to north) South Cronulla, North Cronulla, Elouera, Wanda, Green Hills/Cronulla and Boat Harbour (see Figure 1).

Residential development and formal parkland are the dominant foreshore features along the southern 2km of the Bay. North of Wanda, for a distance of some 1.7km unstable, unvegetated dunes dominated the landscape for at least 200

---

<sup>1</sup>Manager, Manly Hydraulics Laboratory, Public Works Department, 110b King Street, Manly Vale, NSW 2093, Australia

years up until 1975. These dunes bisected the Peninsula, extending inland more than 1.5km, through to Botany Bay. The remaining 1.8km of foreshore consists of foredunes which were initially stabilised in the 1950's by the landholder; the Holt family.

During the period of European settlement, Kurnell Peninsula has undergone many changes of land use. Initially, the areas of natural coastal scrub land were used for grazing purposes. However by early this century South Cronulla had become a weekend recreational retreat. As its popularity grew residential and commercial development took place. Early development was concentrated in the more stable southern region of the Bay but by the 1930's the demand for land pushed the development northward into the unstable dune region at Wanda.

In the early 1950's, Sydney's need for construction and foundry sand focussed attention on commercially viable deposits such as the 30m high transgressive dune field of the Peninsula. In response to this, a major sand extraction industry developed. Over the past 40 years the activities of this industry have resulted in the removal of much of the hind dune region in the centre of the Peninsula.

Severe storms ravaged the Sydney coastline in May-June 1974. These storms resulted in significant erosion of the Bate Bay beaches. The foredune system throughout most of the embayment was destroyed. In response to this damage, coastal process studies were undertaken and a coastal management plan was developed and implemented over a period of 14 years.

The major elements of the plan were:

- nourishment of the embayment by feeding sand into the surf zone at South Cronulla;
- dune reconstruction at North Cronulla;
- seawall construction at Prince Street;
- foredune stabilisation at Elouera and Wanda;
- foredune reconstruction and stabilisation from Wanda to Boat Harbour;
- hinddune stabilisation in the centre of the embayment.

This paper summarises the project from the inception of the coastal process studies to the completion of the management plan and reviews the results.

### **Coastal Process Studies**

Coastal process studies were commenced in 1975 using the methodology outlined by Gordon and Lord (1980). These initial studies provided the basis for the overall management strategy (Foster and Gordon, 1978, and Gordon, unpublished). The coastal processes were then monitored and analysed throughout the 14 years of the project. This enabled on-going "fine tuning" of the management

plan and provided considerable insight as to the effectiveness of the various investigation techniques and the management options employed.

The studies began with extensive bathymetric, seismic and sediment surveys to obtain information on the seabed and subsurface morphology, seabed sediment and reef distribution and the depth of the active profile movement. These studies included side scan sonar, echo sounding and seismic surveys as well as an extensive sediment sampling program. Onshore, a geological survey was carried out to establish the age and mode of formation of the dune features of the Peninsula (Roy and Crawford, 1979).

Longterm shoreline movement trends were examined using both historical ground survey data and photogrammetric analysis of large format vertical aerial photography. The ground survey data was available at a limited number of locations for a period of more than 100 years. The earliest survey (1863) was made available to the study by the Holt family. The photogrammetry focussed on reconstruction of cross sections through the beach and dune region, over time, rather than historical water line movement, as the latter was found to be too unreliable. Thirty five cross sections were established (see Figure 1). These were transferred through the nine sets of photography covering the 35 years prior to implementation of the management plan.

The erosion/accretion rates obtained from this analysis were calculated from both differential volume calculations undertaken for successive cross sections and foredune retreat/advancement measurements taken from comparison of the movement of position of the 3m and 5m contours over time. The average result, reduced as an implied shoreline movement, was then plotted (see Figure 1). Aerial photographs continued to be obtained throughout the implementation phase and the photogrammetry results checked against nine ground survey cross sections established in the embayment to monitor dune and beach movements and to verify the photogrammetric techniques.

Aeolian sand transport was examined by analysing historical survey and photogrammetric data and by developing numerical models of wind born sand transport. The historical information established the rate of landward movement of the transgressive "front" at the rear of the hinddunes, thereby providing the data necessary to calibrate the aeolian sand transport models. Because of the inherent inaccuracies of these models, particularly when applied to a non uniform surface such as a dune field and the need to take into account wetting and drying effects on transport rates, two alternative models were developed. One employed the Bagnold (1974) approach, the other was based on the method of Hsu (1974).

Examination of the longshore surf zone sediment transport processes commenced with a wave refraction/diffraction shoaling analysis for three points in the embayment (see Figure 1, Location A, B and C). The inshore wave height coefficients so obtained were then used in a sediment transport program to calculate

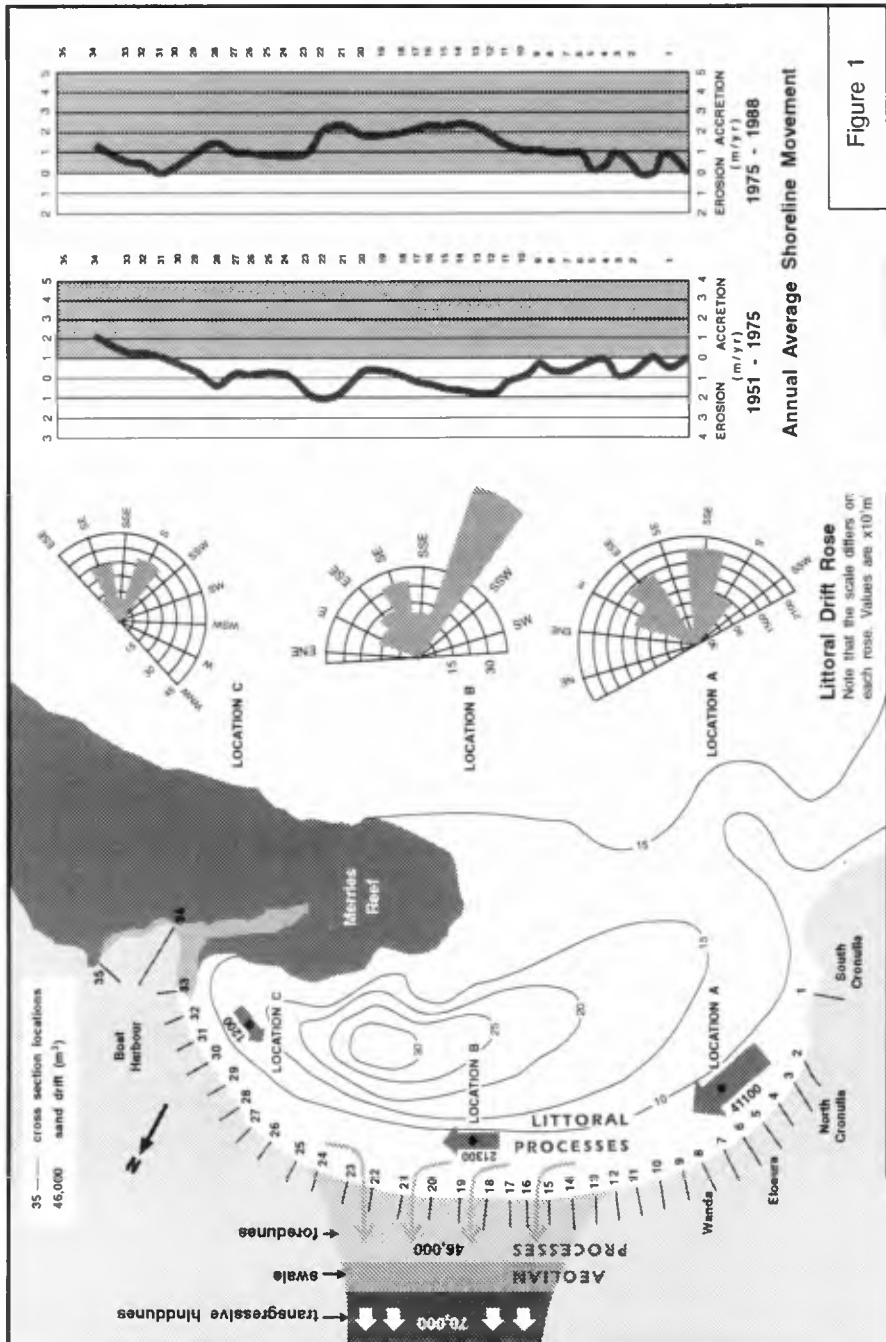

Figure 1

transport roses at each of these points.

The wave refraction analysis was based on a computer program developed from Wilson's method (Wilson, 1966). The results were manually adjusted as outlined in SPM (1973/84) to include diffraction effects. A 46 by 34 numerical grid using a 200 metre grid spacing was adopted and a 10 second deepwater wave period was used for most program runs. The characteristic wave period of 10 seconds was selected after examination of the then available 5 years of data from a Waverider buoy located 3km northeast of Bate Bay in 80m of water. Selected runs were made with 8 and 12 second waves to check sensitivity.

Five offshore wave approach directions were selected to generate a matrix of inshore wave height coefficients. The coherence of the results was checked by plotting the coefficients of refraction/diffraction/shoaling and the wave angle to the contours, along the wave ray, for each deepwater wave approach direction. Discontinuities and/or anomalies were thereby readily identified, examined and numerically smoothed, if appropriate. The inshore wave coefficients given by the refraction/diffraction/shoaling analysis were verified by comparing them to Waverider data from an inshore buoy deployed for two years at Location A, within the bay.

The sediment transport calculations were based on the "SANDGUS" program (published in Gordon and Acikgoz 1984) developed around the CERC equation (SPM 1973/84). This program, which was first developed for this project, uses the annual deepwater wave spectra, shoals, refracts and diffracts that spectra along the rays through the wave coefficient matrices obtained from the refraction/diffraction analysis and then calculates sand transport. The wave coefficient matrices only extended to 10m water depth. Inshore of this depth the model applies the straight parallel contour assumption using Snells Law to calculate refraction. The deepwater wave spectra used was that available from the offshore Waverider site. As the project progressed the data set available from this site increased from 5 years to 20 years and hence some review of earlier calculations was necessary.

For the purposes of this study it was assumed that all longshore transport took place at the break point. This point was calculated for each one metre wave height class. Although an oversimplification, the approach proved quite adequate as no shore normal structures existed or were being considered as management options.

The results of the sediment transport analysis were compared with sand tracer studies. Some 10 tonnes of dyed sand were released into the surf zone at South Cronulla. This material was tracked intensively over a period of 1 month and, to a lesser extent, over a period of 3 months. Initially samples were taken on a 50 metre grid extending 0.5km longshore from the injection point and offshore to 10 metres of water depth. The samples were obtained by divers driving one metre core tubes into the seabed. During the first week the entire grid was covered twice a day. The samples were then sectioned and examined under a microscope. As the grid was

progressively extended the number of grid points rationalised and the sampling rate reduced once the movement pattern of the dyed sand became apparent.

The results of the sand tracer experiment were compared with a data set generated by the "SANDGUS" computer model for the prevailing conditions during the experiment. It was found that for Bate Bay the CERC equation, as presented in SPM 1984, produced results of the same order of magnitude as those obtained from the experiment. This calibration of the CERC constant was seen as critical, as experience elsewhere in NSW had indicated that the constant can vary considerably depending on site conditions.

### **The Sediment Budget of Bate Bay**

Integration of the various studies provided an understanding of the overall coastal process system of the embayment.

The sediment and geological studies showed that Bate Bay is substantially a closed compartment with no significant losses or gains across its longshore boundaries.

Prior to implementation of the management plan, the potential sediment transport rates in the surf zone were calculated to be 41,000m<sup>3</sup>/yr net northward in the southern third of the embayment (Location A), where the gross transport was 700,000m<sup>3</sup>/yr; 21,000m<sup>3</sup>/yr net north transport in the centre of the embayment (Location B) on a gross movement of 165,000m<sup>3</sup>; and 1,200m<sup>3</sup>/yr net southern transport (Location C) on a gross of 86,000m<sup>3</sup> in the northern third of the embayment behind Merries Reef (see Figure 1).

The high values for both gross net drift in the southern end of the embayment were associated with the exposure of this area to a broader range of deepwater wave approach angles and the misalignment of this section of the bay prior to the management plans implementation. The low gross drift in the centre of the embayment was consistent with the relatively high onshore/offshore movements which take place in this area. That is onshore/offshore in the centre of the embayment dominates over the longshore processes. In the northern section of the embayment the low gross and net drift reflect the sheltering of Merries Reef. The net transport rate of 21,000m<sup>3</sup>/yr, northwards, calculated at Location "B" in the centre of the embayment (Figure 1), was consistent with observations that some of the material moving north from the southern end (Location A) had already been lost into the dunes.

The aeolian transport studies were undertaken for both the foredunes and the hinddunes. For the foredunes, the Bagnold approach yielded a net landward potential rate of transport of 24m<sup>3</sup>/m/yr while the Hsu method gave a result of 32m<sup>3</sup>/m/yr (see Figure 2). Based on these results an average rate of 28m<sup>3</sup>/m was adopted as the potential for sand transport in the foredune. This translated into a

net average landward potential for transport of sand in the foredune region of some  $46,000\text{m}^3/\text{m}$ , provided material was available for entrainment.

Applying the same theoretical approach to the hinddunes the calculated annual net landward potential for transport of sand was found to be  $60,000\text{m}^3$ . The analysis of historical survey and photogrammetric data indicated that the average annual movement of the transgressive dune front into the vegetation on the western side of the peninsula was between  $8\text{m}/\text{yr}$  and  $10\text{m}/\text{yr}$  giving a total annual net transport rate westward of  $90,000\text{m}^3$ . Given the assumptions and accuracies of the methods used a figure of  $70,000\text{m}^3/\text{yr}$  was adopted as representing the net westward drift rate in the hinddune.

The difference in availability of sand for entrainment explains the apparent anomaly between the foredune and hinddune transport rates. The beach was an average of  $20\text{m}$  wide whereas the area available to feed the hinddunes was some  $100\text{-}200\text{m}$  wide. This differential in transport was evidenced by the evolving topography of the dunefield. The rate of landward movement of the centroid of mass of the hinddunes had historically been greater than that of the foredunes. This had created an ever widening interdunal swale, the area between the foredunes and hinddunes. The swale was some  $100$  to  $150\text{m}$  wide by 1975.

The photogrammetric analysis supplemented by the historical survey record showed that, prior to implementation of the management plan, longterm coastal retreat was occurring throughout most of the embayment. Figure 1 summarises the recessional trend. Recession rates varied from an average of  $0.5\text{m}/\text{y}$  in the southern end to  $2.0\text{m}/\text{y}$  in the centre of the embayment. The accretion trend shown in Figure 1, from section 30 to 34 in the north of the embayment, was produced by the dune works undertaken in the mid 1950's by the landholder of this portion of the embayment. The high recession rates in the centre of the embayment were associated with the area of unstable foredunes where aeolian processes continuously removed sand from the beach into the transgressive dunefield. The differential recession rates were reflected in the shoreline alignment. The central  $2\text{km}$  of beach became noticeably indented as compared to the overall alignment of the embayment foreshore.

Integration of the recession rates throughout the embayment, for an active profile depth which varied from  $8\text{m}$  at South Cronulla to  $10\text{m}$  in the centre of the embayment and reduced to  $6\text{m}$  in the northern portion behind Marries Reef, indicated that the net loss of was  $51,000\text{m}^3/\text{yr}$ .

Within the accepted accuracies of the methods used to define the coastal processes, this foreshore recession rate of  $51,000\text{m}^3/\text{yr}$  agreed well with the aeolian transport induced loss into the transgressive dune sink of  $46,000\text{m}^3/\text{yr}$  and the net littoral drift feed mechanism of  $42,000\text{m}^3/\text{yr}$ .

In summary, Bate Bay was found to be a closed coastal compartment. The destabilisation of the dunes in the centre of the embayment over 200 years ago allowed an aeolian sink mechanism to develop. The resulting loss of sand from the surf zone, beach and foredunes in the region adjacent to the sink caused the shoreline to retreat. This in turn produced a misalignment of the beach system which propagated to both ends of the bay. The misalignment in turn induced an evolving littoral drift system which increasingly fed sand from both ends of the bay towards the middle. Immediately prior to implementation of the management plan the average annual net quantity involved in this loss was approximately 45,000m<sup>3</sup>.

### **Management Plan - Overview**

The main aim of the management plan was to "plug the sink". Restoration of the beach amenity at the southern end of the embayment and protection of assets threatened in this region were also given high priority. In general, the emphasis was placed on a "soft" management strategy aimed at establishing a well vegetated foredune throughout as much of the embayment as possible. Further, rather than mechanically forcing a new shoreline alignment on the embayment, the technique used involved: the establishment of some initial dunes on the existing alignment; feeding of the surf zone with nourishment sand; allow the natural process to distribute the material throughout the embayment and also allow these processes to adjust the foreshore/dune alignment and the offshore seabed. The final phase of stabilisation included the hinddunes in the centre of the embayment. This work was aimed at retaining sand reserves which may be required in the future for on-going beach nourishment and overcoming the wind blown sand problems associated with these dunes.

The new foredune region was sized to provide a sufficiently large area of stabilised dune to stop the landward loss of beach material by aeolian processes and to provide adequate material to accommodate short term erosion associated with storm events. In the areas where there was insufficient width to establish the necessary foredune because of space constraints, such as at South Cronulla and Prince Street, alternative methods had to be considered. These included the nourishment of South Cronulla Beach and the construction of a seawall at Prince Street where residential buildings were under direct threat from erosion.

The Prince Street seawall option was only selected after an exhaustive series of studies, spanning some 10 years. These studies failed to identify an alternative, acceptable to the community, which would also be more in keeping with the "soft" engineering management philosophy adopted for the remainder of the embayment.

### **Management Plan - Implementation**

The Bate Bay foreshore restoration program commenced in 1975 with the fencing of foredune "paddock" areas along Wanda and Elouera. This was followed by the infilling of blowouts and washthroughs in the foredunes in the centre of the

embayment. Sand catching fences were then erected and well defined beach access tracks constructed.

As the coastal process studies showed that the major sand feed to the aeolian sink in the centre of the embayment was from the south, the decision was taken that, following the initial stabilisation of the foredunes throughout the embayment, sand would be fed into the surf zone process from the south and allowed to distribute by natural means to establish new beach alignments. The nourishment of the embayment was therefore carried out at South Cronulla Beach. The project began during 1977-78. Some 80,000m<sup>3</sup> of sand were trucked from the hinddune region of the centre of the embayment, to South Cronulla. There the sand was spread by bulldozer. Work was halted during the 1977/78 swimming seasons and recommenced in mid 1978 when a further 47,000m<sup>3</sup> were placed. The underwater profile of the surf zone was also allowed to reform by natural processes. A public education program was undertaken in conjunction with the nourishment to overcome community misapprehensions associated with the apparently high initial loss of nourished beach at South Cronulla as sand re-distributed along the beaches to the north and as profile development took place.

While the South Cronulla nourishment project was underway effort was also concentrated in establishing the primary dune stabilising plants in the Elouera-Wanda foredunes and along the Cronulla/Greenhills foreshore. Thus, as the nourishment sand moved north, the dune fields were ready to trap material. Strengthening and fencing of the vegetated dunes in the northern part of the embayment was also undertaken to produce a similar standard of management throughout the embayment. The overall result was a re-alignment of the embayment foreshore and the natural evolution of a viable foredune system.

Revegetation of the hinddunes in the centre of the embayment (Wanda Reserve) commenced in 1983. The revegetation was completed by 1989.

In 1985 work started on the final link in the plan. A 340m long seawall featuring pre-cast concrete armour units (Seabees) was constructed during 1985/86 along the toe of the Prince Street embankment (Hirst and Foster, 1987). This link joined the dune stabilisation work at North Cronulla to that at Elouera and provided protection to the threatened residential buildings in Prince Street. The ends of the wall were returned into the dunes to allow for the expected storm erosion at these points. Rock filled wire mattresses were placed under the beach in front of the structure to prevent toe erosion. A walkway was incorporated into the seawall crest design thus providing a continuous public foreshore pathway from South Cronulla headland to Elouera.

## Results/Discussion

The Bate Bay foreshore is now fully stabilised, some 5km of vegetated foredunes have been successfully established. In the hinddune dune region the

**Figure 2 Accretion of Sand in the Foredues**

**Figure 3 Buildup of Foredune Crest Level**

transgressive dunes stretching some 1.7km along the foreshores have also been stabilised. The sink has therefore been "plugged", the pre-existing longterm shoreline erosion halted and overall foreshore re-alignment achieved. Recreational beaches now extend from South Cronulla to Boat Harbour. The net shoreline and foredune movement over the 17 years following implementation of the management plan has shown an accretional trend, despite the occurrence of several major storms (Figure 1). The accretion has been greater in the centre of the embayment, as was predicted by the coastal process studies.

The point source feed of nourishment at South Cronulla proved to be the most economic method of achieving a "natural" restructuring of the embayment's beach/dune system.

Dune re-building was monitored throughout the project. Figure 2 shows the cumulative accretion rate and Figure 3 summarises the foredune crest level development at 6 of the survey transects located in the centre of the embayment. These figures show that, following the initial mechanical re-construction, accretion was relatively slow over the first 2 years. This outcome was unexpected at the time as shown by the Bagnold and Hsu based prediction of Figure 2. The delay was due to the difficulties experienced in establishing the pioneer plants in such a harsh environment and on such a large scale. An increase in the rate of accretion began in the 3rd year with maximum rates of accretion achieved in the 4th year when the full potential of the aeolian process were focussed towards dune building. By the

5th year accretion started to taper. Although not shown, by the 12th year it was not possible to discern further buildup. In summary, at Bate Bay the time period required to establish a viable foredune system with a diversity of plant life capable of self sustenance, was found to be some 10 years. Intensive management was necessary for the first 5 years although a lower level of support was required for a further 5 years. This timescale was in part a function of the scale of the project.

The net accretion in the dunes and on the beach of some 180,000m<sup>3</sup> was greater than the 127,000m<sup>3</sup> of the nourishment supplied. It is believed that the additional material was supplied through a subtle steepening of the offshore profile, although survey accuracy makes this difficult to quantify. There remains the possibility however that some material which has moved onshore from deeper water during the beach building conditions and is now trapped in the dunes, will be released during a future extreme storm event.

A key element to the success of the Bate Bay project was the detailed coastal processes studies carried out at inception and the ongoing monitoring of those processes, and the systems response, during implementation of the management plan. Central to this approach was the care taken to calibrate and verify the surf zone and aeolian sand transport models.

The total costs of the initial studies and the ongoing monitoring (adjusted to 1991 values) was A\$700,000. While this is a substantial sum it was only 8% of the overall project costs of A\$8.5M and less than 0.2% of the A\$350M value of the assets protected. Further, the stabilisation of the 5.5km of foreshore has allowed expansion of the public recreation areas and for development to take place in the backdune region. Future development of the embayment is centred on retention and maintenance of the newly established foredunes as a buffer zone.

## **6. Acknowledgments**

The Bate Bay project was funded by the Public Works Department, NSW, through the Beach Improvement Programme, by Sutherland Shire Council and by the Soil Conservation Service of NSW. In addition to the assistance provided by these authorities the writer also wishes to acknowledge the assistance and encouragement over the past 17 years of Prof. Doug Foster, Mr Philip Holt and the late Mr Eric Hirst.

## CHAPTER 254

# Present Situation of Sea-Sand Mining in Kyushu Island, Japan and Its Influence on Coastal Environment

M. Hashida<sup>1</sup>, N. Matsunaga<sup>2</sup> and T. Komatsu<sup>3</sup>

### Abstract

The sea-sand mining has been carried out in the coast of western part of Japan since the early 1970's. Mined sea-sand is mainly used as fine aggregate of concrete structures. Mining a large amount of sea-sand near the coast induces the possibility of beach erosion and devastation of fishing grounds. In order to evaluate its influence on coastal environment, the present situation of sea-sand mining has been investigated in seven prefectures of Kyushu Island in Japan. The sea-sand mining in Kyushu Island is classified into two types. One is the mining in the sea areas where sea-sand reserves are limited. In these areas, the compatibility between the sea-sand mining and the protection of coastal environment will become very important in future. The other is the type that sea-sand has been supplied constantly from rivers or other sea areas. In this case, it will be the most important to keep the balance between the amount of mined sea-sand and that of supplied one.

### Introduction

The dependence of fine aggregate of concrete structures on sea sand increases in the western part of Japan. On the other hand, many dams and gates have been constructed across rivers with the object of flood control, water utilization, etc. Both the sea-sand mining and the decrease of sand supply from the rivers may accelerate beach erosion and devastate the coastal

(a)

(b)

(a) Sea-sand being gathered in cargo space.

(b) Drainage of sea water including mud.

environment. Actually, remarkable beach erosion was observed along the coast of the northern part of Kyushu Island, after the sea-sand mining was approved by prefectural governments. The change of longshore current due to man-made coastal structures, the decrease of sand supply from rivers, the frequent occurrence of storms, the sea-sand mining, etc. have been examined as causes of this erosion. However, what are the most essential causes still has not revealed.

Photos 1(a) and (b) show sea-sand being gathered in the cargo space of a barge ship and the state of drainage of sea water including mud, respectively. The environmental problem that the diffusion and sediment of the mud devastate fishing grounds occurs sometimes.

The purposes of this study are to investigate the present situation of sea-sand mining in seven prefectures of Kyushu Island and to examine its influence on the coastal environment.

### Sea-sand mining in Kyushu Island

Figure 1 shows the control system of sea-sand mining in Japan. The sea-sand mining has been performed under the approval of each prefectural government. The Ministry of International Trade and Industry leads for the control system of each prefectural government. The prefectural government gives the approval for the volume of mined sand to sea-sand mining companies. The companies must report the total volume of sea-sand which they mined actually, to the prefectural government every year. The prefectural government must report the total volume of the mined sea-sand to the Ministry of International Trade and Industry. It also negotiates with Fishermen's Union about compensation for devastation of fishing grounds. The standards of the approval or the compensation for the Fishermen's Unions are different in each prefecture. At the present time, there are even prefectures which do not establish any standards.

Figure 1. Control system of sea-sand mining in Japan.

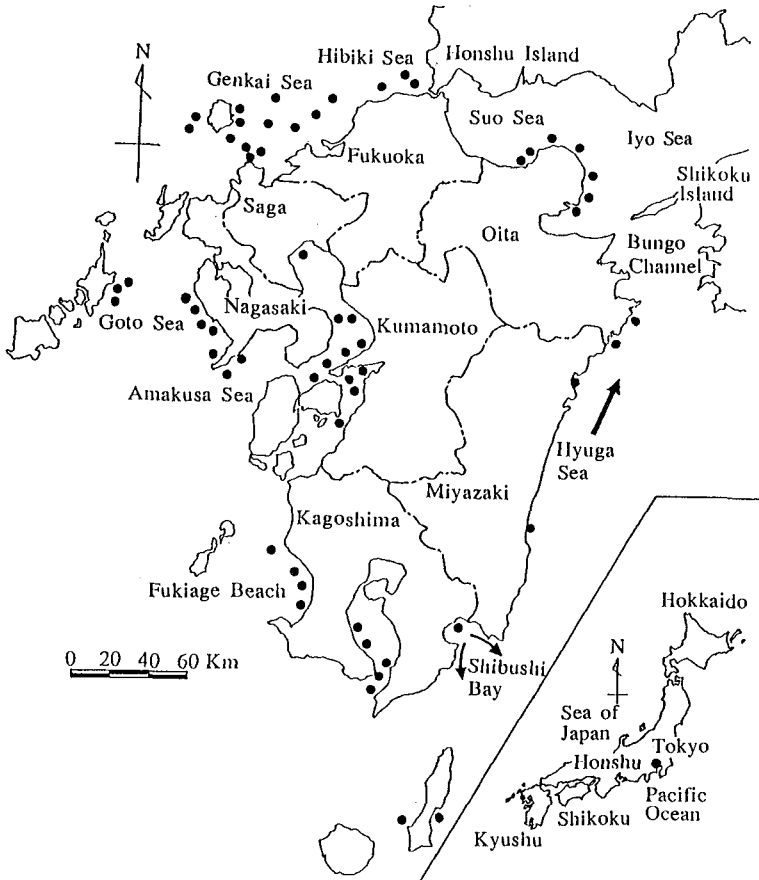

Figure 2. Sites of sea-sand mining in seven prefectures of Kyushu Island.

Figure 3. Volume of sand mined in seven prefectures in 1988.

In figure 2, the sites of sea-sand mining in Kyushu Island are shown. Kyushu Island consists of seven prefectures, i. e., Fukuoka, Nagasaki, Saga, Kumamoto, Oita, Miyazaki and Kagoshima Prefectures. The dash-dot lines indicate the border between the seven prefectures. The black circles show the superior direction of sediment transport. It is seen that many sites exist along the coast of Kyushu Island.

Figure 3 shows the volume of sand mined in the seven prefectures in 1988. The mining of both river sand and land sand has been restricted from the standpoint of the prevention of disaster. Therefore, sea-sand above 70 percent of total sand has been mined in Kyushu Island. Sea-sand mined in Fukuoka, Nagasaki and Kagoshima Prefectures is very large in comparison with that in the other four prefectures. The rate of the volume of sea-sand to that of the total sand shows a yearly increase.

### 1. Fukuoka Prefecture

Figure 4 shows the frequency of storm wind, whose mean velocity is larger than 10 m/s, in Fukuoka Prefecture. During 15 years from 1947 to 1961, a remarkable beach erosion was observed along the coast of the Genkai Sea and the Hibiki Sea. The recession of the shoreline averaged 45 m, and 85 m recession was recorded as a maximum value during the 15 years. The Fukuoka Prefectural Government concluded that extraordinary frequent storms induced this erosion (Kojima, H. et al., 1986). Sea-sand mining started in 1972. Though the

Figure 4. Frequency of storm winds in Fukuoka Prefecture.

frequency of storm decreased after the onset of the sea-sand mining, the progression of beach erosion continued to be seen along some areas of the coast. In Fukuoka Prefecture, a large amount of sea-sand was mined at sea areas shallower than 20 m from 1972 to 1981. When the prefectural government began to investigate the change of shoreline, i. e., in 1981, it also established a restriction on the sea-sand mining. The restriction was that the sea-sand mining has to be performed in principle at sea areas deeper than 40 m after 1981. Generally speaking, a remarkable beach recession has not been observed since 1981's restriction. Therefore, which was the essential cause for this erosion has not still been made clear.

Figure 5 shows the sites of sea-sand mining in the Genkai Sea and the Hibiki Sea of Fukuoka Prefecture. The black triangles indicate the sites shallower than 20 m, and the black circles indicate ones at the water depth over 40 m. Fukuoka Prefectural Government has carried out the level survey along the coast of the Genkai Sea since 1981. The stations are shown by numbered black-rectangles.

Figure 6 shows the correlations between the volume of mined sea-sand and beach elevation at stations 4 and 6 in the Genkai Sea. The open and solid marks indicate the results of level survey and the volume of mined sea-sand, respectively. At the stations, the sea-sand mining was performed at sea areas shallower than 20 m until 1986, but it has been mined only at sea areas deeper than 40 m since 1987. The mining was repeated about twenty times from 1985 to 1986 at Ainoshima and Tsuyazaki. The total volume reached about  $6.0 \times 10^5 \text{ m}^3$ . As shown in this figure, a remarkable erosion was observed at that time. After the sea-sand mining at Ainoshima and Tsuyazaki was stopped in 1987, the beach at station 4 began to recover and reach nearly an equilibrium state. At station 6, the influence of sea-sand mining on the beach elevation did not appear obviously because a small amount of sea-sand was mined at Nogita. The sea-sand mining at Oshima and Nishinoura was continued to 1986. Its influence on beach erosion was not recognized. It may mean that the restriction established by the Fukuoka Prefectural Government was valid. The field investigation on the volume of sea-sand reserved in the Genkai Sea was made by the Ministry of International Trade and Industry. According to its report, sea-sand suitable for the fine aggregate distributes over an area of about  $1.75 \times 10^2 \text{ km}^2$ .

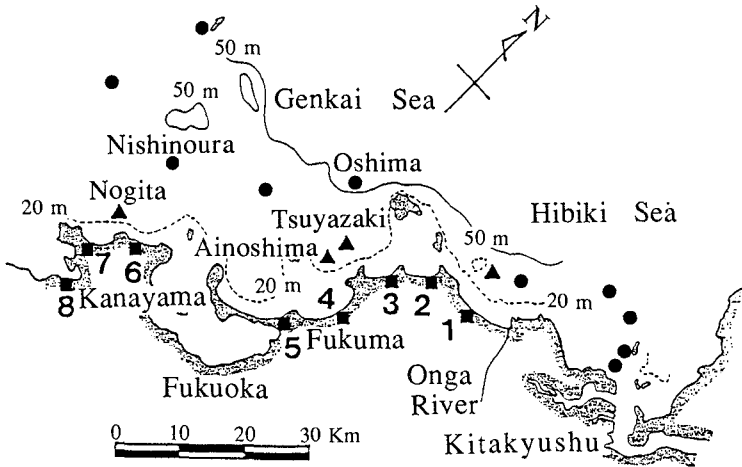

Figure 5. Sites of sea-sand mining ( ● and ▲ ) in the Genkai Sea and the Hibiki Sea, and survey stations ( ■ ).

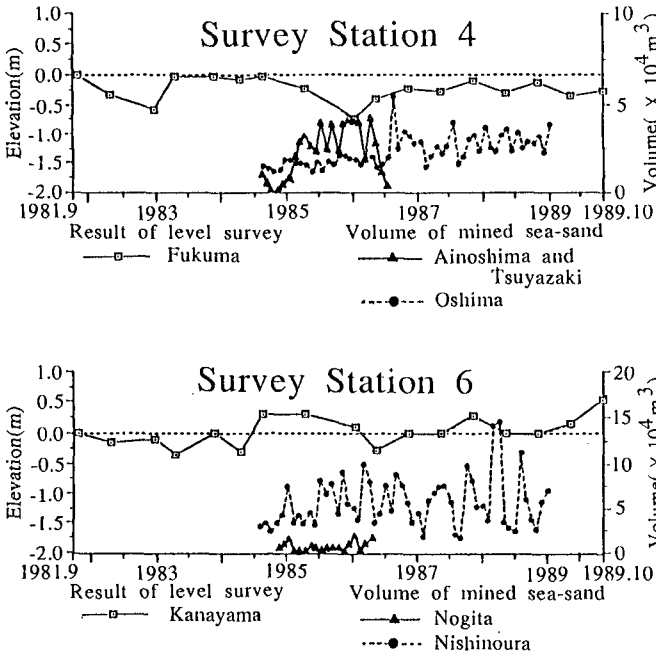

Figure 6. Correlations between volume of mined sea-sand and beach elevation in the Genkai Sea.

## 2. Nagasaki Prefecture

The sites of sea-sand mining in Nagasaki Prefecture are shown in figure 7. The black circles indicate the sites of sea-sand mining. The investigation about the reserves of sea-sand was made in the dotted area by the Ministry of International Trade and Industry. This prefecture is mining the largest amount of sea-sand in Kyushu Island. However, there are few wide, long rivers. Therefore, it seems that the sand supply from river to coast is very little. The Nagasaki Prefectural Government has approved the sea-sand mining in the sea areas where the water depth ranges from 30 m to 70 m. This means that Nagasaki Prefecture is also obliged to seek offshoreward sites. The sea areas have been a good fishing ground for a long time. Surface layer of the region contains a lot of lime composed of shells and dead planktons. Therefore, suitable sea-sand for fine aggregate is very little.

According to this investigation, however, it can be expected that sea-sand of good quality distributes in deeper layer. Its distribution is over about 19.4 km<sup>2</sup>. Recently, a new environmental problem, i. e., the devastation of fishing grounds, is also occurring in this region. The Nagasaki Prefectural Government is looking for countermeasures to realize both sea-sand mining and preservation of nearshore environments.

Figure 7. Sites of sea-sand mining in Nagasaki Prefecture.

### 3. Kumamoto Prefecture

Figure 8 shows the sites of sea-sand mining in Kumamoto Prefecture.

The volume of sand mined in this prefecture was  $1.50 \times 10^6 \text{ m}^3$  in 1989.

The volume tends to increase during the last five years. Sea-sand occupies from 30 % to 40 % of the total volume of mined sand.

The sea-sand mining has been carried out at the Ariake Sea, of which the sites are indicated by the black-circles numbered from 1 to 7.

The sites at the Yatsushiro Sea are shown by the black circles numbered from 8 to 11.

Sandy beach remains only along the numbered coast. The other coasts are either tidal flat or gravel coast.

The source of sand supply to the sea area is only inflow from the rivers.

In the case when sea-sand is mined in these seas, therefore, it is necessary to consider the balance between the volume of sea-sand mining and the volume of sand supply from the rivers.

Figure 8. Sites of sea-sand mining in the Ariake Sea and the Yatsushiro Sea.

### 4. Oita Prefecture

Figure 9 shows the sites of sea-sand mining in Oita Prefecture. According to the statistical report on coast, which is presented by the River Office of the Ministry of Construction, the yearly mean expense of public utility enterprise for beach erosion was 40 million yen over the four years from 1984 to 1987. This is very high next to Nagasaki and Miyazaki Prefectures. The ratio of sea-sand to the total sand is from 60 % to 65 %. The sea-sand mining has been carried out mainly at both the northern part and the southern part. Oita Prefecture mined sea-sand of  $6.55 \times 10^6 \text{ m}^3$  during six years from 1984 to 1989. This volume is nearly equivalent to the volume mined over 14 years from 1970 to 1983. It shows the rapid increase of sea-sand demand. During last six years, a large amount of sea-sand has been mined at Jiromaru Coast (number 5), Morie Port (number 7) and Nishinoura Coast (number 8). At Jiromaru Coast, the sea-sand mining has been carried out because of the accumulation of sea-sand. The sand supply from Jiromaru River is very little and erosive coasts have been observed along the northern part of Jiromaru Coast. Therefore, it is necessary to make clear the source of the sand supply to Jiromaru Coast. Morie Port has a tendency to be buried due to sediment from Yasaka and Takayama Rivers. The volume of

Figure 9. Sites of sea-sand mining in Oita Prefecture.

sea-sand mined in Morie Port is nearly balanced to that of the sediment yield from the rivers. Therefore, the environmental devastation due to the sea-sand mining does not appear in Morie Port. In spite of no rivers along Nishinoura Coast, a large amount of sea-sand has been mined with the object of keeping ship courses and arranging fishing grounds. However, no influence on coastal environment due to the sea-sand mining has been observed for the last 20 years. Therefore, understanding how the sediment transport occurs along Nishinoura Coast is the most important.

### 5. Saga, Miyazaki and Kagoshima Prefectures

Saga Prefecture is mining the smallest amount of sand in Kyushu Island. The total volume of sand is less than about  $8.0 \times 10^5 \text{ m}^3/\text{year}$ , of which most depends on sea-sand. The sea-sand mining has been carried out at four sites. One of them is in the Ariake Sea. The other sites locate in the Genkai Sea. The total volume of mined sea-sand per year is very little. The sea-sand mining in the Genkai Sea has been made at sea areas deeper than 20 m. From these reasons, the influence on coastal environment has not been come to the front.

Miyazaki Prefecture faces the Hyuga Sea. The coast is an erosive large-scale beach. Therefore, the sand mining in sea and river has been prohibited in principle. However, sand and gravel deposited in dams has been dredged to keep up their function. Small volume of sea-sand has been dredged with the object of keeping ship course in Miyazaki Port and Nobeoka Port. It has been used as fine aggregate. The year-mean volume of river sand is about  $4.0 \times 10^5 \text{ m}^3$ , that of sea-sand  $2.5 \times 10^5 \text{ m}^3$ , and that of land sand  $8.5 \times 10^5 \text{ m}^3$ . The total volume is  $1.5 \times 10^6 \text{ m}^3$  per year.

Though Kagoshima Prefecture does not open detailed data about the volume and sites of the sea-sand mining. The year-mean volume of mined sea-sand was about  $2.34 \times 10^6 \text{ m}^3$  during three years from 1987 to 1989. This volume is the third next to Nagasaki and Fukuoka Prefectures.

### Conclusions

In this study, the present situation was investigated about the sea-sand mining in all seven prefectures of Kyushu Island, Japan. Though there are a few prefectures in which the

detailed data on sea-sand mining could not be obtained, we reached the following conclusions.

- (1) Sea-sand reserves of the Genkai, Hibiki and Goto Seas are limited. Therefore, how the sea-sand mining compatible with the protection of coastal environments should be carried out in these seas will become very important in future.
- (2) Sea-sand of the Ariake, Yatsushiro and southern part of Oita Prefecture has been supplied constantly from rivers or seas. In these seas, it is necessary to take into account the balance between the volume of mined sea-sand and the volume of supplied sand .

The authors wish to thank Mr T. Munakata for stimulating discussions and his technical help.

## CHAPTER 255

### PATRAS BREAKWATER FAILURE DUE TO SEISMIC LOADING

By  
Constantine D. Memos<sup>1</sup> and John N. Protonotarios<sup>1</sup>,  
Members, ASCE

#### Abstract

Investigation of the failure mechanism of the Patras breakwater extension revealed that the seismic loading of the mound was amplified considerably due to the soft foundation soil. This loading induced the overriding of the low safety factors of the structure. Approximate analytical expressions were obtained for the hydrodynamic loading during earthquakes. These were in good agreement with previous results. Recommendations for the completion of the works were given to the harbor authority.

#### INTRODUCTION

Patras is a busy port of western Greece serving as a RoRo gateway to Italy. Its location can be seen in figure 1.

Figure 1. Site location map

<sup>1</sup> Civil Engineering Department, National Technical University of Athens, Greece.

The layout of the harbor is shown in figure 2; it includes a long detached breakwater of rubble mound with concrete capping. During the construction of a southern extension, 120m long, of similar design but without the capping, severe and abrupt settlements of the mound took place leading to a discontinuation of the works.

Figure 2. Harbor layout and location of works

A typical cross-section of the new breakwater is contained in figure 3. The primary armor consisted of rock units 4-6t placed at a slope of 1:3 which from -2.0 m downwards steepened to 3:4. The width of the mound at its base, i.e. at -18.0m, reached almost 90 m. It should be noted that the structure was founded on weak soil without any improvement.

Figure 4 shows a characteristic cross-section of the structure as measured before and after the failure. Appreciable settlements of the order of a few metres can be noted.

Figure 3. Typical cross-section of the breakwater extension.

Figure 4. Typical cross-section with outlines before and after the failure

A key element of the present problem was that the failure coincided with moderate seismic activity in the area. Indeed, several earthquakes occurred prior to the major settlement of the structure.

The present research aimed at investigating the dynamic response of the breakwater under construction in order to understand the mechanism that led to its failure. Also, proposals for the completion of the works were to be given to the harbor authority.

The failure mechanism was approached by two complementary points of view, namely hydrodynamic and geotechnical. During the examination of this specific case of failure some more general issues were addressed regarding rubble mounds sitting on soft soils in a seismic area.

In general, the dynamic response of rubble-mound breakwaters has not been so far thoroughly investigated. This can be attributed to the fact that a possible failure of a breakwater entails only a limited reduction of the protection afforded to the harbor. Also, it is usually a matter of routine maintenance to repair such damages by simply adding more stones. For these reasons the current practice of breakwater design is to safeguard stability against wave attack and general soil shear failure, without taking into account the seismic loading. In contrast, the seismic response of similar structures, as earth dams, has been investigated to a far more advanced level, since eventual failure of such structures could well have severe consequences.

An important difference between dams and breakwaters lies in that dams are always designed to sit on firm foundation soils while breakwaters are sometimes

required by other reasons to be constructed on soft soils.

In the following two routes of investigation are presented: the first addresses the hydrodynamic aspects of the problem, i.e. the dynamic loading of the rubble-mound by the surrounding water masses, while the second deals with the seismic analysis of the system "structure-soil".

## HYDRODYNAMIC ANALYSIS AND RESULTS

An investigation of the hydrodynamic characteristics of the problem was undertaken aimed at estimating the hydrodynamic loading on the structure due to the seismic activity and assessing thus its relative importance with respect to the "pure" seismic loading acting directly upon the mound through the underlying soil strata.

A simple estimate of the hydrodynamic pressures can be obtained by taking into account the motion of the virtual mass of water in the vicinity of the structure. There are in general two types of modifications to this estimate referring to the compressibility of the water and the elasticity of the structure. Denoting by  $\omega$  the circular frequency of the horizontal seismic excitation, by  $\omega_1 = \pi c/2h$  the first cutoff frequency of the water body surrounding the structure,  $c$  speed of sound waves in water,  $h$  water depth, and by  $\omega_s$  the natural frequency of the structure, the following remarks can be made.

It has been shown by Chopra (1967) that if  $\omega < \omega_1$ , then in an uncoupled system "breakwater-sea" the compressibility of the water does not play a significant role and can be neglected. In our case we have indeed  $\omega < \omega_1$  by feeding the existing data. In a coupled system "breakwater-sea" the required additional condition for ignoring the water compressibility is  $\omega_1/\omega_s > 2$  (Chopra 1968). This again is applicable in the problem under consideration since the site-specific data give  $\omega_1/\omega_s \approx 7$ .

Regarding the parameter of the elasticity of the structure, recent research has verified that it produces a significant modification on the pressure distribution along the face of a rigid dam with increasing ratio of  $\omega/\omega_1$ . Results by other investigators (Mei et al 1979) show that for  $\omega/\omega_1 < 0.2$  the deviation of the total hydrodynamic force by assuming rigid structure is less than 15%, while for  $\omega/\omega_1 < 0.1$  the difference is negligible, of the order of 1%. In our problem, which represents a typical case of moderate seismic loading, this ratio is about  $\omega/\omega_1 \approx 0.05$ . Such a low value suggests that as a first approximation the elasticity of the structure can be ignored for the calculation of the total hydrodynamic force. However, this is not necessarily the case when one is interested in the detailed structure of the pressure distribution along the face of the breakwater.

Following these qualitative results the investigation proceeded to estimating the major component of the hydrodynamic loading, namely the added mass pressures on a vibrating sloping face in the sea. The nomenclature of the simplified problem can be seen in figure 5. A part of the seawater in contact with the face of the breakwater produces dynamic loading due to the accelerations involved. The corresponding pressures can be calculated analytically by estimating at every level the breadth  $b$  of the water mass that loads dynamically the structure.

Figure 5. Nomenclature of the simplified problem

An impermeable face was assumed and a no-slip condition was applied at the slope. In figure 6 the external forces acting on a horizontal slice of water mass of height  $dy$  are shown.

Figure 6. Forces acting on a water element

The equations of motion read,

$$\text{along } y\text{-axis: } p \cot \theta - p \frac{db}{dy} - b \frac{dp}{dy} = \rho b a_{fy} \quad (1)$$

$$\text{along } x\text{-axis } p = \rho b a_{fx} \quad (2)$$

where  $a_{fx}$ ,  $a_{fy}$  the acceleration of the fluid along  $x$ ,  $y$  axis respectively  
 $p$  the pressure

The continuity equation is produced by equating the displaced water volumes due to the motion of the slope during time  $dt$ . This yields

$$a_{fy} = a_x y / b \quad (3)$$

The boundary condition along the rigid slope can be written in general,

$$a_{fx} = a_x - a_{fy} \cot \theta \quad (4)$$

On the free surface the boundary condition, taking  $p=0$  there, is

$$b = h \cot \theta, \quad y=h \quad (5)$$

Equations (1) to (4) give the following differential equation after some algebra

$$\frac{dp}{dy} = \rho \alpha_x \frac{db}{dy} - \rho b \frac{d\alpha_{fy}}{dy} \cot \theta - \rho \alpha_{fy} \frac{db}{dy} \cot \theta \quad (6)$$

From (3) we obtain:

$$\frac{d\alpha_{fy}}{dy} \cdot b + \alpha_x \sin \theta + \alpha_{fy} \frac{db}{dy} = 0 \quad (7)$$

Now, (6) becomes due to (7)

$$\left(\frac{y}{b} \sin \theta \cot \theta - 2\right) \frac{db}{dy} - (\sin \theta + \cot^2 \theta) \frac{y}{b} + (1 - \sin \theta) \cot \theta = 0 \quad (8)$$

Integrating eq.(8) with respect to  $y$  and employing (5) to define the constant of integration we arrive at

$$\log[2b'^2 - b'y' \cot \theta + (1 + \cot^2 \theta)y'^2]^{1/2} = (1/2) \log(1 + 2\cot^2 \theta) + \frac{\cot \theta}{H} \arctan \left( \frac{4b'/y' - \cot \theta}{H} \right) - \frac{\cot \theta}{H} \arctan \frac{3\cot \theta}{H} \quad (9)$$

where the prime denotes non-dimensionalization with respect to  $h$  and  $H = (8 + 7\cot^2 \theta)^{1/2}$ .

If we define a pressure factor  $c_p = p/\alpha_y h$  with  $\alpha = \alpha_x/g$ , then from (2), (3), (4) we obtain

$$c_p = b' - y' \cot \theta \quad (10)$$

The above analytical expression (9) reduces to the following simple formula for the case of a vertical face

$$b' = 0.707 (1 - y'^2)^{1/2} \quad (11)$$

This specific result compares very well with existing experimental data of Wang et al (1978) and Zangar (1952) as shown in the graph of figure 7 drawn in terms of  $c_p$ .

Apart from the detailed pressure distribution the integrated total force  $F = 0.56\rho\alpha_x h^2$  falls quite close to other analytical results, deviating only by 5% from the classical value  $F = 0.58\rho\alpha_x h^2$  given by Westergaard (1933) for the same case of a vertical face.

Figure 7. Comparison of analytical expression with experimental results

Application of the general expression to a slope with  $\theta = 30^\circ$  gives results that are comparable with experimental data along a central section of the total water depth, but there are deviations from the experimental results at the upper and lower parts of the water column. Nevertheless, the integrated pressure diagram gives again values of the force in good agreement with experimental data exceeding them by about 15%. The deviations of the pressure distribution especially in the lower part of the sloping face can be attributed mainly to the neglected boundary conditions along the sea bed close to the toe of the breakwater. These conditions induce a redistribution of the hydrodynamic pressures on the slope especially to its lower part.

In order to overcome this difficulty a numerical method has been developed which takes into account the conditions along the whole boundary of the water mass. The technique applied to this problem is the boundary integral element method. Variations of the geometry of the boundary, as e.g. sloping sea bed, as well as of its porosity can be accommodated in the model. Due to space limitations this part of the research is not presented here.

The numerical results for the hydrodynamic force based on the previously presented analytical expressions were found to be rather low when compared to the direct seismic loading on the mound through the foundation soil.

The typical cross-section of the breakwater was also checked against wave attack by using a standard method (CERC, 1984). It was found that although in general terms the cross-section was robust, a few modifications could improve considerably its strength, as e.g. extending downwards the seaward armoring. However, such points contributed only secondarily to the initiation of the failure mechanism.

## GEOTECHNICAL AND SEISMIC ANALYSES AND RESULTS

### Geotechnical Conditions

It was already known from the construction of the older main part of the Patras breakwater and its northern extension that the foundation soil consisted of a rather thick layer of soft compressible clay. Thus prior to the construction of the southern extension, a rather extensive investigation program of its foundation soil was under-

taken. A total number of 21 borings reaching a depth of 50m from the sea level were performed covering a zone 125m long and 100m wide, up to 50m away from the axis of the extension. After the 1984 failure an additional very deep boring was performed to a depth of 104m. Apart from the SPT counts, 1-D consolidation tests as well as drained and undrained triaxial tests were performed on specimens taken from all these borings.

The above in situ and laboratory tests revealed that the foundation subsoil consists of a normally consolidated soft clay layer 30 to 38 meters thick underlain by a thick (>50 meters) moderately overconsolidated medium to stiff clay deposit. Some basic geotechnical parameters of the upper soft clay layer vary as follows:

- Standard Penetration Test Count:  $N = 0 \div 15$
- Initial Unit Density:  $\rho = 1.75 \div 1.92 \text{ Mg/m}^3$
- Initial Void Ratio:  $I = 0.72 \div 1.38$
- Natural Water Content:  $W^p = 25\% \div 30\%$
- Plasticity Index:  $I = 17\% \div 27\%$
- Compressibility Index:  $C^p = 0.20 \div 0.42$
- Undrained Shear Strength:  $C_u^c = 5 \div 40 \text{ kN/m}^2$

The lower stiff soil deposit presented the following values for some important geotechnical parameters

- SPT:  $N = 42 \div >50$
- Unit Density:  $\rho = 1.90 \div 2.00 \text{ Mg/m}^3$
- Void Ratio:  $I = 0.69 \div 0.85$
- Compressibility Index:  $C^c = 0.13 \div 0.18$
- Undrained Shear Strength:  $C_u^c = 120 \div 250 \text{ kN/m}^2$

An idealized soil profile with the selected values of the parameters used in the geotechnical analyses is depicted in figure 8.

Figure 8. Idealized soil profile and geotechnical parameters

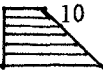

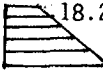

Settlement and Stability Considerations

Settlement and static stability analyses were performed for two stages of construction: one for the phase after the height of the mound had reached the level of 11 meters from its foundation, and a final one for the stage immediately after the completion of construction (height of mound: 18 meters). This was deemed appropriate in order to better simulate the actual history of the construction process, since there was a pause of 6 months after the mound had reached the height of 11 meters, and thus make it possible to account for the changes of the soil parameters caused by the ongoing consolidation process of the upper soft clay layer.

One dimensional settlement analyses yielded as best estimate of the final settlement due to the 11m high rubble mound at its axis approximately 1.5m, whereas the additional settlement due to the rest of the mound was estimated 0.6m, i.e. total settlement 2.1m. The actual settlements was not possible to be measured with accuracy, as they were obscured by the fact that significant amounts of the lower mound material intruded into the soft clay, since no filter zone was provided between the rubble mound and the clay layer. However, the measurements indicated that the total settlement must have been somewhat higher than the above value, approximately 3m; this difference between actual and estimated amount of settlement is mainly due to uncertainties of the clay compressibility parameters estimates, as well as to the limitations of the one-dimensional deformation model considered.

Static stability analyses were performed of the above mentioned two stages of construction. For each stage the undrained shear strength of the upper clay layer was estimated in accordance with the adopted relation  $C_u = 0.20 \cdot \sigma'_v$ , where  $\sigma'_v$  the effective vertical stress, after a suitable degree of consolidation had been assumed. Two suppositions of the distribution of  $C_u$  with depth, uniform and trapezoidal, were considered for each stage. Results produced by the modified Bishop slope stability analysis (Bishop 1955) are presented in table 1.

**TABLE 1**  
**STABILITY SAFETY FACTORS FOR STATIC CONDITIONS**

CONSTRUCTION STAGE (Height of Mound)	UNDRAINED SHEAR STRENGTH DISTRIBUTION IN THE UPPER LAYER $C_u$ (kN/m <sup>2</sup> )	SAFETY FACTOR F
1st Stage (11m)	20 Uniform	1.20
1st Stage (11m)	 10 61.2 Trapezoidal	1.15
2nd Stage (18m)	35 Uniform	1.09
2nd Stage (18m)	 18.2 71.1 Trapezoidal	1.13

It is apparent from these marginal static safety factors that even a moderate dynamic loading might produce failure conditions.

### Seismic Response

In late February 1984 a series of moderate earthquakes of magnitude 3.5 to 4.5 took place in the Patras Gulf near the breakwater site. Immediately after these earthquakes settlements of the order of 3 to 4 meters were measured on the constructed part of the southern extension of the breakwater. In this paragraph we investigate the seismic behavior of the breakwater and its foundation during the strongest of these events, which apparently led to its failure. For this purpose, the bedrock ground motion characteristics were estimated and the seismic response of the "rubble mound-soil foundation" system was calculated, using an appropriate one-dimensional model.

Figure 9 shows a map of the Patras area depicting the epicenters of the two strongest earthquakes with  $M=4.4$  and  $M=4.5$ , corresponding epicentral distances 7 and 8 km, and hypocentral distances 9 and 11 km from the site. According to attenuation relationships suitable for western Greece (Papaioannou 1988), the maximum bedrock ground accelerations were estimated at  $0.015 \div 0.020g$ .

Figure 9. Map showing the location of the epicenters

For the seismic response analysis of the "foundation soil-rubble mound" system as input motions were considered the Kalamata 1986 earthquake record normalized to a peak acceleration of 0.02g (Motion 1) and the Taft earthquake record normalized to a peak acceleration of 0.015g (Motion 2). The first motion was selected because it was recorded at similarly near source site, whereas the second was selected to account for a broader range of fundamental periods.

The seismic response of soil deposit and the rubble mound was calculated by simulating the foundation soils as strata of infinite horizontal extent and the mound as a shear beam (Gazetas 1987). For these analyses the software package SHAKE (Schnabel et al 1972) was used, after a suitable modification. As no dynamic measurements of soil parameters were available, dynamic shear moduli and damping coefficients for the mound and foundation materials were estimated from their density, confining pressure and shear strength characteristics.

Figure 10 shows the variation of initial shear modulus ( $G_0$ ) and shear wave velocity ( $V_{s0}$ ) with the depth of the mound and the soil profile.

Figure 10. Distribution of dynamic parameters

Results of the analyses as summarized in figure 11 and 12 show that the maximum ground acceleration at the top of the soft stratum was amplified by 2 to 2.5 times. These figures also show that the accelerations were moderately amplified within the mound body.

Figure 11. Calculated accelerations along the axis of the mound

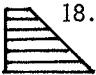

Figure 12. Input and calculated response spectra

Pseudo-dynamic stability analyses were also performed, utilizing the above calculated seismic forces. Results of these analyses are summarized in table 2.

TABLE 2  
STABILITY SAFETY FACTORS FOR SEISMIC CONDITIONS

DISTRIBUTION OF UNDRAINED SHEAR STRENGTH FOR THE SOFT CLAY $C_u$ (kN/m <sup>2</sup> )		SAFETY FACTOR MOTION 1	SAFETY FACTOR MOTION 2
	35 Uniform	0.82	0.75
	18.2 71.1 Trapezoidal	0.88	0.79

The results show clearly that these relatively small earthquakes were sufficient to trigger the failure mechanism of the structure. The main reason for this was the presence of the deep soft clay stratum that amplified considerably the moderate underground seismic motion, overriding the already marginal static safety factor.

## CONCLUSIONS AND RECOMMENDATIONS

Based on the previous analysis of the failure of the Patras breakwater extension the following conclusions can be drawn:

- (1) The failure of the mound was initiated by the seismic activity of February 1984 occurred in the vicinity, which caused the already low safety factors of the structure to fall below an acceptable level. Although the causative earthquakes were rather weak the seismic forces were considerably amplified by the thick soft clay layer on which the mound was founded and caused the shear failure of the low strength foundation.
- (2) The original design needed some improvement to withstand wave attack. However, this played only a secondary role in the failure mechanism.
- (3) The hydrodynamic loading due to the shaking of the mound can be approximated in this particular case by the pressures exerted by the added mass of the water. The structure elasticity as well as the water compressibility can be ignored without affecting appreciably the results.
- (4) The calculated hydrodynamic force due to earthquake activity was small compared to the direct seismic loading on the mound through the foundation soil.
- (5) In general the analytical expression proposed for the hydrodynamic loading on an inclined rigid face is a good first approximation to the total hydrodynamic force and represents an upper bound of the actual load on a porous breakwater face.

The authors believe that this case study represents conditions that can be met in several ports around countries with high seismic activity. Thus a more careful design approach and construction procedure should be followed in such cases. A thorough soil investigation program and a complete seismic analysis included in the design can save unnecessary and costly delays or even failures.

In situations where such adverse conditions are involved, the designer can employ techniques such as: interventions to the geometry of the structure, as e.g. by providing milder slopes or berms; improvement of the foundation soil; use of geotextiles; phasing of progress of works.

Part of the scope of the present research was the proposal of guidelines for the completion of the breakwater extension. In this respect the present geometry of the semi-completed mound, as modified by the wave action over a period of 8 years, has been recorded.

The current layout of the structure as well as standard calculations on armoring against wave attack led us to propose for the trunk section slopes at 1:2 both sides, and for the head of the structure milder slopes at 1:2.5. These new cross-sections were then checked for both static and dynamic stability giving the following factors of safety.

### Trunk section

Static conditions	$F = 1.54$
Dynamic conditions ( $\epsilon=0.06g$ )	$F = 1.18$

### Head section

Static conditions	<i>Short term</i>	<i>Long term</i>
Dynamic conditions ( $\epsilon=0.06g$ )	1.42 1.07	1.76 1.25

The head section was proposed to be completed in phases, since it has been subjected to a smaller degree of preloading and subsequent improvement by consolidation than the trunk section of the breakwater.

Consideration of other methods of foundation soil improvement, such as sand drains, geotextiles, etc, proved uneconomical for this particular case, mainly due to the small size of the project and the fact that a sizeable part of the structure had already been constructed, making thus interventions of the above kind very costly.

Suitable monitoring to record the behavior of the structure with time has been also proposed.

### ACKNOWLEDGEMENTS

This research has been supported by both the General Secretariat for Research & Technology, Greece, and the Patras Harbor Authority, who has kindly supplied us with the relevant data. Nic. Kotta, research assistant at NTUA, performed most of the geotechnical assessment and calculations for static conditions. Our thanks are also extended to the research students M. Symvoulidou, G. Tzivaridou and V. Grosomanides for their help.

## CHAPTER 256

### FUNCTIONING OF GROINS AT WESTHAMPTON BEACH, LONG ISLAND, NEW YORK

Gilbert K. Nersesian<sup>1</sup>, Nicholas C. Kraus<sup>2</sup>, and Fulton C. Carson<sup>3</sup>

**ABSTRACT:** An extended field of 15 long rubble stone groins was constructed in two increments of work at Westhampton Beach, New York, in 1965-66 (11 groins) and in 1969-70 (4 groins), as part of a hurricane storm-protection project. A third increment of work completing the protection to a downdrift point of closure was not undertaken due to political decisions. In addition, the dune and beach fill which was to have been placed in the first 10 groin compartments to complete the protection was not accomplished due to local economic problems. No construction work has been undertaken since 1970. During the 26 years following completion of the original 11 groins, substantial portions of the groin field have been filled naturally by trapping of sediment that moves alongshore with a net rate directed to the west. However, the shore area downdrift of the last westerly groin in the unconstructed increment of work has experienced inordinate recession because of insufficient bypassing of sediment to this area. This paper describes the functioning of the groin field, examining both the extreme downdrift recession and the equally dramatic accretion and beach build up in the groin field, drawing lessons on groin functional design from this historic project.

#### INTRODUCTION

In 1938, the south shore barrier island system along Long Island, New York, was devastated by a hurricane that is the storm of record for this Atlantic coastal area of the United States (Andrews 1938). The barrier islands were greatly eroded and weakened, and erosion was subsequently increased by other extreme hurricanes and extratropical storms that struck the area in 1944, 1950, 1953, 1954, 1958, 1960, and 1962 (USACE 1958, 1963). Since 1962, there have been frequent occurrences of severe extratropical storms, the most

recent being the October 1991 (Halloween) storm and the winter storm of December 10-12, 1992. Many sections of these east-west oriented barrier islands are in danger of breaching and flooding, and property has been lost or jeopardized by erosion. In 1960, storm-protection plans were authorized by the Federal Government for the coastal area between Fire Island Inlet and Montauk Point. One of the reaches included in the project was the barrier island that extends 24.6 km between Moriches Inlet to the west and Shinnecock Inlet to the east (Fig. 1). As part of the plan, groins were constructed initially on the most vulnerable section of the reach, called Westhampton Beach, with the objective of providing a wide beach and dune as a storm-protection measure.

The original plan provided for construction dunes and fronting protective beaches and 23 groins (if needed) in this reach (USACE 1958). Owing to political and economic considerations (Heikoff 1976), only 11 groins were constructed in 1966 in Section 2A without placement of the dune and beach fill along 3.8 km of shore westerly from a point 10.6 km east of Moriches Inlet, as shown on Fig. 2. This work was supplemented in 1970 with completion of four groins in Section 1A along 1.8 km of shore extending west of the existing groins, together with placement of dune and beach fill in the four westerly compartments (USACE 1969). A third increment of work in Section 1B along 2.9 km of shore to the west providing for six additional groins and accompanying fill was not undertaken due to political decisions (Heikoff 1976).

Because construction was halted before implementation of the third increment of work, the downdrift beaches to the west, which would have been spanned by groins, have eroded significantly, as shown in Figs. 3 and 4. In contrast, a huge dune system and wide beach have developed naturally in the 14 groin compartments, fully realizing the original intent of the storm-protection plan for the sections of reach spanned by the groin field. The net potential longshore sand transport rate on these western, fine-to-medium grain size barrier islands is estimated at 300,000 cu m/year to the west (Panuzio 1968).

In the present study, a large, unpublished data set of beach profile surveys and aerial photography was analyzed to quantify the functioning of the groins at Westhampton Beach. These data provide valuable documentation about the site and extensive coastal process information for understanding the general functioning of groins.

## GROIN DESIGN

The project groins, shown in profile in Fig. 5, were designed to reinforce a beach and dune fill intended to provide hurricane and storm protection. The backshore dune had a top width of 7.6 m at elevation +6.1 m National Geodetic Vertical Datum (NGVD), and front and back slopes of 1V:5H. The fronting protective beach had a berm width of 30.5 m at elevation +4.3 m NGVD, with foreshore slopes of 1V:20H from the seaward edge of the berm to elevation -0.6 m, and thence 1V:30H to the existing offshore bottom (USACE 1963).

The groins, which were constructed with quarry stone, have an average spacing of 400 m and are 146.3 m long. The groin design provided a horizontal inshore section 39.6 m long at elevation +4.9 m NGVD, an intermediate section 64.0 m long sloping 1V:15H from the seaward edge of the inshore section to the beginning of a 42.7-m long offshore section at elevation +0.6 m. The groins have side slopes of 1V:2H (USACE 1963). The 15 groins span 5.6 km of shore with the last westerly groin being located 5.0 km east of Moriches Inlet.

## OVERVIEW OF SITE

### Littoral Factors

The origins of the south shore barriers of Long Island are unknown. It is generally believed that the barriers are formed from glacial outwash sediments from the Pleistocene Epoch and have evolved through the Holocene period with rising sea level. The barriers are composed mainly of quartz sand with some garnetiferous and magnetitic sands and shell fragments (Leatherman and Allen 1985).

Tides in the project area are semi-diurnal and have a mean range of 0.9 m and a spring range of 1.1 m. Mean Low Water (MLW) is estimated to be 0.4 m (NOS 1992a) below NGVD. It is estimated that storm tides of +3.0 m NGVD occurred along the project shore during the 1938 hurricane (USACE 1958). Data from observations of the winds in the vicinity of the project area indicate that the prevailing winds are from the southwest with a duration of almost 25 % and secondarily from the northwest of about 20 %. Over 27 % of the winds in excess of 17 m/sec are from the east, 20 % from the northwest and 6 % from the south. Wind speeds as great as 43 m/sec (September 21, 1938) have been recorded at Westhampton Beach. Wind speeds in excess of 22 m/sec have been recorded more frequently during lesser coastal storms (USACE 1958).

Tidal currents at Moriches Inlet and Shinnecock Inlet vary with the tidal stage reversing in direction about every 6 hr. Published values for the maximum average flood and ebb tides at Shinnecock Inlet are 70 and 76 cm/sec, respectively (NOS 1992b). Tidal currents measured during spring tide conditions by the Corps of Engineers in July 1991 (Chu and Nersesian 1992) at Shinnecock Inlet indicated that the maximum average flood and ebb

currents were about 165 cm/sec. For Moriches Inlet the maximum average currents during the same period varied between 243 to 253 cm/sec.

Deep-water heights and return periods in the project area were estimated using a wave climatology study for the South Shore of Long Island, Phase III, Stations 45, 46, 47, and 50. Computed deep-water and breaking wave heights versus return period are shown in Table 1. Breaking wave heights corresponding to the incident wave height were calculated with a refraction coefficient of 1.0 and a flatter post-storm beach slope of 1V:30H. For a 50-year return period, the sea-water level was +3.0 m NGVD, and the wave period was 9 sec. Associated water levels for other wave heights are higher or lower dependent on the return period (USACE 1982, 1986).

Haight	Return Period (years)						
	5	10	20	50	100	200	500
$H'_o$ (m)	4.6	4.9	5.3	5.8	6.2	6.3	6.6
$H_b$ (m)	4.8	5.2	5.4	6.4	6.9	7.4	8.2

$H'_o$  is unrefracted deep-water significant wave height;  $H_b$  is breaking wave height

### Shore History

Examination of prior storm impacts on the shore in the vicinity of the groin field shows that there have been frequent breakthroughs of the barrier beach and dune system as well as creation of new inlets (Andrews 1938, USACE 1963). These impacts, shown in comparative format on Fig. 6, clearly demonstrate that the shore area at Westhampton Beach is susceptible to severe damage by hurricanes and other storms. Of special interest is the shore location about 700 m west of the west bridge at Westhampton Beach where storms created inlets in 1938 and 1962, and a breakthrough in 1958. This location is now bracketed by Groins 5 and 6. Similar repeated impacts can be found in other portions of the project area. The present location of Shinnecock Inlet at the east end of the barrier beach was created by the 1938 hurricane, and later was permanently stabilized by local interests. It was on this basis that the project designers believed there was a definite need to reinforce the dune and beach fill protection with groins.

### ANALYSIS OF DATA

#### Procedure

The data base assembled for this study presently contains 10 beach profile surveys covering the interval 1962-91, seven aerial photographic surveys yielding shoreline positions for the interval 1962-89, and a topometric shoreline mapping survey. The profile surveys typically contain at least three transects per groin compartment and extend from the landward toe of the dune to the 8-m depth. Several aerial surveys extending over the full littoral cell between Moriches Inlet and Shinnecock Inlet enable interpretation of coastal processes through examination of the regional sediment budget, not discussed here. The beach profile and shoreline position data, originally recorded in a variety of formats, were digitized in a controlled georeferenced Geographic Information System for quantitative analysis and visual

Fig. 6. Locations of historic breaching and inlet creation

interpretation. The first-order analysis included time evolution of shoreline position, volume of the dune and berm complex, and bottom morphology change (not discussed here).

Profile surveys selected for comparison were 12/62, 8/66, 7/75, 12/79, and 12/91. Shoreline position survey data from aerial photography taken in 12/62, 12/79, and 3/89 were integrated in the comparative analyses. The 1962 survey is a base survey which closely approximates the pre-groin construction shore position for the original 11 groins. The 1966 survey approximates the pre-groin construction shore position for the second 4 groins.

#### Shoreline Positions at Westhampton Beach

Comparative plots of shoreline positions at Westhampton Beach for five profile surveys and one shoreline survey between 1962-89 using all survey transects are shown on Fig. 7. The horizontal axis on this figure represents the baseline origin position for the plotted data. To better display the trends, shoreline positions were smoothed by moving average. Inspection of this figure shows that shoreline position advanced from approximately 100 to 70 m or 3.7 to 2.6 m/year, respectively, from east to west, along 3,800 m of shore. The

Fig. 7. Smoothed shoreline position in the vicinity of the groin field

general trend of shoreline movement in the first 11 groins during the 1962-89 period was one of continuing advance. From 1989-91 there was minor shoreline recession, which may reflect the impact of the October 1991 storm.

In the shore area encompassed by the second group of 4 groins, shoreline advance over the period 1966-89 was 50 to 55 m, or about 2.3 m/year, and was probably influenced in part by the dune and beach fill that was artificially placed during the second increment of work. In the period 1975-89, there was a shoreline advance of 40 to 20 m or 2.9 to 1.4 m/year, respectively, from east to west, in this area. At a point about 370 m west (downdrift) of Groin 15, the shoreline receded about 6.5 m/year in the period 1975-89. Further westward the rate of recession decreased to about 5.0 m/year. It is noted that the shoreline recession between 1962-75 was 1.9 m/year or less. Accordingly, the rate of recession in the downdrift area tripled following completion of the second increment of work.

#### Shoreline Positions Near Groins

Shoreline position near the groins is more closely examined in Fig. 8. Filling of the groin compartments has resulted in various shoreline alignments through the groin field. Between Groins 1 and 3, the shoreline shows generally straight alignment about 243 m from the baseline origin on Dune Road. Between Groins 3 and 4, the shoreline moved seaward from 243 m to 214 m, respectively, from the origin. This latter shoreline position generally continues westward to Groin 8. Between Groins 8 and 11, the shoreline moved seaward from 214 m to 164 m, respectively, from the origin. Between Groins 11 and 15, shoreline position moved seaward from 164 m to 154 m, respectively, from the origin. The shoreline positions and alignments within the groin demonstrate the natural filling of groin compartments and the bypassing of littoral sediment to downdrift compartments. Between Groins 1

Fig. 8. Shoreline positions in the groin field

and 8, there are two plateaus, indicating that the groin is nearing complete filling in the compartments. It is of interest that the midpoint of the groin field is marked by Groin 8. Comparison of shoreline position between Groins 8 and 11 and between Groins 11 and 15 indicates that filling of the downdrift compartments is proceeding at a much lower rate.

#### Rate of Shoreline Change by Groin Compartment

Mean shoreline change per groin compartment from December 1962 to December 1989 for Compartments 1, 3, 5, 7, 9, 11, 13, and 14 is shown on Fig. 9. The results confirm filling of the groin compartments in the westerly direction. The mean shoreline change for all compartments is shown in Fig. 10, where it is seen that shoreline position in the groin field is approaching equilibrium after 26 years.

#### Comparative Profiles in Center Groin Compartments

Comparative profile plots are shown in Fig. 11 for the centers of Compartments 1, 5, 10, 14, and 15, for surveys taken in December 1962, 1979, and 1991. Compartment 15 is actually the westerly downdrift 400 m of shore area adjacent to Groin 15. The plots clearly show the massive dunes created from trapped sand subsequently moved onshore by wind. These dunes contain vegetation and provide habitat for coastal birds and ground animals.

#### Area and Volume Changes at Westhampton Beach

Computed area extent and volume changes (NGVD intercept to near baseline) in the 14 groin compartments and in the planned, but not constructed downdrift compartments are presented in Figs. 12 and 13. Between 1962-91 the area within the compartments increased by about 75%. Average compartment area in 1991 was about 27,900 sq m, and, based on an average compartment length of 400 m, the average beach width was about 70 m. The

Fig. 9. Mean shoreline change per groin compartment

Fig. 10. Mean shoreline change over the groin field

Fig. 11. Selected profile surveys to 800 m from baseline, Dec. 1962 - Dec. 1991

Fig. 12. Area change above NGVD intercept

Fig. 13. Volume change above NGVD intercept

greatest increase in area of the groin compartments occurred between 1962-79, and the largest losses occurred downdrift of Groin 15 between 1979-91.

The data for the 14 compartments indicate that, between 1962-91, the average area volume compartment increased on average by 129,000 cu m or by 4,450 cu m/year for a total of 1.8 million cu m trapped by the groin field (above NGVD). The average increase in beach elevation over the period of record was 4.6 m. The greatest increase in volume of the groin compartments occurred between 1962-79, and, as in the case of the area plots, the largest losses, 315,200 cu m, occurred downdrift of Groin 15 between 1979-91. Although not discussed here, the beach profile did not steepen or lose volume seaward of the shoreline.

## **DISCUSSION AND CONCLUSIONS**

Review and analyses of the data strongly demonstrate that introduction of groins at Westhampton Beach has resulted in both adverse and positive impacts. The adverse impact, recession of the shoreline in the area downdrift of the groin field, developed as a result of not completing the project construction as originally intended. The adverse impact, caused by administrative, economic, and political decisions and not engineering miscalculation, has left the barrier island in a weakened condition such that it is still subject to being breached or broken through by storms.

The benefit of the groin field, which typically is not discussed in other analyses of the Westhampton groin field project, is that the groin compartments have been filled naturally or are still being filled from east to west, although taking much longer than the planned method of using artificial fill placement. Compartment filling has been accompanied by formation of high primary backshore dunes and several secondary dunes ridges located seaward of the primary dune. The shore area in the 14 groin compartments has not been significantly affected by storm attack, except for one compartment in 1980. The overall benefit of the groin field bypassing and dune building has been to provide a high level of protection to the barrier island over the area it encompasses.

Significant lessons which can be drawn from experience at Westhampton Beach are:

- a. **COMPLETE PROJECT WITHOUT UNDUE DELAY.** The construction of projects involving groins must be completed without significant delay to permit functioning of the system and to minimize impacts on adjacent shores. If there is a question as to whether the work can be conducted in this fashion, then it should not be initiated.
- b. **PERFORM CASE-BY-CASE EVALUATION.** Groins are not universally bad. Use of groins requires the same type of evaluation as is given in consideration of other protective measures to provide a solution for coastal problems on a case-by-case basis.
- c. **EXAMINE THE NEED FOR SHORE REINFORCEMENT WITH GROINS.** Groins may be needed to reinforce or hold protective beach fills, if their need is demonstrated by shore history and storm attack in the area to be protected. Emplacement of groins without concurrent placement of beach fill is strongly discouraged.
- d. **DEVELOP PROPER DESIGN.** The use of groins requires proper design by qualified professionals to ensure their functioning within a shore system. Designers need to be knowledgeable of the littoral forces affecting the area, the longshore sediment budget, and the sensitivity of adjacent shores to changes that groins can precipitate.

- e. ENSURE BYPASSING OF LONGSHORE SEDIMENT. Where longshore transport is essential to providing nourishment to downdrift shores, the use of groins must provide for bypassing of sediment to adjacent shorelines without interruption. The groin field should be filled, and, at the downdrift terminus of the project, the groin system should be tapered to meet the unimproved shoreline area in a smooth fashion.
- f. PROVIDE LONG-TERM PROTECTION. The 15 groins at Westhampton Beach still continue to function after 26 years to hold and build up the dune and beach in the groin compartments. The life of the groin structure can be extended through proper design, construction, and maintenance. Groins can provide positive and economical long-term protection while blending with the natural surroundings.

### ACKNOWLEDGEMENTS

We thank Coastal Engineering Research Center colleagues Mr. Paul Holt for assistance in developing the Westhampton Beach Geographic Information System, Ms. Holley Messing for typographic support, and Mr. Aram Terchunian, First Coastal Corporation of Westhampton Beach, N.Y., for discussions and assistance in providing reference materials. This study was conducted as part of activities of the Beach Fill Engineering work unit, Shore Protection and Restoration Program, U.S. Army Corps of Engineers. Permission was granted by the Chief of Engineers to publish this information.

## CHAPTER 257

### SEA LEVEL TRENDS IN THE HUMBER ESTUARY : A CASE STUDY

PATRICK PARLE<sup>1</sup>

#### ABSTRACT

In 1990 Posford Duvivier were commissioned by the National Rivers Authority to collect, audit and place on a database 550 years of tide data from 15 locations on and in the vicinity of the Humber Estuary, UK. As part of this project 373 years of the data, from 10 locations (key stations), were analysed for trends in relative sea level. The areas covered in the trend analysis included: linear trend estimates on yearly average high tide levels from all the key stations; an examination of variations in trends with location and time; and an examination of the correlation between high water trends, mean tide level trends and low water trends. This paper discusses the trend analysis.

#### INTRODUCTION

The National Rivers Authority (Yorkshire, Severn Trent and Anglian Regions) are responsible for extensive tidal defences around the Humber Estuary in the UK. (see Figure 1). Knowledge of extreme water levels and trends in water level is necessary for the design of tidal defences. To enable these NRA regions to produce a consistent and sound strategy for the design of tidal defences in the Humber area, Posford Duvivier were commissioned by NRA Yorkshire Region to collect and analyse tide data from specified tidal stations. This data was to be placed onto a computer database and analysed for trends in water level and extreme water levels.

550 years of tide data from 15 locations (see Figure 2) on and in the vicinity of the Humber were collected, audited, reduced to a common level (mODN) and time (GMT) base and loaded onto the database. 373 years of this data, from 10 locations (key stations) were analysed for trends in relative sea level. These trends were used to establish a coherent trend for the Humber Estuary. This coherent trend was used to adjust high tide data within the database to a common base date, 1990. This adjusted data was then analysed to produce estimates of extreme water levels for use in the

---

<sup>1</sup>Senior Engineer, Posford Duvivier, Consulting Engineers, Peterborough, UK

design of flood defences.

The areas covered in the trend analysis and discussed in this paper are

- Linear trend estimates on yearly average high tide levels from all the key stations
- The correlation between tide station trends
- The variation of trends with time
- The correlation between High Water trends, Mean Tide Level trends and Low Water trends

## **DATABASE**

The layout of the tide data on the database is shown on Table 1. The database holds the date, time and height of both high and low water. Each high water and following low water is held as a pair. Each pair is given a sequence number unique to that tide. This enables a given tide or set of tides to be identified at each location up the estuary. For each tide an adjusted level (as at 1990) has been estimated based on the coherent estuary trend. This adjusted level is held within the database.

Software has been written to enable data that satisfies a set of user defined criteria to be retrieved from the database. This software also allows the user to carry out extreme value analysis and/or trend analysis on a station's full data set or on a specified set of retrieved data.

## **TREND ANALYSIS METHODOLOGY**

Trend analysis was carried out on yearly averaged tide levels. A considerable amount of trend analysis has been carried out, during previous studies, using yearly average tide levels, and following an examination of trends using individual tide levels, monthly and yearly averages, it was considered appropriate that yearly averages be used in this study.

It was initially thought that river flow and surge tides might contaminate the trend estimates. However, at the key stations river flows did not significantly influence high tide level and any influence of these flows on trend estimates was reduced further by the use of yearly averages. Similarly the use of yearly averages effectively removes the effects of individual surge tides.

The use of yearly average tide levels also damps out "noise" in plots of levels against time. Noise may be due to diurnal tide differences, spring/neap tide cycles, monthly variations, random digitising errors, river flow, atmospheric pressure variations and surge tides.

An assessment of the effects of monthly variations in high tide levels at Immingham indicated that if at least ten months tide data was available for a year the average of this data would be a reasonably accurate estimate of the yearly average. Therefore, in auditing data at all stations, a valid yearly average was considered to exist if at least 10 months tide data existed for that year. Table 2 lists the number of valid yearly average high tide levels at each of the key stations.

Accurate assessment of tide level trends requires data uncontaminated by river flow and as long a data record as possible. Because a considerable amount of key station low water data is affected by river flow, (particularly that at Blacktoft and Goole the two stations with the longest data sets) and because high tide data at the key stations is not significantly affected by river flow, the analysis was concentrated on high tide levels. The correlation between trends in high water levels and trends in both low and mean tide levels was obtained from an analysis of Immingham data.

Trend estimates were based on a straight line fit to the tide data using the method of least squares. It was initially intended that the tide data be examined for both linear and curved trends. However, it was found that future water level estimates based on a quadratic fit to the raw data were very sensitive to errors in the curve parameters, and this method was therefore rejected.

#### **ANALYSIS OF HIGH TIDE LEVELS**

Plots of yearly average high tide level against time were examined for each station and are shown in figures 3(a) and 3(b). These plots were found to be consistent with each other and gave no indication that the trend in high tide level changes up the estuary. However, they show that a considerable variation in the trend estimate could occur depending on the data period examined. Therefore, when comparisons of trend estimates for two stations were being made, simultaneous data was used.

Blacktoft had more valid yearly average high tide level data than any other station, except Goole. Since the Blacktoft data was of a more reliable nature, it was decided to compare trends at each station with trends at Blacktoft. Trend estimates were made for each station and compared with the simultaneous trend at Blacktoft.

The results of this comparison are given in table 3. The actual value of the trend estimates are not important as they cover considerably differing data periods for different stations. For the same reason comparisons should only be made across table 3 not vertically. It can be seen that most of the station trend estimates are within one standard deviation of the Blacktoft estimate.

Within statistical error, therefore, table 3 shows no evidence of a change in trend in yearly average high tide levels as one moves up the Humber estuary. The coherent trend, in high tide level, for the estuary should therefore be based upon trend estimates for the station with the longest set of reliable data, which in the case of the Humber

Estuary was Blacktoft.

## NODAL TIDE EFFECTS

### General

Inspection of Figures 3(a) and 3(b) show that the yearly average high tide levels vary with time. The plot of levels for Blacktoft indicate this variation is cyclical with a period close to 20 years. In a study of yearly average water levels in the Thames, Rossiter (1969) refers to oscillations in annual average levels due to the "Nodal tide". The Nodal tide is due to the variation in the plane of orbit of the moon around the earth. This variation has a period 18.61 years. The nodal tide effect causes the tidal ranges to modulate, resulting in tides having a maximum and minimum once every 18.61 years.

### Nodal Tides

In principle, the nodal tide would cause what is known as the  $M_2^*$  tide component to vary by  $\pm 3.7\%$  over 18.61 years, with minima at 1913.4 (approx.)  $\pm N \times 18.61$  years and maxima at 1922.7 (approx.)  $\pm N \times 18.61$  years. The nodal tide could therefore cause the yearly average high water level at Immingham to vary by about 167mm.

However, the nodal oscillations of real tides appear to be less than the theoretical  $\pm 3.7\%$ . The occurrence of minima or maxima are also slightly (+0.5 year for Immingham) out of phase with the theory. Work by P. Woodworth (1991) of POL indicates that the nodal oscillation on high water level at Immingham would cause the yearly average high tide level to vary by 136mm with a minimum at 1951.1. It should be noted that a variation in average water level of 136mm in 9.3 (18.6/2) years gives a short term "trend" of 14.6mm/year.

The nodal tide causes a significant modulation in tidal range but only a small modulation on mean sea level. Woodworth (1987) cites estimates of the amplitude of nodal tidal oscillations on mean sea level of about 9-10mm.

### Effect of Nodal Tide on Estuary Trend

It is therefore important, when estimating a coherent estuary trend, using high tide data, that the period of data used should be an integral number of 18.61 year periods, should be of sufficient length that the effect of the nodal tide is insignificant, or the data should be corrected for nodal tide effects.

---

\* The  $M_2$  component is the lunar tide component, with period 12.42 hours, which dominates tides around the UK coast

It is not yet known how the effect of these nodal oscillations propagate up an estuary. It is thought that they may not vary much. At Immingham the amplitude of the nodal tide is about 3.0% of the  $M_2$  tide. Assuming the nodal tide propagates up the Humber, as 3% of the  $M_2$  component, this will result in a nodal oscillation of 121mm at Blacktoft.

Correcting the yearly average high tide levels at Blacktoft for this assumed nodal tide effect increases the linear trend estimate for the full data set from 3.57 to 3.71mm/year, see table 4. The use of this nodal tide correction causes a reduction in the standard deviation of the trend estimate from, 0.37 to 0.24mm/year. If an accurate estimate of the nodal tide amplitude were known for Blacktoft a more precise trend estimate could therefore be calculated. A plot of this Blacktoft data with nodal tide correction is given in Figure 4.

This increase in precision, though it may be significant in terms of reduction in the standard error of the trend, did not result in a significant change in the trend estimate. It was therefore decided that the estimation of a coherent estuary trend could be based on a trend estimate for the full Blacktoft data set without correction for nodal tide effects.

A coherent estuary trend of 3.57mm/year  $\pm$  0.37mm/year was thus adopted.

## **RELATIONSHIP BETWEEN TRENDS IN HIGH TIDE LEVEL, MEAN TIDE LEVEL AND LOW TIDE LEVEL**

### **General**

The coherent estuary trend of 3.57mm/year  $\pm$  0.37mm/year can be used to adjust past annual maxima data to the 1990 base date. Assuming that these historic trends continue, extreme water level estimates at future dates can be made. These future extreme levels are the extreme estimates based on annual maxima adjusted to 1990, plus a future rise based on historic trends.

Estimates exist for future sea level rise as published by the Intergovernmental Panel on Climate Change (IPCC) (1990). At present there are large uncertainties on these future sea level rise estimates which take account of global warming. In the near future, given a lessening of the uncertainties on sea level rise estimates, one may wish to use these rise estimates in place of historic trends. The greenhouse effect estimates relate to mean sea level, not yearly average high tide level, however, they do not include for local land movements.

To enable use to be made of future sea level used rise estimates it is thus necessary both to know the relationship between trends in high tide levels and trends in mean sea level and to obtain an estimate of land movement for the Humber area.

It should be noted that mean tide level used in this study  $(HW + LW)/2$  is not the same as mean sea level. However, over a period of time mean tide level is a constant amount above or below mean sea level. Therefore a trend in mean tide level is equivalent to a trend in mean sea level.

### **Relationship from other Studies**

Other studies have stated that trends in high tide and mean sea level are not the same. For example, Pugh (1990) cites two studies which indicate that trends in high tide level are higher than trends in mean sea level. One of these studies by J.R. Rossiter (1969) found that at Tower Pier trends on high tide levels were considerably greater than trends on MTL,  $7.74 \pm 1.16\text{mm/year}$  against  $4.33 \pm .82\text{mm/year}$ . During the same study, however, Rossiter found that the trends on high and mean tide levels at Southend were not statistically different. Another study indicated that at Flushing, Holland, the high tide trend was  $3.3\text{mm/year}$ , against  $2.2\text{mm/year}$  for the mean sea level.

Rossiter's study quoted above covers a data period of 30 years. This data period is less than an integral number of nodal tide periods. His study took no account of the nodal variation in tide levels and may therefore be biased.

### **Relationship from Present Study**

To attempt to correlate trends in high, mean and low tide levels in the Humber, Immingham tide data was examined. As discussed earlier, nodal tide effects result in an oscillation of approximately 136mm in high tide levels at Immingham, with a low at 1951.1. Table 5 gives trend estimates and the standard deviation of these trend estimates for yearly average high, mean and low tide level at Immingham, with and without correction for nodal tide effects. Figure 5 gives plots of these yearly average tide levels with and without nodal corrections.

Ignoring nodal tide effects indicate that high tide level is rising slower than both mean tide and low tide level. However, having corrected the high and low water levels for nodal tide effects the difference between the trends for the three levels is not statistically significant. Correcting for nodal tide effects also gives a significant reduction in the standard deviation of the high and low tide trend estimates.

This study indicates, therefore, that an increase in mean sea level will result in a similar increase in high water level.

### **Future Levels**

Based upon the assumption that the difference between relative sea level rise and global mean sea level rise is, in the Humber, due predominantly to land sinkage, and using the  $3.57\text{mm/year}$  rise as the best estimate of relative sea level trend in the Humber, and the IPCC, (1990) estimate of sea level rise of 1 to  $2\text{mm/year}$  over the last 100

years, we estimate the rate of land sinkage in the Humber as 1.57 to 2.57mm/year. It is acknowledged that this is a simplistic approach and that the difference may be due to other factors, not yet fully understood.

At present, therefore, future trend estimates of relative sea level rise based on estimates of absolute sea level rise should consider this estimate of land sinkage as additional.

## CONCLUSIONS

It was found during the study that

- spatial variation in high tide trends for stations within the estuary was found not to be statistically significant
- nodal tide effects must be considered when water level trend estimates are made based on high tide data. The longer the data set the smaller is the effect of nodal tide on trend estimates
- a coherent trend estimate of 3.57mm/year,  $\pm 0.37$ mm/year was found for the Humber estuary. This estimate is based on the Blacktoft data set (70 years)
- this study indicates that, for the Humber estuary, an increase in mean sea level will result in a similar increase in high water level
- in the Humber area, there is an additional 1.57-2.57mm/year increase in relative sea level over global sea level trends. This may be due to land sinkage.

## CHAPTER 258

### PROJECTS, WORKS AND MONITORING AT BARCELONA COAST

CARLOS PEÑA<sup>1</sup>  
VICENTE CARRION<sup>1</sup>  
ANA CASTAÑEDA<sup>1</sup>

#### 0. INTRODUCCION

Barcelona is the second city in Spain (2.3 million inhabitants) after Madrid (4 million) and is also the city that held the last Olympic Games in July 1992.

Just at the sea-front of the city is the port of Barcelona, the most important in Spain. The coast of the province of Barcelona is divided in two at this point. The northern part of Barcelona's coast runs from this port up to the mouth of the Tordera river, which is the border between the provinces of Barcelona and Girona.

These are 47 kms of the spanish coast which are very heavily degraded in some parts.

In its natural state it was a continuous and broad sandy beach 47 km. long and is some points two or three hundred meters wide, maintained by the sediments transported to the coast by Tordera and other small rivers.

Fig. 1<sup>2</sup> shows the situation of Barcelona in Spain and on the Mediterranean sea.

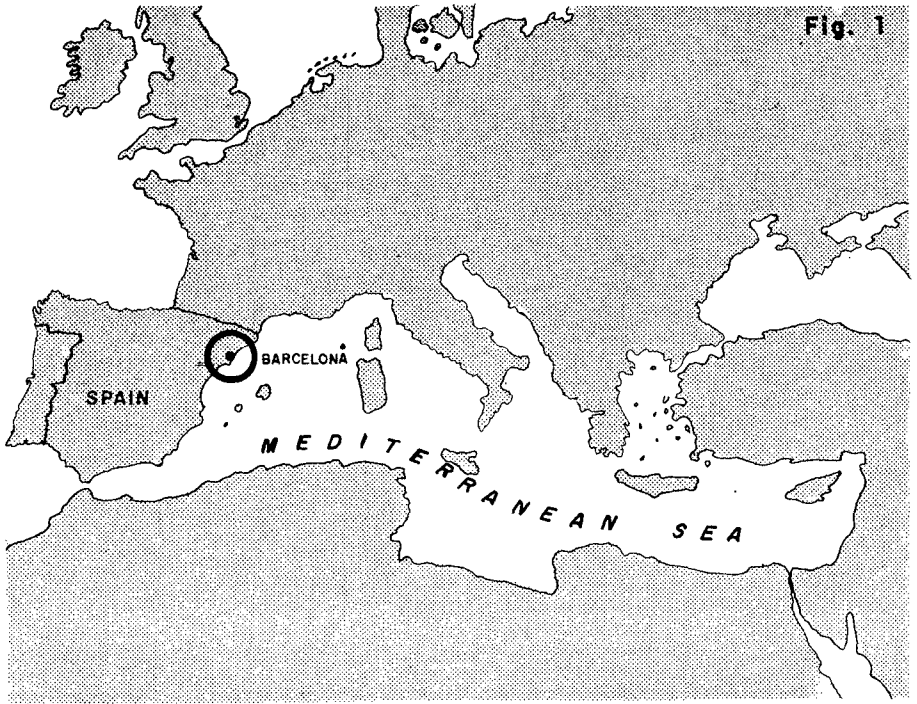

Fig. 2 shows the distribution of wave height all along the different directions focusing on the Barcelona coast. Data of this distribution comes from the well known visual data provided by ships.

Just a look at this fig. 2 shows that there is a potential sand transport capacity from north to south. This sand transport capacity has been evaluated by means of the CERC formula in about 89.000 m<sup>3</sup>/year near Barcelona city.

WAVE HEIGHT DISTRIBUTION (1950 - 1983)

Fig. 2

Let's have now a brief description of the whole sector (from Barcelona's port up to the Tordera delta) in its actual state.

In order to do so, the whole sector has been divided in three different segments.(Fig. 3).

## **1. FIRST SEGMENT (Tordera river - Arenys de Mar)**

The first segment goes from the mouth of the Tordera river up to the port of Arenys de Mar. Although the coastal zone has been heavily developed all along these 22,4 kms., the beaches remain in their natural state since the Tordera river delta maintains its enormous capacity to nourish them with coarse sand. Only in a few points some restoring works and nourishments were needed due to small and inadequate artificial works. As a whole we can say that the beach (not the coastal zone) keeps its natural dynamics and its existence is not threatened by a short-fall in sand.

The sand transportation capacity evaluated by the CERC formula is about 66.000 m<sup>3</sup>/year whith the visual wave heights data as input in the formula.

So, the target here is to mantain and improve the natural sediments dynamics, since the Tordera river and its delta are still capable of providing the amount of sediment needed to mantain all the beaches of this segment.

Actual planning is limited to some located sand nourishments, to remove or cut down some small groins and to prevent the beach being occupied.

## **2. SECOND SEGMENT (Arenys de Mar - Besos river)**

The second segment runs from to the port of Arenys de Mar up to the mouth of the Besos river. It is the most heavily degraded.

### **2.1. HISTORY (induced erosion and countermeasures)**

The first outer attack came from the construction in 1850 of the first Spanish railway. It was built in the easiest way and on the flatest land: the beach.

After this, five marinas or leisure ports were built up. The first one was Arenys de Mar in 1907, at the middle of the whole sector and, as a consequence, a very hard and continued erosion began at the southern part of the port for many kilometres. After Arenys de Mar four other ports were constructed: El Balis in 1972, El Masnou in 1972 Premiá de Mar in 1971 and the last one Mataró in 1989 (see fig. 3)

Since all these ports are total barriers to longshore drift of sediments, the immediate consequence was always the same: a small triangular beach at the northern breakwater of the port and a hard erosion at the south up to next port.

FIG. 3

# BARCELONA COAST

The first counter-measure to halt erosion was taken by the railway company. A long line of quarrestones showed up all along many kilometers in order to prevent the railway collapsing. As the beach disappeared quite quickly, some attempts to recover the beach were made. Eleven groins were constructed between the ports of Arenys de Mar and El Balis but they failed in recovering the beach and the only result was a further degradation in the coast landscape. Other small groins were constructed but generally speaking the beach was progressively disappearing; the environment, from the landscape point of view was going from bad to worse, the railway was at the sea-land border and this limit was (and still is) just a long line of quarrestones.

## **2.2. BEACH REPLENISHMENT AND STRATEGY**

The situation from Arenys de Mar up to the south was a few years ago untenable and in 1985, the Spanish Public Works Ministry planned the recovery of all this part of the mediterranean coast. The first step was the replenishment of the beach with 2.228.888 m<sup>3</sup> of coarse sand (0.4 mm) between the groin of Mongat and the port of Premiá de Mar with the port of Masnou at the middle (Fig. 4). There are 4,9 kms. of the coast recovered by means of simple sand replenishment as a first step. The second and necessary step is to by-pass all the ports in order to restore the littoral drift of sediments. The third step will be the replenishment of the remaining parts of the eroded coast and the forth and last step will be the periodical sand nourishment at the beginning of the whole segment: the southern point of the port of Arenys de Mar. So, if the four ports do by-pass the sand from north to south at the rate of sand transport capacity and at the same rate sand is nourished at the beginning of this sector, littoral drift will be restored and the beach all along 22,9 kms. will be recovered.

Theoretically, since sand transport capacity is evaluated by CERC formula in about 90.000 m<sup>3</sup>/year this will be the volume to nourish every year and the same amount must be by-passed by the ports.

## **2.3. MONITORING**

The subsector replenished at the first step (groin of Mongat - Port of Premia) has been monitored by CEPYC (Spanish Official Maritime Research Center<sup>3</sup>) in order to confirm these hypotheses.

Profiles of the beach have been monitored twice a year in 1987 and 1988 and once a year in 1990 and 1991 (Fig. 5).

---

<sup>3</sup>Centro de Estudios de Puertos y Costas  
C/ Antonio López, 81  
28026-MADRID

FIG. 5

If we focus our attention between the groin of Mongat and the port of Masnou, (see fig. 3) we have 33 profiles of the beach (see fig. 5), each of them taken at May and October 87, May and October 88, May 89, September 90 and November 91. In addition to this, two sand nourishments have been carried out in this period of time. The first one between May 88 and October 88 (the amount was 245.000 m<sup>3</sup>) the second one was between september 90 and November 91 (the amount was 160.000 m<sup>3</sup>).

Figures 6 up to 15 show the result of this monitoring. Let us make a few comments to these profiles.

- Fig. 6 shows the profiles outside the breakwater of the port of Masnou. The sea bottom is growing up because of the sand drifted from the north.
- Fig. 7 shows the profiles at the mouth of the port. Here too, sea bottom is coming up except for the profile measured in 1988 because it was dredged before.
- Fig. 8 shows the profiles about 100 m. from the mouth of the port. We can see that they remain very stable because the port is a total barrier to littoral drift.
- Figs.9 and 10 show the profiles at the points of sand nourishments in 1988 an 1991. These are also the points of most rapid erosion because of the proximity of the port. This is why these profiles move very quickly.
- Fig.11 & 12 show the profiles 20 and 24 at the middle of the stretch.
- Fig.13 and 14 show the profiles near the groin of Mongat. The beach has been quite stabilized.
- Fig.15 shows the profile nº 1 just besides the groing of Mongat where the beach line only retreats under the effect of storms.

The rate at which sand is lost (i.e., drifted to the south) has been measured.

Between May - 87 and May 88..... 110.000 m<sup>3</sup>  
 Between May - 88 and May 89..... 55.000 m<sup>3</sup>

Unfortunately profiles were no longer mesured in the month of May.

Between October 87 and October 88..... 160.000 m<sup>3</sup>  
 Between October 88 and September 90..... 180.000 m<sup>3</sup> (2 years)  
 Between September 90 and November 91.... 120.000 m<sup>3</sup>

-----

P- HEAD OF BREAKWATER

FIG. 6

P- ENTRANCE

FIG. 11

FIG. 12

FIG. 13

FIG. 14

FIG. 15

Between October 87 and November 9..... 460.000 m<sup>3</sup> (4 years)

These results have not yet been checked and compared with the wave-height-visual-data of the same period, but as an average we can provisionally conclude that for this kind of coarse sand (0.5 mm.) CERC formula minimizes longshore transport capacity in about 20%. Differences would probably be greater with finer sand.

### **3. THIRD SEGMENT (Barcelona city sea front)**

This is the third of the three segments of the figure 3. It runs from the mouth of the Besos River up to the port of Barcelona. Works in this segment have been completed just before the Olympic Games, last summer (1992).

A few years ago it was the ugliest and most degraded part of Barcelona's coast. Everybody considered most of the sea-front side of Barcelona as the rubbish dump where everything could be thrown.

In addition to this, there was some groins constructed to assure the discharge of Barcelona sewage draining system (now there are only rain water discharges there).

The landscape has deeply changed; a marina has been constructed as part of the Olympic Games infrastructure, beaches can be found instead of previous rubbish tips, and the groins have been rebuilt in order to assure the stability of the beaches.

A schematic plan of the whole segment can be seen in fig. 16.

The whole segment is being monitored once or twice a year, but as the works have just been completed a few months ago, only the first bathymetry has been carried out and no conclusions are available.

We hope that in next Coastal Engineering Conference in Kobe more conclusions and results can be discussed.

## CHAPTER 259

### STUDY OF 50 YEARS COASTAL CHANGES AT HADERA, ISRAEL

by Dov S. Rosen<sup>1</sup>, MASCE, MIAHR

#### Abstract

An investigation regarding the coastal changes over a period of about 50 years, as depicted from waterline and beach bluff fluctuations was conducted at Hadera-Sdot Yam beach, located at the central sector of the Southeastern Mediterranean coast of Israel. The study was conducted to assess the sedimentological impact of the breakwaters of a neighboring cooling basin, recently built. Processing and analysis methods used, as well as the main findings and conclusions are presented.

#### Introduction

A study of the coastal changes over a period of about 50 years (1937-1989), as depicted from waterline and beach bluff fluctuations measured from bathymetric charts and large scale air photographs was conducted by the author at Hadera-Sdot Yam beach, located at the central sector of the Southeastern Mediterranean coast of Israel (Fig.1). This coast represents a sedimentary unit within the Nile littoral cell extending from the Nile delta to the Haifa Bay. Hence it may serve as a long-term example of the morphodynamics of this littoral cell.

The purpose of the investigation was to assess the sedimentological impact of a cooling basin, built between

---

Figure 1. Location Map of Hadera - Sdot-Yam Beach

1977-1980 for a power plant located at Hadera shore, on its northward neighboring beach, downstream of the general net longshore transport .It was initiated due to claims of progressive erosion at the neighboring Sdot-Yam beach, made by local residents. The claims were supported by apparently significant erosion and beach bluff recession at several places along that beach. The erosion was attributed to be due to the recent construction of the cooling basin breakwaters, which were considered to have stopped the longshore sand transport, inducing progressive erosion to the supposedly "starved" neighboring beach some 1800 m to 2500 m away (Fig. 2). The breakwaters creating the cooling basin cover 700 m of coastline, protruding about 600 m into the sea (to -6 m).

Figure 2. Hadera-Sdot-Yam Coast with Baseline & Sections

### Data Processing and Results

The study was based mainly on the analysis of some 90 aerial photographs of 45 flights and 24 maps and correlation with the wave climate history. The correct determination of the bluff and waterline positions in the various charts and aerial photographs, relative to a fix baseline, parallel to the coastline, represented an important item of the study. In view of the suggestions of other investigators (Lueder-1977, Striem-1965), the prevailing (mean) waterline in the air-photographs at the time they were taken, was marked in the middle of the wet area of beach (dark area - see Fig. 3) and bounded by the visible water line.

The methods employed for the determination of the corrected waterline position (+0.0 m relative to Mean Sea Level - MSL) and of the bluff line position (+2 m above MSL), included:

(a) Analysis of relatively large scale enlargements of the pictures and maps (all at a scale of 1:2500) and marking of the water and bluff lines,

(b) Preparation of a mylar (polyester, i.e. non-shrinking) transparent base map of the area at a scale of 1:2500, on which all present beach features (structures, rocks, etc.) and the baseline and control sections were included ( see Fig. 2)

(c) Measurement of the distances from the base line to the bluff and waterline at each section, by superposing the transparent map on the various maps and air-photographs, using the presence of land marks, or structures and beach rocks.

(d) Assessment of the tide and wave induced super-elevation from wave records and tide records or tide prediction and

(e) Correction of the waterline position line taken from the charts or aerial photograph, due to tide and waves' contributions. Wave set-up correction was based on the Shore Protection Manual (U.S. Army CERC-1984), while for tide correction use was made of the foreshore mean slope at each coastal sector.

The waterline distances measured on the base map were also corrected for varying camera angles and elevations in different air-photographs, by a relatively simple but efficient method. By this method, applicable elsewhere in similar cases, advantage was taken of the presence of beach rocks on the foreshore, near the waterline, with tops at about 0 m to 0.5 m elevation above MSL. By superposing the rocks on the base map with

Figure 3 Example of marking of waterline and bluffline on an aerial photograph (Sdot-Yam 31.07.1970)

Figure 4 Schematic representation of error source in air photographs due to camera angle and elevation differences

those on the pictures, the distances between the base line and the waterline position at nearby sections could be accurately measured (with very little distortion), since the waterline and rock tops were at about the same elevation (Fig. 4). For correct interpretation of the fluctuating positions of the waterline and bluff with time and along the beach, an evaluation of the errors associated with the values computed for their positions due to various factors like paper shrinkage, drafting accuracy, scaling, positioning, etc., was also performed. The overall errors assessed were 5 m for the maps and 10 m for the air-photographs. Then, the waterline and beach bluff fluctuations prior, during and after the construction of the cooling basin breakwaters were analyzed at constant control sections along the base line (Fig. 2). The distance along the base line between control sections was 100 m, except at certain recently eroded sectors, where the distances were shortened to 25 m. Furthermore, the morphologic features of the coastal sector studied (bars, cusps, rip currents, spits, breakwaters, groins, sea walls and antique coastal structures) were also observed. Time histories of the corrected positions of the bluff and waterlines were

plotted for each control section. Results at representative control sections are presented in Figs. 5 through 16. They were compared to the time histories of the yearly maxima of deep water significant wave heights and of the yearly rain volume (Figs. 17 and 18). The whole waterline and bluffline fluctuations for the whole coastal sector are represented in Figs. 19 and 20 respectively. A isolines map of the waterline fluctuation in time and space was prepared from the data of the waterline position during 50 years along the whole sector of coast studied (Fig.21). This map facilitates to depict the location and duration of erosion or accretion in time along the whole coast. A tri-dimensional view of this fluctuations map in time and space is also presented in Fig. 22.

### Analysis of the Results and Conclusions

The results obtained show that this coastal sector was relatively stable until the beginning of the sixties, when a coastal erosion pattern was observed. The observed erosion seems to have occurred due to extensive quarrying of beach sand for construction purposes, forbidden by law since 1966. By the end of the sixties that erosion ceased, but reappeared for a short period at the beginning of the seventies, after an extreme storm in January 1968 and heavy rain 1969 year, which removed the beach sand, probably to the offshore bar. It disappeared from the mid-seventies, but reappeared in limited locations since 1982 due to local reasons. Beach bluff erosion, which encountered at a location remote 1800 m from the cooling basin was assessed to be due to local land reclamation from the sea without adequate scouring protection. At another sector (2100 m to 2300 m remote from the cooling basin ), a 3 m recesses in bluff position was measured in 1988. The erosion occurred after the cooling basin construction, but was induced by the construction of two groins that stopped longshore sand transport within a local pocket beach. A rather surprising result was that although the ending (northern) sector of that coast suffered from a recent small bluff erosion, it accreted some 15 m within the 1956-1964 period. The outcome indicated that the longshore influence of the cooling basin (accretion) extends for about 1500 m of the neighboring beach and nulls at about 1600 m from the lee breakwater (2.5 times its protrusion into the sea) and that a dynamic sedimentologic equilibrium state was reached after about 8 years from the cooling basin construction. Though some recent

erosion was found at a few points as mentioned above, the general waterline and bluff fluctuations remained all within the natural long-term range of fluctuation. No sedimentological impacts were found for the rest of the beach.

## CHAPTER 260

### INTERVENTIONS ON THE COAST SOUTH OF BRINDISI

Giuseppe R. Tomasicchio<sup>1</sup> & Fiore Uliana<sup>2</sup>

#### Abstract

The coast between Torre Mattarelle and Torre San Gennaro (Italy) is deeply eroded. The recent construction of a thermal-electric power plant changed the natural morphodynamic characteristics and the erosion rate. Interventions on the coast were needed. This paper refers about the phases of design and construction of the maritime defence works and tries to call attention about the need of an extensive study before the construction of a power station along the coast.

#### Introduction

The coast between Torre Mattarelle and Torre San Gennaro, a few kilometers South of Brindisi (Puglia-Italy), consists of a cliff with an overhanging slope subjected to continuous erosion due to the combination of geotechnical instability phenomena, run-off from rain water and the action of the sea waves. ENEL (the Italian national board for electricity) in 1982 started the construction of a thermal power plant (4 units, 440 MW each) in this area. The plant required a system to discharge the cooling water formed by two groynes extending to -7.0 m water depth. The part of coast in front and north of the power plant was protected by a 1.8 Km long seawall system. The maritime works started in 1985.

These interventions effected the natural morphodynamic evolution of the coast; the area to the south no longer received material from the north, therefore, retreat of the coastline and cliff instability increased. A visible effect was the relatively fast disappearance of the swimming beach south of the power plant.

ENEL is involved in the protection works for the portion of coast to the south of the power plant.

### The coastline

The planform configuration of the coast represents an independent physiographical unit extending from the prominence at Torre Mattarelle to the headland at Torre San Gennaro, a distance of 6.5 Km. The shoreline develops as a spiral arc from Torre Mattarelle to the swimming beach south of the power plant (fig.1 & 2). After this part an almost straight beach is observed. Afterwards, the coast has a curvilinear trend till Torre San Gennaro (with an orientation from  $40^0$  to  $30^0$  North).

Before any maritime work was started, the sandy emerged beach had an average width of about 5 m for all the coast north and for 1 Km south of the system to discharge the cooling water. Further south, the beach width increased to approximately 15 m.

The cliff has an average height of 13 m above the still water level; next to Torre San Gennaro, the cliff height decreases to about 4 m and then disappears. Only 25 % of the cliff material is sand ( $D_{50}=0.3$  mm), the rest is clay and silt.

Analysis of several samples shown that the submerged beach is composed of material with  $D_{50}=0.3$  mm till water depth -1 m and  $D_{50}=0.075$  mm beyond this limit. The material from the cliff erosion, due to the absence of river estuaries along the coastline, is the only supply for sediment.

To avoid the retreat of the coastline in front of the power plant, a seawall system was built during 1989; the work phases were:

- 1) cliff face adjustment with a slope of 2/3;
- 2) driving of sheet piles in sea bottom along the line representing the external structure of the reef base;
- 3) excavation close to the sheet piles;
- 4) laying on the shore and on the sea bottom of a geotextile cover weighing 300 g/m<sup>2</sup>;
- 5) laying of a "tout venant" bed;
- 6) armour construction consisting of natural rock weighing 500 ÷ 2000 Kg;
- 7) extraction of the sheet piles.

After the construction of the two big groynes to discharge the cooling water and the seawall protecting the coast in front of the power plant, the width of the beach to the south reduced to 1 ÷ 2 m.

### Wave climate and currents

The area is exposed to waves from directions ranging between  $330^0$  and  $120^0$  N. To estimate the offshore wave climate the following informations were used:

- data from KNMI (Royal Dutch Meteorological Institute) for the period 1961-1987 (more than 30000 visual observations of the sea state);
- data for 1983 from the ENEL wave recording system placed out of Brindisi harbour.

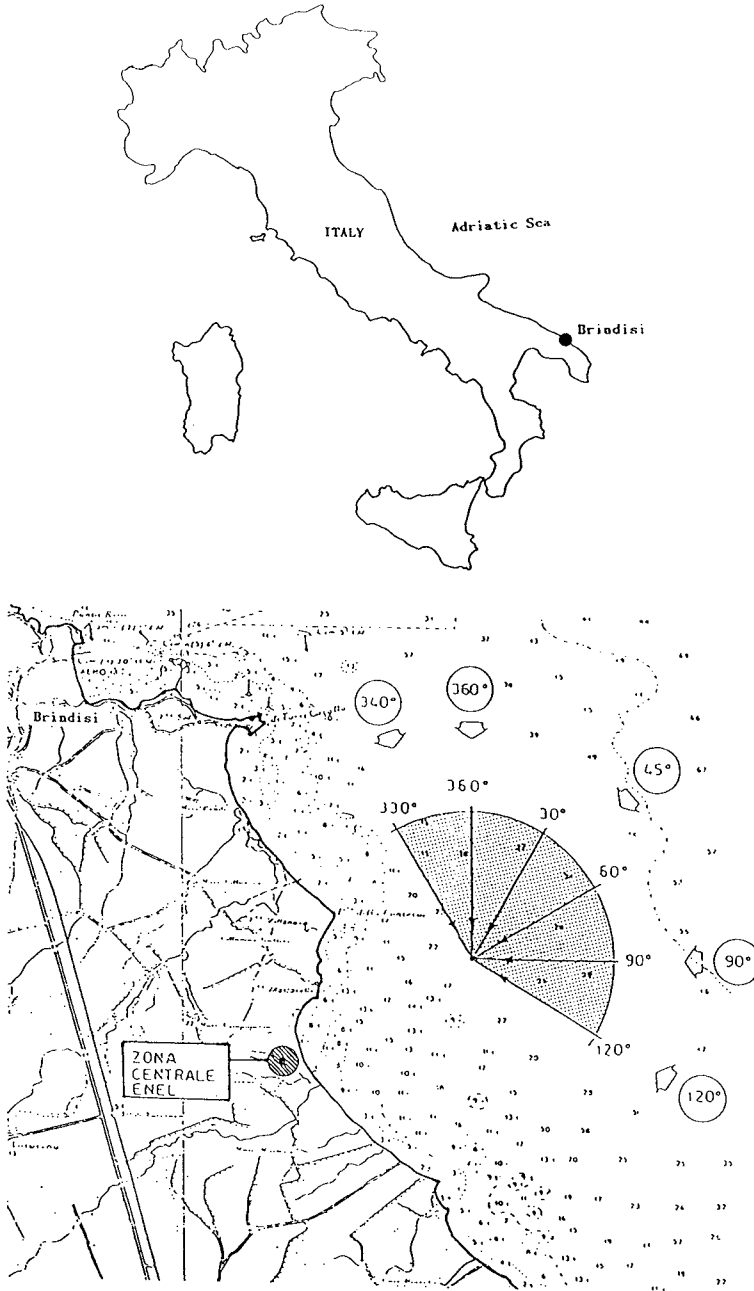

Fig. 1. Location of the power station

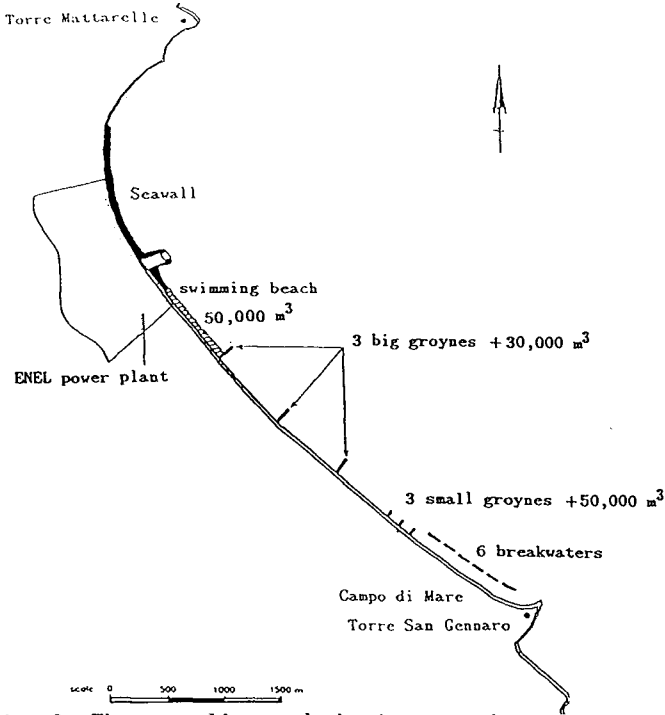

Fig. 2. The coastline and the interventions

years 1961-1980
All directions (330°-120° N)
T = 1 year $H_s = 4.5$ m
T = 10 years $H_s = 6.2$ m
T = 50 years $H_s = 7.5$ m

Direction (°)	$H_s$ for T=1 year	$H_s$ for T=10years
330	3.50 m	5.30 m
0	3.75 m	5.75 m
30	3.50 m	5.30 m
60	3.50 m	5.75 m
90	2.50 m	3.60 m
120	3.00 m	4.30 m

Table 1. Wave climate based on visual observations for different return period T

It was observed (table 1) that the most frequent wave conditions are from the directions  $30^0$  and  $150^0$  N; the last direction is practically out of the sector of exposure of the coast. These characteristics of the wave climate are typical for all the seasons; only during autumn and winter the frequency of waves coming from  $30^0$  and  $60^0$  N is increased.

Five fixed current meters, installed in water  $10 \div 30$  m deep (fig.3), were used to measure currents. The charts from current meter data that ENEL prepared show a large frequency of the currents to S-SE; the currents distribution indicates a net littoral transport to the south. The velocity of the longshore current is rather high (more than 30 cm/s). The observed astronomical tide is small (about 30 cm), consequently the tidal currents are weak.

### Erosion rates and sediment transport calculation

The recent evolution of the shoreline has been assessed using:

- topographical charts by ENEL from years 1982  $\div$  1985;
- aerial photographs series from years 1974, 1981 and 1987.

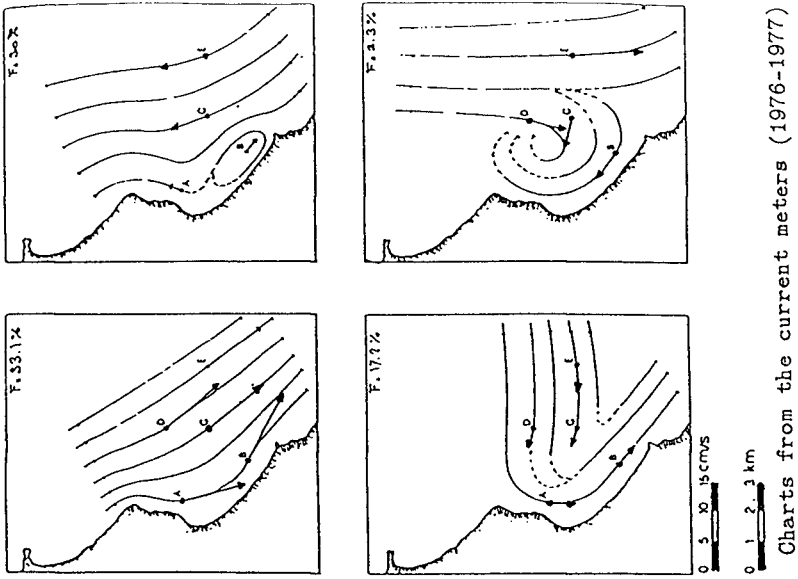

The approximate scale of the photographs was known. The surveys were not perfectly comparable. In the ENEL area the 1987 series were already disturbed because of the works for the sea-water adduction consisting of under water concrete pipe-lines having intake structure about 400 m from the shoreline.

The mean slope of the foreshore along the coast is approximately 1:45.

The observed retreat rate of the cliff (fig.4) before any ENEL intervention was  $1 \div 2$  m/yr for the mid section of the coast and  $0.2 \div 0.5$  m/yr for the remaining part.

The effect of the two groynes forming the system to discharge the cooling water was to subtract for the entire coastline to the south a natural supply of about 20,000 m<sup>3</sup>/yr (assuming that with 1 m coastline retreat a sand volume of 10 m<sup>3</sup>/m is required). This influenced the sediment transport Q distribution, giving an increase in the retreat of the swimming beach coastline from about 1 m/yr of the natural condition to  $4 \div 5$  m/yr (fig. 5).

For the part of coast to the south of the swimming beach, as an average yearly retreat of the coastline, a value of 0.5 m/yr was calculated. The observed yearly erosion of 0.5 m gives consequently a gradient in the longshore transport rate of 5 m<sup>3</sup>/m per year. Basing on almost 4,000 m coastline (south of the power plant), a 20,000 m<sup>3</sup> yearly loss of sand was estimated. An estimated value of the eroded material of the cliff is 50,000 m<sup>3</sup>/yr. Only 25 % of this material (about 13,000 m<sup>3</sup>/yr) consists of sand with a size sufficient to remain stable under the action of the longshore current. Therefore, the erosion of the cliff is not sufficient to increase the dimension of the beach.

Coastal area and position of the current meters  
Fig. 3

Fig. 4

1-before discharge system and seawall construction  
 2-after discharge system and seawall construction

Fig. 5. Q distribution along the coast

In order to evaluate the direction and the entity of the longshore sediment transport, a study concerning the transformation of the waves from offshore to the limit of the surf zone was carried out. Three refraction models were used for the entire coast taking into account five directions for wave incidence. The longshore transport was evaluated in some positions along the coast.

Calculations were performed using the CERC formula, the Bijker formula and the Engelund-Hansen formula. The results have a range of approximately 3 times the smaller value. The results of the computations (Delft Hydraulics, 1990) with the CERC formula are between the results of the Engelund and the Bijker formulae (giving the smallest value).

Run	Conditions			Total Transport in m <sup>3</sup> /day		
	H <sub>0sig</sub> (m)	T (s)	θ <sub>0</sub> (°)	Engelund	CERC	Bijker
1	1.0	4.5	10	1350	1000	450
2	2.0	6.0	10	11400	5650	3500
3	1.0	4.5	20	2500	1950	800

Conditions: - beach profile slope  $m = 1:45$   
 - particle size  $D_{50} = 200\mu\text{m}$   
 - fall velocity  $w = 0.025 \text{ m/s}$   
 - bottom roughness  $r = 0.05 \text{ m}$

H<sub>0sig</sub> : significant wave height (deep water)

T : wave period

θ<sub>0</sub> : angle of approach (deep water)

Table 2. Comparison sediment transports various formulae

The CERC formula is:

$$S = 0.040 \cdot H_b^2 \cdot n_b \cdot c_b \cdot \sin(\beta_b) \cdot \cos(\beta_b) \quad [\text{m}^3/\text{s}]$$

where:

H<sub>b</sub> = significant wave height;

n<sub>b</sub> = ratio group velocity to wave propagation speed;

c<sub>b</sub> = wave propagation speed;

β<sub>b</sub> = angle of approach of waves with respect to the coastline orientation;

b = index indicating the waves at breaking point.

For some of the selected positions along the coast and for some directions of wave approach the calculation was in good agreement with the field observations. The shadow effect of the headland where the town of Brindisi is located and of Torre Mattarelle gives a large effect that was considered using the transport formulae with weighed coefficients.

### Design and its adjustments

The main purpose of the design was to stop the retreat of the coastline to the south of the power plant. This result had to be reached with a multipurpose series of works: in fact the swimming beach just south of the power plant had to assume again the bathing properties, further south the village Campo di Mare (which promenade was already interrupted) had to be protected from the sea action.

The local Authority, in order to protect effectively the coast, approved the design of six detached breakwaters which were constructed during 1991 in front of Campo di Mare village. They are situated in rather shallow water (about 3 m) and present a crest at + 2.5 m above s.w.l.. The six detached breakwaters were designed to take overtopping only during severe wave conditions. These protection works were chosen to give to inhabitants an impressive idea of safety. Moreover, the local Authority approved the design of three big groynes (which length is about 85 m) that were constructed just south of the swimming beach with an inter-distance between two groynes of about 700 m. The groynes reach -2.0 m water depth and present a crest at +2.5 m above s.w.l..

The design considers a nourishing initial material supply:

- 50,000 m<sup>3</sup> just SE of the ENEL power plant (swimming beach);
- 30,000 m<sup>3</sup> together with the three big groynes south of the swimming beach;
- 50,000 m<sup>3</sup> together with the construction of three small groynes (reaching -1.0 m water depth) just N of Campo di Mare. The three small groynes should have the effect of a hinge between the six detached breakwaters and the big groynes.
- a maintenance sand supply of 20,000 m<sup>3</sup> as an average yearly volume.

Together with the construction of the two last detached breakwaters the nourishment of the swimming beach and the construction of the first one of the three big groynes were started. As nourishing material a mixture has been adopted:

- 40 % material with  $D_{50} = 0.26$  mm;
- 60 % material with  $D_{50} = 5.00$  mm.

The nourishing material is composed of 40 % material having a characteristic diameter even smaller than the natural one ( $D_{50} = 0.3$  mm) from the cliff erosion. The net longshore transport brings a large part of the smaller part of the supplied material to the south together with the natural one.

Nowaday a total of 24,000 m<sup>3</sup> material has been placed to re-create the swimming beach; 6,000 m<sup>3</sup> material has been placed south of each of the 3 big groynes.

### Monitoring programme

To assess how well the project performed the desired function and to optimize the nourishment time schedule, an extensive monitoring programme consisting of bathymetric records normal to the coast and tide level measurements has been initiated. The monitoring consists of 26 bathymetric sections extending to a water depth of 10 m, photographs taken from the sea towards the coast at certain months throughout every year. Informations from the monitoring suggested that a slow supply of sand should be arranged.

The three big groynes do not give a satisfactory defence; in fact, some parts of the coastline are still subjected to retreat. This, probably, is due to the too large interdistance between two groynes. Therefore, the construction of some smaller extra groynes is not excluded; the material for their construction could be get removing stones from the too high crest of the existing groynes.

A massive accumulation of sand behind the six detached breakwaters and an evident tendency toward a tombolo are observed (fig.6 & 7); as expected, the last offshore breakwater (measured from Torre San Gennaro) catches most of the longshore sediment transport. During last winter 6,000 m<sup>3</sup> of naturally stored sand were removed and placed close to the headland Torre San Gennaro. After a few weeks that large amount of sand was lost.

An extra intervention for Torre S. Gennaro headland was necessary in order to protect some private houses; the protection works consisted of a seawall with 1÷2 t rock stones and were carried out during autumn 1992.

The first from the North of the three small groynes was built (completed in November 1992, 56 m long, fig. 8). The proposed construction of the two remaining small groynes (together with 50,000 m<sup>3</sup> material supply) is under discussion: these works will be probably omitted. The common idea is to spend some more time observing the behaviour of the coastline.

### Conclusions

This paper tries to emphasize that the design of a large plant along a sandy coastline requires a very attentive design phase for the maritime works. The design should be verified basing also on physical model tests. Sometime, attention during the design phase helps to save future efforts, which are needed to avoid not expected effects. Even if with large tolerance, nowadays, specialized coastal engineers can successfully foresee the coastline development with or without any human intervention. A monitoring programme assists the designer in defining a nourishing time schedule and in a better understanding of the error for the rates of erosion from the not perfect comparability of the surveys.

## CHAPTER 261

### Sandy Beach Stabilization: Preservation of Shirarahama Beach, Wakayama

Yoshito Tsuchiya, M. ASCE<sup>1</sup>, Yoshiaki Kawata, M. ASCE<sup>2</sup>, Takao Yamashita<sup>3</sup>,  
Teruo Shibano<sup>4</sup>, Masahiko Kawasaki<sup>5</sup>, and Shin Habara<sup>6</sup>

#### Abstract

It is recognized that beach erosion has become a major problem in many countries of the world, but especially in Japan in relation to human activities such as development of coastal areas and river basins. Shirarahama beach in Wakayama facing the Pacific Ocean is a typical pocket beach, but due to preservation of the beach by headlands was proposed. The methodology has shown a very good result in making the beach recovered as preservation of the beach by headlands was proposed. The methodology has shown a very good result in making the beach recovered as a stable sandy beach.

#### Introduction

Recently, beach erosion problems have been remarkable in many countries of the world, but especially in Japan due to development of river basins and coastal areas. Many countermeasures have been attempted for preventing the beaches from severe erosion. It has been learnt from the experiences that no possibility of stabilizing the beaches can be expected, but they have only changed to man-made beaches covered with a great number of concrete units. It is therefore suggested in establishing a methodology for beach erosion control that the long-term characteristics of beach processes in the whole area of the beach must be investigated. Recently, nature-learned ideas have been employed gradually in the preservation and stabilization of such sandy beaches.

Wakayama Prefecture, Wakayama 640

In this paper, a methodology for beach erosion control by headlands is proposed for stabilizing a pocket sandy beach which has gradually be eroded due to current urbanization of its hinterland. As seen in Figure 1, Shirarahama beach which is located in Kanayama bay facing the Pacific Ocean is a typical pocket beach consisted of white

(a) Location and sediment source area (b) Survey lines of beach width  
Figure 1. Shirarahama beach in Shirahama-cho, Wakayama and its sediment source area

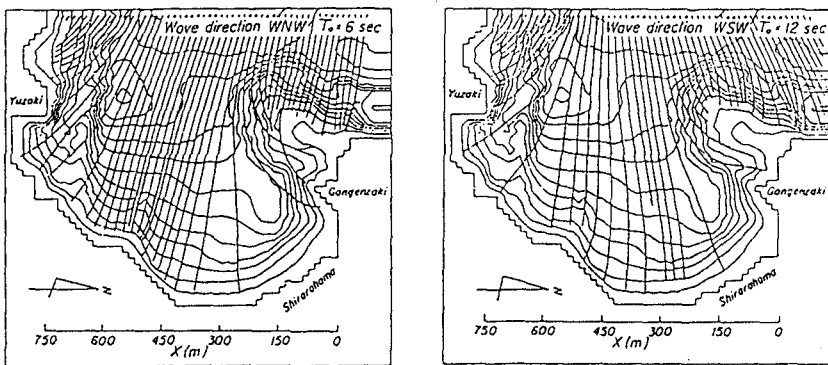

sand, but as sediment input from the hinterland has decreased due to its current urbanization the shoreline has very gradually retreated. Additionally, the area of Shirahama-cho is one of the most famous hot spring resort areas in Japan, so the local government of Wakayama Prefecture has planned to recover the beach by stabilizing and expanding it as possible. Observations of wave, current and shoreline change and field survey of beach and offshore sediment had been carried out since 1976. Numerical predictions of wave transformation, nearshore currents and shoreline change in the beach were also made. It is concluded that the beach has been so well maintained naturally by the sediment source of white sand through the Teratani river, and that it is formed well as a typical sandy pocket beach which had been stable for a long time. Recently, due to lack of the sediment source from the river the shoreline has very gradually retreated, but it is not so severe beach erosion. Based on the characteristics of the pocket beach naturally formed, a methodology for stabilizing the sandy beach by making a stable sandy beach formed by headlands is proposed, and its applicability was examined by physical experiments. After finding the most cooperative condition of two headlands in producing a stable sandy beach by the experiments, the arrangement of the headlands was made. After the construction of headlands, beach nourishment was partly made between the headlands along the original sandy beach, and now being done. It can be concluded at the present stage that a sandy beach is now being formed well and approaching a stable sandy beach between the headlands which was predicted by physical experiments.

Characteristics of Winds and Waves

In the area of Shirarahama beach, there exist two frequent winds which are due to monsoons in winter season and typhoons in summer season, respectively. Monsoon winds are mainly from NW directions from November to February in the next year, and W direction from March to April. Typhoon winds are subjected to typhoon tracks. Therefore there exist two predominant waves; they are monsoon waves from the NNW and NW directions and typhoon waves from the S and WSW directions, respectively. The monsoon waves are 6 to 8 sec in significant wave periods and up to 5 m in significant wave height in deep water, but more frequent than the typhoon waves of which the wave periods are 10 to 14 sec and the significant wave heights are 5 to 6 m frequently and up to about 8 m in deep water.

The wave refraction diagrams for the monsoon and typhoon waves are shown in Figure 2 where the wave periods and directions are assumed as 6 sec and 14 sec, and NW and WSW for the monsoon and typhoon waves respectively. In the figure, the upper and lower figures deal with wider and narrower areas in the wave refraction areas. It was concluded from the wave refraction that both the monsoon and typhoon waves are coming onto the rocky shore which surrounds the beach obliquely, but the shoreline of the sandy beach normally which is located at the end of Kanayama bay. This fact may explain why the sandy beach is formed naturally well as a pocket beach.

(a) In the case of monsoon waves

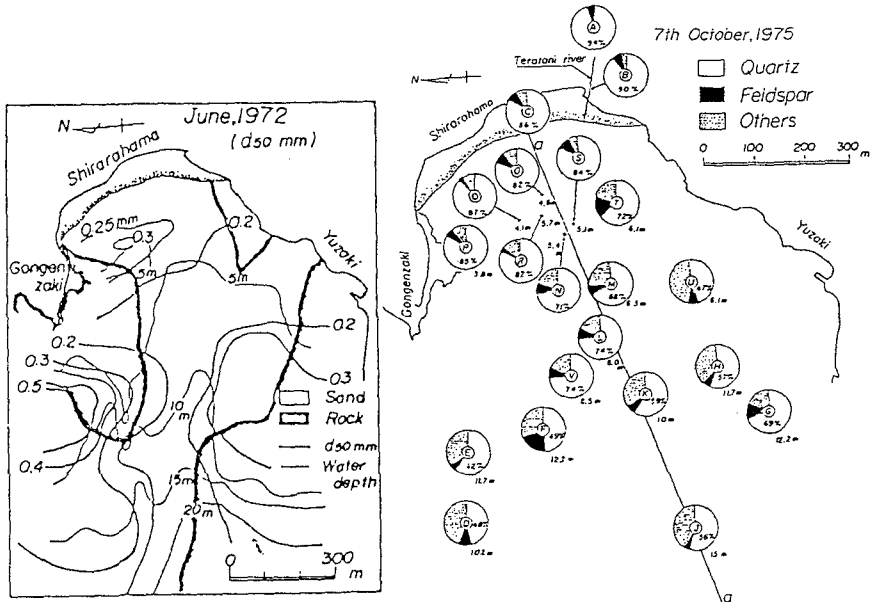

(b) In the case of typhoon waves

Figure 2. Wave refraction diagrams of monsoon and typhoon waves in Kanayama bay

Additionally, the tidal range is about 2.0 m due to semi-diurnal tide. The storm surge was recorded over 1 m in 1961 due to Daini-Muroto typhoon, and the area of sediment sources in the hinterland of the beach has been shown in Figure 1, the main sediment sources

As the area of sediment sources in the hinterland of the beach has been shown in Figure 1, the main sediment sources were due to sediment input from the Teratani river and the area shaded in the figure about twenty years ago. The distribution of mineral composition of sediment on and off Shirarahama beach and Kanayama bay is shown in Figure 3 (a) where the mineral composition is classified by quartz, feldspars and

As the area of sediment sources in the hinterland of the beach has been shown in Figure 1, the main sediment sources were due to sediment input from the Teratani river and the area shaded in the figure about twenty years ago. The distribution of mineral composition of sediment on and off Shirarahama beach and Kanayama bay is shown in Figure 3 (a) where the mineral composition is classified by quartz, feldspars and

(a) Median diameter of sediment (b) Mineral composition of sediment  
 Figure 3. Distribution of median diameter and mineral composition of sediment on and off Shirarahama beach and in Kanayama bay

others which are mainly shell, respectively. The result of mineral composition can explain the sediment sources. The sediment input was a very little from the river, but since then no sediment input can be observed due to development of the hinterland. This fact is only the cause for gradual beach erosion. The distribution of median size of bottom sediment in Kanayama bay is shown in Figure 3 (b) where the depth contours are also shown. It is noted that the sediment of white sand is only on the narrow areas of sea bottom and the beach.

Shoreline Change: Seasonal and Abnormal Changes

Shoreline change in the beach was observed both by direct measurement and aerial photographs to find its seasonal and abnormal changes. Due to monsoon and typhoon waves of which the wave directions are mainly NW and SSW, respectively, the seasonal shoreline change exists as shown in Figure 4 where the beach widths  $w_N$  and  $w_S$ , and  $B_N$  and  $B_S$  are the beach widths defined as shown in Figure 1 (b), the suffixes indicate those near the northern and southern ends, respectively and their ratios are used for seasonal change. The shoreline change for a period of ten years from 1972 is shown in Figure 5. It is recognized that the shoreline has retreated very gradually, and that the abnormal change has taken place sometimes, but the maximum retreat was within 20m and soon recovered. In the case of typhoon the shoreline intends to result in a little accretion near the north end, but retreat near the south end of the beach. Contrarily, in the case of monsoon the shoreline intends to retreat a little near the south

end and to do accretion near the north end. It is however noticed that the sandy beach is nearly in equilibrium even fluctuating a little during the periods of typhoon and monsoon because the incident waves are normally approaching the sandy beach to produce no effective longshore sediment transport in changing the curved beach.

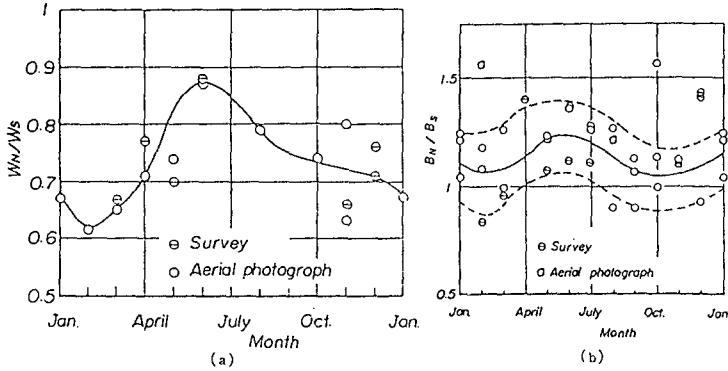

Figure 4. Seasonal change in beach width in terms of beach width ratios on survey lines shown in Figure 1(b)

Figure 5. Shoreline changes between 1972 and 1982 in Shirarahama beach

As previously described, beach change in Shirarahama is also due to strong winds resulting in blown sand in spring season. Strong, but dry winds blow from the NW direction and blown sand takes place on the sandy beach to result in beach change as shown in Figure 6 where the erosive and depositional areas are shown in the periods specified. It is recognized from the results that the northern area is eroded, but eroded sediment is deposited in the southern area. The sandy beach intends to be tilted from the northern to southern ends.

Figure 6. Beach change by blown sand in spring season

#### Longshore Distribution of Wave Power and Prediction of Shoreline Change

In order to investigate the longshore distribution of longshore sediment transport along Shirarahama beach, the wave power which is actually proportional to the rate of longshore sediment transport is employed. By use of wave data for seven years between April in 1970 and March in 1976 at Susami Fishery Harbor which is located about 20 km south from the beach, the longshore distribution of wave power along the beach was calculated. Figure 7 shows the longshore distributions of annual and seasonal wave power along the beach. This figure clearly describes that in the central part of the beach the wave power is nearly vanished, but near the northern end it takes a null point where it increases in the direction of positive wave power north and in the direction of negative wave power south, and near the southern end of the beach it is also vanished, but it takes a null point too where it decreases in the direction of positive wave power south and in the direction of negative wave power north. It is therefore mentioned that at the northern end the beach intends to be eroded, but fortunately no longshore sediment in the northern direction behind Gongenzaki headland which is curved concave may result in no severe retreat of shoreline, and at the southern end the beach intends to accumulate sediment due to both positive and negative wave power in their directions. Due to the positive wave power in the southern area from the null point where the Teratani river is flowing into a little north, white sand as only sediment sources from the river is transported within the beach. In the longshore distributions of seasonal wave power, in summer season (typhoon season) the wave power becomes nearly vanished in almost the beach, but only near the northern end beach change may take place to result in shoreline accretion. This may explain the shoreline change due to typhoon waves. Contrarily, in the winter season (monsoon season) the longshore distribution of wave power is quite similar to the annual one so that the tendency in shoreline change may be similar to the annual change as previously discussed. Near the northern end the wave power may result in to accumulate sediment, but it may tend to retreat shoreline. This tendency may

Figure 7. Longshore distribution of annual and seasonal wave power

(a) Wave power distribution (b) Shoreline change predicted

Figure 8. Longshore distributions of wave power generated by Typhoon 8013 along the beach and predicted results of shoreline change

support the shoreline change clearly due to monsoon waves. It can therefore be recognized from these circumstances that the sandy beach is a typical pocket beach naturally well-formed between Yuzaki and Gongenzaki rocky headlands.

Figure 8 (a), as an example, shows the longshore distribution of wave power which is generated by Typhoon 8013 where the tidal levels are shown in T.P. and observed one, and the area of the sandy beach is specified by arrows A and B respectively in the southern and northern ends. Near the northern end it tends to accumulate sediment a little, but near the southern end it shows to result in some rates of longshore sediment transport in the southern direction. The changes in wave power by the typhoons by which the maximum significant wave height of about 7 m in deep water were calculated. By use of the wave power the shoreline changes by the typhoon were

calculated by one line theory of shoreline change prediction as shown in Figure 8 (b) where the threshold water depth in the sand drift zone was assumed as 7 m. The figure shows that only a little shoreline change takes place by typhoons, but the longshore tendency of shoreline change near the southern end is a little different from those in Figure 2, probably due to sediment input from the neighboring rocky shores where no longshore sediment transport exists actually. The duration of the longshore sediment transport in the northern direction was short say about 10 hrs., but no remarkable shoreline change was observed. It is concluded again from the shoreline change that this sandy beach has been in the table condition as a typical pocket beach.

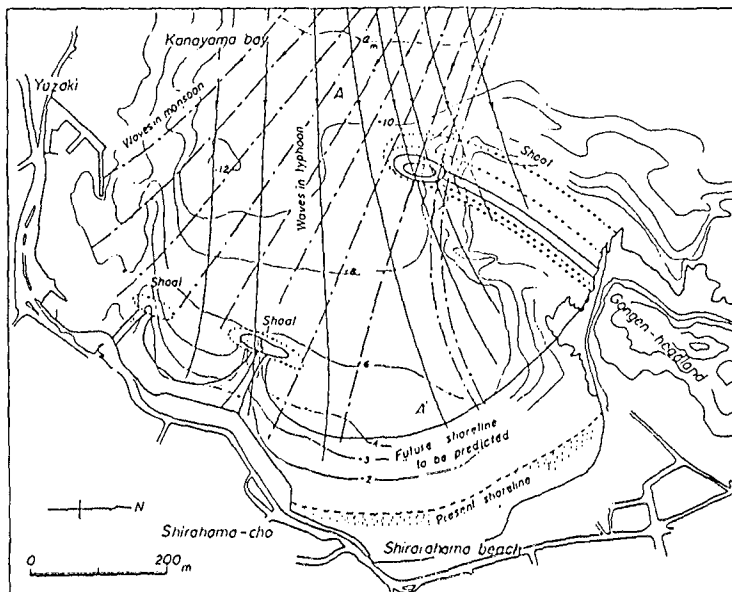

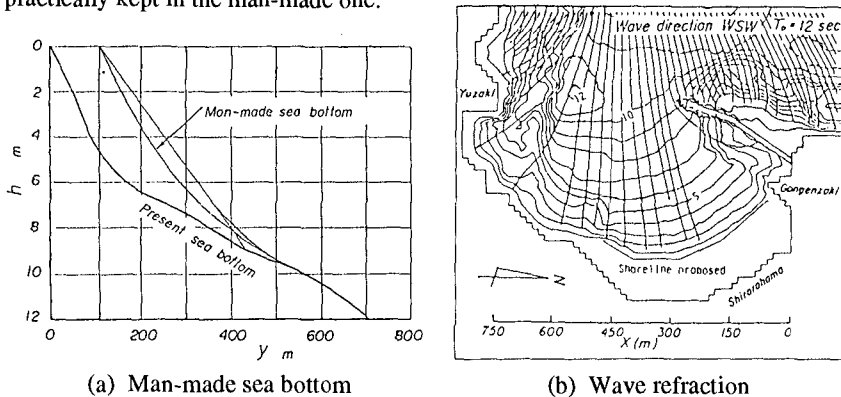

Figure 9. Methodology for preservation of Shirarahama beach by headlands

Additionally, numerical calculations were made to predict nearshore currents by monsoon and typhoon respectively, and drift currents by strong winds during monsoon and typhoon. It was found that a little nearshore circulation exists both in the cases of monsoon and typhoon, but northern drift currents exist by NW wind in monsoon and opposite currents exist by SW wind in typhoon.

#### Methodology for Beach Preservation by Headlands

Based on the natural circumstances of Shirarahama beach as a well-formed pocket beach and their stability, a methodology for preservation must be proposed. Expanding the beach width about fifty meters offshore for utilization of the beach as marine resort, the sandy beach must be stabilized. The main items in the methodology are 1) a couple of stable sandy beaches are formed as shown in Figure 9. By extending Gongenzaki headland about forty meters in under water, the monsoon and typhoon

waves are controlled to reduce their heights effectively and to make a stable sandy beach formed, and constructing a couple of headlands of T-shaped groins, the waves are also controlled to make sandy beaches formed as tombolos. 2) In order to make stable sandy beaches formed between them, sandy beaches to be formed must be cooperated naturally and dynamically to result in a couple of well-formed stable sandy beaches as pocket beaches. The necessary conditions are verified experimentally. And 3) for marine resort the water mixing in the bay as well as the beach are promoted by tides and incident waves. As previously discussed, the incident waves are approaching the present beach nearly normally. This circumstances of wave incidence must be introduced in the formation of stable sandy beaches. The present beach profiles near Gongenzaki headland are reformed as shown in Figure 10 (a). The incident waves are refracted by the man-made sea bottom to approach the beach nearly normally, as shown in Figure 10 (b). Figure 11 shows changes in breaker height at the present and man-made bottom topography by which the present circumstances of wave refraction is practically kept in the man-made one.

 Figure 11. Comparison between breaker heights on present and man-made bottom topography

Experimental Verification on Formation of Stable Sandy Beaches by Headlands

Physical model experiments of which the experimental setup is shown in Figure 12 were carried out by use of the similitude for beach change by Tsuchiya and Itoh (1981)

in nondistorted model with a horizontal and vertical scale of 1/64 and experimental fine sand with a median size of 0.021 cm and specific gravity of 2.65, respectively. Experimental waves are typhoon and monsoon waves from NW and WSW directions of which the periods are 0.75 and 1.30 sec, respectively. By operating a wave generator of monochromatic waves over 800 hrs in total, fifteen runs were performed in various conditions to find the applicability of the proposed methodology and the most effective lengths of headlands in cooperating sandy beaches to be formed between them as stable sandy beaches. In the experiments, waves and nearshore currents in the beach were also examined experimentally to find characteristics of wave transformation and mixing in nearshore currents. Measured data of waves and currents

Figure 12. Experimental setup for verification of formation of stable sandy beaches

were compared with their numerical predictions with fairly good agreement. By use of the man-made topography near Gongenzaki headland, wave transformation in the beach were measured to find the efficiency in wave refraction. Additionally, submerged breakwaters for interrupting offshore sediment transport in the beach were examined. The main results of the experiments can be summarized as:

- 1) Reproduction of the formation of present sandy beach was successfully made in the physical model. It was experimentally verified that the beach is really a stable sandy beach as a pocket beach formed well naturally both by Yuzaki and Gongenzaki headlands in relation to the action of monsoon and typhoon waves.
- 2) Shoreline changes in the cases of headlands used were made experimentally. Some of the experimental results in finding the most suitable arrangement of headlands are shown in Figure 13 where the experimental runs are shown, but the detail are omitted. It was concluded that the necessary extending length of Gongenzaki headland by which a stable sandy beach is formed well was determined as about 30 m, and that the other headland should be made as a T-shaped groin being a small island or shoal by which a stable sandy beach is well formed.
- 3) The efficiency of man-made bottom topography for wave refraction and a submerged breakwater as a barrier for interrupting offshore sediment transport were examined experimentally as shown in Figure 14 where the man-made bottom is shown by shaded area in (a) and the barrier is located in the central area of Kanayama bay as shown in (b). It was concluded that the man-made bottom topography is practically

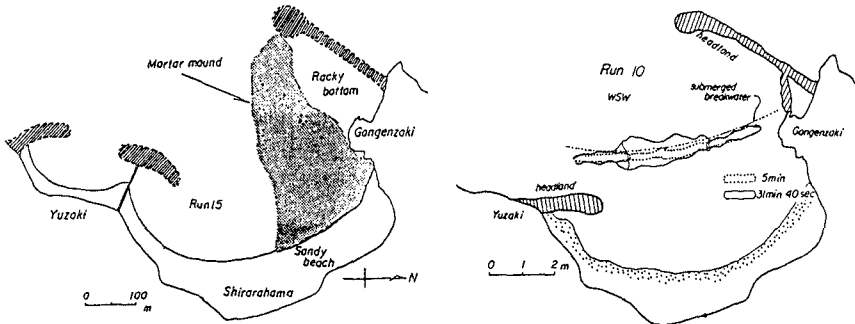

Figure 13. Shoreline changes in the cases of T-shaped groin and inclined groin, and Gogenzaki headland extended about 40 m under water

(a) Bottom topography

(b) Distribution of fluorescent sand

Figure 14. Man-made bottom topography for wave refraction and distribution of fluorescent sand around submerged breakwater as barrier

(a) Impractical beach nourishment (b) Adequate beach nourishment

Figure 15. Shoreline changes in the cases of impractical and adequate beach nourishment in formation of stable sandy beach

effective to make the incident wave refracted to approach normally the beach resulting in a stable sandy beach. It was however noted that the barrier is effective to interrupt

offshore sediment transport, but once sediment has been transported offshore the barrier the sediment can not be transported again onshore through the barrier. It was therefore suggested that such a barrier is not so effective in the formation of stable sandy beaches.

4) The total volume of beach nourishment was experimentally examined in the formation of stable sandy beach by the headlands. As shown in Figure 15 (a), after impractical beach nourishment a stable sandy beach can not be formed well especially near the southern headland of T-shaped groin, and after adequate beach nourishment a stable sandy beach can be well formed as shown in (b). As schematically shown in Figure 16, the formation condition of a stable sandy beach between the headlands can be explained as: By Gongenzaki headland extended, a curved sandy beach is formed

Figure 16. Formation condition of stable sandy beach by headlands

(a) Before beach nourishment (b) After beach nourishment

Figure 17. Examples of nearshore current patterns in stable sandy beach formed by headlands

as A in the figure, but the southern end of the beach extends south. Another sandy beach is formed by the headland of T-shaped groin as shown by B, but the northern

end may extends north. When the two sandy beaches are cooperated by which the southern and northern ends of the beaches must be well-continued smoothly, a stable sandy beach can be well-formed between the headlands.

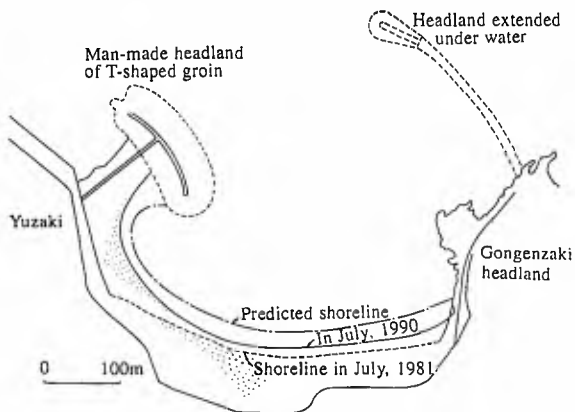

Figure 18. Predicted shoreline of stable sandy beach to be formed by Gongenzaki headland extended and headland of T-shaped groin in Shirarahama beach after adequate beach nourishment and present shorelines after beach nourishment as of 1990

5) Spatial distributions of wave height and current were compared with their numerical results. The comparison was satisfactorily made, and showed that, as shown in Figure 17 for example, mixing phenomena in nearshore current take place due to waves. Based on the experimental verification of the formation of a stable sandy beach, the

Photo. 1. Present aerial view of stable sandy beach being newly formed in Shirarahama beach after beach nourishment as of 1991

shoreline in the formation of stable sandy beach by extending the present shoreline about 50 m offshore is predicted as shown in Figure 18.

#### Construction of Headlands and Beach Nourishment

In 1983 Gongenzaki headland was extended about 40 m, and the headland of T-shaped groin was constructed in 1987. After the construction of the headlands beach nourishment have been made by using nearly same material imported as the original white sand. The total volume of nourished sand is 35,000 m<sup>3</sup> as of 1990. Shorelines along the beach have been measured. In Figure 18, the recent shorelines are shown in comparison with the predicted one. Photo.1 shows the present situation of the newly formed sandy beach between the headlands. The further beach nourishment is needed for the final formation of a stable sandy beach between the headlands, but the shoreline configuration is quite similar to the predicted one.

#### Conclusion

Based on the natural circumstance of Shirarahama beach a methodology of beach preservation by headlands was proposed. The two headlands were constructed and extended, and beach nourishment has being made, but the shoreline configuration has being approaching the predicted final shoreline of a stable sandy beach between the headlands well. It is therefore concluded that the proposed methodology for preservation of Shirarahama beach by headlands could be applied satisfactorily in the formation of a stable sandy beach.

This investigation was partly supported by Grant-in-Aids for Scientific Research, from the Ministry of Education, Science and Culture of Japan, under Grant No. 03452212.

## CHAPTER 262

### Wave Power Conversion by a Prototype Wave Power Extracting Caisson in Sakata Port

Shigeo TAKAHASHI\*, Hiroaki NAKADA\*\*, Hideaki OHNEDA\*\*\*, and Masazumi SHIKAMORI\*\*\*\*.

#### 1. INTRODUCTION

Ocean wave energy is clean and inexhaustible. Repeated oil crises and the urgent need for environmental preservation on a global scale have made utilization of ocean wave energy increasingly important.

The Japanese Ministry of Transport has been developing a wave power extracting caisson breakwater which can absorb wave power and convert it into electric power. The breakwater shown in Fig.1 is a composite breakwater with a special caisson for absorption and conversion of wave power. The caisson has a so-called air chamber where wave power is converted into air power. The air power activates a turbine-generator in the machine room on the caisson. The use of the breakwater as a wave power converter will effectively cut down the power generation cost. This breakwater also aims at the improvement of the wave resisting stability and performance as a breakwater by absorbing the wave energy.

The research and development work on the wave power converter is being carried out through collaboration by the First District Port Construction Bureau, the Port and Harbour Research Institute and the Coastal Development Institute of Technology under the

guidance of the home office of the Ministry of Transport. The Port and Harbour Research Institute had conducted basic research for five years since 1982<sup>1)2)3)4)</sup>. The 1st District Port Construction Bureau, Ministry of Transport, began a field verification experiment for the breakwater from 1987 in the form of a joint study with the Coastal Development Institute of Technology and twenty private companies. A test breakwater was constructed in the summer of 1989 at Sakata Port in Yamagata Prefecture<sup>5)6)7)</sup>. The breakwater began the power generation in the winter of 1989. Photo 1 shows the wave action on the completed caisson and Photo 2 shows the on-land observation house and a tower illuminated by the converted energy.

The field experiments were conducted for the five years from fiscal 1987 through fiscal 1991 aiming at the following items:

- 1) to confirm the design method of the breakwater caisson including the air chamber against wave forces,
- 2) to verify the design method of the air chamber, turbine and generator as a wave energy converter,
- 3) to study methods of constructing the breakwater
- 4) and also to demonstrate utilization of the power output for various uses.

Figure 2 Energy Conversion Process

This paper introduces the system with a wave power extracting caisson in the field experiment and the results of the field experiment, especially on the wave power conversion.

## 2. POWER CONVERSION BY THE CAISSON AND TURBINE GENERATOR

Figure 2 shows the power conversion process by the wave power extracting caisson and its turbine generator. The wave power is converted first into air power in the air chamber, then into turbine power by the turbine and finally into electric power by the generator as follows:

- 1)  $W_i$  denotes the incident wave power which can be obtained from the wave spectrum. The incident wave power is the energy rate which the incident wave transports in an unit time and length.  $W_{iin}$  represents the wave power going into one caisson.
- 2)  $W_a$  denotes the air power converted from wave power in the air chamber, which can be estimated by the vertical speed of water surface movement and the air pressure in the air chamber and the horizontal area of the air chamber. The conversion efficiency  $EFF_a$  from wave power to air power is given by  $W_a/W_{iin}$ . The efficiency depends on the ratio of the air chamber width  $B$  to the wavelength  $L_{1/3}$ , and the turbine diameter  $R_t$  (actually the total area of turbine opening and valve openings, etc.). The conversion efficiency also varies with submerged depth  $d_c$  of the curtain wall of the front wall of the air chamber and the height  $D_0$  of the air chamber<sup>1)2)</sup>. For example, the air chamber width is 13% the wavelength of a wave of 7 s to obtain a high conversion efficiency with a small width as much as possible.
- 3)  $W_{aout}$  represents the wave power released to the atmosphere from control valves and dummy nozzles, while  $W_{at}$  represents the air power into the turbine. The sum of  $W_{aout}$  and  $W_{at}$  equals to the

air power  $W_a$ . The ratio  $W_{at}/W_a$  is defined here as the utilization rate  $E_{ta}$  of air power. The utilization rate of the air power in the system of the experiment is always less than 0.5 because of the existence of the dummy nozzles as will be described in Chapter 3.

- 4)  $W_t$  represents the turbine power which can be obtained from the turbine torque and the rotation speed. The conversion efficiency  $EFF_t$  is given as the ratio  $W_t/W_{at}$ . The fundamental characteristics of the turbine including the turbine efficiency can be obtained from steady wind tests. The turbine efficiency varies with the attacking angle of wind to the turbine blade, and therefore the turbine speed should be controlled to bring a high conversion efficiency <sup>2</sup>.
- 5)  $W_g$  denotes the electric power which can be evaluated by the electric voltage and current. The electric current is determined by the connected electric loads and therefore the electric load should be controlled considering the turbine power. The electric load is controlled using the signal of the speed of turbine in the experiment. The turbine efficiency  $EFF_g$  is given by the ratio  $W_t/W_g$ , which is usually given from a factory test.

The speed of the turbine fluctuates with the frequency of the waves and also that of the wave group. The strength of the fluctuation depends on the inertia moment  $I_{tg}$  of the turbine generator.

- 6) The conversion efficiency  $EFF_{atg}$  from wave to electric power is indicated as the product of  $EFF_a$ ,  $EFF_t$  and  $EFF_g$ . However by the influence of the control valves and dummy nozzles, the actual conversion efficiency  $EFF_{atgo}$  decreases to  $EFF_{atg} \times E_{ta}$ .

### 3. WAVE POWER EXTRACTING CAISSON IN THE EXPERIMENT

#### 3.1 Design of Wave Power Conversion System

A caisson of the Second North breakwater of Sakata Port is used for verification experiments, as shown in Fig. 3. The breakwater is

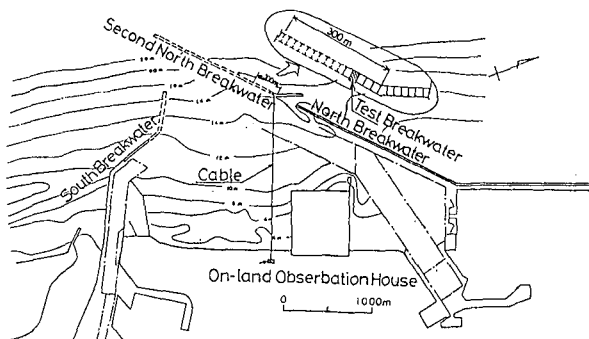

Figure 3 Location Map of Sakata Port

now under construction as a composite breakwater, with a planned length of 1,900 m. The depth of the water is 18 m at the construction site. The sea bottom foundation is mostly sandy with viscous soil in some places. A settlement of the caisson of about 1 m is predicted.

In designing a wave energy converting system, it is necessary to know the wave power available in the designed places and to determine the use of the converted energy. Then the frame plan of the system can be established. The fundamental dimensions of the components of the system such as the diameter of the turbine are determined based on the frame plan. Finally, the components are designed in detail.

Wave data at Sakata Port for about twenty years were analyzed to find the wave conditions there<sup>4</sup>). The system was designed to operate for the waves of 1 to 5 m, and the wave with  $H_{1/3} = 2.2$  m and  $T_{1/3} = 7$  s was selected as a main wave to discuss the conversion efficiencies. However, the design wave for the stability of the air chamber and other devices is  $H_{1/3} = 10.2$  m and  $T_{1/3} = 14.5$  s. Numerical calculations based on the thermodynamics and wave-kinematics theory<sup>123</sup> were conducted to determine the fundamental dimensions of the components of the system.

The wave power extracting caisson has an air chamber of 7 m wide as shown in Fig. 4. The caisson is 20 m long in the direction of the breakwater alignment line. The height is +12.5 m above the datum level level. The horizontal area is 115 m<sup>2</sup>, not including the thickness of the walls.

Figure 5 shows a concept of the machine room. The air flow converts its energy into the kinetic energy by rotating the turbines and the generator shown in Fig. 6, installed at the center of the machine room in the upper portion of the caisson. Two Wells turbines 1,337 m in diameter are employed to get a one-way rotation from the reciprocal flow of the air and sandwich the generator to make a tandem type arrangement canceling the forces

Figure 4 Shape of the Caisson Breakwater

Figure 5 Conceptual View of the Machine Room

Figure 6 Turbine and Generator

that work in the axial direction of the turbines. The generator is a 200 V synchronous generator with a rated output of 60 kW and a maximum revolution of 3,000 rpm.

The protection devices that control the air flow from the air chamber to the turbine consist of three types of valves: the air-flow regulating valve (bypass valve), the pressure release valve and the emergency cutoff valve. Figure 7 shows the air-flow regulating valve. The valve is of a rectangular box with a butterfly valve inside. The air flow can be controlled by the rotation of the butterfly valve. An electric actuator is equipped to rotate the butterfly valve according to the signal of the turbine speed. The valve closes the opening by 1/4 of the full rotation angle when the turbine speed exceeds a certain limit (simultaneously the valve opens the other opening to release the extra air power. If the turbine speed exceeds again the limit, the valve closes the opening again by one more 1/4 of the full angle. When the turbine speed becomes lower than a certain value the valve opens the opening by every 1/4. Power generation is stopped when waves are extremely

large (when the significant wave height is above 5 m) by terminating the air flow to the turbine and simultaneously fully opening the air flow regulating valve.

It should be noted that the diameter of the turbine in the experiments is set to be much smaller than that of the optimum turbine predicted by the amount of air power from the air chamber. This is because of the limitation of research funds. Two dummy nozzles are installed to release the extra air power, which corresponds to almost half of the total air power.

The power generated is transmitted to the on-land observation station through an underwater cable, where it is consumed by electric resistors. Experiments are also being made to utilize the electric power for various appliances to prepare for the application of the system for actual use.

Figure 7 Air-flow Regulating Valve

### 3.2 Operation of the system

The power conversion of the system can be adjusted by changing the setting of the electric load against turbine speed, the threshold pressure of the pressure release valves, and the threshold turbine speed to open/close the air-flow regulating valves.

The system started the power generation from December 1st, 1989. In fiscal 1989, the system was operated rather discreetly under Setting I, while in fiscal 1990, experiments were conducted under Setting III for the optimized control method to generate larger amount of electric power. In the setting III, the electric load is proportional to the 3rd power of the turbine speed and the electric power is 60 kW when the turbine speed is 1800 rpm. The threshold pressures of the two pressure release valves are 1.34 and 1.61  $\text{tf}/\text{m}^2$ , and the air flow regulating valve is controlled to open one step (1/4) at 2000 rpm and to close one step (1/4) at 1700 rpm in the setting III. The results of power conversion with the setting III is described in this report.

Table 1 summarizes the dimensions of the conversion system in the experiment, where  $A_t$ ,  $A_p$ , and  $A_n$  denote the opening area of the turbine, the dummy nozzle, the pressure release valve,

Table 1 Experimental system and Full-size System

respectively,  $C_{dv}$  is contraction coefficient,  $\varepsilon$  is opening ratio of each opening,  $P_{prv}$  is threshold pressure of the pressure release valve. In the table, the dimensions of the full-size system is also listed which will be discussed later.

### 3.3 Measurement

A number of sensors are incorporated in the caisson and the power generating system to make measurements in the following four categories.

- (1) Wave conditions (directional spectrum, heights, periods and directions of incident waves)
- (2) Stability of the breakwater (wave pressure and air pressure)
- (3) Stability of the wall members (stress of the reinforcement)
- (4) Air output and power output (water level and pressure in the air chamber, turbine speed, power output)

Data are amplified and converted into optical signals before they are sent by an opto-electric power combination cable to the observation station on land, where they are analyzed and processed using four personal computers. In addition to the above procedure, detailed data are sampled and stored in a digital recorder, for 20 minutes at one operation, for further analysis of the breakwater stability. However, only the data concerning with the incident waves and the power conversion are discussed in this report.

## 4. OBSERVED WAVES

Figure 8 Variation of Significant Wave and Wave Power

Figure 9 Incident Wave Power

Figure 8 shows the wave data from October 1990 to March 1991. The significant wave height and period, mean wave direction and wave power are shown in the figure. The average significant wave height and period were 1.72 m and 6.2 s, and the average wave power was 13.9 kW/m during this period. The wave height varies very widely and exceeds 5 m several times. The largest value of the significant wave height reached 8.67 m on December 2, 1991. The mean wave direction was usually northwest, which is almost perpendicular to the breakwater alignment. The wave power varies significantly and exceeds even 100 kW/m.

Figure 9 shows the measured and calculated incident wave power. The calculated power is obtained from a standard wave spectrum which was used in the design of the system. For example the calculated incident wave power becomes 18 kW/m at  $H_{1/3} = 2.2$  m and is 67 kW/m at  $H_{1/3} = 4$  m when the mean incident wave angle is 0 degree. The measured values agree well with the calculated ones.

The wave power can be estimated easily by the following formula with significant wave height  $H_{1/3}$  and period  $T_{1/3}$ .

$$W_i = \kappa H_{1/3}^2 T_{1/3} \quad (\text{kW/m}) \tag{1}$$

where,  $\kappa_w$  is 0.4 - 0.5 (kW/m<sup>3</sup>/s) in Sakata. Which is almost equal to the expected value in the preliminary studies<sup>4</sup>). It was also found that the wave power in sakata was reduced to 85 % of that for long crested waves due to directional spreading.

5. WAVE POWER CONVERSION

Figure 10 gives an example of the records of power generation, i.e., the water surface elevation and the air pressure in the air chamber, opening of the air flow regulating valve, pressure difference in the turbine and turbine speed, and power output for 20

Figure 10 Analogue Data of Wave Power Conversion

minutes, that were recorded at 14:00 on November 8 in 1990, when the significant wave height and period were 3.01 m and 7.9 s, respectively, and the incident wave power was 539 kW/20m. The turbine rotation varies from 1250rpm to 2100 rpm and the electric power varies from 20 kW to 60 kW. As the turbine speed exceeds 2000 rpm the air flow regulating valve opens to reduce the air flow to the turbine as shown in the figure. The average electric power is 36.4 kW, and the conversion efficiencies from wave power to air power, from air power to turbine power and turbine power to electric power are 0.59, 0.37 and 0.91, respectively. However, a large amount of air power is released by the dummy nozzles and valves. Therefore, the utilization rate of air power is very low ( 0.34). If all the power is used, the electric power is about 100 kW.

Table 2 shows the monthly averaged values on power conversion from October 1990 to March 1991. For example, the average incident wave power is 20.3 kW/m and average electric power is 13.25 kW/m in January 1991. The time when the electric power is small and less than 1 kW, occupies only 13 % in the month, while the time occupies 51 % in October 1990.

Figure 11 shows the variation of the electric power to the significant wave height. The electric power increases according to the increase of the wave height. However, the electric power becomes almost constant at about 55 kW where the wave height is above 4 m.

Table 2 Power Generation in Each Month

Year/Month	'90/10	'90/11	'90/12	'91/1	'91/2	'91/3
$(W_i)_{ave}$ (kW/m)	3.3	13.0	23.9	20.3	15.0	6.7
$(W_e)_{ave}$ (kW)	6.03	10.65	13.34	13.25	10.88	9.73

Figure 11 Electric Power

Figure 12 Conversion Efficiencies

This is due to the automatic control of the valves. The system can generate electric power from  $H_{1/3} = 1 \text{ m}$  to  $5 \text{ m}$  as designed. The calculated values for the normal incident waves are shown in the figure by a dotted line. The calculated values, which were used in the design of the present system, agree with the experimental ones for small wave angle. The calculation was based on the thermodynamics and wave-kinematic theory<sup>1)2)3)</sup>.

The conversion efficiencies in the experiment are shown in Fig.12. The conversion efficiency from wave to air power is from 0.4 to 0.8. The turbine efficiency is from 0.2 to 0.5. The generator efficiency is about 0.5 when the wave height is large. The total efficiency which is given by the product of  $EFF_t$ ,  $EFF_g$  and  $EFF_i$  is from 0.1 to 0.3 approximately. However this system includes the control valves and dummy nozzles so that the actual efficiency should be multiplied by the air power utilization rate.

The solid lines indicate the prediction by the thermodynamics and wave-kinematic method. The experimental values of the air power conversion efficiency are larger than the predicted values. This is because only one wave power extracting caisson is installed between the reflective caissons and therefore reflected and refracted waves from neighboring caisson can increase the incident wave power into the caisson with wave power conversion.

Figure 13 Power Generation by a Full-size System

Table 3 Prediction of Power Generation

	Unit	Sakata (one year)	Sakata (winter)	Wadamari (one year)	Kashima (one year)
Ave. Significant Wave Height	m	1.19	1.79	1.18	1.50
Ave. Significant Wave Period	s	5.64	6.40	7.13	7.88
Ave. Wave Power	kW/m	10.56	19.42	7.60	13.95
Time Rate of Power Generation	%	40.2	65.0	50.0	67.0
Ave. Electric Power	kW/20m	27.3	49.3	23.0	40.9

6. WAVE POWER CONVERSION BY A FULL-SIZE SYSTEM

The turbine-generator is small in the experiment. A full-size system with a larger turbine generator can produce the electricity more. Figure 13 shows the calculated result of the wave power conversion by a full-size system with an optimal turbine generator for the conditions in Sakata Port. The diameter of the turbine is 2.4 m, which is almost twice that in the experiment. The rated power of the generator is 200 kW. The turbine speed is expected to be 700 rpm and the electric power is 75 kW when the significant wave height is 2.2 m. The electric power becomes 200 kW when the significant wave height is 4 m.

Table 3 shows the predicted wave power conversion by a full-size system in Sakata Port, using the conversion efficiencies in Fig. 13 and the observed wave data from 1990 -1991. In the table the predicted results for Wadamari Port in Okino-erabu Island and

Kashima Port in addition to Sakata Port during only winter time are shown for comparison. The annual average electric power in Sakata Port is 27.3 kW and the average value within winter time is 49.3 kW. In Kashima Port the wave power conversion can be made for 67 % of time and the annual average electric power is 40.9 kW.

## 7. CONCLUDING REMARKS

The field experiment was conducted very successfully, although several severe storms attacked the caisson. The characteristics of the wave-activated power generation by the wave power extracting caisson were revealed and the design method of the system was confirmed in this prototype experiments.

Several tests to utilize the output electricity were also made in the experiments. It is important not only to improve the power converter but also to develop the energy utilization systems. The second stage of the field experiment was already started from April 1992, where several utilization systems including a large-scale water pumping system are to be tested and some improvements of the caisson with the turbine generator will be tested.

The field experiments were carried out under the guidance of the advisory committee chaired by professor Y. Goda. The experiments was conducted by the collaboration with many people. The authors wish to express their sincere gratitude to all the people. The authors also wish to thank Dr. Takayama for his crucial review of the manuscript.

## CHAPTER 12

### ON THE TESTING OF MODELS IN MULTIDIRECTIONAL SEAS

E.R. Funke<sup>1</sup> and E.P.D. Mansard<sup>2</sup>

#### Abstract

Although traditional model testing of marine structures in long-crested, uni-directional (2D) waves can lead to conservative results in certain applications, modern multidirectional (3D) wave generators can produce more realistic sea conditions, leading to the design of more accurate, cost-effective and safer structures. This paper justifies the requirements for testing in 3D seas.

#### Introduction

Although wave simulation has been in use for many decades, the first evolutionary step in wave generation technology started approximately 25 years ago with the simulation of long-crested, uni-directional (2D) random waves. These random waves, varying in height and period, were believed to correspond more realistically to sea states encountered in nature.

The next phase in the evolution of wave simulation techniques addressed the control of non-linear waves. These second order waves, which dominate the frequency bands, both below as well as above the first order waves can, under certain circumstances, be of considerable importance to the response of structures.

The present and possibly final phase in the development of wave generation technology is the introduction of directionality to simulation of sea states by means of wave generators whose wave boards are segmented and are able to move with a "serpentine-like" motion. These three-dimensional (3D) seas are made up of

---

Hydraulics Laboratory, National Research Council of Canada,  
Montreal Road, Ottawa, Canada, K1A 0R6

waves from several directions, and interact to create so-called short-crested seas. Although this concept has been well known for many decades, the ability to individually control, by computer, a large number of contiguous segments has become practical only over the last 15 years. This capability is now expanding very rapidly. It is estimated that there are now 32 institutes throughout the world equipped with this type of wave generator. Nevertheless, most testing of marine structures is still done by two-dimensional irregular regular or wave tests, because many certification authorities still rely on the results obtained from regular wave tests. It is also widely believed that two-dimensional wave simulations of the natural sea state lead to conservative designs, (i.e. results in forces on or motions of structures somewhat greater than in nature).

Therefore, the question arises if it is necessary to provide an expensive multidirectional wave generation capability either when planning new or upgrading existing laboratory facilities. This paper addresses this question.

### Literature Overview

There are now many research publications that compare model tests on marine structures using 2D (unidirectional) or 3D (multidirectional) wave simulation techniques. The results, however, are still somewhat unconvincing, although trends can be identified. Three of the many reasons, which may contribute to a lack of widespread support among design engineers are given below:

- Nearly all laboratories equipped with segmented wave generators for 3D capability, are either totally, or partly, committed to commercial testing work. Consequently, the results of some of the comparative tests are still proprietary to the clients and therefore have not yet been published in the open literature.
- Because multidirectional wave generation technology is relatively recent, there is still disagreement among experts on how best to achieve correct simulations [cf. Sand and Mynett (1987), Miles and Funke 1989 and Miles 1990]. It is difficult and costly to make good quality measurements of the kinematics of three-dimensional waves. In the absence of good measurements, comparisons between multidirectional waves produced in different research institutes are uncertain.
- Many multidirectional sea state simulations have used a spreading index of  $s = 1$  with a  $\cos^2(\theta)$  formulation. This represents only a very limited perspective of the large variety of conditions that may actually prevail.

The Fourier summation technique of wave synthesis is considered to be one of the more satisfactory methods. There are many versions of this method, which would generally lead to similar results if very long wave simulation records were used. However, for scaled physical model studies, the simulations are generally limited to shorter test periods. As a result, several of these currently used synthesis

methods can lead to significant variations in variance and spectral energy distribution, both spatially and temporally. Only the so-called "single summation method", if used over a complete recycling period, will avoid this problem. On the other hand, the single summation method (Miles 1989) also has several variants, some of which may affect the outcome of the test results.

Table 1 summarizes some of the currently available literature on comparative tests between two-dimensional and three-dimensional wave simulations.

### Discussion

The following are a few highlights of the research tabulated in Table 1.

Figure 1a describes the model set-up for the work carried out by Mynett, Bosma and van Vliet (1984). In this study wave loading on a simple, relatively long wave barrier was investigated. The barrier represented a partially submerged gate with 44% immersion and supported by two piers. The barrier was tested to investigate the effect of relative structure-length on wave loading, using both long-crested and short-crested waves.

Figure 1b gives the measured normalized horizontal forces as a function of  $kl$  (*the wave number multiplied by the barrier length*), and compares these to numerical model predictions according to Battjes (1982). When  $s = \infty$ , the spreading function is a spike function, and consequently the sea state is virtually long-crested. On the other hand, for  $s = 1$ , the sea state is short-crested with a broad spreading function [ $\cos^2(\theta)$ ]. As could be expected, a longer barrier is more sensitive to the effects of wave multidirectionality.

As a second example, Figure 2a illustrates a vessel restrained by a single point SALMRA mooring system (Single Anchor Leg Mooring Rigid Arm). The importance of testing such systems in multidirectional seas was first demonstrated by Huntington (1981). His research, which was carried out with an ingenious arrangement of 10 sliding wedge wave generators, placed along a semicircular arch, pointed the way for much of the subsequent development for the testing with realistic sea states.

Figure 2b gives the results that were obtained by Høklie, Stansberg and Werenskiold (1983). These graphs illustrate well how the vessel's motions as well as the forces on the various connecting links differ between short and long-crested wave conditions. All results are presented as a ratio of the standard deviation responses in multidirectional seas to those obtained in long-crested seas. Clearly, roll, yaw and sway are much greater in multidirectional seas. Consequently, the transverse force on the tower and the longitudinal force on the tanker are also much larger.

As a third example the second order long wave phenomenon is considered. As is well known, certain structures, particularly large vessels moored in shallow water, have virtually no response to first order waves, but can experience large motions and mooring forces as a consequence of second order long waves. It is therefore fitting to compare the presence of such second order long waves in either the long-crested wave or the short-crested wave situation. This problem was addressed by Sand (1982).

In two-dimensional (long-crested) waves, all waves with different wave periods propagate in the same direction. The second order long waves are derived from the difference terms derived from pairs of wave frequency components. That is to say, for a component of frequency  $f_1$  and another of frequency  $f_2$ , a second order long wave term of frequency  $(f_1 - f_2)$  is spawned with an amplitude dependent on the water depth and the product of their respective amplitudes,  $a_1 \cdot a_2$ .

In the multidirectional situation, individual frequency components do not travel in the same direction. Although the second order difference frequencies are, as before,  $(f_1 - f_2)$ , their wave lengths are now derived from the vectorial difference given in Figure 3a. The difference wave number vector will be  $k_1 - k_2$ , and will depend on the directional difference,  $\Delta\theta$ , between the two components. The larger the wave number of this difference frequency long wave component, the shorter will be its wave length. Another effect will be that the spreading function of these second order terms will broaden out substantially, as is shown in Figure 3b. It can also be shown that the long wave amplitudes in multidirectional waves are reduced by a factor of 5 to 10, depending on the water depth.

Sand (1982) described this phenomenon, as summarized in Figures 3b and 3c. Figure 3c provides information about the reduction in the wave length of the second order long wave components for bichromatic multidirectional waves. This is presented as a ratio of the resultant wave length difference for the multidirectional case to that for the unidirectional case,  $\Delta L / \Delta L_u$ . The information is given for a normalized frequency, for two frequency ratios  $(f_1 - f_2) / f_2$  and for two angular differences of  $\Delta\theta$ . This result is particularly interesting in connection with natural periods of harbour resonances (i.e. the resonance wave lengths of harbours).

Because the long wave generation process through non-linear wave/wave interaction has been significantly reduced as a result of multidirectionality, it stands to reason that the penetration of this long wave energy into harbours is also reduced significantly. Figure 3d, which was taken from van der Meer (1989) provides an example for two different wave directions relative to the harbour entrance. It also gives the corresponding reductions for a moored vessel's surge motion.

TABLE 1: COMPARISON OF STRUCTURAL RESPONSES IN 2D AND 3D SEAS

TEST STRUCTURE	TYPE OF MODEL	PARAMETERS UNDER STUDY	MAIN CONCLUSIONS FOR TYPICAL CONDITIONS	REFERENCE
Partially submerged barrier supported by two piers	Physical	Horizontal force on the barrier	Reduction in loads up to 50% in 3D seas	Mynett, Bosma and van Vliet (1984)
Haringvliet barrier (Delta project in the Netherlands)	Field study	Fluid dynamic pressures on the barrier	For the highest reliable frequency of the spectrum, the wave load reduction factor due to directional spread could be as small as 0.25.	van Heteren, Botma and Roskam (1989)
Long floating cylinder of arbitrary shape	Theoretical	Wave loads and motions	The 1st order sway and roll force reduction factors could be as low as 0.41 for short-crested seas. Only about 58% of the sway, heave and roll motions obtained under 2D are encountered in 3D situations.	Isaacson and Nwogu (1987)
Forces on a large vertical cylinder	Theoretical and physical	Pressures, forces and moments in 3D seas	The ratio of forces and moments for 3D relative to 2D seas in-line component is: In-line: 0.90 Transverse: 0.45	Huntington and Thompson (1976)
Forces on a pile	Theoretical and physical	In-line and transverse wave forces on a submerged segment	The ratio of RMS values of forces for 3D relative to 2D seas in-line component is: In-line: 0.87 Transverse: 0.50	Isaacson and Nwogu (1988)
Segmented cylinder	Theoretical and physical	In-line and transverse force spectra for a segment above the S.W.L.	The ratio of RMS values of forces for 3D relative to 2D seas is: In-line: 0.83 Transverse: 0.56	Isaacson et al (1988)
Segmented cylinder (submerged segments)	Theoretical and physical	Probability distribution of maxima of resultant forces	Decreasing force maxima with increasing spreading. For instance, the measured values of the ratio of largest force maximum to the standard deviation were 3.98 in long crested and 3.31 in short crested seas.	Nwogu and Isaacson (1989(a))

TABLE 1 (continued 1)

Compliant tower	Physical	In-line, transverse and total response	Directionality has little influence on the total response, but a decrease in in-line response and an increase in transverse response becomes predominant with increasing spreading.	Cornett (1988)
Horizontal accelerations	Theoretical	Spectra of 2 <sup>nd</sup> order horizontal accelerations caused by wave set-down	In shallow water, even for a narrow directional spread, the in-line spectral component of the acceleration could be as low as 10% of the 2D response.	Molin and Fauveau (1984)
Harbour and moored ship	Physical	Low frequency energy within harbour and surge motion	Reduction in 3D seas: up to 30% in low frequency activity and more than 75% in surge motion	van der Meer (1989)
Floating barge, moored	Theoretical and physical	Drift motions and mooring loads	The mean value of the low frequency surge motions was reduced by as much as 50% in 3D seas. The mean, standard deviation and maxima of the mooring line loads were reduced by as much as 37%, 25% and 21% respectively.	Nwogu and Isaacson (1989(b))
Single point mooring	Physical	Motions and yoke / tanker hinge force	In 3D, significant increase in sway, roll and yaw motions and in forces at the hinge points.	Huntington (1981)
Moored vessel in open sea	Physical	Motions and mooring loads	In head seas, mooring loads, sway and yaw motions are larger by a factor of 2 in 3D seas. In beam seas the tendency reverses. In quartering seas, the difference between the results of 2D and 3D are small.	Kirkegaard, Sand, Ottesen-Hansen, and Knudsen (1980)
Large offshore floating structures	Theoretical	Transfer functions of motions and forces	Transverse components of force and motion predicted to be negligible in 2D seas are significant in 3D. Typically, the maximum sway motion represents 59 % of the maximum surge.	Isaacson and Sinha (1986)

TABLE 1 (continued 2)

Coupled, articulated tower/ship system	Theoretical	Wave loading on the yoke and motions of the coupled system	Response in 3D seas: maximum structural response values are about 20-25% lower than those predicted with 2D seas.	Heivacioglu and Incecik (1989)
Bi-articulated mooring column	Physical	Tanker motions and forces on the yoke connections	Head-on conditions: the high frequency motions of sway, roll and yaw are nearly twice as large in 3D as in 2D. The tanker/yoke hinge force is 2 to 2.5 times larger in 3D.	Römeling, Marol and Sand (1984)
Single point moored tanker	Physical	Force on tanker/yoke hinge connection and motions	The longitudinal hinge force is generally increased by a factor of 2.5 in 3D seas while the significant sway and yaw motions are up by a factor of 4.	Høklie, Stansberg and Werenskiold (1983)
Semi-submersible, moored	Physical	Motion and mooring loads	In the low frequency domain, near natural frequencies, heave, pitch and roll motions are reduced by as much as 30% in 3D seas. Similar reduction is also found for the in-line and transverse forces. However, no simple relationship exists between 2D and 3D responses.	Sand, Römeling and Kirkegaard (1987)
Jacket structure on a barge for transportation	Theoretical and physical	Motions of the barge, accelerations at the system's and jacket's centres of gravity and at a mud-mat.	Directional spreading sometimes increases motions, loads and accelerations, and 2D waves may not always provide a conservative approach for design.	Standing, Rowe and Brendling (1986)

### Conclusions

Based on the experience gained with the segmented wave generator system at the Hydraulics Laboratory of the National Research Council of Canada, and on the information available through the published literature or verbal communications, the following statements with regard to the merits of testing in multidirectional waves can be made:

- Whenever significant non-linearities are present in the response of structures to waves, the principle of superposition is not valid. Consequently, it is essential to evaluate such structures through the use of realistic simulations of the natural sea state. Two-dimensional wave simulations are not realistic for this purpose.
- Group-bound long wave activity is significantly lower in three-dimensional than in two-dimensional seas. For the investigation of large floating structures, such as tankers, landing strips, floating plants, which will be subject to wave group-induced drift loads, this will be a significant factor. Three-dimensional waves will lead to smaller drift displacements and mooring loads.
- The excitation of harbour seiches will be smaller with three-dimensional than with two-dimensional waves.
- Structures, which have small torsional resistance, will be subject to larger yaw motions when subjected to three-dimensional seas. Typical examples of such structures are compliant towers or tension leg platforms (TLPs) as well as semi-submersibles.
- Motions of vessels with single point moorings are greater in three-dimensional than in two-dimensional seas, resulting also in larger mooring loads. In particular, "fishtailing" motions will be accentuated.
- Dynamic positioning systems for floating structures will be more difficult to operate in multidirectional than in unidirectional waves.
- Wave loading on fixed, long structures can be assumed to be generally smaller in multidirectional seas.

In summary, the absence of correct three dimensional wave simulations can grossly underestimate design requirements. Although two-dimensional wave simulations can sometimes produce reasonably conservative (i.e. large) results, in many cases it would result in excessive over-design. Therefore, model testing in multidirectional seas is strongly recommended to improve designs of marine structures for cost-effectiveness and safety.

## CHAPTER 34

### Numerical Validation of Directional Wavemaker Theory with Sidewall Reflections

E.P.D. Mansard,\* M.D. Miles\* and R.A. Dalrymple†

#### ABSTRACT

A directional wavemaker theory has been developed by Dalrymple to produce a desired oblique planar wave train at any cross-section in the basin. This theory, which uses the reflections from the sidewalls of the basin, can also account for slowly varying depths. This paper describes a numerical validation of this theory, for the constant depth situation, by a wave diffraction model that was recently verified through an extensive series of experimental investigations.

#### 1.0 INTRODUCTION

To generate a specified multidirectional wave field in a laboratory basin, the board motions of a segmented wave generator are generally computed on the basis of the snake principle. Although this technique is being used extensively, it has some limitations. For instance, it cannot account for the effects of reflection from sidewalls and the diffraction due to a segmented wave generator of finite length. Also, the size of the optimal testing area inside the model basin that results from this technique can be quite small, particularly if the maximum angle of directional spread is large. In order to overcome some of these limitations, research has been under way in leading hydraulics laboratories around the world into improved techniques for the simulation of multidirectional waves.

Funke & Miles (1987) developed an extension of the snake principle which can be used to obtain a larger useful working area in a multidirectional wave basin. This technique, known as the corner reflection method, makes use of intentional reflections from partial sidewalls about 5m long on both sides of the basin, extending from each end of the wave generator. Like the snake principle itself, however, waves generated by this method are still subject to wave diffraction errors.

---

\*Senior Research Officer, National Research Council of Canada

†Director, Center for Applied Coastal Research, University of Delaware, U.S.A.

Recently, Dalrymple (1989) developed a technique by which an oblique planar wave train of any desired angle of incidence can be generated at any pre-selected cross-section in the basin. This technique was based on a splitting procedure used on the mild slope equation to develop a propagation equation for the wave potential within a wave basin with reflecting sidewalls and a bottom which may have a slope in the direction perpendicular to the wave generator. The resulting equation was solved analytically to determine the wave fields as a function of distance from the generator segments, given their motions.

The major advantage of the Dalrymple theory is that diffraction, refraction and shoaling processes are all properly accounted for, within the realm of linear wave theory. It is also possible to use this technique to calculate the segmented wave generator paddle motions required to produce a pure full-width oblique plane wave train at a specified distance,  $D$ , from the wavemaker. Multidirectional wave fields are typically generated by the linear superposition of many oblique plane wave components. If the Dalrymple theory is used to generate each component, instead of the snake principle, then the area of the basin where the desired multidirectional wave field can be accurately reproduced will be much larger.

The analytic solution used in the Dalrymple method is only applicable to the case of a wave basin with full-length reflecting sidewalls. The desired oblique plane waves are obtained only at the specified distance  $D$  from the wavemaker. As the waves propagate further down the basin, they gradually become contaminated by diffraction and reflection from the sidewalls. The undesired reflection effects can be avoided by using side absorbers at distances greater than  $D$ , although diffraction effects will still occur. In many model testing applications, the use of partial-length sidewalls is also necessary to reduce errors which would otherwise be caused by sidewall reflection of the diffracted wave field produced by the structure being tested.

It was therefore decided to carry out a numerical study to investigate the performance of the Dalrymple method in a typical multidirectional wave basin with partial-length sidewalls. Wave paddle motions were calculated by the Dalrymple method and the resulting wave field in the basin was then computed by using the linear diffraction model developed by Isaacson (1989). This model can calculate the wave field at any position in the basin, whereas the Dalrymple theory can only be used in the region between the reflecting sidewalls. Another reason for choosing the Isaacson model was that it has recently been verified by extensive experiments in a directional wave basin by Hiraishi et al. (1991). The present numerical study was restricted to the case of a constant depth basin because the Isaacson model cannot be used for a basin with a sloping bottom. In addition to investigating partial-length sidewall effects, the Isaacson model also provided an independent verification of the paddle motions predicted by the Dalrymple method.

## 2.0 THEORETICAL BACKGROUND OF DALRYMPLE'S THEORY

A brief description of Dalrymple's theory is outlined here. Dalrymple (1989) contains a more detailed presentation.

The wave basin is rectangular with width  $2b$ . The co-ordinate axes are located at the centre of the wave generator with the  $y$  axis directed along the generator and the  $x$  axis directed perpendicularly into the basin. The sidewalls of the basin at  $y = \pm b$  are impermeable.

The mathematical theory used in this model follows the treatment of Dalrymple and Kirby (1988) for the combined diffraction and refraction of waves on sloping beaches. The assumed linear water wave motion is described by a velocity potential satisfying the mild slope equation. This mild slope equation, which governs the progressive wave mode and neglects the evanescent wave mode, can be written as:

$$\Phi(x, y, z, t) = \phi(x, y) \frac{\cosh k(h+z)}{\cosh kh} \cdot e^{-i\omega t} \quad (1)$$

$$\frac{\partial}{\partial x} \left( CC_g \frac{\partial \phi}{\partial x} \right) + CC_g \frac{\partial^2 \phi}{\partial y^2} + k^2 CC_g \phi = 0 \quad (2)$$

where  $CC_g$  is the product of the wave phase velocity and group velocity. The wave number,  $k$ , is related to the water depth,  $h(x)$ , and the angular wave frequency,  $\omega$ , by the linear dispersion relationship.

The above equations are consistent with small amplitude assumptions and the imposition of a mild bottom slope. At the sidewalls of the basin ( $y = \pm b$ ), there is no flow normal to the walls. Therefore,

$$\frac{\partial \phi}{\partial y} = 0 \quad \text{on} \quad y = \pm b \quad . \quad (3)$$

To satisfy these two lateral boundary conditions,

$$\phi(x, y) = \hat{\phi}(x) \sum_{n=0}^{\infty} (a_n \cos \lambda_n y + b_n \sin \gamma_n y) \quad (4)$$

where  $\lambda_n = (n\pi/b)$  and  $\gamma_n = (n + \frac{1}{2})\pi/b$  for  $n = 0, 1, 2, \dots, \infty$ .

The reduced mild slope equation becomes two equations:

$$\frac{\partial}{\partial x} \left( CC_g \frac{\partial \hat{\phi}}{\partial x} \right) + CC_g (k^2 - \alpha^2) \hat{\phi} = 0 \quad (5)$$

where  $\alpha = \lambda_n$  or  $\gamma_n$  depending on which of the forms of the solution in Equation (4) is used.

The reduced wave potential,  $\hat{\phi}$ , can consist of waves propagating in the positive and negative  $x$  directions, i.e.  $\phi^+$  and  $\phi^-$ . Adopting the splitting procedure,

assuming the reflected waves to be small and, therefore, neglecting the negative potential  $\phi^-$ , the total forward propagating velocity potential can be written as:

$$\Phi(x, y, z, t) = (\phi_e^+ + \phi_o^+) \frac{\cosh k(h+z)}{\cosh kh} e^{-i\omega t} \tag{6}$$

where

$$\phi_e^+ = \sum_{n=0}^{\infty} A_{n0} K_{sr}(x, \lambda_n) e^{i \int_0^x \sqrt{k^2 - \lambda_n^2} dx} \cos \lambda_n y \tag{7}$$

$$\phi_o^+ = \sum_{n=0}^{\infty} B_{n0} K_{sr}(x, \gamma_n) e^{i \int_0^x \sqrt{k^2 - \gamma_n^2} dx} \sin \gamma_n y \tag{8}$$

and  $K_{sr}$  is the product of the shoaling and refraction coefficients. The subscripts  $e$  and  $o$  refer to even and odd solutions about the  $y = 0$  axis. Some of the “progressive” waves are evanescent, those for which  $\lambda_n$  or  $\gamma_n > k(x)$ . In most cases, when only the far wave field is required, the largest value of  $n$  to be retained in the summation is only on the order of 10–20. Although the solution for the velocity potential,  $\phi$ , is analytic, the phase integrals are determined numerically by the Euler integration method.

In the parabolic forms of the equation, the condition at the wave paddles ( $x = 0$ ) is an initial condition that forces the wave-induced water motions (defined by  $\partial\phi/\partial x$ ) to match the motion of each wave paddle.

The wave paddle motion is assumed to have a linear phase shift along the  $y$  axis, leading to the generation of a plane wave train with an angle of incidence,  $\theta$ , with respect to the  $x$  axis. Thus, the paddle motion will be described by the real part of

$$X = S_0 g(z) e^{i(\lambda_0 y - \omega t)} \tag{9}$$

where  $g(z)$  is the vertical dependence of the paddle motion over the water depth,  $\lambda_0 = k \sin \theta$  is the  $y$ -component of the wave number of the desired wave and  $S_0$  is the maximum amplitude of the paddle stroke at the mean free surface.

The linearized initial condition for this wave generator, in terms of the horizontal velocity in the  $x$  direction, is specified by even and odd contributions about the  $y$ -axis. Now matching the even and odd solutions to the horizontal velocity determined from the velocity potential at  $x = 0$ , and exploiting various orthogonal properties of the functions that occur in this problem, the expressions for the coefficients  $A_{n0}$  and  $B_{n0}$  simplify to:

$$A_{n0} = -\frac{2(-1)^n S_0 \omega G \lambda_0 \sin(\lambda_0 b)}{(\lambda_0^2 - \lambda_n^2) \sqrt{k^2 - \lambda_n^2} b} \tag{10}$$

and

$$B_{n0} = -\frac{2i(-1)^n S_0 \omega G \lambda_0 \cos(\lambda_0 b)}{(\lambda_0^2 - \gamma_n^2) \sqrt{k^2 - \gamma_n^2} b} \tag{11}$$

for the case of a wave generator spanning the full width of the basin.

The wave field generated in the basin, for a given set of paddle motions, can be computed with these expressions. Alternatively, if it is required to produce a desired oblique plane wave train extending across the full width of the basin at a given  $x$  location, this can easily be done by determining the initial coefficients  $A_{n0}$  and  $B_{n0}$ , not at  $x = 0$  as before, but at the desired location  $x = x_D$ . This yields new values of the coefficients

$$A'_{n0} = \frac{A_{n0} e^{i \int_0^{x_D} \sqrt{k^2 - \lambda_0^2} dx}}{K_{sr}(x_D, \lambda_n) e^{i \int_0^{x_D} \sqrt{k^2 - \lambda_n^2} dx}} \quad (12)$$

and

$$B'_{n0} = \frac{B_{n0} e^{i \int_0^{x_D} \sqrt{k^2 - \lambda_0^2} dx}}{K_{sr}(x_D, \gamma_n) e^{i \int_0^{x_D} \sqrt{k^2 - \gamma_n^2} dx}} \quad (13)$$

where  $\lambda_0$  is evaluated at  $x_D$ . The wave paddle motion is now obtained from Equations 7 and 8 evaluated at  $x = 0$ , resulting in the summation of various sinusoidal motions.

Although Dalrymple (1989) provides some preliminary validation of this technique using the same theory, a more detailed validation has been carried out in this study using the Isaacson (1989) diffraction model, which has recently been verified by an extensive set of physical experiments. A brief description of the Isaacson model and its experimental verification is given below.

### 3.0 THEORETICAL BACKGROUND OF THE ISAACSON MODEL

This model was developed by Isaacson (1989) to predict the wave field in a multidirectional wave basin. It is based on linear wave diffraction theory and uses a boundary element representation of the segmented wave generator and the reflecting walls of the basin.

Isaacson defines a velocity potential satisfying the Helmholtz equation within the fluid region and the boundary conditions along the generator faces and any specified reflecting walls. A suitable radiation condition is also applied so that the remaining parts of the wave basin boundary are treated as perfect wave absorbers.

The potential  $\phi$  may be expressed as the potential due to a distribution of point wave sources along the generator faces and any reflecting boundaries. Thus,

$$\phi(\mathbf{x}) = \frac{1}{4\pi} \int_S f(\xi) G(\mathbf{x}; \xi) dS \quad (14)$$

where  $S$  denotes the horizontal contour along the generator faces and fixed walls and  $f(\xi)$  represents the source strength distribution function.  $G(\mathbf{x}; \xi)$  is a Green's function for the potential at an arbitrary point  $\mathbf{x}$  due to a point wave source located at the point  $\xi$  on  $S$ , and  $dS$  denotes a differential length along  $S$ .

The boundary condition along  $S$  equates the flow velocity component normal to  $S$  to the wave paddle velocity along a generator face and to zero along a reflecting wall. This gives an integral equation for  $f(\xi)$  which is then solved by using a discrete representation of the horizontal contour,  $S$ , with a finite number of short straight elements and assuming the source strength to be constant over each element. Using this approximation, the integral equation is satisfied at the centre of each boundary element and is thus reduced to a set of linear equations for the source strengths. The velocity potential,  $\phi$ , is obtained from the solution of these equations and a discrete version of Equation 14. Once the potential is known, the height and the phase angle of the waves at any point in the basin can be calculated easily.

The most important parameter in this numerical model is the total number of discrete boundary elements that are required to predict the wave field in the basin. Reducing the boundary element length increases the accuracy of the predicted wave field but eventually leads to excessive computational effort. Hiraishi et al. (1991) undertook a numerical investigation to determine the optimum ratio of boundary element length to wave length required to obtain reliable results. These predictions were subsequently validated by an extensive experimental program.

#### 4.0 EXPERIMENTAL VALIDATION OF THE ISAACSON MODEL

The amplitudes and phases of wave trains predicted by this diffraction model for different combinations of wave periods and angles of incidence, were compared to measurements made at more than 200 locations in a test basin. A brief description of this experimental investigation is given below.

The experiments were carried out in the multidirectional wave basin of the NRC Hydraulics Laboratory, which has a length of nearly 20m and a width of 30m. A segmented wave generator consisting of 60 segments, each with a width of 0.5m is located along one 30m side of the basin.

Perforated sheet metal wave absorbers, developed by the NRC Hydraulics Laboratory to yield less than 5% reflection, were installed along the other three sides of the basin. Removable sidewalls could be used to cover the side absorbers, either totally or partially.

In order to scan the sea states prevailing at different locations in the basin, a steel frame was designed to accommodate nineteen wave gauges. This steel frame, shown in Figure 1, was suspended at a single point from a hoist which was in turn attached to a trolley. This trolley ran, through remote-control, on a track under the ceiling over the centre of the basin aligned in a direction normal to the face of the wave generator. The frame could also be rotated about its suspension point to make simultaneous measurements of wave profiles along a line parallel to the crest of an oblique wave.

Validation of the Isaacson diffraction model was carried out using both long-

Figure 1: Photograph of Steel Frame with Wave Gauges

crested normal and oblique regular waves. Waves with periods ranging from 1.5s to 2.25s were produced by the snake principle and also by the NRC corner reflection method, using short reflecting sidewalls of approximately 5m length.

Since the Isaacson model is based on linear theory, wave heights were kept under 20cm. For each sea state, wave measurements at different cross-sections in the basin were carried out by relocating the 19-probe frame at different target positions. At each position, wave generation and data sampling were exercised for 180s. In order to correlate measurements made at the various cross-sections in the basin, the data acquisition was synchronized with the activation of the wave generator. A large number of tests was carried out to ensure repeatability of the sea states. Sufficient time was allowed for the oscillations in the basin to settle down between successive tests. While a detailed presentation of these investigations can be found in Hiraishi et al. (1991), one example of the comparison between numerical and physical model results is presented here.

The points in Figure 2a show the wave height distribution realized at three different measurement lines, as well as the corresponding numerical predictions, for 2s waves propagating in a line parallel to the wave generator. The distances of these lines, measured from the wave paddles and expressed as  $X_c$ , are indicated in the figure.

Figure 2b illustrates results of oblique waves with  $\theta = 30^\circ$ , measured in a line parallel to the wave generator (i.e.  $\alpha = 0^\circ$ ) and parallel to the crest line ( $\alpha = 30^\circ$ ). For the sake of easier comparison, the measured wave heights,  $H$ , are normalized

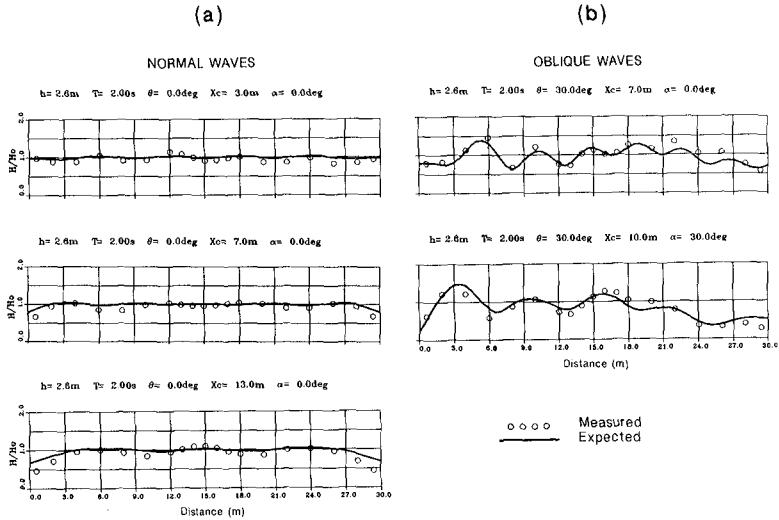

Figure 2: Comparison of Measured and Predicted Waves for Isaacson Model

with respect to the target heights,  $H_0$ . It can be seen from this figure that the measured wave heights agree reasonably well with the predicted ones. Similar cases of good agreement were found for all periods except one that stimulated cross-mode waves in the experimental basin. Interested readers should refer to Hiraishi et al. (1991) for a complete presentation of the results.

Based on these experimental investigations, it was concluded that the Isaacson numerical model can predict the generated wave field quite well for a specified basin layout and a specified set of segmented wave generator paddle motions.

## 5.0 VALIDATION OF DALRYMPLE'S THEORY

### 5.1 Validation Procedure

Since the Isaacson diffraction model has been extensively validated by the experiments described above, it was decided to use it to assess the effectiveness of the Dalrymple method. Although Dalrymple's theory itself can be used to predict the water surface elevation, this can only be done in the region between the reflecting sidewalls. Since the wave field at the wavemaker is rather complex for the Dalrymple method, the accuracy of the oblique plane wave produced may also be limited by the finite width of the wavemaker segments. The Isaacson model allows the wave field to be calculated at all points in a basin of constant depth, and also can model the effects of finite segment width.

Figure 3: Layout of Basins for Verification of Dalrymple's Theory

In view of these considerations, the following procedure was used to investigate the performance of the Dalrymple method in a typical wave basin:

- Use Dalrymple's theory to estimate the required paddle motions of the segmented wave generator for the reproduction of a given sea state at the desired location.
- Use the computed motions as inputs to the Isaacson diffraction model to predict the wave field inside the test basin and determine how accurately the desired sea state can be realized at various locations.

The layouts of the basin used in this numerical procedure are shown in Figure 3. These layouts correspond to the NRC Hydraulics Laboratory basin described above. Two different cases of sidewall lengths were chosen for this study. Figure 3a represents the situation where the two sides are covered fully with reflecting walls, while Figure 3b corresponds to sidewalls extending only 10m from the paddles; the remaining 10 metres on each side consist of absorbers. In both cases, the wavemaker was assumed to have a segment width of 0.5m.

According to Dalrymple's theory, it is possible to reproduce a desired oblique wave train at any cross-section in the basin up to the limit of the reflecting sidewalls. Consequently, the desired wave train can be produced at any distance from 0 to 20m from the wavemaker in the layout of Figure 3a but only at distances between 0 and 10m for the case of Figure 3b.

Figure 4: Wave Height Distributions at  $x_D = 10\text{m}$  for Snake Principle and Dalrymple Method

## 5.2 Results of the Validation Procedure

### 5.2.1 Full-length sidewalls

A comparison of the snake principle with no sidewalls and the Dalrymple method with full-length sidewalls is shown in Figure 4 for a wave train with a period of  $T = 1.2\text{s}$  and a propagation angle of  $\theta = 30^\circ$ . The wave height distributions for both methods were calculated by the Isaacson model. It can be seen that wave height uniformity is greatly improved with the Dalrymple method, not only in the main diffraction zone at the right, but in the centre of the basin as well.

Wave height distributions, at various distances from the wavemaker, are shown in Figure 5 for the basin layout shown in Figure 3a. These were predicted by the Isaacson model using the paddle motions computed by Dalrymple's theory. In Figure 5a, the target sea state is a wave train with a period of  $T = 0.75\text{s}$  and a propagation angle of  $\theta = 15^\circ$ . In Figure 5b, the target wave train has a period of  $T = 1.20\text{s}$  and a propagation angle of  $\theta = 30^\circ$ . In both cases, the reproduction distance,  $x_D$ , is  $10\text{m}$ .

These figures demonstrate the capability of Dalrymple's method. It is interesting to note the complexity of the wave field that is required to be produced near the paddles to simulate the desired water surface elevation at the specified locations. Similarly, the influence on the wave field of the reflection from the solid walls extending beyond  $10\text{m}$  can also be appreciated.

### 5.2.2 Partial-length sidewalls

Figure 6 illustrates results similar to those in Figure 5 but for the basin layout depicted in Figure 3b. A target wave train with  $T = 0.75\text{s}$  and  $\theta = 15^\circ$  was used

and wave fields were calculated for two different reproduction distances,  $x_D$ . The results for  $x_D = 5\text{m}$  and  $x_D = 10\text{m}$  are shown in Figures 6a and 6b, respectively. Figure 6b is particularly interesting since it shows the ability to reproduce the desired sea state at the end of the sidewalls. As expected, the absorbers located beyond the 10m limit of the sidewalls help eliminate the reflections, thus ensuring a reasonably good wave field, even beyond the 10m distance.

Once again, these figures illustrate the validity of Dalrymple's theory. It should be noted that, although the water surface elevation realized at the desired locations is very good, a small variability (less than 5%) seems to exist and tends to increase with wave period. Research is continuing to investigate the reasons for this variability. Possible causes include finite segment width effects and the truncation point used for the summations in the Dalrymple theory (e.g. Equations 7 and 8).

## 6.0 SIZE OF AREA WITH HOMOGENEOUS SEA STATES

For model studies of offshore or coastal structures, it is important to ensure that a large area with a homogeneous sea state is available for testing purposes. For this reason, it is of interest to estimate the size of homogeneous area that can be obtained using Dalrymple's theory.

An example of this is shown in Figure 7 which illustrates the boundary inside the wave basin where the wave heights can be expected to be within  $\pm 10\%$  of the target wave height,  $H_0$ . The two basin layouts shown in Figure 3 have been used. The thick line shows the result for full-length reflecting sidewalls, while the dashed line shows the case of partial-length sidewalls. The sea states illustrated in Figure 5b were used in these calculations for the full-length sidewall case.

It can be seen that the homogeneous area extends over the full width of the basin at the reference distance of  $x_D = 10\text{m}$ , where the target wave train was to be reproduced. At larger  $x$  distances, the width of the homogeneous zone gradually decreases. In this case, it is better to use a 10m sidewall on one side to prevent reflection when  $x > x_D$  and a 20m sidewall on the opposite side to reduce diffraction effects. However, in the general multidirectional case, with waves propagating in both positive and negative directions, it would be best to use partial-length sidewalls on both sides. More calculations of this kind are under way in order to determine the optimum sidewall length for various multidirectional wave situations.

## 7.0 CONCLUSIONS

Dalrymple has proposed a theoretical model to reproduce a planar, oblique wave train at any predetermined cross-section in a multidirectional basin. This theory, which uses reflections from sidewalls and the mild slope equation for varying water depth, was validated numerically for a constant depth situation using the Isaacson diffraction model. The results indicate that Dalrymple's method is indeed a

Figure 5: Dalrymple Method Wave Height Distributions for 20m Sidewalls at Various  $X$  Distances from the Wavemaker.

Figure 6: Dalrymple Method Wave Height Distributions for 10m Sidewalls at Various X Distances from the Wavemaker.

Figure 7: Size of Area with  $\pm 10\%$  Uniformity for  $T = 1.20\text{s}$  and  $\theta = 30^\circ$

powerful tool that can enhance the model testing capability of a multidirectional wave basin. Further work is planned at NRC to evaluate the Dalrymple method experimentally in a basin with a sloping bottom.

## CHAPTER 99

### 3-D Analysis of Flow around a Vertical Cylinder on a Scoured Bed

Tomonao Kobayashi<sup>1</sup>

#### ABSTRACT

Velocity distributions around a vertical cylinder on a scoured seabed under waves have been evaluated in three dimensions using a laser Doppler anemometer and the mass-consistent model to explain the mechanism of local scouring in the wave fields. Through their comparisons with the measurements over a flat bottom under the same conditions, effects of the scoured seabed configuration on the vortex behavior around a cylinder and the near-bed flow structures have been clarified. Namely, the scoured seabed topography causes deformation of the vortices and the flow field from a quasi-two-dimensional structure observed above the flat bed into a complex three-dimensional structure. The flow around a cylinder has also been simulated numerically with a three-dimensional vortex segment model. The results have shown a good agreement with those in the experiments.

#### 1. INTRODUCTION

Prediction of local scouring around nearshore and offshore structures is a need for engineers, and many researchers have been challenging to estimate the scour depth and shape. For example, Well and Sorensen (1970) have found the relationships of the ultimate scour depth with the Shields number, Reynolds number, etc. in experiments. Sumer *et al.* (1992) have reported laboratory tests on the scouring and expressed the scour depth as a function of the Keulegan-Carpenter (K.C.) number with continuous sediment motion on beds. However, to develop a reliable prediction model for the local scouring, we need a deeper understanding of the scouring mechanism and the flow features near the bed around structures.

Characteristics of the flow around a vertical cylinder in steady currents have been investigated extensively (*e.g.*, Shen *et al.*, 1969; Breusers *et al.*, 1977). It has been found that a horseshoe vortex above the scoured bed is a dominant factor in the scour process, and that the vortex has a close relationship with the bed profile near the cylinder. The vortex behavior above the scoured bed is thus a very important factor to consider in the estimation of scouring.

Table 1. Conditions of laboratory experiments.

Water Depth	$h$	100 mm
Water Period	$T$	1.5 s
Wave Height	$H$	38 mm
Ursell Number	$U_r$	83.8
Cylinder Diameter	$D$	48 mm
Maximum Velocity above the Bed	$U_{\max}$	167 mm/s
Keulegan-Carpenter Number	K.C.	5.2

In the wave-related field, relatively few studies have been conducted on this topic. Nishizawa and Sawamoto (1988) and Sumer *et al.* (1992) have studied the flow around a vertical slender cylinder under waves using flow visualization techniques. They have reported relationships between the flow characteristics and the K.C. number based on experimental results for a flat bottom only. In case of a scoured bed, there has been even less literature, probably because the flow near the scoured seabed shows a highly complex three-dimensional pattern owing to the complicated scour shape and the unsteadiness of the main flow itself. It should be emphasized, however, this unsteady three-dimensional near-bed flow with vortices governs the local scouring around the cylinder.

The purpose of this study is to recognize the characteristics of the flow around a vertical cylinder on the scoured bed under waves. First, to show the typical features of the flow and vortices, the measurements of three-dimensional velocity distributions around the cylinder are presented for cases of both the flat bottom and the scoured bed. Then, the results of flow simulation are shown, which have been obtained with a numerical model developed as an initial step to build up a local scouring model.

## 2. EXPERIMENTAL PROCEDURE

### 2.1. Experimental Conditions

Velocity distributions have been measured around a vertical slender cylinder on the flat bottom and on the scoured seabed under the same conditions, which are shown in *Table 1*. The reason why these conditions have been selected is that under them, clear scouring had occurred on a movable bed as described below. *Figure 1* shows the time variation of a water surface elevation in one wave period and the vertical distributions of horizontal velocity near the flat bottom at several phases without disturbances due to the cylinder.

In order to determine the scoured bottom topography around the cylinder, a movable bed test has been conducted using sand with the medium diameter  $d_{50} = 0.6\text{mm}$  and the density  $\rho_s = 2.68\text{g/cm}^3$ , for which the maximum Shields number  $\Psi_m$  is 0.025.

The modified final topography is shown in *Fig. 2*, where the wave direction is from the left to the right. The coordinates  $x$ ,  $y$  and  $z$  are in the streamwise, the lateral and the vertical directions, respectively, and their origin is set on the centerline of the cylinder at the elevation the initial flat bottom. The actual

scoured bed topography has been almost symmetric with respect to the vertical  $x$ - $z$  plane. Furthermore, as explained later, the flow pattern has been also satisfactorily symmetric. Hence the bed profile has been modified to be symmetric and employed in the following experiment.

As shown in *Fig. 2*, a pair of deep scour holes are found at the two side edges of the cylinder (the hatched part), and two hills are formed near the down-wave edges.

**2. 2. Experimental Apparatus**

Velocity distributions around the vertical cylinder were measured in full detail using a two-dimensional laser Doppler anemometer, which was set on a movable

*Fig. 1.* Water surface profile and velocity distributions above the flat bottom.

*Fig. 2.* Contour map of the scoured bed around a vertical cylinder.

table. A personal computer was used to control the movable table and a wave maker, and to acquire the output from the anemometer and a wave gage. Thus the velocity distributions around the cylinder near the bottom were automatically recorded by the computer. Nearly 5,000 points of velocity measurement were distributed around the cylinder, and the phase-average velocity data for 100 waves were obtained at each point.

Since the K.C. number is low as shown in *Table 1*, the flow pattern was highly symmetric with respect to the vertical  $x$ - $z$  plane; the symmetry plane is  $y = 0$  mm. Therefore the velocity distributions were measured only in one side ( $y \geq 0$ ). The anemometer directly measured only the two velocity components  $u$  and  $w$ , in the  $x$  and  $z$  directions, respectively. The velocity component  $v$  in the  $y$  direction was not measured but estimated with the following MASCON model.

### 2.3. MASCON Model

The MASCON (mass-consistent) model, developed by Sherman (1978) to adjust field measurement data of wind, is useful to estimate three-dimensional velocity distributions as properly adjusted in a mass-consistent flow field over a complex topography. This model has often been applied to the adjustment of the field velocity data in meteorology. However, its applications to laboratory experiments are very few (*e.g.*, Hino *et al.*, 1989). In the present study, this model is applied to the evaluation of the velocity component  $v$ , which was not measured in the experiments.

The specific function of this model is

$$E(u, v, w, \lambda) = \int_V \left[ \alpha_x^2 (u - u_0)^2 + \alpha_y^2 (v - v_0)^2 + \alpha_z^2 (w - w_0)^2 + \lambda \left( \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} \right) \right] dx dy dz \quad (1)$$

where  $u_0$ ,  $v_0$  and  $w_0$  are observed velocity components,  $u$ ,  $v$  and  $w$  are adjusted ones,  $\lambda$  is the Lagrange multiplier, and each  $\alpha$  is a Gauss precision modulus.

The solutions which minimize a value of this function  $E$  satisfy the following relations.

$$u = u_0 + \frac{1}{2\alpha_x^2} \frac{\partial \lambda}{\partial x} \quad (2)$$

$$v = v_0 + \frac{1}{2\alpha_y^2} \frac{\partial \lambda}{\partial y} \quad (3)$$

$$w = w_0 + \frac{1}{2\alpha_z^2} \frac{\partial \lambda}{\partial z} \quad (4)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \quad (5)$$

$$\frac{1}{\alpha_x^2} \frac{\partial^2 \lambda}{\partial x^2} + \frac{1}{\alpha_y^2} \frac{\partial^2 \lambda}{\partial y^2} + \frac{1}{\alpha_z^2} \frac{\partial^2 \lambda}{\partial z^2} = -2 \left( \frac{\partial u_0}{\partial x} + \frac{\partial v_0}{\partial y} + \frac{\partial w_0}{\partial z} \right) \quad (6)$$

Values of the adjusted velocity component  $u$ ,  $v$  and  $w$  are estimated from *Eqs.* (2) to (6).

Since the purpose of the application of this model to the present study is to evaluate the velocity component  $v$  from the other two measured velocity components  $u_0$  and  $w_0$ , the condition that  $\alpha_y^2$  is larger enough than  $\alpha_x^2$  and  $\alpha_z^2$  must be introduced. Otherwise the adjusted velocity components  $u$  and  $w$  would severely deviate from the measurements of  $u_0$  and  $w_0$  in this model. Hence, values 1.0, 5.0 and 1.0 are employed for  $\alpha_x$ ,  $\alpha_y$  and  $\alpha_z$ , respectively, and  $v_0$  is set to be zero in this study.

### 3. EXPERIMENTAL RESULTS

#### 3.1. Flow Field above the Flat Bottom

First the velocity distributions above the flat bottom were measured under the conditions given in *Table 1*. *Figure 3* shows the phase-average velocity distributions in horizontal planes at  $z = 2\text{mm}$  and  $z = 8\text{mm}$ . The direction of wave propagation is from the left to the right, and the phase  $\theta = 0$  corresponds to the time when the wave crest passes the location of the cylinder. Since *Fig. 3* shows the velocity distributions in horizontal planes, the velocity components  $u$  and  $v$  are indicated by vectors, and the  $w$ -component is shown as contour lines in the figure. Solid and dashed contour lines mean ascending and descending flows, respectively.

A pair of vortices are shed in the wake region after the passing of the wave crest or the trough as shown in *Fig. 3 b, d, g and i*. As the waves are finite amplitude waves, whose Ursell number is 83.8, the main flow under the wave crest is much stronger than that under the wave trough as shown in *Figs. 1 and 3*. However, the weak opposite-directional main flow continues longer than the strong shoreward flow under the wave crest. Hence, the vortices shedding from the cylinder at the up-wave side of the cylinder grow bigger than the ones at the down-wave side of the cylinder as represented in *Fig. 3 b, d, g and i*. These vortices at the up-wave side of the cylinder induce the intense flow on the surface of the cylinder, as shown in *Fig. 3 e and j*. Then, this intense flow supposedly picks up sand and forms a pair of the scour holes at the two side edge of the cylinder in *Fig. 2*. According to the contour maps showing the distributions of  $w$ , concentration of the intense descending flow occurs in the wake, whereas the weak ascending flow regions extend widely around the cylinder to balance the descending flow.

The difference of the velocity distributions between the planes at  $z = 2\text{mm}$  and  $z = 8\text{mm}$  is negligible. The velocity distribution at the plane  $z = 22\text{mm}$  is also similar to them. This indicates that the flow field above the flat bottom is approximately two-dimensional, namely, uniform in the vertical direction.

*Figure 4* shows the distributions of the flow with vorticity vectors at the wave phase  $\theta = \pi/8$ , immediately after the wave crest passing. It is seen in *Fig. 4*, the axis of the vortex shed from the cylinder is nearly vertical. This fact also means that the flow field above the flat bottom is almost two-dimensional or uniform in the vertical direction. The shed vortex is deformed down-wave near the bottom owing to the strong descending flow in the wake.

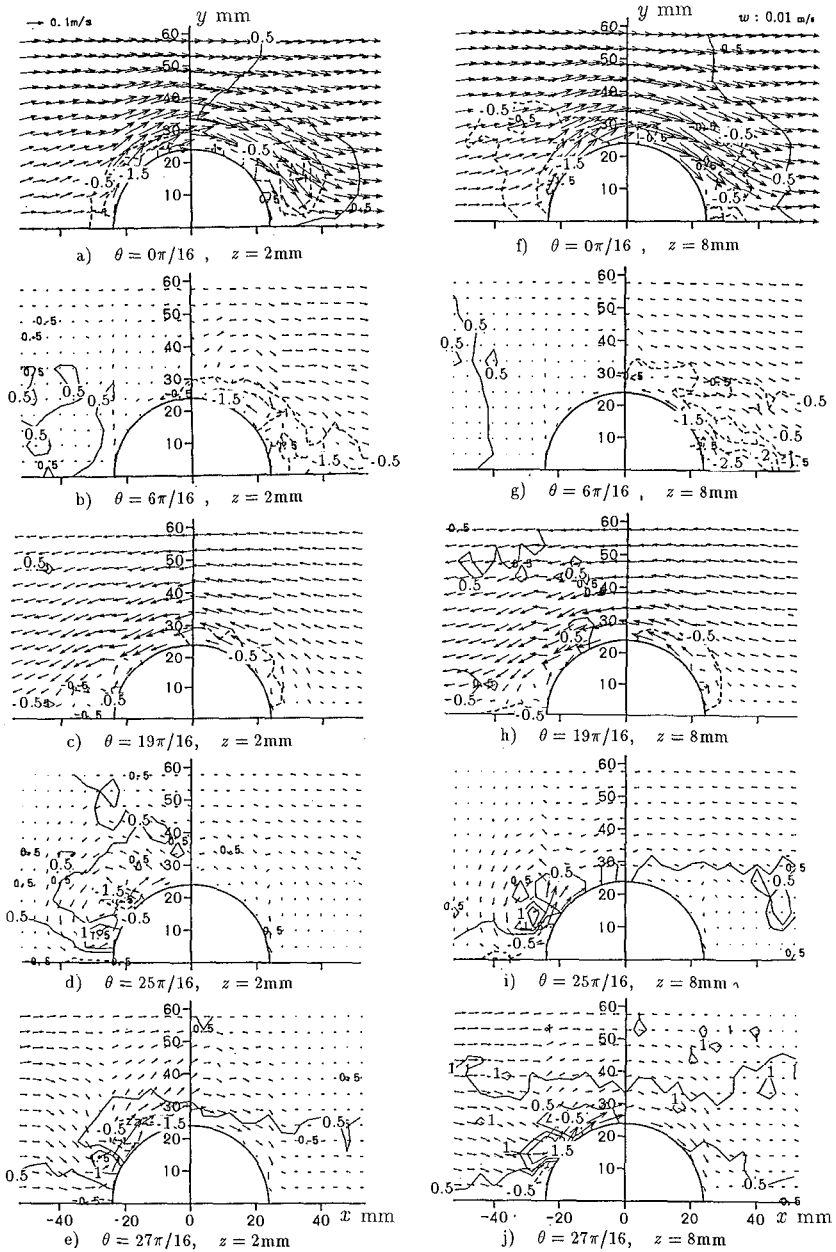

Fig. 3. Phase-average velocity distributions in horizontal planes at  $z = 2\text{mm}$  and  $z = 8\text{mm}$  above the flat bottom. Solid and dashed contour lines show ascending and descending flows ( $w$ -component) respectively.

Fig. 4. Vorticity vector distributions above the flat bottom at  $\theta = \pi/8$ .

### 3. 2. Flow Field above the Scoured Seabed

The velocity distributions above the scoured seabed were measured under the same conditions with those for the flat bottom (*Table 1*). To perform the measurement, the scoured bottom topography shown in *Fig. 2* was modeled in wood and surfaced with sand of  $d_{50} = 0.6\text{mm}$ . *Figure 5* shows the velocity distributions in horizontal planes at different heights above the scoured seabed at  $\theta = 0$  and  $\theta = \pi/4$ . The flow structure is very complex because of the scoured bed topography. It is observed that the flow rises over the slope from the scour hole to the hill, and that strong ascending flow occurs at the down-wave side edge of the cylinder. At the phase  $\theta = \pi/4$ , the wake grows in the lee of the cylinder, where the strong flow toward the opposite direction appears at the heights  $z = 6\text{mm}$  and  $z = 10\text{mm}$ . This is not clearly observed at other heights.

*Figure 6* shows the velocity distributions in the vertical  $x$ - $z$  planes at the phase  $\theta = \pi/4$ , in which the cylinder is represented by pairs of the vertical straight lines, the velocity components  $u$  and  $w$  are shown as vectors, and the  $v$ -component is indicated by contour lines. The direction of wave propagation is again from the left to the right. In the symmetry plane ( $y = 0\text{mm}$ ), the descending flow appears in the wake, while in the other planes a vortex with a horizontal axis is clearly seen.

*Figure 7* shows the time evolution of this horizontal vortex. The vortex develops as the wake grows after the wave crest passing, and then it disappears when the main flow decelerates. It is observed from this figure that this vortex induces local intense flow near the bed in a very short period. Under the present conditions, the intensity of this flow was enough to pick up sand. Then, it is seemed that this vortex has a close relationship with the local scouring around the cylinder.

The structure and the time evolution of the vortex are shown in *Figs. 8* and *9*, respectively, with vorticity vectors. The bird's-eye view in *Fig. 8* shows that an arch-shaped vortex with its feet on the hills is formed in the lee of the cylinder, and the side view indicates that the vortex leans down-wave. The vortex concentration is strong at the feet and becomes weak upward or towards the symmetry plane.

According to *Fig. 9*, the arch-shaped vortex does not appear immediately

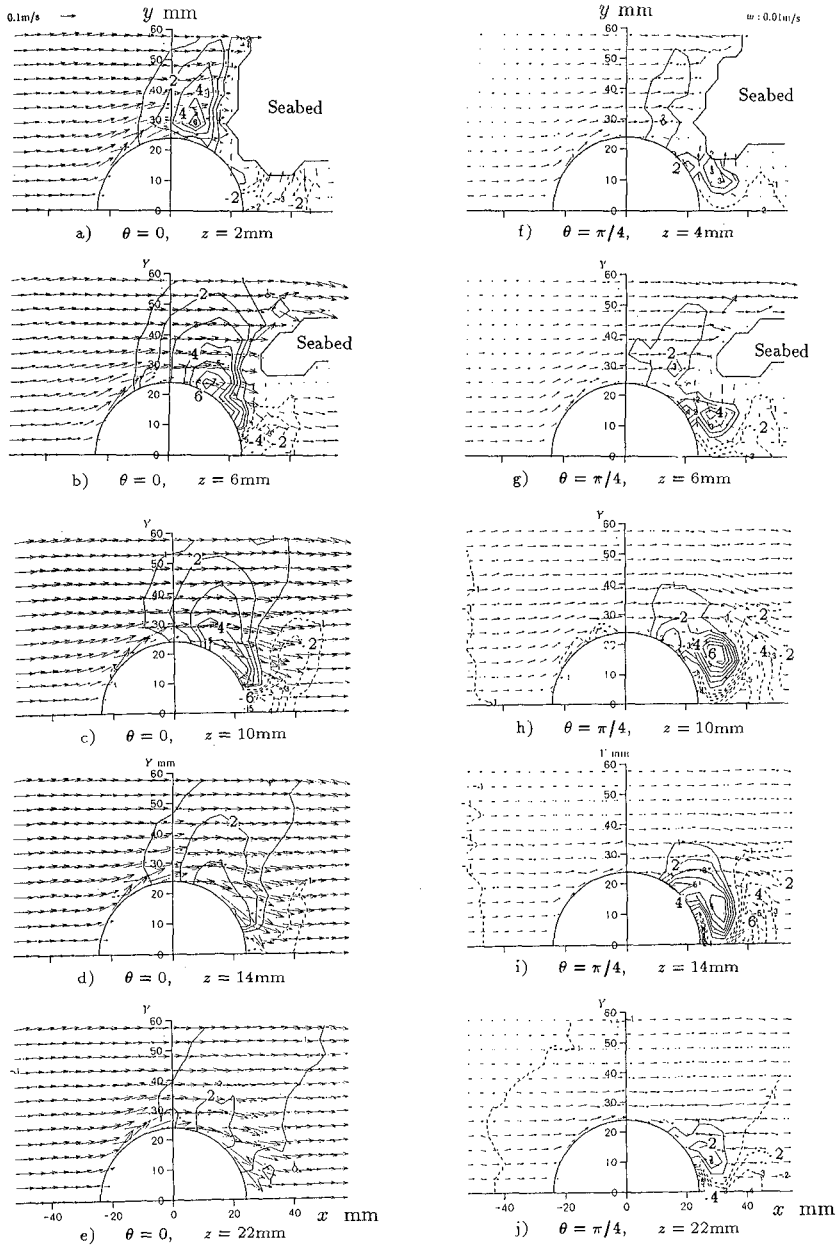

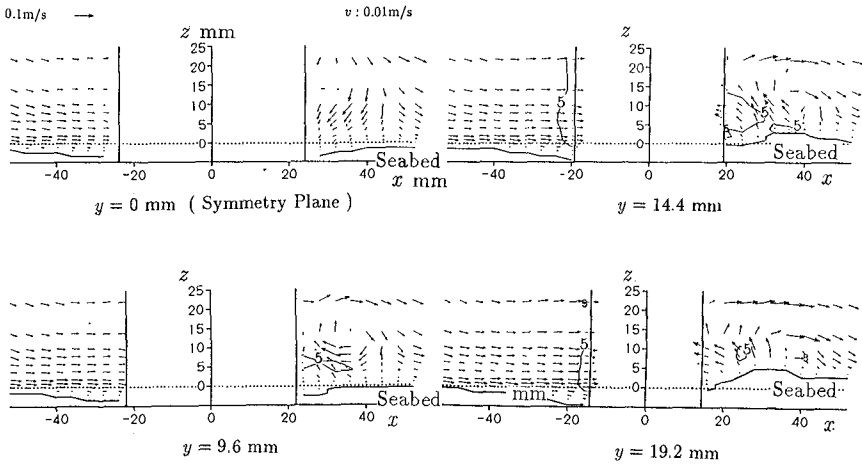

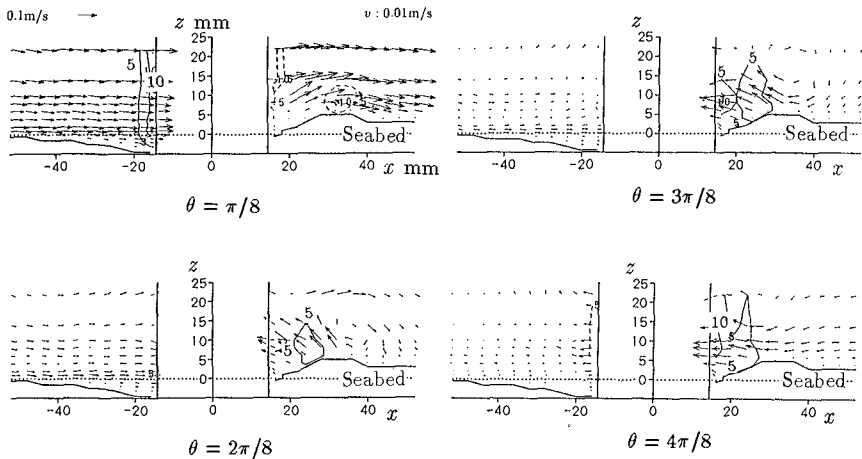

Fig. 5. Velocity distributions in horizontal planes above the scoured seabed.

before and at the phase of wave crest passing ( $\theta = 0$ ); the vortex starts to be produced soon after the crest passing, and then gradually develops and leans down-wave. It is concluded from *Fig. 9* that the interaction of the vortex shed from the cylinder and the separation over the hills induces the arch-shaped vortex above the scoured bed.

*Fig. 6.* Velocity distributions in vertical planes above the scoured seabed at  $\theta = \pi/4$ .

*Fig. 7.* Time evolution of the horizontal vortex ( $y = 19.2\text{mm}$ ).

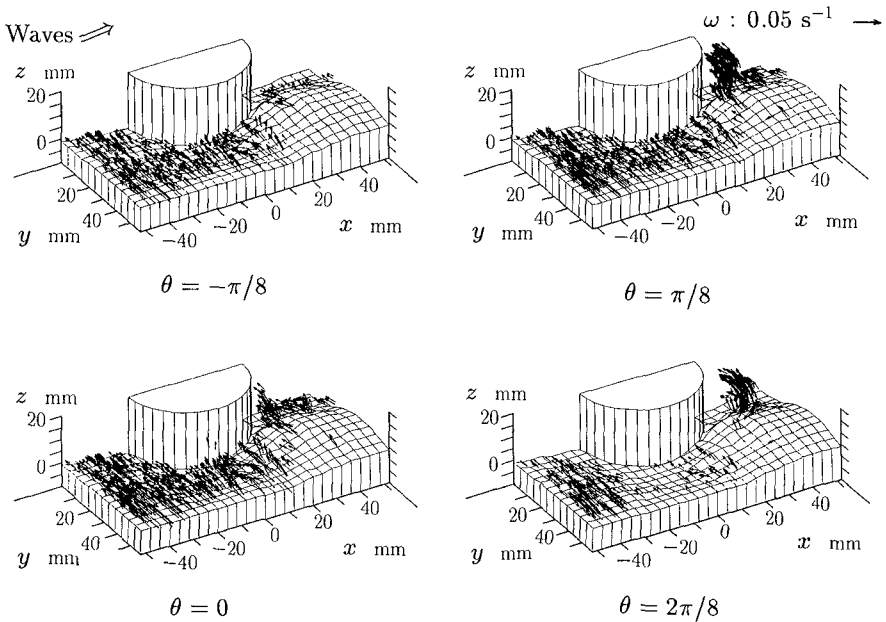

**3.3. Comparison between the Two Flow Fields**

The results of the two experiments are compared to study the effects of the bottom profile on the flow structures.

The vorticity vector distributions in *Fig. 4* indicate that the axis of the vortex shed from the cylinder is almost vertical above the flat bottom. Consequently the flow structure does not change significantly in the vertical direction. On the other hand, as shown in *Figs. 8* and *9*, the velocity distributions over the scoured seabed are very complex and the vortex is deformed into arch-shape. The separation over the hill forces the vortex shed from the cylinder to change to this

*Fig. 8.* Vorticity vector distributions above the scoured seabed at  $\theta = \pi/4$ .

*Fig. 9.* Time evolution of the vortex above the scoured seabed.

arch-shaped one, as explained in the last section. Then this vortex drives local intense reversing flow close to the bed near the down-wave edge of the cylinder as shown in *Fig. 9*. Furthermore the flow produces the scour hole at the down-wave edge of the cylinder between two hills as represented in *Fig. 2*.

From the comparison between the vorticity distributions above the flat bottom and the scoured seabed, it is thus concluded that the deformation of the vortex shed from the cylinder is caused by the effect of the locally scoured seabed configuration. In other words, the rugged seabed topography causes change in the shedding and developing processes of the large vortex from the quasi-two-dimensional to the complex three-dimensional structure.

#### 4. NUMERICAL SIMULATION

##### 4.1. Vortex-Segment-Model

A three-dimensional Vortex-Segment-Model has been adopted to simulate the flow around a cylinder. This model is one of the Discrete-Vortex-Methods, which deal with a flow field as a vorticity field and are useful to understand the behavior of vortices. Since an element of this model is a vortex segment with finite length, each segment does not satisfy Kelvin's circulation theorem rigidly. However, the model treats a vortex filament as a group of the segments, and hence the theorem is almost fulfilled in this model. Its validity has been reported by Shirayama *et al.* (1984) and others. Differing from the other Discrete-Vortex-Methods, this model can easily express the cut-and-connect processes of vortex filaments and the production of vorticity on the surfaces of solid boundaries due to the non-slip boundary condition. This model is thus useful to simulate the flow fields with the solid boundaries in them.

In this model the structure of a vortex segment is assumed as illustrated in *Fig. 10*, and an induced velocity vector for each vortex segment is given by

$$\mathbf{u}(\mathbf{x}) = -\frac{\Gamma}{4\pi} \int_{r_1}^{r_2} \frac{(\mathbf{x} - \mathbf{s}) \times \mathbf{t}(\mathbf{s})}{|\mathbf{x} - \mathbf{s}|^3} ds, \quad (7)$$

where  $\mathbf{u}(\mathbf{x})$  is the induced velocity vector at a point  $\mathbf{x}$ ,  $\mathbf{s}$  is a position vector along the axis of the vortex segment,  $\mathbf{t}(\mathbf{s})$  is a unit vorticity vector at the position  $\mathbf{s}$ , and  $r_1$  and  $r_2$  are the positions of the two ends of the segment. A finite core radius of the vortex segment is assumed in this model for the stability in numerical

*Fig. 10.* The structure of a vortex segment in the Vortex-Segment-Model.

Fig. 11. Computational domain.

computation. To simulate the flow field, a large number of vortex segments are distributed in the computational domain.

#### 4.2. Results of the Simulation

The model has been applied to the numerical simulation of the near-bottom flow field around a vertical slender cylinder under waves. The bottom of the computational domain is flat as shown in Fig. 11. The non-slip condition is imposed on the surfaces both of the cylinder and of the flat bed, and therefore the vorticity is produced on these solid boundaries. The numerical simulation has been conducted under the condition that the Ursell number is 25 and the K.C. number is 5.0, which is close to that of the laboratory experiments.

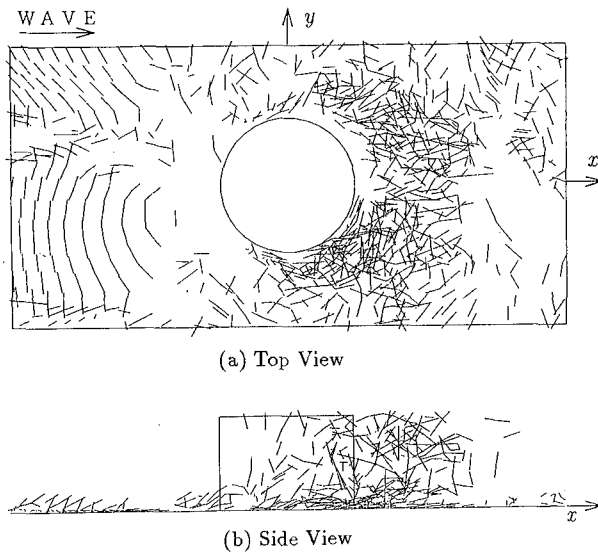

Fig. 12. Vortex segment distributions at  $\theta = \pi/4$ .

To satisfy the solid boundary conditions mirror-imaged vortex segments are introduced for the flat bottom boundary, and fixed vortex segments are put on the surface of the cylinder. In addition, new vortex segments are generated in close proximity from the solid boundaries to satisfy the non-slip condition in every computational steps.

Figure 12 displays one of the vortex segment distributions obtained by this model. As shown in this figure, flow fields are represented with a number of vortex segments. Under the computational conditions of this study, the distributions of vortex segments are almost symmetric with respect to the vertical  $x$ - $z$  plane, which is consistent with the experimental results.

The evaluated velocity distribution in the horizontal plane near the bed and the corresponding experimental result are shown in Fig. 13. It is found that the vortex shedding is well simulated in this case. These figures indicate a fairly good agreement, which implies the validity of this numerical model.

## 5. CONCLUSION

The near-bed velocity distributions around the vertical slender cylinder under waves have been measured and estimated in full detail above both the flat bottom and the scoured seabed. The following characteristics of the flow have been

(a) Result of the Numerical Simulation ( $z = D/20$ )

(b) Experimental Result ( $z = D/8$ )

Fig. 13. Velocity distribution in a horizontal plane at  $\theta = \pi/4$ .

found. Above the flat bottom, the axis of the vortex shed from the cylinder surface is almost straight and vertical. On the other hand, the arch-shaped vortex is formed over the scoured seabed. This arch-shaped vortex drives the local intense reversing flow close the bed near the down-wave edge of the cylinder. It is therefore clear that the rugged seabed shape has a significant influence on the shedding and deforming processes of large vortices to change the flow pattern from the quasi-two-dimensional to the complex three-dimensional structure. Since this three-dimensional vortices cause local intense flow near the bed, the behavior of the vortices is thus very important to study local scouring processes around a vertical cylinder.

In addition the flow around a cylinder over the flat bottom has been simulated numerically with a three-dimensional Vortex-Segment-Model. The results of the simulation have shown a good agreement with those obtained in the laboratory experiments. Hence it is concluded that the numerical model presented here is a promising one for analysis of the scour process and for prediction of the scouring.

#### ACKNOWLEDGEMENTS

I thank Professors A. Watanabe and M. Isobe of the University of Tokyo for their suggestions in this study.

# A description of the "acqua alta" event on 5th October

the Organizing Committee

## Introduction

""Certainly the "acqua alta" on the first morning of the Conference was a memorable event which every coastal engineer should experience in part because it underscores one of the problems that may face the next generation of coastal engineers. Our colleagues that were unable to attend the Conference will be envious of the *opportunity* to wade to the first session, barefoot and shoes and socks in hand! The sessions and chapters in the Proceedings on the history and plans relating to Venice Lagoon and the protective barrier islands will serve as valuable source documents for the future. The venue in Venezia was both appropriate and unforgettable."" (from a letter of Robert Dean).

What a better introduction than these few words of the new CERC President. Following this stimulation the Organizing Committee has asked some near participants<sup>1</sup> to supply a description of the event in order to fix the experience of those who were present and to give a pale idea to those who could not attend the Conference.

## The meteo- and oceanographic situation

On the first days of October 1992 the meteorological situation over the Mediterranean Sea was characterized by an almost uniform and relatively high atmospheric pressure distribution. Wind speeds and wave heights were very low throughout the basin, due mainly to local actions. This situation changed abruptly on October 3rd (Saturday), when an energetic flow of north-westerly cold air entered the Gulf of Lion from the Carcassonne passage between the Pyrenées and the Massif Central in south-western France (see figure 1.a, relative to 00 UTC 3 October '92).

Interacting with the still warm water of the Western Mediterranean Sea, this led to an intense cyclogenesis. A low centered over Corsica developed (see figure 1.b, relative to 00 UTC 4 October '92) with southerly winds on its eastern side, i.e. over Italy. The flow was intensified by the opposing high pressure zone located over eastern and northern Europe.

The southerly wind produced high wave conditions on the Ionian Sea, particularly on the facing Italian coasts. Over the Adriatic Sea the parallel Appennines ridge on the Italian side and the Dinaric Alps on Yugoslavia

---

<sup>1</sup>Luciana Bertotti, CNR-ISDGM Venice, provided the meteorological description, Manlio De Boni, TEI Milano, the wave records, Giovanni Cecconi, Consorzio Venezia Nuova, and Paolo Canestrelli, Centro Previsioni Maree Venezia, provided the description of the tide, Leopoldo Franco and Ferruccio Egori the photographs.

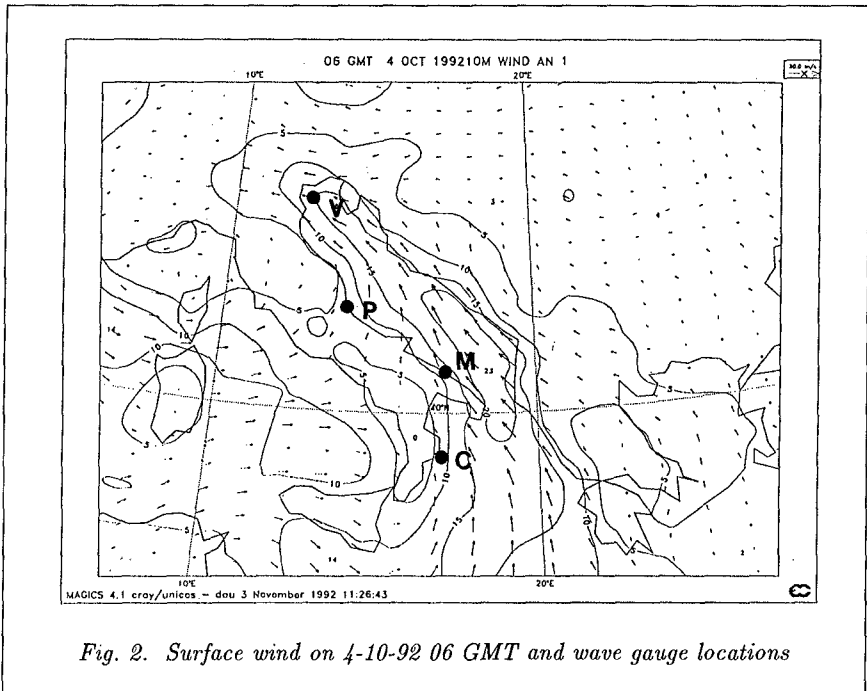

Fig. 1. Weather map at 3-10-92 (a) and 4-10-92 00 UTC (b)

channeled the flow leading to an intense south-easterly wind all along the Adriatic Sea. This is well shown by the distribution of surface wind at 06 UTC 4 October '92 obtained with the meteorological model of the European Center for Medium Range Weather Forecasts, Reading, U.K. (see figure 2).

Wave reacted rapidly. The peak conditions were reached in the first 12 hours of 4 October, with significant wave height  $H_s = 2.0$  m at Pescara, in the mid Adriatic, and  $H_s = 3.4$  m at the oceanic platform of ISDGM, 8 miles off the coast of Venice. The two positions, together with the more southerly Monopoli location in the Adriatic Sea and Crotone in the Ionian coast, are indicated by black dots in figure 2. Figure 3 shows the time series of  $H_s$  at these four locations throughout the storm.

*Fig. 2. Surface wind on 4-10-92 06 GMT and wave gauge locations*

The later decrease of wind speed, following the expansion and filling of the atmospheric low, left in the Adriatic Sea a swell propagating towards North-West, clearly recognizable in the records of figure 3.

### The storm surge in Venice

On Sunday the 4th, at neap tide, without any storm surge, a maximum level of 40 cm due only to the astronomical tide was expected at Punta della Salute, but because of the strong wind along the Adriatic Sea and the local atmospheric low pressure the water level reached 119 cm, with a storm surge component of about 80 cm (see figure 4).

Due to the persistent meteorological conditions, the water level raised on

Fig. 3. Time history of recorded wave height in the Adriatic Sea

the following day, the first day of the Conference, flooding the town since 6 am. The flood lasted almost five hours till 11 am reaching the maximum level of 126 cm at 9 am just in time for the opening lecture. During the peak San Marco Square was covered by 46 cm of water and 50 % of the town was flooded.

Should the storm surge have occurred in a spring tide period, when the normal high water level is 75 cm, the water would have been 35 cm higher and the flood would have reached 80% of the town (cf. figure 5).

### The effects

The flood caused more damages and delays than usual due to the peculiar time of occurrence: early on Monday morning, following immediately a holiday. Visitors in particular had difficulties in getting a pair of boots and the 120 cm high walk-ways were not high enough to give a dry passage to the people without boots.

Photo 1 gives you a "look of the quay" near San Marco Square on Monday morning. On the opposite side of the channel participants in the Conference were entering Fondazione Cini with some trouble, cf. photo 2.

Notwithstanding the surprise of participants in the Conference, the flood on Monday October the 5th was not an exceptional one. During the years 1980-'89 this level was exceeded twelve times (cf. figure 5) and its return period is close to one year.

Comparing this flood to historical records, the water depth reached in San Marco Square was just one third of that reached on November 4th 1966, when the most severe recorded flood reached 114 cm water depth in San Marco Square (194 cm recorded water level).

The Conference event was actually much more unexpected than his bare return period tells. Actually most events occurs in late fall and winter and near spring tide and the return period of the "unexpected" storm surge is about 5 years. The storm surge may be decomposed into a quasi static component and in a seiche component, whose main period is ~ 21 hr. During sunday and monday the seiche component was in phase with the astronomical tide; in the following days the seiche amplitude was decreasing and the phase was lost, determining a rapid reduction of high water level.

Subsidence has some influence on the effects of high storm surge events. The reference level above which tide is measured in Venice is the mean sea level in 1897. Nowadays the mean sea level as a consequence mainly of subsidence is about 22 cm above datum and increases at the approximate rate of 0.1 cm/year.

	Normal spring tide	4 Nov. '66	5 Oct. '92	Normal "acqua alta"
Mean sea level	22	20	22	22
Astronomical tide	50	25	20	38
Storm surge	-	150	84	60
quasi static	-	100	40	30
seiche	-	50	44	30
