From the interface continuity of mass flux and Eq.(25), the parenthesized term becomes

$$w_{-h_1} + u_{-h_1} \frac{\partial h_1}{\partial x} = -\frac{\partial}{\partial x} [\epsilon u_s (h_0 - h_1)] \quad (26)$$

Finally, this gives

$$w(z) = -\frac{\partial}{\partial x} [u(z + h_1)] - \frac{\partial}{\partial x} [\epsilon u_s (h_0 - h_1)] \quad (27)$$

Integration of Eq.(6) from  $-h_1$  to  $\eta$  gives

$$0 = \frac{\partial}{\partial x} \int_{-h_1}^{\eta} u dz - \left( \frac{\partial \eta}{\partial x} u_{\eta} - w_{\eta} \right) - \left( \frac{\partial h_1}{\partial x} u_{-h_1} + w_{-h_1} \right)$$

Using the free surface kinematic boundary condition and Eq.(26) for the parenthesized terms, the last equation finally yields the continuity equation:

$$\frac{\partial \eta}{\partial t} = -\frac{\partial}{\partial x} [u(\eta + h_1)] - \frac{\partial}{\partial x} [\epsilon u_s (h_0 - h_1)] \quad (28)$$

### 3.3 Second-order Approximation

To get a second-order formulation of the governing equations, the results of the first-order equations for the vertical velocities and pressures are utilized. Neglecting terms of  $O(\varepsilon^3)$  and higher in the nondimensional equations and using the dimensional counterparts, the following results are obtained:

Equation (2):

$$\frac{\partial w}{\partial t} = -g - \frac{1}{\rho} \frac{\partial p}{\partial z}$$

Using Eq.(27), this becomes

$$-\frac{1}{\rho} \frac{\partial p}{\partial z} = g - \frac{\partial^2}{\partial t \partial x} [u(z + h_1)] - \frac{\partial^2}{\partial t \partial x} [\varepsilon u_s (h_o - h_1)] \quad (29)$$

Integrating Eq.(29) from  $z$  to  $\eta$  and applying the free surface dynamic boundary condition lead to

$$\frac{p(z)}{\rho} = g(\eta - z) - \frac{\partial^2}{\partial t \partial x} \left[ u \frac{1}{2} \{ (\eta + h_1)^2 - (z + h_1)^2 \} \right] - \frac{\partial^2}{\partial t \partial x} [\varepsilon u_s (h_o - h_1) (\eta - z)] \quad (30)$$

Equation (5):

$$C_r \frac{\partial w_s}{\partial t} = -g - \frac{1}{\rho} \frac{\partial p_s}{\partial z} - \frac{\varepsilon \nu}{K_p} w_s$$

The left-hand side is evaluated using the first-order form of  $w_s(z)$ , Eq.(24), resulting in

$$-\frac{1}{\rho} \frac{\partial p_s}{\partial z} = g - \frac{\partial^2}{\partial t \partial x} [C_r u_s (z + h_o)] - \frac{\partial}{\partial x} \left[ \frac{\varepsilon \nu}{K_p} u_s (z + h_o) \right] \quad (31)$$

Integrating from  $z$  to  $-h_1$  and invoking the interface continuity of pressure and Eq.(30), the last equation becomes

$$\begin{aligned} \frac{p_s(z)}{\rho} = & g(\eta - z) - \frac{\partial^2}{\partial t \partial x} \left[ \frac{u}{2} (\eta + h_1)^2 \right] - \frac{\partial^2}{\partial t \partial x} [\varepsilon u_s (h_o - h_1) (\eta + h_1)] - \\ & - \frac{\partial^2}{\partial t \partial x} \left[ C_r \frac{u_s}{2} \{ (h_o - h_1)^2 - (h_o + z)^2 \} \right] - \frac{\partial}{\partial x} \left[ \frac{\varepsilon \nu}{K_p} \frac{u_s}{2} \{ (h_o - h_1)^2 - (h_o + z)^2 \} \right] \end{aligned} \quad (32)$$

Equations (30) and (32) highlight the effect of the vertical velocity on the pressure distribution. The last four terms in the last equation are due to the inclusion of the local vertical velocity in the second-order formulation and show that in oscillatory flows where this component is nontrivial, the distribution of pressure in both water layer and porous layer is not hydrostatic.

Next, in consonance with the vertical integration of the equations for the pressures, a depth-integrated horizontal velocity  $U$  is defined in the water layer such that

$$u(x, z, t) = U(x, t) + u^*(x, z, t) \quad (33)$$

where

$$U = \frac{1}{h_1 + \eta} \int_{-h_1}^{\eta} u dz \quad (34)$$

and  $u^*$  is the horizontal velocity deviation along the vertical and is  $O(\varepsilon^2)$ . The velocity  $u$  can then be expanded as a power series in the parameter  $\varepsilon$ ,

$$u(x, z, t) = \varepsilon u_1(x, t) + \varepsilon^2 u_2(x, z, t) + \varepsilon^3 u_3(x, z, t) + \dots \quad (35)$$

From Eq.(34),

$$U = \varepsilon \hat{u}_1 + \varepsilon^2 \hat{u}_2 + \varepsilon^3 \hat{u}_3 + \dots \quad (36)$$

where

$$\hat{u}_1 = \frac{1}{h_1 + \eta} \int_{-h_1}^{\eta} u_1 dz \dots$$

The terms following  $\varepsilon \hat{u}_1$  in Eq.(36) are of  $O(\varepsilon^3)$  and higher and may be dropped out giving

$$U \approx \varepsilon \hat{u}_1 \quad (37)$$

Returning to the governing equations with Eqs.(35) and (37), the terms on the left-hand side reduce to the following:

$$\begin{aligned} \frac{\partial u}{\partial t} &= \frac{\partial U}{\partial t} + O(\varepsilon^3) + \dots \\ u \frac{\partial u}{\partial x} &= U \frac{\partial U}{\partial x} + O(\varepsilon^4) + \dots \\ w \frac{\partial u}{\partial x} &= O(\varepsilon^3) + \dots \end{aligned}$$

Substitution of these equations into Eq.(1), with the third-order and higher terms neglected, leads to the following:

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} = -\frac{1}{\rho} \overline{\frac{\partial p}{\partial x}} \quad (38)$$

where the overbar represents an averaging over the relevant depth. With the pressure  $p$  dependent on  $z$  and the left-hand side of Eq.(38) expressed in terms of depth-averaged values, Eq.(30) for the pressure  $p(z)$  is differentiated with respect to  $x$ , depth-averaged evaluating all integrals, then substituted in the last equation. This finally gives the horizontal momentum equation in the water layer:

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} = -g \frac{\partial \eta}{\partial x} + \frac{\partial^3}{\partial t \partial x^2} \left[ \frac{U}{3} (\eta + h_1)^2 \right] + \frac{\partial^3}{\partial t \partial x^2} \left[ \frac{\varepsilon U_s}{2} (h_o - h_1) (\eta + h_1) \right] \quad (39)$$

$U_s$  in Eq.(39) defined as

$$U_s = \frac{1}{h_o - h_1} \int_{-h_o}^{-h_1} u_s dz \quad (40)$$

was obtained from a similar development for the porous layer. Parallel developments for the terms on the left-hand side of Eq.(4) using Eq.(40) give, to second order,

$$C_r \left( \frac{\partial U_s}{\partial t} + U_s \frac{\partial U_s}{\partial x} \right) = -\frac{\overline{1 \partial p_s}}{\rho \partial x} - \frac{\overline{\epsilon \nu}}{K_p} u_s - \frac{\overline{\epsilon^2 C_f}}{\sqrt{K_p}} \sqrt{u_s^2 + w_s^2} u_s, \quad (41)$$

Using Eq.(32) for  $p_s(z)$ , the right-hand side of Eq.(41) is evaluated, integrating all terms with overbars. This finally gives the horizontal momentum equation in the porous layer:

$$\begin{aligned} C_r \left( \frac{\partial U_s}{\partial t} + U_s \frac{\partial U_s}{\partial x} \right) = & -g \frac{\partial \eta}{\partial x} + \frac{\partial^3}{\partial t \partial x^2} \left[ \frac{U}{2} (\eta + h_1)^2 \right] + \\ & + \frac{\partial^3}{\partial t \partial x^2} [\epsilon U_s (h_o - h_1) (\eta + h_1)] + \frac{\partial^3}{\partial t \partial x^2} \left[ \frac{C_r U_s}{3} (h_o - h_1)^2 \right] \\ & - \frac{\partial^2}{\partial x^2} \left[ \frac{\epsilon \nu}{K_p} \frac{U_s}{3} (h_o - h_1)^2 \right] - \frac{\epsilon \nu}{K_p} U_s - \frac{\epsilon^2 C_f}{\sqrt{K_p}} \sqrt{U_s^2 + W_s^2} U_s, \end{aligned} \quad (42)$$

The momentum equations (39) and (42) and the depth-integrated continuity equation (28), comprise a second-order formulation of the transformation of a surface disturbance in a depth-varying region with a porous layer, taking into account the effect of vertical acceleration, finiteness of the surface displacement and the momentum loss in the porous layer.

Under ordinary conditions,  $W_s$  in Eq.(42) is much less than  $U_s$ . By invoking the assumption that  $H/h \ll 1$  and noting that the interface and impermeable boundaries are rigid and that the porous layer has a homogeneous makeup, the second-order formulation can be simplified to the following set of nonlinear equations:

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} [U(\eta + h_1)] + \frac{\partial}{\partial x} [\epsilon U_s h_p] = 0 \quad (43)$$

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + g \frac{\partial \eta}{\partial x} - \frac{h_1^2}{3} \frac{\partial^3 U}{\partial t \partial x^2} - \frac{\epsilon h_p h_1}{2} \frac{\partial^3 U_s}{\partial t \partial x^2} = 0 \quad (44)$$

$$\begin{aligned} C_r \left( \frac{\partial U_s}{\partial t} + U_s \frac{\partial U_s}{\partial x} \right) + g \frac{\partial \eta}{\partial x} - \frac{h_1^2}{2} \frac{\partial^3 U}{\partial t \partial x^2} - \left( \frac{C_r h_p^2}{3} + \epsilon h_p h_1 \right) \frac{\partial^3 U_s}{\partial t \partial x^2} \\ - \frac{\epsilon \nu}{3 K_p} \frac{\partial^2}{\partial x^2} [U_s h_p] + \frac{\epsilon \nu}{K_p} U_s + \frac{\epsilon^2 C_f |U_s|}{\sqrt{K_p}} U_s = 0 \end{aligned} \quad (45)$$

These equations can be applied in determining the wave field for progressive and oscillatory waves. Although wave motion is usually characterized by periodicity, this property is not a prerequisite in applying the equations since the time dimension has been explicitly included. Hence, these equations can be applied to both regular and irregular waves with suitable boundary conditions.

The assumption of order  $(h/l)^2$  in the nondimensionalized velocities precludes the application of the equations in deep water. In addition, consideration of the nonlinearity of the boundary conditions for the free surface conforms approximately to the region where finiteness of wave height is important. Therefore, the region of validity of the equation falls approximately where the cnoidal wave theory is valid. Lastly, the equations are applicable in a region where the only energy loss is through friction in the porous layer. When breaking is present, the additional energy dissipation must be considered.

#### 4 Breaking Wave Transformation

Wave breaking usually occurs on the breakwater upslope resulting in dissipation of wave energy. The amount of energy dissipated by this phenomenon has been related to the mass flux rate across a vertical section beyond the breaking point. For a submerged permeable breakwater, considering that the mass flux is due to flow across both water and porous layers, the energy dissipated is accounted for by adding an energy dissipation term per unit mass,  $f_D U$  in the water layer and  $f_D \epsilon U_s$  in the porous layer, to the left-hand sides of Eqs.(44) and (45).

The dissipation function  $f_D$  (dimension:  $\text{time}^{-1}$ ) for breaking on a sloping impermeable bed has been given by Watanabe and Dibajnia (1988). Recognizing the points of departure of the breaking dissipation over a submerged porous breakwater from that over an impermeable bed, the dissipation function was modified as

$$f_D = \alpha_D \tan \beta' \sqrt{\frac{g}{h'_1}} \sqrt{\frac{\varphi - \varphi_r}{\varphi_s - \varphi_r}} \quad (46)$$

where  $\alpha_D = 2.5$ ,  $\tan \beta'$  is the effective bottom slope at the breaking point,  $h'_1 = h_1 + \epsilon h_p$ ,  $\varphi = |\bar{\eta}|/h'_1$ ,  $\varphi_r = 0.4(|\bar{\eta}|/h'_1)_b$ ,  $\varphi_s = 0.5(0.57 + 5.3 \tan \beta')$ . The subscript  $b$  indicates values at the breaking point.  $|\bar{\eta}|$  is the effective amplitude defined as  $|\bar{\eta}| = 0.50(\eta_c - \eta_t)$  where  $\eta_c$  and  $\eta_t$  are the surface displacements of the crest and trough, respectively. A breaking criterion based on the experiments of Rojanakamthorn et. al. (1990) was used to locate the breaking point.

#### 5 Application and Results

In applying Eqs.(43) to (45) within a region where structures are present, the waves reflected from the structure are subtracted through the offshore boundary by considering an appropriate boundary condition. For one dimension, this is expressed by

$$\eta(x_o, t + dt) = \eta_I(x_o, t + dt) + [\eta(x_o + C_o dt, t) - \eta_I(x_o + C_o dt, t)] \quad (47)$$

where  $C$  is the celerity, subscript  $I$  refers to a prescribed incident wave and  $o$  refers to the offshore location. At the onshore boundary, complete transmission

of the transformed wave is enforced through the radiation condition:

$$\left. \frac{\partial \eta}{\partial t} \right|_{x=x_D} = -C_D \left. \frac{\partial \eta}{\partial x} \right|_{x=x_D} \tag{48}$$

where the subscript  $D$  refers to the onshore location. The velocity  $U$  is similarly prescribed.

Figure 2: Submerged permeable breakwater

Equation (43) to (45) have been discretized for numerical computation using an eight-point finite-difference computational module on a staggered mesh. Calculation was carried out from still water conditions alternately for the velocities and  $\eta$ . The equations were tested for the case of monochromatic wave propagation on a horizontal bottom without any porous body by comparing with a theoretical solution for the spatial and temporal profiles of  $\eta$ . Calculation gives profiles that conform very well with those given by the second-order cnoidal wave theory.

Laboratory experiments were performed to examine the applicability of the nonlinear model to predicting wave transformation over a submerged permeable breakwater. The set-up is given in Fig. 2. One of the gauges was located beyond the structure to describe the disintegrated wave. In the calculations the properties of the fluid and porous material were:  $\nu = 1.3 \times 10^{-6} \text{m}^2/\text{s}$ ,  $\epsilon = 0.44$ ,  $K_p = 2.06 \times 10^{-8} \text{m}^2$ ,  $C_f = 0.428$ ,  $g = 9.8 \text{m/s}^2$  and  $C_r = 1.0$ . The porosity was measured directly in the laboratory and  $K_p$  and  $C_f$  are fixed by the size of the gravel used.

Figures 3 and 4 show the comparison of the wave profiles at different locations when no breaking was observed anywhere in the wave flume. In Fig. 3, the relative depth of submergence  $H/y_c$  is 0.29 and the relative depth  $h/L$  offshore is 0.073. It can be seen that the weak disintegration at the breakwater lee is predicted by the second-order equations. Using the nonlinear incident wave based on the experiments for the offshore boundary condition leads to a large reflection

Figure 3: Wave Profiles (Case 1, Non-breaking transformation)

from the breakwater (Station 2) and a secondary peak at the first crest station. In Fig. 4, the water depth was reduced so that  $H/y_c$  becomes large, leading to a strong disintegration leeward. Although the high-frequency components of the disintegrated wave are not reproduced, the general pattern is predicted by the second-order equations.

For breaking transformation, the dissipation function is evaluated at all points beyond the breaking point using Eq.(46). Figure 5 shows a comparison of the wave profiles from calculation and experiments for a short period incident wave. The breaking point was located at  $x = 2.95\text{m}$  in both calculation and experiment. For this case, the wave height was increased so that  $H/y_c = 0.99$  and  $h/L = 0.136$ . It is evident that the model predicts the wave height distribution well. However, the second-order equations fail to yield the secondary component of the transmitted wave at the lee.

Figure 4: Wave Profiles (Case 2, Non-breaking transformation)

## 6 Conclusions

1. Basic equations of nonlinear wave transformation over a porous layer are derived.
2. For non-breaking transformation on the submerged permeable breakwater, the equations predict the wave height and the profile well. However, the disintegrating characteristic of the transmitted waves is weakly predicted by the second-order equations.

When  $H_i/y_c$  is less than about 0.29, the agreement is good while for higher ratios, the agreement is not good especially at the breakwater lee.

3. For breaking transformation, the wave profiles are predicted well prior to the region leeward of the breakwater where the waves disintegrate. Although the wave profile is not reproduced so well after breaking, the wave height distribution is predicted fairly well by the present model of wave breaking.

## CHAPTER 84

### MODEL TESTING OF WAVE TRANSMISSION PAST LOW-CRESTED BREAKWATERS

B. L. Davies<sup>1</sup> and D. L. Kriebel<sup>2</sup>

#### Abstract

Small-scale model tests were conducted to assess the wave transmission characteristics of low-crested breakwaters. The goals of this study are to quantify the wave transmission characteristics of these breakwaters for various structure heights, water depths, and wave conditions. The tests were conducted on cross-sections of solid and rubble breakwater models using both regular and irregular waves. A new parameter,  $(F-Ru)/H_i$ , is then proposed to represent transmission past a breakwater for all values of breakwater freeboard.

#### Introduction

Several recent studies have considered the wave transmission characteristics of low-crested breakwaters in which the armor stones were small enough to be remolded by the incident wave action, e.g. Ahrens (1987a) and van der Meer (1990). For such cases, Ahrens (1987a) has proposed that the breakwater porosity can be characterized by the Bulk Number, which represents the number of stones in the breakwater cross-section. These studies then provide wave transmission data for breakwaters with high Bulk Numbers, in the range of 200 to 600, and sometimes more.

In the United States, however, most low-crested breakwaters are not built with such small armor stones and Bulk Numbers in the range of 10 to 50 are most common. As a result, some of the recent data on wave transmission may not be applicable to realistic breakwater design conditions. In the present study, wave

transmission results from physical model tests are presented for low-crested breakwaters with Bulk Numbers in the range of 12 to 36. The breakwaters considered here are so-called statically-stable homogeneous breakwaters, e.g. van der Meer (1991), which contain a single uniform stone size selected in the traditional way according to the Hudson Formula to be stable under wave attack.

The overall objective of this study is to expand the existing database on wave transmission past low-crested breakwaters for conditions that would normally be encountered in design. Toward this goal, more than 250 small-scale physical model tests were carried out on two-dimensional solid and rubble breakwater cross-sections in the Coastal Engineering Wave Basin at the United States Naval Academy. This study was similar in scope to that of Seelig (1980). The primary goal was to investigate the parameters which affect the transmission of waves past the types of low-crested or reef breakwaters currently being constructed in the United States. Figure 1 illustrates the variables of interest.

Figure 1. Reef Breakwater Definitions

### Experimental Setup

Laboratory tests were performed in the United States Naval Academy's Coastal Engineering wave basin. Figure 2 shows the side view of the test setup. The wave basin measured 16.61 meters long, and has a piston-type wavemaker that can generate either regular or irregular waves. The basin was then sub-divided by 2 plexiglass walls to form a test channel with a width of 0.61 meters. The test channel consisted of 3 segments. The first segment, 2.44 meters long, consisted of a 1:15 slope. The second segment, 4.88 meters long, was comprised of a level false bottom. In the final segment, 1.22 meters long, the false bottom was replaced by a wave absorbing gravel beach. Between the end of the channel and the back wall of the wave basin, there existed a 1.30 m wide space which prevented the ponding of water behind the breakwater test sections. A second wave absorbing

Figure 2. Side View of the Test Channel

beach was placed in front of the back wall of the tank. Numerous tests were conducted to document the effectiveness of the wave absorption system. In all cases studied, the value of wave reflection did not exceed 10%.

Capacitance wave gages were used to measure wave heights in front of and behind the breakwater. For the regular wave tests, three wave gages were generally used. Gages were placed 0.91 and 1.52 meters behind the breakwater and the results were averaged to yield the height of the transmitted wave, in a manner similar to Ahrens (1987b). The incident wave height was measured through the use of a single wave gage which was moved in front of the model from the base of the model to the top of the sloping beach. Through the movement of the gage, the incident and reflected wave heights were obtained from the partial standing wave envelope. The irregular wave tests utilized four wave gages, two in front of the model and two in the lee of the structure. Both pairs of these gages constituted a so-called Goda array, e.g. Goda and Suzuki (1976), which when analyzed has the capability of yielding the incident and reflected significant wave heights in front of and behind the breakwater at all frequencies in a random sea. The separation distance between these gages was 15.24 cm. The first pair of gages were located 76 cm in front of the breakwater while the lee pair were located 91 cm behind the model.

The breakwaters studied were two dimensional models, for which the transmission characteristics of different wave conditions and breakwater freeboards were of most interest. As a result, several design variables were held constant. The side slopes of the breakwater were built with a standard slope of 1:1.5, based on study of several recent reef breakwater projects in the United States. The weight of the armor stone was obtained through use of the Hudson (1959) equation. Despite the recent availability of alternate methods of sizing armor stone, the Hudson equation is still used to determine the size of the rock used in almost all current reef breakwater projects in the United States. For this model study, where limestone with a specific weight of  $2659 \text{ kg/m}^3$  was used, the Hudson equation yielded an armor stone weight of 0.18 kg and a diameter of approximately 5.1 cm, based on a maximum wave height of 10.2 cm in the test channel. Following this

analysis, the available stones were sieved and only rock that fell between the limits of 3.8 to 6.4 cm in diameter and 0.13 to 0.23 kg was accepted. Finally, the crest width was established from recommendations in the Shore Protection Manual of the U.S. Army Corps of Engineers (1984). The crest width used in this study was taken as 3 times the median stone diameter or 15.2 cm.

One unique aspect of these tests is that this design process yielded an order of magnitude smaller Bulk Numbers than the previous tests of Ahrens (1987a) or van der Meer (1990). Bulk Number is defined as:

$$B_n = \frac{A_t}{d_{50}^2}, \quad (1)$$

where  $A_t$  is the area of the breakwater cross section and where  $d_{50}$  is the median diameter of armor stone. The Bulk Number is therefore proportional to the number of stones in the cross-section. Based on the characteristics of the breakwater discussed above, the values of Bulk Number tested in this study ranged between 12 and 36, depending upon the breakwater crest height. Typical values for breakwaters built in the U.S. range from 10 to 50, e.g. Fulford (1985), so that values tested were within the range of recent prototype conditions.

Solid and rubble breakwaters were both tested during the course of this study. The solid models, which served as the limiting condition of zero permeability, were constructed of PVC to the same geometry specifications as the rubble structures. The crest heights tested for both types of models were 10.2, 15.2, and 20.3 cm tested in water depths of 10.2, 15.2, and 20.3 cm of water above the false bottom in the test channel. This produced a 3x3 test matrix. However, the two extreme cases were not tested, so that a 10.2 cm breakwater was not tested in 20.3 cm of water and likewise, a 20.3 cm breakwater was not tested in 10.2 cm of water. The purpose of this investigation was to study wave transmission past breakwaters at or near the still water line, with freeboards of +5.1 cm, 0.0 cm, and -5.1 cm.

The solid breakwater tests were conducted using regular waves only. Four frequencies were tested at each crest height and water depth combination. These frequencies were 0.55, 0.7, 0.9, and 1.1 Hz. In turn, at each of these frequencies four wave heights were generated. These wave heights extended up to heights which were close to breaking. The regular wave tests for the rubble breakwaters were run in exactly the same manner. The irregular wave tests were only conducted using the rubble models. These tests utilized the same combinations of crest height and water depth as did the regular wave study. With the irregular waves, JONSWAP spectral peak frequencies of 0.7 and 0.9 Hz were tested, and at each peak frequency, two significant heights were tested.

### Results--Regular Waves

Results for solid and rubble breakwaters subjected to regular waves are presented in Figures 3-6. Figures 3 and 4 illustrate the change in the wave transmission coefficient,  $K_t$ , or  $H_t/H_i$  for various wave steepness conditions,  $H_i/gT^2$ , breakwater geometries,  $h/h_s$ , (see Figure 1), and relative water depths,  $h/gT^2$ . These figures illustrate the dependence of wave transmission on wave steepness and relative water depth. They are especially valuable in illustrating the trends associated with various wave steepness conditions and breakwater freeboards where freeboard is defined as  $F = h_s - h$ .

Breakwaters with a high water depth to structure height ratio,  $h/h_s = 1.5$ , as shown in Figures 3a and 4a for solid and rubble breakwaters respectively, exhibit a trend of very high transmission for very low wave steepness, with diminishing values of  $K_t$  for very high steepness waves. This can be attributed to the fact that the breakwater, being below the still water level, allows waves of very low steepness to pass directly overhead with very little attenuation of the incident wave energy. Incident waves with very high steepness, on the other hand, are closer to breaking and the breakwater will succeed in "tripping" the wave, leading to energy dissipation. This situation is seen for both the solid and rubble breakwaters and  $K_t$  values are seen to approach about 0.5 for higher values of wave steepness.

The next conditions considered, in Figures 3c and 4c, are for breakwaters with a positive freeboard, where  $h/h_s < 0.75$ . The trend shown for this situation is different from that shown above for a breakwater with a negative freeboard and yields very different trends for the rubble and solid breakwaters. Figure 3c shows the case for the solid breakwaters studied. In this case, considering that the structure is impermeable, no wave energy will overtop the breakwater for very low steepness waves so that values of  $K_t$  are equal to zero in this portion of the graph. As the steepness of the waves increase, the wave runup will begin to overtop the breakwater and nonzero values of  $K_t$  are witnessed. As the wave steepness continually increases, the values for the transmission coefficient seem to approach a value between 0.4 to 0.5.

Rubble breakwaters, as shown in Figure 4c, illustrate a much different trend due to their porosity. Initially, even for very low steepness waves, there is transmission due to the flow through the permeable structure. The most interesting trend, however, is the fact that as wave steepness increases,  $K_t$  decreases, so that the breakwater is more effective in dissipating the energy of the steeper waves. In these cases, the waves are not able to run up the surface of the rubble structure to the same degree that they were able to run up the smooth surface of the solid breakwater. Thus, much less of the incident wave is able to overtop the structure, and instead must pass through the pores of the structure. In the process of passing through the structure, the higher steepness waves are not able to pass through the

**Figure 3.**  $K_t$  as a function of wave steepness for several structure geometries for solid breakwaters.

Figure 4.  $K_t$  as a function of wave steepness for several structure geometries for rubble-mound breakwaters.

breakwater as "cleanly" as are the low steepness waves. Within the breakwater, energy dissipation is likely related to the water particle velocities squared, much like head loss in turbulent fluid flow through pipes. Due to this, high steepness waves dissipate a greater percentage of their energy within the pores of the breakwater accounting for the downward trend in the data for steeper waves.

The final category of breakwaters considered are those with a zero freeboard, whose water depth to structure height ratio is equal to one. Figures 3b and 4b illustrate this case for solid and rubble breakwaters respectively. The trends shown in these figures are once again very similar for both solid and rubble breakwaters. As the wave steepness parameter increases,  $K_t$  seems to approach a limiting value of about 0.5. This limiting value appears to fit well within the trends established by Figures 3a, 3c, 4a, and 4c. Figures 3b and 4b also illustrate a weak transmission dependence upon relative water depth. For low values of relative water depth and low steepness waves, the transmission is greater than 0.5. As the steepness and relative water depth increase, however, there is less dependence upon relative water depth. In conclusion, Figures 3 and 4 show that values of  $K_t$  depend heavily upon wave steepness and breakwater geometry, and to a more limited degree on the relative water depth parameter,  $h/gT^2$ .

In addition to wave steepness, the relative freeboard parameter,  $F/H_i$ , was investigated as a controlling parameter for wave transmission. Figure 5 shows the values of  $K_t$  as a function of the relative freeboard parameter for both solid and rubble structures. The prediction equation of van der Meer (1991) is also superimposed along with its corresponding 90% confidence bands. Van der Meer's equation is defined as:

<i>Range of validity</i>	<i>Equation</i>
$-2.00 < F/H_i < -1.13$	$K_t = 0.80$
$-1.13 < F/H_i < 1.2$	$K_t = 0.46 - 0.3(F/H_i)$ (2)
$1.2 < F/H_i < 2.0$	$K_t = 0.10$ ,

and was meant originally for application to random wave transmission. The relative freeboard parameter has been the most widely studied of all parameters relating to wave transmission. Goda (1969), Seelig (1980), and Ahrens (1987a, 1987b) are just a few of the authors who correlate transmission past a breakwater to this parameter.

As illustrated by the data in Figure 5, when the relative freeboard of either a rubble or solid structure is negative, the transmission coefficient is relatively high. In these cases, the incident waves are able to pass over top of the structure with little interaction from the structure, especially for the lower steepness waves (small  $H_i$ ) as was illustrated above in Figures 3 and 4. In some cases for the solid breakwaters,  $K_t$  actually reaches a value of 1 for various cases of large negative relative freeboard. On the other hand, when the relative freeboard of the structure

**Figure 5.** Transmission of regular waves past solid and rubble breakwaters using traditional freeboard parameter.

**Figure 6.** Transmission of regular waves past solid and rubble breakwaters using new freeboard parameter.

is positive, the transmission coefficient is relatively low in both cases. In this extreme, however, the solid breakwater differs greatly from the rubble breakwater due to the latter's porous nature.

The solid breakwater in the positive extreme of the relative freeboard actually reaches a limiting value of zero since the structure only allows transmission once wave run up overtops the structure. The rubble breakwater, on the other hand, gives a minimum value of  $K_t$  at a relative freeboard value of about one. As the relative freeboard approaches higher positive values, the trend is once again back toward a larger  $K_t$  value due to flow through the structure. Since the highest value of freeboard was set at 5.1 cm, the controlling factor in these high values of  $F/H_i$  is the wave height. As a result, this parameter illustrates that the breakwater will allow significant transmission through the structure for very small waves even if the freeboard is much higher than the incident wave.

Relative freeboard is a good parameter for describing the transmission past breakwaters with either positive or negative freeboard, but for breakwaters with zero freeboard, it has some disadvantages. This is illustrated in Figure 5 where this parameter is unable to discriminate values of  $K_t$  for the cases of zero freeboard. For these cases, this parameter yields  $K_t$  values anywhere from 0.4 to 0.8 and lacks any dependence on the incident wave height. Despite this drawback, it is apparent that the predictive equation given by van der Meer for random waves does a reasonable job in predicting the trends in the data for regular waves, and a majority of the data taken in this study falls within the error boundaries established by van der Meer.

Because the relative freeboard parameter is not effective at zero values of freeboard, a new parameter is proposed in Figure 6 to describe the transmission past a reef breakwater at all values of freeboard. This new parameter,  $(F-Ru)/H_i$ , incorporates the potential vertical wave run up,  $Ru$ , (see Figure 1), based upon the Irribarren Number,  $\xi$ , and therefore contains an influence of wave steepness in a way similar to that proposed by Allsop (1983). This parameter is also similar to the overtopping parameter suggested by de Waal and van der Meer (1992). The potential wave run up used in this parameter was first proposed by Ahrens and McCartney (1975) in the form:

$$\frac{Ru}{H_i} = \frac{a\xi}{1 + b\xi}; \quad \xi = \frac{\tan\theta}{\sqrt{H_i/L_o}} \quad (3)$$

where  $L_o$  is the deep water wavelength and  $a$  and  $b$  are empirical coefficients which have the values of  $a = 0.775$  and  $b = 0.361$ , as proposed by Gunbak (1979).

As can be seen by Figure 6, this parameter does a better job in representing the data under all conditions of freeboard. Note that transmission past solid breakwaters is essentially zero when  $(F-Ru)/H_i$  equals zero, as is to be expected.

Transmission past rubble-mound structures is then minimized when  $(F-Ru)/H_i$  is approximately equal to zero, that is when the potential run up just equals the crest height. In the case of large positive values of the parameter, somewhat larger transmission is indicated. In general, these larger transmission values are again associated with the smallest incident wave heights tested at the lowest frequencies.

In conclusion, Figures 5 and 6 show that wave transmission does not significantly differ between the solid and rubble-mound structures, despite the low Bulk Numbers tested. Only for conditions where the breakwater crest is higher than the run up limit were results dramatically different, due to wave propagation through the porous rubble cross-section. Figure 6 illustrates that this transition will occur, for the conditions tested in this study, at a  $(F-Ru)/H_i$  value of approximately -0.4. Thus, below this value, solid breakwaters are shown to be a reasonable approximation of porous reef breakwaters when modelling wave transmission. In addition, these findings also show that the Bulk Number does not seem to be a primary parameter in determining wave transmission since impermeable structures yield similar transmission results as do extremely porous breakwaters.

### Results--Irregular Waves

Figures 7 and 8 present results obtained for rubble-mound breakwaters subjected to irregular waves, along with the earlier results for regular waves. For irregular waves, both the incident and transmitted wave heights are defined in terms of the significant height,  $H_s$ . Correlations were also performed using the root-mean-square wave height, but these results did not agree as well with the regular wave data. A possible reason behind this is that the energy dissipation and head losses in the porous structures are better modeled by  $H_s$ . Because the significant wave height represents the higher incident wave heights in random waves, it is more representative of the waves most affected by losses within the breakwater.

Both Figures 7 and 8 illustrate that the irregular waves tested followed the same trend and correlated well with the regular waves. Van der Meer's predictive equation for describing transmission as a function of  $F/H_i$ , again predicts the trend well and most of the random wave results fall within the suggested error bands. Once again, however the new  $(F-Ru)/H_i$  parameter is better able to discriminate  $K_t$  values for conditions with a zero freeboard, and the minimum wave transmission again occurs when this parameter is approximately equal to zero. This is shown to be the same for regular and irregular waves. Again, as was shown in Figure 6, the higher transmission for extreme positive and negative values of the new parameter are in all cases the result of very small waves of low frequency. Although the number of experiments performed with random waves was limited, the initial results indicate that regular wave results are useful for approximating the transmission of random waves defined by the significant height and peak frequency.

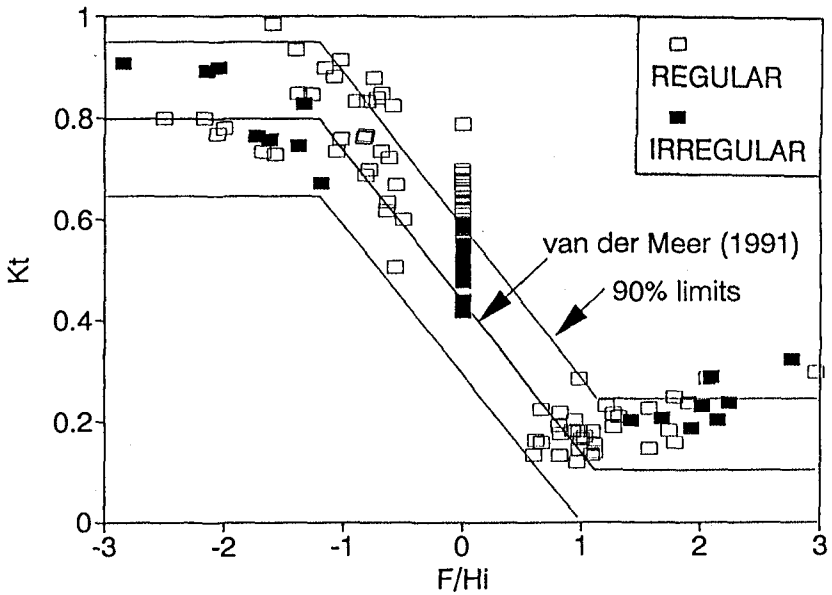

Figure 7. Transmission of regular and random seas past a rubble breakwater using traditional freeboard parameter.

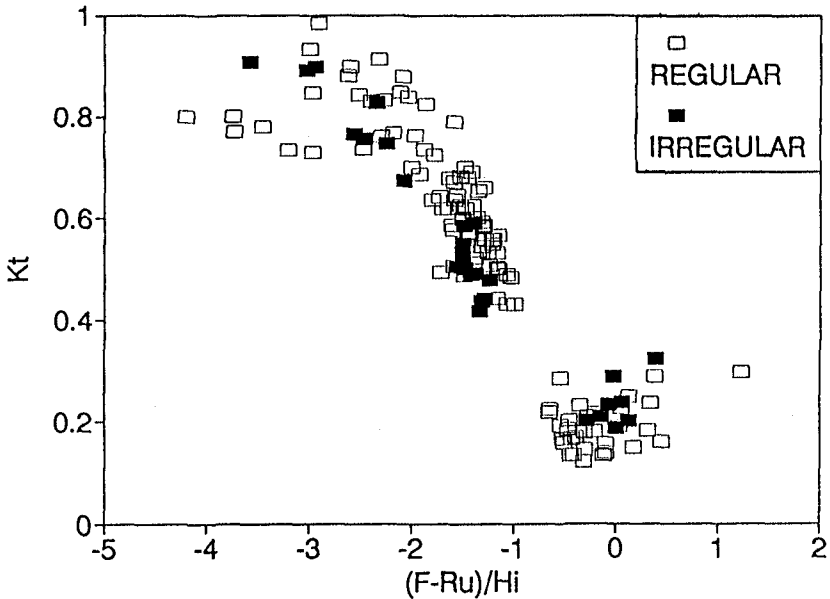

Figure 8. Transmission of regular and random seas past a rubble breakwater using new freeboard parameter.

## Conclusions

In general, this study found that breakwater freeboard, incident wave height, and wave run up, as a measure of wave steepness and potential overtopping, are the primary parameters determining transmission past low-crested breakwaters. A new parameter,  $(F-Ru)/H_i$  is proposed to describe the transmission characteristics of these structures. This parameter is able to spread the data for zero freeboard conditions, unlike the commonly used  $F/H_i$  parameter. In addition, solid breakwaters are shown to be a suitable approximation for transmission studies of rubble structures of values for  $(F-Ru)/H_i < -0.4$ ; and, regular wave results are shown to be a suitable approximation of irregular waves of similar significant height and peak frequency. Finally, comparisons of solid impermeable breakwaters to very porous rubble-mound structures shows that there are observable differences in transmission, but that the Bulk Number does not seem to exert a large influence on the wave transmission characteristics.

## Acknowledgments

The authors would like to thank John Ahrens for his assistance in planning the laboratory phase of this study and Louise Wallendorf for her invaluable assistance in the wave basin.

## CHAPTER 85

### GRAVITY DRAINAGE: A NEW METHOD OF BEACH STABILISATION THROUGH DRAINAGE OF THE WATERTABLE

Greg A. Davis<sup>1</sup>, David J. Hanslow<sup>1</sup>, Kevin Hibbert<sup>1</sup> & Peter Nielsen<sup>2</sup>

#### ABSTRACT

Beach nourishment to provide an erosion buffer and increase amenity is a well established coastal management option and is favoured because it is a relatively "soft" option with few aesthetic drawbacks. This paper describes how enhancement and stabilisation of the natural accretion processes may be achieved by a low-cost beach drainage system. The project described here shows that the watertable and shoreline can be lowered by a drainage system installed in the beachface. A prototype system was installed on Dee Why Beach, New South Wales, Australia in February–March 1991 and has been continuously discharging water until the present (November 1992). A number of minor storms have exposed and caused some damage to drainage material but the system continues to work.

Survey data are being collected at regular intervals to show the effects of the drainage system on the watertable and the morphology of the beach. Analysis of changes in morphology in both drained and undrained segments of the beach shows a significantly more stable beachface in the area of the drained beachface.

#### INTRODUCTION

Protection of coastal assets may be provided by seawalls while on coastlines with longshore littoral drift, groynes may provide both protection and a beach amenity. However, these hard structures may be aesthetically displeasing and may have adverse effects on adjacent areas of the coastline. Beach nourishment is not perceived to have these drawbacks. However,

- 
1. Coast & Rivers Branch, NSW Public Works Department, Sydney, Australia
  2. Department of Civil Engineering, University of Queensland, Brisbane, Australia

beach nourishment projects may have a limited life and therefore require further nourishment in the future. Recently a new technique of beach stabilisation through watertable drainage has been reported in the literature (eg, Parks 1989; Terchunion 1989; Bruun 1989; Ogden and Weisman 1991). This technique may extend the life of beach nourishment works thereby reducing the on-going costs.

Beach watertable drainage is thought to enhance sand deposition on wave uprush while diminishing erosion on wave backwash. The net result is an increase in subaerial beach volume in the area of the drain. Previous experimental work by Chappell et al. (1978) on a natural beach involving localised watertable drainage concluded that ". . . the evidence from these experiments very strongly supports the idea that beach aggradation can be induced by maintaining the beach watertable at a low level". The larger prototype drainage/pumping installations used by Terchunion (1989) in Florida; and Hansen (1986), Vesterby and Parks (1988) in Denmark also strongly suggest that beach aggradation may be artificially induced by beach watertable drainage. These installations have all employed systems of buried pipes and electrically powered pumps. The current paper describes an alternative to this technology. The idea is to achieve lowering of the watertable without pumps by enhancing the beach's own drainage capacity or hydraulic conductivity through the use of strip drains (Figure 1).

Duncan (1964) and Grant (1946, 1948) observed that beaches tend to erode as the tide falls and accrete as the tide rises. This is attributed to the effect of the watertable and its position relative to the offshore mean water level. As an incoming tide rises above the beach watertable, a proportion of the wave run-up infiltrates the beach face. This results in a reduction in the backwash volume and net beach accretion, particularly in the upper swash zone. As the tide falls, the beach watertable lags behind the offshore mean water level and thus contributes outflow to the swash zone. This contribution aids the backwash and causes net seaward movement of sediment. If this argument is correct, then it is the local watertable exit point

Figure 1 — Effect of the strip drain on the watertable

and its movement over a tidal cycle which is important for beach accretion and erosion and not the overall back beach watertable. Increasing the drainage capacity of the beach could be expected to decrease the time lag between oscillations of the beach watertable and the offshore mean water level and lower the watertable exit point within the wave run-up distribution of the beach.

This paper presents data relating to the effect of the drainage system on the beach watertable characteristics and some preliminary observations of the beach morphodynamics.

### STUDY AREA

The beach drainage system was installed in the central part of Dee Why Beach, which is an open coastal embayment approximately 14km north of Sydney's Central Business District (Figure 2). The beach faces the South East

which is the dominant direction of large swell waves from the Tasman Sea. The wave climate is highly variable and only weakly seasonal (Trenaman and Short, 1987). The tidal regime of the New South Wales coast is described by Easton (1970) as microtidal semidiurnal with a diurnal inequality, with a range up to 2m. Dee Why Beach occupies a drowned embayment and is flanked by rock headlands. The beach/barrrier system encloses a small lagoon which is only occasionally open to the ocean. The beach has undergone recession over recent geological time and this recession is thought to be continuing (Chapman et al. 1982).

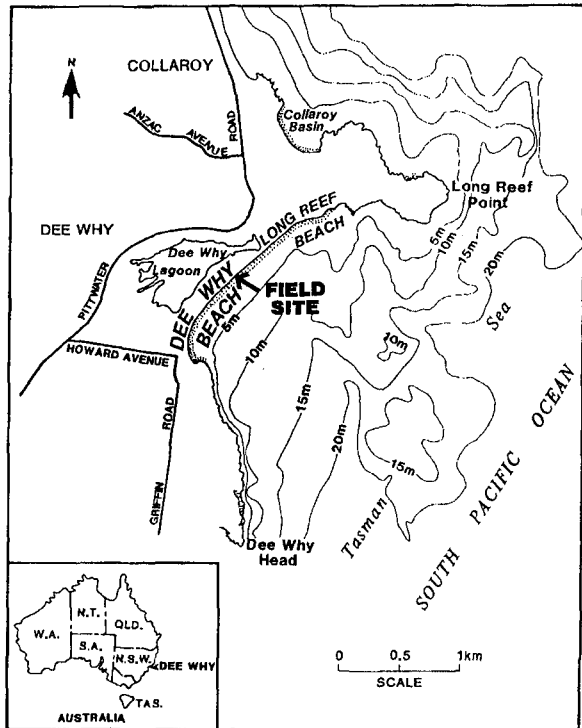

Figure 2 — Location diagram

and this recession is thought to be continuing

Mean swash zone grain size is of the order of 0.5mm. The surf zone is generally characterised by rhythmic topography with crescentic or transverse bars and regular rip channels. The beach may range between a reflective state with cusps after calm periods and a more dissipative bar/trough system after storms (Nielsen & Hanslow, 1991).

## MATERIALS AND INSTALLATION

The beach drainage system used in this installation incorporated an array of shore normal strip drains made of geotextile fabric enclosing a plastic core in an "egg-carton" configuration. The ends of the drains are covered with geotextile to prevent ingress of sand.

This type of drain is commonly used to drain ground-water from roads, parks and playing fields, etc. In these applications the drains are laid vertically. For the beach drainage system the drains were laid horizontally below the sand surface so as to minimise the risk of exposure during storms or rip formation. They were spaced from 5 to 15m apart and occupy 160m of the central part of Dee Why beach. A total of 18 drains were installed by 28 March, 1991. Drain installation was conducted during a period of spring low tides and small waves. A 27 tonne excavator was used to dig a series of 4 or 5 parallel trenches in the beach, finishing the job just before low tide. The drainage material was then laid and the trenches filled before the tide rose significantly. By this method, the seaward ends of the drains were buried to a level varying from -0.4m to -0.7m with respect to mean sea level (MSL).

The strip drain array was installed with the drains being parallel to one another and shore normal. This means that the landward ends of the drains have the greatest head due to elevated watertable and the seaward ends have the lesser head of the swash zone mean water level. Therefore, there is always a seaward flow potential. The location of the drains is indicated in **Figure 3**.

## WATERTABLE CHARACTERISTICS

### DATA COLLECTION

The impact of the drainage system on the beach watertable was assessed using the following techniques. All levels are to Australian Height Datum (AHD) which is approximately MSL.

Long-term watertable data were collected from a permanent beach well which housed a pressure transducer and data logging equipment. This well is in the drained area of the beach and located such that the sand elevation was approximately 3m AHD under normal conditions.

Short term observations of mean level were obtained using arrays of up to 95 stilling wells deployed in the beach. Water level inside the wells correspond to the local watertable. Levels were determined by surveying the well tops and then measuring the depth to the watertable. Wells were also used to determine the location of the shoreline in the drained and undrained sections of the beach. Wells were placed along a shore-normal transect with a spacing of between 2 to 5m.

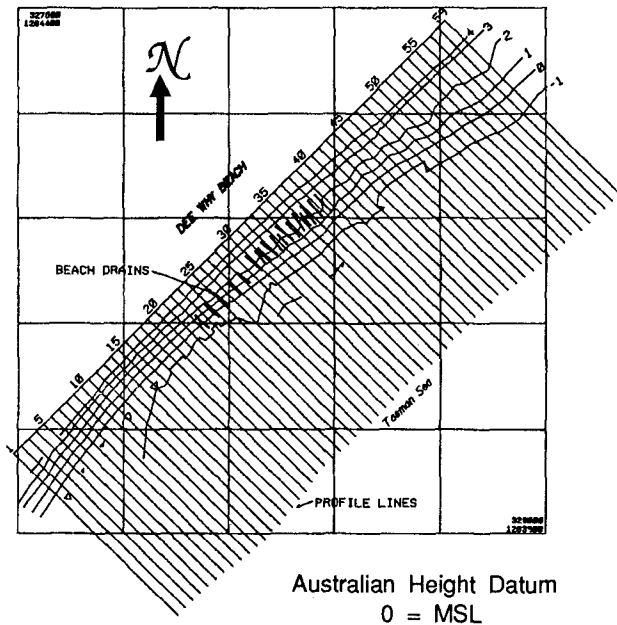

Figure 3 — Survey date 5–9–91. Location of beach drains and profiles for contour analysis

This spacing gives an accurate definition of the exit point of the watertable onto the beachface, and the intersection of mean water surface and the beachface, or shoreline.

The relative position of the shoreline or watertable exit point with respect to the run-up was determined by counting the number of waves running up past each of a number of beach wells or stakes marking points of known beach elevation. This was done over 20 minutes along drained and undrained transects, enabling calculation of the percentage of waves passing the watertable exit points on different sections of beach.

## RESULTS

### General

The drainage system has been deployed continuously in an open coastal beach for approximately 18 months. Observation of the treated intertidal beach shows, particularly at low tide, the marked seepage zones caused by outflow from the buried drains. Outflow from the drains has been observed to result in minor scour on very low tides. This scour appears to be limited by 'armouring' or increased coarseness of sediment around the drain ends. During

periods when the beach has been relatively wide, these effects have become less apparent. On the rising tide, the seepage zones apparent at low tide give way to infiltration zones as local infiltration directly over the drains is evidenced by marked narrowing of the zone of watertable outflow in those areas, extending over a width of 3 or 4m. The drains experienced some damage from rip-cell formations resulting in up to 4m of the drains having to be cut off in the swash zone. However, subsequent accretion has since covered the damaged drains and all have since continued to discharge water.

### Watertable Data

Figure 4 shows the response of the watertable at the permanent beach well before and after installation of the drains. The deep water wave height and tide record are also presented. This figure clearly shows that the placement of the drains immediately lowered the watertable and reduced the asymmetry of the tidal response. Table 1 shows comparison of lag times and rates of change of water levels deduced from analysis of months of watertable and tide records.

FIGURE 4 — Watertable record at permanent beach well and the deepwater wave height ( $H_{orms}$ ) and tide levels (between 20-2-91 and 2-3-91)

Figure 5 shows a shore-parallel section of the beach in which the effect of a single drain in the inter-tidal zone of the beachface was monitored over a half tide cycle. The watertable is lowered by about 0.3m at the location of the drain and the effect is seen to diminish with increasing distance from the drain. Figure 6 compares watertable profiles in two morphologically similar shore-normal transects, one in the drained section

**Table 1** — Relative lag time and rate of change in water level before and after installation of drains.

Lag Time (hrs)	Before Installation of Drains		After Installation of Drains	
	Low Tide	High Tide	Low Tide	High Tide
	4.10	1.50	3.30	1.10
Average Rate of Change in Water level (cm/hr)	Falling Tide	Rising Tide	Falling Tide	Rising Tide
	4	8	8	15

**Figure 5** — Effects of a single drain on the watertable at various times (EST)**Figure 6** — Watertable for a typical drained transect and a similar undrained transect

and another in the undrained section of the beach. Again, at the drain the watertable was lowered approximately 0.3m along the transect.

#### Beachface Watertable Exit Point

The point of emergence of the watertable onto the beachface is important because it influences the swash zone dynamic sediment budget which is the key to the success of the beach drainage technique. The comparison of the watertable exit point at high tide on 24 April, 1991 for the drained and undrained beach transects in relation to the wave run-up at the time is presented in **Figure 7**. On the drained transect 44% of waves transgressed the watertable exit point while 29% did so in the undrained section. This means that at high tide the

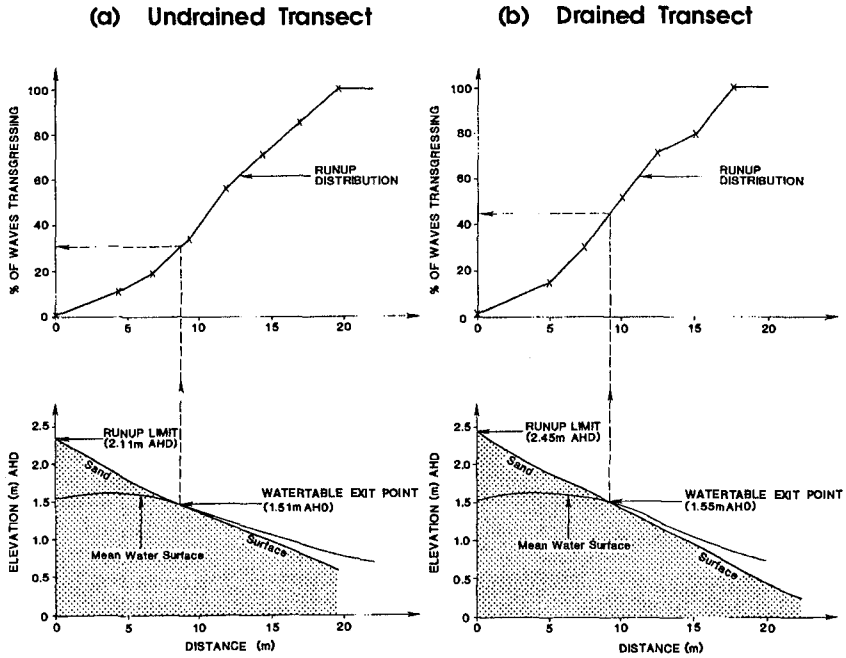

Figure 7 — Percentage of waves transgressing the watertable exit point on (a) Undrained and (b) Drained transects

watertable occurs lower within the run-up distribution on the drained section of the beach.

**BEACH MORPHOLOGY**

**DATA COLLECTION**

Variability of the location of the beach contours was used to assess the effects of the drainage system on beach morphology by comparing results for the drained and undrained section of the beach.

Pre-drainage beach morphology was determined using photogrammetric analysis of historical aerial photography. Fifteen dates of photography between 1961 and 1991 were analysed. Beach topography was contoured down to the water line using a Wild AC1 Stereo Restitution Instrument which plotted the position of the contours in plan view. A beach length of approximately 600m of the beach was contoured for each date of photography.

Post drainage beach surveys have been carried out every 10–15 days since drain installation. Again, the survey area comprised about 600m of beach centred about the drained section. Surveys were generally extended from the fence line (4.5m MSL) to approximately –1.5m MSL.

#### DATA ANALYSIS

Contour location data were determined for a series of parallel transects as shown in **Figure 3**. Distances from a base line to the 4m, 3m, 2m, 1m and 0m contours were measured along 60 transects for each beach survey taken since drain installation and for photogrammetric surveys prior to drain installation. These transects were spaced 10m apart and cover the drained section of the beach as well as equal portions of the undrained beach to the north and south. Measurements of contour location for each contour were compiled into data matrices consisting of distances at each profile and survey date.

#### BEACH STABILITY

Variation in contour position over time was assessed by determining the mean and standard deviation of the contour location at each profile.

An indication of the relative stability of different portions of the beach both before and after drain installation is presented in **Figure 8**. Here the standard deviation of the 1m and 2m contours are presented for the photogrammetric (i.e. undrained) data, together with the standard deviation of the 0m, 1m and 2m contours for the survey data collected since drain installation. The standard deviations from the photogrammetric data set are generally higher. This is because a number of the photography sets used were taken specifically to record eroded post-storm beach (profiles 22–38) morphology. This figure also shows that the variance in contour position is lower in the drained section of the beach than the areas either side. This contrasts with the photogrammetric data which shows increasing variance in the 2m contour towards the north and rhythmic variation of the 1m contour.

#### PRINCIPAL COMPONENTS

Beach morphology in the survey area since the installation of the drains has displayed considerable variability associated with both storm activity and rip current migration. For much of the time since the installation of the drains the beach has been characterised by rhythmic topography associated with rip cell formation and migration, this situation only changing during storms when the whole beach was cut back and assumed a more uniform shape.

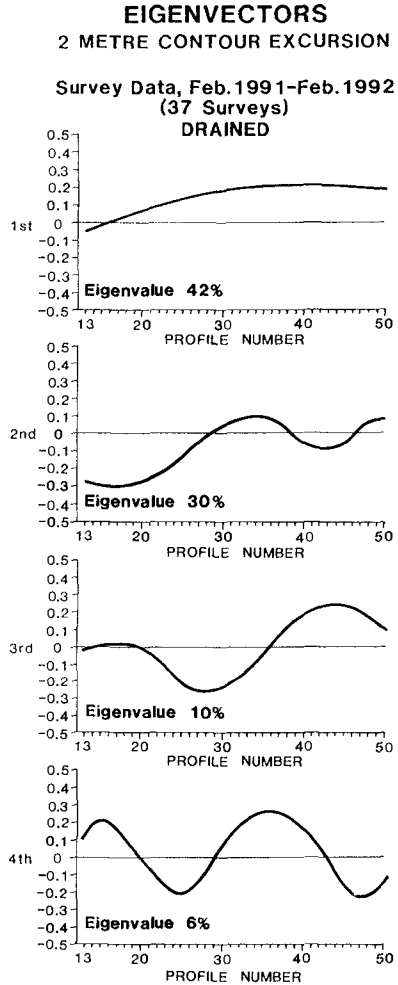

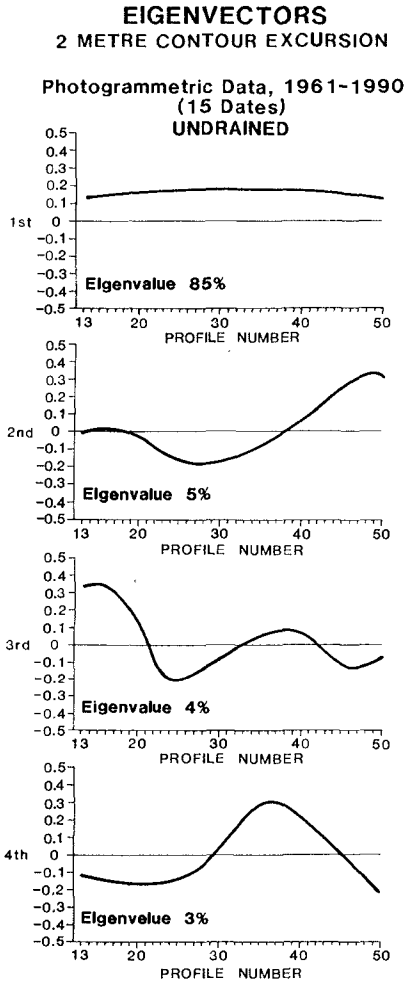

The results of the principal components analysis reflect this variation in beach morphology, showing several important components. Results are presented in **Figure 9** and **Figure 10** for the 2m contour. The first

**CONTOUR EXCURSION STANDARD DEVIATION**

**Figure 8** — Contour excursion standard deviation for photogrammetric data and survey data

**Figure 9** — Principal Components of the photogrammetric data

**Figure 10** — Principal Components of the survey data

component in each case reflects the onshore offshore sediment exchange associated with beach erosion/accretion. Subsequent components reflect the rhythmic topography produced by rips and seasonal longshore sediment exchange together with the effect of the drains.

Examination of the second component of survey data shows general stability (neither erosion nor accretion) in the region of the drains. This function is not found in the principal components of the photogrammetric survey data which appear similar to the subsequent components of the survey data. This component supports the contour variation analysis provided earlier which showed greater stability in the region of the drains and shows that the drains have added a significant morphological pattern to the beach behaviour. Principal Components 3 and 4 in the survey data and 2, 3, 4 in the photogrammetry reflect various rip conditions which are probably related to different incident wave conditions.

## CONCLUSIONS

The drainage material has been in place for approximately 18 months and is still performing well. There have been no operating or maintenance costs. Storm damage to the seaward ends of individual drains has reduced the efficiency of these drains but has not stopped the system from working. Although a general reduction in the watertable and shoreline levels sufficient to increase the stability of the beachface was achieved, a more closely spaced array of drains would be expected to increase these effects. In addition, a placement procedure providing a lower drainage system would reduce the potential for storm and rip damage without greatly reducing the draining capacity of the system.

It has been demonstrated that it is possible to alter the beach watertable by gravity drainage. Further, lowering the watertable by the method described has resulted in a stabilising of the beachface morphology in the local area.

If the nexus between watertable lowering and beach aggradation suggested by earlier researchers exists, then gravity drainage of the beachface watertable will prove to be a highly cost-effective means of beach stabilisation. It has the potential for significantly extending the life of beach nourishment programs.

## ACKNOWLEDGEMENTS

This project was initiated and funded by the New South Wales Public Works Department. The authors wish to thank the many members of the Coast and Rivers Branch who have contributed to the project. In particular, Rolyn Sario, Roderick Bowen and Alex Reed for their help with the data collection and analysis, Krystyna Starmach for the drafting and Caroline Harrington for the desktop publishing.

## CHAPTER 86

### Harmonic Generation and Transmission Past a Submerged Rectangular Obstacle

Andrew M. Driscoll <sup>1</sup>, Robert A. Dalrymple <sup>2</sup> and Stéphan T. Grilli <sup>3</sup>

**Abstract :** Experiments were conducted in a wave flume to study the harmonic evolution of a normally incident linear monochromatic wave train as it propagated over a submerged impermeable obstacle of rectangular cross-section. The reflection and transmission characteristics of the system were studied and compared to a linear scattering model, which was found to overpredict the transmission coefficients. The experiment was also simulated using the fully nonlinear model by Grilli *et al.* (1989), which performed well given its inviscid potential assumptions.

#### Introduction

The scenario of a linear wave train impinging on a submerged rectangular obstacle may be considered as a simplified representation of numerous physical phenomena, such as wave reflection and transformation over offshore reefs, bars and submerged breakwaters, which occur along actual coastlines. For this reason, the situation has been studied by numerous authors in the past 30 years, including Takano (1960), Mei and Black (1969), Losada (1991) and Rey *et al.* (1992), with the aim of analytically predicting the reflection and transmission characteristics for a given incident wave condition and obstacle geometry.

These authors have considered the problem completely in the linear context; an incident linear wave is partially reflected upon passing a submerged rectangular obstacle, with both transmitted and reflected energy propagating at the same frequency as the incident wave.

<sup>3</sup>M. ASCE, Department of Ocean Engineering, University of Rhode Island, Kingston, RI 02881

Such assumptions become suspect as  $\mu (= kh)$  becomes small and  $\delta (= a/h)$  becomes large over the obstacle. Under these circumstances, significant harmonic generation may occur over the obstacle, as has been observed by Seelig (1980) and Rey *et al.* (1992). The wave condition found downwave of the obstacle for such a nonlinear situation is likely to have energy distributed not only at the fundamental frequency, but at a number of higher harmonic frequencies as well.

The goals of this research are : (i) to perform a series of laboratory experiments to scrutinize the spectral transformation which occurs when a linear wavetrain passes over a submerged rectangular obstacle; (ii) determine the performance of the standard linear scattering theory for a situation where nonlinearity is significant over the obstacle; and (iii) to evaluate the ability of the fully nonlinear potential model by Grilli *et al.* (1989) to simulate the laboratory data.

## Experimental setup

The experiments were conducted in a precision wave flume with dimensions 30 m long by 0.6 m wide by 1 m deep. Repeatable wave trains were generated with a computer-controlled horizontal piston wavemaker, and a 1:35 impermeable slope at the opposite end of the tank functioned as a wave absorber. A submerged impermeable rectangular obstacle the width of the flume was fixed to the bottom of the tank 7.0 m from the wavemaker paddle. The water depth was  $h_o = 0.5$  m, and the obstacle depth was  $h_1 = 0.12$  m, so that the obstacle vertical aspect ratio is  $\frac{h_o - h_1}{h_o} = 0.76$ . The obstacle length was 0.78 m, i.e.,  $1.58h_o$  or slightly more than twice its height.

Two sets of experiments were carried out. In the first experimental set, a single sine wave condition (incident height  $H_i = 2.50$  cm, period  $T = 1.70$  s, with  $ka = 0.019$ ) was produced on seven occasions. By moving the position of four wave gages prior to each run, an array of 28 gage locations was created (fig. 1).

The second experimental set consisted of 12 additional runs with the same wave height but with wave periods ranging from 0.8 s to 1.9 s. A 3-gage array was placed between the obstacle and the wave generator, thereby allowing the reflection coefficient ( $K_r$ ) to be determined as a function of the incident wavenumber (fig. 2). Two additional gages were placed at locations downwave of the obstacle for redundant measurement of the transmission coefficient ( $K_t$ ).

## Experimental results

Spectral analyses of the 28 wave gage locations in the experimental data set yield the amplitudes of the individual harmonics, and reveal the nonlinear transformation undergone as incident linear waves pass over the obstacle (fig. 3). It is seen that significant harmonic generation occurs over the obstacle, and that

Figure 1: Experimental setup for spectral evolution portion of experiments.

Figure 2: Experimental setup for reflection/transmission portion of experiments.

spatial amplitude modulation is present downwave of the obstacle. Such downwave amplitude modulations are certainly not due to reflection-induced partial standing waves, as reflection from the 1:35 slope is quite small (measured at less than 2 % at the first harmonic frequency). It must thus be concluded that the situation downwave of the obstacle is still quite dynamic with respect to harmonic evolution.

**Comparison: linear scattering model vs. experiment**

As the wave condition downwave of the obstacle has been shown to be both nonlinear and spatially varying, it is of interest to compare the experimentally measured values of  $K_r$  and  $K_t$  to those predicted analytically by a linear scattering model such as that of Losada (1991). The comparison, given in fig. 4, shows that the linear model predicts  $K_r$  quite well, but consistently overpredicts  $K_t$ . This overprediction is presumably due to the transfer of energy to the higher harmonics, and also to frictional and turbulent losses. From fig. 4, it is also seen that the measured value of  $K_t$  varied between gage location A and gage location B by as much as 5 % or more.

## Boundary element method (BEM) model

The two-dimensional nonlinear potential model by Grilli *et al.* (1989,1990), and its most recent extensions, are used to compute wave propagation over the submerged obstacle. With the velocity potential being defined as  $\phi(x, t)$ , the velocity is given by  $u = \nabla\phi = (u, w)$ , and the continuity equation in the fluid domain  $\Omega(t)$  with boundary  $\Gamma(t)$ , is a Laplace's equation for the potential,

$$\nabla^2\phi = 0 \quad \text{in } \Omega(t) \quad (1)$$

Using the free space Green's function  $G(x, x_l) = -\frac{1}{2\pi} \log |x - x_l|$ , equation (1) is transformed into a Boundary Integral Equation (BIE),

$$\alpha(x_l)\phi(x_l) = \int_{\Gamma(x)} \left[ \frac{\partial\phi}{\partial n}(x)G(x, x_l) - \phi(x)\frac{\partial G(x, x_l)}{\partial n} \right] d\Gamma(x) \quad (2)$$

where  $x = (x, z)$  and  $x_l = (x_l, z_l)$  are position vectors for points on the boundary,  $n$  is the unit outward normal vector, and  $\alpha(x_l)$  is a geometric coefficient.

On the free surface  $\Gamma_f(t)$ ,  $\phi$  satisfies the full nonlinear kinematic and dynamic boundary conditions,

$$\frac{Dr}{Dt} = \left( \frac{\partial}{\partial t} + u \cdot \nabla \right) r = u = \nabla\phi \quad \text{on } \Gamma_f(t) \quad (3)$$

$$\frac{D\phi}{Dt} = -g\eta + \frac{1}{2}\nabla\phi \cdot \nabla\phi - \frac{p_a}{\rho} \quad \text{on } \Gamma_f(t) \quad (4)$$

respectively, with  $r$ , the position vector of a free surface fluid particle,  $g$  the acceleration due to gravity,  $\eta$  the vertical elevation of the free surface (positive upwards and  $\eta = 0$  at the undisturbed free surface),  $p_a$  the pressure at the surface, and  $\rho$  the fluid density.

No-flow conditions are prescribed along solid boundaries, and, in the present applications, cnoidal waves are generated on the boundary  $\Gamma_{r1}(t)$  by specifying a piston wavemaker motion, as in laboratory experiments (see Grilli & Svendsen 1990, for detail).

**The time integration :** The time stepping, follows the Eulerian-Lagrangian approach used by Dold & Peregrine 1984. It consists of integrating free surface conditions (3) and (4) at time  $t$ , to establish both the new position of the free surface  $\Gamma_f(t)$ , and the boundary conditions at time  $t + \Delta t$  ( $\Delta t$  denotes a small time step increment). Second-order Taylor expansions are expressed in terms of  $\Delta t$  and of the Lagrangian time derivative (as defined in (3)), for both the position  $r(t)$  and the potential  $\phi(t)$  on the free surface. Coefficients in the series

are calculated by solving two Laplace problems—for  $\phi$  and  $\frac{\partial\phi}{\partial t}$ —at each time step (see detail in Grilli, *et al.* 1989).

**Numerical implementation :** The BIE (2), equivalent to Laplace problems (1) for  $\phi$ , and the equivalent BIE problem for  $\frac{\partial\phi}{\partial t}$  are solved by a higher-order BEM, using a set of collocation nodes on the boundary, and elements to interpolate between collocation nodes. Quasi-spline elements are used on the free surface, and isoparametric quadratic elements elsewhere. Each integral in (2) is transformed into a sum of integrals over each boundary element. Non-singular integrals are calculated by standard Gauss quadrature rules. A kernel transformation is applied to the weakly singular integrals, which are then integrated by a numerical quadrature exact for the logarithmic singularity. Details of the numerical implementation can be found in Grilli, *et al.* 1990, along with a discussion of corner problems associated with surface piercing bodies such as wavemakers.

**Discretization and numerical parameters :** A limitation of the BEM model is that any wave breaking in the computational domain effectively halts the solution algorithm. An adjustment of tank boundaries, hence, had to be made to prevent breaking on the slope of the numerical wave flume. Tank boundaries were re-defined such that the most downwave portion of the slope made the transition to a shallow shelf just below the breaking depth. Fig. 5 shows the re-defined tank boundaries which includes a region of constant depth  $h_o = 1$  and length  $21h_o$ , and a 1:35 slope with a shelf of constant depth  $h_1 = 0.34$ , at the upper part of the slope, from  $x' = \frac{x}{h_o} = 44$  to 56. A rectangular bar of height  $0.76h_o$  and width  $1.58h_o$  is located with its axis at  $x' = 14.83$ . As a transmitting boundary condition was not available in the model, reflection off the back wall of the numerical wave flume became a limiting condition. The comparison of BEM model vs. experiments must thus be made in the time between the initiation of paddle motion and the arrival of back wall-reflected energy at the most downwave gage location in the BEM model ( $x' = 21$ ).

The free surface discretization is made of 224 quasi-spline elements, and there are 73 quadratic elements on the bottom and lateral boundaries. The interval between nodes on the free surface is 0.25, and 0.50 on the horizontal bottom, the slope, and the shelf bottom. To increase resolution and accuracy on and above the bar, this interval is reduced to about 0.20 along the bar three sides. The total number of nodes is 365. This corresponds to a CPU time of 7.63sec (IBM3090/300) per time step. Time step is automatically selected in the model, to ensure optimum accuracy and stability of calculations.

## BEM model vs. experiment

A comparison is made between computations and experiments, for which both experimental and numerical set-ups correspond to closely identical conditions, with the waves being generated from still water using a piston wavemaker in

Figure 5: Geometry of the numerical wave flume, as re-defined for entry into BEM model. The shown axes are nondimensionalized with the water depth,  $x' = x/h$  and  $z' = z/h$ .

both cases. In the present case, a cnoidal wave of height  $H'_i = \frac{H_i}{h_o} = 0.05$ , and period  $T' = T\sqrt{\frac{g}{h_o}} = 7.52$  is generated at the leftward lateral boundary of the computational domain, and the corresponding incident wave profile is within 2% of a simple sine wave of length  $\frac{L}{h_o} = 6.75$ , as measured in the experiments. The model is run for over 20 wave periods, and no adjustment of time lag between both data sets is made before comparison. This, hence, represents a very demanding test of the model performance.

Fig. 6 shows a water surface comparison between the experimental and BEM results. A similar comparison is shown in fig. 7 for time series at locations 0.72 m and 1.92 m downwave of the obstacle. The BEM results are seen to deviate from the experimental results in both amplitude and phase. The nature of this deviation is better revealed by a frequency-domain comparison (fig. 8) which, due to the limitation of the non-breaking BEM requirement, is possible only for the first 8 waveforms following a 10-second startup period. The BEM model is shown to predict harmonics of similar amplitude to those observed in the experiments, with the exception of the first harmonic, which is overpredicted.

This discrepancy in first harmonic amplitude is likely due to the influence of flow separation as the wave-induced velocity oscillations interacted with the corners of the submerged obstacle. As such flow separation was observed in the experiments, the disagreement in the first harmonic amplitude between the BEM model and experiment is not surprising, given the inviscid potential flow assumptions of the model.

As a check, the flow separation loss incurred as a waveform passes the obstacle may be estimated with a crude analytical approach. A simple nonlinear friction representation is assumed,  $\eta_1 - \eta_2 = \frac{f}{2g}|u|u$ . If the obstacle is assumed thin in relation to the wavelength, quasi-steady flow is assumed, and frictional

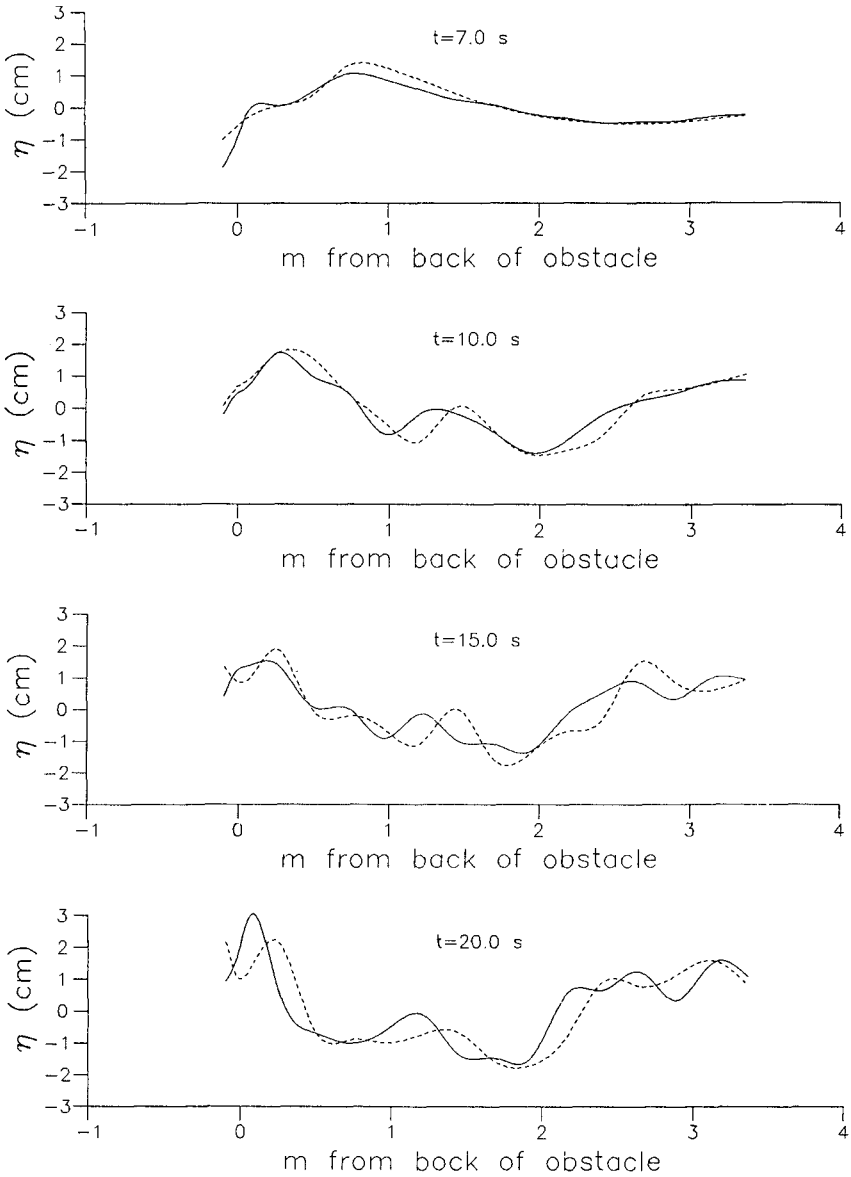

Figure 6: Water surface comparison of BEM model to experiment at  $t=7.0$  s,  $t=10.0$  s,  $t=15.0$  and  $t=20.0$  s after the initiation of paddle motion; (---)=BEM model, (—)=experiment.

Figure 7: Time series comparison of BEM model data to experiment, at locations 0.72 m and 1.92 m downwave of obstacle; (---)=BEM model, (—)=experiment.

Figure 8: Comparison of spatial amplitude modulations, BEM model and experiment; (---)=BEM model, (—)=experiment, (★, ☆)=1st harmonic, (●, ○)=2nd harmonic, (■, □)=3rd harmonic, (▲, △)=4th harmonic.

effects are averaged over a wavelength, it may be shown that

$$\eta_1 - \eta_2 = \frac{4(h/h_o - 1)^2 a^2}{3\pi h_o^2 \omega^2 \cosh^2 kh} [\sinh kh - \sinh k(h - h_o)]^2 \quad (5)$$

where  $\eta_1$  and  $\eta_2$  are the water surface elevations prior to and after the obstacle,  $f$  is an empirical friction-loss coefficient,  $u$  is the amplitude of the depth-averaged velocity downwave of the obstacle,  $a$  and  $h$  are the amplitude and depth behind the obstacle and  $h_o$  is the depth on top of the obstacle. The friction coefficient  $f$  for this case is given by  $f = (h/h_o - 1)^2$ .

Introducing the downwave first harmonic amplitude from the BEM results ( $\sim 1.25$  cm) and the other relevant parameters into 5, we find  $\eta_1 - \eta_2 \simeq 0.16$  cm. This agrees well with the discrepancy between BEM and experimental amplitudes of approx 0.15 cm.

The downwave higher harmonic amplitude modulations are less pronounced in fig. 8 compared to fig. 3, when the tank was fully developed. Nonetheless, the BEM model does predict spatial amplitude modulations which are qualitatively similar to the experimental results. The degree of disagreement present is certainly also due to the influence of flow separation at the first harmonic frequency, as a misrepresentation of the first harmonic component will be passed on as erroneously simulated higher harmonics as well.

## Conclusions

The spectral evolution of an incident regular wave train has been traced as it propagated over a submerged rectangular obstacle, and comparisons have been made between the experimental data and both a traditional linear scattering model and a BEM model. The experimental data revealed the existence of spatial amplitude modulations downwave of the obstacle.

The linear model of Losada (1991) was shown to predict the reflection coefficient quite well, despite the high degree of nonlinearity present in the vicinity of the obstacle. However, it was seen that the transmission coefficient was consistently overpredicted due the linear model's omission of energy transfer to higher harmonics and energy dissipation. An implication of the above results is that the linear scattering approach may underestimate the effectiveness of a structure (ie, submerged breakwater) under highly nonlinear situations.

The BEM model by Grilli *et al.* (1989) was found to simulate downwave spatial amplitude modulations qualitatively similar to those found in the data. Comparisons, however, were hampered by the presence of flow separation in the experiments which could not be modelled in the BEM formulation. It is conjectured that the BEM model would have simulated the experiments more ac-

curately, had the obstacle depth been greater, thus inducing less flow separation.

## CHAPTER 87

### THE SUBMERGED PLATE AS A WAVE FILTER

#### THE STABILITY OF THE PULSATING FLOW PHENOMENON

Dr.-Ing. Kai-Uwe Graw \*\*

#### ABSTRACT

For many applications it is possible to reduce the wave motion in the protected area sufficiently using the submerged plate as a wave filter. The horizontal submerged plate, which hardly obstructs the cross-section of the flow, cannot be explained by the Wiegel approach at all. A strong pulsating flow opposite to the direction of the wave propagation originates beneath the plate during wave attack. New velocity measurements, carried out with an ultrasonic 3D-probe in the region below the plate, make it now possible to explain the principle much more in detail. They show that the flow phenomenon at the plate is very stable, the flow is nearly as strong if the region below the plate is partly closed.

#### 1. REASONS FOR THE INVESTIGATIONS

The protection of coastlines and harbours against wave attack is mainly achieved by the use of solitary breakwaters. Their negative features are that they hinder:

- a) the water exchange between the open sea and the protected area (diverted sediment transport, deteriorated water quality) and
- b) the view over the open sea.

Underwater breakwaters are not visible, but the water exchange does not increase as much as the efficiency decreases. One possibility to enhance the performance without hindering the water exchange is the use of a semi-submerged vertical wall which obstructs the energy flux near the surface. However, this leads to construction problems (destruction of the

---

\*\* Senior Research Engineer

Wasserbau und Wasserwirtschaft, Bergische Universität GH Wuppertal  
Pauluskirchstraße 7, 5600 Wuppertal 2, Germany

wall in large waves), and also in this case the structure is visible. The breakwater type which reduces all these secondary problems is the rigid horizontal submerged plate mentioned in this paper. The plate cannot be used to stop the wave motion in the protected area, but its efficiency is sufficient for many applications.

Figure 1: The submerged plate

## 2. THE SUBMERGED PLATE: THE WAVE FILTER

The performance of "normal" breakwaters can be explained by using the Wiegel approach. This means that the part of the wave energy in the regions covered by the structure is reflected, a very small part of the energy is dissipated at its surface and the other part passes by.

Figure 2 shows one series of the different measurements performed by Dauer [1984]. The figure shows the results for the shortest of the plates used (the length is only 1.333 times the water-depth,  $l/d=1.333$ ).

The performance of the plate is not adequate in two cases:

- ① All long waves ( $L/l > 6$ ) are not reduced sufficiently, the wave height reduction is approximately 25%.
- ② Furthermore it can be seen, that the plate which is submerged by more than one third (40%) of the water-depth does not really work.

All waves not longer than 3.5 times the plate length ( $L/l < 3.5$ ) are reduced by more than 50%. The largest value of the wave height reduction is approximately 80%.

The best results were obtained for the three smallest values, but one important reason for this is wave breaking above the plate, connected with large forces exerted on the plate. For a submergence depth between 20 and 30% of the water depth a sufficient wave height reduction was observed, not caused by wave breaking. These results were confirmed for

Figure 2: Wave height reduction at the plate [Dauer, 1984]

different plates longer than two times the wave length ( $l/d > 2$ ). The wave height reduction is relatively constant (50 - 70%) in the wave length range between  $L/l = 0.4$  and 4.

Examining a normal solitary breakwater, this principle is correct; looking at the semi-submerged vertical wall, it does not cover the whole problem but it is a good approximation. The horizontal submerged plate which hardly obstructs the cross-section of the flow cannot be explained by the Wiegel approach at all. For this reason, and as it performs well only in a particular region of the wave spectrum, it shall be called a wave filter from now on.

### 3. THE PULSATING FLOW

Dick [1968] noticed a flow around a horizontal plate submerged beneath waves, but he did not give any explanation for it. Analyses of the flow behaviour, based on flow visualization experiments [Graw, 1988; Graw, Kaldenhoff, Stieglmeier, 1989], and measurements of the wave height were presented by Hoeborn [1986]. She first gave an explanation based on a resonant flow behaviour. Continual experiments have shown that the dissipation of energy at the plate is caused in the wake behind the plate [Fischer, 1990; Fischer, Jirka, Kaldenhoff, 1991]. A finite element model gave us the possibility of calculating the energy equilibrium at the plate quite well, but the forecast of the flow was still uncertain. New velocity measurements, carried out with an ultrasonic 3D-probe in the region below the plate, make it now possible to explain the principle much more in detail. They show that the flow phenomenon at the plate is very stable, the flow is nearly as strong if the region below the plate is partly closed.

direction of wave propagation →

Figure 3 a: Pulsating flow beneath the plate

The physical principle of the plate as a wave filter can be explained as follows:

- ① The propagating water wave reaching the horizontal plate is divided into two parts: the energy flux above the plate is transformed into a new - shorter - gravity wave determined by the reduced water depth in this region, the one below the plate is a propagating pressure distortion travelling slower than the wave above.
- ② As soon as the first short gravity wave overflowing the plate reaches the region behind the plate, once more a new wave is formed, which travels away and has the same wave-length as the original wave, but less energy. Furthermore a part of the energy of the wave overtopping the plate also propagates into the region below the plate (backwards!).
- ③ If the length of the plate is such that at the same time there are a wave trough at the front edge and a wave crest at the end of the plate (resonance), and if the amount of this energy is relatively large compared to that travelling forward (no shallow water waves), a strong pulsating flow opposite to the direction of the wave propagation originates (figure 3).
- ④ The energy transferred back by this flow to the region before the plate makes it impossible for the pressure distortion caused by following waves to propagate into the region below the plate, the flow grows stronger. Thus a part of the energy is reflected by the structure. Figure 4 shows the particle orbits in front of the plate. It can be seen that the region below the plate is closed for the wave energy of the incoming wave.

Figure 3 b: Pulsating flow beneath the plate

Figure 4: Diverted particle orbits in front of the plate

Figure 5 shows how the flow grows as the waves are passing by (in comparison with the undisturbed orbital motion). This flow is the physical reason why energy is reflected by this structure. As it depends on the energy equilibrium between the front and the rear below the plate, the plate acts as a wave filter. The mean parameters for the description of the performance are the ratio of wave-length ( $L$ ) to length of the plate ( $l$ ) and the relative immersion of the plate.

Figure 5: Development of the pulsating flow

Figure 6: Pulsating flow with obstruction below the plate

In order to construct this wave filter it is necessary to build a connection between the plate and the bottom of the sea. The possibility of a durable realization increases if it is possible to build a very solid connection. The answer to the question if it is possible to partially obstruct the region below the plate without destroying the pulsating flow is given in figure 6. The kinetic energy of the three pulsating flows shown here is nearly the same.

Figure 7: Performance of the breakwater

The phenomenon of the pulsating flow is not disturbed by the blockage and, connected with that, the performance of the wave filter is not reduced. Figure 7 shows the wave height reduction observed during the present experiments. The two measurements series shown were not performed with constant values of the wave height, accordingly they are named small and large waves. It is clearly visible that the wave height reduction also depends on the height of the incoming waves (and therefore on the depth distribution of the kinetic energy of the waves).

#### 4. CONCLUSIONS AND OUTLOOK

The experiments - that are presented here very briefly - show that the performance of the "plate as a wave filter" is a phenomenon which is stable even if the region below the plate is partly blocked up. This is a necessity because the plate has to be fastened to the ground of the sea somehow. As it is possible to build a solid construction, this way it seems possible to construct an economic, durable and strong breakwater.

The submerged plate as a wave filter is the only construction which allows to reduce the wave height without obstructing the flow region with the largest energy flux - the surface region - because a large amount of the wave energy is diverted into the deeper regions. This means that problems with the construction of common wave breakers as the destruction by very large waves, corrosion problems, etc, are reduced.

The diversion of energy also introduces a new principle for the construction of a wave energy converter. Today all known devices are placed somehow near the surface of the sea, including again all the problems mentioned above. The possibility of such a new wave energy device is being investigated at our institute at the moment.

## CHAPTER 88

### Wave impact forces on mixed breakwaters

Stéphan T. Grilli<sup>1</sup>, M. ASCE, Miguel A. Losada<sup>2</sup>, and Francisco Martin<sup>2</sup>

**Abstract :** Flat impact of a solitary wave on a mixed breakwaters is experimentally and numerically studied, using a 2D nonlinear potential flow model. Free surface profiles, internal velocities, instantaneous pressure and pressure envelope on the wall, and on the berm, are analyzed based on both measurements and calculations. Results show, a converging flow occurs above the berm, followed by a small vertical jet, with large acceleration, that is responsible for large impact pressure on the wall. Short duration peak pressures occur above SWL, and quite large pressures also occur on the berm, as far away as twice the local depth from the wall. Maximum pressure force and overturning moment on the wall reach up to 9 and 15 times corresponding hydrostatic values based on water elevation at the wall.

### Introduction

Mixed breakwaters are made of the combination of a vertical wall and a rubble mound berm (Fig. 1). Under wave action, they function as vertical walls during high tide, and as mound breakwaters during low tide. The design of mixed breakwaters requires that their upper part be safe against sliding and overturning due to wave impact pressure. Laboratory and field experiments show, impacts of normally incident breaking waves are the most severe (Goda, 1985). Geometrical parameters of the breakwater, such as berm depth,  $d = h - h_1$ , and length, in water of depth  $h$  (Fig. 1), control conditions under which impulsive breaking of incident waves of height  $H$  can occur on the wall.

Extensive experimental work was carried out over the past 50 years for the evaluation of the peak pressure on vertical seawalls. Results were analyzed mostly based on Bagnold's simple theory (Goda 1985). Kirkgöz 1991 (KIR), in his recent review of this experimental work, shows that the average maximum pressure on vertical walls,  $p_{max}$ , varies between 20 and 75 times  $\rho gH$  (where  $\rho$  is the water density, and  $g$  the acceleration of gravity), and that the highest maximum pressure can reach up to 220 times this value. Variations in maximum pressure depend on the incident wave type (periodic, solitary) and characteristics, on the experimental scale, and on the type and location of measuring devices. In addition, maximum

<sup>2</sup>Professor and Graduate Student, Departamento de Ciencias y Técnicas del Agua y del Medio Ambiente, University of Cantabria, Santander 39005, Spain

pressures on the wall vary with the bottom slope in front of the wall. Kirkgöz 1982, based on laboratory experiments, showed that greatest impact pressures are obtained with a 1/10 slope in front of the wall. KIR also showed that largest impact pressures are obtained for an inclined wall, with a 10° to 20° backward slope with respect to the vertical. Finally, as far as scale effects are concerned, Führböter 1985 showed that experimental pressures obtained in small-scale tests are larger than prototype pressures, due to increasing aeration effects at larger scale.

In the same line, Partensky 1988 showed, based on laboratory experiments with mixed breakwaters, that highest pressures are exerted on the wall when the colliding wave has an almost vertical face. In this case, the maximum impact force on the wall,  $F_{Hx}$ , can rise to more than 10 times the hydrostatic force,  $F_{Hx} = \frac{1}{2}\rho g(d + \eta)^2$ , based on wave elevation  $\eta$  at the wall.

In the experimental studies reported above, results were mostly analyzed, using statistical theories and semi-empirical methods. Few viable theoretical approaches indeed exist that can model waves close to breaking over an arbitrary bottom and structure geometry, and thus be used to analyze the magnitude of impact pressures as a function of the detailed incident wave flow. In fact, only two theoretical approaches have been developed so far, that have been successfully applied to calculating wave impact on vertical walls: (i) Solution of two-dimensional (2D) fully nonlinear potential flow equations, using a Boundary Integral Equation method (BIE) (e.g., Cooker and Peregrine 1991 (CP)); (ii) Solution of 2D Euler equations, using a Volume Of Fluid method (VOF) (e.g., Wang and Su 1992). The first method turns out to be very efficient and accurate in dealing with this problem, but is limited to prior to wave breaking first occurs. The second method is less accurate but is somewhat more efficient in dealing with wave breaking and discontinuities. Experimental results for wave impact on the wall can be classified into three types, that must be considered when developing theoretical or numerical models: (i) Non-breaking waves; (ii) Waves with flat impact on the wall (i.e., with an almost vertical front face); (iii) Waves with falling breaking jets, and imprisoned air under the wave (e.g., plunging breaker). Models based on satisfying continuity equation in the fluid, like the BIE method, can deal with cases (i) and (ii), in which very little or no air entrainment occurs, but they cannot deal with case (iii), further than the time the breaking jet impinges on the wall.

Experiments and calculations with non-breaking waves (case (i)) do not show occurrence of large impact pressures on the wall. The wave pressure and total wave force, instead, gently increase following the same pattern as wave runup on the wall. For sufficiently large incident waves, however, more complex pressure variations can be obtained, in the form of two successive pressure maxima, slightly before, and slightly after the time of maximum runup (see, results by Grilli and Svendsen 1991ab, using a BIE model and solitary waves). This double maximum is also supported by experiments. For flat impact of long waves on a vertical wall (case (ii)), calculations by CP confirmed experimental observations. Results showed, a maximum impact pressure of up to  $60\rho g d$  occurs at the wall, while a vertical jet starts forming, with

vertical velocity and acceleration of up to  $20\sqrt{gd}$  and  $8000g$ , respectively. CP also found, water compressibility does not play an important role in the process, provided no air is entrained, but suggested, wall and free surface roughness (not included in the calculations) are likely to be significant in reducing theoretical maximum pressures.

Figure 1: Sketch of a mixed breakwater, and main geometrical parameters.

In the present study, laboratory experiments are performed to measure wave impact pressure on the vertical wall of a mixed breakwater, in a similar case (ii) as above, for which incident wave front face is almost vertical at the time of impact, and there is no or very little air entrainment. Solitary waves are used as incident waves, both for simplicity, and because they are believed to have the largest impulse, impact force and runup on structures. They also represent a simplified tsunami model. Experimental results are compared with computational results obtained using the 2D fully nonlinear BIE potential model by Grilli *et al.* 1989, 1990 (GSS). Largest impact pressures on the wall are obtained for incident waves with large height to depth ratios. This was achieved in the calculations by CP, by introducing very high but quite arbitrary long waves into their model. Wave propagation over a flat bottom and impact on a vertical wall were then calculated. The present numerical model works for arbitrary geometry and incident wave conditions. Hence, this enables us to closely reproduce the experimental set-up in the numerical model (Fig. 2a), while studying a more realistic coastal structure.

## Laboratory experiments

Experiments are conducted in the 70x2x2m wave flume of the University of Cantabria. Solitary waves are generated using a computer-controlled hydraulic piston wavemaker, at one extremity of the flume. The wave generation method is similar to that of Goring 1978. The flume width is divided into two subsections, the smallest one, in which a plywood step is built on the bottom, being 0.9m wide. A vertical plate is fixed above the step, to complete the mixed breakwater. The distance from the wavemaker paddle to the breakwater step is approximately 45m. The step height is  $h_1 = 20\text{cm}$ , and the water depth in the flume is adjusted to  $h = 30\text{cm}$ , so that the step aspect ratio is  $h_1' = 0.667$  (primes denote nondimensional variables : length is divided by depth

$h$ , time by  $\sqrt{\frac{h}{g}}$ , and celerity by  $\sqrt{gh}$ ). The experimental set-up is illustrated in Figure 1.

A solitary wave is generated by the wavemaker at  $150h$  from the step, and propagates down the flume. The incident wave profile modifies its shape while propagating down the tank, mostly due to higher-order nonlinear effects not included in Goring's first-order solution (Grilli & Svendsen 1991b). The incident wave eventually stabilizes in the form of a slightly smaller solitary wave, after  $80h$  or so of propagation. Side-wall and bottom friction also lead to a small decrease in wave height. This was studied by Losada *et al.* 1989 (LVM), who found the decrease to be almost negligible when all tank surfaces are maintained smooth enough. To eliminate both of these (frictionless and friction) effects of amplitude reduction from the experimental results and thus make the comparison with the potential flow model more accurate, LVM measured incident wave height at a small distance in front of the bottom step. A similar procedure has been adopted in the present experiments, in which a solitary wave is generated in the tank, such that it has the height  $H = 9.67\text{cm}$ , or  $H' = 0.322$ , at  $x' = -7$ , where incident wave height is defined. Experiments are first realized without the vertical wall in the breakwater, thereby re-creating conditions of the study by LVM. In this case, the incident wave overturns over the step as a plunging breaker. The vertical wall is then added to the breakwater model and its horizontal position is adjusted to  $x' = 5.69$ , in order to make the incident wave impact the wall with an almost vertical front face. Hence, final length of the mixed breakwater berm is  $5.69h$ .

Water surface elevation is measured using wave gages placed at the tank center-line. Characteristics of the gages are : DHI capacitance gages type 202/60, with wave meter amplifiers 102/E (linearity better than 0.5%). Total water depth is recorded every 0.01s, over a period of about 10s for each experiment. Due to a limited number of gages (5), identical experiments are repeated several times, and gages, attached to a movable carriage, are moved to different locations until the full experimental region is covered. A one-gage overlap is maintained between successive repetitions, in order to check the repeatability of experiments. Experiments are discarded when differences in measured surface elevations are larger than 1.5mm, or 0.5% of the water depth, between two repetitions of an experiment. A very high degree of repeatability of experiments is found when applying this criterion, confirming the good control of all experimental procedures.

Flow velocities are recorded above the step, in front of the vertical wall, using a 6W LASER phase Doppler anemometer, Dantec 60x10 optical fibers, and a Dantec 58N20 particle dynamics analyzer. The positioning system is a Dantec 57H00 traversing system, that moves the optical fibers over a  $2.5 \times 2.5\text{cm}$  grid. The sampling frequency is variable, with burst detection (100-800Hz).

Dynamic pressure is measured using piezoelectric pressure gages that automatically eliminate hydrostatic pressure due to still water level (SWL). Corrected total pressure  $p$  is presented in the following. Characteristics of the gages are : transducer

type PDCR 830-201-Druck Limited, with strain amplifier DHI 106/E (linearity better than 0.1%), and the sampling frequency is 600Hz. Diameter of the pressure gages is about 15mm. The pressure is recorded at 11 locations along the vertical wall (Fig. 3), from  $z' = -0.23$  to  $z' = 0.77$ , and at 9 locations on the berm (Fig. 3), from  $x' = 4.69$  to  $x' = 5.62$ .

Experimental results are detailed in a following section.

Figure 2: Computed surface elevations with  $H' = 0.322$ : (a) for the mixed breakwater, curves a-f,  $t' = 3.46, 5.73, 7.55, 9.03, 10.10, 10.70$ ; (b) for the step in the bottom, curves a-f,  $t' = 3.46, 5.70, 7.47, 8.93, 9.98, 10.77$ .

## Numerical experiments

The fully nonlinear 2D potential model by GSS, and its most recent extensions, are used in the numerical computations. In this model, continuity equation takes the form of a Laplace's equation, expressed in a BIE formulation discretized using a higher-order Boundary Element Method. Time integration is based on a second-order Taylor expansion, similar to that introduced by Dold & Peregrine 1986, expressed in a mixed Eulerian-Lagrangian representation. Both dynamics and kinematics free surface boundary conditions are exactly specified in the model, and no-flow conditions are prescribed along solid boundaries. Solitary waves are generated at the computational domain leftward boundary, as in laboratory experiments, by simulating a piston wavemaker motion according to Goring's 1978 procedure. It should be reminded, that computations based on potential flow theory are only valid up to the instant waves overturn and break, and that potential flow also implies, dissipations and flow separation cannot be modeled. Details of the numerical implementation can be found in GSS, along with a discussion of problems associated with surface piercing bodies such

as wavemakers. Details of the generation of solitary waves by a piston wavemaker are also given in Grilli & Svendsen 1990.

As already mentioned, computations closely reproduce the experimental set-up (Fig. 2a). To reduce computation time, however, the horizontal length of the computational domain in front of the berm ( $x < 0$ ) is reduced to  $20h$ , versus  $150h$  in the laboratory experiments. A solitary wave is generated in the model, and its initial height is adjusted in order to be  $H' = 0.322$ , at  $x' = -7$ , as in the experiments. The origin of time,  $t' = 0$ , for both experimental and numerical results corresponds to the instant, the crest of the incident wave crosses the point  $x' = -7$ .

Numerical data are selected to ensure good accuracy of the results, considering both the domain geometry and the incident wave condition. The discretization uses 161 nodes on the free surface, and 160 spline boundary elements. Other boundaries are discretized using 3-node quadratic elements. The total number of nodes is 256, which leads to a computing time of about 3s per time step (IBM 3090/300, including saving and postprocessing of results). The initial distance between nodes on the free surface is  $\Delta x' = 0.1606$ . Time steps are automatically selected, as in Grilli & Svendsen 1990, to ensure optimal accuracy and stability of the computations (constant mesh Courant number condition, starting with  $\Delta t' = 0.08$ ). The accuracy of the computations is checked by verifying conservation of wave mass above SWL, and total energy. With the selected numerical data, both of these stay constant to within 0.05% during most of the wave propagation. Slightly after maximum impact pressure occurs on the wall, however, a small jet starts forming at the wall (see next section), with very large vertical velocity and acceleration. Discretization nodes—identical to Lagrangian markers—tend to concentrate in this jet, and time step reduces accordingly. This makes numerical errors in wave mass and energy increase, and computations have to be stopped (shortly after the last surface profile shown in Fig. 2a). For the last computed wave profile, the time step has reduced to  $\Delta t' = 0.0012$ , and the numerical error on wave mass is 0.10%. Total number of time steps, however, is only about 300.

Computations with the step in the bottom and no vertical wall have also been made, using similar numerical data, to compare with the experimental procedure of selecting the position of the vertical wall in the mixed breakwater (Fig. 2b). Numerical results essentially agree with experiments. The incident wave overturns over the berm at  $x' = 5.56$ , with a local breaking index  $\frac{H_b}{d} = 1.31$  (curve f in Fig. 2b). Details of these computations and related problems can be found in Grilli *et al.* 1992.

Numerical results with the mixed breakwater are detailed in the next section.

## Results and discussions

Experimental and numerical results are presented and discussed in parallel in the following, for the case of Fig. 2a ( $H' = 0.322$ ).

**Free surface elevation.**— Figure 2a shows computed free surface elevations up to

Figure 3: Blow-up of Fig. 2a, close to the wall ( $t' = 9.88, 10.10, 10.30, 10.47, 10.60, 10.65, 10.70$ , left to right), with location of pressure sensors (b1-b8) and (w1-w8).

the instant of maximum impact pressure on the vertical wall ( $t' = 10.70$ ), and Figure 3 shows a blow-up of these near the wall, over a period of 0.82 time unit.

Results in Fig. 2a show, wave height increases up to a maximum,  $H'_{max} = 0.384$  (curve b), upstream of the step, and decreases downstream of the step, to  $H'_{min} = 0.321$  (curve c). For larger  $x$ , wave height increases again, up to the instant of maximum impact on the wall. Computed free surface envelope is compared to measurements in Fig. 4. One sees, the agreement between both of these is quite good up to the step ( $x' = 0$ ). Downstream of the step ( $x' > 0$ ), the agreement is less good, and the model overpredicts maximum wave height by about 15%. This is due to energy loss by flow separation at the step, not included in the model (see LVM for detail).

Figure 4: Free surface envelope of incident wave : (o) experimental; (—) numerical. Experimental envelope of reflected wave (x).

In Fig. 3, one also sees, a small jet starts forming close to the wall, in the last surface profile. Maximum water velocity and acceleration in the jet reach about

$20\sqrt{gd}$  and  $9800g$ , respectively, at this stage. These large values are similar to those obtained by CP, and provide a physical justification for the occurrence of large impact pressure on the wall. The internal velocity field (discussed in the next section) indeed shows, the wave flow strongly converges, in a jet-like manner, towards the upper part of the wall, while its horizontal momentum gradually transforms into vertical acceleration. This acceleration, in turn, is balanced by a large pressure gradient close to the wall (as can be seen from Euler equations).

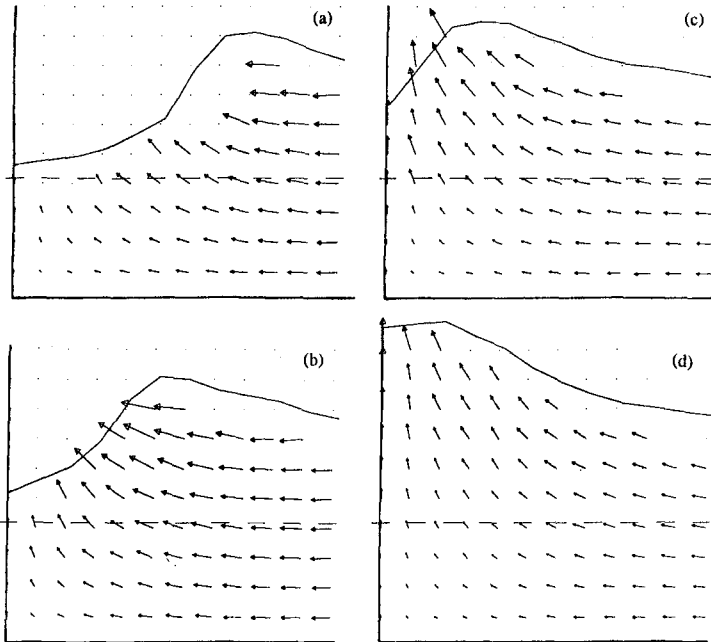

Figure 5: Internal velocity field at  $t' =$  : (a) 9.25; (b) 9.75; (c) 10.25; (d) 10.75.

**Internal flow velocity.**— Fig. 5a-d shows velocities measured over the berm. In (a), the incident wave approaches the wall with quite uniform and horizontal velocities under its crest. In (b), velocities start converging, and slightly increasing at the front face. In (c), the jet starts forming close to the wall, with vertical velocities larger than horizontal ones. From (c) to (d), a “flip through” motion occurs at the wall, i.e., the wave front face rotates, forward of a free surface point of approximate coordinates (5.23,0.42), and this upward motion has quite a large acceleration. These successive stages are also observed in calculations (Fig. 3). Maximum measured acceleration of the waterline at the wall is  $12g$ , and its maximum measured velocity is  $3\sqrt{gd}$ . Both of these occur close to stage (d). These are quite smaller, however, than the extrema found in the calculations.

**Instantaneous pressure on the wall.**— Figure 6 shows measured pressure at locations

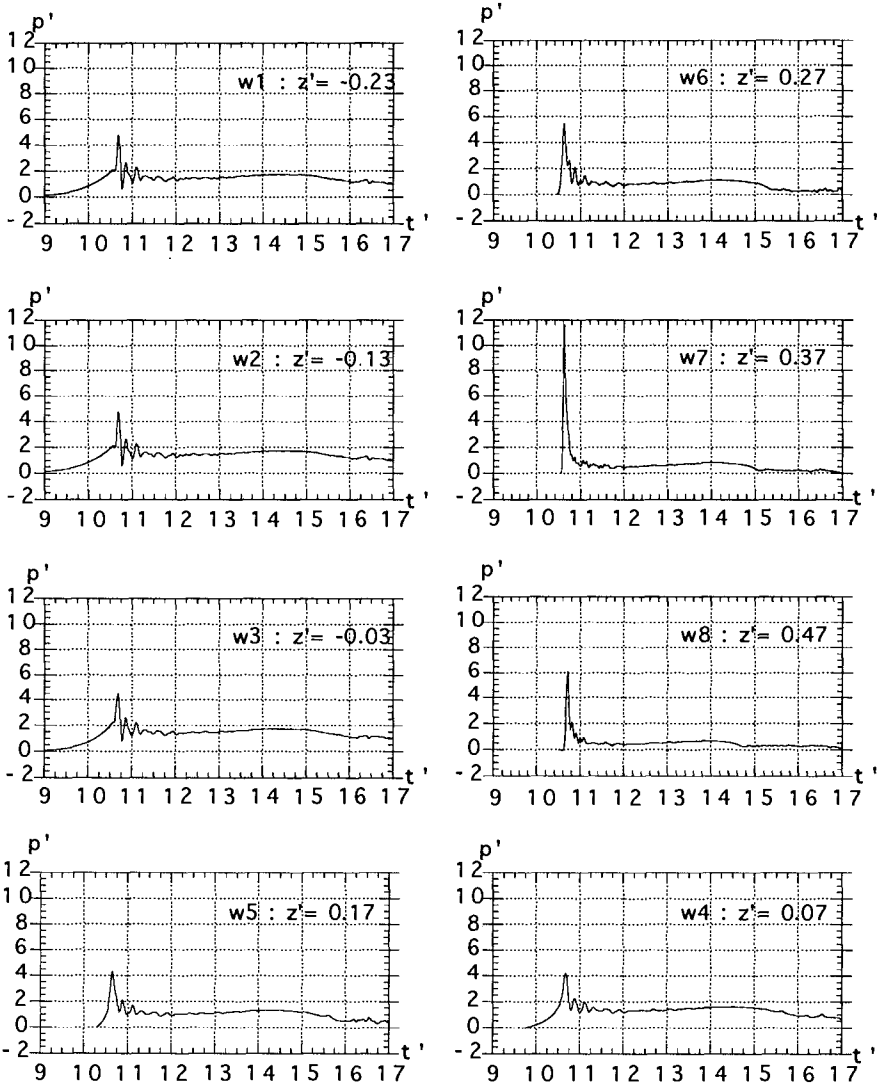

Figure 6: Pressure on the wall  $p'(t')$ , at  $x' = 5.69$ , as a function of  $z'$ .

(w1-w8) along the wall (Fig. 3). Dashes denote pressures that have been divided by the maximum pressure in still water,  $p_H = \rho g d$ . All pressure diagrams exhibit a peak of different magnitude, around time  $t' = 10.65$  (versus 10.70 in computations). This means, local pressures almost simultaneously reach their maximum, and the envelope of maximum pressure can be used to calculate the maximum impact force on the wall. This was also observed by KIR.

Maximum peak pressure is  $p'_{max} \simeq 12$ , at gage w7, i.e., at  $z' = 0.37$  above SWL. Peak pressure decreases both for larger and smaller values of  $z'$ , but stays quite constant under SWL, down to the bottom. All peak pressures are followed by small high frequency oscillations. Structural vibrations of the vertical wall model have been eliminated by using a stiff thick plate, and stiffeners. Thus, high frequency oscillations can be a sign, a small quantity of air is imprisoned between the wave and the wall during the impact. Based on pressure diagrams in Fig. 6, however, air entrainment seems to be quite minor.

**Instantaneous pressure on the berm.**— Figure 7 shows measured pressure at locations (b1-b8) on the berm (Fig. 3). All pressure diagrams exhibit a peak of decreasing magnitude when  $x'$  decreases, i.e., when moving away from the wall. Peak pressure is reached at, or close to  $t' = 10.65$ , for all locations. All peak pressures again are followed by small high frequency oscillations. Maximum peak pressure is  $p'_{max} \simeq 3.7$ , at  $x' = 5.62$ , i.e., very close to the wall.

Although it had been suggested earlier that peak pressures might be large on the bottom, it is, to our knowledge, the first time, comprehensive measurements of wave pressure on the berm of a breakwater have been made. The large impact pressures on the bottom, as far away as  $2.4d$ , require that they be considered when analyzing the berm stability, particularly for porous berms with large permeability (coarse granular media), in which significant pore pressures can transmit, and uplift isolated armour blocks. This is obviously a point for further study.

**Maximum pressure and force on the wall.**— Figure 8 shows instantaneous computed pressure distributions on the wall, for the same times as successive water profiles in Fig. 3 (solid lines). Symbols in Fig. 8 represent maximum pressure measured at each location, (w1-w9), during 9 repetitions of the experiment.

Results show, maximum computed and measured pressures reach 24 and 12 times  $p_H$ , respectively, and large pressures also occur down to the toe of the wall (as expected from Fig. 6 and 7 and discussion above). Maximum pressure is located above SWL, at  $z' = 0.39$  and  $0.37$ , in the computations and in the experiments, respectively. At these locations, the pressure increases from zero up to the maximum over  $\simeq 0.10$  time units. This can be seen from Fig. 6 for the experiments. Computed hydrostatic pressure is,  $\rho g(\eta - z) = 0.36p_H$ , at  $z' = 0.39$ , i.e.,  $1/66 p'_{max}$ . Global shape of the pressure diagram is well predicted in the numerical model. Maximum pressure, however, is overpredicted in the model. This could be due to the following few reasons : (i) the incident wave is about 15% smaller in the experiments, due to

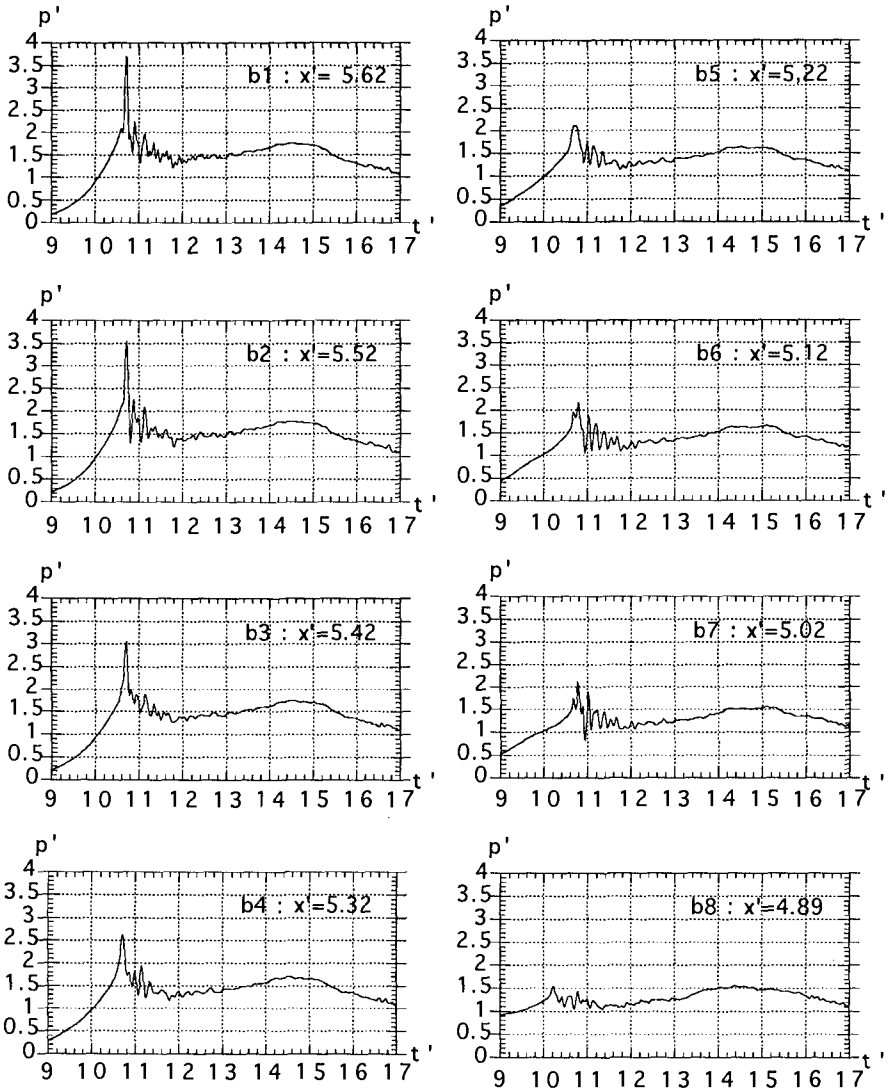

Figure 7: Pressure on the berm,  $p'(t')$ , at  $z' = -0.33$ , as a function of  $x'$ .

energy loss at the step. This leads to smaller impact pressures in the experiments; (ii) actual maximum pressures may have been "missed" in the measurements due to their very short time duration, and due to the size and location of pressure gages. The large dispersion of the measured pressure for  $z' > 0$  in nearly identical repetitions of experiments, tends to support this hypothesis; (iii) the roughness of the wall and of the free surface may limit the intensity of the jet formation in the experiments (i.e., accelerations and velocities) and, thereby, the magnitude of the maximum pressure (as suggested by CP). This is supported by the relatively low acceleration and velocity measured for the waterline along the wall in the experiments (see above).

As discussed above, maximum pressure envelope should be almost identical to instantaneous maximum pressure diagram (last solid profile in Fig. 8). Hence, it can be used for calculating maximum impact force. Figure 9 shows the instantaneous pressure force on the wall,  $F'_x$  (scaled by  $\frac{1}{2}p_H d$ ) as a function of time, in both experiments (solid line) and computations (chained line, up to maximum impact). The experimental force is simply based on integrating pressure diagrams in Fig. 6. Results show, numerical and experimental results quite well agree up to maximum impact. Computations, however, as could be expected from the pressures, overpredict maximum force.

As far as stability of the wall is concerned, Fig. 10 shows the time variation of computed force on the wall  $F'_x$ , and moment with respect to the toe of the wall  $M'_b$  (scaled  $\frac{1}{6}p_H d^2$ ), up to  $t' = 10.69$ . These are compared to hydrostatic force  $F'_{Hx}$  and corresponding moment  $M'_{Hb}$ , based on wave elevation  $\eta$  at the wall. Last force and moment shown on the figure are about 3 and 5 times larger than corresponding hydrostatic values, respectively. Peak impact pressures were obtained for a slightly later time,  $t' = 10.70$ , for which  $F'_x = 58.1$  and  $M'_{Hb} = 245.5$ , i.e. 9 and 15 times hydrostatic values, respectively.

## Conclusions

Present experimental and numerical results are bringing new light into the creation of large wave impact pressures on a vertical wall. Peak pressures on the wall have clearly been linked to a converging flow, and to the formation of a small scale jet, with large vertical velocity and acceleration. Large impact pressures have also been measured and calculated on the berm, as far away as twice the local depth from the wall. Such pressures might be of importance for the stability of porous berms. Water compressibility and air entrainment do not seem to be important factors in the present case. Computational results are well supported by experiments.

Based on these results, the numerical model can now be used for predicting wave pressure forces on breakwaters of various geometric configurations, keeping in mind the limitations of potential flow theory. Later studies will include: sensitivity analysis of impact pressure to the geometry (e.g., effect of streamlining); design implication for the sliding and overturning stability of the vertical wall, under wave impact pressure (a method based on wave impulse is being considered).

## CHAPTER 89

### LOADS ON SLOPING SEADYKES AND REVETMENTS FROM WAVE-INDUCED SHOCK PRESSURES

JOACHIM GRÜNE <sup>1</sup>

#### ABSTRACT

This paper deals with detailed studies on wave-induced pressures on sloping seadykes and revetments. The presented results are found as well from extensive field measurements at the coast of the German Bight as from full - scale laboratory tests in the LARGE WAVE CHANNEL (GWK) at Hannover, Germany. Summaring the results, a generalisation of shock pressure occurrence with respect to deterministic and stochastic characteristics and a "dynamic" loading model is presented.

#### INTRODUCTION

Shock pressures occuring on sloping dyke surfaces are damped more frequently compared to those on vertical walls. Furthermore, especially under real sea state conditions, partly they are mixed with pressure components from waves and wave run-ups. This results in a more complex analysis of shock pressures.

The author has demonstrated (GRÜNE, 1988a and 1988b), that for detailed statements on the loads from shock pressures an analysis of pressure-time histories from high-speed records is necessary instead of a simple peak value analysis. A scheme for the definition of shock pressure-time history parameters ( anatomy parameters ) was presented ( Fig. 1 ) and its application was shown examplarily for compression domain with the pressure-time histories of individual breaking waves, measured in field. Furthermore first examples of some results from the anatomy parameter analysis have been presented. In this paper further results of the ongoing research work will be presented.

## SHOCK PRESSURE ANALYSIS

As shown by GRÜNE (1988a and 1988b), the numberless different occurring shapes of pressure-time histories may be summarized by parameters ( anatomy parameters ) as defined in fig. 1, and divided into two domains:

Fig. 1 Definition of anatomy parameters

- the compression domain ( Index K ) from the beginning up to the peak pressure
- the decompression domain ( Index DK ) from the peak pressure value to the minimum pressure at the beginning of the quasi-static domain, with the following anatomy parameters:

$P_{ws}$	[ $10^4$ Pa ]	- pressure at begin ( thickness of watersheet )
$P_{max}$	[ $10^4$ Pa ]	- maximum ( peak ) pressure value
$P_{stat}$	[ $10^4$ Pa ]	- min. pressure at begin of quasi-static domain
$\Delta t$	[ s ]	- total times
$\Delta \Delta t$	[ s ]	- minimum significant times
$M U$	[ $10^4$ Pa/s ]	- mean velocities
$Max U$	[ $10^4$ Pa/s ]	- maximum significant velocities

The application of this parameterizing mode is demonstrated in fig. 2 for both domains by an example of an individual shock pressure event, measured in field on a slope 1:4 in vertical steps of 9 cm. In this figure the local distributions of the anatomy parameters, analyzed from the measured pressure-time histories, are plotted versus  $\Delta D / H$  1/3, which is the vertical distance from stillwaterlevel related to significant waveheight  $H$  1/3.

From such distributons of single shock pressure events some general remarks may be stated: It is obviuos, that for the higher peak pressures  $P_{max}$  the rising times  $\Delta t$  tend to minimum values in the range of about 10 to 50 milliseconds and the corresponding rising velocities to maximum values of about 10 to 1000 m/s. Further higher peak pressures only occur, where the watersheet pressures  $P_{ws}$  are low or tends to zero, which demonstrates the wellknown damping effect of a watersheet (FÜHRBÖTER, 1986). Below the range of highest peak pressures on the dyke

COMPRESSION DOMAIN

DECOMPRESSION DOMAIN

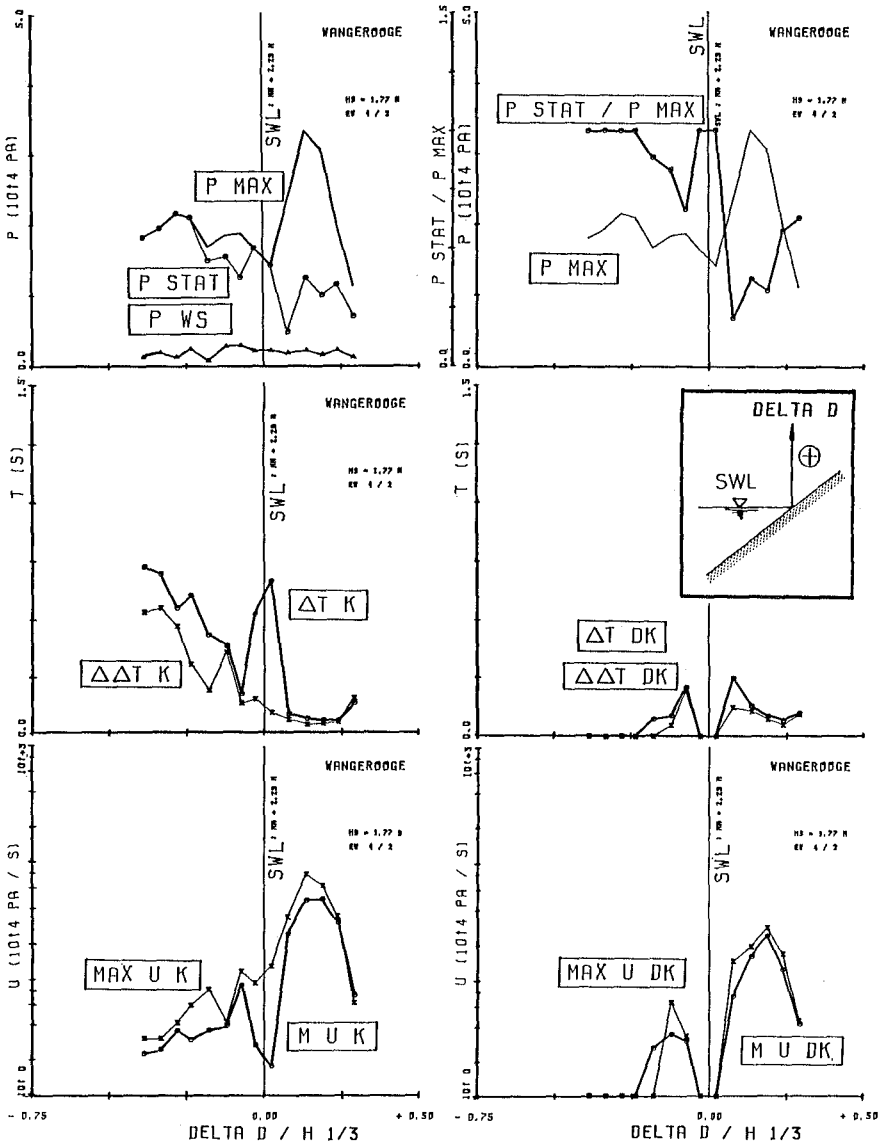

Fig. 2 Local distributions of anatomy parameters

surface, the decompression times and velocities have ( tend to ) zero values, where the pressures  $P_{stat}$  are equal to the ( tend to same value as ) the  $P_{max}$  ones.

It must be mentioned, that the selected example in fig. 2 is a typical one of the classic types and therefore it represents a certain generalisation. Nevertheless, also chaotic types show more or less similar elements, as demonstrated by GRÜNE (1988a). Thus such an analyzing method makes a distinctiveness in relation to real shock pressure occurrence possible.

### GENERALISATION OF SHOCK PRESSURE OCCURRENCE

In spite of all the different shock pressure types including the chaotic ones, it was possible to evaluate a generalized model of occurrence with respect to deterministic and stochastic characteristics. The deterministic parts of the model are represented by the local distributions of the anatomy parameters as given in fig. 3 for both domains. The x-axis  $\Delta D / H$  in fig. 3 is related to the point on the surface, where  $max P_{max}$  occur, instead of the stillwaterlevel in fig. 2. For the stochastic parts stand the superposition with the stochastic fluctuations of the anatomy parameters as shown in the following.

The local distributions in fig. 3 may be divided into five different local ranges, which in figs. 3 and 4 are marked from 1 to 5, each range represents a certain state during the wave breaking process on the slope surface ( fig. 4 ):

- Nr. 1 : This range represents the approaching steep wave front.
- Nr. 2 : At this range the steep wave front has its maximum height, which means the breaker point.
- Nr. 3 : This range gives the area between breaking wave front and the area, where the breaker tongue hits the slope surface. In this range the most chaotic pressure-time histories were found due to the enclosed air pockets with high turbulence.
- Nr. 4 : This is the range, where the breaker tongue hits the surface and thus where real significant shock pressures occur.
- Nr. 5 : This range represents the steep front of wave run-up.

Comparing the distributions of both domains in fig. 3, there are considerable differences for the time parameters. This is mainly due to the fact, that during the wave breaking process the compression times have substantial values except on the local range, where the breaker tongue hits the surface, whereas the decompression times mostly tend to zero values, either because the quasi-static pressures  $P_{stat}$  have the same magnitude as  $P_{max}$  or because the decompression shapes of the pressure-time histories have the same characteristics as the compression shape. This comes out more clearly by comparing the time distributions with the velocity distributions. Low time values and low velocity values indicate poor or no similarity between compression and decompression characteristic, whereas low times together with high

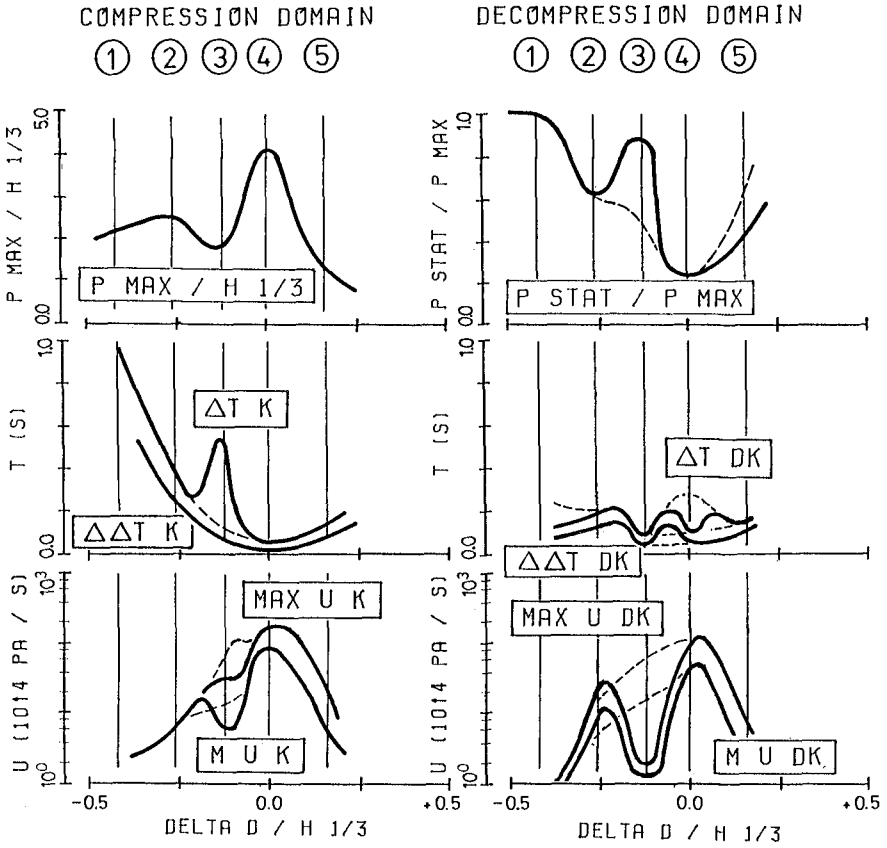

Fig. 3 Local distributions of deterministic parts of anatomy parameters

Fig. 4 Scheme of local ranges representing the wave breaking process

velocity values indicate a strong similarity between both domains. Furthermore the model demonstrates, that real shock pressures on slopes only are induced by the breaker tongue hitting on the the surface. Consequently for theoretical considerations the BAGNOLD piston model from the author's physical point of view cannot be used with respect to maximum pressure values on slopes.

### RELATIONS BETWEEN ANATOMY PARAMETERS

Due to the occurrence of numberless different shapes of pressure-time histories the data of the different anatomy parameters at a first sight spread like stars at the sky, but nevertheless there are some clear tendencies and some envelope conditions. There are many possibilities of relating the parameters among one another, in this paper all parameters are related to the peak values  $P_{max}$ .

In fig. 5 the parameter  $P_{ws}$ , which represents the thickness of the watersheet before the shock pressure occurrence, is related to  $P_{max}$ . The clear tendency comes out by the envelope curve and also by the density-distribution of the data cloud, that higher peak values  $P_{max}$  only occur with decreasing watersheet thicknesses.

Similar tendencies in dependence on higher peak values exist for some more parameters, for example in fig. 6 the time parameters  $\Delta T$  and  $\Delta \Delta T$  of both domains are plotted versus  $P_{max}$ . The ratios between both parameters gave no tendency. Differences between  $\Delta T$  and  $\Delta \Delta T$  may be found by the envelope curves and also be seen by the density distribution.

The mean velocities  $m U$  of both domains are plotted in fig. 7 versus  $P_{max}$ . The data have a wide range of spreading just as the maximum velocity ones. The ratios between the maximum and mean velocities  $max U / m U$  of both domains are given in fig. 8. From the density distribution it can be stated, that in most cases the maximum velocities are roughly in the same order of magnitude or only a few times higher than the mean velocities and furthermore, that there is less scatter for the decompression ratios. For higher peak pressures  $P_{max}$  the maximum velocity values may be roughly up to five times higher than the mean values.

Fig. 5  $P_{ws}$  versus  $P_{max}$

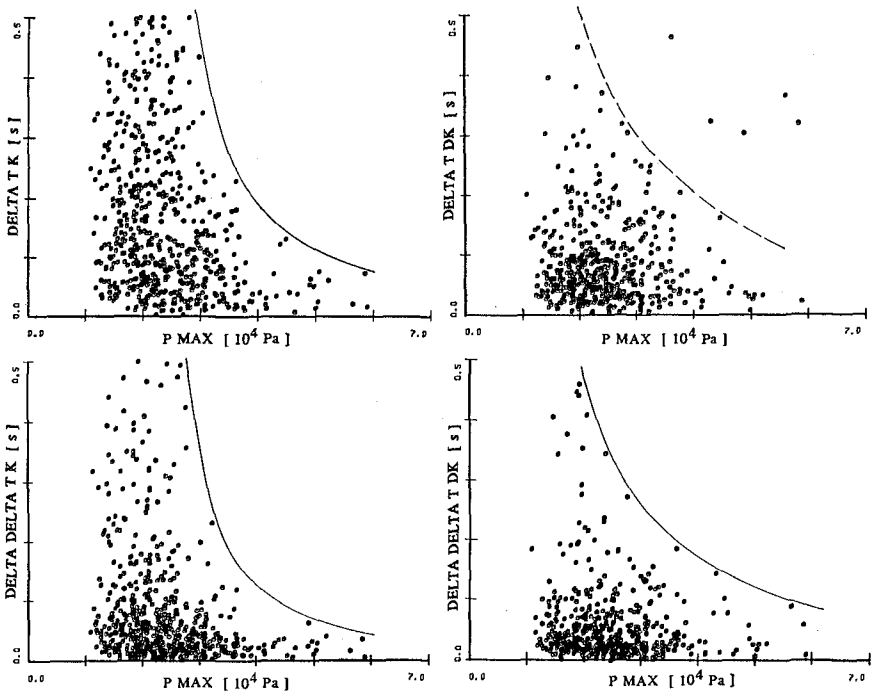

Fig. 6 Total and min. significant compression and decompression times versus  $P_{max}$

Comparisons between compression and decompression parameters are given in figs. 9 and 10. In fig. 9 the ratios for total and minimum significant parameters are plotted versus  $P_{max}$ . It is obvious, that in both domains generally the times can be shorter or longer compared to the other domain, but with higher peak pressures  $P_{max}$  the compression times decrease relatively more compared to the decompression times and thus the ratios tend to values around 1.0. The comparison of the velocity ratios

Fig. 7 Mean and maximum compression and decompression velocities versus  $P_{max}$

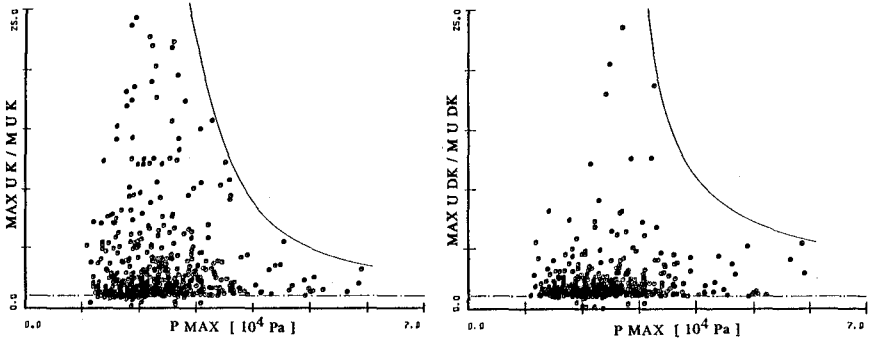

Fig. 8 Ratios between maximum and mean velocities of both domains versus *Pmax*

Fig. 9 Comparison between both domains for total and min. significant times

Fig. 10 Comparison between both domains for mean and maximum velocities

in fig. 10 shows more smaller ratio values for mean velocities *m U*. The density-distribution of the data indicate, that in most cases in both domains the velocity values are roughly in the same order of magnitude.

### COMPARISON OF PEAK PRESSURES FROM FIELD AND LABORATORY

The peak pressures measured in field were compared with those from large-scale laboratory tests, which have been done in the LARGE WAVE CHANNEL (GWK) of Universities at Hannover and Braunschweig, Germany (GRÜNE, FÜHRBÖTER, 1976). A research program is running since years, which includes investigations on shock pressures and wave run-up on different uniformly and combined sloped dykes. All dyke profiles have a sand core covered with an asphalt concrete layer ( same construction as used for field measurements ). The same types of shock pressure sensors and data recording systems were installed in the channel as used for the field measurements (GRÜNE, MALEWSKI, 1985). The first tests on slope 1:4 were done mostly with regular waves. The aim was to produce a collectiv of at least 200 single shock pressure events during each test for statistical considerations and to check the spatial width of pressure occurrence (FÜHRBÖTER, 1986).

For comparison of regular wave test data with field data some facts have to be considered:

- firstly one don't know, which wave height should be used. This problem is an old and suffering one, since tests were run in laboratories.
- secondly one have to notice, that regular waves have a more or less constant breaker point and thus the zone, where the breaker tongue hits the slope surface, is a rather narrow one. The thickness of the watersheets from the regular wave run-ups of the preceeding waves also are rather constant, mostly with a certain value (FÜHRBÖTER, 1986). Both conditions are contrary to irregular wave conditions, where the thickness together with the hitting zone of the breakertongue have a broad spreading characteristic. These conditions can be attenuated by the three-dimensionality of real sea state waves and by non oblique wave attack. This may result in higher

Fig. 11 Pressures on dyke surface induced by regular and irregular waves

shock pressures, if the breaker tongue of a high wave hits the slope surface at such a moment, when the watersheet is zero or tends to zero. Furthermore, as demonstrated in fig. 11 for the same pressure sensor and roughly the same waveheights, each regular wave gives a peak pressure value, which cannot be found for irregular waves. This leads to different statistical characteristics of the data (GRÜNE, 1988b).

In fig. 12 the statistical peak pressure values  $P_{99.9}$  from field and from GWK-tests with regular waves (FÜHRBÖTER, 1986) have been compared. Each value was derived from log-normal distributions of all peak pressures measured during one time interval on a slope 1:4 with all installed sensors. Both the data from field and laboratory are related to mean wave heights  $H_m$ . For all data the agreement is rather poor, but it must be mentioned, that there are also differences between the field data, due to different wave climate characteristics at the two locations. The wave characteristics of the laboratory tests were similar to those at Eiderdamm location. It is obvious,

Fig. 12 Comparison between field and large scale test data with regular waves

Fig. 13 Comparison between field and large scale test data with regular waves

that higher field pressure values were found. Further comparisons have shown, that even, if one relate the field data to significant waveheight  $H/3$ , there are some few higher pressure data. A comparison of field data for the slope 1 : 6 with GWK data (SPARBOOM et al., 1991) in fig. 13 shows a fairly well agreement. The differences of the GWK data between both slopes are rather small compared with those, found for field data (GRÜNE, 1988b).

Fig. 14 shows a comparison with a few GWK data, measured with irregular waves on slope 1:6. The data are as well related to mean waveheights  $H_m$  as to waveheights  $H/3$ . The agreement is much better compared to data measured with regular waves, nevertheless the laboratory data give the impression of a tendency to higher pressure values. If one use the actual measured maximum peak pressure values  $max P_{max}$  of each measured time interval or test, instead of the statistical values

Fig.14 Comparison between field and large scale test data with irregular waves

Fig. 15 Comparison between field and large scale test data with irregular waves

*P* 99.9, then the agreement between field and laboratory is quite well for these data as shown in fig. 15. Further comparisons have shown a quite well agreement with field data even for laboratory data from regular wave tests by using the *max Pmax* parameter related to *Hm*. From this results one may state, that comparison between field and laboratory data from regular waves tests both should be related to mean waveheight *Hm*, which is also the cleanest way from the definition point of view.

**A " DYNAMIC " LOADING MODEL**

A first approximation for a loading model has based on the local peak pressure parameter distributions, found for individual breaking wave events (GRÜNE, 1988b). Although the several values of these distributions have small phase lags mutually, they may give a realistic approximation of a worst-case loading model. The next developing step was, to evaluate actual synchronous pressure distributions without any phase lag from the recorded pressure-time histories.

On the lefthand in fig. 16 the pressure-time histories of one individual shock pressure event, measured with the sensors D8 to D21 in local steps on the surface, are plotted. The horizontal time axis is divided in 12 steps and for each time step the

Fig. 16 Measured pressure-time histories (lefthand part) and evaluated actual pressure distributions (righthand part) for one individual breaking wave

pressure values at the certain levels were used to evaluate actual pressure distributions on the surface as plotted in the righthand part of fig. 16. There the time axis is the vertical axis, whereas the horizontal axis represents the slope surface, defined as the vertical distance from stillwaterlevel *SWL* related to  $H/3$ . From comparisons between the evaluated maximum actual pressure distributions and the local peak pressure distributions from the pressure-time histories it was found, that the actual distributions mostly are a bit narrower.

Based on such actual pressure distributions, a new version of the loading model was created, which is given in fig. 17. Compared with the first version the shape was modified with respect to linear geometrical pressure boundaries for simpler application. Each of these geometrical boundary conditions ( marked with a circled number in fig. 17 ), which are derived from the anatomy parameter results, have to be varied systematically within certain ranges ( listed in Table 1 ), to find out the

## CHAPTER 90

### NUMERICAL MODELING FOR WAVE ENERGY DISSIPATION WITHIN POROUS SUBMERGED BREAKWATERS OF IRREGULAR CROSS SECTION

George Z. Gu<sup>1</sup> and Hsiang Wang<sup>2</sup>

#### Abstract

In the design of a porous submerged breakwater, the maximum wave energy dissipation within the breakwater is desirable. To calculate the energy dissipation, the process is simulated numerically in this study using the Boundary Integral Element Method (BIEM). The breakwater is idealized as a homogeneous porous medium and the flow inside the breakwater is modeled by a non-linear porous flow model which is linearized iteratively based on the equivalent energy principle in the numerical model. To fully explore the advantage of BIEM, a boundary integral expression for wave energy dissipation developed in an earlier work by the authors is used to replace the traditional domain integral expression. As a result, the efficiency of the numerical model is greatly increased. The numerical model was run for a number of cases and the results show that the maximum wave energy dissipation can be achieved at a practical permeability level (or stone size). The good agreement between the numerical results and the experiment data for non-breaking waves indicates that the wave energy dissipation within porous breakwaters can be adequately predicted by the numerical model.

#### Introduction

Due to increasing demand for beach protection in recreational areas, submerged breakwaters may become more and more popular over traditional sub-aerial ones. The advantages of submerged breakwaters as compared to sub-aerial ones are of low cost, aesthetics (they do not block the view of the ocean) and effectiveness in triggering early breaking of the incident waves. More general, a low crest sub-aerial breakwater may become submerged during storm surge or after being damaged.

<sup>2</sup>Professor, Coastal and Oceanographic Engineering Dept. of U. of Florida, Gainesville, FL, 32611

In the design of a porous submerged breakwater, one of the important aspects is to assess the energy dissipation within the structure due to turbulence and friction. Maximum energy dissipation (equivalently, minimum wave transmission) is usually desired.

The wave transmission, reflection and energy dissipation has been studied experimentally by Dick (1968), Dattatri (1978), Seelig (1980) and many other investigators. The measurements in these model tests were generally limited to the free surface oscillations on the weather and lee side of a submerged breakwater. As pointed out by Kobayashi et al. (1989), such measurements do not reveal the hydrodynamic processes over and within porous submerged breakwaters. In terms of theoretical modeling, a great deal of contributions have been made by Sollitt et al. (1972), Madsen (1974), Ijima et al. (1974), Sulisz, 1985 and others to the problem of wave interaction with sub-aerial porous breakwaters. Kobayashi (1989) successfully modeled the wave interaction with impermeable submerged breakwaters. However, the process of wave energy dissipation within porous submerged breakwaters has not been investigated thoroughly enough to guide practical designs.

In this paper, a numerical model using the Boundary Integral Element Method (BIEM) is developed to model wave interaction with porous submerged breakwaters. In general, wave attenuation over a porous submerged breakwater is affected by three mechanisms: reflection by the structure, breaking over the structure and damping due to percolation inside the porous structure. The wave energy dissipation are mainly caused by wave breaking and flow percolation. The main focus of this study is on the process of wave energy dissipation due to percolation.

The submerged breakwater is modeled as an infinitely long, shore parallel structure. The porous body of the structure is assumed to be a homogeneous porous medium, and described by the non-linear unsteady percolation model.

### Governing Equations and Boundary Conditions

The computation domain of the problem consists of two sub-domains, the fluid domain and the domain(s) of the submerged porous media (more than one porous domain if the breakwater has multiple layers). In the fluid domain, the water is considered inviscid and incompressible. The flow induced by gravity waves is assumed irrotational. Thus, the governing equation in this domain, for the velocity potential function  $\Phi$ , is the Laplace equation,

$$\nabla^2 \Phi = 0 \quad (1)$$

with fluid velocities being defined as

$$u = -\frac{\partial\Phi}{\partial x} \tag{2}$$

$$w = -\frac{\partial\Phi}{\partial z} \tag{3}$$

Further more we assume sinusoidal wave motion such that

$$\Phi = \phi e^{i\sigma t} \tag{4}$$

While in the porous domain, the viscosity of the fluid cannot be ignored since the flow is largely within the low Reynolds number region. The flow induced by sinusoidal linear waves can be described by the non-linear unsteady porous flow model used by Sollitt and Cross (1972)

$$-\frac{1}{\rho}\nabla P(x,y,z,t) = \sigma\left(\frac{1}{R} + i\beta + \frac{C_f}{\sqrt{\sigma\nu R}} |\vec{q}(x,y,z,t)|\right)\vec{q}(x,y,z,t) \tag{5}$$

or

$$-\frac{1}{\rho}\nabla p(x,y,z,t) = \sigma(f_1 + f_2 |\vec{q}|)\vec{q} \tag{6}$$

with

$$\Psi(x,y,z,t) = \psi(x,y,z)e^{i\sigma t}$$

$$f_1 = \frac{1}{R} + i\beta; \quad f_2 = \frac{C_f}{\sqrt{\sigma\nu R}}$$

where  $\Psi$  can be  $P$  or  $\vec{q}$  or any other wave field variable;  $P(x,y,z,t)$  is the pore pressure function inside porous media;  $\nu$  and  $\rho$  are the kinematic viscosity and the density of sea water, respectively;  $R$  is the permeability parameter defined as

$$R = \frac{\sigma K_p}{\nu}$$

$K_p$  is the intrinsic permeability of the porous media, measured under the conditions of steady flows; it is empirically related to particle diameter by (Engelund, 1953)

$$K_p = \frac{n^2 d_s^2}{a_0 (1-n)^3} \tag{7}$$

where  $a_0$  is an empirical constant and it is taken to be 570;  $n$  is the volumetric porosity;  $\sigma$  is the wave frequency;  $\beta$  is the inertial resistance parameter and  $C_f$  is a non-dimensional constant characterizing the non-linear resistance. In this study,  $\beta = 4.6$  and  $C_f = 1.0$ , as determined by a seabed experiment (Gu and Wang, 1990, Gu, 1990);  $\vec{q}(x,y,z,t)$  is the complex vector of discharge velocity in the porous medium.

Due to the mathematical difficulties in applying the non-linear model directly, the common practice is to linearize Eq.(6) such that

$$-\frac{1}{\rho}\nabla p = \sigma f_0 \vec{q} \quad (8)$$

where  $f_0$  is the linearized resistance coefficient which is a constant for a particular problem. This coefficient can be obtained by using the principle of equal energy dissipation, as will be discussed later. At this point, we assume that  $f_0$  is a known complex constant. Substitution of the above equation into the continuity equation gives the Laplace equation for  $p$ ,

$$\nabla^2 p = 0 \quad (9)$$

The boundary conditions for the fluid domain are:

$$\frac{\partial \phi}{\partial z} = \frac{\sigma^2}{g} \quad z = 0 \quad (10)$$

$$\frac{\partial \phi}{\partial n} = 0 \quad z = -h(x) \quad (11)$$

On the lateral boundary of lee side,  $x = l'$ ,

$$\frac{\partial \phi}{\partial n} = \frac{\partial \phi}{\partial x} = -ik'\phi \quad \text{with} \quad gk' \tanh k'h' = \sigma^2 \quad (12)$$

where  $h'$  is the water depth at  $x = l'$ .

While on the lateral boundary of weather side,  $x = -l$ ,

$$\frac{\partial \phi}{\partial n} = 2ik\phi_I - ik\phi \quad \text{with} \quad gk \tanh kh = \sigma^2 \quad (13)$$

in which  $\phi_I$  is the incident wave potential and  $h$  is the water depth at  $x = -l$ . For the porous domain(s),

$$\frac{\partial p}{\partial n} = 0 \quad \text{on impermeable surface(s)} \quad (14)$$

$$\left. \begin{aligned} \rho \frac{\partial \phi}{\partial t} &= p \\ \frac{\partial \phi}{\partial n} &= -\frac{1}{\rho \sigma f_0} \frac{\partial p}{\partial n} \end{aligned} \right\} \text{between fluid and porous domains} \quad (15)$$

$$\left. \begin{aligned} p_i &= p_j \\ \left(\frac{1}{f_0} \frac{\partial p}{\partial n}\right)_i &= -\left(\frac{1}{f_0} \frac{\partial p}{\partial n}\right)_j \end{aligned} \right\} \text{between two different porous domains} \quad (16)$$

where  $i$  and  $j$  refer to different porous domain.

Numerical Formulation of Boundary Integral Element Method

The boundary value problem stated in the previous section is solved numerically using the boundary integral element method (BIEM or BEM) owing to the irregular geometries of porous submerged breakwaters. The method has been proved to be a powerful and convenient method for problems governed by the Laplace equation.

Under the assumption of continuous and second order differentiable, the wave potential function  $\phi$  in the fluid domain  $D_1$  bounded by a closed boundary  $C_1$  can be expressed by

$$\alpha\phi(\mathbf{x}_0) = \oint_{C_1} [\phi(\mathbf{x}) \frac{\partial G}{\partial n}(\mathbf{x}_0, \mathbf{x}) - G(\mathbf{x}_0, \mathbf{x}) \frac{\partial \phi}{\partial n}(\mathbf{x})] ds \quad (17)$$

where  $G(\mathbf{x}_0, \mathbf{x})$  is a free space Green's function and  $\alpha$  is a coefficient depending on the position of point  $\mathbf{x}_0$ , ( $\alpha$  is  $2\pi$  when  $\mathbf{x}_0$  is an interior point and equals to the inner angle of the boundary when it is a boundary point);  $\mathbf{x}_0$  is a point in the domain  $D_1 \cap C_1$  and  $\mathbf{x}$  is a boundary point on  $C_1$ . The free space Green's function for normal incident wave is

$$G(\mathbf{x}_0, \mathbf{x}) = \ln r(\mathbf{x}_0, \mathbf{x}) = \ln \sqrt{(x_0 - x)^2 + (z_0 - z)^2} \quad (18)$$

Discretizing the boundary  $C_1$  into  $N$  segments, the Eq.(17) becomes

$$\alpha_i \phi_i(\mathbf{x}_{0i}) = \sum_{j=1}^N \int_{C_{1j}} \left[ \frac{\phi(\mathbf{x})}{r(\mathbf{x}_{0i}, \mathbf{x})} \frac{\partial r(\mathbf{x}_{0i}, \mathbf{x})}{\partial n} - \ln r(\mathbf{x}_{0i}, \mathbf{x}) \phi_n(\mathbf{x}) \right] ds \quad (19)$$

To evaluate the integrals, the curving segments  $C_{1j}$  are replaced by straightline segments. Each segment is then modeled by a linear element which assumes a linear variation of  $\phi$  and  $\phi_n$  over the segment. The line integration over each element can be carried out by introducing an auxiliary coordinate system (Liggett and Liu, 1983).

By applying the boundary conditions given in the previous section, Eq.(19) yields a set of linear algebraic equations with unknowns of  $\phi_i$  and  $\phi_{ni}$  ( $i=1,2, \dots N$ ). In matrix form, it can be expressed as

$$\begin{bmatrix} \mathbf{A}_1 & \mathbf{A}_2 \end{bmatrix} \begin{Bmatrix} \phi_f \\ \phi_c \end{Bmatrix} = \begin{bmatrix} \mathbf{B}_1 & \mathbf{B}_2 \end{bmatrix} \begin{Bmatrix} \phi_f \\ \phi_{nc} \end{Bmatrix} + \mathbf{b} \quad (20)$$

where  $\mathbf{A}_i$  and  $\mathbf{B}_i$  ( $i = 1, 2$ ) are the known matrices determined purely by boundary geometries,  $\phi_c$  and  $\phi_{nc}$  are the vectors of the unknown potential function and its normal derivative on the interface (common) boundary,  $\phi_f$  and  $\phi_{nf}$  are the vectors of the unknown potential function and its normal derivative along the boundaries other than the interface (common) boundary,

$\mathbf{b}$  is the known vector containing  $\phi_I$  resulting from the radiation boundary condition on the weather side lateral boundary.

In the porous domain, a similar expression can be derived by replacing  $\phi$  with  $p$  in Eq.(19). Introducing  $p_n = 0$  on impermeable boundaries and carrying out the same operations, the resulted matrix equation for  $p$  and  $p_n$  is

$$\begin{bmatrix} \mathbf{C}_{11} & \mathbf{C}_{12} \\ \mathbf{C}_{21} & \mathbf{C}_{22} \end{bmatrix} \begin{Bmatrix} \mathbf{p}_c \\ \mathbf{p}_b \end{Bmatrix} = \begin{pmatrix} \mathbf{D}_{11} \\ \mathbf{D}_{21} \end{pmatrix} \mathbf{p}_{nc} \quad (21)$$

where  $\mathbf{p}_c$  and  $\mathbf{p}_{nc}$  are the vectors of pressure function and its normal derivative along the common boundary and  $\mathbf{p}_b$  is the pressure vector on the impervious bottom of the porous domain.

Based on Eq.(21) and solving  $\mathbf{p}_{nc}$  in terms of  $\mathbf{p}_c$  by eliminating  $\mathbf{p}_b$ , a relationship between  $\mathbf{p}_{nc}$  and  $\mathbf{p}_c$  can be established

$$\mathbf{p}_{nc} = \mathbf{E} \mathbf{p}_c \quad (22)$$

with

$$\mathbf{E} = (\mathbf{D}_{11} - \mathbf{C}_{12} \mathbf{C}_{22}^{-1} \mathbf{D}_{21})^{-1} (\mathbf{C}_{11} - \mathbf{C}_{12} \mathbf{C}_{22}^{-1} \mathbf{C}_{21}) \quad (23)$$

Substitution of the matching conditions stated in Eq.(15) into Eq.(22) and then into Eq.(20) yields

$$\bar{\mathbf{A}} \phi = \mathbf{b} \quad (24)$$

with

$$\bar{\mathbf{A}} = [\mathbf{A}_1 - \mathbf{B}_1 \quad \mathbf{A}_2 + \frac{i}{f_0} \mathbf{E} \mathbf{B}_2]_{N \times N} \quad (25)$$

and

$$\phi = \begin{Bmatrix} \phi_f \\ \phi_c \end{Bmatrix}_{N \times 1} \quad (26)$$

This is a determinant equation with complex matrix elements and it can be readily solved by a complex equation solver if the linearized coefficient  $f_0$  for the resistances in the porous flow model is given. Unfortunately, it is still an unknown at this point and has to be determined by the linearization process.

#### Linearization of The Non-linear Percolation Model

The principle for the linearization is the equivalent energy dissipation by both linear and non-linear systems, i.e.

$$(E_D)_l = (E_D)_{nl} \quad (27)$$

For the energy dissipation  $E_D$  within a control volume (domain)  $V$  of porous medium during the time period  $T$ , the traditional expression (Sollitt et al, 1972, Madsen, 1974 and Sulisz, 1985) is

$$E_D = \int_V \int_t^{t+T} \vec{F} \cdot \rho \vec{q} dt dv \quad (28)$$

where  $\vec{F}$  is the dissipative resistance per unit volume of the porous medium, which is a function of the spatial coordinates and the time.

Since the domain integral in Eq.(28) is very awkward for a boundary element model, an equivalent expression in the form of boundary integration has been developed (Gu and Wang, 1991, Gu, 1990):

$$E_D = -\frac{T}{2} \int_C p^* u_n, ds \tag{29}$$

Where  $C$  is the common boundary of the fluid and the porous domains and  $p^*$  is the complex conjugate of  $p$  and  $u_n$  is the velocity normal to  $C$ , which is different for the linearized and for the non-linear systems. The ‘.’ sign is used here because  $E_D$  is considered as a positive value.

The physical explanation of Eq.(29) is that the energy dissipation inside the porous domain in one wave period  $T$  is equal to the net energy flux into the domain in the same time period. By expressing the energy dissipation in such a boundary integral, the advantage of BIEM can be well explored.

Equating  $(E_D)_l$  to  $(E_D)_{nl}$  and taking approximately  $|\vec{q}| \simeq |p_n / \rho \sigma f_0|$ , the linearized coefficient  $f_0$  can be found to be

$$f_0 = \frac{\int_C p_n p^* ds}{\int_C \frac{p_n p^*}{f_1 + f_2 |p_n / \rho \sigma f_0|} ds} \tag{30}$$

Equation (30) can be easily solved by iteration.

Numerical Results

As an example, two submerged breakwaters are computed with the model. One breakwater is made of concrete, therefore impermeable, and the other one is made of quarry stones of  $d_s = 0.4$  meters. The dimensions and the wave conditions are identical for both structures. The crest of the breakwater is 12 meters wide with 1.6 meter submergence in a water of 4.6 meters deep. The slopes are 1:1.5 on both sides. The wave envelopes and the waves at  $t=0$  are shown in Fig. 1. Comparing the two wave envelopes, it is obvious that the transmitted wave height by the permeable breakwater is less than that by the concrete one due to wave energy dissipation inside the breakwater. The dissipation is  $1.0 - K_T^2 - K_R^2 = 29\%$  of the total wave energy.

Fig. 2 illustrates the transmission and reflection coefficients for a submerged porous breakwater with a scale of 1:20 of the one in Fig. 1. In Fig. 2 the coefficients are plotted against the permeability parameter  $R$  for four

different wave heights,  $H = 2.0, 4.0, 6.0$  and  $8.0$  cm. The wave period is kept constant, at  $T = 1.2$ s. The transmission coefficient is shown to have a minimum value for each wave height for a particular stone size (around  $R \approx 1.0$ ,  $d_s \approx 1.6$  cm). A close examination of the resistances showed that this minimum transmission or maximum energy dissipation is achieved when the dissipative resistance (velocity related) is equal to the non-dissipative (acceleration related) resistance.

It can be observed in the figure that the permeability corresponding to the minimum transmission increases with increasing incident wave height, whereas the energy dissipation rate remains more or less the same. When the permeability (or equivalently the stone size) is greater than a certain value, say  $R = 10.0$  ( $\log R = 1.0$ ), the wave transmission decreases with increasing wave height. This means that larger stones are more effective for protection against storms. The curves in Fig. 2 also implies that the stone size (or permeability) should be large enough so that it will not fall to the left of the trough for the design wave height.

### Laboratory Experiment

The experiment was conducted in the Coastal Engineering Laboratory of Coastal and Oceanographic Engineering Department, University of Florida. The tank was 25 meters long, 0.6 meters wide and 1.7 meters deep with glass walls on both sides. The wave maker is of piston type furnished with an absorbing system which was designed to absorb the wave energy reflected back to the piston. The tank is also equipped with a motorized rail cart on the top to facilitate wave envelope measurements.

The model of the porous submerged breakwater was of trapezoidal shape made of river gravel of  $d_{50} = 0.93$  cm. It has the same configuration as the one shown in Fig. 1 with a scale factor of 1:20. The measurements were concentrated on wave reflection and transmission, although the wave envelope over the breakwater crest was also measured.

In the experiment, the measurements of transmission and reflection coefficients were carried out for 9 wave periods ranging from  $T = 0.642$  seconds to  $T = 1.778$  seconds with several different wave heights for each wave period. Both non-breaking and breaking waves were tested. Here 'breaking' refers to white caps over the breakwater crest, not breaking of incident waves.

It was observed in the experiment that higher order harmonics occur on the down wave side of the breakwater model, as opposed to monochromatic waves predicted by the numerical model. Fig 3 is the energy spectrum of a typical transmitted wave record. The data also showed that in general, the

wave energy of the first three modes accounts for more than 98% of the total transmitted wave energy.

In order to compare with the numerical results which is based upon the energy balance of the fundamental waves, an equivalent height for a transmitted wave was defined for the experimental data by summing the wave energy of the harmonics i.e.

$$(H_t)_{eq} = \sqrt{\sum_{i=1}^N (H_t)_i^2} \approx \sqrt{\frac{8}{\gamma} E} \quad (31)$$

where  $(H_t)_i$  is the wave height of the  $i$ -th order harmonic wave, which can be determined by the corresponding spike area of the spectrum diagram and  $E$  is the total energy per unit area of all the harmonics.

Figure 4 and 5 are the plots of the transmitted and reflected wave heights versus the corresponding incident wave heights. Also plotted are the predicted values by the numerical model. The agreement between the data and the prediction is reasonably good for transmitted waves before breaking occurs. Although the agreement for the reflected waves is not as good, it is not difficult to envision a good agreement for the energy dissipation ( $E_D = H_i^2 - H_t^2 - H_r^2$ ), because of small amplitude for the reflected waves. From Fig. 4 and 5, it is clear that the breaking occurs when the incident wave height is about  $H_i = 4.2$  cm. After the waves break over the crest, the numerical model limited to non-breaking waves apparently over estimates the transmitted wave heights. When the incident wave height is over the breaking threshold (4.2 cm for this case), the transmitted wave height in the experiment changes only slightly, if at all, with the increasing incident wave height. The reflected waves are not noticeably affected by the breaking over the crest.

In Fig. 6, the wave envelopes (normalized by the incident wave heights) predicted by the model are compared with those of measured in the experiment for the case of  $T = 0.856$  seconds; both non-breaking and breaking cases are shown. In the non-breaking case, although the measured wave envelope above the breakwater crest is shifted slightly upward, the numerical model is able to predict, with sufficient accuracy, both the variation patterns and the magnitudes of the wave heights (the distances between the two envelope profiles). Good agreement was also found for the non-breaking portion of the breaking wave cases. The upward shift of the mean water level in the data is believed to be caused by set-up over the crest.

### Conclusions

An efficient numerical algorithm using boundary integral method was developed to compute the energy dissipation inside submerged rubble-mound breakwaters of irregular cross sections. The porous flow model simulating the porous breakwaters includes both the velocity induced linear and non-linear resistances as well as the acceleration induced inertial resistance. The replacement of the domain integral expression for the energy dissipation—commonly required by the linearization of the porous flow model—by a boundary integral is a key element in achieving the efficient numerical algorithm.

The numerical results show that under a given wave condition the rate of energy dissipation in a porous structure has a well defined maximum when the dissipative (velocity related) resistance is equal to the non-dissipative (acceleration related) resistance. It is shown that porous submerged breakwaters, if designed properly, could be more effective than impervious ones with same dimensions. It is also shown that large stones (or high permeability) is more effective for protection against storms than small stones.

Laboratory experiments were also conducted under both non-breaking and breaking wave conditions. The energy dissipation and wave envelope over the crest predicted by the model agree well with the experiments for non-breaking cases and for the non-breaking portion of the breaking cases. For breaking waves, the crest submergence of the breakwater appears to play a dominant role in limiting the wave energy transmission.

## CHAPTER 91

### Two Dimensional Effects in Modelling Berm or Reshaping Breakwaters

Kevin R. Hall  
Department of Civil Engineering  
Queen's University  
Kingston, Ontario, Canada

#### Introduction

In recent years, the failure of many large conventional type breakwater structures has led to a careful examination of the physical processes of wave-structure interaction. Although naturally armouring structures, which gain their stability as a consequence of profile readjustment due to wave action, have been around in various forms for hundreds of years, the high incidence of failure of conventional structures has led to their increased use in the past decade.

The interaction of an incident wave with a rubblemound breakwater results in complex flow patterns involving unsteady non-uniform flow (Hall (1987)). In most cases, it is desirable to construct a breakwater which works in harmony with the flow field; that is to construct a structure with a geometry and armour stone weight gradation which results in natural profile readjustment and subsequent minimization of the applied hydrodynamic loadings.

A reshaping or berm breakwater can be described as a mound of rock, often comprised of a wide range of stone sizes, which undergoes reshaping as a result of wave-structure interaction. As a consequence of this wave action, a stable profile is developed. Two major processes occur in the development of the stable profile. First, the overall geometry of the structure responds to the nature of the hydrodynamic loadings. Material is sorted and redistributed into a profile which acts to minimise the applied forces by altering the flow field kinematics. Secondly, this natural sorting leads to consolidation (densification) of the armour layer as stones that move eventually find voids into which the

nest.

This type of structure has been used extensively in the past decade and it has been found that these structures are significantly less expensive than more conventional breakwaters designed in accordance with guidelines given in design manuals such as the US Army Corps of Engineers Shore Protection Manual. The armour stones required are smaller than those required by conventional stability formulae and a much wider gradation can be used. This allows for the design to be based on the actual quarry output rather than some pre-conceived specification for stone for which a quarry must be found. Experimental studies have indicated that the reshaped breakwater profile can be closely predicted for the design wave conditions and the available material properties. This profile can be used as an initial design. Currently model studies are used to optimize the design and minimise the cost.

Limited research on the two dimensional stability of these breakwaters has been undertaken in the past decade; and although virtually no research has been undertaken with respect to the three dimensional stability of these structures, Hall et al. (1983), Hall (1987), and Burcarth and Frigaard (1987) have shown that significant three dimension effects can exist. These effects may be classified as purely three dimensional effects (due to attenuation of energy within the cross section) or effects resulting from the variation of the angle of wave attack, thus affecting the erosion prone areas (particularly the head of the breakwater). The later effects are typically what is thought of as being dominant; however, Hall et al. (1983) has shown that the difference between test results from narrow flumes and wider three dimensional test sections (for incident waves parallel to the trunk of the structure) can be substantial. The tests reported in this paper were designed to evaluate these effects, in particular to evaluate if the reshaping of these breakwaters is influenced by the flume width used in the tests.

#### Testing Programme

Experimental studies were undertaken using the facilities of the Coastal Engineering Research laboratory of Queen's University, Kingston, Canada. The studies were undertaken primarily to investigate the mechanism of reshaping of berm breakwaters and to evaluate the specific influence of the various parameters that may affect the reshaping process. These parameters include

wave height, wave period, wave groupiness, duration of each segment of the design storm, the gradation of the armour stones, and the percentage of rounded stones occurring in the gradation.

Tests were run in a 22 x 26 metre three dimensional basin where three separate "flumes" having widths of 1.2, 2,4 and 4.0 metres were constructed parallel to each other. Identical test structure were built in each of the flumes and were then subjected simultaneously to the same wave conditions. Basin layout is shown in Figure 1.

Profiles of the test breakwaters were measured at several locations along the structure following each segment of the design storm as shown in Figure 1. The profiler used to measure the three dimensional profiles was a trailing arm profiler which provided a continuous reading of the elevation of the breakwater with horizontal distance.

Tests undertaken in the three dimensional modelling programme utilized a core material shown in Figure 2. Two different gradations of armour were used having the following characteristics:

	$D_{50}$ (mm)	$D_{85}/D_{15}$	$D_{max}$ (mm)
Gradation 1	19	1.9	32
Gradation 2	14	2.0	27

Tests were undertaken on a berm breakwater whose general configuration is shown in figure 3. The basic geometry of the test structure was determined based on the large number of berm breakwaters tested at various institutions in Canada and abroad. This configuration has been found to be easy to construct in prototype. Five capacitance type water level transducers were placed just in front of the breakwater to measure the dynamic water level fluctuations. An additional water level transducer was placed immediately in front of the paddle to measure the deep water wave conditions.

Preliminary work was done before the breakwater was built to synthesize, generate and sample the waves and determine the appropriate span settings (settings that control the maximum excursion of the wave paddle) for the wave paddle. All the tests in subsequent experiments were then carried out using the same waves and same span settings. Additionally, the wave records measured during tests with the breakwater in place were separated into

incident and reflected components. In most cases, excellent agreement was obtained between results of the reflection analysis and those measured with no structure in the flume. The bounded long wave component resulting from the occurrence of wave groups was removed from the analysis using a software filter.

All tests were conducted with irregular waves synthesized using the GEDAP procedure of the National Research Council of Canada Hydraulic Laboratory. Jonswap spectra were generated having periods of peak energy density, ranging from 1 second to 2 seconds and significant wave heights from 6 cm to 14 cm.

The notation of a design storm consisting of several segments of specific wave height-period combinations, which altogether simulate the growth and decay of waves during a hypothetical design storm was utilized in the tests. A total of four design storms were utilized in the three dimensional tests and are detailed in Tables 1 to 4.

Each segment of each storm was run for a time equivalent to 3000 waves attacking the structure. Profiles were measured before the test and after each segment of test. For certain tests, several intermediate profiles were measured after 500, 1000, 1500 and 2000 waves. To assess the long term reshaping process, some tests were carried out for a duration of 36000 waves with profiles measured every 3000 waves. These tests were used to assess the reshaping of breakwaters as a function of storm segment duration. The berm breakwater was considered to have failed when erosion of the berm progressed landward to the intersection of the horizontal berm with the upper 1:3 slope (see figure 3). A total of 12 series of tests were undertaken and are described in Table 5.

12	2-3D *GF=1.2	.45

#### Test Procedures

The following general procedures were followed during each test:

- (1) A test was not commenced until the water surface in the flume was completely calm.
- (2) Predetermined settings on the hydraulic wave generator were used for all wave conditions.
- (3) The same number of samples of water level variations were taken. Sampling would start on the passage of the third wave.
- (4) The locations of the water level transducers did not vary for test to test.
- (5) Observations were made regarding stone movement resulting from wave attack, both initially and after the breakwater profile reached near equilibrium.

- (6) The breakwater was not rebuilt following each segment of wave attack. Rebuilding of the entire breakwater was done following the completion of a test storm and carried out under water, to simulate, as close as possible, prototype construction conditions.
- (7) The water level transducers and profiler were calibrated every 3 days and were found to remain stable over the duration of the testing programme.

### Results

It was found that the largest portion of berm erosion occurred during the attack of the first few relatively big waves in the wave train. The zone in which movement of stones occurred was located at the seaward edge of the berm. The stones moved by rolling about the slope. On passing of the first few waves, there was little sign of motion of stones in the landward region of the berm; the principal mode of reshaping was by rounding-off of the exposed corner of the berm.

After approximately five to ten big waves, there was very little mass movement, and subsequently, stones moved individually rather than "en masse". With time, the initial berm receded and armour stones were individually removed by the wave forces and deposited at some other location on the slope. With each impinging wave breaking on the berm, stones were removed from the outer edge of the berm and carried by uprush and downrush moving to and fro on the profile formed as a result of erosion. A net migration of stones offshore was observed from the profiles measured followed each section of the design storm. The reshaping process was usually too slow to be noticeable to the human eye (apart from the initial "shakedown" of the mound).

Figure 4 gives an example of average berm erosion (measured from the seaward edge of the structure) as a function of significant wave height for a particular test. In general comparable recession rates were observed in each flume over the course of the design storm. The net recession in each flume at the end of the test is typically within a range of 5-10%. Considering that on average 450 to 500 mm of erosion is experienced and given that  $D_{50} = 14\text{mm}$ , then  $\pm$  one stone would give a resolution of approximately 6%. Thus the range of 5-10% indicates no significant difference in the performance of each section.

Table 1 Example Wave Climate 4

Segment	$H_s$ (m)	$T_p$ (s)	Duration (min)
1	.12	1.2	60
2	.14	1.4	70
3	.16	1.6	80
4	.18	1.8	90
5	.20	2.0	100
6	.18	1.8	90
7	.16	1.6	80
8	.14	1.4	70

Correct interpretation of the data can only be carried out by analysis those data in which the berm structure were stable (in this case, a stable structure was one in which berm erosion did not progress landward of the upper 1:3 slope). Figure 5 provides an illustration of the relationship between flume width and  $B/H_{peak}$ , where B is the starting berm width (equal to the total amount of recession) and  $H_{peak}$  is the significant wave height at the peak of the design storm. In general,  $B/H_{peak}$  increases with increasing flume width (thus indicating more reshaping for all wave climates).

Figure 6 shows the influence of groupiness factor on relative shaping ( $B/H_{peak}$ ). For low values of groupiness, no significant difference in reshaping exists (as a function of flume width). As the groupiness factor is increased then the flume width becomes more important. The most significant difference in reshaping between the 4 m and the 1.2 and 2.4 m flumes occurs at the highest value of groupiness. Values of  $B/H_{peak}$  for flume widths of 1.2 and 2.4 m are relatively constant whereas  $B/H_{peak}$  shows an increase with increasing groupiness for the 4 m flume results. These findings are in agreement with Hall et al (1989) and leave questions regarding the validity of two dimensional tests to evaluate the stability of berm or reshaping breakwaters.

### Conclusion

A series of tests was undertaken utilizing various width "flumes" containing identical breakwaters simultaneously subjected to identical wave conditions. It was found that the extent of reshaping increased with increasing flume width. This effect was more pronounced when subjecting the structure to wave trains having a high groupiness factor.

This trend sheds doubt with respect to the validity of undertaking narrow flume two-dimensional tests of berms or reshaping breakwaters. At present, until further research can be undertaken, it is recommended that only fully three dimensional tests be undertaken when designing berm breakwaters, (even when incident wave conditions are parallel to the breakwater crest).

## CHAPTER 92

### **Preliminary Analysis of the Stability of Rubblemound Breakwater Crown Walls**

by

David G. Hamilton<sup>1</sup> and Kevin R. Hall<sup>2</sup>

#### ABSTRACT

A series of two-dimensional hydraulic model tests was carried out to investigate the stability of rubblemound breakwater crown walls. The effect of seven design parameters on the minimum mass required for a crown wall to remain stable was studied: wave height, wave period, crown wall height, water level, front slope of the breakwater, position of the crown wall and length of stabilizing legs. Observations regarding the type of wave interaction, degree of overtopping, superstructure movement and overall hydraulic stability were studied. The coefficient of friction at the crown wall/breakwater interface was also measured. The crown wall superstructure was located on the crest of a conventional multi-layer breakwater and was subjected to both regular and irregular wave attack. Preliminary analysis of this data set is presented which shows trends established for each of the seven design parameters.

#### INTRODUCTION

Crown walls are designed, on a small scale, to provide pedestrian and vehicular access onto and along the crest of rubblemound breakwater structures. On a larger scale, crown walls support and protect pipelines and other services from the damaging forces of storm generated waves.

Crown walls are subjected to a complex set of forces including those resulting from direct wave impact and uplift pressure caused by the phreatic surface motion in the rubblemound. Since the physics of the hydrodynamic forces on crown walls is very complex, an accurate mathematical description of these forces, both spatially and temporally, along the front face and base of the crown wall is presently unattainable. Well designed hydraulic models are currently the only reliable design tool available, although these are subject to problems of scale effect due to the inability to obtain equality of Froude, Reynolds and Weber criteria. It is of paramount importance that the permeability of each layer is modelled correctly in order to minimize these scale effects.

In one of the most comprehensive investigations of crown walls, Jensen (1983 and 1984) examined the forces on these structures by measuring the pressure distribution along the front face and base of the superstructure. A dimensionless empirical relationship was derived in order to predict the maximum horizontal wave force on the front face of a crown wall. Jensen's equation was calibrated to fit the model data using three sets of dimensionless coefficients which were valid for three specific crown wall configurations.

Bradbury et al. (1988) extended Jensen's work by modelling structures with different armour unit configurations fronting crown walls. The maximum horizontal force on the front face of the crown wall was measured for each of the crown wall/crest armour geometries using a system of strain gauges mounted inside a force table. By using an armour coefficient for a single wave climate, the authors extended Jensen's equation to six different crown wall/crest armour configurations. However, the authors point out that each of the two armour unit coefficients are only valid for a single random wave condition. They state that further studies are required to verify these armour unit coefficients over a wider range of incident wave conditions.

Although other studies of crown walls have been conducted, these two investigations are the most comprehensive. However, the results obtained from both of these studies could not be extrapolated with confidence to the range of breakwater/crown wall configurations of interest in this study.

This present study was undertaken in a two-dimensional wave flume at the Coastal Engineering Research Laboratory at Queen's University. The tests were developed to determine what influence seven design parameters had on the minimum mass for which a given crown wall configuration would remain stable: wave height, wave period, crown wall height, water level, front slope of the breakwater, position of the crown wall and length of stabilizing legs. Observations regarding the type of wave interaction, superstructure movement and overall hydraulic stability of the crown wall/breakwater were also studied. Finally, the hydraulic performance of each crown wall configuration was evaluated and classified as either an overtopping or a non-overtopping structure for a given design wave climate.

The testing programme consisted of 49 tests covering the range of breakwater/crown wall configurations and water levels presented in Table 1.

## EXPERIMENTAL SETUP

All experiments were carried out in a 0.9-m wide wave flume with an overall length of 47 m and an overall depth of 1.8 m. Tests were conducted with three different still water levels; 0.800, 0.850 and 0.875 m above the flume bottom. Both regular and irregular wave attack was used. A minimum of twelve combinations of wave height and wave period were used for each crown wall/breakwater configuration, as shown in Table 2. For some tests, as many as eight wave heights (for each wave period) were tested in order to better define trends in the stability data.

C = Crown wall resting on Core layer.

01 = Test 1

The conventional multi-layer rubblemound breakwater consisted of a core layer (13-mm angular stone), a filter layer (40-mm angular stone) and an armour layer (two layers of 80-mm angular stone). Other characteristic properties are given in Table 3. All of the angular stone was assumed to have a specific gravity of 2.65.

Three types of crown walls were tested, as shown in Figure 1. Configuration 1 consisted of a vertical wall connected to a base plate. Crown wall heights of 40, 70 and 100 mm were tested. Configuration 2 was similar with the exception of an additional set of stabilizing legs penetrating the core layer. The objective of these legs was to increase the stability of the crown wall during wave attack. Three different pairs of stabilizing legs were constructed, with lengths of 10, 30 and 50 mm. Configuration 3 was used to simulate a walkway by removing the vertical crown wall and the stabilizing legs. Each structural member of the crown wall superstructure was fabricated using aluminum alloy having a specific gravity of 2.8.

The stability of the crown wall was tested in two positions. First, the crown wall was placed on top of the core at the breakwater crest, as shown in Figure 2a. It was assumed that for any future breakwater designs, the crown wall would be placed in this position. From a stability perspective, this was the ideal position since the crown wall is protected from direct wave impact forces during wave attack. As it was critical to isolate the horizontal resistance of the crown wall to frictional resistance, see Figure 2b, armour units were placed (seaward and landward of the structure) so that they added no additional stability to the crown wall.

In the second position, the crown wall was constructed on top of the armour layer along the breakwater crest (Figure 3). If crown walls could be designed to remain stable in this position, the armour units would not need to be removed to construct crown walls on existing breakwaters. However, installing the crown wall on top of the armour stone created two problems. First, it was difficult (if not impossible) to place the crown wall on top of the armour stones while maintaining the proper horizontal and vertical alignment along the breakwater crest. Secondly, the horizontal resistance created by friction between only a few armour stones and the base of the crown wall was considerably less than that found when the crown wall was constructed on the core of the breakwater. To resolve these two problems, a gravel bed was prepared along the crest of the breakwater by placing core material in the large voids between each armour stone. The crown wall was removed after completing each test and if any undermining or erosion had taken place, the gravel bed was reconstructed.

Preliminary studies were undertaken to determine the coefficient of friction at the breakwater/crown wall interface. A device was designed to enable the horizontal resistance of the crown wall to be measured over the range of crown wall mass which would be required during stability tests. Linear regression analysis resulted in a best fit line having a coefficient of friction,  $\mu = 0.51$ , as shown in Figure 4. This agrees with prototype estimates of  $\mu = 0.50$  to  $0.55$  (Jensen, 1984), and  $\mu = 0.60$  Goda (1985) between concrete superstructures and quarry stone.

The minimum wall and base thickness of prototype crown walls was assumed to be 0.20 m, as this thickness would provide adequate coverage for reinforcing steel within a crown wall. As this model was designed at a geometric scale of approximately 1:20, the minimum crown wall mass used throughout this study was approximately 6.5 kg, depending on the crown wall configuration.

DETERMINATION OF MINIMUM STABLE MASS

Minimum stable mass (MSM) was defined as the minimum mass for which a given crown wall/breakwater configuration would remain stable while being subjected to certain design wave conditions. The MSM of a crown wall represented the point of limiting equilibrium between stable and unstable conditions. At this minimum mass, the crown wall could withstand a variety of complex and interactive forces resulting from direct wave impact, uplift pressure resulting from phreatic surface motion in the breakwater and forces associated with overtopping.

Results obtained from tests using Type 1 and 3 crown walls (Figure 1a and c) were classified into one of three categories; stable, unstable and minor displacements. The failure mode for each of these tests was found to be a sliding failure. A test was categorized as stable if the crown wall remained stationary during exposure to wave attack. In some tests vibrations of the crown wall were observed, although any resultant displacement would exclude such a result from

this category. Minor displacement test results were defined as tests in which the crown wall was displaced less than 10 mm during wave attack. This category included instances in which the crown wall would undergo a parallel slide, or alternatively, displacements of only one end of the crown wall. Test results in which the crown wall was displaced more than 10 mm were defined as an unstable. This category included three types of displacements of the crown wall. The two most common types of failures were displacements of the crown wall parallel to its original position or displacements of only one end of the crown wall. In some instances a catastrophic failure occurred in which the crown wall was forced over the landward side of the breakwater.

Test results for the Type 2 crown wall (Figure 1b) were classified as either stable or unstable. The mode of failure in each of these tests was found to be a quasi-overturning failure. The minor displacement failure category was not used for Type 2 crown wall tests since any measurable overturning of the crown wall was considered to be a failure.

Figure 5 is an example of typical test results from one test in the data set. The curve shown in the figure passes through the data points representing the minimum stable mass of the crown wall at different wave heights. This curve represents a reasonably accurate relationship between the mass of a crown wall and the incident wave height at the point of limiting equilibrium between stable and unstable conditions.

Test results presented later in this paper are based on the minimum stable mass of the crown wall. This will allow comparisons between different test results to be readily made.

Figure 5 Variability of Crown Wall Stability

## PRELIMINARY RESULTS

### *Wave height*

The following trends between incident wave height and minimum stable mass (MSM) were observed during preliminary analysis of the data set. Figure 6 shows typical test results.

Each test commenced with small waves and gradually the incident wave height was increased. When relatively small waves attacked the structure, the wave runup and internal phreatic surface would continue to fluctuate although no forces would be applied to either the base or the front face of the crown wall. Under these conditions a unit increase in the incident wave height had no influence on the stability of the crown wall.

Once the incident wave height was large enough for the wave runup and internal phreatic surface to reach the base elevation of the crown wall, a linear relationship between MSM and wave height was found. This agrees with results published by Jensen (1983 and 1984) and Bradbury et al (1988). This linear relationship continued until the waves were large enough to induce a significant amount of greenwater overtopping. At this point, the rate of increase of the MSM continued to decrease and a horizontal asymptote was approached.

### *Height of crown wall*

Figure 7 shows an example of the minimum mass required to ensure stability of a crown wall for three different crown wall heights. All of the available data consistently demonstrated that the stability of a crown wall increased with decreasing crown wall height. Three other conclusions were also worth noting. First, when the wave height was only 0.10 m, all three crown walls were found to have the same minimum stable mass (MSM). This was expected because for wave heights less than 0.10 m, no water overtopped the lowest crown wall (0.04 m high). Secondly, results of tests having a crown wall height of 0.040 m showed that the MSM remained constant once the incident wave height exceeded approximately 0.20 m. As stated earlier, this threshold wave height was directly related to the initiation of green water overtopping. Thirdly, the threshold wave height was found to increase with increasing height of the crown wall. This was also expected; a larger wave height was required to overtop a higher crown wall.

Eight tests were conducted using the Type 3 crown wall. All results demonstrated that this structure was substantially more stable than Configuration 1 and 2, under the same conditions. During most tests this crown wall was stable at the minimum mass. However, when the crown wall was on the armour layer and was subjected to very large waves, the stability of the structure increased with increasing wave period, decreasing water level and decreasing front slope steepness.

### *Freeboard*

The stability of each breakwater/crown wall configuration was evaluated for three different values of freeboard; 25, 50 and 100 mm. Tests consistently showed that the stability of a crown wall increased as the water level decreased.

### *Wave period*

The influence of wave period on the stability of a crown wall was tested for wave periods of 1.25, 1.75 and 2.25s. In general, the stability of a crown wall increased with decreasing wave period.

### *Breakwater front slope*

The front slope of the breakwater was also found to influence the stability of a crown wall. Two front slopes were tested,  $\text{Cot}\theta = 1.5$  and  $3.0$ , as these are the two extreme slopes usually found on prototype breakwaters. The data showed that, in general, the stability of a crown wall increased as the steepness of the front slope decreased.

### *Position of crown wall*

The influence of crown wall position was evaluated by conducting one set of tests with the crown wall resting on the core at the breakwater crest and another set with the crown wall resting on the armour layer. Figure 8 shows typical results from both sets of tests. The data demonstrated that for all wave conditions and breakwater/crown wall configurations, a crown wall was substantially more stable when resting on the core at the breakwater crest. These results seem reasonable when the following points are considered. First, when the crown wall rests on the core, the armour stones fronting the crown wall dissipate a significant amount of wave energy. Secondly, the armour units fronting the crown wall protect the superstructure from direct wave impact when the crown wall is resting on the core of the breakwater. Thirdly, the maximum elevation of the phreatic surface is lower when the crown wall is positioned on the core as compared with tests conducted with the crown wall on the armour layer, due to the difference in permeability of the two layers.

### *Stabilizing legs*

The influence of stabilizing legs on the stability of a crown wall is illustrated in Figure 9. Incorporating stabilizing legs into the design of a crown wall significantly increased the overall stability of the superstructure. However, the 30 and 50 mm stabilizing legs were no more effective at increasing the stability of a crown wall than 10 mm legs.

Figure 7 Influence of Crown Wall Height

Figure 9 Influence of Stabilizing Legs

Figure 6 Influence of Incident Wave Height

Figure 8 Influence of Crown Wall Position

Test results indicate that the use of stabilizing legs transformed what would otherwise be a purely sliding failure into a quasi-overturning failure. This change in failure mode occurred since less force was required to drag the seaward leg of the crown wall out of the core material (quasi-overturning failure) compared to the force required to cause a purely sliding failure.

## IRREGULAR WAVE TESTS

All of the results discussed above were obtained using regular sinusoidal waves. Five of these regular wave tests were repeated using irregular wave trains (see Table 1) to determine how the stability results of each set of tests could be correlated. A JONSWAP wave spectrum was synthesized using the National Research Council of Canada GEDAP laboratory control package.

Irregular wave test results were plotted as a function of regular wave test results, presented in Figure 10. Each data point indicates the irregular and regular wave height at which a specific crown wall configuration became unstable; the minimum stable mass. Assuming a irregular wave Rayleigh distribution, the irregular wave height,  $H_i$ , was defined using the equation,  $H_i = k\sigma$ . It was determined that  $H_i = 5.1\sigma$  gave the best correlation between the two sets of data. This represents the average wave height of the highest 10% of the waves,  $H_{10}$ , in the irregular wave train. Therefore, tests undertaken using irregular waves reproduced the same results as regular wave tests if  $H_{10}$  of the irregular wave train was equal to the wave height of the regular wave train.

(Irregular wave train defined by  $H_i = 5.1\sigma$ )

## CONCLUSIONS

Tests were conducted to evaluate the influence of seven design parameters on the hydraulic stability of crown walls. By determining the mass of each crown wall configuration at the point of limiting equilibrium between stable and unstable conditions (minimum stable mass), the following general trends have been established.

(1) During exposure to moderate wave climates, the magnitude of the wave forces on each crown wall configuration were found to be proportional to wave height. However, once the waves were large enough to induce greenwater overtopping, the wave induced forces approached a maximum. The data set showed that for each breakwater/crown wall configuration an upper limit exists, independent of wave climate, at which the destabilizing wave forces remain constant.

(2) The stability of each breakwater/crown wall configuration was found to increase with decreasing crown wall height, decreasing water level, decreasing wave period and decreasing front slope steepness.

(3) The forces exerted on a crown wall resting on the core of a breakwater were substantially less than those tests conducted with the crown wall resting on the armour layer. This demonstrated that the armour units fronting a crown wall dissipated a significant amount of wave energy and protected the superstructure from direct wave impact. It also demonstrated that decreasing the permeability of the material below the crown wall (core vs. armour material) significantly decreased the maximum elevation of the internal phreatic surface, and thereby reduced the uplift pressures.

(4) Stabilizing legs substantially increased the stability of each crown wall configuration. Short legs were found to be equally as effective as longer stabilizing legs.

(5) The coefficient of friction below the model crown wall was found to be similar to prototype estimates of the friction coefficient between a reinforced concrete superstructure and quarry stone.

(6) Irregular wave tests, simulating a JONSWAP spectrum, reproduced the same crown wall stability as regular wave tests, if  $H_{T0}$  of the irregular wave train was equal to the wave height of the regular wave train.

## ACKNOWLEDGEMENTS

The authors would like to express their appreciation to Public Works Canada, Marine H.Q. and Small Craft Harbours, Department of Fisheries and Oceans, Canada for providing financial support for this study.

## CHAPTER 93

### NEW STABILITY FORMULA FOR DOLOSSE

<sup>1</sup>A H HOLTZHAUSEN and <sup>2</sup>J A ZWAMBORN

#### ABSTRACT

This paper describes the derivation of a stability formula for dolosse based on the physical model test results of Scholtz et. al. (1982) and Holtzhausen et. al. (1990). The derivation of the formula is based on dimensional analysis and subsequent curve fitting with a non-linear multi-variate regression model. The statistical treatment of the data made it also possible to estimate the confidence intervals.

Variables included in the formula are wave height, wave period, percentage displacement, dolos waist-to-height ratio, and armour unit density. Since not enough data were available to describe the effect of armour slope, only data for a slope of 1:1.5 were used. The test conditions and thus the derived formula represents deep water wave attack, that is, without a specific foreshore slope.

#### INTRODUCTION

A large number of model test results from tests carried out in South Africa over more than 10 years were used as a basis for the development of a new stability formula for dolosse. Since the tests included regular and irregular wave tests and were all done in the same test facility under identical conditions, their results provide an excellent basis for such a formula and also for the establishment of the variability in the stability which must be expected. Standard statistical analysis techniques were employed to achieve these results.

Although the new formula provides a useful tool for the initial design of dolos armouring, particularly for sensitivity and risk analyses, it must only be used for cases which are representative of the actual test conditions and which fall within the range of the variables used in the tests, that is , for deep water conditions, a 1:1,5 armour slope, dolos waist ratios between 0.33 and 0.40 and dolos unit densities from 1.8 to 3.0. Furthermore, the formula does not take into account

the structural strength of individual units and it will therefore be representative of prototype conditions only for relatively small percentages damage.

## DESCRIPTION OF TEST PROCEDURES

### Model layout and Dolos Characteristics

The tests were done in the 127 m long (effective length), 3 m wide and 1,1 m deep wind-wave flume in Stellenbosch. The flume was divided into three 0,75 m wide test channels leaving two narrow dummy channels on either side. Identical breakwater test sections (except for the test dolosse) were constructed in each of the 0,75 m wide channels. The waves approached the dolos slope on a horizontal bottom with a depth of 0,8 m (Figure 1).

Figure 1. Section of model slope and model dolosse

The test areas were  $750 \times 750 \text{ mm}^2$  and the dolosse were placed in six 125 mm (about 2 h, where h is 'dolos height') wide bands of different colours, with three above and three below still-water level, that is, 208 mm below to 208 mm above the water level (about  $1,5 H_d$ , where  $H_d$  is the 'design wave height') (Zwamborn, 1980). A 'mean' packing density of  $\phi_{n=2} = 1.00$  was used. The underlayer consisted of 16,5 g selected stone and was 43 mm thick. The breakwater core was built of loose bricks covered with an approximately 200 mm thick layer of 1 to 5 g gravel (Holtzhausen et. al., 1990).

### Wave Generation and Measurement

Regular waves with a period of 1.75 s were used in the tests done to investigate the effect on stability of unit density (Scholtz et. al. 1982). The effect

of waist-to-height ratio ( $w_r$ ) and wave period were investigated with irregular waves generated by Seasim wavemakers (Holtzhausen et. al. 1990). These wavemakers are equipped with a wave absorption control unit making it possible to absorb reflections from the breakwater structure. Only results obtained with a Jonswap spectrum were used for fitting the stability formula.

Waves were measured by means of twin-wire resistance type probes. For the irregular wave tests three probes were positioned in each of the three channels at distances 5,55, 5,80 and 6,20 m from the model slope. These three sets of three probes were each used to separate the incident and reflected spectra. A three-point method using a least squares technique for decomposing the measured spectra from three known probe positions developed by Mansard and Funke (1980) was used.

The wave data calculated from the recordings made during the actual tests at the three probes in each channel (9 probes altogether) were used to calculate the mean incident wave height for each test.

### **Test procedures**

A test series consisted of 60 minutes of wave action (24 'bursts' of 2.5 minutes in the regular wave tests to avoid re-reflection, Scholtz et. al., 1983) for each wave height starting from the smallest wave height and increasing the wave height in steps of about 20 mm until failure occurred or until the biggest wave was reached (normally about 5 to 8 steps). Depending on the wave period, between 1800 and 2900 waves attacked the dolosse during each wave step.

The return period (55 to 80 minutes) of the input wave sequence used for the irregular waves was mostly longer than the actual test period used (60 minutes), with the result that the wave conditions mostly varied right through a test. All the repeat tests were started at the same position in the wave sequence, therefore the same section of the wave sequence was used for the different tests.

Dolosse of different densities or different waist-to-height ratios were tested side by side in the flume. To eliminate the effect of small differences in wave conditions in the three channels, the positions of the test dolosse were alternated in the three channels.

## **MODEL TEST RESULTS**

### **Available Test Data**

Results from the following tests were used in fitting the stability equation:

Regular waves,  $T=1.75$  s,  $w_r=0.33$ :

Density, $\rho_s$ (g/cm <sup>3</sup> )	Mass, W (g)	$D_n = (W/\rho_s)^{1/3}$ (mm)	Number of repeat tests
1.810	62	32.5	6
2.390	83	32.6	6
3.020	106	32.7	6

Irregular Waves with Jonswap spectrum:

Waist ratio $w_r$	Number of repeat tests for peak wave periods $T_p$			
	$T_p=1.25$ s	$T_p=1.50$ s	$T_p=1.75$ s	$T_p=2.00$ s
0.33	3	3	8	3
0.36	3	3	8	3
0.38	3	3	3	
0.40	3	3	7	3

Each test consisted of approximately 6 different wave heights which means that these data represent approximately 500 data points of damage versus wave height. Although tests were also carried out for  $w_r=0.43$  it was decided to leave out these results since this waist-to-height ratio becomes rather impractical (very low stability).

### Effect of Unit Density on Dolos Stability

Scholtz et. al. (1982) interpreted their results in terms of the Hudson formula which is given by:

$$W = \frac{\rho_s H^3}{K_d \Delta^3 \cot \alpha}$$

where, H is the wave height,  $K_d$  the stability number,  $\Delta$  the relative dolos density and  $\alpha$  the breakwater slope.

The effect of unit density on stability in this equation is given by  $W/\rho_s \propto 1/\Delta^3$  or  $V \propto 1/\Delta^3$  where V is the volume of a dolos. Scholtz et. al. found that this relationship did not apply to dolosse and modified it to:  $V \propto 1/\Delta^x$ . The following table from Scholtz et. al. (1982) shows the values found for the coefficient "x" at various levels of displacement:

Dolos displacements (%)	1	2	5	10
"x"	2.21	2.22	2.28	2.49
95 percent confidence limits	1.18 to 3.24	1.78 to 2.66	1.92 to 2.64	1.87 to 3.11

These results clearly show that "x" for dolosse is less than the value of 3 as suggested by the Hudson formula. The value of "x" for the stability formula was selected as 2.22 since this corresponds to a reasonable displacement level (approximately 1 to 5 percent) for design purposes. The effect of density on stability of dolosse for the formula presently being developed was therefore taken as:  $V \propto 1/\Delta^{2.22}$ . This reduced effect of density on dolos stability can be explained by the fact that interlocking contributes significantly to dolos stability.

It was decided to describe the size of an armour unit in terms of  $D_n$  (similar to Van der Meer, 1988) where  $D_n = V^{1/3}$ , since this simplifies the final equation. In terms of  $D_n$  the effect of unit density is therefore:  $D_n \propto 1/\Delta^{0.74}$ , compared to the Hudson formula which suggests an effect of unit density on armour size as  $D_n \propto 1/\Delta$ , representing no interlocking or friction between armour units.

### Effect of Unit Density on Rock Stability

Although rock stability does not affect the derivation of a stability formula for dolosse directly, comparisons with results obtained for rock can be useful. Brantzaeg (1966) reports on extensive tests (using regular waves) done by Kydland and Sodefjed to establish the effect of unit density on rock stability. The tests were done on slopes of 1:1.25, 1:1.5 and 1:2 for densities ranging from 1830 kg/m<sup>3</sup> to 4520 kg/m<sup>3</sup> and with a very narrow grading. It is stated specifically that any consistent differences in shape between different groups of rocks were avoided. Van der Meer (1988) also tested with different densities but concluded that no clear trends could be found in his results, essentially due to differences in the shape of rocks with different densities.

Sodefjed's results for "y" in the formula  $D_n \propto 1/\Delta^y$  are given in the following table:

cot $\alpha$	Value of y	
	1 % damage	10 % damage
1.25	0.71	0.73
1.50	0.70	0.71
2.00	0.91	0.96

This table shows that the effect of density was much the same on the 1:1.25 and 1:1.5 slopes while stability on the 1:2 slope was definitely more dependent on armour unit density. This is again due to the interlocking effect, also described by Price (1979). As the slope is made flatter, the interlocking between adjacent units decreases so that stability is more dependent on weight only.

According to Hudson's formula the value of "y" should be 1 if stability is only dependent on weight. The results of Sodefjed seem to indicate that for slopes of 1:2 (and most likely also for flatter slopes) the effect of density is correctly described in the Hudson formula (and therefore also the Van der Meer formula) for rocks. However, for steeper slopes the effect of density on stability is less and closely resembles that found for dolosse on a slope of 1:1.5. It can be expected that the effect of density on stability of dolosse will also be a function of the slope angle, although somewhat less than for rock due to the dolos interlocking shape.

## DERIVATION OF DOLOS STABILITY FORMULA

### Basic Assumptions

The result obtained by Scholtz et. al. (1982) on the effect of unit density on stability was assumed to apply also to irregular waves, different wave periods and different waist-to-height ratios. Although this assumption is not necessarily accurate for the full test range on which the final formula will be based, it was extensively tested (confirmed) whereas Hudson and Van der Meer based their estimate of the effect of unit density on theoretical considerations only.

### Selection of Dimensionless Variables

The variables considered in the present study are wave height,  $H_s$ , wave period,  $T_p$ , dolos size,  $D_n$ , dolos waist-to-height ratio,  $w_r$ , unit density,  $\rho_s$ , and dolos percentage displacement,  $N_{\%d}$  (displacements larger than dolos height,  $h$ ). Of these six variables both  $w_r$  and  $N_{\%d}$  are already dimensionless so that only the remaining four variables have to be grouped into dimensionless parameters. The relation between the damage number,  $N_o$  (Van der Meer, 1988), and  $N_{\%d}$  is given by:  $N_{\%d} = 4.32 N_o$ , based on the number of dolosse used in the CSIR tests. To enable the description of zero damage values with a power formula damage was defined as:  $N_{0.1} = N_{\%d} + 0.1$ .

Dolos unit density is expressed non-dimensionally with  $\Delta$ . As mentioned

before, Scholtz et. al. determined the effect of  $\Delta$  on  $D_n$  as:  $D_n \propto \Delta^{-0.74}$ . The effects of unit density, wave height and dolos size (for a slope of 1:1.5) can now be grouped into one parameter called the modified stability number,  $N_{sm} = H_s / (\Delta^{0.74} D_n)$ .

The wave period is normally expressed non-dimensionally as the wave steepness  $s_{op} = H_s / L_{op}$ , where  $H_s$  is the significant wave height at the toe of the structure and  $L_{op}$  is the deepsea wave length based on the peak wave period:  $L_{op} = T_p^2 g / (2\pi)$ , where  $g$  is gravitational acceleration. The wave period was also expressed as:  $T_{np} = (L_{op} / D_n)^{1/2}$ , where  $T_{np}$  is called the peak wave period number.  $T_{np} = T_p$  when  $D_n = g / (2\pi)$  i.e. the armour mass is approximately 9 000 kg (density of 2400 kg/m<sup>3</sup>).

The advantage of expressing  $T_p$  by  $T_{np}$  is that  $T_{np}$  changes only with  $T_p$  (for a specific dolos size) whereas  $s_{op}$  changes with both  $H_s$  and  $T_p$ .

**Basic Form of Equation**

The parameters with which to correlate the test data are thus the modified stability number,  $N_{sm}$ , either the wave steepness,  $s_{op}$  or the peak wave period number,  $T_{np}$ , the waist-to-height ratio,  $w_r$  and the adjusted percentage displacement,  $N_{0.1}$ . In terms of these parameters (using  $s_{op}$  to describe wave period) stability can be expressed as:

$$N_{sm} = f(N_{0.1}, s_{op}, w_r) \tag{1}$$

To comply with standard regression procedures  $N_{0.1}$  (the dependent variable) was made the subject of the formula and it was assumed that Equation 2 would adequately describe the trends found by Holtzhausen et. al. (1990):

$$N_{0.1} = A_1 N_{sm}^{B_1} s_{op}^{C_1} N_{sm}^{D_1} w_r^{E_1} s_{op}^{F_1} N_{sm}^{G_1} \tag{2}$$

where  $A_1$  to  $G_1$  are constants to be determined through regression. A non-linear regression (Statgraphics 1990) gave a regression coefficient of 0.86 (86 percent of variation in the data is described by the formula) and showed that the values of  $D_1$  and  $G_1$  were very close to zero. By setting these constants equal to zero, Equation 3 is obtained:

$$N_{0.1} = A_2 N_{sm}^{B_2} s_{op}^{C_2} w_r^{D_2} s_{op}^{E_2} \tag{3}$$

**Regression with respect to  $s_{op}$**

A regression of Equation 3 once again gave a regression coefficient of 0.86 suggesting that this equation is just as good as Equation 2. After rounding off some constants and doing another regression (which also gave an R-squared

value of 0.86), Equation 4 was obtained:

$$N_{0.1} = 26700 N_{sm}^{5.26} s_{op}^3 w_r^{20} s_{op}^{0.45} \dots(4)$$

The observed versus predicted values (316 data points) of this regression is shown in Figure 2.

Figure 2. Predicted versus observed dolos stability

It is important to note that the effect of storm duration could not be addressed due to the test procedure that was followed. To apply the results to a specific design problem the equivalent prototype storm history can be obtained by scaling up the following values: dolos weight = 80 g, duration of each wave step = 1 hour, wave height increase for each step = 20 mm.

**Regression with respect to  $T_{np}$**

A similar regression to that done with Equation 4 was also carried out using  $T_{np}$  instead of  $s_{op}$  and the following result was obtained:

$$N_{0.1} = 0.109 N_{sm}^{6.57} T_{np}^{0.33} w_r^{1.20} T_{np}^{0.55} \dots(5)$$

As anticipated the R-squared value of Equation 5 was also 0.86 and the plot of observed versus predicted values was very similar to that obtained with Equation 4 (Figure 2).

If damage is calculated with Equation 5 a design condition is evaluated in which the wave period remains constant while the wave height is increased (in steps of 20 mm for 80 g units, each step lasting 1 hour).

**RELIABILITY OF EQUATIONS**

**Comparison of equations**

Figure 3 shows the effect of waist ratio on the adjusted percentage displacement,  $N_{0.1}$  over the range of wave period numbers used in the present tests for  $N_{sm}=2.75$ . Figure 4 shows the effect of  $N_{sm}$  on  $N_{0.1}$  over the same range of wave periods for  $w_r = 0,33$ . These figures show a good agreement in damage between Equations 4 and 5. Over all the data points used in fitting the equations, the average difference in  $N_{0.1}$  was less than 0.05 per data point. As stated before, the regression coefficients of these two equations were virtually identical (0.86) and therefore both equations can be applied with the same degree of confidence.

Figure 3. Comparison of the two equations for  $N_{sm} = 2,75$

Figure 4. Comparison of the two equations for  $w_r = 0,33$

**Variation in Predicted Values**

Based on the test data, plots were made of the residuals, E, of the damage,  $N_{0.1}$ , (difference between observed and predicted values) of Equation 4 versus  $N_{sm}$ ,  $S_{op}$ , and  $w_r$ . It appeared that E was independant of all variables except the modified stability number,  $N_{sm}$ . The residuals were therefore divided into groups representing different values of  $N_{sm}$  and the mean and standard deviation of each group was determined. As expected the means were all very close to zero. The standard deviation of E versus  $N_{sm}$  is shown in Figure 5. A power fit to this data gave the following equation:

$$\sigma_E = 0.051 N_{sm}^{3.32} \quad \dots(6)$$

where  $\sigma_E$  is the standard deviation of the residuals.

Figure 5. Standard deviation of damage ( $\sigma_E$ ) versus stability ( $N_{sm}$ )

The result obtained by analyzing the residuals of Equation 5 in the same way is also shown in Figure 5, from which it is obvious that the residuals of Equations 4 and 5 are virtually identical and that Equation 6 also applies to the variability of Equation 5. The reason that there is a big increases in  $\sigma_E$  as  $N_{sm}$  increase is due to the sharp increase in  $N_{0.1}$  with  $N_{sm}$  (see also Figure 7).

To obtain confidence intervals for Equations 4 and 5, the random variate E with zero mean and standard deviation  $\sigma_E$  as given by Equation 6, should be added to the right hand side of these equations. The best assumption on the type of distribution of E is that it is normally distributed. It should be remembered that this variation applies to a section of the breakwater of  $23D_n$  (width of test section) and assuming independence between different sections, the standard deviation of E over a width of "n" times  $23D_n$  could be decreased by  $\sigma_E/\sqrt{n}$  (equation for the standard deviation of the average of "n" identical independant normal variates).

Figure 6. Comparison individual test variations with Equation 6

The variate E takes account of the natural variability of dolos stability (due to random packing) and of the errors due to possible imperfections in the stability Equation 5. To obtain an idea of the "natural variability", eight repeat tests done with a peak wave period of 1.75 s ( $T_{np} = 12$ ) and dolosse with waist ratios of 0.33, 0.36 and 0.40 were analyzed. The results of  $\sigma_E$  versus  $N_{sm}$  for each test, shown in Figure 6 together with a plot of Equation 6, show that the variability found for the full data set (Equation 6) is close to that found for individual tests. Figure 7 shows a plot of  $N_{0.1}$  versus  $N_{sm}$  (together with 90 percent confidence intervals) of tests done with  $w_r = 0.33$  and  $T_{np} = 12$ . The dotted lines represent a simple power fit of  $N_{0.1}$  versus  $N_{sm}$  as determined for the specific test condition while the solid lines are from Equation 5, by adding E from Equation 6. These Figures 6 and 7 show that the confidence limits based on Equations 4 to 6 compare well with those determined on the basis of one specific test condition.

Figure 7. Comparison of confidence bands individual repeat tests versus stability equations

### Implication for Future Model Tests

If it is assumed that the standard deviation found in the present tests can also be expected in general for other similar tests, it is possible to estimate the required number of tests to ensure that the right conclusion is drawn from a limited number of physical model tests. If two armouring options ( $X_1$  and  $X_2$ ) are to be compared at an  $N_{sm}$  value of, say, 2.9, the required difference,  $\delta$ , in damage,  $N_{0.1}$ , to ensure that the most stable option is correctly identified is shown in the following table as a function of the number of repeat tests (each test representing a  $23D_n$  wide test section). In this table the probability of obtaining an incorrect results, that is, a more stable result from the option that has the lowest average stability, is set equal to 10 percent.

Number of repeat tests	$\delta$ difference in $N_{0.1}$	Typical values of $N_{0.1}$ for $X_1$ and $X_2$	
		$X_1$	$X_2$
1	3.07	2	5.1
2	2.18	2	4.2
3	1.78	2	3.8
4	1.54	2	3.5
5	1.38	2	3.4

$$* T_{no} \approx 12, w_r = 0.33$$

This shows that a difference,  $\delta$ , in mean damage of about 3 percent is needed if only one test is done but with four repeat tests this difference reduces to 1.5 percent. This table illustrates clearly why it is important to do repeat tests.

### Aspects related to Prototype Dolos behaviour

The real question in prototype is not only how many dolosse will be displaced, but rather what the real damage will be (displacements plus breakages). In previous studies (Holtzhausen et. al. 1990) it was reported that the number of dolosse rocking for more than one third of the time was approximately equal to the number of dolosse that had been displaced over a distance exceeding their own height,  $h$  (this was independant of the level of displacement). This suggests that, for the breakwater trunk, the percentage displacement is a good indication of the movement on the slope. Therefore, with further research it would most likely be possible to predict the number of broken dolosse based on the percentage displacement. Prototype tests done on dolos breakages (Zwamborn et. al., 1989) together with observations of damage on existing structures, confirm that total damage can be approximated as twice the number of displaced dolosse for dolosse weighing less than 25 t. However, the structural performance of slender type concrete armour units still require much research to reliably predict

armour breakages.

The range of Reynolds numbers ( $Re = D_n(gH_s)^{1/2}/\nu$ , where  $\nu$  = kinematic fluid viscosity) for the tests, the results of which were used to fit the stability equations, was from  $1,8 \cdot 10^4$  to  $4,4 \cdot 10^4$ . It is therefore possible that Reynolds scale effects influenced tests results, implying that the results could be slightly conservative.

**SUMMARY**

A large number of dolos test results have been summarised into two stability equations, giving the option to express wave period in terms of deepsea wave steepness,  $s_{op}$  (changes with wave height and wave period), or in terms of the peak wave period number  $T_{np}$  (changes only with wave period for constant  $D_n$ ):

$$N_{0.1} = 26700 N_{sm}^{5.26} s_{op}^3 w_r^{20} s_{op}^{0.45} + E$$

$$N_{0.1} = 0.109 N_{sm}^{6.57} T_{np}^{0.33} w_r^{1.20} T_{np}^{0.55} + E$$

where:  $N_{sm} = \frac{H_s}{\Delta^{0.74} D_n}$

- $s_{op} = H_s/L_{op}$
- $T_{np} = (L_{op}/D_n)^{1/2}$
- $L_{op} = T_p^2 g/(2\pi)$
- $T_p =$  peak wave period
- $w_r =$  dolos waist to height ratio
- $E =$  error term used to describe the random nature of dolos slope stability

The error term is assumed to be normally distributed with a mean of zero and a standard deviation of:

$$\sigma_E = 0.051 N_{sm}^{3.32}$$

The range of conditions covered by these equations is:

Parameter	Minimum	Maximum
$w_r$	0.33	0.40
$T_{np}$	8.6	14.0
$N_{sm}$	0.7	4.5
$N_{0.1}$	0.1	30.0
Reynolds no.	$1.85 \cdot 10^4$	$4.35 \cdot 10^4$

The range of wave steepnesses can be evaluated using  $T_{np}$ . Wave heights were increased in steps of approximately 0.6 times  $D_n$ , each wave height lasting 1 hour (model dolos mass = 80 g) and damage was cumulative. The wave period was kept constant as the wave height was increased. The water depth at the toe of the breakwater was 25 times  $D_n$ .

These above equations should only be applied to situations falling within this range of test conditions.

## CHAPTER 94

### Effect on Wind Speed to Wave Run-up

Jea-Tzyy Juang <sup>1</sup>

#### Abstract

In theoretical study, when the maximum run-up on sea wall was happened, the shape of the run-up wedge is assumed to be a parabola with its vertex at the bottom of the first wave trough. The another assumptions are the conservation of mass and momentum. In model test, four kinds of dyke slope (1:0.5, 1:1, 1:2, 1:3) were choiced and the tests of the wind speed from 0 to 16 m/s accompany with a range of wave steepness were completed. The experimental data shows that the general form of the equations to developed was correct. Comparison of the theoretical estimations and the experimental data are coincident very well. Besides, the relation coefficient between the exponential value  $n$  of the parabolic runup shape with the surf parameter ( $\xi$ ) was ranged in 0.19 to 0.65 in different kinds of dyke slope have been found also. At last, in general speaking, in spite of the strength of the wind speed, the relative run-up becomes the biggest when the dyke slope was 1:2.

#### Introduction

In case to determined the height of the sea wall, the height of the wave run-up is one of the most important factor. Parameters which will effect the run-up height

-----  
<sup>1</sup> Deputy Director, Institute of Harbour and Marine Technology,  
83, Lin-Hai Rd., Wu-Chi, Taichung Hsien, Taiwan 43501,  
Rep. of China.

was included not only the wave steepness, the relative depth before the toe of the coastal structure, but also the bottom slope. However, one of the most important parameter which always been neglected is the onshore strong wind speed. During the typhoon season, the seawall was attacked not only by the big waves which was propagate from the deep sea but also by the onshore strong wind speed which always induced a big increasing of wave run-up and produced an enormous amount of wave overtopping. Therefore, the study of the correlation between the onshore wind speed to the wave runup was need to understand.

Analytical Consideration

Based on the results of the dimensional analysis by Tsuchiya (1978), the correlation between the influence factors of wave run-up to the height of the relative run-up can be summarized as follows:

$$\frac{R}{H} = f_1\left(\frac{H}{L}, \tan \theta, \frac{h}{H}, \frac{d}{H}, \frac{\sqrt{K}}{H}\right) \dots\dots\dots(1)$$

- where H: Incident wave height
- L: Incident wave length
- θ : Angle of the slopping dyke to the bed
- h: Water depth before the toe of the slopping dyke
- d: Roughness on the surface of the slopping dyke
- K: Rate of percolation

Therefore, in case of the constant water depth, the smoothed slope dyke surface and the unpercolated dyke conditions, the above formula can be simplified as

$$\frac{R}{H} = f_2\left(\frac{H}{L}, \tan \theta\right) \dots\dots\dots(2)$$

When a wave run-up on a breakwater and at its maximum condition, the flow velocities are essentially zero and all the energy of this run-up water is in the form of potential energy. By knowing the shape and position of this hypothetical runup wedge, this potential energy can be calculated. Cross and Sollitt (1972) proposed that the shape of the runup wedge is assumed to be a parabola with its vertex at the bottom of the first wave trough as shown in Fig.1.

Fig.1 The shape of the runup wedge

The corresponding equation is

$$Y = M X^n - A \dots\dots\dots(3)$$

in which Y is the water surface elevation above the still water level; X is the distance from the trough shoreward; A is the amplitude at the trough and M, n are the shape parameter.

It follows directly that the potential energy of the run-up wedge at maximum runup is simply as

$$\begin{aligned}
 PE &= \rho g \left\{ \int_{x_1}^{x_2} \frac{Y^2}{2} dx - \frac{R^3}{6 \alpha} \right\} \\
 &= \frac{1}{2} \rho g \left\{ \int_{x_1}^{x_2} (M \cdot X^n - A)^2 dx - \frac{R^3}{3 \alpha} \right\} \\
 &= \frac{1}{2} \rho g \left\{ \frac{M^2}{2n+1} (X_2^{2n+1} - X_1^{2n+1}) - \frac{2 \cdot MA}{n+1} (X_2^{n+1} - X_1^{n+1}) \right. \\
 &\quad \left. + A^2 (X_2 - X_1) - \frac{R^3}{3 \alpha} \right\} \dots\dots\dots(4)
 \end{aligned}$$

Two boundary condition can be obtained when the parabola run-up curve run across to the sea water level at point X<sub>1</sub> and the maximum run-up R at X<sub>2</sub>. Therefore, from Eq.3 we know that:

$$R = M(X_2)^n - A \implies X_2 = \left(\frac{R+A}{M}\right)^{1/n}$$

$$0 = M \cdot X_1^n - A \implies X_1 = \left(\frac{A}{M}\right)^{1/n}$$

Substitute the above two boundary condition into Eq. 4, the potential energy of the wave run-up can be converted as

$$\begin{aligned} PE = & \frac{1}{2} \rho g \left\{ \frac{M^2}{2n+1} \left[ \left(\frac{R+A}{M}\right)^{(2n+1)/n} - \left(\frac{A}{M}\right)^{(2n+1)/n} \right] \right. \\ & - \frac{2MA}{n+1} \left[ \left(\frac{R+A}{M}\right)^{(n+1)/n} - \left(\frac{A}{M}\right)^{(n+1)/n} \right] \\ & \left. + A^2 \left[ \left(\frac{R+A}{M}\right)^{1/n} - \left(\frac{A}{M}\right)^{1/n} \right] - \frac{R^3}{3\alpha} \right\} \dots\dots\dots(5) \end{aligned}$$

As the water wave propagate across a fluid, it can transfer the energy flux. Based on the small amplitude wave theory, the average energy flux in unit width and over a wave period can be obtained as

$$TE = \frac{1}{8} \rho g H^2 \cdot L \cdot \left\{ \frac{1}{2} \left[ 1 + \frac{2kh}{\sinh(2kh)} \right] \right\} \dots\dots\dots(6)$$

By way of the assumption that the energy contained in the run-up wedge is evaluated from the net energy flux into a control volume which enclosing the runup wedge and the partial standing wave system, the related equation between the incident wave and the relative runup height can be expressed as

$$\begin{aligned} & \frac{M^2}{2n+1} \left[ \left(\frac{R+A}{M}\right)^{(2n+1)/n} - \left(\frac{A}{M}\right)^{(2n+1)/n} \right] - \frac{2MA}{n+1} \left[ \left(\frac{R+A}{M}\right)^{(n+1)/n} \right. \\ & \left. - \left(\frac{A}{M}\right)^{(n+1)/n} \right] + A^2 \left[ \left(\frac{R+A}{M}\right)^{1/n} - \left(\frac{A}{M}\right)^{1/n} \right] - \frac{R^3}{3\alpha} \\ & = C_e \cdot \frac{L}{4} H^2 \left\{ \frac{1}{2} \left[ 1 + \frac{2kh}{\sinh(2kh)} \right] \right\} \dots\dots\dots(7) \end{aligned}$$

where  $C_e$  indicate the coefficient of energy loss by the influence of surface and bottom frictions during the process of the wave run-up.

In accordance with the above mentioned equations, if the value of  $M$ ,  $n$  and  $C_e$  can be identified from surf parameter then by trial and error method, the height of the wave run-up can be computed.

On the heels of the effect on wind speed to wave run-up. The first thing must to determined was the additional wave which was induced by the strong wind that was blowing from the seaside to the shoreline during the typhoon season. Falvey (1974) using the momentum balance method over a control volume which includes the boundary layer of the air and the statistical relationship for the significant wave height. He suggested a correlated equation between the significant wave height, the wind speed and the fetch length as follows:

$$H_{1/3} = (3.1 \times 10^{-7} \cdot U_{10}^2 + 1.6 \times 10^{-3} \cdot U_{10}) \cdot \left( \frac{F}{g} \right)^{1/2} \dots\dots(8)$$

in which  $U_{10}$  is the onshore wind speed at the height of 10 meters from the still water level and  $F$  is the fetch.

If  $F$  is measured in kilometers,  $U_{10}$  in meters per second,  $H_{1/3}$  in meters and with  $g=981 \text{ cm/s}^2$ , the above equation becomes

$$H_{1/3} = (3.1 \times 10^{-4} \cdot U_{10}^2 + 1.6 \times 10^{-2} \cdot U_{10}) \sqrt{F} \dots\dots\dots(9)$$

At last, the work of the combination of the incident wave and the additional wave which was induced by the onshored strong wind must to determined. Due to the phenomenalism of wave-wave interaction is not so distinct. Therefore, the method of the linear addition of the wave energy was choiced to applied for temporary.

### Experimental Equipment and Procedures

Experiments were conducted in a wave tank 15 meters long, 40 cm wide and 80 cm deep. Both walls of the wave tank are constructed of strengthed glass throughout and the bottom is constructed of stainless steel of a plane surface. A blower was installed just upon the wave maker at one end of the tank while the sloping dyke model was constructed at the another end as shown in Fig.2.

The incident wave characteristics were measured using a capacitate wave gage at the location where the toe

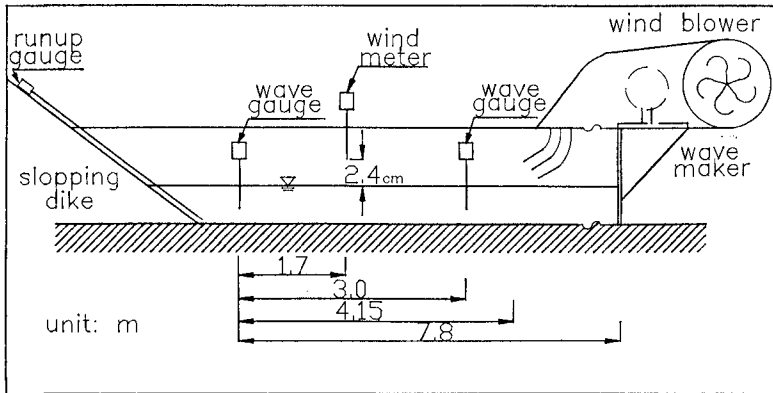

Fig.2 Diagram of Experimental Facility

of the structure was placed and the runup wave was measured on the inclined dike surface at the same way.

In experiment, the slope of the wave tank was maintained at horizontal and four kinds of dike slope (1:0.5, 1:1, 1:2 and 1:3) was choiced and the tests of the wind speed from 0 to 16 meters per second accompany with some range of wave steepness was completed.

### Results and Discussion

By way of the analysis to the wave run-up pictures which was taken from the experiments in different kind of conditions ( many kinds of dike slope and different kind of the incident wave steepness). We can find that the parabola shape of the wave runup was influenced by the surf parameter  $\xi$  ( $=\tan\theta / \sqrt{H/L}$ ). The correlation between the shape parameters of the parabola runup  $M$ ,  $n$  and the surf parameter  $\xi$  was shown in Fig.3 and 4 separately. From those figures, we can systematic out the following relationship between  $\xi$  to  $M$  and  $n$  in some kind of the dike slope.

$$\begin{aligned}
 (1) \quad S = 1:0.5 \quad ; \quad M &= 54.226 \xi^{-3.5} \\
 n &= 1.0075 \xi^{0.1909} \\
 (2) \quad S = 1:1 \quad ; \quad M &= 5.993 \xi^{-3.683} \\
 n &= 0.608 \xi^{0.5865}
 \end{aligned}$$

Fig.3 Correlation between M and  $\xi$

Fig.4 Correlation between n and  $\xi$

(3)  $S = 1:2$  ;  $M = 1.748 \xi^{-4.674}$   
 $n = 0.858 \xi^{0.6361}$

(4)  $S = 1:3$  ;  $M = 0.437 \xi^{-3.185}$   
 $n = 0.873 \xi^{0.5854}$

As to the effect on the onshore wind speed to the relative wave runup height, the results of the computation and the experiment was shown in Fig.5 (1)-(4). In those figures, we can find that in steep slope, for example when the dike slope is 1 to 0.5 and 1 to 1 with vertical to horizontal, the relative wave run-up will decreased first to some degree then increased when the value of the wind parameter ( $U/\sqrt{gH_0}$ ) was increased. But in gentle slope, that is the slope of the dyke is 1 to 2 and 1 to 3, the relative wave runup height was increased almost immediately when the value of the wind parameter was increased.

Fig.5 Correlation between the relative runup and the wind parameter (1)

Fig.5 Correlation between the relative runup and the wind parameter (2)

Fig.5 Correlation between the relative runup and the wind parameter (3)

Fig.5 Correlation between the relative runup and the wind parameter (4)

If we pay the another attention to the incident wave steepness to stand for the wind parameter. The effect on the onshore wind speed to the relative wave runup height can be find as shown in Fig.6(1)-(4). From those figures, we can understand that the effect on the onshore wind speed to the relative wave runup height was more obviously in steeper slope ( $S=1:0.5, 1:1$ ) than in milder slope ( $S=1:2, 1:3$ ). However, the relative wave runup height will be increased when the onshore wind speed was increased are doubtless as shown in those figures. However, in general speaking, in spite of the strength of the wind speed, the relative run-up becomes the biggest when the dyke slope was 1:2.

Fig.6 Correlation between the relative runup and the incident wave steepness (1)

Fig.6 Correlation between the relative runup and the incident wave steepness (2)

Fig.6 Correlation between the relative runup and the incident wave steepness (3)

Fig.6 Correlation between the relative runup and the incident wave steepness (4)

### Conclusions

- (1) The parabolic shape of the wave runup was quite unsimilar in the condition of the different dyke slope and the incident wave steepness.
- (2) The exponential value in the relationship between  $n$  and the surf parameter  $\xi$  was between 0.19 to 0.65.
- (3) The effect on the onshore wind speed to the relative wave runup height was more obviously in steeper slope than in milder slope.
- (4) In general speaking, in spite of the strength of the wind speed, it is remarkable that the relative run-up becomes the biggest when the dyke slope was 1:2.

# CHAPTER 95

## SCATTERING OF WATER WAVES BY VERTICAL CYLINDERS WITH A BACKWALL

Shohachi Kakuno \*, Kazuki Oda\*, and Philip L.-F. Liu \*\*

### Abstract

The scattering of small amplitude water waves by an array of vertical cylinders with a solid vertical backwall is studied theoretically and experimentally. In the theoretical study, a method of matched asymptotic expansions is developed without considering real fluid effects. The energy loss due to flow separation near cylinders is modeled by introducing a complex blockage coefficient. The theories are compared with laboratory data.

## 1 Introduction

The slit-type breakwater consists of a vertically slitted front wall and a solid backwall as shown in Figure 1. The closely spaced cylinders cause flow separation and hence energy dissipation. This type of device is particularly effective in reducing wave action inside a harbor. It has gained popularity in many countries, where either the materials for building rubble-mounted breakwaters are lacking or usable water space is limited. Many studies for the slit-type breakwater have been performed since Jarlan's original work(1961). Most recently a semi-analytical approach has been reported by Fugazza and Natale(1992).

Figure 1. Slit-type breakwater.

\*Dept. of Civil Engrg., Osaka City University, Osaka, 558, Japan.

\*\*Joseph DeFrees Hydraulics Lab., School of Civil & Environmental Engrg., Cornell University, Ithaca, NY. 14853, USA.

The purpose of this study is to consider rigorously the mechanics of the interactions of water waves with the slit-type breakwater. The effects of the cross-section of the cylinders and energy dissipation caused by flow separation behind the cylinders are taken into consideration. The present work is the continuation of a previous study by Kakuno and Liu(1992) with additional consideration of the backwall.

## 2 Formulation of the Problem : Potential Flow Theory

A train of small amplitude monochromatic waves incidents normally upon an array of vertical cylinders with a vertical backwall. The distance between the centers of two adjacent cylinders is denoted as  $2B$  and water depth is a constant  $h$ . The distance between the center line of the array of cylinders and the backwall, we call it wave chamber width hereafter, is denoted as  $l$ .

Ignoring the possibility of flow separation in the vicinity of the cylinders, a potential flow theory is first formulated. Defining the velocity potential for the periodic wave motion as

$$\Phi(x, y, z, t) = \phi(x, y) \frac{\cosh k(h+z)}{\cosh kh} e^{-i\omega t} \tag{2.1}$$

where  $\omega$  is the wave frequency, and  $k$  the wave number which is the solution of the well-known dispersion relation

$$\omega^2 = gk \tanh kh. \tag{2.2}$$

The velocity potential on the still water level,  $\phi(x, y)$ , satisfies the Helmholtz equation

$$\nabla^2 \phi + k^2 \phi = 0, \tag{2.3}$$

in the flow domain with the no-flux boundary condition

$$\frac{\partial \phi}{\partial n} = 0, \tag{2.4}$$

on the perimeters of the cylinders and the backwall.

The incident waves propagate in the positive  $x$ -direction and their potential is expressed as

$$\phi_{inc} = e^{ikx}. \tag{2.5}$$

The scattered wave potential, which is the difference between the total wave potential  $\phi$  and the incident wave potential, must satisfy the radiation boundary condition at infinity. The radiation boundary condition, which requires the scattered waves be outgoing at infinity, can be stated as

$$\phi - \phi_{inc} \rightarrow Re^{-ikx}, \quad \text{as } x \rightarrow -\infty \tag{2.6}$$

where  $R$  is the reflection coefficient.

In the region of the wave chamber, two types of waves exist : waves propagating in positive and negative  $x$ -direction. Thus,

$$\phi \rightarrow T e^{ikx} + Q e^{-ikx}, \quad \text{as } 0 \ll x < l \quad (2.7)$$

where  $T$  and  $Q$  are the ratios of amplitudes of these waves to that of the incident wave, respectively. If we apply the no-flux boundary condition on the front line of the backwall to these two waves, we obtain

$$Q = e^{2ikl} T. \quad (2.8)$$

### 3 A Method of Matched Asymptotic Expansions

To find analytical solutions for the velocity potential,  $\phi$ , we develop a systematic procedure using a method of matched asymptotic expansions. First, the flow domain,  $0 < y < B$ ,  $-\infty < x < l$  is divided into two far-fields and a near-field. The near-field region is the flow domain in the vicinity of cylinders with the length scale of  $O(B)$ . The far-field regions are the flow domains far away from the cylinders, i.e.  $O(|x|/B) \gg 1$ , in which the length scale is the wave length. A method of matched asymptotic expansions is developed based on the assumption that  $kB = \varepsilon \ll 1$ .

#### 3.1 Far-Field Solutions

If we match the far-field solutions and the near-field solution far away from cylinders, so that  $O(|x|/B) \gg 1$  but  $O(|kx|) \ll 1$ , then evanescent modes can be discarded. In terms of the near-field coordinates  $(\bar{x}, \bar{y}) = (x/B, y/B)$ , (2.6) and (2.7) can be rewritten as:

$$\phi = e^{i\varepsilon\bar{x}} + R e^{-i\varepsilon\bar{x}}, \quad \bar{x} < 0 \quad (3.1a)$$

$$\phi = T e^{i\varepsilon\bar{x}} + e^{2ikl} T e^{-i\varepsilon\bar{x}}, \quad \bar{x} > 0. \quad (3.1b)$$

Expanding the reflection and the transmission coefficients in a power series of the small parameter  $\varepsilon$ , we have

$$R = \sum_{m=0}^{\infty} \varepsilon^m R_m, \quad (3.2a)$$

$$T = \sum_{m=0}^{\infty} \varepsilon^m T_m. \quad (3.2b)$$

Substituting (3.2) into (3.1), we obtain the inner expansions of the far-field solutions:

$$\begin{aligned} \phi &\sim (1 + R_0) + \varepsilon[R_1 + i(1 - R_0)\bar{x}] \\ &+ \varepsilon^2 \left[ R_2 - iR_1\bar{x} - \frac{(1 + R_0)\bar{x}^2}{2} \right] \\ &+ \varepsilon^3 \left[ R_3 - iR_2\bar{x} - \frac{R_1\bar{x}^2}{2} + \frac{i(R_0 - 1)\bar{x}^3}{6} \right] + \dots, \quad \bar{x} < 0 \end{aligned} \tag{3.3a}$$

$$\begin{aligned} \phi &\sim (1 + e^{2ikl})T_0 + \varepsilon[(1 + e^{2ikl})T_1 + i(1 - e^{2ikl})T_0\bar{x}] \\ &+ \varepsilon^2 \left[ (1 + e^{2ikl})T_2 + i(1 - e^{2ikl})T_1\bar{x} - \frac{(1 + e^{2ikl})T_0\bar{x}^2}{2} \right] \\ &+ \varepsilon^3 \left[ (1 + e^{2ikl})T_3 + i(1 - e^{2ikl})T_2\bar{x} - \frac{(1 + e^{2ikl})T_1\bar{x}^2}{2} - \frac{i(1 - e^{2ikl})T_0\bar{x}^3}{6} \right] \\ &+ \dots, \quad \bar{x} > 0. \end{aligned} \tag{3.3b}$$

The reflection and transmission coefficients,  $R_m$  and  $T_m$ , are to be determined by matching (3.3) with the outer expansions of near-field solutions.

### 3.2 Near-Field Solutions

In the near-field the potential function is also expanded in a power series of  $\varepsilon$ , i.e.

$$\phi = \sum_{m=0}^{\infty} \varepsilon^m \phi_m. \tag{3.4}$$

In terms of the near-field coordinates  $(\bar{x}, \bar{y})$  the governing equation, (2.3), can be rewritten as

$$\frac{\partial^2 \phi}{\partial \bar{x}^2} + \frac{\partial^2 \phi}{\partial \bar{y}^2} + \varepsilon^2 \phi = 0. \tag{3.5}$$

Substituting (3.4) into (3.5), we obtain a series of governing equations

$$\frac{\partial^2 \phi_m}{\partial \bar{x}^2} + \frac{\partial^2 \phi_m}{\partial \bar{y}^2} = 0, \quad m = 0 \text{ and } 1 \tag{3.6a}$$

$$\frac{\partial^2 \phi_m}{\partial \bar{x}^2} + \frac{\partial^2 \phi_m}{\partial \bar{y}^2} + \phi_{m-2} = 0, \quad m = 2, 3, 4, \dots \tag{3.6b}$$

The boundary condition requires that the no-flux condition be satisfied for all  $\phi_m$ , i.e.  $\partial\phi_m/\partial n = 0$  ( $m = 0, 1, 2, \dots$ ) along solid surfaces.

The solution of the Laplace equation and the homogeneous solutions of Poisson equation can be interpreted as a uniform flow passing an opening in a channel. The dimensional velocity potentials for the uniform flow,  $\phi'$ , can be written asymptotically as

$$\phi' \sim U'(x \pm C') + F' \quad x \geq 0 \quad (3.7)$$

in which  $U'$  is the velocity intensity,  $F'$  is an arbitrary constant and  $C'$  is the blockage coefficient. The blockage coefficient depends on the geometry of the cylinder and is independent of the wave characteristics. A brief discussion on the blockage coefficient for the circular and rectangular cylinders is given in Kakuno and Liu(1992). Rewriting (3.7) in a dimensionless form in terms of the near-field coordinates, we have

$$\phi \sim U \left( \bar{x} \pm \frac{C}{\varepsilon} \right) + F, \quad \bar{x} \geq 0 \quad (3.8)$$

in which

$$C = kC' \quad (3.9)$$

is the dimensionless blockage coefficient and is of order of magnitude of one or smaller. The scales in (3.8) and (3.9) are used so that the dimensional blockage coefficient,  $C'$ , can become large when the opening of the gap is small in comparison with the distance between two cylinders.

The velocity intensity  $U$  and the constant potential  $F$  are also expanded in terms of the small parameter,  $\varepsilon$ , i.e.

$$U = \sum_{m=0}^{\infty} \varepsilon^m U_m, \quad F = \sum_{m=0}^{\infty} \varepsilon^m F_m. \quad (3.10)$$

Substitution of (3.10) into (3.8) yields the outer expansions of the near-field potentials which are the solution of the Laplace equation.

### 3.3 Matching

After matching the far-field solutions of the leading order with the near-field solutions of the same order, the leading order coefficients may be obtained. The subsequent order coefficients may be calculated from the perturbation scheme with the known coefficients of the preceding order, that is,

$$U_0 = 0, \quad (3.11a)$$

$$F_0 = \frac{1 - iC(1 - e^{2ikl}) + e^{2ikl}}{1 - iC(1 - e^{2ikl})}, \quad (3.11b)$$

$$T_0 = \frac{1}{1 - iC(1 - e^{2ikl})}, \quad (3.11c)$$

$$R_0 = \frac{-iC(1 - e^{2ikl}) + e^{2ikl}}{1 - iC(1 - e^{2ikl})}, \quad (3.11d)$$

$$U_1 = i(1 - e^{2ikl})T_0, \quad (3.12a)$$

$$F_1 = \frac{-iM(iC - e^{2ikl} - 1)}{1 - iC(1 - e^{2ikl})}F_0, \quad (3.12b)$$

$$T_1 = \frac{(i + C)M}{1 - iC(1 - e^{2ikl})} F_0, \tag{3.12c}$$

$$R_1 = \frac{i[(1 + e^{2ikl}) - iC(1 - e^{2ikl})]M}{1 - iC(1 - e^{2ikl})} F_0, \tag{3.12d}$$

$$U_2 = \frac{e^{2ikl}M}{1 - iC(1 - e^{2ikl})} F_0, \tag{3.13a}$$

$$F_2 = \frac{(1 + e^{2ikl})T_2 + R_2}{2}, \tag{3.13b}$$

$$T_2 = \frac{(i + C)M}{1 - iC(1 - e^{2ikl})} F_1, \tag{3.13c}$$

$$R_2 = \frac{[i + C - (C - i)e^{2ikl}]M}{1 - iC(1 - e^{2ikl})} F_1, \tag{3.13d}$$

where  $2M$ , a net flux across the surface of the cylinder generated to compensate the flux by a symmetric part of the particular solution of the Poisson equation, is determined by

$$2M = - \int_{\Gamma} \frac{\partial}{\partial n} \left( -\frac{\bar{x}^2}{2} \right) ds = -\frac{S}{B^2} \tag{3.14}$$

where  $\vec{n}$  is pointing outward from the fluid region,  $\Gamma$  is the surface of the cylinder, and  $S$  is the half of the cross sectional area of the cylinder.

### 3.4 Reflection Coefficient

Up to the  $O(\varepsilon^2)$  the reflection coefficient can be expressed as

$$R = R_0 + \varepsilon R_1 + \varepsilon^2 R_2. \tag{3.15a}$$

The absolute value of the reflection coefficient of leading order is unity, which fulfill the energy conservation, regardless of the wave characteristics, the wave chamber width, and the porosity of the front wall, or  $C$ . The whole solution which includes higher-order terms, therefore, does not satisfy the energy conservation principle. In particular, the deviation of that solution from the principle become significant in the vicinity of region of  $l/\lambda = 0.5$ , where  $\lambda$  is the wave length.

### 3.5 Free surface displacement inside and outside the wave chamber

For design purpose, the free surface displacement in front of and behind the front wall, and in front of the backwall should be predicted. Knowing the phase difference in the free surface displacement inside and outside the wave chamber is helpful to get insight into the wave mechanics around the breakwater.

From the linear wave theory the free surface displacement can be related to the velocity potential  $\Phi$  through the free surface boundary condition

$$\eta = \Re e \left[ -\frac{1}{g} \frac{\partial \Phi}{\partial t} \right]_{z=0} \tag{3.16}$$

Substituting (2.1) into the above equation and collecting the real part of the resulting equation, we obtain

$$\eta = \frac{\omega}{g} \sqrt{\alpha^2 + \beta^2} \sin \left[ \omega t + \tan^{-1} \frac{\alpha}{\beta} \right] \tag{3.17}$$

where

$$\alpha = -\Im m[\phi(x, y)], \tag{3.18a}$$

$$\beta = \Re e[\phi(x, y)]. \tag{3.18b}$$

The phase difference in the free surface displacement inside and outside the wave chamber is, therefore,

$$\theta = \tan^{-1}(\alpha_O/\beta_O) - \tan^{-1}(\alpha_I/\beta_I) \tag{3.19}$$

where the subscript "O" and "I" stand for "outside" and "inside" of the wave chamber.

### 4 Energy Dissipation Model

As shown in (3.7) the outer expansions of the near-field solutions represent uniform flows with a difference in potential level. This difference denoted by the blockage coefficient,  $C'$ , can be related to the pressure drop between the front and the rear of the front wall. In the dimensional form, the dynamic pressure is defined as

$$P = -\rho \frac{\partial \Phi}{\partial t} = i\rho\omega\phi(x, y) \frac{\cosh k(h+z)}{\cosh kh} e^{-i\omega t} \tag{4.1}$$

Substituting (3.7) into the above equation, we obtain the dynamic pressures in front of and behind the wall

$$P = i\rho\omega[U'(x \pm C') + F'] \frac{\cosh k(h+z)}{\cosh kh} e^{-i\omega t}, \quad x \gtrless 0 \tag{4.2}$$

If we neglect terms whose order are higher than  $O(k^2)$ , the pressure difference between  $P_+$  and  $P_-$  is

$$\Delta P = P_- - P_+ = 2\rho C' \dot{U} \tag{4.3}$$

where

$$\dot{U} = \frac{dU}{dt}; \quad U = U' \frac{\cosh k(h+z)}{\cosh kh} e^{-i\omega t} \tag{4.4}$$

Therefore, the blockage coefficient  $C'$  plays a role of a coefficient of inertia resistance which is proportional to the acceleration of the oscillating flow  $U$ , (4.4).

To include the effects of energy dissipation due to flow separation in front of and behind the front wall, we assume that the flow separation is confined within the near field region. We assume that the energy dissipation causes an additional pressure drop, which is linearly proportional to the oscillating velocity  $U$ . Thus

$$\Delta P = 2\rho C' \dot{U} + 2\rho C'_i \omega U \tag{4.5}$$

in which  $C'_i$  can be considered as an empirical coefficient modeling the effects of energy dissipation. The simple model (4.5) can be derived in a different way. We introduce the blockage coefficient  $C'$  in (4.2) as a complex constant, i.e.

$$C' = C'_r + iC'_i \tag{4.6}$$

so that  $C'_r$  is the actual blockage coefficient based on the potential flow theory. Substituting (4.6) into (4.2), we can derive (4.5) with  $C'$  being replaced by  $C'_r$ . The significance of the simple relations stated in (4.5) and (4.6) is that when the energy dissipation is important, one can calculate the reflection coefficient (3.15) by replacing  $C$  by  $C'$ .

It is well known that the energy loss due to the flow separation is proportional to the square of the flow velocity through the opening, i.e.

$$\frac{\Delta P}{\rho g} = f' \frac{V^2}{2g} \tag{4.7}$$

where  $f'$  is the energy loss coefficient and  $V$  is the average velocity at the opening ( $x = 0$ ). Because the dissipation model introduced in (4.5) is linear in the velocity field, we must ensure that the same total energy loss (work done) over a wave period is determined by the quadratic resistance law and by the linear model. By equating the work done (energy loss) calculated from the linear model and the one calculated from quadratic resistance law, we get

$$\frac{C'_i}{B} = \frac{|\tau|(H/\lambda)f}{9\pi/4 (a/B)^2 (B/\lambda)} \left[ \frac{\sinh^2 kh + 3}{\sinh 2kh + 2kh} \right] \tag{4.8}$$

and

$$f = f' \gamma \tag{4.9}$$

in which "a" denotes the half-width of the opening, "H" is the incident wave height,  $\gamma$  is an empirical coefficient, and  $\tau$  is the ratio of the uniform velocity far away from the cylinder to the water particle velocity of the incident wave at the same position, and expressed as

$$\tau = (1 - e^{2ikl})T. \tag{4.10}$$

Equation (4.8) relates  $C'_i$  to the wave characteristics,  $H/\lambda$ ,  $\tau$ ,  $kh$ , and the geometry of the cylinder,  $a/B$  and  $B/\lambda$ . Only one dimensionless coefficient,  $f$ , need to be determined. The value of  $f$  may hold the same as that for the case without the backwall, say, 1.5 for rectangular cylinders.

## 5 Comparison Between Theoretical Solutions and Laboratory Data

To validate the theoretical models with the value of  $f = 1.5$  for rectangular cylinders, experimental data obtained in Osaka City University are compared with theoretical results.

The cylinders used are square. The experiments are performed in a wave tank, which is 1.0m wide, 50m long and 1.75m deep. The side lengths of the square cylinders are 15cm for the case of  $B/l = 0.129$  and 5cm for other cases. The water depth is kept constant at  $h = 50\text{cm}$ . The wave steepness  $H/\lambda$  varies slightly around 0.01. The wave heights are measured in front of and behind the front wall and in front of the backwall.

From Figure 2(a) to Figure 2(d), the laboratory data for the reflection coefficients are compared with the theoretical results obtained for  $f = 1.5$ , for different parameters,  $a/B$  (porosity),  $B/l$ , and  $h/B$ . The theoretical results obtained from the leading term only and from higher-order terms are shown in the figures. The discrepancy between these two types of the results is slight except the region of  $l/\lambda = 0.5$  where the higher-order solutions exhibit singular behavior. The agreement between data and theoretical results from the leading term only is good so that it is suffice for practical use to employ only the leading term. In Figure 3, the all experimental data of the reflection coefficients are plotted against the theoretical results. Both are in good agreement except for the region where the values are close to unity.

Figure 4 shows an example of the comparison in the free surface displacements at three locations inside and outside the wave chamber. The vertical displacements are normalized by the incident wave amplitude. Figure 5 plots the phase difference between the locations inside and outside the chamber. Both figures are the results based on the leading order approximation. The locations at which the free surface displacements are measured are indicated in the captions of each figure. The agreement between data and theory is again good for these results. Note that nodes appear behind the cylinders at a definite value of  $l/\lambda$ . Sudden jumps shown in the phase difference, which is about  $\pi$ , are because that the location of the wave gauge behind the cylinder ( $x_2$ ) is in the vicinity of a nodal point.

Figure 4. Comparison between theoretical and experimental data for free surface displacements,  $x_1/l = -0.125$ ,  $x_2/l = 0.125$ ,  $x_3/l = 0.917$ .

Figure 5. Comparison between theoretical and experimental data for phase differences between inside and outside the chamber,  $x_1/l = -0.125$ ,  $x_2/l = 0.125$ ,  $x_3/l = 0.917$ .

## 6 Conclusion

A modified method of matched asymptotic expansions has again been applied to study the wave interactions with a slit-type breakwater. The energy dissipation caused by the flow separation behind the cylinders is considered in the theory. Theoretical results with the empirical coefficient for square cylinders determined in the previous study are verified by experimental data. It is shown that the leading order solutions are accurate and can be used to calculate reflection coefficients and the wave action in the vicinity of the breakwater.

## CHAPTER 96

### HYDRAULIC MODEL EXPERIMENTS ON SEAWALLS

by

J.W.Kamphuis<sup>1</sup>, K.A.Rakha, J. Jui.

#### ABSTRACT

The preliminary analysis of a set of three-dimensional tests on an infinite beach backed by a seawall is presented. The longshore sediment transport rate in front of the seawall was found to decrease as the beach in front of the seawall eroded. The location of the breaker peaks in the suspended and bed load sediment transport rate moved slightly offshore, and the bedload peak in the swash zone disappeared as the beach eroded. The local ratio of  $H/d$  approached a constant value as the beach eroded for most of the tests, however the erosion depth in front of seawalls cannot be simply related to offshore wave height.

#### INTRODUCTION

The function of a seawall is to protect the land behind it by fixing the land-sea boundary. It does not protect either the beach fronting it or adjoining unprotected beaches. Since seawalls are usually built along eroding rather than stable shorelines, they have commonly been perceived as causing or contributing to erosion rather than simply responding to a pre-existing erosion problem. When a seawall is constructed on an eroding coast, existing erosion processes will continue to decrease the size of the beach in front and eventually the beach in front of the seawall will disappear if there is inadequate sediment supply. The seawall protection solution prevents further recession of the coastline; it does not stop the physical processes which cause erosion. The extent to which a seawall affects the processes on

---

<sup>1</sup>Department of Civil Engineering  
Queen's University, Kingston, Ontario, Canada K7L 3N6

the fronting and adjacent beaches at any one time largely depends on the location of the seawall relative to the active shoreface and only indirectly on the level of wave action to which it is subjected.

Kraus (1988) presented an extensive review of approximately 100 technical papers on the effect of seawalls. Since most laboratory studies used wave flumes and investigated cross-shore sediment transport processes only, the effect of the seawall on the longshore sediment transport rate could not be deduced.

The set of experiments presented here was performed as a part of a comprehensive three-dimensional study of the effects of seawalls on the nearshore processes. The fundamental case of an infinite beach backed by a seawall is considered here. Wave heights, wave setup, longshore velocity distributions, longshore sediment transport rates, and longshore sediment transport distributions were measured. Preliminary analysis of the data is presented here.

## EXPERIMENTS

Five tests were carried out in a three-dimensional model basin (Figure 1). These tests are an extension of previous three dimensional sediment transport studies carried out in the same facility (Kamphuis, 1991a, 1991b, 1991c). A vertical seawall was constructed on a sandy beach of median grain size 0.12 mm. The test conditions are summarized in (Table 1). A time series of waves, simulating a Jonswap wave spectrum was used with a 10 degree incident wave angle, a peak period of 1.15 seconds and wave heights varying from 0.05 to 0.09 m. The random wave signal repeated itself after 200 waves.

A plane beach of initial slope 1:10 was first prepared for each test. This initial profile was allowed to reshape itself under wave action to approach equilibrium. The water level in the basin was chosen so that only about one percent of the incident waves impacted on the seawall at the top of the beach when the beach approached equilibrium, thus simulating a seawall well back on the beach. The water level was then raised in all tests except Test A to simulate storm surge. This resulted in the initial percentages of wave impact on the seawall as shown in Table 1. The tests were continued until a new equilibrium profile in front of the seawall was approached.

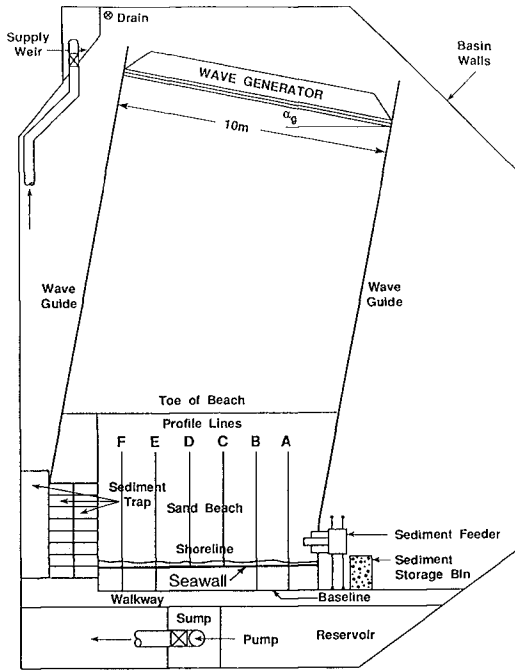

FIGURE 1 EXPERIMENTAL FACILITY

FIGURE 2 PROFILE DEVELOPMENT

TABLE 1  
TEST SUMMARY

TEST	GENERATED WAVE CONDITIONS			SURGE	TEST DURATION	
	Height Hs (cm)	Period Tp (sec)	Angle $\alpha$ (deg)	S (cm)	t (hr)	% touch
A	7	1.15	10.0	0.0	32	1.0
D	7	1.15	10.0	2.2	12	20
E	9	1.15	10.0	-	14	10
F	5	1.15	10.0	-	22	10
G	7	1.15	10.0	1.6	18	10

Each test consisted of a series of hourly segments. Wave heights, longshore velocity distributions, and beach profiles were measured during each segment. Wave heights were recorded using capacitance type wave gauges. One wave gauge was mounted offshore to record the incident wave height. Fifteen wave gauges were mounted on a horizontal beam at regular intervals of 0.2 m through the breaking zone. Longshore velocities were measured using a mini electro-magnetic current meter. Profiles of the beach in front of the seawall were measured along six parallel lines evenly spaced along the seawall. The profiles presented here are the average of profiles B,C,D, and E (Figure 1).

A sediment trap was located at the downdrift end of the beach but within the wave guides. It was designed to separate the bedload from suspended load and to measure their distributions across the swash and surf zone. Sediment Transport rates were measured every 15 minutes. Sediment transport distributions were measured every 4 hours. A detailed description of the sediment trap layout can be found in Kamphuis (1991c).

To represent an "infinitely long" beach, it is necessary to maintain parallel contours along the study area. For this purpose, sediment was supplied at the updrift end of the beach by a feeder at a rate comparable to the sediment transported along the beach.

## RESULTS

The tests essentially consist of two groupings. There are 3 tests with 7 cm high incident waves, with 1, 10, and 20 % of the waves directly impacting the seawall at the beginning of the test (Tests A,G, and D). Then there are 3 tests in which 10 % of the waves are initially incident on the seawall but in which the nominal incident wave height is 9, 7, and 5 cm (Tests E,G, and F). Test G is common to both sets. Figure 2 shows examples of the profile change with time. Figure 3 shows the initial and final profiles for all the tests.

The beach in front of the seawall gradually disappeared and the sand was eroded to well below the water level. The eroded sediment was deposited offshore, and a nearly horizontal plateau was formed. The horizontal plateau extended seaward to the breaker location. Very near the seawall a local scour hole was also observed in all the tests.

Figure 4 shows examples of the suspended, bed, and total longshore sediment transport rates as they evolved in time. All rates decreased as the foreshore eroded, because energy dissipation resulting from breaking decreased towards the end of the test. As the depths increased, more wave reflection and less breaking occurred. The longshore sediment transport rates tended toward equilibrium values.

Figure 5 shows an example of the development of the suspended and bed load distributions with time. The peaks of the distributions moved slightly offshore, following a slight offshore movement of the breaker location. As the test progressed the bedload peak in the swash zone disappeared and both distributions tended to have one single peak near the breaker location.

## PRELIMINARY ANALYSIS OF RESULTS

The present data set together with additional tests will be used to develop a Quasi-3D numerical model. This model will be an extension of the work of Briand (1990) by including wave reflection off the seawall. In the present paper a preliminary, general analysis of the data will be presented.

Figure 6 shows the wave height profiles at the ends of the tests. It is seen that the wave heights increase up to the breaking point and then decrease as wave energy dissipates. Up to breaking, the wave height profile is entirely predicted by combining small

FIGURE 3  
INITIAL AND FINAL PROFILES

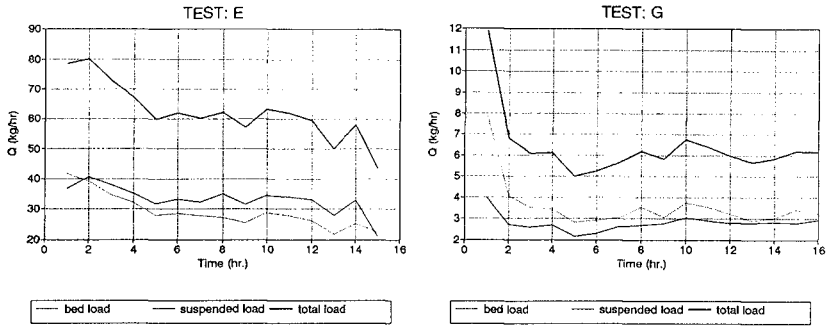

FIGURE 4 SEDIMENT TRANSPORT RATE

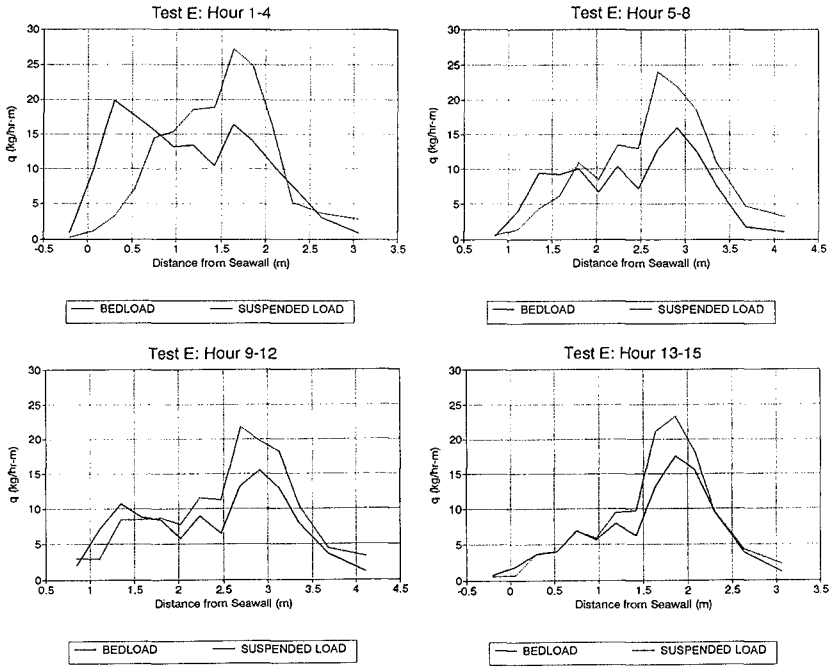

FIGURE 5 SEDIMENT TRANSPORT RATE DISTRIBUTION

FIGURE 6

WAVE HEIGHT DECAY

FIGURE 7

WAVE HEIGHT TO LOCAL DEPTH RATIO

amplitude shoaling theory, Snell's law and bottom friction (Kamphuis 1991a). Breaking is predicted by the incipient breaking criterion of Kamphuis (1991b) and the decrease in wave height is predicted by Kamphuis' (1993) adaptation of the energy dissipation rate proposed by Dally et al (1984). At about 1.5 m from the structure, however, the profile indicates a substantial reduction in wave energy dissipation rate. The remaining wave energy is simply reflected back to sea.

the simple ratio  $H_s/d$  and it is seen that near the structure water depth is indeed directly related to the wave height. In fact the ratio is about the same (0.7) for all tests except Test E (which is thought to contain a small error in depth measurement).

The average depth over the plateau from the seawall to the breaker ( $d_p$ ) is shown in Table 2.

TABLE 2  
SUMMARY OF PROFILE RESULTS

TEST	INPUT CONDITIONS			FINAL RESULTS		
	$H_s$ (cm)	$S$ (cm)	% touch	$H_{sb}$ (cm)	$X_b$ (m)	$d_p$ (cm)
A	7	0.0	1	7.4	2.5	7.4
G	7	1.6	10	7.7	2.3	7.7
D	7	2.2	20	8.7	2.2	9.2
E	9	-	10	9.2	2.6	7.7
G	7	1.6	10	7.7	2.3	7.7
F	5	-	10	6.2	1.9	7.5

For Tests A, G, and D, it was found to be approximately equal to the breaking significant wave height. This seems to support the idea that scour depth is related to incident deep water wave height (Kraus, 1988). For Tests E, G and F, however,  $d_p$  is almost constant, even though the wave height decreases from 9 to 5 cm. This would tend to indicate that depth is not related to wave height in a simple manner.

Depth of water over the plateau is actually a complex interaction between wave height, water level, the beach, and the seawall. This interaction may be explained using the conceptual model in Figure 8.

Assume that a beach profile is in equilibrium with the incident wave climate, as in Figure 8a. Its depth ( $d$ ) is defined everywhere out to a closure depth,  $d_c$ . If a storm surge ( $S$ ) raises the water level, the whole equilibrium profile will rise to follow the new water

FIGURE 8 CONCEPTUAL MODEL OF EROSION NEAR A SEAWALL

level (Figure 8b). To raise the beach profile, however, requires additional sand and normally the existing profile must supply this, resulting in a profile recession ( $R$ ) as shown in Figure 8c. The eroded area ( $E$ ) must balance the area of deposition ( $D$ ) and hence  $R$  is a function of  $B$ , the berm or dune height above the water. This mechanism has been described by Bruun (1962) and others.

If a seawall is introduced (Figure 8d), a portion of the erosion zone ( $X$ ) is now no longer available to feed the deposition zone. The thickness of the deposition layer will be less and hence the water depth will be

greater. Reflection off the seawall, however, causes an increase in depth near the structure adding a volume of sand (Y) to the erosion volume. The total erosion volume with a seawall in place is therefore  $(E-X+Y)$ . Since Y is normally less than X, as shown for example by Barnett (1988),  $d'$  is normally greater than  $d$ . Storm surge therefore results in greater water depth near the structure (relative to the raised water level). Similarly, it may easily be shown that the depth increases when S increases.

Tests A,G and D began on the same equilibrium profile. Storm surge increased the depth over the plateau. Larger storm surge resulted in larger depths of water. This in turn permitted larger wave heights to occur over the plateau and interaction with these larger wave heights produced the final profiles.

Tests E,G and F began with different initial profiles; the wave height varied from 9 to 5 cm. The larger wave heights produced a larger runoff which means that the seawall was placed relatively further back in Figure 8. This implies that X was smaller and Y was larger, causing  $(E-X+Y)$  to be larger and the resulting water depth to be smaller. At the same time to increase the percent of waves impacting the structure from the 1% on the original equilibrium profile the test value of 10% required a larger storm surge for the larger wave heights. This caused the depths to be larger. Here we have two processes which compensated for each other in Tests E,G and F, resulting in the almost constant value of  $d_p$ .

The breaker location  $X_b$  moved further offshore for the larger wave heights (Table 2). This provided a longer distance for energy dissipation to occur. A calculation using the Kamphuis (1993) modification of the Dally et al (1984) wave dissipation model shows that a distance of 0.3 m is required to reduce the wave height from 9 cm to 7 cm in Test E, and 0.48 m to reduce the wave height from 7 cm to 5 cm in Test G. The actual differences between the breaker locations were found to be 0.3 m for Tests E and G, and 0.4 m for Tests G and F. Thus, a longer breaker distance permitted the higher offshore wave heights to reduce to the same heights close to the seawall, as shown in Figure 7. This resulted in similar depths over the plateau.

The depth of scour to wave height relationship is simple, but physically rather meaningless. Our research (not presented here because of page limits) has shown that scour depth can also be related to the wave climate

using energy dissipation and critical shear stress concepts.

To determine whether seawalls accelerate erosion, a comparison with beaches without structures is required. (Kraus, 1988). Long term tests are underway to make such comparisons. Preliminary results indicate that seawalls do not create disastrous increases in erosion rates, but this work is not complete at the present time.

#### CONCLUSIONS

The equilibrium profile developed in front of the seawall is a complex function of the initial profile, the storm surge, and the wave climate.

The longshore sediment transport rate decreased as the beach eroded in front of the seawall.

The location of the breaker peaks in the longshore suspended and bed load sediment transport rate distribution moved slightly offshore as the beach eroded. The bedload peak in the swash zone disappeared as the foreshore eroded.

The local depth was found to be closely related to the local wave height; the ratio  $H/d$  approached a constant value as the beach approached an equilibrium condition. However, average scour depth in front of a seawall can not be simply related to offshore wave height.

#### ACKNOWLEDGMENTS

This study was carried out under the Strategic Grants Program of the Natural Sciences and Engineering Research Council (NSERC) of Canada. The careful hydraulic testing was carried out by J. Kooistra and J. Jui.

## CHAPTER 97

### MOVEMENT AND STATIC STRESS IN DOLOSSE: SIX YEARS OF FIELD MONITORING AT CRESCENT CITY

Thomas R. Kendall, <sup>1</sup>M. ASCE  
and  
Jeffrey A. Melby, <sup>2</sup>A.M. ASCE

#### ABSTRACT

Breakwater failures have often been caused by or at least exacerbated by a structural failure of concrete armor units, especially when the units are the more slender type such as dolosse. To aid in the development of a structural design procedure for complex concrete armor units, post-construction monitoring of movement and stress in dolosse has been ongoing on the outer breakwater at Crescent City, California since its rehabilitation in 1986. This paper describes the significance of static stress in large (38-tonne) dolosse and documents the continued rapid growth of dolos static stress in a relatively nested shallow-water breakwater. New data from 1990, 1991 and 1992 have modified the previously suggested conclusion that dolos static stress was increasing at a decreasing rate (Kendall and Melby, 1989). These new data suggest that while dolos movement has continued to subside, static stress has been building approximately linearly.

This paper is divided into two basic sections:  
(1) general background on dolos design considerations and the monitoring program being carried out at Crescent City, including new techniques for the

photogrammetric monitoring of armor unit displacement; and (2) breakage, displacement, and static stress results through the sixth year of monitoring.

## BACKGROUND

Following the rehabilitation of the Crescent City Outer Breakwater with dolosse in 1986, extensive field data were collected on incident waves, dolos loading and displacement. These data have been collected in support of a program whose objective is the development of a structural design procedure for dolosse based on breakwater design wave conditions. The procedures developed are intended to be applied to other armor types in addition to dolosse. The monitoring program and design procedure development are detailed in several publications, including Kendall, et al (1985), Howell (1986 and 1988), Kendall (1988), Howell and Melby (1991), Melby (1992 and in publication), Melby and Turke (1992), and Howell, et al (in publication).

The need for a dolos structural design methodology has been apparent in the United States since the early 1970's when the units were first introduced to the U.S. Dolosse were recognized for their excellent hydraulic stability and judged to be an economic armor unit choice for the severe wave climate of the northern California Coast. The north and south jetties at Humboldt, California were armored with two layers of 38-tonne dolosse around the head sections as part of their rehabilitation in 1971-1972 and 36-tonne dolosse were placed on the Crescent City Outer Breakwater as part of its rehabilitation in 1973-1974.

Uncertainty in the loading criteria applicable for any structural design of the dolosse led to two different approaches for the initial Humboldt and Crescent City dolos rehabilitations. The first dolosse at Humboldt were typically reinforced while those at Crescent City were unreinforced. Most of the Humboldt dolosse were reinforced with standard cage reinforcing using 40ksi (276MPa) steel rebar. Twelve No. 8 (2.5-cm diameter) longitudinal and four No. 4 (1.25-cm diameter) tie bars were placed in each fluke and shank under a 6-in (15-cm) concrete cover, representing 75 lbs of steel per cubic yard of mix ( $44\text{kg/m}^3$ ). However, analysis supported by field tests suggested that the quantity and strength of steel were not sufficient enough to contribute strength after concrete cracking. For the field tests, pairs of cage-reinforced, steel-fiber-reinforced, and unreinforced units were clamped together at the flukes

and then forced apart with hydraulic jacks operating on the opposite flukes. These test results plus the added cost of reinforcing led to the decision to experiment with exclusively unreinforced dolosse at Crescent City.

The majority of the unreinforced dolosse placed at Crescent City subsequently failed leading to the 1986 rehabilitation and monitoring program. Kendall and Melby (1989) provide more detail on these dolosse and their subsequent failure.

The second rehabilitation with dolosse at Crescent City was completed in September 1986 and monitoring began shortly thereafter. A total of 680 steel-fiber-reinforced 38-tonne dolosse were used in the repair. None of the original broken 36-tonne dolosse were removed as part of the rehabilitation. Fiber reinforcing (80 lbs of steel fiber per cubic yard of mix or  $47 \text{ kg/m}^3$ ) was used in the new dolosse, in part, as an experiment. Lab and field tests indicated that the fibers did not significantly increase the strength of the concrete, but did add toughness which would help hold the units together after fracture. The flexural strength of the concrete was measured at 984 psi (6.8 MPa) (Kendall and Melby, 1989).

The dolos section of the monitored breakwater (Figure 1) is located in 7.5 to 9 meters of water and is subjected to depth-limited breaking waves of up to 10.5 meters in height with peak periods between 15 and 20 seconds (Hales, 1985; Kendall, 1988).

Figure 1 - Typical cross-section through the dolos section of the Crescent City Outer Breakwater

### Dolos Stress Monitoring

Dolos stress data have been derived from strains measured with gages internally mounted in select dolosse grouped together near the center of the dolos field. Twenty such dolosse were originally placed for the monitoring program. The strain signals are used to measure two moments and a torque at the shank-fluke interface of the dolos (Howell, 1988). Burcharth and Howell (1988) and Melby (1989) provide discussions on the computation of maximum principal tensile stress for a cross-section in the dolos shank and the comparison of that stress with concrete splitting strength as a failure criteria.

Two types of stresses have been recorded with the instrumented dolosse at Crescent City: wave-induced pulsating stresses and static stresses. Dolos stress data from the initial intensive monitoring period (1987-88) have been used to demonstrate that the mean over the sampled dolos field of the maximum wave-induced pulsating stress is linearly related to the average of the highest one-tenth of the waves in a 30-minute time series. Furthermore, the distribution about the mean of the maximum wave-induced pulsating stress is well described by the Rayleigh distribution (Howell and Melby, 1991). For the 38-tonne dolosse at Crescent City, however, these pulsating stresses were found to be nearly an order of magnitude lower than the recorded static stresses caused by self weight and settling-induced nesting or wedging forces. In many instances, the dolos static stress has consumed well over half of the concrete splitting strength.

Dolos static stress continues to be monitored from a diminishing sample of instrumented dolosse at Crescent City. Static moment data, which are reduced to principal stresses, are collected from the still functioning dolosse each summer. The data are sampled from each dolos at 1Hz for six minutes. Typically, with six functioning dolosse, the sampling rotates to each dolos once every hour. The minimum collection period is generally 24 hours. Only data passing a series of reliability tests are retained. These tests include verifying that the RMS error in each six-minute data file is within the range produced by environmental noise, i.e. temperature variations and small wave loads. If a single dolos repeatedly fails the reliability tests, then that dolos is dropped from the data acquisition system.

### Displacement and Breakage Monitoring

To better understand the overall behavior of the dolos field, the stress samples are supplemented by detailed surveys of dolos movement and breakage. Periodic aerial photography and low-altitude, high-resolution photogrammetry have been the primary tools used in this supplemental data collection. In addition, available nearby National Oceanic and Atmospheric Administration (NOAA) buoy records have been retrieved to track wave power offshore of Crescent City.

For the photogrammetric monitoring of displacement, targets were established on 26 dolosse. Eighteen of these are located in the instrumented section and eight are distributed uniformly throughout the remainder of the dolos field. Twenty two of these dolosse are located in the upper dolos layer and have been marked with three targets each; this allows their movement to be described with six degrees of freedom. The remaining four dolosse, which are located in the lower dolos layer of the test section, have only one clearly visible surface. Therefore, only a single target has been established on each of these.

In addition to the data collected from targeted dolosse, less precise data have been collected from dolosse which are not targeted. The detection and quantification of movement among non-targeted dolosse has been done both by using photo overlays (Kendall, 1988) and by using an application of time-lapse photography where the exposure from one flight is stereopaired with an exposure from a subsequent flight (Kendall and Melby, 1989).

Further details of the survey techniques used to supplement the instrumented dolosse measurements are provided by Kendall (1988), Kendall and Melby (1989), and Howell, et al (in publication). A recent improvement worthy of note is the use of extremely low-altitude photogrammetry acquired from a helicopter. This is discussed briefly in the following paragraphs.

#### Helicopter Photogrammetry

To improve the accuracy of photogrammetric data acquired at Crescent City, extremely low-altitude photogrammetry has been recently acquired by using a helicopter as the photo platform (Davis and Kendall, 1992). A mapping camera has been mounted on a helicopter in such a way that vibration- and

motion-free aerial mapping photography can be collected. The width of the breakwater literally fills the low altitude images allowing very rigid stereo models to be set. The flight line is now along the breakwater axis with the helicopter flying at an elevation of around 60m. Stereo images exposed from this low platform have scales on the order of 1:360 as compared to the 1:1200 scale obtainable from a fixed wing platform. The larger scale imagery does require that roughly five times as many models be set, but the ease of interpretation and increased accuracy easily compensate for this.

With a fixed wing platform, accurate readings to the nearest 3cm are possible. However, comparisons between all retained target readings generated from simultaneous ground and photogrammetric surveys of the dolosse indicated that agreement between the two methods had averaged just better than 5cm. With the helicopter as the photo platform, the total three-dimensional vectorial discrepancy never exceeded 2cm. A similar improvement is also being realized for the work with non-targeted dolosse.

Using the helicopter as the photo platform produced such scale and resolution that the roughly 8-cm wide cross-shaped targets originally established on the dolosse were simply too wide. To improve target definition, a smaller circular target divided into quadrants has been placed on top of each original target.

#### MONITORING RESULTS THROUGH THE SIXTH YEAR

This section summarizes the observations of dolos breakage, spatial distribution and types of dolos displacement, evidence of long-term nesting, evolution of static stress, and structural safety during the monitoring period between the fall of 1986 and summer of 1992.

##### Breakage

No above surface breaks nor significant movement of broken pieces have been observed since the second season; the breakage count remains that reported by Kendall (1988), i.e. seven post-placement broken dolosse, six of which broke during the initial nesting storm sequence. The majority of the breaks have occurred at a shank-fluke interface.

Refined measurements have been made of the

displacements experienced by broken dolosse. These measurements have shown that three of the broken dolosse experienced single-point displacements as large as 3m. However, these dolosse likely broke prior to experiencing the majority of the evident displacement and other broken dolosse clearly experienced minimal displacement while some unbroken dolosse experienced large displacements (Kendall, 1988). Therefore, the general conclusion remains that dolos breakage, while typically associated with some amount of movement, at least from adjacent units, is not necessarily associated with significant movement and vice versa.

Kendall (1988) suggested that, because of the high static stresses in many of these large dolosse, the magnitude of movement is not as significant in dolos breakage as the extent to which that movement causes a detrimental shift in boundary conditions (i.e. one that increases static loading). The build up of static stress with subtle movements and dolos wedging will be discussed more in subsequent discussions of long-term nesting and static stress history.

#### Spatial Distribution and Types of Dolos Displacement

The spatical distribution and types of dolos displacement have been described previously by Kendall (1988) and Kendall and Melby (1989). Generally speaking, the patterns have remained the same as those described earlier. With the exception of the only two dolosse observed to have moved during the sixth year, the dominant movement has continued to be upslope with slight settling plus rotation about the vertical or z-axis of the dolos (yaw).

Upslope movement has also been observed in the physical model for Crescent city and is believed to be an uprush dominated movement associated, at least in part, with the structures mild slope (Kendall, 1988; Jensen, 1984).

#### Evidence of Long-term Nesting

Long-term nesting has been documented by tracking the percent exceedence of single point displacements within the entire visible dolos field (approximately 400 dolosse) by season as shown in Figure 2. This necessarily includes untargeted dolosse so the measurement is limited to a determination of the magnitude of displacement experienced by a single identifiable point on each displaced dolos. This presentation clearly suggests that dolos movement has generally continued to subside with the possible

exception of the 1991-92 season.

Figure 2 - Percent exceedence of single point displacements within the visible dolos field by season. Note the trend of generally fewer displacements in successive seasons with the exception of the 1991-92 season.

With few exceptions, once a unit moved it failed to register a significant subsequent displacement, i.e. the unit nested with the movement and appears to have remained relatively stable. When a previously displaced unit did experience further movement, it was typically displaced a distance equal to or less than the initial displacement experienced. Units which have been repeatedly displaced were rarely observed to do so in the same direction but tended to move in directions which were 90 to 180 degrees different than their original displacement direction, perhaps indicative of rocking.

Overall, the general trend reflects nesting, especially in light of the wave power history shown in Figure 3(a) which suggests that the first winter season, when most of the movement occurred, was actually one of the milder ones. The more extreme subsequent storms seasons have generally produced less movement.

During the monitoring period, a small percentage of individual waves is likely to have approached the depth-limited design height. However, the design storm which was used in the physical model has yet to be experienced at the site.

Figure 3 - (a) Timing of dolos displacement surveys relative to offshore wave power;  
 (b) time history of targeted dolos displacements;  
 (c) time history of dolos static stress; design splitting tensile strength is approx 700 psi.

The wave power history plot (Figure 3(a)) also indicates the timing of all targeted dolos displacement surveys; the results of these surveys are shown in Figure 3(b). For the targeted dolosse (about seven percent of the visible dolos field), the displacement history is resolved into translations and rotations.

The net or total rotation values shown represent the largest rotational displacement about the dolos centroid experienced by any point on the dolos surface. Because a more thorough sampling of surface points has recently been conducted, the resultant rotational displacement values shown here are slightly higher than those reported earlier by Kendall, Davis, and Leach (1987) and Kendall and Melby (1989).

The general pattern during the first few years also differs somewhat from that presented in 1989. As explained in the earlier paper (Kendall and Melby, 1989), the data set at that time contained some questionable readings which were still being verified. The subsequent filtering of many of these data has produced a slightly less patterned looking time series. The previously suggested trend of a summertime reversal in dolos field movement is no longer apparent.

The time series of Figure 3(b) tracks the average value of cumulative displacement of all targeted dolosse from their original location. This reflects gross trends created by similar displacements occurring throughout the targeted dolos field, and masks some types of displacement experienced by dolosse which have repeatedly displaced. While this produces a more smoothed time history, few dolosse have experienced repeated displacements of major significance and the plot is not considered misleading. Figure 3(b) again suggests that the bulk of the structure's nesting occurred during the first season and that only minor adjustments have occurred since then with the possible exception of the 1991-92 season.

The increased movement reflected in Figures 2 and 3(b) for the 1991-92 season has actually resulted from only two dolosse, both of which happen to be in the targeted population. These two units are located near the water line and were displaced downslope between .5 and 1m. This movement could be wave induced but downslope has not been a typical direction; most wave-induced displacements have been uprush dominated or upslope. Furthermore, the wave power, if responsible, was relatively low during the last year. Another potential explanation could be the 6.9 Richter

scale earthquake of April 1992 whose epicenter was approximately 150 km south of Crescent City. However, large earthquakes do not necessarily cause dolos movement. A 6.9 Richter scale earthquake which occurred about 100 km west of Crescent City in August 1991 failed to produce a noticeable response in the visible dolosse. Another scenario is that the supports were pulled out from beneath these units as a result of subsurface breaks. Sonar records cannot be used to confirm the suspected subsurface breakage but an observed pattern of increasing static stress with time does suggest that some breakage is to be anticipated. The static stress history is discussed further in the following section.

### Static Stress History

The history of average static stress is compared with the wave power and displacement histories in Figure 3(c). In less than six years, sampled stress levels have risen over 80% while the average cumulative displacement of targeted dolosse has risen about 30%. The 1990, 1991 and 1992 data have shed new light on the post-nesting growth of static stress. The best-fit curve is no longer suggestive of any tapering off of the post-nesting stress growth as indicated in 1989, but rather of a steady increase of about 26 psi (0.18 MPa) per year. The flexural strength of the concrete suggests a splitting tensile strength on the order of 700 psi (4.8 MPa). Therefore, the yearly increase reflected in the plot represents about 4% of the applicable concrete design capacity. Increasing static stress with time has been attributed to subtle dolos movements and unit-to-unit wedging (Kendall and Melby, 1989).

Its important to point out that the sample size for the static stress history has been variable and extremely small. The number of reporting dolosse has fallen off from 14 to six (i.e. as little as 1% of the dolos population placed in 1986). Each data point in Figure 3(c) represents the mean of all functional dolosse; an examination of just the six dolosse which have remained more or less faithful throughout the monitoring period suggests that the annual increase may be as much as 6% of the design capacity.

### Structural Safety

The structural factor of safety applicable to the Crescent City dolosse is already something less than unity when applying a conservative approach based on

field results (Melby, 1992). The pattern of increasing static stress with time is not yet factored into the design procedure. Incorporation of this pattern further reduces the safety of the structure.

The average reported static stress is now in excess of 350 psi (2.4 MPa) and one dolos is reporting static stresses in excess of 500 psi (3.5 MPa). This leaves little residual strength for continued static stress growth, pulsating wave loads, and impact loads. No impact loads have been recorded at Crescent City. However, the magnitude of pulsating loads has been reported to be as great as 70 psi (0.48 MPa) from the prototype data (Howell, et al, 1989) and as high as 110 psi (0.76 MPa) in the physical model (Markle, 1989).

## CONCLUSIONS

The procedures used to monitor movement and static stress in the dolosse at Crescent City have been revisited and updated and the monitoring results through the sixth year have been reported.

Helicopter photogrammetry has produced significant increases in the accuracy with which dolos displacements are measured.

Dolos movement has continued but at levels well below that experienced during initial nesting; static stress has been building approximately linearly as a result of subtle dolos movements and unit-to-unit wedging.

Static stress is the most significant design parameter for these large dolosse and the increase in static stress with time has reduced the structural safety of the armor layer.

Monitoring at Crescent City is scheduled to continue for at least the next three years. Future proposed work includes collecting cores from select dolosse to test for any reduction in concrete strength due to fatigue.

## ACKNOWLEDGMENTS

The work described in this paper has been conducted as part of the Crescent City Prototype Dolos Study and the Monitoring Completed Coastal Projects Program sponsored by the U.S. Army Corps of Engineers (USACE). The authors would like to acknowledge contributions

from the following individuals to this effort: Victor Liu, Len Madalon and Alicia Wong of USACE San Francisco District, the staff of Richard B. Davis Company, Eric Meindl of the National Data Buoy Center, and Dennis Markle of the Coastal Engineering Research Center, USACE Waterways Experiment Station.

## CHAPTER 98

### IRREGULAR WAVE INTERACTION WITH PERMEABLE SLOPES

Nobuhisa Kobayashi<sup>1</sup>, and Andojo Wurjanto<sup>2</sup>

**ABSTRACT:** A one-dimensional, time-dependent numerical model is developed to simulate the flow over a rough permeable slope as well as the flow inside a permeable underlayer of arbitrary thickness for specified normally-incident irregular waves. The numerical model has been shown to be capable of predicting the time series and spectral characteristics of the reflected waves and waterline oscillations on a 1:3 rough slope with a thick permeable underlayer. The computed results are examined in detail to quantify the hydrodynamic processes which are difficult to measure in experiments. The computed results for the rough permeable and impermeable slopes are also compared to quantify the differences caused solely by the thick permeable underlayer.

#### INTRODUCTION

The permeability effects on wave run-up and reflection as well as armor stability have been regarded by previous researchers to be important for the design of highly permeable coastal structures such as berm breakwaters. Our quantitative understanding of the hydrodynamic processes involved with irregular wave interaction with permeable slopes is still rudimentary, although extensive hydraulic model tests have been performed.

Kobayashi and Wurjanto (1990) developed a numerical model for predicting the flow on a rough permeable slope as well as the flow in a thin permeable underlayer for normally incident irregular waves. This numerical model was limited to a thin permeable underlayer because it neglected the region landward of the waterline on the rough slope and the inertia terms in the horizontal momentum equation for the flow in the thin permeable underlayer. This numerical model turned out to be of limited practical use since the permeability effects of the thin permeable underlayer were found to be minor or negligible. Wurjanto and Kobayashi (1992) developed an improved numerical model by eliminating most of the shortcomings of the previous model as explained in the next section.

#### NUMERICAL MODEL FOR THICK PERMEABLE UNDERLAYER

Fig. 1 shows the symbols used in the improved numerical model where the prime indicates the dimensional variables. In Fig. 1,  $x'$  = horizontal coordinate taken to be positive landward with  $x' = 0$  at the toe of the slope;  $z'$  = vertical coordinate taken to be positive upward with

Figure 1: Definition Sketch for Numerical Model for Thick Permeable Underlayer

$z' = 0$  at the still water level (SWL);  $z_b' = z'$  - coordinate of the upper boundary of the permeable underlayer excluding the primary cover layer whose roughness effect is included by the bottom friction factor  $f'$  for the flow over the rough slope;  $z_p' = z'$  - coordinate of the lower boundary of the permeable underlayer which is assumed impermeable;  $d_t'$  = water depth below SWL at  $x' = 0$  where it is assumed that  $z_b' = z_p'$  at  $x' = 0$ ;  $\eta'$  = free surface or water table elevation above SWL;  $x_s' = x'$  - coordinate of the upper waterline defined as the location of  $\eta' = z_b'$ ;  $x_w' = x'$  - coordinate of the lower waterline defined as the location of  $\eta' = z_p'$ ;  $h'$  = water depth above the permeable slope given by  $h' = (\eta' - z_b')$  in the region  $0 \leq x' \leq x_s'$ ;  $u'$  = depth-averaged horizontal velocity above the permeable slope;  $h_p'$  = water depth inside the permeable underlayer given by  $h_p' = (z_b' - z_p')$  in the region  $0 \leq x' \leq x_s'$  and  $h_p' = (\eta' - z_p')$  in the region  $x_s' \leq x' \leq x_w'$ ;  $q_b'$  = volume influx per unit horizontal area into the permeable underlayer which is taken to be positive downward; and  $u_p'$  = vertically-averaged horizontal discharge velocity inside the permeable underlayer where the actual velocity is given by  $u_p'/n_p$  with  $n_p$  = porosity of the permeable underlayer.

Computation is performed using the dimensionless variables and parameters defined as

$$t = \frac{t'}{T'}; x = \frac{x'}{T'\sqrt{gH'}}; x_s = \frac{x_s'}{T'\sqrt{gH'}}; x_w = \frac{x_w'}{T'\sqrt{gH'}} \quad (1)$$

$$z = \frac{z'}{H'}; z_b = \frac{z_b'}{H'}; z_p = \frac{z_p'}{H'}; d_t = \frac{d_t'}{H'}; \eta = \frac{\eta'}{H'}; h = \frac{h'}{H'}; h_p = \frac{h_p'}{H'} \quad (2)$$

$$u = \frac{u'}{\sqrt{gH'}}; q_b = \frac{T'q_b'}{p_q H'}; u_p = \frac{u_p'}{p_q \sqrt{gH'}}; p_q = n_p p_u \quad (3)$$

$$p_u = \left[ \frac{n_p}{\beta_0(1-n_p)} \frac{d'_p}{T'\sqrt{gH'}} \right]^{1/2}; \quad \mu = \frac{\alpha_0(1-n_p)^2\nu}{\beta_0\rho_u d'_p \sqrt{gH'}} \quad (4)$$

in which  $t'$  = time;  $T'$  and  $H'$  = characteristic wave period and height used for the normalization, respectively;  $g$  = gravitational acceleration;  $p_q$  and  $p_u$  = dimensionless parameter expressing the order of magnitude of  $u'_p/u'$  and  $(u'_p/n_p)/u'$ , respectively;  $\nu$  = kinematic viscosity of the fluid;  $d'_p$  = characteristic stone diameter in the permeable underlayer;  $\alpha_0$  and  $\beta_0$  = empirical constant associated with the laminar and turbulent flow resistance, respectively (Madsen and White 1975); and  $\mu$  = dimensionless parameter expressing the order of magnitude of the laminar flow resistance as compared to the turbulent flow resistance.

The numerical model of Wurjanto and Kobayashi (1992) computed  $m = uh$ ,  $h = (\eta - z_b)$ ,  $q_b$  and  $m_p = p_u h_p u_p$  in the region  $0 \leq x \leq x_s$  where  $h_p = (z_b - z_p)$ , as well as  $m_p$  and  $h_p = (\eta - z_p)$  in the region  $x_s \leq x \leq x_w$  as a function of  $t$  and  $x$  using the one-dimensional, time-dependent equations of conservation of mass and  $x$ -momentum for the flow fields over and inside the permeable underlayer. It is assumed that  $m_p$  and  $h_p$  are continuous at  $x = x_s$ . The initial time  $t = 0$  for the computation marching forward in time is taken to be the time when the specified incident wave train arrives at  $x = 0$  and there is no wave action in the region  $x \geq 0$ . At the seaward boundary  $x = 0$  where  $h_p = 0$  is assumed, the normalized incident wave train,  $\eta_i = \eta'_i/H'$ , is prescribed as a function of  $t$  and the normalized reflected wave train,  $\eta_r = \eta'_r/H'$ , is computed as a function of  $t$  from the characteristics advancing seaward.

The numerical model is compared with the three test runs denoted by runs P1, P2 and P3 conducted by Cox (1989). The upper boundary of the permeable gravel underlayer was located at  $z'_b = (-d'_t + x' \tan \theta')$  with  $d'_t = 0.40$  m and  $\cot \theta' = 3$ . Its lower boundary was situated at  $z'_p = -d'_t$  for  $0 \leq x' \leq 0.566$  m and  $z'_p = -d'_t + (x' - 0.566) \tan \theta'$  for  $0.566$  m  $\leq x'$  where its thickness perpendicular to the impermeable base was  $0.566 \sin \theta' = 0.179$  m. The single layer of the gravel whose thickness was the median gravel diameter  $d'_p = 2.1$  cm is regarded as the primary cover layer. The other input parameters associated with (4) are taken as  $n_p = 0.48$ ,  $\nu = 0.01$  cm<sup>2</sup>/s at 20°C,  $\alpha_0 = 1140$  and  $\beta_0 = 2.7$ .

The significant wave height  $H'_s$  and the mean period  $T'_m$  of the zero upcrossings of the measured incident wave train are taken as the height  $H'$  and the period  $T'$  used for the normalization of the governing equations. The values of  $H' = H'_s$  and  $T' = T'_m$  for the three runs are listed in Table 1. The other values listed in Table 1 are as follows:  $\xi$  = surf similarity parameter based on  $H'$ ,  $T'$  and  $\cot \theta' = 3$ ;  $t_{max}$  = normalized duration of the measurement and computation;  $H_{m0}$  = spectral estimate of the normalized significant wave height;  $T_p$  = normalized spectral peak period;  $\xi_p$  = surf similarity parameter based on the spectral parameters  $H'_{m0} = H_{m0}H'$  and  $T'_p = T_pT'$ ; and  $f'$  = bottom friction factor estimated from the rough impermeable slope tests. The values of  $H_{m0}$  and  $T_p$  are obtained from the normalized incident wave spectrum  $S_i(f_*)$  with  $f_*$  = normalized frequency defined as  $f_* = f'_*T'$  computed from  $\eta'_i(t)$  for  $0 \leq t \leq t_{max}$  for each run. The frequency range of resolution of the measured incident and reflected waves based on three wave gages was  $0.12 < f_* < 1.6$  for run P1,  $0.15 < f_* < 2.0$  for run P2, and  $0.19 < f_* < 2.6$  for run P3 (Kobayashi et al. 1990). Table 1 also lists the values of  $p_q$  and  $\mu$  defined in (3) and (4). For these runs, the discharge velocity inside the permeable underlayer is generally small relative to the fluid velocity over the permeable slope, while the laminar flow resistance in the permeable underlayer is small as compared to the turbulent flow resistance.

Wurjanto and Kobayashi (1992) has shown that the numerical model can predict the time series and spectral characteristics of the measured reflected waves and waterline oscillations on the 1:3 permeable slope where the waterline meter measured the temporal variation of the elevation  $Z'_r$  above SWL of the intersection between the instantaneous free surface  $z' = \eta'$  and the straight line  $z' = (z'_b + \delta'_r)$  with  $\delta'_r \approx 2.75$  cm in the experiment. As a result, additional

Table 1: Three Test Runs Compared with Numerical Model

Run No.	$H'$ (cm)	$T'$ (sec)	$\xi$	$t_{max}$	$H_{mo}$	$T_p$	$\xi_p$	$f'$	$p_q$	$\mu$
P1	6.85	1.08	1.72	170.98	1.01	1.09	1.88	0.05	0.043	0.074
P2	5.35	1.36	2.44	268.98	1.03	1.56	3.75	0.05	0.041	0.088
P3	4.57	1.74	3.39	210.01	1.06	1.58	5.22	0.10	0.038	0.104

computed results are presented hereafter to elucidate the interaction processes of irregular waves with the rough permeable slope with the thick permeable underlayer. In the following, the computed results for run P2 are shown as typical results but the computed results for runs P1 and P3 are similar unless stated otherwise.

Fig. 2 shows the computed spatial variations of  $\eta$ ,  $u$ ,  $p_q q_b$  and  $m_p = p_u h_p u_p$  at  $t = 125.0$ , 125.5 and 126.0 where the shaded area shown with the variation of  $\eta$  corresponds to the permeable underlayer. Comparison of the variations of  $\eta$  and  $u$  reveals the sequence of water uprushing and downrushing on the permeable slope from  $t = 125.0$  to  $t = 126.0$ . The variations of  $p_q q_b$  indicate water flowing into the permeable underlayer during wave uprush and water outflow in the region below the trough of the free surface. The variations of  $m_b$  show the flux inside the permeable underlayer which appears to be driven mainly by the hydrostatic pressure gradient related to  $-\partial\eta/\partial x$  as is the case with the thin permeable underlayer (Kobayashi and Wurjanto 1990).

Fig. 3 shows the computed normalized spectra  $S_z^U$  and  $S_z^L$  of the upper and lower waterline oscillations, respectively. The upper waterline is taken as the normalized waterline elevation  $Z_r = Z'_r/H'$  on the permeable slope, whereas the lower waterline corresponds to the normalized elevation above SWL of the intersection between the instantaneous water table  $z = \eta$  and the straight line  $z = (z_p + \delta'_r/H')$  with  $\delta'_r = 2.75$  cm parallel to the impermeable slope  $z = z_p$ . Fig. 3 reveals that the permeable underlayer attenuates the high-frequency wave components significantly but damps the low-frequency wave components little as expected.

Fig. 4 shows the spatial variations of  $\bar{m} = \overline{uh}$ ,  $p_q \bar{q}_b$  and  $n_p \bar{m}_p = p_q \overline{u_p h_p}$  where the overbar indicates the time averaging over  $0 \leq t \leq t_{max}$ . The time-averaged volume flux per unit horizontal area,  $\bar{q}_b$ , is into or out of the permeable underlayer above or below the still waterline located at  $z_b = 0$ , respectively, where  $z_b = 0$  at  $x = 1.22$  for run P2. Correspondingly, the time-averaged volume flux  $\bar{m}$  and  $\bar{m}_p$  above and inside the permeable underlayer are landward and seaward, respectively, in the vicinity of the still waterline. The overall mass balance requires that  $\bar{q}_b$ ,  $\bar{m}$  and  $\bar{m}_p$  must approach zero at  $x = 0$ . In Fig. 4,  $\bar{m}$  approaches a very small negative value at  $x = 0$ . This implies that the numerical model may not predict the small time-averaged quantities very accurately partly because they are small relative to the corresponding time-varying quantities.

#### COMPARISON BETWEEN PERMEABLE AND IMPERMEABLE SLOPES

The additional computed results for the 1:3 rough permeable slope are presented hereafter in comparison with the computed results for the corresponding impermeable slope without the permeable underlayer. These runs corresponding to runs P1, P2 and P3 are denoted by runs I1, I2 and I3. The numerical model for impermeable slopes was shown to be capable of predicting the time series and spectral characteristics of the reflected waves and waterline oscillations on the 1:3 rough impermeable slope (Kobayashi et al. 1990). The measured reflected waves and waterline oscillations on the permeable and impermeable slopes were compared by Kobayashi et al. (1991) who found it very difficult to generate identical incident wave trains for the permeable

Table 2: Computed Values of  $\bar{r}$ ,  $\overline{Z_r}$ ,  $R_s$ ,  $R_{max}$  and  $N_{sc}$  for Permeable (P) and Impermeable (I) Slopes.

Run No.	$\bar{r}$		$\overline{Z_r}$		$R_s$		$R_{max}$		$N_{sc}$		$N_s$
	P	I	P	I	P	I	P	I	P	I	
1	0.09	0.20	0.06	0.12	0.57	0.91	1.01	1.48	1.16	0.49	2.29
2	0.15	0.55	0.05	0.14	0.78	1.52	1.11	2.20	1.49	0.38	1.78
3	0.26	0.66	0.05	0.11	0.94	1.72	1.85	3.24	1.43	0.45	1.52

and impermeable slope tests in a wave tank. In the present comparisons, the measured incident wave train for run PJ with J = 1, 2 and 3 is specified as input to the computation for run IJ so that the incident wave trains for runs PJ and IJ become identical. Moreover, the numerical models allow us to examine the permeability effects on the quantities which are very difficult to measure.

Fig. 5 compares the computed spatial variations of  $\eta_{max}$ ,  $\bar{\eta}$  and  $\eta_{min}$  as well as  $u_{max}$ ,  $\bar{u}$  and  $u_{min}$  for runs P2 and I2 where the subscripts *max* and *min* indicate the maximum and minimum values with respect to  $t$  over  $0 \leq t \leq t_{max}$ . The presence of the thick permeable underlayer reduces the vertical range of the free surface elevation  $\eta$  and the magnitude of the depth-averaged horizontal velocity  $u$  on the slope. The wave setup  $\bar{\eta}$  on the impermeable slope approaches  $\eta_{max}$  asymptotically since  $\bar{h} = (\bar{\eta} - z_b) > 0$  in the region reached by uprushing water during  $0 \leq t \leq t_{max}$ , whereas the wave setup  $\bar{\eta}$  on the permeable slope is connected to the wave setup inside the permeable underlayer. The negative value of  $\bar{u}$  on the impermeable slope is related to undertow on a beach (Kobayashi et al. 1989), whereas the time-averaged fluxes for the permeable slope shown in Fig. 4 result in the positive value of  $\bar{u}$  above the still waterline located at  $x = 1.22$  for runs P2 and I2. This suggests that the permeability may affect the net cross-shore transport of gravel and sand.

Fig. 6 shows the computed reflection coefficient  $r$  as a function of the normalized frequency  $f_*$  for runs P2 and I2 where  $r$  is defined as  $r = [S_r(f_*)/S_i(f_*)]^{1/2}$  with  $S_r$  = normalized reflected wave spectrum calculated from  $\eta_r(t)$  for  $0 \leq t \leq t_{max}$ . The computed values of  $r$  exceeding unity for run I2 may not be correct since  $r$  should not exceed unity unless additional waves propagating seaward are generated in the region  $x > 0$ . Fig. 6 indicates that the permeable underlayer dissipates the incident high-frequency wave components but damps the incident low-frequency wave components little. This is consistent with the computed results shown in Fig. 3. The average reflection coefficient  $\bar{r}$  may be defined as  $\bar{r} = [(m_o)_r/m_o]^{1/2}$  where  $m_o$  = zero moment of  $S_i(f_*)$ ; and  $(m_o)_r$  = zero moment of  $S_r(f_*)$ . The computed values of  $\bar{r}$  for the six runs listed in Table 2 increase with the increase of the surf similarity parameter  $\xi$  and  $\xi_p$  given in Table 1. Comparison of the values of  $\bar{r}$  for the permeable and impermeable slopes for given  $\xi$  and  $\xi_p$  indicates that the thick permeable underlayer reduced  $\bar{r}$  by a factor of more than two.

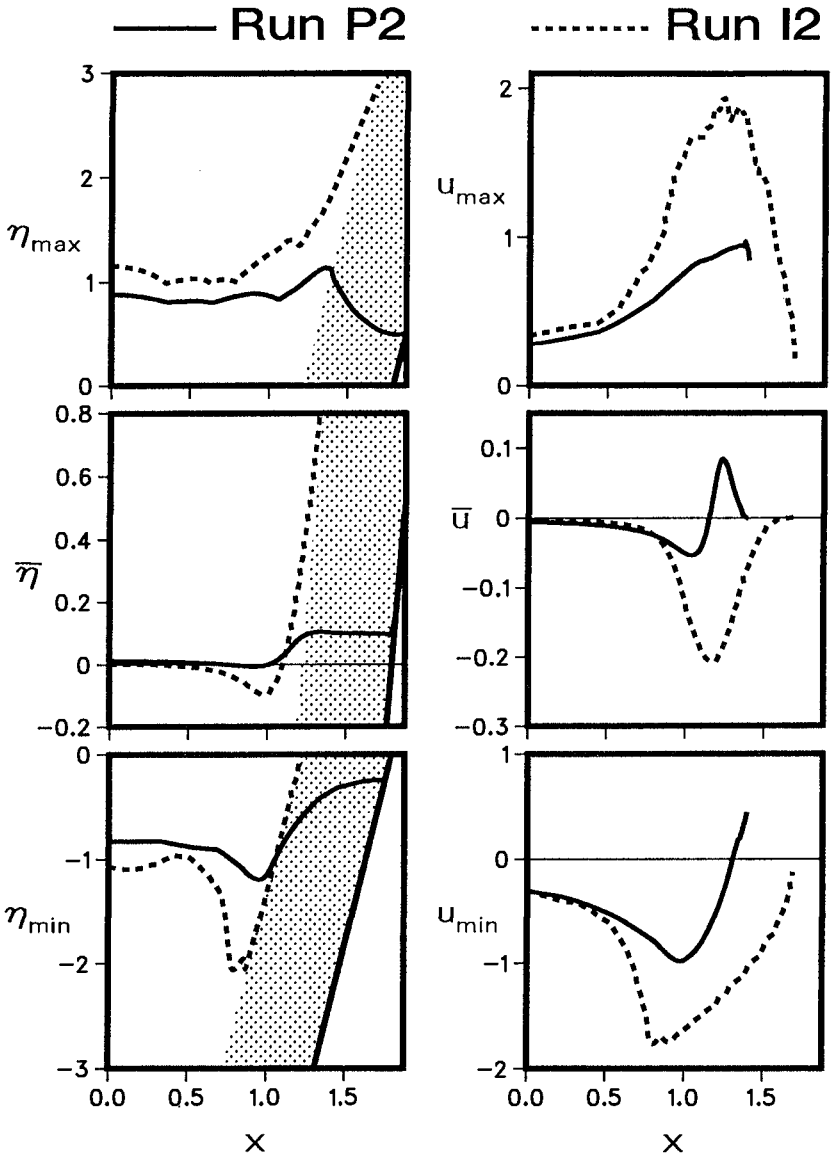

Figure 5: Computed Spatial Variations of  $\eta_{max}$ ,  $\bar{\eta}$  and  $\eta_{min}$  as well as  $u_{max}$ ,  $\bar{u}$  and  $u_{min}$ .

Figure 6: Reflection Coefficient  $r$  as a Function of Normalized Frequency  $f_*$ .

Fig. 7 shows the computed spectrum  $S_z^U$  of the normalized upper waterline elevation above SWL,  $Z_r(t)$ , for  $0 \leq t \leq t_{max}$ . The permeable underlayer reduces both high-frequency and low-frequency wave components unlike the computed results shown in Figs. 3 and 6. The interaction of uprushing and downrushing water on the impermeable slope seems to generate additional low-frequency wave components, whereas the permeable slope appears to absorb the incident waves with little water uprushing as shown in Fig. 2. The computed time series  $Z_r(t)$  for  $0 \leq t \leq t_{max}$  are also analyzed using the zero upcrossing method described by Kobayashi et al. (1990). Table 2 lists the computed values of  $\bar{Z}_r$ ,  $R_s$  and  $R_{max}$  for the six runs where  $\bar{Z}_r$  = time-averaged upper waterline elevation above SWL;  $R_s$  = normalized significant run-up defined as the average of the highest one- third run-up elevations above SWL; and  $R_{max}$  = maximum run-up elevation above SWL during  $0 \leq t \leq t_{max}$ .  $R_s$  and  $R_{max}$  increase with the increase of  $\xi$  and  $\xi_p$  given in Table 1. Moreover, the thick permeable underlayer reduces  $\bar{Z}_r$ ,  $R_s$  and  $R_{max}$  by a factor of slightly less than two. Fig. 7 also shows the exceedance probability  $P$  as a function of  $R_p/R_s$  with  $R_p$  = normalized run-up corresponding to the specific value of  $P$  together with the Rayleigh distribution. The probability distribution of the normalized run-up,  $R_p/R_s$  is affected little by the permeable underlayer whose effect on run-up may be accounted for by  $R_s$  only.

Fig. 8 shows the computed spatial variations of  $\bar{E}$ ,  $\bar{F}$ ,  $\bar{D}_p$  and  $\bar{D} = (\bar{D}_f + \bar{D}_B)$  for the flow over the permeable and impermeable slopes where  $\bar{E}$  = normalized specific energy;  $\bar{F}$  = normalized energy flux per unit width;  $\bar{D}_p$  = normalized energy flux per unit horizontal area into the permeable underlayer which is zero for the impermeable slope;  $\bar{D}_f$  and  $\bar{D}_B$  = normalized rate of energy dissipation per unit horizontal area due to bottom friction and wave breaking, respectively. The one- dimensional energy equations and associated quantities have been explained by Kobayashi and Wurjanto (1990) and Wurjanto and Kobayashi (1992). For the permeable slope as compared to the impermeable slope,  $\bar{E}$  does not increase much near the still waterline and the decrease of  $\bar{F}$  starts from  $x = 0$ , while  $\bar{D}_p$  is dominant as compared to  $\bar{D}$  calculated from  $\bar{D} = (-d\bar{F}/dx - \bar{D}_p)$ . For the impermeable slope with  $\bar{D}_p = 0$ , the comparison of  $\bar{D}_B$  and  $\bar{D}_f$  for runs I1, I2 and I3 indicates that  $\bar{D}_B$  is dominant for run I1 and  $\bar{D}_f$  is dominant for run I3, while  $\bar{D}_B$  and  $\bar{D}_f$  are equally important for run I2 as shown in Fig. 8.

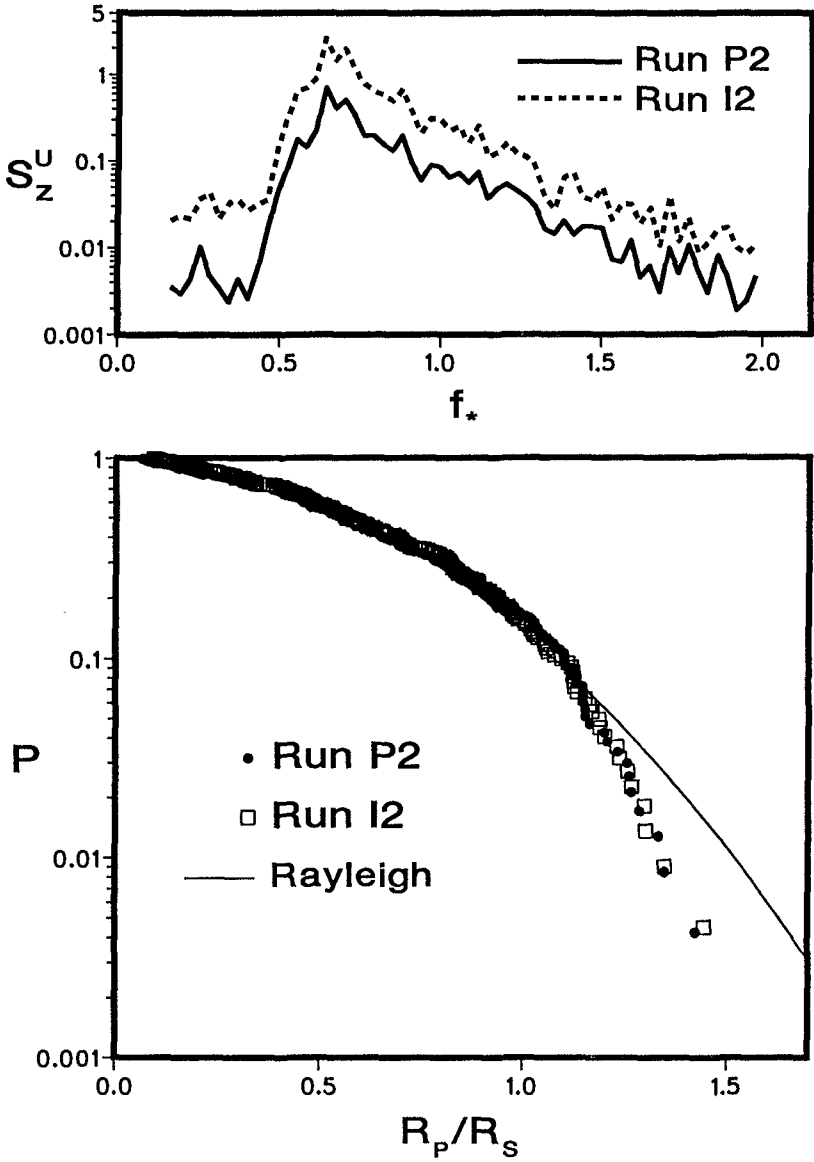

Figure 7: Computed Upper Waterline Spectrum  $S_z^U$  and Exceedance Probability  $P$  of Normalized Run-up  $R_p/R_s$  as Compared with Rayleigh Distribution.

Figure 8: Time-Averaged Energy Fluxes and Dissipation Rates for Flow over Permeable and Impermeable Slopes.

Finally, the permeability effect on armor stability is examined. Kobayashi and Wurjanto (1990) expressed the hydraulic stability condition against sliding or rolling of an armor unit on a rough permeable slope in the form

$$N_s = H'(s-1)^{-1} (\rho s/W')^{1/3} \leq N_R(t, z_b) \quad (5)$$

where  $N_s$  = stability number;  $H'$  = characteristic wave height taken as the significant wave height  $H'_s$ ,  $s$  = specific density of the armor units;  $\rho$  = fluid density;  $W'$  = median mass of the armor units; and  $N_R$  = armor stability function varying with the normalized time  $t$  and the armor location on the slope represented by  $z_b$ . For the gravel used in the experiment,  $s = 2.7$ ,  $W' = 14.8$  g and  $(W'/\rho s)^{1/3} = 1.76$  cm. The values of  $N_R$  at given  $t$  are computed in the region  $h' \geq d'_p$  since the armor units are assumed to be fully submerged. The local stability number  $N_{sx}(z_b)$  is defined as the minimum value of  $N_R(t, z_b)$  at given  $z_b$  during  $0 \leq t \leq t_{max}$ . The critical stability number  $N_{sc}$  is defined as the minimum value of  $N_{sx}(z_b)$  for the region  $z_b \geq -d_t$ . Table 2 lists the computed values of  $N_{sc}$  for the six runs together with the measured value of  $N_s$  for each run. Fig. 9 shows the spatial variations of  $N_{sc}(z_b)$  for runs P2 and I2 with  $N_s = 1.78$ .

The numerical model predicts that the gravel units in the region  $N_{sx} < N_s$  should slide or roll. Cox (1989) observed that loose gravel units on the permeable slope remained at their initial locations, whereas those on the impermeable slope were dislodged during the tests. Fig. 9 indicates the intense movement of loose gravel units in the wide region of the impermeable slope but the limited movement of loose gravel units on the permeable slope. As a result, the computed results are qualitatively consistent with the observations and the empirical formula of van der Meer (1988), although the sliding or rolling of gravel units may not result in the dislodgement of the gravel units from their initial locations. Fig. 9 also shows the spatial variations of  $\eta$ ,  $u$ ,  $du/dt$  and  $N_R$  at the time  $t = t_{sc}$  when the minimum value of  $N_R$  with respect to  $z_b$  equals the critical stability number  $N_{sc}$ . For run I2 with  $t_{sc} = 91.83$ , the critical armor stability occurs during wave uprush when the landward fluid velocity and acceleration are very large. For run P2 with  $t_{sc} = 197.66$ , the critical armor stability occurs during wave downrush when the seaward fluid velocity and acceleration are large. It is noted that the stability analysis of Kobayashi and Wurjanto (1990) neglects the direct effect of  $q_b$  on the armor stability and may not be very accurate.

## CONCLUSIONS

The numerical model developed for predicting the flow over a rough permeable slope and the flow inside a permeable underlayer has been used to elucidate the interaction processes of irregular waves with a thick permeable underlayer. The computed results have also been compared with those for the corresponding rough impermeable slope to examine the differences caused solely by the permeable underlayer. The thick permeable underlayer has been shown to increase the armor stability considerably and reduce the wave reflection and run-up significantly. Most of the computed results presented herein have been observed visually or described qualitatively by previous researchers. The numerical models yield quantitative data with high spatial and temporal resolutions. The numerical models also allow one to perform sensitivity analyses easily by changing only one input parameter in each numerical simulation. For example, it may be important for the design of berm breakwaters to examine the sensitivity of the computed results to the thickness, porosity and stone diameter of the permeable underlayer.

Figure 9: Spatial Variations of Local Stability Number  $N_{sx}$  and Flow Conditions at Time of Minimum Armor Stability.

## CHAPTER 100

### VERTICAL WAVE BARRIERS: WAVE TRANSMISSION AND WAVE FORCES

David L. Kriebel<sup>1</sup>

#### ABSTRACT

Wave interaction with a vertical slotted wave barrier, also called a wave screen or slit-type breakwater, is considered. A theoretical analysis is presented based on application of the continuity, momentum, and energy equations to flow through the slots in the breakwater, accounting for head losses associated with flow constriction and re-expansion. As a result, relatively simple expressions are found for the wave transmission coefficient and for the wave forces on the wall. These are then verified by laboratory experiments with regular waves.

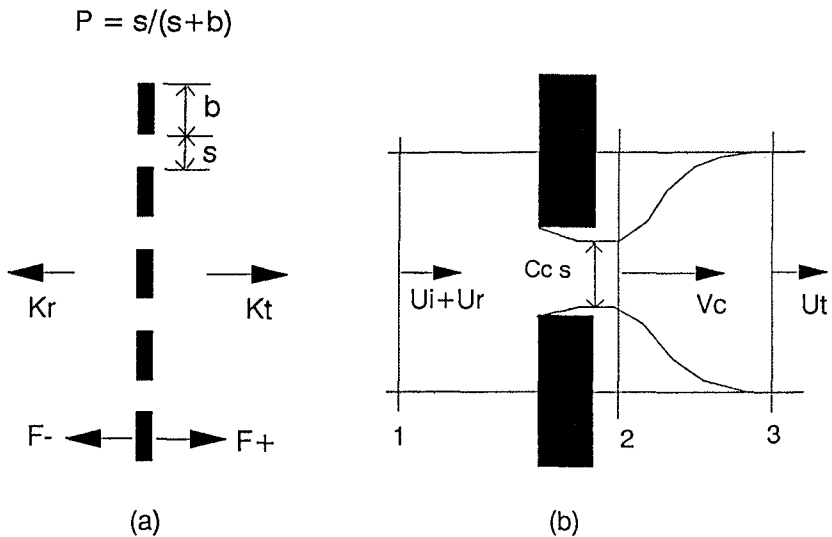

#### INTRODUCTION

Vertical-wall breakwaters are sometimes used to protect marinas and small boat harbors from both wind waves and boat wakes. These breakwaters encompass a variety of structures and have many names in the literature, including wave barriers, wave screens, and even wave "fences". In the Chesapeake Bay and other locations in the United States, these structures are most often built from marine lumber in the form of vertically-slotted walls extending to either full or mid-depth. Despite the growing use of such structures, however, relatively little comprehensive design information is available on either their wave transmission characteristics or on the wave forces that they would experience. As a result, these breakwaters have performed poorly in some instances, since even small gap spaces between the wall members allows a significant transmission of wave energy.

A definition sketch showing the plan-view of a slotted or slit-type vertical wave barrier with rectangular wall elements is shown in Figure 1. The primary variable defining the structure permeability is the porosity of the cross-section,  $P$ , defined as the ratio of the gap space,  $s$ , to the centerline-to-centerline spacing of the wall elements,  $s+b$ . Assuming that the wall is subjected to plane long-crested waves of height  $H_i$  with crests parallel to the wall, it is then of interest to describe the transmission coefficient,  $K_t = H_t/H_i$ , and the reflection coefficient,  $K_r = H_r/H_i$ , in terms of the porosity and in terms of the relative water depth and wave steepness. In addition, it is of interest to describe the wave force on one wall element,  $F$ , in either the positive or negative directions.

**Figure 1.** Definition sketch showing plan view of:  
(a) wall cross-section and (b) detail of flow through breakwater gap.

Vertical slotted or slit-type wave barriers have been actively studied for more than thirty years. Wiegel (1961), for example, estimated the transmission coefficient by assuming that the transmitted wave energy flux over width  $s+b$  was equal to that portion of the incident wave energy flux passing through the gap over width  $s$ . As a result, a simple expression for transmission was proposed as  $K_t = P^{1/2}$ . It is known, however, that this approach underestimates the transmission because it neglects the effects of wave reflection. In actuality, the pressure gradient across the wall is increased by the presence of the reflected wave and this drives more flow through the gap than is accounted for in Wiegel's method.

Recent analyses of these slit-type vertical wave barriers have been made using a variety of more complete analytical techniques. The most advanced solutions are based on potential flow methods and examples include the works of Kakuno (1983), Kojima et al. (1988), and Fugazza and Natale (1992). In these methods, the velocity potentials are found for the linear incident and reflected waves by applying both far field boundary conditions and matching conditions at the wall boundary. While solutions have been obtained for the wave transmission coefficient based on this approach, results have not been presented for the wave forces on the wall.

In contrast, simpler solutions based on fundamental hydraulics principles have also been proposed by Hayashi et al. (1966), Hayashi et al. (1968), Mei et al. (1974), Kondo (1979), and Urashima et al. (1986). These methods, also summarized by Mei (1983), have been developed for shallow water waves where wave pressures are hydrostatic and where flow velocities are uniform over depth. As a result, the equations for conservation of mass, momentum, and energy may be applied directly in two-dimensions in order to find the wave transmission coefficient. In most of these cases, solutions are also presented for the wave forces imparted on the wall by shallow water waves.

In the present paper, a hydraulic model similar to that of Hayashi et al. (1966) and Mei et al. (1974) is proposed for conditions of arbitrary water depth. It is assumed that both the wave transmission and wave forces are determined primarily by the strong horizontal fluid velocities that are driven through the breakwater gaps by the large pressure gradients that occur over the width of the wall. These maximum pressure gradients, and the associated maximum horizontal velocities, are largest during both the crest and trough phases of the wave. Because of this, it is assumed that the conservation equations can be applied first in horizontal layers and then depth-integrated to obtain the total wave transmission or the total wave force. Experimental verification of this simplified hydraulic theory is then presented based on recent laboratory experiments conducted at the U.S. Naval Academy.

## SIMPLIFIED HYDRAULIC THEORY

Consider the flow between two streamlines located along the centerline of adjacent wall elements and separated by width  $s+b$  as shown in Figure 1b. Conservation of mass requires the net discharge to be identical at each of the three sections shown in Figure 1b. As a result, the velocities at each of the three sections are related as:

$$u_i + u_r = C_c P V_c = u_t \quad (1)$$

where  $V_c$  is the velocity in the contraction and where  $C_c$  is the contraction coefficient, taken as  $C_c = 0.6 + 0.4P^3$  following Mei (1983). Based on linear wave theory, the velocities at the wave crest phase may then be given by

$$u_i = \sigma \frac{H_i}{2} Z_u \quad u_r = -\sigma \frac{H_r}{2} Z_u \quad u_t = \sigma \frac{H_t}{2} Z_u \quad (2)$$

where  $Z_u = \cosh(kh + kz) / \sinh(kh)$ ,  $k$  is the wave number,  $h$  is the water depth, and  $\sigma$  is the wave frequency. Because all velocities oscillate in time as  $\cos(\sigma t)$ , the wave heights are then related as

$$H_i - H_r - H_t \quad (3)$$

and the reflection and transmission coefficients are related as

$$K_r - 1 - K_t \quad (4)$$

Application of the momentum and energy equations then allows the pressure gradient across the wall to be determined. The momentum equation, applied between sections 2 and 3 in Figure 1b, is first used to find the pressure in the contraction in terms of the transmitted wave pressure and velocity. The energy equation, applied from section 1 to 2, is then used to relate the incident and reflected pressures to the pressure in the contraction. Combining these expressions, and using equation (1), finally yields the pressure drop across the wall as

$$p_i + p_r - p_t = \left(\frac{1}{C_c P} - 1\right)^2 \frac{1}{2} \rho u_t^2 \quad (5)$$

The right-hand-side of equation (5) represents the head loss through the gap as a quadratic function of the transmitted wave velocity. Following the method of equivalent linearization, e.g. Mei (1983), this may then be approximated as

$$p_i + p_r - p_t = K_{LOSS} \frac{4}{3\pi} \rho u_{tm} u_t \quad (6)$$

where  $u_{tm}$  is the magnitude of the transmitted wave velocity and where  $K_{LOSS}$  is the head loss coefficient. This is given as  $K_{LOSS} = ((1/C_c P) - 1)^2$  based on the flow constriction and expansion but will be modified later to account for other effects. As a result of the linearization, the velocities and pressures in equation (6) may be given by linear wave theory but the head loss on the right-hand-side will still retain a nonlinear effect of wave steepness.

**SOLUTION FOR WAVE TRANSMISSION**

The results presented above may now be extended into three dimensions to allow for variable pressures and velocities over the water depth, and to determine the overall transmission coefficient. Referring to Figure 2, it is first assumed that equation (6) models the pressure drop across the wall in any horizontal layer. It is further assumed that the dynamic pressures at any elevation are given by linear wave theory as

$$p_i = \rho g \frac{H_i}{2} Z_p \quad p_r = \rho g \frac{H_r}{2} Z_p \quad p_t = \rho g \frac{H_t}{2} Z_p \quad (7)$$

where  $Z_p = \cosh(kh + kz) / \cosh(kh)$ . Substitution of these expressions into equation (6), making use of equations (2) and (3), and integrating over depth then gives the following expression for wave transmission

$$\rho g H_i (1 - K_p) \int_{-h}^0 Z_p dz - K_{LOSS} \frac{1}{3\pi} \rho \sigma^2 H_i^2 K_t^2 \int_{-h}^0 Z_u^2 dz \quad (8)$$

The vertical integrations in this expression, from the seafloor  $z = -h$  to the still water level  $z = 0$ , are consistent with linear wave theory and account for the variable head losses over depth. As may be seen in Figure 2, the head losses are much larger near the surface than at the seafloor. It is also noted that by integrating to  $Z = 0$ , the head losses are assumed to be identical during both the crest and trough phases.

**Figure 2.** Illustration of vertical distribution of pressure and velocity.

Carrying out the operations in equation (8) ultimately yields a simple quadratic equation for the wave transmission coefficient as

$$T_t K_t^2 + K_t - 1 = 0 \quad (9)$$

where the variable  $T_t$  may be termed the *transmission function* and is equal to

$$T_t = K_{LOSS} \frac{1}{6} \frac{H_i}{L} \frac{\sinh 2kh + 2kh}{\sinh^2 kh} \quad (10)$$

The solution for wave transmission in arbitrary water depth is then found to have a form similar to that given by Mei (1983) in shallow water as

$$K_t = \frac{-1 + (1 + 4T_t)^{1/2}}{2T_t} \quad (11)$$

The solution for  $K_t$  in equations (10) and (11) contains the effects of both the relative water depth and the wave steepness, in addition to the breakwater porosity as reflected in the head loss coefficient. Figure 3 shows the variation in  $K_t$  as a function of porosity and relative depth for a fixed value of wave steepness. This shows that transmission is lower in shallow water than in deep water, because of the uniform velocities and therefore larger head losses over depth in shallow water. In addition, the transmission is essentially equal to that in deep water once  $h/L > 0.3$  or so. Figure 4 then shows the variation with wave steepness for deep water conditions. This illustrates that the head losses increase, and that the transmission decreases, for waves of higher steepness.

The functional dependencies on wave steepness and porosity may be displayed more clearly by considering deep water conditions, consistent with the experimental phase of this study, where  $T_t = K_{LOSS} H_i / 3L_o$  and where  $L_o$  is the deep water wavelength. As shown by Mei (1983, p. 263), the solution for wave transmission may be simplified based on series expansions of equation (11). For small amplitude waves or large gap spaces (small values of  $T_t$ ), it is found that

$$K_t = 1 - T_t = 1 - K_{LOSS} \frac{1}{3} \frac{H_i}{L_o} \quad (12)$$

On the other extreme, for large amplitude waves and narrow gap spaces (large values of  $T_t$ ), it may be shown that

$$K_t = \left( \frac{1}{T_t} \right)^{1/2} = \left( \frac{3}{K_{LOSS}} \frac{L_o}{H_i} \right)^{1/2} \quad (13)$$

Figure 3. Example of wave transmission as a function of relative depth.

Figure 4. Example of wave transmission as a function of wave steepness.

## SOLUTION FOR WAVE FORCES

The wave force per unit length on one wall element,  $f$ , may be determined by applying the momentum equation from section 1 to 2 as shown in Figure 1b. Wave forces are then found from the differences in the specific forces on either side of the wall, assuming that the pressure in the contraction is impressed over the wake behind the wall. In water of arbitrary depth, this is applied to each fluid layer and the force per unit length is found to vary as

$$f = (p_i + p_r - p_t) (s+b) - \rho g H_i (1-K_r) Z_p (s+b) \quad (14)$$

Depth integration from the seafloor to the still water surface, consistent with linear wave theory, then gives the total force on one wall element,  $F$ , as

$$F = \rho g \frac{H_i}{k} \tanh(kh) (1-K_r) (s+b) \quad (15)$$

This expression is similar to the force exerted by linear standing waves on a solid wall of width  $b$ , denoted by  $F_o$  and given by

$$F_o = \rho g \frac{H_i}{k} \tanh(kh) b \quad (16)$$

As a result, the normalized force on one wall element of a slotted or slit-type vertical wave barrier may be expressed in the form

$$\frac{F}{F_o} = \frac{1 - K_r}{1 - P} \approx (1 - K_r)(1 + P) \quad (17)$$

where  $P$  is the wall porosity. According to equation (4), it is also found that the forces are directly proportional to the wave reflection coefficient. The maximum wave force reduces to the usual solution for linear standing waves when the wall porosity and the transmission coefficient approach zero. In general, however, the force on a permeable wall depends on the wall porosity, the relative depth, and the wave steepness, due to the dependence of the transmission coefficient on these parameters.

In the experimental phase of this study, wave forces were measured on walls with large gap spaces in some tests; and, in fact, some tests were performed on a single rectangular wall element placed in the center of the wave tank such that the porosity was essentially equal to unity. Under this extreme condition, the force on the wall element predicted by equation (17) is equal to zero. However, non-zero forces were measured and these measured forces were, as expected, well-represented by the Morison equation as the sum of drag and inertia forces.

Therefore, two empirical modifications of equation (17) were introduced. First, the inertia force on a rectangular wall element was included so that the total force on the wall was actually modelled as

$$\frac{F}{F_o} = (1-K_p)(1+P) \cos \sigma t - \pi C_m \frac{t}{L} K_t \sin \sigma t \quad (18)$$

where  $t$  is the wall thickness and  $C_m$  is the inertia coefficient, assumed to equal  $C_m = 1 + 0.325\pi b/t$  or 4.06 for rectangular members with a width-to-thickness ratio of 3 as used in this study. In addition, the head loss coefficient was modified as

$$K_{Loss} = \frac{3\pi}{16} C_D + \left( \frac{1}{C_c P} - 1 \right)^2 \quad (19)$$

where  $C_D$  is the viscous drag coefficient on a single rectangular element, assumed to equal two in this work. As the porosity approaches unity, the second term in equation (19) goes to zero and the first term then leads to the same drag force as would be found from the Morison equation, as may be shown based on the series expansion introduced in equation (12). On the other hand, as the porosity approaches zero, the second term governs and may be an order-of-magnitude larger than the first term.

## EXPERIMENTAL VERIFICATION

Verification of the theoretical results is based on physical model tests conducted at the United States Naval Academy Hydromechanics Laboratory in a wave tank 36.6 m long, 2.4 m wide, and 1.55 m deep, equipped with a flap-type wavemaker. A full-depth vertical wave barrier was constructed of wooden wall elements having a width,  $b = 7.62$  cm, and a thickness,  $t = 2.54$  cm. Five gap spacings were then tested, with  $s = 0.84, 1.27, 2.54, 3.81,$  and  $7.62$  cm. Single wall members were also tested. As a result, data is available for wall porosities  $P$  of 0.10, 0.14, 0.25, 0.33, 0.50, and 0.97.

Test were conducted using regular waves with four different wave frequencies, three of which produced deep water waves with  $h/L > 0.5$ . Deep water waves were considered here because many wave barriers are constructed in or adjacent to marinas or navigation channels where they are subjected to short-period wind waves or boat waves that are actually in deep water relative to their wavelength. At each frequency, up to three values of wave height were tested producing values of wave steepness of  $H/L = 1/40, 1/20,$  and  $1/15$ . Incident and transmitted waves were measured with fixed wave gages located near the wavemaker and 1 to 3 m behind the wall respectively. Wave forces were measured by attaching one of the vertical wall members, manufactured out of aluminum to provide additional stiffness, to a force gage.

## EXPERIMENTAL RESULTS

Examples of theoretical and experimental results for deep-water regular wave transmission are shown in Figure 5. In Figure 5a, transmission coefficients are shown for each of the four wave frequencies tested for a constant wave steepness of  $1/40$ . Figures 5b and 5c show similar results for a constant wave steepness of  $1/20$  and  $1/15$  respectively, although only three wave frequencies were actually tested at the higher steepness due to wavemaker limitations. As can be seen, the theory provides reasonable predictions of the transmission at all values of wall porosity and at all three values of wave steepness. In general, there was no discernable dependence in the data on wave frequency at a given value of porosity, consistent with the theoretical predictions. In addition, despite the linearizing assumptions made in the theory, predictions are quite good even for the higher wave steepness. One notable aspect of these results, however, is that for low steepness waves in deep water, wave transmission may be as high as 70 or 80 percent even for wall porosities of just 0.15 to 0.25.

Typical results for wave forces on the instrumented vertical wall element are shown in Figure 6. Figure 6a shows results for a wave steepness of  $1/40$  while Figure 6b shows results for a steepness of  $1/20$ . Measured forces reported here are actually the average of the positive and negative maximum forces, since the linear theory does not distinguish between force magnitudes at the crest or trough phase of the incident wave. The forces are then given in dimensionless form as the average measured force divided by the force predicted by linear standing wave theory. One result of this normalization, however, is that results differ for each wave frequency as porosity increases so that forces at different relative depths do not collapse to a single curve.

In Figure 6, it may be seen that the simplified hydraulic theory provides a reasonable estimate of measured forces for all values of porosity and for both values of wave steepness. Interesting features of the force predictions are that: (1) for very low values of porosity, predicted forces are mostly independent of relative depth and collapse to a single curve and that (2) once porosity exceeds about 0.5, dimensionless forces are nearly constant but differs for each relative depth. Reasons for this behavior may be seen in equation (18). At small values of porosity, the first term in equation (18) governs and, since the transmission coefficient is not a function of relative depth for these deep water conditions, the predicted dimensionless force is therefore the same for all frequencies tested. On the other hand, as the porosity becomes large, the second term in equation (18) governs and leads to a dependence of the dimensionless force on the wall thickness-to-wavelength ratio. It is noted that there is more scatter in the force data at the lower wave steepness since the measured forces for some of these conditions, particularly for  $h/L = 1.20$ , were very small and influenced by the sensitivity of the force gage

Figure 5. Comparison of measured and predicted deep water wave transmission. (a)  $H/L = 1/40$  and (b)  $H/L = 1/20$ , and (c)  $H/L = 1/15$ .

**Figure 6.** Comparison of measured and predicted deep water wave forces: (a)  $H/L = 1/40$  and (b)  $H/L = 1/20$ .

Some tests were also performed with random waves; however, space limitations prevent a complete discussion of these results. In general, it was found that the simplified hydraulic theory worked well for random wave transmission and wave forces when the significant wave height and peak wave period were used to characterize the random sea. As a single parameter, the significant wave height seemed to characterize the random sea better than the root-mean-square wave height. Apparently, the significant height gives a larger overall head loss that more closely approximates the actual head losses of the larger waves in a random sea.

## CONCLUSIONS

Methods presented in this paper allow a straightforward calculation of wave transmission and wave forces for a vertical slotted or slit-type wave barrier. As shown by both theory and experimental data, wave transmission decreases as the wave steepness increases and as the porosity decreases. However, wave forces increase under these same conditions. As a result, wave transmission can be decreased only at the expense of a large increase in the wave force on the wall. This trade-off between wave transmission and wave forces often leads to wall designs that are too porous and allow too much wave transmission in order to be economical to construct, particularly if the wall is to be attached to an existing pier as is often the case.

Under the assumption that both high wave transmission and high wave reflection are undesirable near marinas or entrance channels, the wall porosity associated with the maximum energy dissipation may be found. Based on an energy balance, the dissipated wave energy will equal

$$E_{DISS} = E_i - E_t - E_r = 2 E_i K_t (1 - K_t) \quad (20)$$

where equation (4) has been used to related  $K_r$  to  $K_t$ . As a result, it is found that the maximum wave energy dissipation occurs when  $K_t = 0.5$ . For values of wave steepness considered in this paper, and for deep water waves, this requires wall porosities in the range of 0.09 to 0.17 to maximize the energy dissipation. Based on constructed vertical wave barriers that the author has visited, porosities are generally larger than this by a factor of two or even three in some cases. Thus, the wave transmission coefficient is often more than 0.70 and is usually higher than intended or desired. Smaller gap spaces are therefore recommended when possible and where increased wave forces will not jeopardize the integrity of the supporting structure.

## ACKNOWLEDGEMENTS

This work was supported by the Ocean Technology Program of the National Science Foundation as part of a Presidential Young Investigator Award. The author would like to thank Louise Wallendorf of the Naval Academy Hydromechanics Laboratory and former students Laurie Wood, Troy McClelland, and Eric Thomas for carrying out the laboratory work. The author would also like to acknowledge several useful discussions with Robert G. Dean of the University of Florida who recently proposed a similar hydraulic model for wave transmission in an unpublished consulting report.

## CHAPTER 101

### INTERACTION OF NONLINEAR WAVES WITH COASTAL STRUCTURES

J.J. Lee <sup>1</sup>; C. Chang <sup>2</sup>; F. Zhuang <sup>2</sup>

#### ABSTRACT

Interaction of transient nonlinear waves (modeled by solitary waves with moderate wave height) with submerged breakwater has been studied both numerically and experimentally. The emphasis is on the comparison between the numerical solution and the laboratory experiments on the wave transformation and the water particle velocity of the induced flow field.

For the numerical analysis, the Boundary Element Method (BEM) has been used for analyzing the wave field induced by the coastal structure. For the laboratory experiments the wave profiles are obtained by resistance type wave gauge; the two dimensional water particle velocities are obtained by a four-beam Laser Doppler Velocimeter (LDV) equipped with frequency shifting and with a fiber optics system. The LDV measurements are directed to obtain the detail of the wave kinematic properties important for ascertaining the dynamics of the modified wave field in the vicinity of the submerged breakwater. This serves as a critical check for the validity of the numerical computations.

Results of the numerical model have been found to compare well with the experimental data for the conditions studied in both the wave profiles and the water particle velocities beneath the waves as they interact with the breakwater.

# 1 Numerical Analysis

For the numerical analysis, the problem is formulated as a two-dimensional boundary value problems. The fluid in the solution domain is assumed to be incompressible and the flow irrotational, the viscous force is neglected. Potential theory is used for such flow condition and the Laplace's equation is obtained as the governing equation:

$$\nabla^2 \phi(\mathbf{x}, t) = 0 \quad \mathbf{x} \in \Omega(t). \quad (1)$$

The solution to the Laplace's equation is expressed as a boundary integral using the free space Green's function  $G(\mathbf{x}_i, \mathbf{x}_j) = -\frac{1}{2\pi} \log |\mathbf{x}_i - \mathbf{x}_j|$  and Green's theorem:

$$\alpha(\mathbf{x}_i) \phi(\mathbf{x}_i) = \int_{\Gamma(\mathbf{x})} \left[ \frac{\partial \phi}{\partial n} G(\mathbf{x}, \mathbf{x}_i) - \phi(\mathbf{x}) \frac{\partial G(\mathbf{x}, \mathbf{x}_i)}{\partial n} \right] d\Gamma(\mathbf{x}) \quad (2)$$

where  $\mathbf{x}_i$  and  $\mathbf{x}$  are position vectors for position on the boundary ( $\mathbf{x}_i$  can also be any where within the domain),  $\Gamma(\mathbf{x})$  is the boundary of the fluid domain  $\Omega$ ,  $\mathbf{n}$  the unit outward normal vector and  $\alpha(\mathbf{x}_i)$  a geometric coefficient.

The kinematic and the fully nonlinear dynamic free surface conditions are considered, i.e., on the free surface  $\Gamma_s$ ,  $\phi$  satisfies the following kinematic and dynamic boundary conditions:

$$\frac{D\mathbf{r}}{Dt} = \left( \frac{\partial}{\partial t} + \mathbf{u} \cdot \nabla \right) \mathbf{r} = \mathbf{u} = \nabla \phi \quad (3)$$

$$\frac{D\phi}{Dt} = -gy + \frac{1}{2} |\nabla \phi|^2 - \frac{p_a - p_o}{\rho} \quad (4)$$

with  $\mathbf{r}$  the position vector of a fluid particle at the free surface,  $g$  the acceleration due to gravity,  $y$  the vertical coordinate,  $p_a$  the pressure at the surface,  $p_o$  a reference pressure and  $\rho$  the fluid density.

The method used to update both the new position of the free surface and the potential function  $\phi$  on the free surface at the next time step was first suggested by Dold and Peregrine (1986). Similar procedure was also used by Grilli, Skourup & Svendsen (1989). Based on the Taylor expansion in a Lagrangian formulation (following a fluid particle on the surface), the explicit expressions for the position vector  $\mathbf{r}(t + \Delta t)$  and the potential function  $\phi(t + \Delta t)$  can be expressed as an infinite series as follows:

$$\mathbf{r}(t + \Delta t) = \mathbf{r}(t) + \sum_{k=1}^n \frac{(\Delta t)^k}{k!} \frac{D^k \mathbf{r}(t)}{Dt^k} + O[(\Delta t)^{n+1}] \quad (5)$$

$$\phi(\mathbf{r}(t + \Delta t), t + \Delta t) = \phi(\mathbf{r}(t), t) + \sum_{k=1}^n \frac{(\Delta t)^k}{k!} \frac{D^k \phi(\mathbf{r}(t), t)}{Dt^k} + O[(\Delta t)^{n+1}]. \quad (6)$$

The terms containing the material derivatives of  $\mathbf{r}$  and  $\phi$  in the above two equations are determined by first expressing them in terms of the potential function  $\phi$  and its time and spatial derivatives  $(\frac{\partial\phi}{\partial n}, \frac{\partial^2\phi}{\partial t\partial n}, \dots)$  and then solve the time and spatial derivatives by solving successions of Laplace's problems for the velocity potential  $\phi$  and its time derivatives. Each solution provides the nonlinear free surface boundary conditions for the next one. This is applicable because the Laplace's equation is indeed valid for all the time derivatives of  $\phi$ . The repeated solution of the Laplace's equation is actually quite simple after the coefficient matrix of the boundary element method has been formed and decomposed into an upper and a lower diagonal matrix. This is so because the coefficient matrix is only a function of the geometry and remain unchanged throughout the repeated solution process.

The Boundary Integral Equation is solved by using the so called Boundary Element Method which discretize the boundary into a finite number of elements. The boundary integration is performed on each element for a given  $\mathbf{x}_i, i = 1, 2, \dots, N,$

$$\alpha(\mathbf{x}_i)u(\mathbf{x}_i) = \sum_{k=1}^N \left\{ \int_{\Gamma_k} \left[ \frac{\partial u}{\partial n} G - u \frac{\partial G}{\partial n} \right] d\Gamma + \int_{\Gamma_k} \left[ \frac{\partial u}{\partial n} G - \bar{u} \frac{\partial G}{\partial n} \right] d\Gamma \right\}. \quad (7)$$

This produces a system of  $N$  linear algebraic equations for  $N$  unknowns. The integral equation is solved twice in the present study for both  $\phi$  and  $\partial\phi/\partial t$ . This gives a second order accuracy in the time marching scheme.

Interior solutions at the interior point  $x_j$  can be obtained using

$$2\pi\phi(x_j) = \int_{\Gamma} [\phi(x_i) \frac{\partial}{\partial n} (\ln r) - \ln r \frac{\partial}{\partial n} \phi(x_i)] ds \quad (8)$$

when all the potential values and normal potential derivatives on the boundary (for all  $x_i$ ) are known. Normally the value of the potential function inside the domain is not as important as its derivatives with respect to  $x$  and  $y$  because these values represent the velocity components at the interior points. The calculation of these velocity components can be performed by making direct derivatives of Equation 8 with respect to  $x$  and  $y$ , respectively,

$$2\pi \frac{\partial}{\partial x} \phi(x_j) = \int_{\Gamma} [\phi(x_i) \frac{\partial}{\partial x} (\frac{1}{r} \frac{\partial r}{\partial n}) - \frac{\partial}{\partial x} (\ln r) \frac{\partial}{\partial n} \phi(x_i)] ds \quad (9)$$

$$2\pi \frac{\partial}{\partial y} \phi(x_j) = \int_{\Gamma} [\phi(x_i) \frac{\partial}{\partial y} (\frac{1}{r} \frac{\partial r}{\partial n}) - \frac{\partial}{\partial y} (\ln r) \frac{\partial}{\partial n} \phi(x_i)] ds. \quad (10)$$

Only  $\phi$  at the interior point  $x_j$  is differentiated since that is where the derivatives are wanted. From Equation 9 & 10 it is seen that the values of  $\phi, \frac{\partial\phi}{\partial n}$  inside the integral are those on the boundary and they are not involved in the differentiation of the function.

## 2 Experimental equipment and experimental procedures

Experiments involving propagation of solitary waves over various submerged breakwater configurations are conducted in a wave tank 15.2 meter long, 39.4 centimeter wide, and 61 centimeter deep. The side-walls of the wave tank are made of glass and offer excellent transparency for laser beams. A programmable piston type wave generator is installed at one end of the tank and a sloping beach is installed at the other end of the wave tank.

Two different breakwater configurations are used in the experiment. The first breakwater is 45 inch wide, 4.5 inch high and is made of plywood. The second breakwater is of one third in width with the same height and is made of lucite. The breakwater is sunk and fixed to the bottom of the wave tank by adding lead weight.

The wave generating device is a piston type wave generator. It is powered by a hydraulic piston whose motion is controlled by a personal computer. The computer determines a voltage time history which defines the trajectory of the wave plate through a hydraulic-servo system. The wave generation program used by the computer allows motions of the wave machine to be prescribed for generating small amplitude periodic waves, finite amplitude periodic waves, and solitary waves.

Tap water is used to fill the wave tank to the desired depth. The depth is measured using a point gage which is mounted to a movable carriage traveling on a rail system installed at the top of both side walls of the wave tank. Resistance type wave gages are used to measure water surface elevations as a function of time. Three wave gages are installed at desired locations to make simultaneous wave profile measurements. The wave gages are connected to a Sanborn four channel oscillograph recorder which records the measurements on an oscillograph paper.

The water particle velocities are measured using a portable four-beam, two-component, fiber optic Laser Doppler Velocimeter (LDV) manufactured by TSI, Inc.. The LDV system used in the experiment consists of a 100 mW argon-ion laser, transmitting and receiving optics, a fiberoptic probe, frequency shifting and signal processing instruments. A multicolor beam separator separates the incident laser beam into four beams, two blue beams and two green beams. The four laser beams are focused into one point within the flow field to form a two-component system. Figure 1 provides a flow chart of the LDV system used for the present experiment. Two photomultipliers convert optical signals into electric signals. Two frequency shifters help attain accurate flow measurements in applications where high turbulence or flow

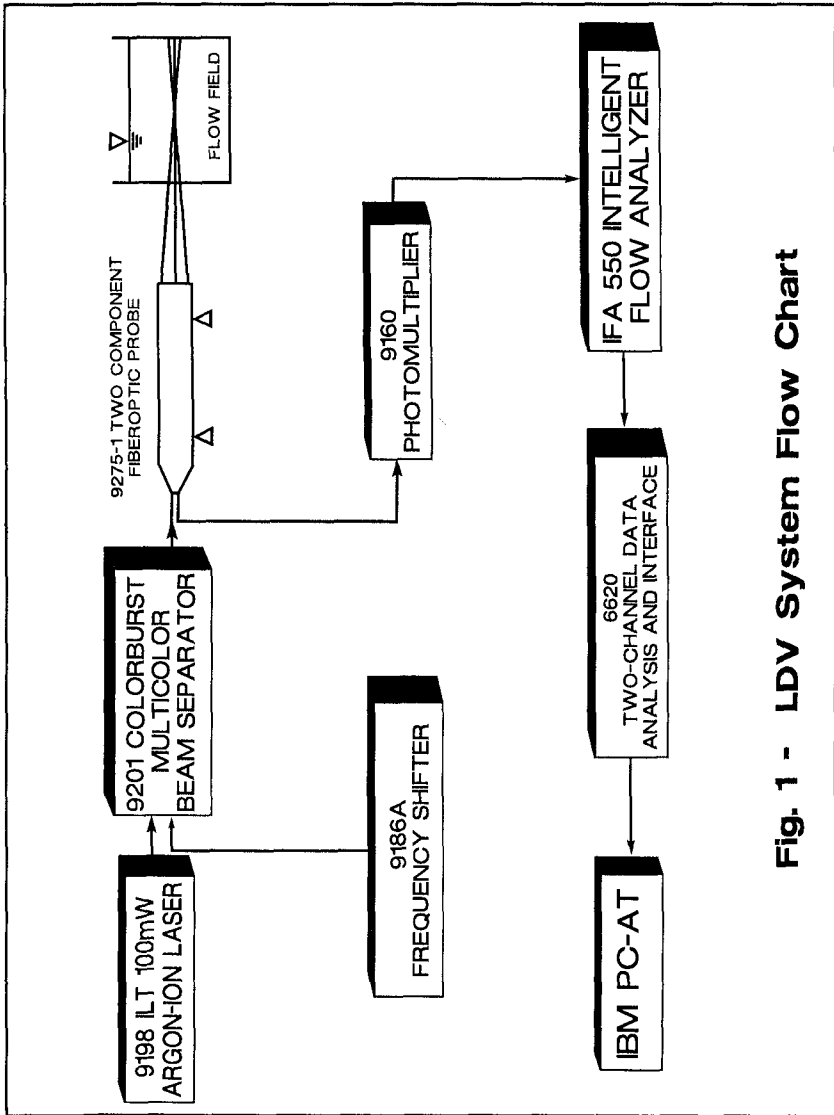

Fig. 1 - LDV System Flow Chart

reversals are anticipated. A fiberoptic probe which features focusing and receiving optics in one compact unit offer considerable ease for setting up the LDV system. Two IFA550 signal analysis systems are used for signal analysis. This is done by using a personal computer which manages the LDV measurements, stores velocity measurements, and displays the velocity-time history on the monitor. The whole LDV system is installed in a room close to the wave tank. When velocity measurements are needed, only the portable fiberoptic probe is moved to the measuring station and is mounted to a traversing mechanism which offers three dimensional positioning of the measuring point. Seeding is one of the key elements affecting the performance of the LDV measurements. Seeding particles must be small enough to move with the flow yet large enough to scatter sufficient light for ideal signal quality. Titanium Dioxide powder ( $\text{TiO}_2$ ) is used in the experiment and is proved to be a good seeding agent for water in the wave tank used for the present experiments.

### 3 Presentation and Discussion of Results

Figure 2 shows the wave profiles obtained from the numerical model at different time steps as the incident solitary wave propagates over a submerged breakwater which is at one-half of the water depth. The wave height/water depth ratio is 0.2, still water depth is 9 inches and the breakwater width is ten times the breakwater height. It should be noted that the vertical scale in Figure 2 is greatly distorted for easy visualization of the wave profiles. From Figure 2 it is seen that the frontal slope of the solitary wave is steepened when the propagating wave approaches the shallower water depth region. It is evident that the submerged breakwater acts to breakup the solitary wave with significant oscillatory tails.

Figure 3 shows the wave profiles computed at three locations: five water depth upstream, five water depth downstream, and on the top of the breakwater. The wave profiles computed from the present numerical model are compared with the wave profiles recorded from the present experiments. It should be noted that the wave profiles shown in Figure 2 are for the Lagrangian system and the time history of the computed wave profile shown in Figure 3 has been converted to the Eulerian reference system so that the computed wave profiles can be compared with the experimental wave profile directly. A comparison of the numerical results and the experimental wave profiles at the three locations shown in Figure 3 clearly demonstrate that the numerical model predicts the wave profile well. It is interesting to note that the peak amplitude of the transmitted solitary wave at the location five water depth downstream of the breakwater is actually larger than the amplitude of

Figure 2: Transformation of solitary wave over submerged breakwater

Figure 3: Comparison of wave profiles at three different locations (— present theory, ··· experiment)

the incident solitary wave before interacting with the breakwater. The shape of wave profile is different at the three locations showing the different degree of interaction with respect to transmission, reflection, and the varying water depths effect.

Figure 4 shows the numerical model and the experimental data on the horizontal and vertical water particle velocity at the same three horizontal locations and at 0.1 water depth below the still water level. In each of the three figures shown the horizontal velocities are significantly larger than the vertical velocities. Comparing the numerical and experimental results one can see that the agreement is quite good even though there is some scattering when the velocity is very small. The good agreement between the theory and experiment for the two components of the water particle velocities provides another critical check of the reliability of the numerical model.

Experiments for different water depths resulting in several cases for different relative submergence of the breakwaters have been conducted. LDV measurements for horizontal and vertical components of the water particle velocities have also been conducted at many different locations. However, space limitation does not permit presentation of these additional results.

Experiments have also been conducted for the case of breakwater crest height exactly at the still water level. Thus the incident solitary wave will travel across the top of the breakwater as if wave is traveling at zero water depth. A sketch of this series of experiments is shown in Figure 5. Wave profiles are measured at three stations: one at 10 water depth upstream of the breakwater (45" upstream), another at 3.33 water depth downstream of the breakwater (15" downstream) and the third station at 10 water depth downstream of the center of the breakwater (45" downstream).

The incident solitary wave height is  $H/h = 0.2$ . The measured wave profiles are presented in Figures 6-8. The ordinates of these three figures represent the wave height ( $H$ ) normalized with respect to the water depth ( $h$ ). The abscissa represents the real time in seconds.

From Figure 6 it is clear that the majority of the first wave represents the incident solitary wave and the second wave represents the reflected wave from the upstream edge of the breakwater. The shape of the reflected wave is quite similar to the solitary wave also. The wave profile shown in Figure 7 represents the transmitted wave profile at 15" downstream after the solitary wave has traveled above the breakwater crest region (at zero water depth). It shows that the primary wave is followed by a series of oscillatory tails. These oscillatory wave trains have been reformed into more regular oscillatory waves as they traveled further downstream as evidenced in the wave profile presented in Figure 8. It is interesting to observe the physical nature of the transmitted wave as it travels above the breakwater crest at

Figure 4: Comparison of water particle velocities at three different locations (— present theory; ··· experiment, u component; ▲▲▲ experiment, v component)

Figure 5  
 Sketch of an experimental set up showing the breakwater height, still water depth and locations of three wave profile measurement stations (not to scale)

Figure 6: Wave record at 45" upstream of the center of breakwater (station 1)

zero depth. The jet like water mass is translated into the shoreward region of the breakwater. This water mass which is above the still water level then plunge into the shoreward region by the continuous effect of the gravity forces causing the water mass in the shoreward region to exhibit significant undulations. Velocity measurements in this region have also been performed but due to space limitation they are not presented herein. Comparing the wave profiles shown in Figure 6, 7, and 8, it is clear that the breakwater serves to break up the incident wave resulting in significant higher frequency wave components in the shoreward region. This physical phenomenon is significant for the assessment of basin response of the shoreward coastal region.

## 4 Conclusions

The interaction of solitary wave with submerged breakwater has been studied both experimentally and numerically using a boundary element method. For incident solitary wave with moderate wave height and when the breakwater is deeply submerged the numerical results have been compared with the experimental data. It is shown that the agreement between the numerical results and the experimental data has been excellent. The comparison was performed in terms of the wave profiles at various stations and the horizontal and vertical components of the water particle velocities in the vicinity of the breakwater. The LDV measurements of particle velocities are shown to be effective in resolving the velocity time history.

A series of experimental data is also presented for solitary wave interacting with the breakwater which has the same height as the still water depth. Only the experimental data is available for this aspect of the study. Since the incident wave actually travels in a certain region of zero water depth before propagating toward the shoreward region, the present numerical method would not be able to simulate this flow condition. The experimental data show that a series of higher frequency oscillatory tails is generated in the shoreward region. This transmitted wave is reformed to become a series of well defined oscillatory wave as they propagate further away from the breakwater.

## 5 Acknowledgment

The authors are grateful for the generosity of Dr. Fredric Raichlen for permitting them to conduct the experiments at Caltech's W.M. Keck Laboratory of Hydraulics and Water Resources. The LDV system used in this study was partially supported by an NSF grant to USC under grant No. 8906898.

Financial support from the USC Foundation for Cross-Connection Control and Hydraulic Research for this study is gratefully acknowledged.

## CHAPTER 102

### Ponta Delgada Breakwater Rehabilitation Risk Assessment: with respect to Breakage of Armour Units

H. Ligteringen <sup>1</sup>, J.C. van der Lem <sup>1</sup>, F. Silveira Ramos <sup>2</sup>

#### Abstract

The outer portion of the Ponta Delgada Breakwater in the Azores was constructed in the sixties, applying an armour layer of 25 t Tetrapods on a slope of 3 in 4. After two decades of recurring damage and repairs, a redesign and rehabilitation were undertaken. An armour layer of 40 t Tetrapods on a slope 1 in 2 proved to meet the more severe design wave conditions established for the rehabilitation. This was the most attractive solution from cost and constructability viewpoint. To check the risk of breakage of these units under design conditions, the rocking was analysed both in hydraulic model and by means of an analytical simulation program. This allows to assess the actual impact velocities of rocking units and the percentage breakage under given wave conditions.

## Introduction

Since the major failures of some large rubble mound breakwaters in the period 1978 - 1982 the importance of concrete strength of armour units has become evident. Research was undertaken into this aspect and a joint-industry research project in The Netherlands succeeded in developing algorithms for impact velocities of rocking armour units and the stresses in the concrete. A simulation program was developed to compute the percentage breakage in the armour layer, using these algorithms. (Ligteringen et al, 1990).

The simulation program ROCKING was validated on the basis of several failure cases. One of the first applications in design was for the rehabilitation of the Ponta Delgada breakwater and is presented in this paper.

After a description of the original design and the general approach followed for rehabilitation, the details of the ROCKING analysis are presented.

## Breakwater Extension at Ponta Delgada

The port of Ponta Delgada on the island of San Miguel in the Azores is protected by a breakwater of which the outer 1000m is located in over 20 m water depth (Figure 1). This new part was designed and built in the sixties as a rubble mound structure, using an armour layer of 25 t Tetrapods at a slope of 3 in 4 (Figure 2).

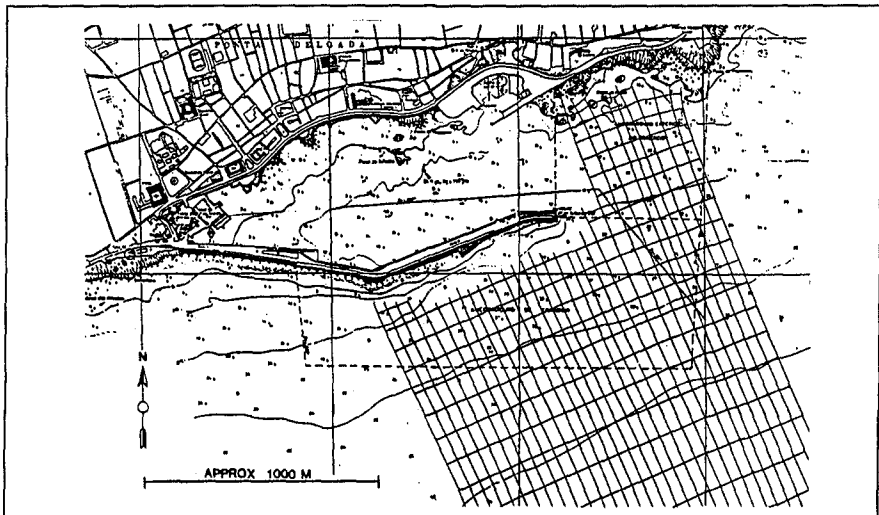

Figure 1. Ponta Delgada Breakwater Lay-out

The design wave height for the project was determined at  $H_s = 6.5$  m, having a return period of 50 year. Using a mass density of  $2.5 \text{ t/m}^3$  for the concrete, this meant a stability coefficient of 7.5, which is considered to be acceptable for a Tetrapod armour layer. The head of the breakwater was built as a vertical wall structure, composed of 5 caisson elements.

Unlike the older part of the breakwater, which had required relatively little maintenance, this new extension gave several problems, including displacement of Tetrapods, settlements of and cracks in the large superstructure, and settlements of the caissons at the head. Consecutive repair works were carried out in 1977/'78, 1983/'84 and in the period 1986 till 1988. It was after this rather extensive repair that the Portuguese Government ordered a detailed study into the causes of damage and the necessary improvements. This study was awarded to Consulmar in Portugal, with specialist assistance provided by Frederic R. Harris in the Netherlands.

Figure 2. Original Breakwater Design

### Rehabilitation Study

The study comprised re-analysis of the wave climate at Ponta Delgada, assessment of the main causes of the damage to the existing structure, generation and evaluation of alternatives for rehabilitation and selection of the concept for detailed design and construction.

The deep-water wave climate at the Azores was established by using hindcast storm data for the area covering a period of 8 years, obtained from the U.K. Meteorologic Office, refraction computations and in-situ measurements by a wave buoy. Because the execution of the measurements was delayed, a two-step approach was followed: a preliminary wave climate was defined for the first phase of the study, while for the detailed design the wave measurements and additional hindcast computations would provide the final design conditions.

The preliminary results indicated the 100-years wave height at the site to be about  $H_s = 10$  m. Spectral periods could range from  $T_p = 10$  to 18s.

Relevant wave directions for Ponta Delgada were in the sector  $90 - 270^\circ$ . The refraction analysis did not show significant concentrations of wave energy. As an example one such computation has been shown on Figure 1.

The great difference with the original design wave height explained most of the damage. Since its construction the structure had seen several storms with wave heights at or above design level. Along the older part of the breakwater the water depth had provided a natural limitation of the wave height to levels at or below the original design value, but along the new part much higher waves could reach the structure. Hydraulic damage to the armour layer at the seaward and leeside slopes (due to overtopping), but also higher forces on the superstructure and on the end-caissons were the result.

The development of alternatives was based on the following criteria:

- small damage was acceptable for the 100-yrs wave conditions ( $H_s = 10$  m,  $T_p = 10-18$ s)
- run-up and overtopping should be reduced to avoid ongoing damage to the superstructure.
- minimum cost for the rehabilitation and improvement.

Four basic solutions were developed, as shown on Figure 3:

- A. A berm placed directly in front of the existing structure, with its crest at -5.0m CD and a small slope towards -10.0m CD.
- B. A submerged breakwater at 150m distance seaward of the existing structure.
- C. A strengthening of the seaward face of the existing breakwater, maintaining the slope of 3 in 4.
- D. A strengthening of the seaward face at a reduced slope of e.g. 1 in 2.

Preliminary designs were made for each solution, based on test data for comparable structures, e.g. alternatives studied for the Sines and San Ciprian rehabilitations. Also aspects of constructability and future maintenance were taken into account. The main results are indicated on Fig. 3. Subsequently cost estimates were prepared for each solution.

Figure 3. Basic Solutions

Comparison of the four solutions showed that A and B would be far more expensive than solution D, which in turn was slightly more expensive than solution C. Notwithstanding the latter price difference, the overall evaluation led to selection of solution D, for several reasons:

- (i) in both solutions the application of large size Tetrapods should be checked during detailed design on possible breakage of these units. In this respect Solution D gave some "reserve" strength, which Solution C did not have.
- (ii) the overtopping of Solution D was estimated to be lower, due to the larger volume of the seaward body.
- (iii) the new layer of Tetrapods will underwater be entirely placed on a new secondary armour and hence more reliable. Above water the preparation of the existing Tetrapod layer and placing of the new units could be achieved accurately.

A more detailed cross-section of the selected concept is given on Figure 4. The proposed solution for the head was to place a rubble mound structure around the caissons. For the primary armour of this rubble mound 70 to 80 ton Antifer Cubes were selected, because Tetrapods of this size were considered to be too vulnerable with respect to breakage.

Figure 4. Selected Concept

### Detailed Design

Based on the selected concepts, the tasks for detailed design were to check and optimize both trunk and roundhead in modeltests, and to analyse the rocking and potential breakage of the 40 t Tetrapods on the trunk. The procedure followed during this phase of the project is given on Figure 5.

DETAILED DESIGN PROCEDURE	
WAVE ANALYSES	- 1 YEAR WAVE BUOY - HINDCAST MAJOR STORMS - COMPARISON BUOY/HINDCAST
MODEL TEST	- 2D AND 3D TESTS - HYDRAULIC STABILITY, ROCKING AND OVERTOPPING
TETRAPOD STRENGTH ANALYSIS	- ROCKING SIMULATION - COMPARISON MODEL/COMPUTER - BREAKAGE ASSESSMENT

Figure 5

As mentioned before the results of 1 year of buoy-recordings came only available during the detailed design. The final determination of the design

wave climate included the following analyses:

- from the measurement a total of 35 storm records were selected of which the highest reached a peak wave height of  $H_s = 9.0$  (December 1989).
- execution of additional hindcast computations by UKMO of the selected storm periods using the same model applied for the earlier hindcast analysis.
- comparison of measured and computed wave conditions, to evaluate the accuracy of the hindcast results and to correct for a possible bias in the computed wave climate.

It was fortunate for this analysis that some severe storms occurred during the year of measurements. The buoy kept functioning and an exceptional good basis for validation of the hindcast-model was obtained. The comparison between measured and computed wave heights for the most severe storm is shown on Figure 6, other records gave a similar good comparison. It could be concluded that the hindcast model gave an accuracy of the peak wave heights within 10%.

Figure 6. Comparison Measurements with Hindcast

Figure 7. Gumbel distribution of extreme wave heights

The extreme values of wave heights at the breakwater location (original series and additional storms, including refraction effects) were analysed, using several distributions. The best fit was obtained from a Gumbel distribution. As shown on Figure 7, a 100-years wave height  $H_s = 9.6$  m is obtained. Taking into account the above mentioned uncertainty of the hindcast results the value  $H_s = 10.0$  m was maintained as the design wave height.

As the next step in the design process model tests were carried out at the Laboratório Nacional d'Engenharia Civil (LNEC) in Portugal. Two- and three-dimensional tests were carried out on a combined model of trunk and head, scale 1 to 58. The model was subjected to storm sequences, comprising runs with  $H_s = 4, 6, 8, 10$  and  $12$  m. Other parameters varied are the wave period:  $T_p = 10, 13$  and  $18$  s; and the water level: Lowest Low Water Level (0 m CD) and a high level due to tide and storm set-up (+2 m CD). Measurements included recording of wave conditions, hydraulic damage, overtopping and the rocking of armour layers and berms. The latter measurements were made by observations during the tests and by black-and-white photograph overlays after each test run.

The results of the tests on the trunk confirmed the preliminary design to be adequate, but for the level of the toe berm at the seaward face. This had

to be lowered to -10.0mCD.

Of importance for the evaluation of the design with respect to rocking and breakage of Tetrapods was the comparison of hydraulic model with the corresponding results of the simulation model, as presented below.

Rocking Analysis

A schematic representation of the simulation program ROCKING is given on Figure 8. Input parameters for the simulation are:

- (i) loads:  $H_s$ ,  $T_p$  and number of waves  $N$ .
- (ii) structural parameters: relative mass density  $\Delta$  and nominal diameter of the armour unit,  $D_n$ .
- (iii) concrete quality: characteristic tensile strength  $f$ .

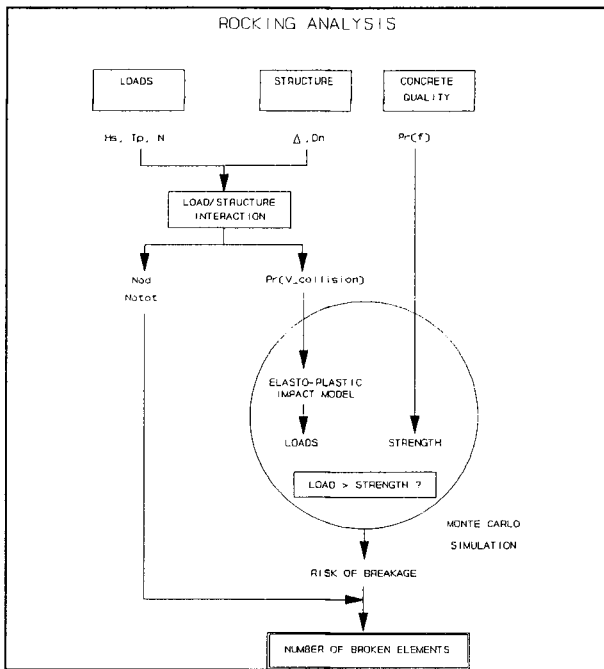

Figure 8. Schematic representation of ROCKING Analysis

For the determination of wave-structure interaction analytical formulae are used, which calculate the number of displaced units in the primary armour layer (Nod) for a given set of input parameters. Based on extensive tests on the correlation between hydraulic damage, rocking intensity and acceleration (Van der Meer and Heydra, 1990), the model generates the following results:

- (i) the sum of displaced and rocking units (Notot), from which the number of rocking units can be deduced.
- (ii) Impact velocity at collision of two adjacent units, given as a distribution function.

The latter distribution function is combined with the tensile strength of units (also given as a distribution function) in a stochastic determination of the risk of breakage for the applied input parameters. This is done by means of Monte Carlo simulation. For a large number of collisions the sampled value of impact velocity is translated into a peak-load exerted by the colliding units, applying a non-linear elasto-plastic impact model. (Van Mier and Lenos, 1991). Loads are converted into stresses, assuming at random one of a number of typical orientations for each of the two units. The calculated stresses are compared with the tensile strength, sampled from the distribution, and if the stress exceeds the actual tensile strength the unit is assumed to be broken.

The Monte Carlo simulation gives the percentages of rocking units, that will break in the pertaining wave conditions, or the risk of breakage. By multiplication with the number of rocking units the number of broken units, is obtained.

The actual simulation for the 40 t Tetrapods was carried out for the design wave conditions only, as shown on Figure 9. The concrete characteristics were taken in accordance with Portuguese standards, but for the relation between compression and tensile strength different expressions were applied, to test the sensitivity of the results for this value.

On Figure 10 a first comparison of measured results and computed displacement and rocking is presented. This gives a check on the validity of the empirical models for hydraulic displacements and rocking used in the simulation program.

The observed values show the range obtained from the model tests for the different wave periods. The percentage displaced units is very well predicted by the formula for Tetrapods, while the percentage rocking units is slightly overpredicted by the formula.

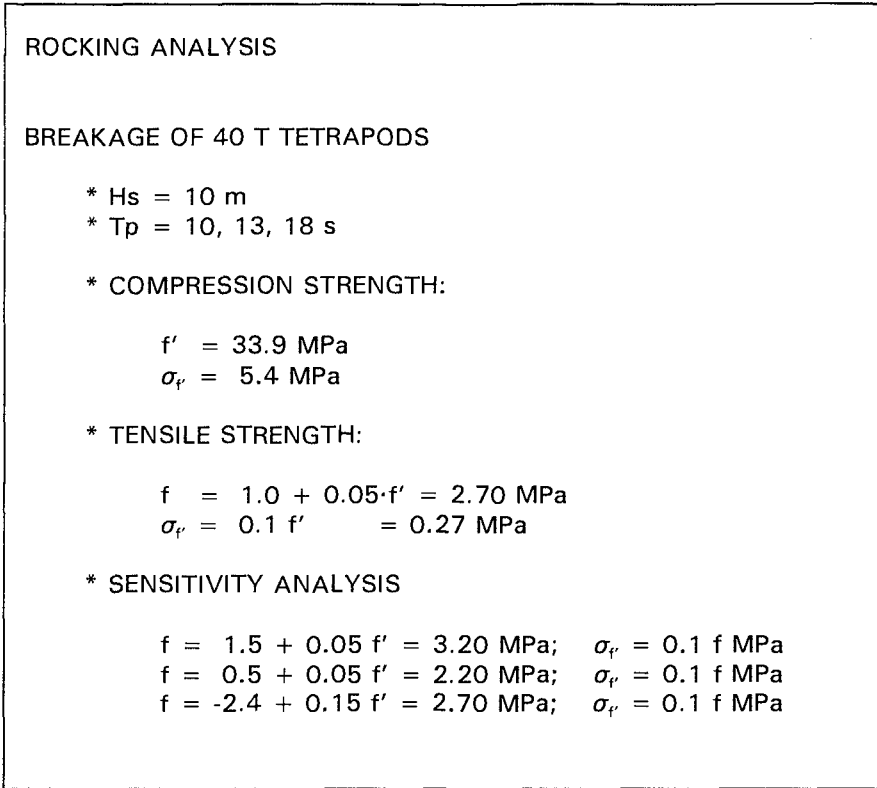

Figure 9. Boundary Conditions Rocking Analysis

The final results of the simulation are presented on Figure 11, depicting percentage of broken Tetrapods for  $H_s = 10$  m and the total damage, including the hydraulic damage given on Figure 10. The main conclusion is that the maximum percentage of total damage (3.5%) for the design wave condition is acceptable. Further it can be observed that the long wave periods are more critical for the hydraulic damage as well as for breakage. Finally the sensitivity of the results for the applied variations of the tensile strength is very limited (this does not mean that tensile strength is not important).

Figure 10. Comparison ROCKING results with test results

Figure 11. Results ROCKING analysis: risk of breakage.

Discussion of Results

The simulation program ROCKING allows to assess the additional damage to an armour layer due to breakage of the concrete units caused by rocking. The model proves to be a valuable design tool in cases such as presented in this paper, namely when the breakwater is protected by armour units of a size, which makes them susceptible to breakage.

The present version of ROCKING still has a number of limitations:

- (i) it can only handle primary armour layers comprising Cubes and Tetrapods.
- (ii) the empirical formulae describing wave-structure interaction are based on limited test data. Further testing is needed on influence of slope angle.
- (iii) the model assumes broken units to be eliminated from the slope, while in actual fact broken units may either cause further damage or

wedge themselves and contribute to the strength.

Further research will be needed to improve the range of application and the accuracy of the prediction.

Finally it is stressed that the model only describes breakage due to rocking. Other breakage may occur during placing or due to the static load on units, in particular those in the lower part of the armour layer.

### Acknowledgement

The program ROCKING was developed as the result of a joint-industry research project in The Netherlands, in which participated Frederic R. Harris B.V., F.C. de Weger International B.V., Royal Volker Stevin, Hollandsche Beton Groep N.V., Ballast Nedam Engineering B.V., TNO-Bouw, Delft University of Technology, Delft Hydraulics and Rijkswaterstaat.

## CHAPTER 103

### DURABILITY AND TESTING OF STONE FOR USE IN RUBBLEMOUND STRUCTURES

O.T. Magoon,<sup>1</sup> W.F. Baird,<sup>2</sup> J.P. Ahrens,<sup>3</sup> B.Edge,<sup>4</sup> H.D.Converse,<sup>5</sup>  
D.D. Davidson,<sup>6</sup> S.A. Hughes,<sup>7</sup> H.F. Burcharth,<sup>8</sup> D.D. Treadwell,<sup>9</sup>  
C.I. Rauw,<sup>10</sup> and A.W. Sam Smith<sup>11</sup>

Rubblemound structures protected from wave action by a layer of quarried rock (stones) are the most common form of breakwaters. While extensive guidelines and procedures exist to select the size of stone there is very little information available on procedures to be followed to assure the quality of the in-place stone. This subject is not covered in depth in the principal breakwater design manuals such as the U.S. Army Corps of Engineers Shore Protection Manual (1984).

However, review of existing breakwaters show that deterioration of the stone is a common problem and some projects have experienced very serious difficulties in assuring the placement of durable stone.

Review of construction specifications used throughout the world shows considerable variability in testing procedures required to define properties of the stone and different criteria to measure acceptability of a stone.

In response to these issues a two-day seminar was held in Cleveland, Ohio on 22 and 23 May 1991, sponsored by the Rubblemound Structures Committee of the Waterways, Port, Coastal, and Ocean Division of the American Society of Civil Engineers. Cleveland was an important location because of the serious deterioration of some of the stones placed on the Cleveland breakwater.

1. President, American Shore & Beach Preservation Association, 2. Principal, W.F. Baird & Associates, 3. Engineer, Sea Grant Program, NOAA 4. Principal, Edge & Associates 5. Coastal Engineer, U.S. Army Corps of Engineers, 6. Engineer, U.S. Army Corps of Engineers, 7. Engineer, U.S. Army Corps of Engineers 8. Professor, University of Aalborg, 9. Principal, Treadwell & Rollo Inc., 10. Consulting Engineer, Creegan & D'Angelo, 11. Consulting Engineer

Contractors, researchers, geologists, and design engineers were invited to discuss their common concerns associated with the durability of quarried rock on a breakwater. The results of this seminar are presented in the conference proceedings by Magoon, et.al.(1)

Some initial observations by the participants were as follows:

- Problems associated with stone durability are relatively widespread, based on the number of problem breakwaters described.
- Problems of stone durability may be as much a result of blasting and handling practices as they are the result of weaknesses in the properties of the rock.
- There are no reliable, systematic procedures for assuring rock of acceptable durability exists on the completed structure (other than to involve a geologist or engineer with considerable experience both with the type of rock and its use in the marine environment, and with construction procedures).
- In general, specifications addressing stone quality, as well as the handling and placement of stones on the breakwater, vary considerably from project to project and, in some instances, are unsatisfactory. It appears that inspection and quality assurance has on many breakwater projects been unsatisfactory.

The experience of all the participants, as discussed at the seminar, represent an extremely valuable source of information.

Some of the principal conclusions and overall observations for this seminar are as follows:

- There are considerable differences between North American and European procedures for defining the quality of rock.
- For any given procedure, there is not demonstrated criteria that will assure acceptable quality of stones on a breakwater.
- The stone type is not necessarily a useful guide. There is considerable variability in the quality of a particular type of stone.

- Previous successful use at a quarry does not assure acceptable stone. Stone quality may vary within a quarry and different production practices may limit stone durability.
- There must be coordination between laboratory investigations, production procedures and the design effort, field inspections, in order to achieve acceptable quality for breakwater stone.
- Stone quality may be, in some instances, achieved by re-designing production procedures which may, in turn, require different designs. For example, cut stones can be produced in some locations relatively inexpensively and with minimum damage to the stone. However, a rubblemound structure design using cut stones in a regular pattern requires considerable attention and more information than exists in current literature.
- The subject of stone durability is receiving considerable attention for researchers at Queen Mary College, London, the U.S. Army Corps of Engineers, Ohio River Division Laboratory, Cincinnati, and the Waterways Experiment Station, Vicksburg, Mississippi. However, it will take time before field data will substantiate recommended procedures.

In summary, there needs to be as much care expended in determining the in-place quality/durability of stone as there is in designing the structure. Considerable guidance is provided by the various authors in the seminar proceedings on methods of selecting and producing durable stone for coastal structures. However, there is no completely reliable testing method to assure that the stone's performance will be satisfactory.

# CHAPTER 104

## Dynamic Response of Vertical Structures to Breaking Wave Forces - Review of the CIS Design Experience-

J.G. Marinski<sup>1)</sup>; H. Oumeraci<sup>2)</sup>

### Abstract

The necessity of a dynamic analysis and the dynamic approaches available in the CIS, formerly Soviet Union, for the stability of vertical structures subject to breaking wave impact loads are first briefly discussed. The different steps of the dynamic method recommended by the Russian Design Guidelines VNIIG-77 are presented. The results obtained by using the different static and dynamic methods for a numerical example are compared. Finally the effect of the nonlinear behaviour of the foundation of the structure under impact loads is discussed.

### Introduction

A large experience is available in the CIS, formerly Soviet Union, on prototype measurements, hydraulic model investigations and dynamic analysis of vertical breakwaters. The stability of these structures has long been recognised as being a purely dynamic problem when subject to breaking wave impact loads. In this case, the widely accepted (particularly in Japan and western countries) static approaches using static loads and static stability analysis is not sufficient and should be supplemented or replaced by dynamic approaches.

It is the main objective of this paper to review and discuss the CIS design experience in this field. Emphasis will particularly be put on dynamic analysis, as compared to the commonly used static analysis.

### Necessity of Dynamic Analysis

The failures experienced all over the world by vertical breakwaters have clearly shown that the traditional design approach (static stability analysis) can neither explain nor predict the most relevant failure modes and mechanisms observed in the field (OUMERACI et al., 1991).

Some of the further reasons for accounting for the effect of impulsive loading due to breaking waves in the stability analysis of vertical structures are given below.

In Fig. 1, wave loadings and accelerations of a caisson breakwater simultaneously measured in large-scale model tests are shown (OUMERACI et al., 1991).

<sup>2)</sup> Dr.-Ing., Senior Researcher, Franzius-Institut, University of Hannover, Germany

FIG. 1: EFFECT OF IMPACT FORCE ON CAISSON BREAKWATERS

By comparing the effect of impact force 1 and that of the quasi-static force 2 on the response of the structure, it is seen that the commonly suggested opinion that only quasi-static pressure forces are relevant for the stability of vertical structures cannot be confirmed.

On the other hand, the rocking motions of the caisson breakwater are transmitted to the rubble mound foundation and to the seabed which may result in an accumulation of irreversible deformations, and thus in the initiation of failure. These rocking motions are expected to be particularly high for breaking waves with large entrapped air pockets, since this generally results in force oscillations with periods in the range of the natural period of oscillations of the structure (OUMERACI et al, 1992).

Furthermore, the local impact pressures with high magnitude and relatively short duration may be important for the structural stability of the components of the structure in the impact zone.

### **Brief Review of Methods for Dynamic Analysis of Vertical Structures**

In the CIS, the application of dynamic methods for the stability analysis of vertical breakwaters subject to breaking wave loads already started in the fifties (PETRASHEN, 1956).

Most of the methods developed in the CIS for the dynamic analysis of vertical breakwaters are generally based on a lumped parameter model of a rigid

body on a homogenous, elastic and isotropic half space. The difference between the various methods mainly consists in the type of soil parameters used in the conceptual model.

By briefly reviewing the available literature in this field, three schools of thoughts appear to emerge which are represented by PETRASHEN, SMIRNOV and LOGINOV, respectively.

PETRASHEN (1956) was certainly the first to suggest dynamic methods for the stability analysis of vertical breakwaters. His first suggestion concerns a rigorous mathematical formulation which is difficult to apply to a practical problem. His second suggestion, however, was almost fully empirical (PETRASHEN, 1956). Since the latter was essentially based on the results of very small-scale model tests (empirical design diagrams), it was not accepted in the design practice.

In the model of SMIRNOV & MOROZ (1983), the vertical structure is considered as a rigid body with three degrees of freedom, and the elastic half space is described by the JOUNG Modulus  $E_S$  and POISSON'S ratio  $\nu$  of the foundation soil beneath the structure. This method has also found no acceptance in the design practice, although it generally leads to much larger stress and deformation in the soil than the static approach.

The model of LOGINOV (1962) is the only one which has been recommended for design practice by VNIIG-77. Since design guidelines and standards generally reflect to a great extent the state of the art in the related field and country, this method (called here "VNIIG Method") will be discussed below in more detail.

### VNIIG Method for Dynamic Analysis of Vertical Structures

As already mentioned, the dynamic analysis recommended in the Design Guidelines VNIIG (1977) is principally based on the method developed by LOGINOV (1962). The latter makes use of the

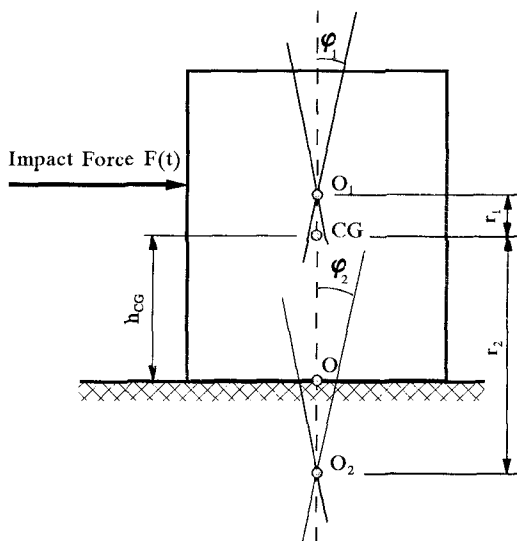

FIG. 2: DYNAMIC SYSTEM CONSIDERED BY VNIIG-77

large experience available in the field of the dynamics of machine foundation, particularly the methods introduced by SAVINOV (1955) and BARKAN (1948). In these methods, the subsoil is considered as an elastic half space. This means that the structure on an elastic foundation described by coefficients of subgrade reaction according to SAVINOV (1955) exhibits horizontal and rocking motions. The vertical motions which is assumed to be uncoupled is not considered.

In addition, the damping is neglected in the equations of motion, since only the first maximum amplitude is considered to be of interest for the stability of the structure. The dynamic system considered is given by Fig. 2, showing that the structure may rotate around point  $O_1$  and  $O_2$  located on the vertical axis through the centre of gravity  $C$  of the structure; i.e. the rotating and swaying motions have been replaced by the rocking motions around  $O_1$  and  $O_2$ . The different steps of the procedure recommended by VNIIG (1977) are described below.

**Step 1: Evaluation of Force Impulse and Load Durations**

The typical impact pressure history is schematised in Fig. 3 where  $t_r$  is the rise time up to  $p_{max}$ ,  $t_D$  the duration of the impact pressure and  $p_s$  the maximum quasi-static pressure.

FIG. 3: TYPICAL PRESSURE HISTORY

FIG. 4: PRESSURE IMPULSE DISTRIBUTION

The distribution of the pressure impulse on the structure front is given in Fig. 4 where:

$$z' = (0.55d_3 + 0.1H) \tag{1}$$

$$p_{im} = \frac{k_p}{\pi^2 \cdot g} \cdot \gamma_w \cdot a' \cdot v = 0.065 a' v \tag{2}$$

- with  $g$  = acceleration of gravity [ $m/s^2$ ]
- $k_p$  = 6.17 empirical coefficient [-]
- $\gamma_w$  = specific weight of water [ $t/m^3$ ]
- $v$  = velocity of the impinging wave [ $m/s$ ] according to the following formula:

$$v = 1.2 \sqrt{g \cdot d_3} \tag{3}$$

$a'$  = height of the wave impact zone [m] which is defined by the relationship:

$$\frac{a'}{H} = 1.6 \tanh \left( \frac{2H}{d_3} - 1.34 \right) \sin \frac{8\pi H}{L} = \leq 1.1 \tag{4}$$

$H$  = wave height [m]

$L$  = wave length [m]

$d_3$  = water depth at the wall [m]

The force impulse  $R_{im}$  [ts/m] is then obtained by:

$$R_{im} = k'_a \cdot p_{im} \left( d_2 + \frac{1}{2} z' \right) \tag{5}$$

where  $k'_a$  = empirical coefficient which accounts for the irregularity of the distribution of the pressure impulse along the wall (length  $l_C$ ):

$$k'_a = \frac{k_a \cdot a' + 1.3 k_a (d_2 + z' - a')}{d_2 + z'} \tag{6}$$

$$k_a = 0.55 + 0.15 \tanh \frac{H}{l_C} \tag{7}$$

$l_C$  = length of the caisson [m]

The point of application of the resultant force impulse  $R_{im}$  is located at a distance  $r_{im}$ :

$$r_{im} = \frac{d_2^2 + z' d_2 + z' \cdot \frac{2}{3}}{2d_2 + z'} \tag{8}$$

from the caisson base (Fig. 4).

The relative rise time  $t_r$  and the relative impact duration  $t_D/T$  of the resultant force corresponding to the impulse  $R_{im}$  is obtained from Fig. 5 as a function of the relative depth  $d_3/a$  ( $T$  = wave period).

**Step 2: Calculation of Natural Periods of Oscillations**

The swaying and rotating motions of the structure are combined to give rocking motions around  $O_1$  and  $O_2$  located above and under the centre of gravity  $C$ , respectively (Fig. 2).

FIG. 5: IMPACT DURATION AND RISE TIME OF HORIZONTAL FORCE

The points  $O_1$  and  $O_2$ , located at a distance  $r_1$  and  $r_2$  from the centre of gravity  $C$ , are determined according to the following formula:

$$r_{1,2} = \frac{h_0 \omega_x^2}{\omega_x^2 - \omega_{1,2}^2} \tag{9}$$

where:  $h_0$  = distance of the centre of gravity from the caisson base

$\omega_{1,2} = \frac{2\pi}{T_{N_{1,2}}}$  angular frequency of the free oscillation around  $O_1$  and  $O_2$ , respectively [rad/s] which is determined by:

$$\omega_{1,2} = \frac{1}{2\vartheta} \left[ (\omega_x^2 + \omega_\varphi^2) \pm \sqrt{(\omega_x^2 + \omega_\varphi^2)^2 - 4\vartheta(\omega_x^2 + \omega_\varphi^2)} \right] \tag{10}$$

where:

$$\vartheta = \frac{\theta_C}{\theta_0} \tag{11}$$

$\theta_C$  = mass moment of inertia around the centre of gravity  $C$  [ $\text{tm}^2$ ]  
 $\theta_0 = \theta_C + mh_0^2$  = Mass moment of inertia around the centre of caisson base  $O$  [ $\text{tm}^2$ ]

$$\omega_\varphi = \sqrt{\frac{C_\varphi \cdot I}{\theta_0}} \tag{12}$$

$$\omega_x = \sqrt{\frac{C_x \cdot A_f}{m}} \tag{13}$$

- where:  $m$  = mass of the structure  
 $A_f$  =  $a \cdot l_C$  = Area of the caisson base [m<sup>2</sup>]  
 $l_C$  = length of the caisson [m]  
 $I$  = moment of inertia of surface  $A_f$  [m<sup>4</sup>]  
 $\omega_\varphi$  = natural angular frequency of rotation around centre of caisson base O [rad/s]  
 $\omega_x$  = natural angular frequency of swaying motion [rad/s]  
 $C_x$  = coefficient of subgrade reaction for swaying motion [t/m<sup>3</sup>] which is defined according to SAVINOV (1955):

$$C_x = 0.7 \cdot C_z \tag{14}$$

with

$$C_z = C_o \left[ 1 + 2 \frac{a + l_C}{A_f} \right] \sqrt{\frac{W'}{2a}} \tag{15}$$

- where:  $C_z$  = coefficient of subgrade reaction for vertical motion [t/m<sup>3</sup>]  
 $a$  = width of the caisson base [m]  
 $l_C$  = length of the caisson [m]  
 $W'$  = submerged weight of the caisson [t/m]  
 $C_o$  = coefficient of subgrade reaction determined from field measurements or from Tab. 1 as a function of the thickness of the rubble mound foundation  $d_r$ , the width of the caisson base  $a$  and the type of the subsoil [t/m<sup>3</sup>]  
 $C_\varphi$  = coefficient of subgrade reaction for rotational motion [t/m<sup>3</sup>] according to SAVINOV (1955):

$$C_\varphi = C_o \left[ 1 + 2 \frac{a + 3l_C}{A_f} \right] \sqrt{\frac{W'}{2a}} \tag{16}$$

**Step 3: Calculation of Maximum Amplitude of Oscillations**

The angle of rotation around  $O_1$  and  $O_2$  are  $\varphi_1$  and  $\varphi_2$ , respectively. These angles and the resulting horizontal motion  $\delta$  at the base of the caisson are shown in Fig. 6.

$$\varphi_1 = \frac{2 k_{d_1} \cdot M_{im,1}}{\vartheta_{O_1} \cdot \omega_1^2 \cdot t_D} \quad [ rad ] \tag{17}$$

Characteristics of foundation		$C_o$ [kN/m <sup>3</sup> ]
1	<ul style="list-style-type: none"> <li>Rubble with small thickness <math>d_r/a \leq 0.25-0.30</math> on sandy subsoil, silty clay, peaty clay, peat or very soft clay</li> <li>on silty sand or very soft clay</li> </ul>	1250 - 1500
2	<ul style="list-style-type: none"> <li>Rubble with small thickness <math>d_r/a = 0.25-0.30</math> on sand or relatively stiff clay</li> <li>Rubble with medium thickness <math>d_r/a = 0.35-0.40</math> on soft soil (clay and sand)</li> </ul>	2000 - 3000
3	<ul style="list-style-type: none"> <li>Rubble with medium thickness <math>d_r/a \approx 0.40</math> on relatively compact subsoil (sand and clay)</li> </ul>	2500 - 4000
4	<ul style="list-style-type: none"> <li>Rubble with large thickness <math>d_r/a \geq 0.45</math> on subsoil with medium stiffness (sand and clay)</li> </ul>	4000 - 6000
5	<ul style="list-style-type: none"> <li>Rubble mound with large thickness <math>d_r/a \geq 0.45</math> on compact soil (gravel, compact sand, hard clay)</li> </ul>	6000 - 8000
6	<ul style="list-style-type: none"> <li>Concrete bags or concrete blocks</li> </ul>	11000 - 13000
7	<ul style="list-style-type: none"> <li>Rock</li> </ul>	30000 - 50000

TAB. 1: EVALUATION OF COEFFICIENT OF SUBGRADE REACTION  $C_o$

FIG. 6: DEFINITION OF ROTATION ANGLE  $\phi_I$  AND  $\phi_{II}$  AND DISPLACEMENT  $\delta$

$$\phi_2 = \frac{2 k_{d_2} \cdot M_{im,2}}{\delta_{O_2} \cdot \omega_2^2 \cdot t_D} \quad [ rad ] \quad (18)$$

The horizontal motion at the base of the caisson is given by:

$$\delta = \varphi_2 (r_2 - h_0) - \varphi_1 (r_1 + h_0) \tag{19}$$

where  $M_{im, 1}, M_{im, 2}$  = moment of the force impulse around  $O_1$  and  $O_2$ , respectively [t·m/m]

The dynamic coefficient  $k_{d1}$  and  $k_{d2}$  are obtained from response curves like those shown in Fig. 7 as a function of the ratio  $t_D/T_{N1,2}$  and  $t_r/t_D$ .

FIG. 7: RESPONSE CURVES AND DYNAMIC COEFFICIENT  $k_D$

**Step 4: Evaluation of Stability against Sliding**

The safety coefficient  $\eta_{SL}$  against sliding of the caisson is given by:

$$\eta_{SL} = \frac{(W' - n R_u) \mu}{R_s + n R_u} \tag{20}$$

- where  $\mu \approx 0.6$  friction coefficient (concrete - rubble mound)
- $R_u$  = uplift force [t/m]
- $W'$  = submerged weight of the caisson [t/m]
- $R_s$  = shear resistance [t/m]:

$$R_s = C_x \cdot \delta \cdot a \tag{21}$$

$$n = t_1 / T_N \leq 1$$

$t_1$  = time of occurrence of the maximum amplitude of motion [s],  $t_1$  is obtained from Fig. 8 as a function of  $t_D / T_N$  and  $t_r / t_D$

$t_D$  = impact force duration

FIG. 8: TIME OF OCCURRENCE OF MAXIMUM OSCILLATION

**Step 5: Evaluation of Maximum Normal Soil Stress**

The normal soil stress induced by the oscillation of the caisson in the foundation is given by:

$$\sigma_{1,2} = \frac{W' - nR_u}{a} \pm \left[ (\varphi_1 + \varphi_2) \cdot \frac{a}{2} \cdot C_\varphi + \frac{n \sum M}{W_r} \right] \tag{22}$$

where:  $W_r = a^2/6$  [m<sup>3</sup>]

$\sum M$  = moments around the centre O of the caisson base due to  $W'$ ,  $R_u$  and  $R_p$

$n = t_1 / T_{Ni}$  from Fig. 8

$\sigma_{1,2} = \text{max. normal soil stress under the caisson edges}$  ( $\sigma_1 = \text{shoreward}$  and  $\sigma_2 = \text{seaward}$ )

### Discussion of the Methods

#### a) Comparison of Existing Standard Design Methods

In order to compare the existing standard methods for the analysis of the stability of vertical breakwaters, the numerical example and the structure shown in Fig. 9 are considered.

Wave Conditions:  $H = 5.0\text{m}$ ;  $T = 7.8\text{s}$

FIG. 9: STRUCTURE FOR COMPARISON OF STANDARD DESIGN METHODS

The results of the calculation by using the methods of SNIP-82 (static approach), VNIIG-77 (static and dynamic approach), PETRASHEN (dynamic approach) and GODA (static approach) are summarized in Tab. 2 showing that:

- GODA method appears to be more conservative than the existing standard methods in the CIS with respect to the bearing capacity of the rubble mound foundation.
- The static approach of SNIP-82 appears to be the most conservative method with respect to the stability against sliding.

#### b) Comparison of Linear and Nonlinear Calculation

A model which accounts for the nonlinear behaviour of the foundation of a vertical structure subject to breaking wave impact loads has been suggested by LOGINOV (1969). In order to compare the results obtained by this model and the dynamic approach of VNIIG-77, the structure and the numerical example shown in Fig. 10 are considered.

Method	SNIP-82 (1982)	VNIIG-77 (1977)	PETRASHEN (1956)	GODA (1974)
Dynamic Force [kN/m]	-	316	1045	-
Rise Time [s]	-	0.39	0.075	-
Static Force [kN/m]	610	496	620	495
Uplift Force [kN/m]	120	140	71.4	140
$p_{\max}$ [kN/m <sup>2</sup> ]	76.5	62.4	220.0	52.0
$M_h$ [kNm/m]	3254	2730	-	3400
$M_u$ [kNm/m]	640	746	380	746

TAB. 2: RESULTS OF COMPARISON BETWEEN STANDARD DESIGN METHODS

FIG. 10: STRUCTURE FOR COMPARISON OF LINEAR AND NONLINEAR CALCULATIONS

The results of this comparison are summarized in Tab. 3, showing that much larger amplitudes of oscillations of the structure (and thus larger soil deformations) and slightly larger periods of oscillations are obtained by using a linear model instead of a nonlinear one.

Description of Parameters		RESULTS		
		Prototype Measurements	Nonlinear Calculations (LOGINOV, 1969)	Linear Calculation (VNIIG 77)
$R_{im}$	kNs/m	130	102	102
$P_{im}$	kNs/m	14.5 - 16.5	15	15
$F_{h,max}$	kN/m	715	497.3	497.3
$P_{max}$	kN/m <sup>2</sup>	160	62.4	62.4
$(r_2 - h_{CG})$	m	1.50	1.67	1.34
<b>Periods of oscillations</b>				
$T_1$	s	-	0.155 **)	0.158 **)
$T_2$	s	-	0.50 **)	0.55 **)
$t_D$	s	1.0	1.0	1.0
$t_r$	s	0.4	0.5	0.5
$\varphi$	rad	-	$0.541 \cdot 10^{-3}$ **)	$0.733 \cdot 10^{-3}$ **)
$\delta$	mm	1.0 - 1.1	1.2 *)	1.63 *)
*) By using static calculations $\delta = 4$ mm				
**) linear description yields overestimated results for deformations (by +35%) and oscillation periods (by up to +10%) as compared to nonlinear description				

TAB. 3: RESULTS OF LINEAR AND NONLINEAR CALCULATIONS

### Concluding Remarks

As the stability of vertical breakwaters against sliding and the bearing capacity of the rubble mound foundation are concerned, GODA method and further standard static methods used in the CIS are more conservative than the dynamic approach recommended by the Russian Design Guidelines VNIIG-77. However, this so-called "dynamic approach" appears to have some limitations which may be due to a) uncertainties in the impact load characteristics used for the calculations and b) uncertainties of the measurement (prototype and model tests) of the structure motions used for model validation (low natural frequency of the accelerometers).

Furthermore, it is suggested that nonlinear behaviour of the foundation of vertical structures should be accounted for in the case of breaking wave impacts for which soil deformations larger than 0.1 mm are expected. However, the use of linear model appears to yield conservative results with respect to soil deformations.

## CHAPTER 105

### A ROBUST ARMOR DESIGN TO FACE UNCERTAINTIES

Josep R. Medina,<sup>1</sup> Member ASCE

#### ABSTRACT

A new rubblemound breakwater cross section design named D-armor breakwater is presented. The D-armor cross section shows a significantly larger active armor area than the conventional cross section. The D-armor breakwater shows a similar resistance to the initiation of damage, but a significant increase of resistance to total failure. The observed structural response has a wave height range about 30% wider than the range corresponding to the conventional breakwater; the new section reshapes to an efficient S-shape armor near the total failure point. The D-armor breakwater appears to be a reasonable first step towards a convenient evolution from the conventional breakwater to more efficient designs; the wider structural response makes it appropriate for construction sites with large uncertainties in the estimation of the worst wave conditions in its lifetime.

#### INTRODUCTION

During the last decades, a continuous effort has been developed towards a better understanding of the structural and hydrodynamic factors affecting the stability of rubble-mound breakwaters. There are two main goals of the research effort: a) New calculation procedures for a more reliable and accurate estimation of the structural response in lifetime to optimize the designs; and b) New designs to reduce the construction cost, maintenance and risk of failure in its lifetime.

The design waves of a variety of maritime projects can only be decided assuming large uncertainties (see Goda, 1988). On the other hand, there are still significant differences in the calculation procedures proposed by different authors to estimate the structural response of conventional breakwaters for given wave

---

conditions (see SPM, 1984; Van der Meer, 1988; Bruun et al., 1990; Teisson, 1990; and Medina et al., 1990). Additionally, a number of concrete armor unit designs have been proposed and used in conventional cross sections; however, some of the most costly failures involved the use of special concrete armor units (Sines, San Ciprián, Tripoli, Arzew, Giona Tauro, etc.). Finally, some new breakwater cross sections are being proposed to reduce construction cost or to increase armor resistance; however, some failures have been reported recently (St. Paul berm breakwater) with only a few unconventional breakwaters actually built. This paper focuses the attention on a new breakwater cross section which may be considered a rational alternative design to allow a safe evolution from the conventional section used worldwide to more economically efficient unconventional designs.

A variety of alternative designs to the conventional rubblemound breakwater cross section have been proposed; the S-shape and berm type breakwaters are the most popular unconventional designs. In spite of the limited number of prototypes built according to these new designs, there is an increased number of laboratory results which indicate some of their advantages. However, the current practice for the design and construction of mound breakwaters is conservative; the frequent breakwater failures, and the unknown risks associated with designs that lack experimental verification, may explain the general opposition of designers to adopt radical changes in the classic mound breakwater cross section.

This paper describes a new rubblemound breakwater design: the D-armor breakwater. A comparative tentative analysis of the functional performances of the conventional, the S-shape, the berm, and the D-armor breakwater cross sections is given. The D-armor design appears to incorporate most of the best features of the different alternatives. It has a failure function that covers a wider range of wave heights than the conventional breakwater making the new design a robust solution to face large uncertainties associated with long term wave actions at a construction site.

## **D-ARMOR: A ROBUST DESIGN**

From a structural point of view, the D-Armor breakwater is similar to a conventional design with a significant increase of the armor thickness in the area where the mean water level crosses the external armor profile of uniform slope. Figs. 1-a and 1-b show the cross sections corresponding to the conventional and D-armor breakwaters. Before damage, the external profile is the same; however, when armor erosion increases the D-armor design progressively transforms to an S-shape breakwater (see Fig. 1-c). Because of this characteristic, the structural performance is similar to the conventional breakwater at low levels of armor erosion, but the reshaping process significantly increases the resistance capacity as an S-shape breakwater. Therefore, the D-armor design has the large structural response flexibility required to face the high levels of uncertainty usually associated with the design wave storms. Contrary to the conventional or S-shape breakwaters, the D-armor breakwater may be designed to reshape significantly during its lifetime.

Although the D-armor design is expected to reshape in its lifetime, it is totally different than the berm or reshaping breakwater illustrated in Fig. 1-d. The berm type breakwaters also have failure functions covering a wide range of wave heights and extremely high acceptable armor erosion levels. However, the berm breakwaters have large rock movements along the breakwater which are not present in the D-armor breakwater. The armor elements may be compacted in the reshaping process, but the rock displacements in the D-armor design are very short in comparison with the displacements observed in berm breakwaters.

**Figure 1.- Rubble-Mound Breakwater Cross Sections: a) Conventional; b) D-Armor; c) S-Shape; and d) Berm Type.**

The methodology used by Medina et al.(1990) to study the stability of the armor layer of rubble-mound breakwaters has been applied to experiments in the wave flume at the Universidad Politécnica de Valencia (30x1.2x1.2 m). The wave flume was divided in two parts to check simultaneously a conventional and a D-armor breakwater cross section. The stability of a deep water model with  $W_{50}=130g$  was analyzed and a preliminary test result using regular waves is given in Fig. 2, and compared to the data provided by Ergin et al.(1989), by Torum and Naess(1988), and by the SPM(1984). The D-armor breakwater shows a start of damage limit similar to a conventional breakwater. It shows an acceptable damage limit (reshaping) similar to the S-shape breakwater. The D-armor design is more resistant to total destruction than a conventional breakwater, it is more flexible than the S-shape breakwater, and it shows far shorter rock displacements in the reshaping process than the berm type breakwater.

Most breakwaters are built at a construction site where the long term wave climate or the maximum water depth (MSL to sea bed) can only be estimated with large uncertainties. In those cases, low risk and economically-efficient solutions demand robust designs with a flexible structural response having a wide margin

between start of damage and total destruction. To face large uncertainties in wave action, economic optimization leads to very conservative and expensive designs for brittle structural responses, and to less expensive and safer designs for flexible structural responses.

Figure 2.- Normalized Failure Functions Corresponding to Conventional, D-Armor, S-Shape, and Berm Breakwaters.

## DESCRIPTIONS OF EXPERIMENTS

In order to analyze the structural performance of the D-armor breakwater, series of 2-D experiments were conducted at the UPV wave flume (30x1.2x1.2 m), divided in two parts to test simultaneously a conventional and a D-armor cross section. A transparent glass divider was used for the verification of the same wave attack on the two cross sections during the experiments. Two capacitance wave gauges were placed in front of the model to analyze the incident and reflected wave train using a modified version of the method of Goda and Suzuki(1976). Fig. 3 shows the longitudinal cross section and plan view of the wave flume used in the experiments. The piston type wave paddle, hydraulically controlled with a servomechanism, was able to move according to the desired time series given by a PC used for the wave generation, recording, and analysis.

Fig. 4 shows the cross section of the conventional and D-armor breakwaters used for the experiments. Fig. 4a describes a typical deep water conventional section similar to that proposed by SPM(1984), with a cap on the top of the structure to

minimize overtopping. On the other hand, Fig. 4b describes a deep water D-armor section in which the armor thickness has been significantly increased in the area where the MWL crosses the armor, while the maximum armor water depth has been reduced from  $2H_d$  to  $1.5H_d$ .

Figure 3.- UPV Wave Flume: a) Longitudinal Cross Section, and b) Plan View.

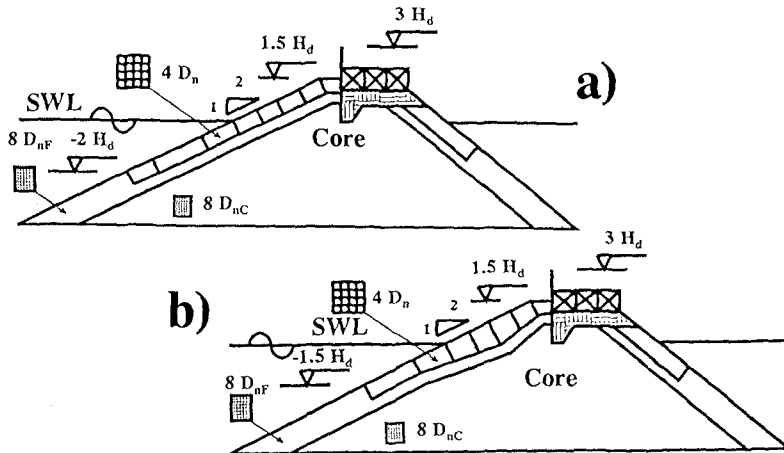

Figure 4.- Breakwater Model Cross Sections: a) Conventional, and b) D-Armor.

The armor was built of angular quarrystones with a uniform gradation, a median weight of  $W_{50}=130$  g, and a maximum deviation of 25% according to the SPM recommendations. The mean mass density was  $\rho_r=2.65$ , the slope was 2/1, and the zero-damage design wave height according to SPM(1994) was  $H_d=12$  cm

( $K_D=4$ ). The mean weight of the filter material and core was  $W_F=7.5$  g and  $W_C=4.3$  g, respectively; the corresponding equivalent cube sizes (Iribarren's terminology) or nominal diameters (Van der Meer's terminology) were  $D_n=(W_{50}/\rho_r)^{1/3}=3.66$  cm,  $D_{nF}=(W_F/\rho_r)^{1/3}=1.42$  cm, and  $D_{nC}=(W_C/\rho_r)^{1/3}=1.18$  cm. The armor thickness was  $2D_n$  in the conventional section, while it varied from  $2D_n$  to  $3.5D_n$  in the D-armor section. The filter thickness was about  $3.5D_{nF}$  in both sections. The stability of the cap was not analyzed, but its stability was guaranteed using extra lead ingots to avoid cap displacements. The stones of the armor were painted with different colors and placed in five bands of  $3D_n$  width above the SWL, and two bands of width  $4.5D_n$  and  $7.5D_n$  below SWL. The conventional section had an additional stone band to complete the armor section.

## Regular Waves and Random Waves

To evaluate the structural response of the D-armor breakwater, 10 tests with regular waves and 10 tests with random waves were conducted in the UPV wave flume from the no damage level to the total failure point of both the conventional and the D-armor breakwater models. The conventional section reached the total failure point first in all the tests; therefore, it was necessary to protect the destroyed conventional armor to continue the test with the D-armor model, in order to avoid a total collapse of the overall conventional structure. Once both armors were destroyed, all the armor stones were removed and classified by colors, to rebuild the profiles of both filter layers to put the armor units in their corresponding place for a new test.

The tests with regular waves were planned to be free of paddle reflected waves. The Iribarren's number ( $Ir=[\tan \beta]/[2\pi H/gT^2]^{0.5}$ ) was kept constant for all the runs of each test; different values of  $Ir$  were used for each test in the range  $1.7 < Ir < 4.2$ . Starting from the zero-damage design wave height,  $H_d=12$  cm, the wave height was increased 10% each run ( $H=H_d [1.1]^k$ ;  $k=0,1,2,\dots$ ) until total failure of the armor layer. Only a few waves were generated each run to avoid reflections on the paddle; therefore, the run of each energy level was repeated many times until an equilibrium profile was obtained in both breakwater models.

The tests with random waves were planned for not being free of paddle reflected waves. Seven minutes of random wave generation of JONSWAP spectra ( $\gamma=1$  and  $\gamma=10$ ) using the DSA-FFT method produced between 200 and 300 waves depending on the  $Ir$  value of the run. An Iribarren's number for random waves defined as  $Ir=[\tan \beta]/[2\pi H_{m0}/gT_{02}^2]^{0.5}$  was constant for all the runs of each test; different values of  $Ir$  were used for each test in the range  $2.2 < Ir < 3.5$ . Starting from the zero-damage design wave height,  $H_{10}=H_d=12$  cm, the wave height was increased 10% each run ( $H_{10}=H_d [1.1]^k$ ;  $k=0,1,2,\dots$ ) until total failure of the armor layer.

The measured characteristics of the incident wave trains do not exactly fit the desired waves; therefore, the results shown in this paper refer to the wave

characteristics actually measured and not the theoretical characteristics indicated as generated waves. According to the planned experiments, each test should keep constant the Iribarren's number ( $Ir$ ); however, the measured value of  $Ir$  for each run in each test showed small variations about the mean value, most of them in the interval  $\pm 1\%$ . The mean value of the measured  $Ir$ , of all the runs of each test, was taken as the actual measured  $Ir$  of the test.

## EXPERIMENTAL OBSERVATIONS

For a first evaluation of the D-armor versus the conventional breakwater, 10 tests with regular waves were carried out with  $1.7 < Ir = [\tan \beta] / [2\pi H / gT^2]^{0.5} < 4.2$ . Fig 5 shows the stability numbers ( $N_s = H / \Delta D_p$ ) corresponding to the start of damage and total failure point for both sections. SPM(1984) indicates a stability number for start of damage of  $N_s = 2$  ( $K_D = 4$ ), and a stability number for maximum damage (40% to 50%) of  $N_s = 3.12$ ; the  $N_s$  values suggested by SPM(1984) are near to the minima of the stability curves represented in Fig. 5, in agreement with the fact that the design method proposed by the SPM(1984) does not take into consideration the design wave period. The D-armor breakwater shows a start of damage curve similar to the conventional breakwater, but the total failure curve is qualitatively different, showing in all the cases analyzed a significantly higher resistance to total failure.

Figure 5.- Stability Numbers for start of Damage and Total Failure Corresponding to the Conventional and D-Armor Breakwaters.

According to the structural performance characteristics represented in Fig. 5, the D-armor breakwater shows a minimum stability number for total failure 15% higher than that corresponding to the conventional breakwater. However, the sea wind waves are not regular waves but irregular waves; a more realistic analysis of the structural response may be achieved using random waves.

## Criteria for the Measurement of Armor Damage

There are significant discrepancies in the literature about the quantitative definitions of the start of damage, the partial damage, and the total failure criteria. Therefore, it is convenient here to define first the concept of armor damage used in this paper.

Iribarren(1965) used the equivalent cube size,  $(W/\rho_r)^{1/3}$ , to normalize armor damages. Iribarren defined the total failure point as the erosion of the armor section affecting 100% of (his definition) the active zone, which had an area of  $9 D_n^2$ . Van der Meer(1988) also used the same concept re-named as nominal diameter,  $D_n=(W/\rho_r)^{1/3}$ , to normalize the measurements of the erosion of the armor layer. The erosion corresponding to the failure criterion given by Van der Meer(1988) was  $8 D_n^2$  (filter layer visible, slope:  $\cotan(\beta)=2/1$ ). On the other hand, SPM(1984) defined the damage as a percent of the armor units displaced from its breakwater active zone. However, while Iribarren(1965) defined his active zone as  $9(W/\rho_r)^{2/3}$  (two layer armor), SPM(1984) defined its active zone as that one which "extends from the middle of the breakwater crest down the seaward face to a depth equivalent to one zero-damage wave height below the still water level". Therefore, Medina et al.(1992) found that the total failure criterion is equivalent to an erosion of the armor layer of  $8 D_n^2$ ,  $9 D_n^2$ , or  $14 D_n^2$ , depending of who is the author in the above referred publications. On the other hand, Medina et al.(1990) presented a large scale experiment with partial armor damages higher than  $20 D_n^2$ . It is evident that the total failure point is quite subjective in the literature. In this paper, the total failure point is defined as the level of armor erosion which suddenly shows a sharp decrease of armor resistance with significant displacement of stones from the filter layer.

The start of damage point is also difficult to define. Van der Meer(1988) considered the start of damage point as an erosion of  $2 D_n^2$ ; however, SPM(1984) indicates an erosion of 0 to 5% of the active armor zone (0 to  $1.6 D_n^2$ ) as a no-damage condition. In this paper, the start of damage is defined as the point with a minimum, but detectable erosion of the armor. After 20 subjective evaluations of start of damage points, it was found that  $1.0 D_n^2$  is a reasonable estimation of the minimum detectable damage: the start of damage point. This quantitative definition of the start of damage point is in agreement with the no-damage condition in SPM(1984) because  $1.0 D_n^2 \approx 3\%$  of the active armor zone.

Between the start of damage and the total failure points, the armor damage was calculated as the eroded area of the armor profiles corrected for errors and settlement. Single profiles centered in both the conventional and the D-armor models were obtained using rods separated  $1.25 D_n$  with articulated circular feet having a diameter of  $0.75 D_n$ . A flexible aluminum chain mat was placed on the eroded armor to regularize the penetration of the rods into the armor. The distances in the profiles were normalized by  $D_n=(W/\rho_r)^{1/3}$ . The origin of coordinates was located at the waterline where the SWL crossed the original armor profile. The normalized dimensionless profiles obtained in this experiment were similar to those shown by

Medina et al.(1990) from the large scale experiment conducted in the O.S.U. Wave Research Facility. For the lower damage levels, damages were estimated counting colored stones moving among bands of different color (assuming 38% porosity), and high levels of damage were estimated from the rod profiles.

**Experimental Results**

In this experiment, and in the large scale experiment described by Medina et al.(1990), the erosion profiles show an almost constant neutral point between the erosional and the accretional armor areas. The water depth of that neutral point,  $h_n$ , was observed to be about  $h_n = H_d$  independently of the level of armor damage. Fig. 6 shows the maximum depth of the neutral points,  $h_n$ , for both D-armor and conventional breakwaters. The depth of the neutral points appears to be independent of  $Ir$  with an 80% confidence band covering the range  $0.8H_d$  to  $1.5H_d$ . The D-armor breakwater was built with filter stones below  $h = 1.5H_d$ , and no significant movement of those small stones were observed during the tests; therefore, there seems to be no activity of the armor stones below  $h = 1.5H_d$ .

**Figure 6.- Maximum Depth of the Neutral Point.**

Fig. 7 shows the maximum damage measured,  $D_{max}$ , in both the conventional and D-armor breakwaters. The maximum damage seems to be independent of  $Ir$ ; the D-armor breakwater showed  $D_{max}$  larger than the conventional breakwater, and the difference roughly corresponds to the increase of the D-armor thickness (area:  $11.8D_n^2$ ). The extra volume of armor stones used to increase the armor thickness of the D-armor breakwater appears to be fully active during the armor erosion process

before the total failure of the structure, contrary to the armor stones placed below  $h=1.5H_d$  (area:  $7.3D_n^2$ ) in the conventional section, which appear to be inactive during the erosion process. From both Figs. 6 and 7, the inefficiency of the conventional breakwater is apparent, as is the possibility of improving the breakwater cross sections by concentrating the volume of armor stones in the active zones where the wave action is more intense.

Figure 7.- Maximum Armor Damages Measured During the Experiment.

Although it is evident that the D-armor breakwater has as many as 50% more active armor stones than the conventional breakwater, it is convenient to present the measured failure functions with random waves, in order to give an appropriate description of both structural responses. The first problem to be solved concerns the definition of variables in the representation of failure functions of breakwaters under random waves. A simple representation of damage versus  $H_{m0}=4[m_0]^{0.5}$  is not appropriate because it is well known that the damage depends also on the number of waves in the run, the value of  $I_r$ , etc. Therefore, it is necessary first to normalize the variables used in the representation of failure functions.

In this paper, the damage  $D$  is a dimensionless variable of the armor erosion because the magnitudes of lengths and distances have been normalized by the nominal diameter  $D_n$ . Taking into consideration the fifth power relationship between damage and wave height shown by the failure functions given by SPM(1984), Van der Meer(1988), and Medina et al.(1990) for conventional breakwaters, the ordinates in the failure functions of this paper have been transformed using the expression  $[D/1.6]^{0.2}$ . According to Medina et al.(1992), the failure function suggested by SPM(1984) for rough quarrystones fits the line

$$\frac{H_{10}}{H_d} = \left[ \frac{D}{1.6} \right]^{\frac{1}{5}} \quad (1)$$

The runs of random waves had different number of waves,  $N_w$ , Iribarren number,  $Ir$ , and groupiness parameter,  $\alpha$ . In order to normalize the characteristic wave heights (abcisa), the formulas of Van der Meer(1988) and the preliminary conclusions given by Medina et al.(1990) were used. According to Van der Meer(1988), the damage  $D$  is proportional to  $H_{m0}^5$ ,  $[N_w]^{0.5}$ , and  $[Ir]^{2.5}$  if  $Ir \leq 3.5$ . The minimum armor stability using the Van der Meer's formulae is obtained for  $Ir=3.5$ ; if  $N_w=1000$  and  $Ir=3.5$ , the estimation of damage provided by this formulae is fairly coincident with the estimation given by the SPM(1984). On the other hand, according to Medina et al.(1990), the damage  $D$  is proportional to  $H_{m0}^5$ , and  $[\alpha]^{0.5}$ , in which  $\alpha$  is the envelope exceedance coefficient used by Medina et al.(1990) to characterize the wave groupiness of irregular wave trains attacking rubblemound breakwaters. Therefore, the standard characteristics of the irregular wave train to represent failure functions were:  $N_w=1000$ ,  $Ir=3.5$ , and  $\alpha=1$ .

In the conditions for normalization given above, the failure functions of the conventional breakwater fairly showed the expected fifth power relationship between dimensionless damage and wave height for the complete wave height range, but the observed mean stability numbers for all the damage levels were about 7% lower than the stability number predicted by the Van der Meer's formula. On the other hand, the D-armor breakwater showed two radically different parts in the failure functions: a)A fairly fifth power relationship between damages and wave heights for low and moderate damages up to 50%  $D_{max}$ , and b)A higher resistant upper tail of the failure function. The stability numbers of the start of damage point, and the low levels of damage, appear to be 5% to 10% smaller than the conventional breakwater; however, the stability number corresponding to the total failure point is 10% to 15% higher than the conventional breakwater.

Analyzing the results obtained from the tests using regular and random waves, the global structural response patterns are clear. In all the cases tested, the D-armor was significantly more resistant to total failure than the conventional breakwater. The difference in resistance to total failure depends on  $Ir$  for regular waves, and is relatively constant for random waves. The stability number of the D-armor for total failure and random waves is 10% to 15% higher than the conventional breakwater. In most cases tested, the D-armor was less resistant to the start of damage point and to low levels of damage. The stability number of the D-armor for the start of damage point and low damage levels appears to be 5% to 10% lower than the conventional breakwater.

The above described behavior of the D-armor breakwater suggests an alternative definition of armor damage, appropriate for these kind of structures with as much as 50% more armor erosion capability before total failure. One could

consider only "initiation of damage" the identifiable damage levels below the extra active armor area of the D-armor section ( $11.8 D_n^2$  in this experiment), which approximately corresponds to the difference between the maximum damage of the D-armor and the conventional breakwaters. The new definition of the armor damage applicable to D-armor breakwaters in this experiment is  $D^* = D - 11.8$ . One could also reduce the stability numbers corresponding to the D-armor breakwater by a factor of 1.15 to fit the total failure point of both breakwaters, which is equivalent to a reduction of the weight of the armor stones by a factor of 2/3. With this new definition of armor erosion to equalize the maximum armor damage, and with the reduction of median armor mass to equalize the total failure point, the new failure functions are those represented in Fig. 8.

Using lighter armor stones (factor 2/3), and the definition of damage which equalizes the maximum armor erosion, the D-armor breakwater shows fairly the same failure function as the conventional breakwater. This D-armor breakwater would show identifiable minor damages ( $D^* = [D - 11.8] < 0$ ) for values of  $H_{10}$  in the range:  $0.65H_d < H_{10} < 1.15H_d$ ; and the same structural response until total failure as the conventional breakwater with heavier stones. Therefore, a prototype based on the D-armor concept is expected to be significantly cheaper than the conventional breakwater with the additional advantage of having a wider wave height range of acceptable minor damages. These properties make the D-armor breakwater a cost-efficient design especially indicated for construction sites with large uncertainties on the design wave condition.

Figure 8.- Equalized Failure Functions Corresponding to the D-Armor and the Conventional Breakwaters.

All the cases were tested with approximately constant mean water level; therefore, appropriate designs for construction sites with large tide ranges may require a modification of the D-armor breakwater shown in Fig. 4b. On the other hand, the results are consistent with the intuitive concept on which the D-armor design is based: it is structural and cost efficient to concentrate the armor volume in the area where maximum erosion is expected. Therefore, the first tentative D-armor design shown in Fig. 4b should be adapted to the specific tidal range and overtopping conditions to get full advantage of the new concept. As a matter of fact, some preliminary tests not shown in this paper indicate that a D-armor breakwater may be extremely cost-efficient with respect to conventional breakwaters, if significant overtopping is acceptable for the design conditions.

## CONCLUSIONS

A D-armor mound breakwater cross section is presented and conceptually compared with conventional, S-shape, and berm breakwaters. A systematic comparison between a conventional and the corresponding D-armor design is given. The UPV wave flume (30x1.2x1.2 m) was divided in two parts to test simultaneously both sections with exactly the same wave attack. The results were obtained from 10 tests with regular waves and 10 tests with random waves, all of them developed from the no damage level to the total failure of the armor layer. The observed damages are consistent with the interpretation that the increase of the armor volume near the SWL fairly corresponds to the increase of the active volume of the armor layer. Considering this extra volume of armor stones as an acceptable erosionable part of the D-armor (minor, but identifiable damages), the D-armor structural performance is similar to the conventional breakwater with two clear advantages: 1<sup>st</sup>) A 15% higher stability number for moderate and high levels of armor erosion, and 2<sup>nd</sup>) A 50% wider wave height range of acceptable damages about the SPM design wave condition. The first advantage allows the design of a cheaper armor layer in prototypes using lighter stones and achieving the same stability; the second advantage makes the design appropriate to face large uncertainties in the design wave action in its lifetime.

The global view of the results noted above points out the inefficient design of the conventional breakwater. The deep water cross section proposed by SPM(1984) indicates the use of armor stones in inactive areas ( $h > H_d$ ), while critical armor areas near the MWL are only protected by a  $2D_n$  thick armor layer. New structural and cost-efficient breakwater cross sections are necessary to surpass the old conventional design. However, any unconventional design implies new and unknown risks due to new problems like control of construction versus design, new and unexpected modes of failure, etc. The uncertainty to new and unknown risks due to any new design, and the reasonable aversion to risk of most designers, constructors, and decision makers, breaks down the application in practice of new laboratory tested efficient designs. Therefore, the migration from the conventional design to new cost-efficient designs will be an step by step process, in which each step does not imply an excessive jump on the generally accepted designs. The D-

armor breakwater is a new concept which has shown in the laboratory to have significant economic advantages over the conventional design, and does not appear to be an excessive conceptual and constructive jump from the conventional breakwater.

As noted above, the D-armor breakwater may be a reasonable first step for a safe migration from the inefficient conventional breakwater to new structural and cost-efficient designs. It shows less inactive armor area, and 50% more active area with a wide acceptable wave height range of minor damages (initiation of damage) and 15% higher stability number for high damage levels up to total failure. It appears to have the same or low construction cost with higher stability. On the other hand, it has a reasonably low risk to unknown aspects. The D-armor design shows a structural response with extremely high flexibility, making it appropriate to face high uncertainties in the design wave conditions at the construction site; therefore, it seems to be a reasonable economically-efficient alternative to the conventional design in both deep and shallow waters.

## CHAPTER 106

# Dolos Design Using Reliability Methods

Jeffrey A. Melby and George F. Turk \*

### Abstract

Historically, concrete armor unit design has not included conventional structural design methods. The primary reason is the lack of knowledge of the loads and the resulting structural response. Also, complex and random boundary conditions and wave loading made the engineering problem difficult. With recent advances in concrete armor unit stress prediction and measurement methods, we can begin to utilize conventional structural design methods in concrete armor design. This paper adapts conventional structural reliability design methods in the Load and Resistance Factor Design (LRFD) format to allow a unified approach to both reinforced and unreinforced dolos design. Stress prediction methods are validated for several well known structures. Then LRFD methods are described and applied generically for both unreinforced and reinforced dolos design. The reliability methods described herein are adaptable for general concrete armor unit design.

## 1 Reliability Methods

Conventional land-based concrete structures are typically designed using Load and Resistance Factor Design (LRFD) methodology. It has been argued that conventional structural design methods are not applicable to the dolos structural design problem because the random and highly variable wave loading and boundary conditions cannot yet be specified. With recent advances in concrete armor unit stress prediction and measurement methods, the reliability methods appear to be readily adaptable to concrete armor design. The primary advantages of the LRFD format are:

- follows conventional structural engineering practice
- provides measures of the uncertainty for both the loads and the strength
- permits robust, unified unreinforced and reinforced concrete design

The LRFD methods are particularly appropriate for breakwater armor design because the large uncertainties associated with breakwater armor hydraulic and structural response can be quantified and presented in a familiar format. Also, historically, breakwater armor designers often put structural steel reinforcement in armor without knowledge of the loads or internal response and without reasonable analysis methods. Typical concrete armor designs were therefore not economical when designed with reinforcement. But even with current dolos stress prediction methods, efficient reinforcement design

---

could not previously be done because of the need to specify component forces. But conventional structural engineering techniques provide the means to distribute this armor layer design stress to the component forces. The existing armor layer stress prediction methods along with the component force relations enclosed within the LRFD framework, therefore, provide a complete procedure for concrete armor design.

The LRFD methods outlined herein are based on reliability methods as described in Ellingwood, et al (1980). The balanced LRFD design equation can be expressed as the equilibration of a factored load with a factored strength or

$$\gamma Q_n = \phi R_n \quad (1)$$

where  $\gamma$  and  $\phi$  are the load and strength factors and  $Q_n$  and  $R_n$  are the nominal load and resistance, respectively. The strength coefficient and load factor take into account the appropriate uncertainties.

The loads on breakwater armor units are difficult to determine due to the complexity and randomness of both hydrodynamics and boundary conditions. Therefore, the methods currently used to describe the loads on concrete armor units are indirect, specifying the maximum armor layer stress as a function of environmental parameters such as wave height, structure slope, and armor weight. Previous publications show methods for determining the design stress level using probability of exceedance curves and expected levels of exceedance (Howell and Melby 1991). To couple these previously described methods and the LRFD method, the load factor is chosen so as to preserve the design probability of exceedance as follows.

$$E = \Phi(-\beta) \quad (2)$$

where  $\Phi$  is the unit normal cumulative distribution and  $\beta$  is the reliability index. The load factor can be determined as

$$\gamma = \phi \frac{R_n Q_m}{R_m Q_n} \exp \left[ -\Phi^{-1}(E) \sqrt{V_R^2 + V_Q^2} \right] \quad (3)$$

where  $Q_m$  and  $R_m$  are the mean load and resistance and  $V_Q$  and  $V_R$  are the load and resistance coefficients of variation, respectively. The limit states are given by ACI (1989) and Ellingwood (1980) as  $\phi = 0.85$ ,  $R_m/R_n = 1$ , and  $V_R = 0.2$  for torsion and  $\phi = 0.90$ ,  $R_m/R_n = 1.05$ , and  $V_R = 0.11$  for flexure (ACI 1989).

In this report, previously published dolos stress prediction methods are used to preliminarily define the loads. The stress is distributed to the component forces which are then used as the loads in the LRFD formulation. The result is a comprehensive design methodology for dolosse that includes strength enhancement specification and conforms with present structural engineering design practice. The methods allow the designer to compare the economies of different strength enhancement options including high strength concrete, shape modification, and steel bar reinforcement in a unified format to achieve the most efficient dolos design. The basic methods outlined herein are general and can be adapted to any armor unit shape.

## 2 Design Stress Prediction

Concrete armor unit design has progressed a great deal during the last few years. This rapid progress is, in large part, due to the prototype dolos structural response data set

and associated research accomplished under the Crescent City Prototype Dolos Study (CCPDS). Figure 1 shows 38-tonne dolosse being placed on the breakwater at Crescent City. In the prototype study, dolos structural response data and numerical models were

Figure 1: 38-tonne Dolosse at Crescent City, CA

used to link design parameters such as dolos size, shape, and material specifications to the measured stress statistical moments. Using these methods, the Crescent City stress distributions could be extended to other structure geometries (Howell and Melby 1991). The dolos small-scale-model load cell was verified as a tool to measure pulsating stresses in the physical model (Markle 1990). The CCPDS has been widely reported and other primary publications include Howell (1988), Melby and Howell (1989), Kendall and Melby (1990), and Rosati and Howell (1990).

The dolos stress prediction methodology is based on stochastic methods because of the random nature of both the loading and the boundary conditions. Separate distributions for static and pulsating stresses have been generated and are combined using the methods that follow. The result is a single maximum design stress for the armor layer for a specified probability of occurrence.

In general, the static stress will be much larger than the pulsating stress (Melby and Howell 1989). The static nondimensional stress log-normal distribution is given in Equation 4 with mean and standard deviation given in Equation 5 and 6 and shift parameter given in Equation 7 (Howell and Melby 1991). The original distribution based on measured stress statistics has been extended for the general design case by modifying the statistics for the dolos size, density, waist ratio, and stacking depth. The waist ratio is the ratio of the depth of the shank (center section) to the length of a fluke (end

sections).

$$p(\sigma'_s) = \frac{1}{\sigma'_s \beta \sqrt{2\pi}} \exp \left[ -\frac{1}{2} \left( \frac{\ln \sigma'_s - \alpha}{\beta} \right)^2 \right] \quad (4)$$

$$\alpha = \ln[k_r(\alpha_{cc} + a)] - \beta/2 \quad (5)$$

$$\beta = \sqrt{\ln \left( \frac{\beta_{cc}}{\alpha_{cc} + a} \right)^2 + 1} \quad (6)$$

$$a = S_L \left[ \frac{1}{\gamma} (N_L - 1) - \frac{1}{\gamma_{cc}} \right] \quad (7)$$

In the above equations,  $\alpha_{cc} = 26$  and  $\beta_{cc} = 12$  are the Crescent City prototype nondimensional mean and standard deviation, being nondimensionalized by the product of fluke length and weight density,  $\gamma_{cc} = 2456 \text{ kg/m}^3$  is the Crescent City dolos weight density, and  $N_L$  is the number of armor layers. The waist ratio coefficient, given by

$$k_r = 5.14 - 28.74r + 66.07r^2 - 52.08r^3 \quad (8)$$

was determined using a fully deterministic FEM analysis with several representative boundary and loading conditions.

The maximum pulsating or wave-induced stress is a function of the design wave height,  $H_n$  and a wave stress constant,  $k_{ps}$ . The Rayleigh distribution of the form

$$p(\sigma_p) = \frac{\pi \sigma_p}{\bar{\sigma}_{pmax}^2} \exp \left[ -\frac{\pi}{4} \left( \frac{\sigma_p}{\bar{\sigma}_{pmax}} \right)^2 \right] \quad (9)$$

best describes the dolos pulsating response. The mean of the maximum pulsating stress, which is linearly related to the average of the highest one-tenth of the waves can be expressed by the empirical relationship

$$\bar{\sigma}_{pmax} = k_{ps} H_{1/10} \quad (10)$$

where

$$k_{ps} = 0.036 \text{ MPa} \quad (11)$$

per meter of wave height and  $H_{1/10}$  is computed using the zero-downcrossing method of analysis, i.e., the difference between the maximum and the preceding minimum between two successive zero downcrossings in a time series. Note that during the prototype data acquisition period, the maximum pulsating stress was approximately  $\sigma_1 = 1 \text{ MPa}$ , which occurred during a design event.

The modified static and pulsating distributions are convolved, assuming they are independent, to get a combined stress distribution which is integrated to get a stress exceedance distribution. This distribution is used along with a design probability of exceedance,  $E$ , to determine a design stress. This stress is interpreted as that which will be exceeded in  $E$  percent of the armor units. Note that this is a hydraulically stable design stress because the impact stress is not yet included in the calculations. We do not include impact stresses because of the unknown scale effects in the instrumented impact tests and because of the uncertainties associated with uninstrumented drop test results. All of the calculations for stress prediction are performed within a PC computer-based program called CAUDAID.

Extensive physical model tests utilizing the small-scale load cell instrumentation were used to validate the static log-normal distribution (Melby 1992). But, as noted by Melby, the mean for the prototype data is significantly greater than that of the scaled physical model data. There are several reasons for this difference including the flat slope of the prototype breakwater, surface friction scale effects, and overly stiff instrumented cross sections in the small-scale units. Utilization of the modified prototype static distribution, rather than the load cell measured results, is likely to be conservative. But as shown later in this paper, these modified prototype distributions appear to predict the design stresses well.

The data reported in Burcharth et al. (1991) and Anglin et al. (1990) are based, for the most part, on scale model results utilizing the load cell structural instrumentation scheme. The results published by these two authors were accomplished through careful laboratory examinations and their results appear to be very reliable. As noted above, this load cell instrumentation scheme has also been employed by the present authors but has only been validated for pulsating response. Scale effects in both static and impact load cell measured responses may introduce unconservativeness in the dolos load prediction process. Thus the load cell measured results are not included in this paper.

## 2.1 Application of Maximum Stress Prediction Methods

The stress predictions described in the previous section have been applied to several dolos armored breakwaters (Table 1). The LRFD methods were not used in this section so that actual computed stress levels could be shown clearly. Each example breakwater, with the exception of Cleveland and Sines was physically surveyed by the authors within the last 6 months. Cleveland and Sines breakwaters have been thoroughly studied by others and therefore provide excellent examples. The 1974 rehabilitation of the Crescent City breakwater was not used as an example because many of the dolosse were broken due to storms that occurred during construction. In Table 1,  $Age$  is the difference in years between original construction and the last survey;  $H$ , the wave height in meters;  $W$ , the weight in tonnes;  $N$ , the number of dolosse placed;  $S$ , the specific gravity;  $r$ , the waist ratio;  $\cot(\alpha)$ , the breakwater slope;  $E$ , the probability of exceedance used in the calculation of the design stress, which is the surveyed number of broken dolosse as a percentage of the total number of dolosse placed;  $\sigma_1$ , the maximum principal stress as computed in CAUDAID in MPa; and  $f_t$ , the concrete tensile strength in MPa.

Each structure has its own design peculiarities which effect the design stress as follows.

- Crescent City: Flat structure slope makes structure extremely stable and limits breakage; conservative stress estimates will always be high.
- Humboldt: Conventional reinforcement adds approximately 20% to resistive capacity as reflected in high  $f_t$ .
- Nawiliwili: No peculiarities; relatively simple application of stress prediction methods.
- Waianae: Wide fronting reef limiting wave energy;  $E = 1$  does not include 170 construction related breaks.

Table 1: Application of Design Methods

SITE	Age	H	W	N	S	r	$\cot(\alpha)$	$E$	$\sigma_1$	$f_t$
Crescent City	7	11	38	680	2.46	0.32	5	1	8.1	7.0
Humboldt	10	12	38	4772	2.46	0.32	2	1	8.5	8.4
Nawiliwili	15	7	10	485	2.30	0.32	2	8	3.6	3.8
Waianae	13	4	1.8	6633	2.30	0.32	2	1	3.5	3.8
Honolulu, H	16	8	5.5	4516	2.30	0.32	2	4	3.5	3.0
Honolulu, T	16	8	3.6	13790	2.30	0.32	1.5	4	3.0	3.0
Cleveland	5	4	1.8	29500	2.30	0.32	2.0	4	2.4	2.5
Sines	1	14	42	19000	2.55	0.35	1.5	5	6.2	5.0

- Honolulu: Wide fronting reef; estimated concrete strength is low by U.S. construction standards.
- Cleveland: Estimated concrete strength is very low.
- Sines: Damage primarily due to single storm, long slope, deep water.

Given no peculiarities, the stress prediction methods will reasonably predict long-term cumulative damage of a relatively stable structure (Nawiliwili) but will overpredict short term damage (Sines) and damage on an extraordinarily stable structure (Crescent City). Although the stress prediction methods do not include impact response, the conservativeness in the predicted stress appears to allow enough safety to account for all loading over the structure life. Because the design goal is to achieve an armor layer design that does not require periodic rehabilitation and has an extremely low probability of catastrophic failure during its design life, the stress prediction program is appropriate for conservative design load determination and it was used as input to the following LRFD methods.

### 3 LRFD - Optimizing Design Methods

#### 3.1 Strength Enhancement Options

As shown in Table 1, the design stress for the large dolosse at Crescent City exceeds the tensile strength. Also, because these dolosse were built without significant reinforcement and because the average stress level is increasing over time (Kendall and Melby 1990), the dolos breakage is expected to continue and a rehabilitation will likely be required before the design life is reached. For the Crescent City breakwater, a strength enhancement of the design dolosse is required. Melby (1992) showed that, as a general rule, for dolosse exposed to design wave heights above 7m, the stress exceeds the commonly used concrete strength of 3.6 MPa and strength enhancement is required. The designer has several strengthening options including fiber reinforcement, increased concrete strength, modified shape, and steel reinforcement.

Metal fiber reinforcement was used in Crescent City and Humboldt, California dolosse. The Crescent City dolos tensile rupture strength was very high (Kendall and Melby 1990) using approximately 1 % fibers; but this high strength is likely attributable to the concrete mix characteristics and not the fiber. With approximately 50 kg of steel added per cubic meter of concrete, a mere seven percent tensile strength increase was reported from tests conducted during trial mix designs. One of the major problems encountered during prototype casting was the tendency for the steel fibers to congregate or "ball up" during concrete mixing. Recent evidence indicates that fiber reinforcement is not likely to increase the strength enough to make it economical.

Increasing the concrete tensile strength can be practical in the U.S. because high strength concrete is now commonly used. Also, recent tests of high strength silica fume concrete indicate that the ratio of tensile to compressive strength is maintained for compressive strengths up to about 107 MPa (Saucier 1984). But the compressive strength can only be increased economically to about 70 MPa at this time. The corresponding tensile strength of this concrete mix is approximately 7 MPa.

For armor unit design, the primary design input site parameters include directional wave energy, water depth, breakwater slope, and position on breakwater. The designer is free to optimize the design by varying the dolos weight, shape, density, packing density, and material strength. In practice though, the dolos shape and concrete properties are fixed, with a waist ratio of  $r = 0.32$ , a packing density of  $k_{\Delta} = 0.94$ , a specific weight of approximately 2.3, and a compressive strength of  $f'_c = 36$  MPa. This leaves only the dolos weight as a variable. But in order to achieve an optimized design, none of these parameters should be fixed. Also, for some designs it may be more economical to reinforce slender dolosse than use unreinforced stout dolosse.

Utilizing the previous stress prediction methods, it is a simple process to minimize the stress level by varying the dolos shape, packing density, and material properties. For a given waist ratio, incorporating reinforcement in the optimizing process is straight forward, as will be shown. But our ability to fully optimize the dolos design by maximizing dolos strength and hydraulic stability is limited because knowledge of dolos stability and stress versus waist ratio is still needed. Also, no research has been done to determine the response of very slender dolosse ( $r \leq 0.31$ ). Yet with efficient reinforcement schemes, slender reinforced dolosse may be a viable option because the amount of concrete is reduced and the wave energy dissipation of the armor layer is increased. Integrating reinforcement, shape modification, and stability analysis into a general optimizing design procedure using existing knowledge is therefore a great challenge.

In order to explore the advantages of shape modification on stability, previous research results were used. Zwanborn et al. (1988) provided stability results for dolos waist ratios of 0.33, 0.36, 0.38, and 0.40. In the following analyses, these stability data were highly simplified by averaging multiple curves for various surf similarity parameters and extrapolating to slender waist ratios. Figure 2 shows the resulting Hudson (1958) stability coefficient versus waist ratio curve. This curve is simply used in the general optimization process herein and is not intended for design purposes.

### 3.2 LRFD Formulation

The design stress is a result of combined bending and torsion loads. To resist combined loading, the strength due to torsion is generally different than the strength due to flexure.

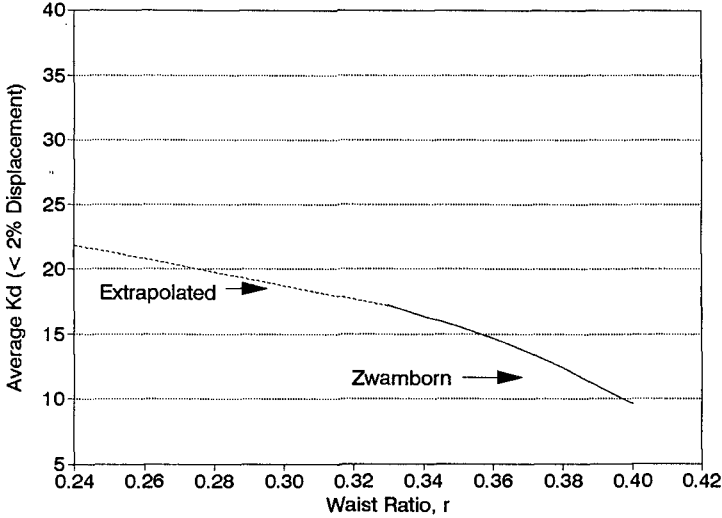

Figure 2: Hydrodynamic Stability from Zwamborn et al.(1988)

Also, reinforcement schemes must be designed for torsion and flexure separately in order to maximize efficiency. Therefore, a strength failure criterion in the form of a moment-torque circular interaction curve has been adopted for both unreinforced and reinforced dolos design, i.e.,

$$\left(\frac{T_c}{T_{cr}}\right)^2 + \left(\frac{M_c}{M_{cr}}\right)^2 = 1 \tag{12}$$

$M_{cr} = S_M f_{ct}$  is the flexural cracking moment in the absence of torsion and  $T_{cr} = S_T f_{ct}$  is the torsional cracking moment in the absence of flexure. Here  $S_M$  and  $S_T$  are the flexural and torsional section moduli and  $f_{ct}$  is the tensile splitting strength.  $M_c$  and  $T_c$  are the respective moments at failure in the presence of combined bending.

The principal stress as computed by CAUDAID can be used as the loading criterion if the statistical variability of the torsional and flexural contributions to this principal stress are known. For this analysis, we assumed  $M = S_M k_M \sigma_1$  and  $T = S_T k_T \sigma_1$ , where the torsional and flexural section moduli are given by  $S_T = 0.2105(rC)^3$  and  $S_M = 0.10526(rC)^3$ , respectively. Here  $C$  is the fluke length and  $r$  the waist ratio. The stress contribution factors are taken from Crescent City prototype data as  $k_T = 0.6$  and  $k_M = 0.6$ . These values require further refinement and will be addressed in the future.

Using Equation 12, the torsional and flexural concrete strength in combined loading can be expressed as

$$T_c = \frac{T_{cr}}{\sqrt{1 + 4 \left(\frac{M_c}{T_c}\right)^2}} \tag{13}$$

$$M_c = \frac{M_{cr}}{\sqrt{1 + 0.25 \left(\frac{T_c}{M_c}\right)^2}} \tag{14}$$

With  $k_T$  and  $k_M$  equal to 0.6,  $M_c/T_c = 0.5$ , and the combined loading torsional and flexural strengths are 70 % of the respective pure torsional and flexural strengths. Also, design fluke stress levels are conservatively estimated to be equivalent to those in the shank, although they are assumed to be created from pure flexural loading. This is perhaps overly conservative but is done here in order to illustrate the general analysis procedure.

The load factor in Equation 1 has been determined using Equation 3 and the values given in Section 1 for the limit states. The load factor was found to range from 1.0 to 1.2 over a range of typical values of the exceedance probability. A value of  $\gamma = 1.0$  was used herein because of the conservativeness inherent in the calculation of the design stress. With the strength and loading defined, the LRFD balanced equation,  $\gamma Q = \phi R$ , becomes for torque

$$\gamma S_T k_T \sigma_1 = \phi 0.7 T_{cr} \quad (15)$$

$$1.0(0.6)\sigma_1 = 0.85(0.7)f_{ct} \quad (16)$$

$$\sigma_1 \approx f_{ct} \quad (17)$$

and for moment

$$\gamma S_M k_M \sigma_1 = \phi 0.7 M_{cr} \quad (18)$$

$$1.0(0.6)\sigma_1 = 0.9(0.7)f_{ct} \quad (19)$$

$$\sigma_1 \approx f_{ct} \quad (20)$$

The approximation is done in order to show the basic methodology as simply as possible in this brief format.

### 3.3 Unreinforced LRFD

The preceding stress prediction methods, shape modification and high-strength concrete, waist ratio stability and combined loading strength reduction have all been incorporated into the LRFD design formulation above to determine the optimal unreinforced dolos weight for a given design wave height. For the unreinforced dolos analysis, stable dolos weights were computed for several waist ratios using the Hudson equation with a given wave height, structure slope of  $\cot \alpha = 2$ , specific gravity of  $S = 2.34$ , packing density of  $K_\Delta = 0.94$ , and  $K_D$  of half the value shown in Figure 2 (i.e., no-rocking). These stability coefficients were chosen to be conservative. Using the Hudson stable weight, the design maximum principal stress, which is the load side of the LRFD Equations 17 and 20, was computed using CAUDAID with  $E = 5\%$ . On the resistance side of the LRFD formulation, concrete splitting tensile strengths were estimated using compressive strengths of 35 MPa and 70 MPa and the ACI splitting strength recommendation of  $f_{ct} = 6\sqrt{f'_c}$ . Note that the strengths and loading moments were reduced for combined loading in Equations 13, 14, 15, and 18 but the final LRFD equations reduced to equating the design stress to the splitting tensile strength (Equations 17 and 20).

Figure 3 shows the hydraulically and structurally stable weight for unreinforced dolosse as a function of wave height for the three waist ratios and two concrete strengths. Note that the maximum wave height that can be successfully resisted for unreinforced dolosse over the design life of the structure is approximately 7.5m using high strength

concrete. For larger wave heights it is necessary to reinforce with structural steel. The effects of waist ratio can be clearly seen in this figure. The more slender the dolos, the less the required weight. But the figure shows that, for a given wave height, high strength concrete might be required for a more slender design dolos while not for the stouter dolos. It is clear that dolos design optimization could save a considerable amount of money through minimizing the concrete costs.

Figure 3: Unreinforced Structurally and Hydraulically Stable Dolos

### 3.4 Steel Reinforced LRFD

Two options exist for the steel reinforcement; deformed bars and prestressed tendons. In the U.S., the Corps of Engineers has placed conventionally reinforced dolosse on the Humboldt, Ca. Jetties; Manasquan Inlet, N.J. Jetties; and on several Hawaiian breakwaters. In most cases, no information was available about the magnitude of flexural and torsional loading. This resulted in inadequate hoop steel to resist torsional moments and improperly sized longitudinal reinforcing. With appropriate information about the nature of the loading, proper amounts of steel can be used to greatly strengthen dolosse.

Conventional reinforcement corrosion can be a significant problem. As a unit is loaded, tensile stresses within the concrete are transferred to the steel dowels along their development length only after the concrete cracks. Depending on the nature and severity of the loading condition, these cracks often extend through the concrete cover layer. Also, if the steel bars deform outward during concrete pouring then the amount of bar cover can be reduced. In the marine environment, cracks provide a conduit for seawater intrusion and subsequent chloride ion attack. This results in corrosion of the steel, and ultimately the eventual failure of the unit.

For the moderate to severe wave climate, prestressed concrete offers a solution for

strengthening dolosse that would otherwise crack. Prestressed concrete also has an enhanced ability to resist impact loads and fatigue.

### 3.4.1 Conventional Steel Bar Reinforcement Design

With conventional steel bar design, the torsional steel is specified first, and then the flexural steel. As per ACI (1989), resistance to torsional loading is computed as  $T_n = T_c + T_s$ , where  $T_n$  is the nominal torsional strength, and  $T_c$  and  $T_s$  are the nominal concrete and steel torsional strengths, respectively. Thus, the torsional resistance provided by the hoop steel is computed by

$$T_s = \frac{\gamma k_T T_u - \phi T_c}{\phi} \quad (21)$$

and the area of steel by  $A_s = T_s / R_h f_y$  where  $R_h$  is the distance from the center of section and  $f_y$  is the steel yield strength. To offset pure torsional forces, an equivalent amount of longitudinal steel is placed in the spacing between hoops as is contained in a single hoop.

Contrary to the preceding torsional reinforcement design, resistance offered by the concrete tensile strength is not considered in flexure. Nominal strength is reached when a crushing strain at the extreme fiber occurs as the tension steel yields. Strains in the steel and concrete are assumed directly proportional to the distance from the neutral axis. Unlike conventional structures where ductile failure indicates imminent collapse, armor unit design benefits from a brittle failure where a high steel-to-concrete ratio reduces crack width and formation under service loading. Although the stress-strain distribution across the section is nonlinear, a rectangular distribution is used to facilitate design. A concrete stress intensity of  $0.85f'_c$  is assumed to be uniformly distributed across an equivalent compressive zone. With the compressive force defined, an equivalent tension force comprised of the sum of forces generated by symmetrically placed steel is assumed. These forces become the components of a moment couple dependent on an unknown neutral axis location, requiring an iterative solution. The procedure to specify flexural steel is straight forward and the reader is referred to ACI (1989).

Using the aforementioned conventional reinforcement analysis methods, it was found that the reinforcement scheme of 12 equally spaced #6 bars in 16-ton dolosse at Manasquan, NJ provided approximately a 20% increase in flexural capacity and little increase in torsional capacity.

Figure 4 shows the results of a more general analysis with the weight of reinforcing steel required within a stable dolosse versus design wave height.  $f_s$  is the steel yield strength. Note that while the packing density is held constant, the porosity of the armor layer varies with waist ratio. Therefore to permit comparison of differing strengthening schemes, the amount of steel is given per  $100m^2$  of breakwater surface. Again, the effects of waist ratio can be clearly seen. The more slender the dolos, the less the number required to armor the breakwater. This significantly offsets the increase in steel required for slender units. Also note that, although high strength concrete was analyzed, the resulting curves are not shown because they do not differ significantly from those of normal strength concrete. This is because most of the resistance in a conventionally reinforced dolos comes from the steel. It must be noted that even though a substantial

amount of steel is specified, conventionally reinforced dolosse are still susceptible to cracking and, hence, a possible reduction in service life.

Figure 4: Conventional Reinforcing Steel Required

**3.4.2 Prestressed Steel Reinforcement Design**

Prestressing is a means of applying a precompression load to a structural member regardless of the dead or live loads acting on the structure. For the plane stress assumption, as precompression is added, the failure plane becomes more vertical and the section less susceptible to pure shear related inclined cracking.

Prestressed concrete design methodology differs from that of conventional reinforcement because both the torsional and flexural tensile strength of the concrete must be considered. Prestressing acts to directly apply an axial compressive force. The magnitude of the prestressing force is governed by the loading mode. The principal stress reduction factor as a function of a given precompression stress is

$$\xi = 0.5 \left( k_M - \lambda + \sqrt{(k_M - \lambda)^2 + 4k_T^2} \right) \tag{22}$$

where  $\lambda$  is the ratio of applied precompressive stress to design principal stress, as computed by CAUDAID, and  $k_M$  and  $k_T$  are 0.6. Substituting the moment-torque interaction relation into Equation 1 yields

$$\gamma \xi k_T \sigma_1 = 0.5 \phi \sqrt{\frac{f'_c}{1 + 4 \left( \frac{k_M S_M}{k_T S_T} \right)^2}} \tag{23}$$

for torsion with a similar relation for flexure. Again, ACI (1989) standard design practice methods were used to determine the amount of steel required.

Figure 5 shows the amount of steel required for the given design wave for the same  $100m^2$  of breakwater surface as used in the conventional reinforcement design.  $f_{pu}$  is the steel strength. Again, the slender reinforced dolos appears to be more efficient than the stouter one. Comparing Figures 4 and 5 shows that the prestressed dolos made with normal strength concrete requires slightly less steel than the conventionally reinforced dolos. But, using high-strength concrete, it is clear that the combination of prestressing and high-strength concrete is a much more efficient than conventional reinforcement.

Figure 5: Prestressed Steel Required

## 4 CONCLUSIONS

In this paper conventional structural reliability methods have been adapted to the design of dolos. The loading was specified using a PC-based stochastic stress prediction algorithm incorporating Crescent City prototype dolos stress distributions. These site specific static and pulsating stress distributions are modified in the program according to the user specified dolos weight, armor unit density, number of layers, waist ratio, and wave height. The static and pulsating stress distributions are combined to get a design distribution which is used along with a design probability of exceedance to get a maximum probable stress level for the design armor layer. The LRFD methods are formulated so as to preserve this exceedance probability or the expected amount of breakage on the breakwater over the design life. It is shown that these methods predict the stress levels in dolos armored breakwaters well. The LRFD methods are further employed to allow the design of steel bar reinforcement.

The new design methodology is used to compare various strength enhancement options for dolosse including shape modification, high strength concrete, conventional steel

rebar reinforcement, and high strength prestressed reinforcement. It is shown that for wave heights below about 7.5m stouter dolosse and high strength concrete can be used effectively. Steel bar reinforcement may be required in dolosse for wave heights above 7.5m. It is shown that in some cases it may be economical to use slender dolosse with reinforcement than to use stouter dolosse without reinforcement. Finally, prestressing was found to be slightly more efficient than conventional steel bar reinforcement when used with normal strength concrete but superior when used with high strength concrete.

## 5 ACKNOWLEDGEMENT

The work described in this paper was conducted as part of the Coastal Research and Development Program of the Coastal Engineering Research Center, Waterways Experiment Station, US Army Corps of Engineers. Permission to publish this paper was granted by the Chief of Engineers.

## CHAPTER 107

### LABORATORY INVESTIGATION ON THE STABILITY OF A SPHERICAL ARMOR UNIT OF A SUBMERGED BREAKWATER

N. MIZUTANI,<sup>1</sup> K. IWATA,<sup>2</sup> T. M. RUFIN JR.,<sup>3</sup> and K. KURATA<sup>4</sup>

#### Abstract

The stability of the armor unit in relation to the wave force acting on a spherical armor unit of a submerged breakwater was discussed experimentally in this paper. Stability models were derived to relate the stable weight of the spherical armor unit with the wave forces acting. The proposed models were in good agreement with the experimental results. And the vicinity around the leading crown-edge was revealed to be the most critical location of the submerged breakwater.

#### 1. INTRODUCTION

The submerged breakwater is one type of coastal structure that can compensate the demerits of a detached breakwater in the prevention of beach erosion. In the design of submerged breakwater, stable weight of the armor unit must be properly evaluated. The critical stable weight of the armor unit depends largely on an accurate estimation of the wave forces and on a complete understanding of its generating mechanism and the wave characteristics; thus, it is necessary to estimate the stability in relation to wave forces in assessing the overall effectiveness of such structure. A number of researches has been conducted on the stability of armor units and many estimation methods have been proposed, such as Hudson (1959) and Van Der Meer (1987). Uda et al. (1989) developed an estimation method of stable weight of armor units of an artificial reef based on the laboratory experiment of armor stability. However, previous researches show that very few studies about wave force acting on armor units have been conducted; although there has been some study on wave forces acting on an armor rubble of a rubble-mound slope breakwaters (Iwata et al., 1985), still its wave force characteristics are not fully clarified. Hence, this paper aims to present experimentally the stability of a spherical armor unit of a submerged breakwater in relation to the wave forces acting on it.

2. EXPERIMENTAL PROCEDURE

The stability tests and the laboratory observations of wave forces acting on a spherical armor unit on a submerged breakwater were carried out using an indoor wave tank (25 m long x 0.7 m wide x 0.9 m deep). The submerged breakwater, as shown in Fig. 1, was installed on a horizontal bed. The model of the breakwater was prepared using spheres, diameter  $D = 0.03$  m, to exclude complexities due to shape complexity of natural stones. The porosity of the submerged breakwater was 26%. Two separate sets of experiments under different water depths were performed in this study, hereafter to be referred to as EXPT90 and EXPT91 respectively.

Fig. 1 Schematic diagram of submerged breakwater.

2.1 Stability Measurement

Eight and 12 samples of spheres of the same diameter but varying in weight were prepared for EXPT90 and EXPT91, respectively. Regular waves with different wave periods (EXPT90:  $T = 1.0, 1.41, 1.60$  s; EXPT91:  $T = 1.0, 1.4, 1.80$  s) were generated in this experiment. For every designated locations on the submerged breakwater, the critical wave height of each sample in each period were determined. Critical wave height is defined as the minimum wave height required to move a given sample of sphere. The determination was made by generating series of experimental trials with different values of wave height until the critical wave height is attained. Then, the corresponding water surface elevations and horizontal and vertical water particle velocities ( $u$  and  $w$ ) were measured with electric capacitance-type wave gauges and an electromagnetic-type velocimeter. For EXPT91, wave forces in horizontal and vertical directions ( $F_x$  and  $F_z$ ) were also measured with cantilever-type wave force meters. Measurements were conducted for both embedded and non-

Fig. 2 Methods of wave force and velocity measurements.

embedded conditions and the methods of stability measurement for each set of experiment are given in Fig. 2. However, the half-embedded condition was adopted in EXPT90 since few movements in embedded conditions were observed.

## 2.2 Wave Force Measurement

Wave force measurements were also performed in this study to determine the fundamental characteristics of wave forces under a given wave conditions. Regular waves with the same periods as in the stability measurements were generated. Four different values of wave height ( $H_I = 0.03, 0.05, 0.07, 0.10$  m) which include both non-breaking and breaking wave conditions were assigned in this experiment. For each wave condition, the water surface profile, horizontal and vertical water particle velocities and wave forces were measured for both non-embedded and embedded conditions using the same instruments as in the previous experiments. The methods of wave force and velocity measurement are shown in Fig. 2.

Figure 3 shows the schematic illustration of the wave force meter devised for this experiment. It consists of a supporting rod and a cantilever with a sensing sphere on its head. The cantilever was covered with shield of appropriate shape to minimize the flow-turbulent effect. The wave force acting on the sphere causes strain on the cantilever and the output signal of the strain gauge on the cantilever together with the calibration table gives the magnitude of the wave force. The natural frequencies of wave force meters are more than 10Hz, which are much higher than the incident waves but its effect on wave forces is negligible and is removed using a low pass filter. The same diameter of sensing sphere was chosen for the non-embedded condition, however, a smaller diameter,  $D = 0.025$  m, of sensing sphere was used for the embedded condition in order to prevent contact with the surrounding spheres.

Fig. 3 Schematic diagram of cantilever-type wave force meter.

### 3. Stability of the Armor Unit

The relationship between the dimensionless critical stable weight of the armor unit  $W'_c/\rho g D^3$  and the dimensionless maximum velocity  $u_m/\sqrt{gd}$  is shown in Fig. 4, where  $W'_c$  is the critical stable weight of the armor unit in water,  $\rho$  is the density of water,  $g$  is the gravitational acceleration and subscript  $m$  indicates the maximum value. In the figure, the dimensionless maximum velocities corresponding to  $KC_x$  number equal to 10 and 20 are also indicated, where  $KC_x = u_m T/D$  is the Keulegan-Carpenter number. It is shown that the dimensionless critical stable weight is proportional to the velocity when  $KC_x$  is less than 10. On the other hand, it is proportional to the maximum velocity squared for  $KC_x$  larger than 10.

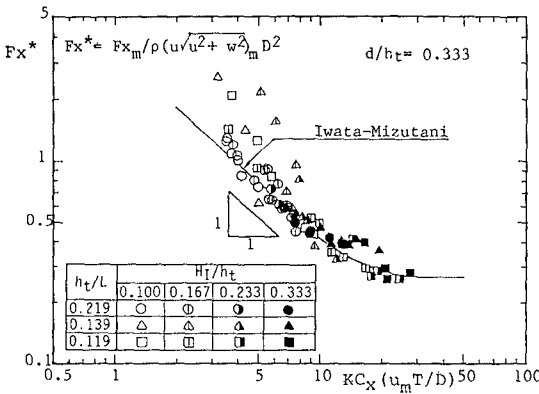

Fig. 4 Relationship between  $W'_c/\rho g D^3$  and  $u_m/\sqrt{gd}$ .

Figure 5 shows the relationship between the dimensionless maximum wave force  $F x_m/\rho(u\sqrt{u^2+w^2})_m D^2$  and  $KC_x$ . In the figure, the mean value obtained for an isolated sphere (Iwata and Mizutani, 1989) is also plotted. It can be observed that  $F x_m/\rho(u\sqrt{u^2+w^2})_m D^2$  is inversely proportional to  $KC_x$  when

(a) non-embedded(EXPT90)

Fig. 5 Relationship between  $F x_m/\rho(u\sqrt{u^2+w^2})_m D^2$  and  $KC_x$ .

$KC_x < 10$ . The inclination becomes mild when  $10 < KC_x < 20$  and it approaches a constant value when  $KC_x > 20$ . These tendencies are quite similar to those of isolated spheres. This clearly shows that the drag force is dominant over the inertia force when  $KC_x > 20$ ; conversely, the inertia force is a significant component when  $KC_x < 20$ , especially when  $KC_x < 10$ . And this causes the difference in the inclination of variation as given in Fig. 4. Thus, it can be concluded that the inertia force is also an important force component for the stability of the armor unit. Furthermore, this result suggests that a more accurate estimation of stable weight of an armor unit will be attained if it is expressed in terms of the wave forces acting rather than by its velocity.

**4. STABILITY MODEL**

In all stability trials, the motion of all samples was observed to be a rotating-type. This signifies that the spherical armor units starts to move when the overturning moment overcomes the restoring moment. Thus, the relationship between the stable weight and the wave force acting is obtained from the equilibrium state of moments. The force components considered in the system are the wave forces, gravitational force, buoyant force and frictional force. However, the frictional force between spheres is not considered in the analysis; since, the contact area between spherical armor units is very small and its contribution is considered to be negligible as compared to the other forces. This treatment, however, leads to a conservative estimation in the engineering point of view. The schematic diagram of the equilibrium state is shown in Fig. 6, and the following equations are obtained from this balance of moments.

For the non-embedded condition:

$$\frac{W_c}{\rho g D^3} = \left( \frac{2\sqrt{2}}{\cos \theta - 2\sqrt{2} \sin \theta} \right) \frac{F p_m}{\rho g D^3} + \frac{B_F}{\rho g D^3} + \frac{F n_m}{\rho g D^3} \tag{1}$$

For the embedded condition:

$$\frac{W_c}{\rho g D^3} = \frac{F z_m}{\rho g D^3} + \frac{B_F}{\rho g D^3} + \frac{F x_m}{\rho g D^3} \tag{2}$$

Fig. 6 Balance of moment and force.

Fig. 7 Relationship between  $Fz_m$  and  $Fx_m$ .

where  $Fp_m$  and  $Fn_m$  are the maximum tangential and normal components of wave force, respectively, and  $B_F$  is the buoyant force.

In the given equations, the third term should be the instantaneous value when the wave force component in the first term becomes maximum. However, based on the experimental results, there are cases that the normal and tangential wave forces or vertical and horizontal wave forces attain its maximum values almost instantly. This phenomenon corresponds to the most dangerous condition of armor stability; thus, the maximum values instead of the instantaneous values are adopted in the third term of the given equations.

However, for easier evaluation of the stable weight, the given equations should be expressed in terms of one wave force component. Figure 7 shows an example of the relationship between  $Fz_m$  and  $Fx_m$ . From the figure, the orthogonal wave forces are correlated by a linear relationship as given in the following equation.

$$Fn_m = \phi Fp_m \quad Fz_m = \phi Fx_m \quad (3)$$

where  $\phi$  is the coefficient determined by least square method and varies with the settlement condition (non-embedded or embedded) and location on the submerged breakwater.

Substitution of Eq.(3) into Eqs.(1) and (2) yields the final form of the stability model and are given as follows:

For the non-embedded condition:

$$\frac{W_c}{\rho g D^3} = \left( \frac{2\sqrt{2}}{\cos \theta - 2\sqrt{2} \sin \theta} + \phi \right) \frac{Fp_m}{\rho g D^3} + \frac{B_F}{\rho g D^3} \quad (4)$$

$$\phi = 1.0$$

For the embedded condition:

$$\frac{W_c}{\rho g D^3} = \left( \frac{1 + \phi}{\phi} \right) \frac{Fz_m}{\rho g D^3} + \frac{B_F}{\rho g D^3} \quad (5)$$

$$\phi = 0.7 \text{ for armor units on the crown}$$

$$\phi = 1.6 \text{ for armor units on the slope}$$

The proposed model, hereafter to be referred as MODEL A, expresses the stable weight in terms of two wave force components together with the buoyant force. Some of previous research, however, considered only one wave force component which is in the direction of movement. This type of condition is also considered in this paper, another model without the third term of Eqs. (1) and (2) is derived as given in Eqs. (6) and (7) and hereafter to be referred as MODEL B.

For the non-embedded condition:

$$\frac{W_c}{\rho g D^3} = \frac{2\sqrt{2}}{\cos \theta - 2\sqrt{2} \sin \theta} \frac{F_{p_m}}{\rho g D^3} + \frac{B_F}{\rho g D^3} \tag{6}$$

For the embedded condition:

$$\frac{W_c}{\rho g D^3} = \frac{F_{z_m}}{\rho g D^3} + \frac{B_F}{\rho g D^3} \tag{7}$$

The comparisons between experimental results and the proposed models are given in Fig.8, from which an excellent agreement between the calculated value of MODEL A and the experimental value is revealed. On the other hand, MODEL B underestimates the stable weight as shown in Fig.8(b) and (c). This implies that the normal component of wave force for the non-embedded condition and the horizontal component for the embedded condition are both

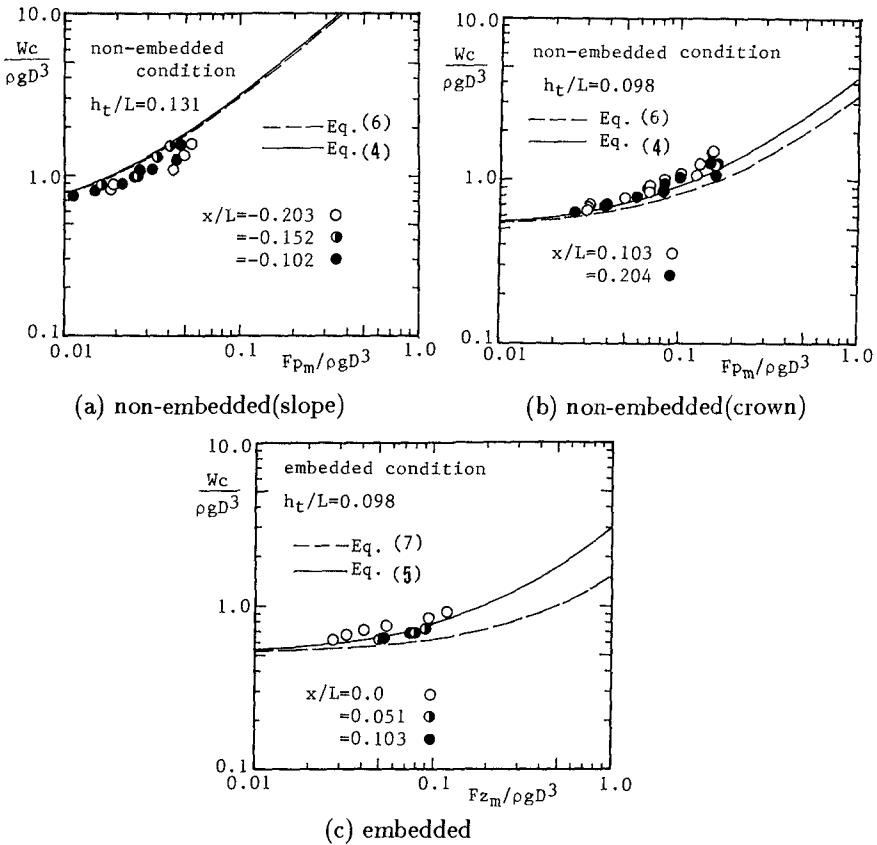

Fig. 8 Relationship of  $W/\rho g D^3$  with maximum dimensionless wave force.

significant in the armor stability. The normal component of wave force enlarges the upward force, thereby, making the non-embedded armor unit more unstable. Whereas, the horizontal force enlarges the overturning moment of the embedded armor unit.

Based on these two models, it is shown that the third terms are very important in a precise estimation of the armor stability. Thus, it can be concluded that both wave force components should be taken into account for an accurate estimation of stable weight of an armor unit. Very small difference between MODEL A and MODEL B is obtained for the non-embedded armor unit on the sloping part; since, in this situation, the tangential component of wave force is dominant over the normal component.

### 5. Maximum Wave Force

The proposed models express the stable weight of an armor unit in terms of the maximum wave forces acting on it. Therefore, an accurate estimation of wave force is required in the evaluation of stable weight.

Figures 9 and 10 show the variations of the dimensionless maximum wave forces,  $Fx_m/\rho gHD^2$  and  $Fz_m/\rho gHD^2$  with dimensionless distance from the leading crown-edge,  $x/L$ , as obtained from the wave force measurement experiments, where  $x$  is the horizontal distance measured from the leading crown-edge and  $L$  is the wavelength. Regardless of  $h_t/L$ , where  $h_t$  is the still water depth at the toe of the submerged breakwater, the variations under the same  $H_I/h_t$  value are quite similar. However, different variations of  $Fx_m/\rho gHD^2$  are obtained between non-breaking and breaking conditions. In Fig. 9, a typical variation of non-breaking and breaking wave conditions are shown with broken and solid lines, respectively.

For the non-embedded condition,  $Fx_m/\rho gHD^2$  increases with  $x/L$  on the slope and it reaches a maximum value near  $x/L = 0.0$ , regardless of wave breaking. On the crown,  $Fx_m/\rho gHD^2$  under breaking wave condition first decreases rapidly with increasing value of  $x/L$ , then takes a very large value when breaking waves attack the armor unit; and then finally decreases again. Under the non-breaking wave condition,  $Fx_m/\rho gHD^2$  decreases gradually with  $x/L$ , but a very large value at  $x/L = 0.7$  is again attained. In general,  $Fx_m/\rho gHD^2$  on the crown under the non-breaking wave condition is larger than that of the breaking wave condition except in the vicinity of the crown-edge.

For embedded condition, the variation of  $Fx_m/\rho gHD^2$  with  $x/L$  is smaller as compared to the non-embedded condition, because the variation of its velocity is also small.

The variation of  $Fz_m/\rho gHD^2$  with  $x/L$  is shown in Fig.10; however, the values of  $Fz_m/\rho gHD^2$  and its variation with  $x/L$  and  $H_I/h_t$  are smaller than those of  $Fx_m/\rho gHD^2$ . The quantity  $Fz_m/\rho gHD^2$  for both embedded and non-embedded conditions show no significant difference in magnitude except at  $x/L = 0.0$  where it becomes large under the non-embedded condition.

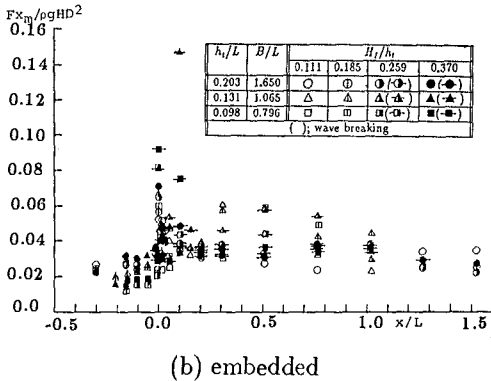

Fig. 9 Relationship of  $F x_m / \rho g H D^2$  with  $x/L$ .

The relative crown depth,  $d/h_t$  also has a significant effect on wave force, where  $d$  is the depth of water from the crown. Experimental results show that a smaller  $d/h_t$  results in a larger wave forces, although the figures corresponding to larger  $d/h_t$  are not shown in this paper (Iwata et al. 1991,1992, Mizutani et al., 1991, Rufin, 1992).

Fig. 10 Relationship of  $Fz_m/\rho g H D^2$  with  $x/L$ .

The relative crown depth,  $d/h_t$  also has a significant effect on wave force, where  $d$  is the depth of water from the crown. Experimental results show that a smaller  $d/h_t$  results in a larger wave forces, although the figures corresponding to larger  $d/h_t$  are not shown in this paper (Iwata et al. 1991,1992, Mizutani et al., 1991, Rufin, 1992).

Fig. 11 Relationship of  $u_m/\sqrt{gH}$  with  $x/L$ .

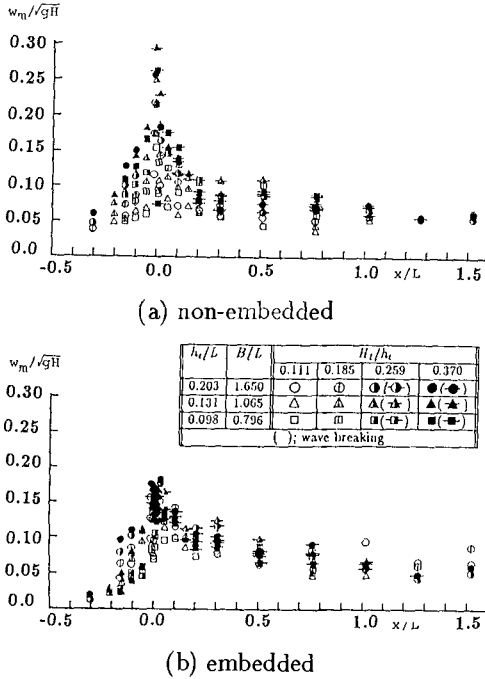

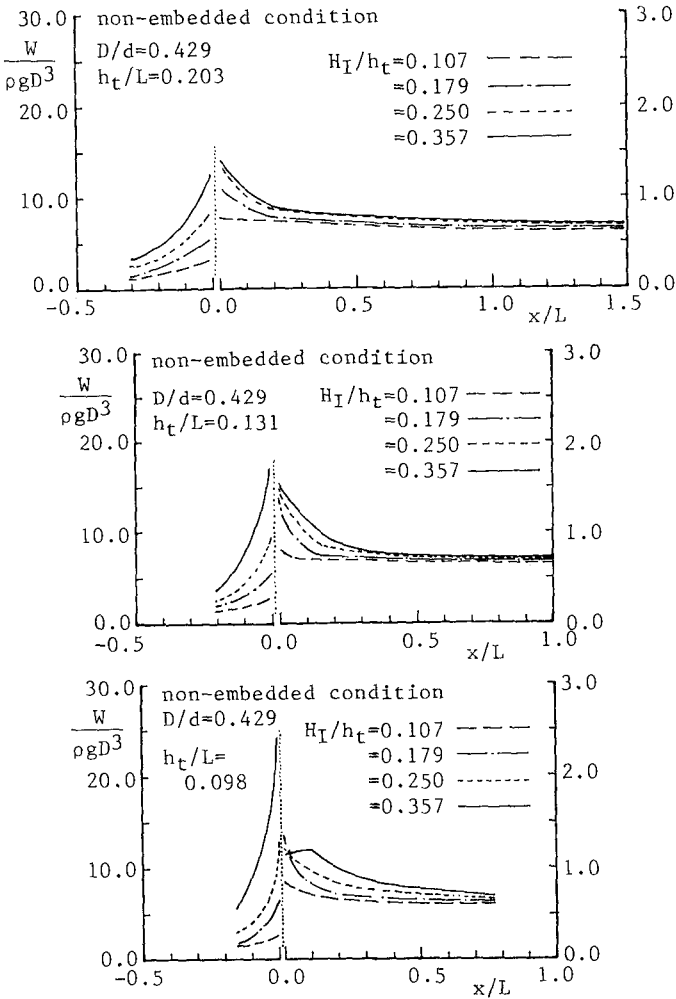

Fig. 12 Relationship of  $w_m/\sqrt{gH}$  with  $x/L$ .

These characteristics of wave forces are well correlated with the water particle velocities. The variation of dimensionless maximum particle velocities  $u_m/\sqrt{gH}$  and  $w_m/\sqrt{gH}$  with  $x/L$  are given in Figs. 11 and 12. On the slope, the velocity becomes larger with increasing  $x/L$ , due to wave shoaling, then attains a maximum value at the crown-edge. On the crown, the dimensionless maximum velocity decreases with  $x/L$  because of energy loss due to friction in the permeable structure and also due to wave breaking. A clear difference between the non-embedded and embedded conditions is observed in the horizontal component; however, no significant difference in the vertical component is observed. With regards to the effect of  $d/h_t$ , it was revealed that the dimensionless maximum velocity increases as  $d/h_t$  decreases (Iwata et al. 1991,1992, Mizutani et al., 1991, Rufin, 1992). These tendencies are similar to the dimensionless maximum wave forces. This means that the variation of dimensionless maximum wave forces is largely attributed to the velocity characteristics.

**6. STABLE WEIGHT OF SPHERICAL ARMOR UNIT**

Substituting the variation of maximum wave forces into Eqs. (4) and (5), the stable weight of the armor unit along the submerged breakwater is obtained. A plot showing the variations of the dimensionless stable weight of the spherical armor unit with  $x/L$  is given in Fig. 13. The discontinuity of the distribution at the leading crown-edge of the non-embedded condition is attributed to the significant contribution of the gravitational force. On the crown, the gravitational force acts only as a restoring force; however, some part of it acts as an overturning moment on the slope.

(a) non-embedded

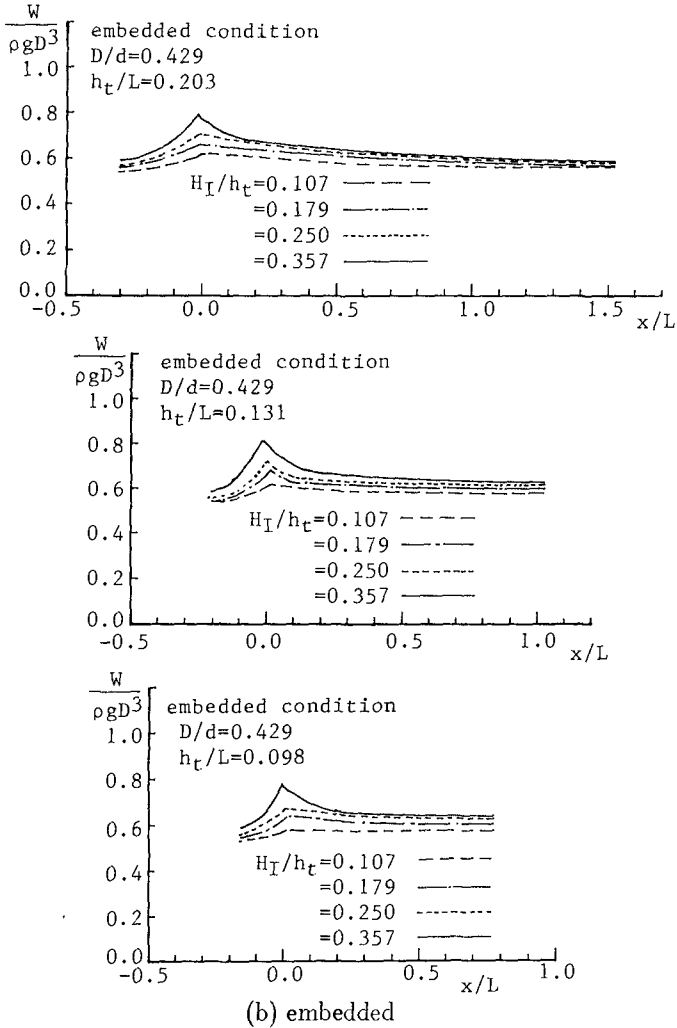

Fig. 13 Variation of  $W/\rho g D^3$  with  $x/L$ .

It is confirmed from the figures that the stable weight increases with increments of wave height on the slope where wave breaking does not occur. And the stable weight is greater around the vicinity of the crown-edge and at the location where wave breaks or where the horizontal roller and oblique-down vortex attack the armor units. Except at the vicinity of the crown-edge, there is a very little difference in the stable weight of the armor unit on the crown.

**7. CONCLUSION**

Results obtained from this study can be summarized as follows:

- (1) The vicinity around the crown-edge is revealed to be the most critical lo-

cation on the submerged breakwater.

- (2) A breaking wave greatly affects the stability of armor units.
- (3) Both horizontal and vertical or tangential and normal wave forces should be taken into account in the estimation of stable weight of armor units.
- (4) Stability models are derived to relate the stable weight of the armor unit with the wave forces acting. Also, the variations in the stable weight of spherical armor units on the submerged breakwater are given graphically.

#### ACKNOWLEDGMENT

The study presented was supported by Grant-in-Aids for Scientific Research from the Ministry of Education, Science and Culture of Japan, under Grant No. 03201138 (Head: Professor M. Hattori, Chuo University) and Grant No. 04201140 (Head: Professor Y. Iwagaki, Meijo University). The scholarship awarded by Offshore Mechanics and Polar Engineering Council and the International Society of Offshore and Polar Engineers to Mr. Teofilo Monge Rufin, Jr., one of the authors, is deeply appreciated.

## CHAPTER 108

New types of shore protection. Possibilities of application along the coast of France

P. Monadier\*, F. Ropert\*, B. Bellessort\*\*, J. Viguier\*\*

### ABSTRACT

The first part of this article gives an overview of the development works that have been carried out to date along the French coast, covering types, operating principles and impacts. A "philosophy" is identified with regard to the schemes implemented so far and those recommended for the future: rather than static structures that resist the action of the sea, it would often be preferable to substitute dynamic structures and schemes that work in harmony with it. Much research is being carried out on designs of this type. An analysis and summary of this work is given in the second part of this article. Most such work is currently at the experimental stage and no "miracle" solution has been found so far. Local conditions must be examined carefully before deciding to use any of the new alternatives being proposed.

### 1. INTRODUCTION

Until now, shore protection works on the French coast have usually involved the use of:

- rockfill, for transverse structures (groynes) and longitudinal structures on the upper beach (sea walls) or at sea (breakwaters),
- masonry or concrete structures (groynes, sea walls),
- beach nourishment, sometimes combined with stabilisation works (groynes, breakwaters).

The side-effects of these structures are not without drawbacks (for example, beach erosion), while blending them into the environment may pose problems.

---

\* SCTPMVN, 2 boulevard Gambetta, 60321 Compiègne, France

\*\* SOGREAH, 6 rue de Lorraine, 38130 Echirolles, France

In order to combat these negative features, various new solutions have been proposed in outline and even implemented in different parts of the world.

The Service Central Technique des Ports Maritimes et des Voies Navigables (SCTPMVN) commissioned SOGREAH firstly to carry out bibliographical research into the various new types of protection and to make an objective critical analysis of them, and secondly to examine the possibilities of applying them along the coast of France.

The operating principles of the various processes have been grouped under five headings: action on the hydraulic medium, use of geotextile, artificial seaweed, gentle methods, miscellaneous.

## 2. THE FRENCH COAST: TYPES OF SCHEME - OPERATION

### 2.1 The need for development works

Coastal development works (other than at ports) have various aims:

Natural processes:

- protection against sea erosion (e.g. cliffs in the Caux region),
- protection of low-lying areas against flooding (e.g. Ile de Ré),
- protection against changes in shoreline (e.g. La Coubre spit),
- reclamation and polder construction (e.g. Mont Saint Michel).

Human activities:

- Development linked directly with tourist and resort activities, namely sea fronts (e.g. La Baule, Royan, Les Sables d'Olonne) or artificial beaches (e.g. Prado, Mourillon, Larvotto).

- Coastal defence works (sea walls, dikes, groynes).

### 2.2 Overview

The French coast comprises 3300 km of soft terrain (i.e. 59% of the total, including 2000 km of beaches and 1300 km of marshland) and 2300 km of rocky formations.

The structures built along the coast include:

- 1300 transverse structures (groynes), totalling 125 km,
- 800 longitudinal structures (sea walls and bulkheads), totalling 375 km.

The total length (500 km) represents about 10% of the entire coastline (5500 km), i.e. a mean density of 50 m/km. On the basis of 5000-10 000 French francs per linear metre, the present cost of these works would be 3-5 billion francs.

The greatest density of structures is found in regions where loose formations are prevalent and where there is intense resort development, for example 175 m/km in Lower Normandy and 155 m/km in Languedoc-Roussillon and the central Atlantic coast. It is lowest in regions with loose formations but little development, such as Aquitaine (85 m/km) or a broken rocky coastline, such as Brittany (63 m/km). In Provence, where the coast consists mainly (75%) of hard rocks, the density of 100 m/km corresponds to a great extent to artificial beaches.

### 2.3 Operation

It is particularly important and instructive to analyse the operation of these schemes. Indeed, such an analysis must form the basis for future designs and justify the use of new methods.

The schemes may be divided into two basic categories, namely static ("hard" structures, such as bulkheads and sea walls that are "opposed" to the sea) and dynamic works (consolidation, by-passing, dune development, which are an attempt at compromise). Until recently, static methods were the ones most commonly used. They have often had negative impacts connected with two main factors:

- insufficient knowledge of the natural phenomena involved, resulting in inappropriate, wrongly sized or badly situated schemes,
- consideration of problems at the wrong scale, i.e. by taking into account administrative and not sedimentological areas.

The following points should be stressed in particular:

- Longitudinal structures have broken the beach-dune links that helped to regulate beach evolution and contribute to beach nourishment. They have disturbed both transverse and longitudinal balances by introducing resistant points that have finished by creating protrusions which then suffer preferential wave attack.

- Sea walls and bulkheads are often located too close to the sea and have given rise to erosion as a result of wave reflection and breaks in the natural equilibrium profile of the sea bed.

- There are serious problems of erosion on the down-current side of groyne because of a shortage of sediment supply. This problem is never solved correctly.

Structures of this type have therefore often produced erosion processes requiring other types of remedial work. This all has a snowball effect. A few examples may be given:

- On the regional scale, the coastal regime in the Seine-Somme area has been strongly affected by the various harbour works implemented over the last 200 years and by widespread pebble extraction. What was once a

continuous stretch of coast 150 km long is now segmented by harbours, while the stock of sediment (pebbles) has been impoverished.

- On the local scale, most large beaches developed inside bays are being eroded, mainly on account of the negative effects of coastal development works (as at La Baule, Les Sables d'Olonne and Royan).

- Numerous small harbours have produced localised disruptions, in particular when they are situated inside bays, as at Bormes-les-Mimosas, Cavalaire or Pornichet.

Until now, dynamic (or so-called "gentle") methods have been used relatively infrequently, for two main reasons:

- They do not provide any "universal" solution. The more active the coastal regime, the more difficult it is to contemplate using them. For example, they would be well suited to many small bays in Brittany but unacceptable on the coast of Aquitaine.

- In addition to the initial investment required, they usually involve maintenance, which is rarely appreciated by local and regional authorities.

### 3. NEW METHODS

Over the past two or three decades, the financial aspects involved (protecting 1 km of coast now costs 5-10 million francs) and increasing environmental awareness have favoured the use of "gentle" methods and at the same time encouraged research into new ones, mainly of the dynamic type. The various methods now being considered, experimented or studied may be grouped into five broad categories:

- action on the hydraulic medium,
- use of geotextiles,
- artificial seaweed and planting,
- gentle methods,
- miscellaneous.

#### 3.1 Action on the hydraulic medium

##### a. Modifications in wave propagation

Investigations have concerned:

- the recomposition of waves following artificial creation of a phase shift, the result of which is a transmitted wave carrying less energy than the incident wave: oscillating wall of water (PRINCIPIA),

- recomposition of cone-diffracted waves producing a wave front parallel to the coast (SOGREAH-LCHF study),

- reflection of waves on artificial bars (sand-filled geotextile tubes) according to the Bragg principle (NCEL).

These processes have all remained at the experimental stage as far as shore protection is concerned.

b. Attenuation of wave energy

Research in this field has concentrated more on various types of breakwater:

- submerged breakwaters,
- submerged moored floating breakwaters (Japan),
- pneumatic breakwaters (Great Britain, CIS),
- discontinuous pile-mounted breakwaters (CIS),
- miscellaneous types of breakwaters: tyres, cement pontoons, articulated breakwaters (Cornic, C1000).

Most of these studies have remained at the experimental stage. Often, the structures only operate correctly under specific hydrographic and oceanographic conditions.

c. Slightly reflecting structures

The function of these structures is to stabilise the coastline by limiting wave reflection and the formation of surf, which cause coastal erosion: Jarland caissons, Igloo blocks, ARC chambers (SOGREAH), Delta breakwaters (Berger Staemfli).

The results obtained are generally satisfactory.

### 3.2 Use of geotextiles in beach protection

The main types of mattress that have been tested are Armorflex, Nidaplast and Enkamat. The various procedures involving structures with a geotextile envelope are Longard, Sandtex, Robusta and Cornic. Most of these procedures are derived from those used in rivers or lakes and there have been many drawbacks in using them in a maritime context, such as stability and fragility of the textiles, damage of human origin, etc.

### 3.3 Artificial seaweed - planting

a. Artificial seaweed

So far, there have been no convincing results, although many tests have been carried out throughout the world.

### b. Planting (in particular Posidonia)

Planting Posidonia is now well understood, but there are still problems with this technique in the field of coastal protection, including growth time and area of planting.

### 3.4 Gentle methods

Gentle methods are meant to work in harmony with the sea. Usually, they should be considered not as a basic solution but as a complementary measure. The main types include:

- development of dunes (a new solution includes stabilisation using a gel),
- the creation of artificial coastal strips (Maguelo),
- beach nourishment, which is an attractive solution that is still little used in France and which poses certain problems in terms of the quantity and quality of material used and maintenance,
- by-passing; this technique is virtually unused in France so far; there are problems in terms of installation, maintenance and cost price.
- acceptable coastline retreat; this solution can only be envisaged under well-defined coastal conditions (in particular geographic and economic). It must be acceptable to the authorities and persons concerned.

### 3.5 Miscellaneous

This heading covers many different methods, many of which are still at the experimental stage, for instance:

- drainage of the foreshore (Stabeach system),
- artificial reefs created by electrolysis,
- planting on clay breakwaters (using geotextiles),
- cylindrical groynes and breakwaters (SOGREAH).

## 4. CONCLUSIONS

Many solutions are currently at the experimental stage. There would appear to be no "magic" solutions. In fact, it would seem rather a case of looking at the positive aspects of developing and adapting systems that already exist but that are sometimes "forgotten" because of technical or financial problems (e.g. beach nourishment, by-passing).

## CHAPTER 109

### FIELD ANALYSIS OF WAVE ACTION ON BREAKWATER

Alessandro Muraca (\*) - Vito Rossi (\*\*)

#### Abstract

Field analysis of breakwater damage progression has been performed using monitoring programs which included both photographic and topographic surveying. Reliable information on cover blocks displacement were obtained using a metric camera and a digitizer. Measured damage was compared with those estimated using empirical formulae.

A computer model, capable of predicting damage progression, has been also calibrated using in site collected data. Predicted damage has been satisfactory also for long time interval period.

#### Introduction

Field measurements have been carried out on a breakwater built up to protect a water intake dockyard for the power plant of Montalto di Castro (Tyrrhenian Sea, Italy). Cover consists of two strata of rocks, randomly placed by land based equipment, whose average diameter is equal to about 1 meter. The weight of primary armour ranges from 2 to 4 tons and the seaward slope is 1:2. The water depth in front of the structure is about 5 m. The structure is faced by one Waverider Datawell and one Wave-Track directional Endeco: the first installed in 1978, the second in 1986. From December 1991 Wave Track Endeco was replaced by a directional wave rider Datawell .

A field analysis of breakwater behaviour is necessary to evaluate the capability of commonly used design formulae for predicting the damage level ,due to wave attacks, attained by mound structure. Photogrammetric techniques combined with adequate ground control represents a common method for monitoring breakwater damage progression (Ackers, 1983; Gebert, 1984; Kluger, 1982; Pope, 1983; CETN, 1984).

-----  
(\*) Faculty of Engineering - Viale Ungheria, 43 - Udine, Italy

(\*\*) ENEL-CRIS Servizio Idrologico - Mestre (Venice), Italy

Accurate field investigations relied upon the use of photography, supported by topographic measurements. Both metric and non metric cameras were used to photograph the breakwater cover layer. Metric photographs were analysed using a stereoscope; this allowed both a better evaluation of cover blocks movements and a good estimation of the rotation of visible stones.

An accurate time and frequency domain study was made on recorded wave climate; moreover wave grouping aspects, its statistical properties and possible affects on breakwater stability were analysed. Recorded wave parameters were introduced in four commonly used stability theories. Comparison between the empirical design methods and prototype behaviour were made and found to be satisfactory.

Analysis of wave records and results of field inspections were also used to calibrate a computer program for predicting breakwater damage progression. By this model damage progression can be estimated as a function of real sea state records.

### Theoretical Damage Prediction

Breakwater stability analysis has been made over the past 30 years by using the Hudson formula (Hudson 1959). In recent years experiments in large wave flumes with irregular waves and careful analysis of prototype damage have led to the formulation of new theories which comprehend also random wave characteristic effects. Losada and Gimenez-Curto developed an exponential model as a function of surf similarity parameter to represent rubble-mound breakwater stability (Losada and Gimenez-Curto, 1980). This stability function is given by :

$$P = \frac{H_s^3 \cdot \gamma}{(S-1)^3} \cdot A(I - I_b) \cdot \exp[B(I - I_b)] \quad (1)$$

A and B are coefficients whose value is the function of foreshore slope and type of cover layer block. In plane H, T expression (1) could be plotted as an "interaction curve", equal to a set of the points which produce the same value of armour unit weight (Losada, 1980).

More recently Sawaragi and Ryu (Sawaragi, 1983) have analyzed in detail group effects on mound stability. These authors have discovered that a strong correlation exists between Goda spectral peakedness parameter  $Q_p$  and the energy sum of grouped waves  $E_{sumj}$  (Sawaragi and Ryu, 1985).

This relationship is expressed as follows:

$$E_{sumj} = H_s (0.042 Q_p + 0.125) \quad (2)$$

For an exact significance of  $E_{sumj}$  the reader is referred to Sawaragi, 1985. The linear relationship between sum energy of grouped waves ( $E_{sumj}$ ) and the spectrum peakedness parameter ( $Q_p$ ) has been verified using wave data recorded at Montalto di Castro. Both parameters have been evaluated at wave rider depth. Computed values of  $E_{sumj}$  were very similar to those estimated using eq. 2. The comparison is reported in Fig. 1.

Irregular wave experiments showed that the percentage of damage suffered by breakwater ( $D\%$ ) is a function of the above mentioned parameters according to the following expressions:

$$D\% = 153.8 \cdot \left[ \frac{E_{sumj}}{\gamma \cdot l a^2} \cdot \frac{tg \alpha}{tg \phi} \right] - 30.1 \quad (3)$$

$$D\% = \left[ \frac{\gamma a \cdot H_s^2}{\frac{1}{\gamma^3}} \cdot \frac{tg \alpha}{tg \phi} \cdot \frac{6.15 Q_p + 20}{P^{\frac{2}{3}}} \right] - 30.1 \quad (4)$$

Sawaragi defines the degree of damage as the percentage of destroyed volume with respect to the total volume of cover layer. According to Sawaragi a displacement takes place when armour units are moved over a distance greater than the overall size of blocks (Sawaragi, 1983).

More than 300 experiments were done by Van der Meer to analyse the effect of storm duration, wave period, group characteristics and spectral shape (Van der Meer, 1987, 1988). The effect of cover layer and sub layer permeability were also carefully investigated. Surprisingly group effects were not found to have a significant effect. More recently, stone shape and layer thickness influence were also analyzed using an expression comparable with Van der Meer formulation (Bradbury, Lothan, Allsoy, 1990) and new stability formulae were found for both overtopped and submerged breakwaters (Van d. Meer 1991). Van der Meer found two different relationships to determine stable rock block dimensions, for plunging and surging waves.

**Plunging waves** (I z < I c)

$$\frac{H_s}{\Delta \cdot D} \cdot \sqrt{Iz} = 6.2 \cdot p^{0.18} \cdot \left( \frac{d}{\sqrt{n}} \right)^{0.2} \quad (5)$$

**Surging waves** (I z ≥ I c)

$$\frac{H_s}{\Delta \cdot D} = \bar{p}^{0.13} \cdot \left( \frac{d}{\sqrt{n}} \right)^{0.2} \cdot \sqrt{\cot \alpha} \cdot (Iz)^p \quad (6)$$

Transition from plunging to surging is given by the following expression:

$$Ic = \left( 6.2 \cdot p^{0.31} \cdot \sqrt{tg \alpha} \right)^{1/(p+0.5)} \quad (7)$$

Using Van der Meer theory a mathematical method capable of describing revetment damage progression has been calibrated.

This analysis is possible by introducing a parameter that can be referred to as "equivalent sea state". This is equal to a time parameter describing the duration of a fixed sea state capable of causing the same amount of damage of different wave climate conditions (Muraca, 1989). Rearranging formulas (5) and (6) "equivalent sea state" results equal to :

$$D_1 = a \cdot \left( \frac{d \cdot p^{0.9}}{Iz^5} \right)^2 \cdot \left( \frac{\Delta^5 \cdot D^5}{H_s} \right)^2 \cdot T_m \quad (8)$$

$$D_2 = b \cdot \left( \frac{d}{p^{0.65}} \right)^2 \cdot \left( \frac{I_z^p \cdot \cot \alpha}{H_s^2} \right)^5 \cdot (\Delta^2 \cdot D^2)^5 \cdot T_m \quad (9)$$

where  $D_1$  and  $D_2$  are for plunging and surging waves respectively and  $a$  and  $b$  are dimensional coefficients depending on the units used in the above formulas.

The following steps were used to implement the stability model:

- 1) Evaluation of data from gauge records and calculation of wave parameter at the front of the structure depth;
- 2) Computation of minimum sea state capable of causing significant damage to the structure, in order to attain a lower limit below which the wave data recorded can be disregarded;
- 3) Interpolation between sea states and computation of Van der Meer 's damage parameter with free interval time steps.

All these operations have been implemented on a Vax Digital Computer.

Superimposition of the effects of a sequence of sea states, such as those registered by wave gauges, and the damage description starting from whatever revetment condition is thus modelled.

#### Site investigation

The investigated breakwater is provisional and undergoes large damage during severe storms. From autumn 1984 the structure has been regularly surveyed by contractors. An accurate zonation of cover layer according to the degree of suffered damage and the number of blocks necessary to rebuild the original sections have been registered at the end of each major event. From 1988, a more accurate survey of damage has been programmed. Two stretches measuring about 15 meters of the structures have been delimited by permanent rods and more visible blocks at different levels have been marked by water resistant paints. Once in two months three pictures were taken of each of the selected parts and the exact position of marked blocks was surveyed using topographical instruments. These operations were also repeated at the end of storms, when the structure was subjected to significant damage.

Cover layer photographs have been analyzed using direct linear transformation, a method developed by Abdel Aziz and Marzan and Karara at Illinois University (Abdel, 1971, 1974; Marzan, 1975). This technique is applicable after measurement by topographic instruments of the position of seven marked blocks, visible in each picture. Using a computer program and a digitizer has allowed a satisfactory precision in the estimation of the movement of cover layer blocks.

The computer program was based on direct linear transform method of Marzan. The lowest movements estimated with this technique were within the range of five to ten

centimetres and the possible errors in predicted position only seldom were over 0.5 meter. From autumn 1989 metric camera and digital photogrammetric stereo workstation was also applied for inspection. The photographs have also been viewed in pairs under a stereoscope: this provided a three dimensional image of the breakwater primary layer and good estimation of rotation of all visible blocks. A higher degree of accuracy in cover blocks displacements estimation was possible by using the photogrammetric workstation ; this was an appreciable advantage for the evaluation of global damage.

Since no underwater inspection was scheduled the following considerations refer only to the above water level part of the structure. However it is believed that this information provide a reasonable indication of the general condition of the breakwater cover layer.

Field survey were made on the following dates:

<b>Topographic</b>	<b>Photographic</b>
June 21 1988	June 21 1988
July 14 1988	July 14 1988
Sept 23 1988	Aug. 25 1988
Nov. 02 1988	Nov. 05 1988
Jan. 11 1989	Jan. 27 1989
Mar. 06 1989	Mar. 15 1989
May 02 1989	May 02 1989
June 12 1989	
July 06 1989	July 07 1989
Nov. 15 1989	Oct. 21 1989
Jan. 10 1990	Jan. 10 1990
June 26 1990	
July 09 1991	July 20 1991
July 16 1992	July 18 1992

The strongest storms were recorded in January and November 1987 and at the end of March 1988. The cover layer, which was seriously damaged, was repaired at the end of these storms.

Frequency and zero up-crossing time domain analysis of wave gauge records were made. An accurate study was also carried out to analyse wave grouping aspects registered by Datawell Waverider.

The length of runs were determined for two threshold values: the significant wave heights and average heights of the highest one-tenth waves. Possible resonance conditions were analyzed according to Sawaragi and Bruun and Gunbak theories (Sawaragi, 1985; Bruun Gunbak, 1978). Thus a continuous knowledge of structure behaviour and wave regime was available.

### Results and Discussion

The sea state characteristic of the major storms registered have been treated with the above mentioned methodology. Bathymetry is regular in front of the structure and bottom slope is equal to 1:80. Goda technique for random sea waves was applied for transforming Waverider information from deep to shallow water (Goda, 1975, 1985). A comparison between predicted and measured damage was done for the major storms registered. Hudson, Losada, Sawaragi and Van der Meer theories has been applied to compute theoretical damage level. Two severe events were registered in January 1987 and March 1988. The results of analysis of wave records, for March 1988 storm, are shown in Tab.1.

DATE	HOUR	H1/10 (cm)	T1/10 (s)	H1/3 (cm)	T1/3 (s)	Qp
30-03-88	18	307	6.8	253	6.9	2.2

Tab.1 Wave statistics from Waverider data - 30 March through 1 April 1988 (significant wave heights below 2.5 m are disregarded).

In both cases the structure suffered very severe damage.

Run lengths of groups exceeding significant and average of highest one-tenth waves were analyzed. During the March 1988 storm nearly all groups with heights over significant ones were within Sawaragi critical region and the breakwater suffered the highest observed damage: part of the filter was discovered and large portions of cover blocks were carried away. Tab. 2 shows damage estimations according to Hudson, Sawaragi and Van der Meer theories.

<b>PERIOD</b>						
Ja.-Ap.89		2.5			3	
Jul.90-92		4			5.2	

Tab. 2 Comparison of measure and predicted damage in selected events.

In June 1987 the damages were, in the same order mentioned previously, 20, 60 and 7 (Tab. 2). The maximum significant wave height and average height of the highest one-tenth waves, both computed in front of the structure, were introduced using Hudson formula. Predicted damage was closer to measured one using significant wave height.

Interaction and breaking limit curves for the Montalto breakwater have been plotted and compared with wave characteristic estimated in front of the structure. Interaction curve separates on plane (H, T) stability and instability zones (Losada, 1980). Significant wave characteristics, estimated at structure depth, for the March 1988 storm were compared with interaction curve. All significant waves were found to fall inside the stability area. To attain the instability region the average height of one tenth of waves should be used.

In shallow water this wave parameter seems more suitable for comparison between wave attacks and Losada stability function. For Sawaragi theory the maximum value of  $D\%$  parameter has been considered. For each wave gauge record significant wave heights at structure depth were computed with the theory of Goda while  $Q_p$  was estimated directly from Waverider records (eq. 4). No theory is available to transfer  $Q_p$  parameter at different depths (Mansard, 1987, 1988). However, because of the complexity of the shoaling mechanism, an exact transfer of wave data, especially those referred to wave grouping, from deep to shallow water depth is not possible through the existing theories (Mansard and Funke, 1988; Nelson, 1988).

Recently an application based on the TMA and Doneland models was used to transfer wave frequency spectrum from deep to shallow water, and results seem promising (Rebaudengo, 1992).

However all these methods are not applicable if there are significant non linearities. Since the variability of  $Q_p$  is not predictable, the peakedness value introduced in Sawaragi formula was estimated at wave rider depth. This could explain the higher differences between measured and predicted damage levels (Tab. 2). However

bathymetry is regular in front of the structure and bottom slope lower than 1:80 ; as a consequence  $Q_p$  computed at the Waverider depth is believed to be comparable with that in front of the structure (Rye, 1982).

To find out the degree of variability of  $Q_p$  parameter with water depth, some wave records at different depths were carefully analyzed. Data are referred to different Italian sites where two or more wave-riders are located at different depths, but aligned orthogonally to the coastline.

As shown in Fig. 2 the range of  $Q_p$  variability seems to be not significant in the range 13 to 50 meters of depths. An attempt to transfer the Esunj parameter from deep to shallow water was made using different shoaling theories for a single wave registered in time domain ; however results were not satisfactory.

The stability model was applied to determine the damage using the Van der Meer theory. Significant wave heights below 2.5 m were disregarded. After many computer trials and in site measurements to calibrate the program, this value of wave height value was found to be the minimum below which the estimated damage using the Van der Meer method, for a three hours wave attack, is negligible (Muraca, 1989).

The computer model allowed, in all examined events, a reliable prediction of breakwater damage due to wave attack ( see Tab. 2 for January 1987 and March 1988 storms ).

In 1988 the breakwater cover layer was repaired. During the first four months of 1989 the structure suffered only a slight damage. At the end of April 1989 the measured damage according to Van der Meer theory was equal to 2.5.

To test the capability of computer program in reproducing damage evolution, wave data of January-April 1989 were inserted as input. The test result was completely satisfactory since the final predicted damage was very close to the measured damage (Fig. 3).

A lengthy duration test was made inserting recorded wave data from July 1990 till June 1992. Also for the two year period the predicted damage was very closed to the measured damage (Fig. 4).

A continuous description of damage level evolution, based on Van der Meer's theory, then seems possible with satisfactory approximation. Nevertheless, some indetermination remains in estimation of wave parameter at shallow water depth, although the site measurements and wave data were carefully analysed.

### Conclusion

Photographic and topographic surveying have been applied for monitoring the stability of a rubble mound breakwater. Reliable estimation of cover blocks displacements can be obtained using non metric camera and direct linear transform method of analysis.

The use of a metric camera and digital photogrammetric workstation has allowed a high degree of accuracy.

A comparison between in site measured and predicted damage for a prototype breakwater has been made applying four different theories. A mathematical model for continuous damage description, based on Van der Meer stability analysis, has been calibrated with in site measured data.

This model describes superimposition of different sea states and evaluates the damage starting from different structure conditions. Predicted damage with stability model has been satisfactory also for very long simulation period.

A knowledge of the response of the structure for a real or project sequence of sea states can be helpful in programming maintenance or to decide if damage attained can be critical for the whole stability of the structure.

### LIST OF SYMBOLS

d	= Van der Meer damage level
D	= median diameter of stones of armour layer
D%	= Sawaragi damage index
Esumj	= Energy sum of grouped waves
H	= wave height
Hs	= significant wave height
I	= Iribarren number
Ic	= transition Iribarren number
Ib	= Iribarren number for breaking condition
Iz	= Iribarren number using Rice average wave period and Hs
la	= average dimension of armour stone
m <sub>n</sub>	= spectral moment of n order
n	= number of waves
Qp	= Goda spectral peakedness parameter
p	= Van der Meer permeability parameter
P	= weight of stable stone
S	= specific gravity of armour rock ( $\gamma / \gamma_a$ )
Tm	= average wave period ( $\sqrt{m_0 / m_2}$ )
$\alpha$	= angle of seaward slope of the structure
$\gamma$	= specific weight of stone
$\gamma_a$	= specific weight of water
$\phi$	= natural angle of repose of stone
$\Delta$	= relative mass density (S - 1)

# CHAPTER 110

## Wave Energy Dissipation on and in Rubble Mound Structures

M. Muttray<sup>1)</sup>, H. Oumeraci<sup>2)</sup>, C. Zimmermann<sup>3)</sup>, H. W. Partenscky<sup>4)</sup>  
University of Hannover, SFB 205, Franzius-Institut, Hannover/ Germany

### Abstract

The results of large-scale model tests are presented on the wave energy dissipation in the various layers of an Accropode armoured mound breakwater and on the interaction between external and internal wave motion. An attempt is also made to describe the "discontinuity" of the waterline at the boundary between layers of different porous materials. Wave reflection coefficients of the structure as well as dissipation and transmission coefficients through the different layers are evaluated as a function of the incident wave parameters.

### Introduction

In a previous paper it was shown that a) an improvement of the evaluation of the reflected wave energy is required as it represents an important portion of the incident wave energy, b) most of the incident wave energy is dissipated within the armour and underlayer and that a better description of the wave-induced flow in these regions is needed and (c) a good knowledge of the external flow and its interaction with the internal flow is needed as this represents a prerequisite for the development of a mathematical/numerical model for the internal flow field (OUMERACI & PARTENSCKY, 1990).

In this respect, further large-scale model tests have been performed in the Large Wave Flume (GWK), Hannover. The main objectives of these tests consist in the study of a) the interaction of the external and internal wave motion and b) the energy dissipation within the various layers of the structure, especially that dissipated in the first layers (high turbulent flow).

The present paper principally intends to present and discuss the first results of these tests which will certainly have some implications for the simulation of the wave-induced flow on and in rubble mound structures by using small-scale model tests and mathematical/numerical models (WIBBELER & OUMERACI, 1992).

### Experimental Set-up and Test Conditions

The experimental set-up in the Large Wave Flume (GWK) of Hannover is given in Fig. 1, showing

- b) the location of the wave gauges in front of and behind the structure.

a) Location of Wave Gauges

b) Location of Pressure Cells and 'Wave Run-up' Gauges

FIG. 1-EXPERIMENTAL SET-UP IN THE LARGE WAVE FLUME (GWK)

Four wave gauges in deeper water are used to determine the incident and reflected wave by using the 3-wave-gauge-procedure (MANSARD & FUNKE, 1987). Ten wave gauges on the foreshore are installed to analyse the wave field in front of the structure. The positions of these gauges are shown in Fig. 1a.

A cross section of the breakwater model with the position of the pressure cells and the wave run-up gauges is shown in Fig. 1b. Six wave run-up gauges and six static pressure cells were used to record the surface elevation on and in the structure. In order to measure the pressure variation in the most turbulent zone, 19 dynamic pressure cells were placed within the first layers of the structure.

The mean grain size of the core material (crushed stones) is  $d_{50}=4\text{cm}$  and the uniformity coefficient  $U=d_{60}/d_{10}=2.2$ . The underlayer is made of crushed stone of 0.5-5.0 kg ( $d_{50}=12\text{ cm}$ ), whereas the armour is composed of a single layer of 40kg Accropodes.

Regular waves with heights  $H=0.20\text{-}1.80\text{m}$  and periods  $T=3.0\text{-}12.0\text{s}$ , and irregular waves (TMA Spectra) with significant heights  $H_s=0.20\text{-}1.20\text{ m}$  and peak periods  $T_p=3.0\text{-}12.0\text{s}$  were used. Most of the wave spectra had a groupiness factor  $GF=0.77$ . However, some tests were carried out with groupiness factors  $GF=0.6\text{-}0.9$  in order to examine the effect of the groupiness factor on the results. The water depths in the wave flume was varied from  $d=4.20\text{m}$  to  $d=4.80\text{m}$ .

In the results presented below only non-overtopping test conditions are considered, i.e. regular waves with  $H=0.20\text{-}0.85\text{m}$  and  $T=3.0\text{-}12.0\text{s}$  and irregular waves with  $H_s=0.20\text{-}0.70\text{m}$  and  $T_p=3.0\text{-}12.0\text{s}$

For the conditions tested, REYNOLDS numbers (related to the grain size of the core material) in the range of  $10^5$  to  $10^6$  are expected within the core material; i.e. no scale effects due to the dissimilarity of viscous forces will occur.

## Discussion of Experimental Results

### **General Considerations**

As already mentioned, only tests with non-overtopping wave conditions are considered. In addition, no wave breaking occurs in front of the structure. In this case, the incident wave energy is splitted up into reflected, dissipated and transmitted wave energy.

$$E_i = E_r + E_d + E_t \quad (1)$$

The wave reflection coefficient ( $K_r$ ), the dissipation coefficient ( $K_d$ ) and the transmission coefficient ( $K_t$ ) are correlated by the relationship:

$$K_r^2 + K_d^2 + K_t^2 = 1 \quad (2)$$

$$\text{with } K_r = \sqrt{\frac{E_r}{E_i}}, \quad K_d = \sqrt{\frac{E_d}{E_i}} \quad \text{and} \quad K_t = \sqrt{\frac{E_t}{E_i}}$$

and where  $E_i$ ,  $E_r$ ,  $E_d$  and  $E_t$  are the incident, reflected, dissipated and transmitted (through the structure) wave energy components, respectively. Each of these energy components is considered to be expressed by the corresponding wave height squared ( $E_i \sim H_i^2$ ). The total dissipated wave energy  $E_d$  may be divided into the dissipated energy component on and in the armour layer ( $E_{da}$ ), on and in the underlayer ( $E_{du}$ ) and in the core ( $E_{dc}$ ),

$$E_d = E_{da} + E_{du} + E_{dc} \tag{3}$$

so that the following relationship for the corresponding local dissipation coefficients will result:

$$K_{da}^2 + K_{du}^2 + K_{dc}^2 = 1 \tag{4}$$

with  $K_{da} = \sqrt{\frac{E_{da}}{E_d}}$  ,  $K_{du} = \sqrt{\frac{E_{du}}{E_d}}$  and  $K_{dc} = \sqrt{\frac{E_{dc}}{E_d}}$

Eqs. (2) & (4) build the principal basis for the analysis and discussion of the experimental results . The porous structure and its geometry being given, the quantities involved in Eqs. (2) & (4) are determined by the prevailing water depth and incident wave parameters. The relative water depth ( $d/L$ ) and the wave steepness are expected to be the most relevant influencing parameters, since they strongly affect the shapes and kinematics of the waves at the structure. Since the latter are commonly described by the surf similarity parameter, its application to characterise the prevailing breaker types in the case of relatively high reflection coefficients and high velocity currents during the wave run down process on steep slopes is briefly discussed.

FIG.2 WAVE MOTION OUTSIDE AND INSIDE THE BREAKWATER

### Interaction Between External and Internal Wave Motion

Based on the wave motion simultaneously recorded at wave gauges 5-14 (Fig.1a) and "run-up gauges" 1-6 (Fig.1b), a detailed description of the external wave motion and the wave motion in the different layers of the breakwater is given, illustrating how the internal and external flow field influence each other.

The wave motion in front of the structure is described by using video records and the wave gauges located in that area. These records are intended to be used for the description of the breaker types, the volume and the velocity of the waves.

An example of the temporal variation of the surface elevation outside and inside the breakwater is shown in Fig.2 for an incident wave period  $T=4.5s$ , a wave height  $H=0.82m$  and a water depth  $d=4.50 m$ .

FIG.3 PRINCIPLE SKETCH FOR DISCONTINUITY ANALYSIS

An attempt is made below to partially describe the "discontinuity" of the waterline at the boundary between two layers of different porous materials. A

discontinuity of the waterline is generally expected at the boundary of two layers with different hydraulic resistance. Even by using the wave run-up gauges as shown in Fig.1b this discontinuity can not be described accurately. Despite the limitations resulting from this measurement procedure, an attempt is made to get an approximate description of the waterline within the first layers during the wave run-up and run-down process. For this purpose three angles  $\alpha$ ,  $\beta$ ,  $\gamma$  are defined in Fig.3. The definition of these angles is based on the assumption, that the free surface at the outer slope would continue to be represented by a *straight line* if the first layers had 100% porosity and no hydraulic resistance. It is therefore suggested that the deviation of the waterline from its straight course is caused by the relative difference in hydraulic resistance between two successive layers. Angles  $\alpha$ ,  $\beta$  and  $\gamma$  describe this deviation at the boundaries between the outer slope (Accropode layer), filter layer and core material, respectively. It is suggested that the analysis of the relationship between these angles and the wave parameters should lead to an approximate description of the discontinuity of the waterline at the boundary between two adjacent layers.

FIG.4 TEMPORAL RELATIVE VARIATION OF ANGELS  $\alpha$ ,  $\beta$  AND  $\gamma$

The temporal relative variation of the three angles  $\alpha$ ,  $\beta$  and  $\gamma$  during one wave period starting with the wave run-down at its lowest elevation is shown in Fig.4. Angle  $\alpha$  reaches a maximum at the highest run-up on the armour layer,  $\beta$  and  $\gamma$  at the highest run-up on the underlayer and on the core material, respectively. It is seen

that the maximum value of angle  $\gamma$  occurs later than that of angle  $\beta$  and that the occurrence of the maximum value of angle  $\beta$  is much more delayed as compared to that of angle  $\alpha$ .

In addition, it is found that the variation of  $\alpha$ ,  $\beta$  and  $\gamma$  strongly depends on the wave height. This is shown by Fig.5 illustrating the increase of angle  $\alpha$  with incident regular wave heights. This increase was expected, since angle  $\alpha$  was supposed to describe the hydraulic resistance of the Accropode layer and thus represents a measure of the hydraulic loss (dissipated energy). The same trend is also found for angles  $\beta$  and  $\gamma$ , but the effect of the wave height is less pronounced than for angle  $\alpha$ .

FIG.5 EFFECT OF WAVE HEIGHTS ON ANGLE  $\alpha$

### Wave Reflection Coefficients

The separation of induced and reflected wave components from the measured partial standing wave system taking place in front of a sloping porous structure still represents one of the most difficult tasks in hydraulic model tests. In Fig.6, the partial standing wave in front of the structure is shown for different wave conditions.

Due to non-linearities, cross-wave phenomena and measurement inaccuracy, simultaneous wave records at more than two different locations in the wave flume (in the direction of wave propagation) is required. Therefore, four wave gauges with different spacing in front of the structure are used. Depending on the prevailing wave periods, three wave probes are optimally selected for the reflection analysis. Details of the reflection analysis used in this study are given by MANSARD & FUNKE (1987).

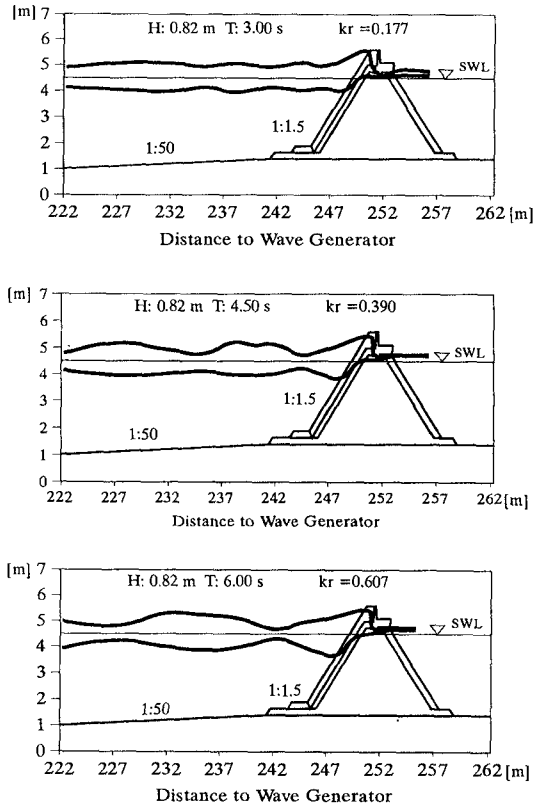

FIG. 6 PARTIAL STANDING WAVE IN FRONT OF THE BREAKWATER

Reflection coefficients  $K_r$  are determined as a function of relative depth  $kd$  ( $k=2\pi/L$ ), wave period  $T$ , wave height  $H$ , wave steepness  $H/L$  and onshore surf similarity parameter  $\xi$  ( $= \tan \alpha / (H/L)^{0.5}$ ).

Fig.7 shows the relationship between wave period and reflection coefficient  $K_r$ , which is stronger for irregular waves than for monochromatic waves. The wave periods on the x-axis refer to prototype conditions in which  $H_s=1.60-6.60\text{m}$  and  $H/L=.005-0.063$  were considered for this figure. For large values of the wave period, reflection coefficients of more than 50% may result and the reflection coefficient for regular waves is about up to 10% larger than for irregular waves.

FIG. 7 REFLECTION COEFFICIENT VS. WAVE PERIOD

The reflection coefficient for Accropode armour is also found to be nearly the same as for Tetrapod armour (Fig.8). The large scatter shown in Fig.8 also indicates that the surf similarity parameter does not represent an optimal mean for the description of the reflection process.

**Dissipation and Transmission Coefficients**

Wave-induced pressures have also been measured along the outer slope (seaward), so that the inflow boundary conditions may be described by both pressure (dynamic) and surface elevation (static).

FIG. 8 REFLECTION COEFFICIENT VS. SURF SIMILARITY PARAMETER

FIG. 9 PRESSURE DISSIPATION WITHIN THE FIRST LAYERS (LOWER ELEVATION, FAR FROM SWL)

The damping rates of the wave-induced pressure in a direction normal to the outer slope is plotted for different wave parameters. The related pressure gradients are evaluated as a function of the wave height, wave period and wave steepness.

Fig.9 illustrates for instance how the dynamic pressures are damped along the line through the locations of the pressure cells 7, 12 and 16. The pressure dissipation in the underlayer is a little higher than that inside the core. The damping rate is related to the wave period. At shorter wave periods ( $T=3.0$  s), the damping in the first layer is about 2.5 times higher than at longer periods ( $T=9.0$  s). Inside the core, however, it is only about 1.75 times higher. Comparing the damping along the line through the pressure gauges 8, 13, 17 and 19 (Fig.10) and along the line through the gauges 7, 12 and 16 (Fig.9) it can be seen that there is a slight increase of the damping rate for all wave conditions when the location of the line considered becomes closer to still water level (turbulent zone).

By considering a direction normal to the outer slope, the pressure gradients within the armour layers may reach values which are more than twice of those in the underlayer and more than four times of those in the first layers of the core material.

By assuming that the wave energy is proportional to the squared wave height ( $E \sim H^2$ ), the reflected, dissipated and transmitted wave energy components are analysed according to Eqs.(1)&(3) and as a function of the incident wave parameters. For this analysis the data recorded by wave gauges and wave run-up gauges has been used.

FIG.10 PRESSURE DISSIPATION WITHIN THE FIRST LAYERS (HIGHER ELEVATION, CLOSE TO SWL)

For instance, the results in Fig.11 illustrate the variation of the various energy components as a function of the wave period  $T_p$  for irregular waves with significant wave heights  $H_s=0.2-0.7m$ . The wave parameters in Fig.11 correspond to wave conditions in the Large Wave Flume (GWK). As expected, the reflected and transmitted part of the wave energy increases with increasing wave period while the dissipated energy decreases. In order to better examine the variation of the different components of the dissipated energy described by Eq.(3), Fig.12 has been prepared. It shows in more detail the variation of the dissipated energy in the armour layer, in the filter layer and in the core material as a function of wave period  $T_p$  and for the same wave conditions as in Fig.11. It is seen that the effect of the wave period on the wave energy dissipation is stronger in the outer layers and that in the core material almost no effect can be identified.

FIG. 11 WAVE ENERGY COMPONENTS VS. WAVE PERIOD

**Concluding Remarks**

The knowledge of reflected waves is determinant for the evaluation of the further dissipated and transmitted wave energy components. Therefore, particular attention has been devoted to the separation of the reflected waves from the measured partial standing wave system. This problem is, however, not definitely solved and the evaluation of reflected waves still remains an estimate.

A further topic which has been particularly dealt with, is the interaction of the wave motion outside the structure and the internal wave-motion. The results which have been reached so far, are expected to contribute to the better understanding of

the coupling mechanisms between external and internal flow which can generally not be satisfactorily described by small-scale model simulation and by existing numerical codes (WIBBELER & OUMERACI, 1992).

The attenuation of wave height and wave-induced pressure in the direction of wave propagation inside the structure is very fast within the first layers. The rate of attenuation tends to strongly increase with increasing wave height.

FIG. 12 WAVE ENERGY DISSIPATION IN DIFFERENT LAYERS VS. WAVE PERIOD

As expected, less wave energy is dissipated by a single armour layer (Accropodes) than by a double armour layer (Tetrapods). Consequently, more wave energy has to be dissipated within the underlayer of the Accropode armour than within the underlayer of the Tetrapod armour; i.e. particular effort should be devoted to the design of the underlayer when a single armour layer is used.

It is hoped that the results presented in this paper will eventually contribute :

- (a) to get a better insight into the geohydrodynamic processes affecting the overall stability of the structure as well as the stability of the armour units and further structure components;
- (b) to improve the description of the wave-induced flow on and in the structure and thus to evaluate properly the actual forces on the armour units and further elements of the structures;
- (c) to improve the commonly used simulation tools (small-scale models and numerical codes) by providing reliable data for their validation.

Further research is directed to developing a theoretical method for the approximate evaluation of the dissipated wave energy components in the structure as a function of the wave parameters and the hydraulic properties of the porous media.

### **Acknowledgements**

This study is supported by the German Research Council (DFG), Bonn. It is part of a research programme on breakwaters within the Coastal Engineering Research Unit (SFB 205) at the University of Hannover, Germany.

## CHAPTER 111

### Armour Displacements on Reshaping Breakwaters

P.A. Norton<sup>1</sup> and P. Holmes<sup>2</sup>

#### Abstract

A computer simulation model for the reshaping of dynamically stable breakwaters under normally incident, monochromatic waves has been developed. The proposed model is used to simulate initial reshaping as well as transport on the developed profile. Preliminary validation of the model has been carried out by comparison with data obtained from experimental tests on a berm breakwater.

#### Introduction

The concept of reshaping breakwaters has recently received a significant amount of attention although such structures have been in existence for many years. Potential design problems associated with reshaping breakwaters concern the extent of initial profile reshaping and the implications of rock degradation on overall structural integrity. Rock durability has been the subject of a number of investigations including the work of Latham (1988) and more recently Magoon (1992) although there is no model relating incident wave conditions to stone mobility on the seaward slope.

Van der Meer (1990) developed a computational model, based on empirical equations, which can be used to

<sup>2</sup> Professor of Hydraulics,

Dept. of Civil Eng., Imperial College, South Kensington,  
London, SW7 2BU, UK.

predict profile changes. The need for more detailed information, without physical model testing, has led to the development of a numerical model which includes some representation of individual elements of the structure.

A reshaping simulation model has been developed by combining a numerical description of both wave loading and the particulate structure of a breakwater armour layer. A one-dimensional model is used to describe wave-induced velocities on the seaward slope. Rock armour units within the armour layer are represented by equivalent spherical particles. A force model is used to assess armour stability and initiate displacements on the slope. With a good calibration procedure it is possible to simulate rock displacements resulting from exposure to given wave conditions.

### Particulate Structure

The armour layer of a breakwater is numerically represented by a random assembly of spherical particles. From a specified grading curve for the rock material, the equivalent spherical diameter is calculated for each stone class. The proportion of each size of spheres is also determined followed by random selection and finally placement within the packing volume. The structure is built-up in a series of horizontal layers of variable thickness to form the required initial profile.

Placement involves a vertical drop, from an appropriate location in the horizontal plane, followed by a rolling sequence until a statically stable position of minimum energy is found. If necessary, it is possible to achieve increased packing density by using a more selective placement procedure. For static stability, the centre of gravity of the object sphere must lie within the triangle formed by the three contact points in the horizontal plane. The following geometric equations must be simultaneously satisfied for the object sphere to be in contact with three supporting spheres,

$$(x_0 - x_1)^2 + (y_0 - y_1)^2 + (z_0 - z_1)^2 = (r_0 + r_1)^2 \quad (1)$$

$$(x_0 - x_2)^2 + (y_0 - y_2)^2 + (z_0 - z_2)^2 = (r_0 + r_2)^2 \quad (2)$$

$$(x_0 - x_3)^2 + (y_0 - y_3)^2 + (z_0 - z_3)^2 = (r_0 + r_3)^2 \quad (3)$$

in which  $x$ ,  $y$  and  $z$  are the co-ordinates of the sphere centre,  $r$  is the radius and the subscript 0 indicates the object sphere whilst the subscripts 1, 2, 3 identify the three supporting spheres. Longitudinal and transverse

sections through the numerically constructed armour layer of the berm breakwater are illustrated in figure 1. There are approximately 3000 spherical particles in total. The transverse section shows the structure width to be 0.3m (or  $9D_{n50}$  where  $D_{n50} = (M_{50}/\rho_s)^{1/3}$  in which  $M_{50}$  is the average stone mass and  $\rho_s$  is the mass density of the stone) which is sufficient to minimize the influence of the side-wall boundaries. Above the berm it can be seen that there are two layers of spheres which correspond to two layers of rock in the physical model. This layer is extended beyond the crest level of the physical model as the numerical wave model is not able to simulate overtopping by waves.

Figure 1. Numerically Constructed Armour Layer

### Wave Loading

A mathematical wave model is used to calculate the water particle velocities and accelerations on the seaward slope. Figure 2 provides a definition sketch for the wave model.

Figure 2. Definition Sketch

The governing differential equations, as derived by Kobayashi (1990), for the flow on and within a permeable slope are given for:

(i) external flow:

$$\frac{\partial h}{\partial t} + \frac{\partial(hu)}{\partial x} = -q_b \tag{4}$$

$$\frac{\partial(hu)}{\partial t} + \frac{\partial(hu^2)}{\partial x} = -gh \frac{\partial \eta}{\partial x} - \frac{1}{2} f_w u |u| - u_b q_b \tag{5}$$

in which  $h$  is the water depth,  $u$  is the depth-averaged velocity,  $g$  is gravitational acceleration,  $f_w$  is a wave friction factor,  $q_b$  is the discharge into permeable layer and  $u_b$  is the horizontal discharge velocity at interface

(ii) internal flow:

$$\frac{\partial(h_p u_p)}{\partial x} = q_b \tag{6}$$

$$\frac{\partial(h_p u_p)}{\partial t} + \frac{1}{n} \frac{\partial(hu_p^2)}{\partial x} - u_b q_b = -gnh_p \frac{\partial \eta}{\partial x} - gn h_p (a + b |u_p|) u_p \tag{7}$$

in which  $h_p$  is the depth of permeable layer,  $u_p$  is the discharge velocity in permeable layer,  $n$  is the porosity of armour layer,  $\nu$  is the kinematic viscosity of fluid and further:

$$a = \frac{\alpha(1-n)^3 \nu}{n^2 g D_{n50}} \quad b = \frac{\beta(1-n)}{n^3 g D_{n50}^2} \tag{8}$$

A preliminary verification of the permeable slope wave model has been carried out with velocity measurements on the seaward slope of a reshaped berm breakwater.

Figure 3. Model Berm Breakwater

The initial profile of the berm breakwater is illustrated in figure 3. The berm breakwater was reshaped using 4000 irregular waves from a Pierson-Moskowitz type spectrum with a significant wave height,  $H_s=0.180\text{m}$  and mean period,  $T_M=1.93\text{s}$ .

Maximum uprush (positive) and downrush (negative) velocities, measured using a MINILAB ultrasonic current meter, can be compared with calculated values in figure 4 for the specified regular wave conditions. The velocities are measured at mid-depth and the calculated values are depth-averaged values. Calculated maximum downrush velocities appear to be in relatively good agreement with measured values although the calculated velocities are consistently greater. There are more significant differences observed with the uprush velocities. The measured uprush velocities are much lower than expected and are not considered reliable due to poor performance of the current meter in highly aerated flows as observed during the uprush phase.

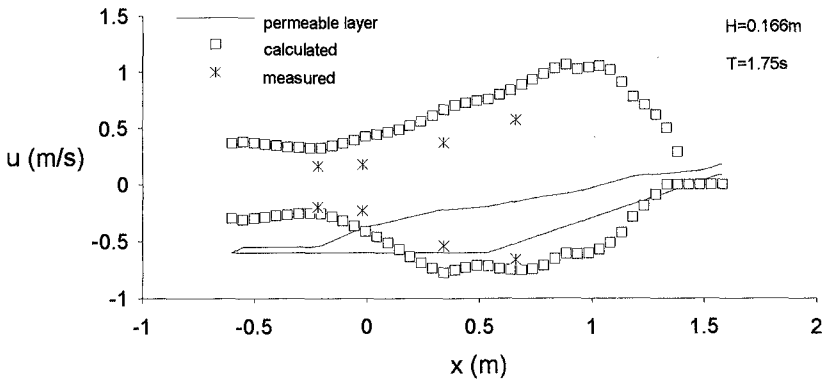

Figure 4. Measured and Calculated Maximum Velocities

The wave model requires the estimation of three input parameters which may be adjusted for calibration purposes. Some guidance for the selection of a suitable wave friction factor,  $f_w$  in equation 5, can be given by the formula developed by Madsen (1975) although a value of  $f_w=0.3$  was adopted after calibrating the model against observed maximum run-up levels. For the internal flow resistance, the laminar and turbulent flow coefficients,  $\alpha$  and  $\beta$  in equation 8, must be specified for the rock material. Values of  $\alpha=8000$  and  $\beta=2.4$  were selected based on the results of experimental investigations by Burcharth (1991).

Armour Initiation

To assess the stability of individual elements on the surface layer of the seaward slope, a failure mode must first be assumed. The most common displacement mechanism for single stones can be observed in the laboratory to be of a rotational nature. Den Breker (1985) found that almost 90% of rock armour displacements could be characterized by a rolling motion as opposed to sliding or lifting. For initiation it is thus appropriate to consider disturbing and restoring moments acting about a possible point or axis of rotation.

Disturbing forces resulting from the hydrodynamic wave loading are determined using a Morison-type equation including drag,  $F_D$ , inertia,  $F_I$ , and lift,  $F_L$ , force components given as:

$$F_D = 0.5\rho_w C_D (C_{SD} \frac{\pi}{4}) D^2 u |u| \tag{9}$$

$$F_I = \rho_w C_M (C_{SI} \frac{\pi}{6}) D^3 \frac{du}{dt} \tag{10}$$

$$F_L = 0.5\rho_w C_L (C_{SL} \frac{\pi}{4}) D^2 u^2 \tag{11}$$

in which  $\rho_w$  is the mass density of water and D is the particle diameter. The values selected for the force coefficients are based on the results obtained by Tørum with a drag coefficient,  $C_D=0.35$  and an inertia coefficient,  $C_M=0.20$ . For the lift coefficient,  $C_L=0.15$  is chosen although there is no guidance on suitable values. The resultant in-line force,  $F_x (=F_D+F_I)$ , is assumed to act through the centre of gravity of the projected area which is exposed to the surface flow. The vertical component of force,  $F_z (=F_L)$  perpendicular to the direction of the flow is assumed to act through the centre of gravity of the body.

The coefficients,  $C_{SD}$ ,  $C_S$  and  $C_{SL}$  are included to take into account the influence of partial submergence which may be necessary for particle locations between the maximum run-up and run-down levels. The submergence coefficients,  $C_{SD}$  and  $C_{SL}$  represent the reduction in projected area in the vertical and horizontal planes respectively, whilst  $C_S$  is associated with the reduced volume.

In addition to the hydrodynamic loading, the buoyancy force resulting from the displaced fluid must also be considered. The buoyancy force,  $F_B$ , acts through

the centre of gravity of the body in a direction perpendicular to gradient of the local, instantaneous free-surface as previously considered by Brandtzaeg (1966). The magnitude of the force can be calculated using the following expression:

$$F_B = \rho_w g (C_{SI} \frac{\pi}{6}) D^3 \quad (12)$$

The buoyancy force is separated from the particle weight as information concerning the gradient of the free surface is available from the wave model. The force is normally assumed to act vertically upwards. Restoring forces resisting movement comprise of the weight of the body:

$$W = \rho_s g \frac{\pi}{6} D^3 \quad (13)$$

as well as friction and interlocking forces.

Previous research by Wang (1990) indicates that friction and possibly interlocking forces can be directly related to the weight of the particle. In an attempt to include the combined influence of friction and interlocking, a coefficient,  $C_{FI}$ , is introduced. The selection of suitable values for  $C_{FI}$  is discussed further in the section describing the reshaping simulation model. The following condition must be satisfied during the specified duration to ensure initiation of movement:

$$e_1 F_{ZX} > e_2 (C_{FI} W) - e_3 F_B \quad (14)$$

in which  $F_{ZX}$  is the resultant wave force ( $F_{ZX} = \sqrt{F_X^2 + F_Z^2}$ )  $e_1$ ,  $e_2$  and  $e_3$  are the moment arms for the wave loading, effective particle weight and buoyancy force respectively. The moment arm for each component of force is found by calculating the perpendicular distance from the line of action of the applied force to the point or axis of rotation. A diagram of the system of forces, for a simplified particle geometry, considered for initiation is given in figure 5.

The wave loading is calculated for each particle and during a single wave cycle, based on calculated local depth-averaged velocities and accelerations. If the disturbing moments exceed the restoring moments for a specified minimum duration,  $t_{MN}$ , then movement is initiated in the direction under consideration. Usually, three possible directions of movement are considered

which are defined by the relative position of the supporting particles.

Figure 5. Forces Applied to Single Particle

For the purposes of predicting forces on individual particles it is more appropriate to consider a velocity outside the boundary layer. This is consistent with the measurements made by Tørum (1992) in which velocities and forces were measured on a berm breakwater slope from which force coefficients have been derived.

Reshaping Simulation

The reshaping simulation involves the application of two separate models which are linked by an iterative procedure. Initially, the surface of the armour layer is numerically profiled and an average profile is obtained from three longitudinal sections with measurements at intervals of  $D_{150}$ . To provide input to the wave model, a greater resolution of profile measurements will be required. Additional data is obtained by linear interpolation between points of the average measured profile.

Once a converged solution has been obtained from the wave model, temporal variations of water depth, velocity, acceleration and gradient of the free surface during a complete wave cycle are stored for 25 *sampling stations* along the slope.

One limitation of the displacement model is that only surface particles which are exposed to the external flow are considered to be potentially mobile. These particles are identified by having contact with only three supporting particles.

The stability of each surface particle is considered in turn commencing with particles nearest the toe of the slope. The wave-induced horizontal and vertical components of force are calculated using the data from the wave model. Velocities and accelerations at the precise particle location are obtained by interpolation of data stored for the two nearest sampling stations.

The magnitude of the discrete displacement,  $d_{MN}$ , must be small enough to provide a good resolution of particle displacements but sufficiently large to minimize computational times. For the simulations carried out,  $d_{MN} = 5D_{150}$  was found to be adequate.

If threshold conditions are obtained, the particle is given a discrete displacement of length  $d_{MN}$  in the direction selected as the path of least resistance. This is the direction which is associated with the maximum ratio of disturbing to restoring moments. Periodic boundary conditions are applied; thus if a particle passes through the sides of the computational domain, it is re-introduced at the opposite side. By this means any sidewall effects are eliminated. After displacement, a rolling sequence is used until the particle is relocated in a statically stable position.

After all surface particles are considered and displaced if hydrodynamically unstable, the process is repeated a further four times. The adjusted slope is then re-profiled for new input to the wave model followed by further displacement of surface particles. The complete iterative procedure described is repeated until there is negligible profile change from two successive particle relocation operations although there may be oscillatory displacements on the slope.

The process of particle *nesting*, particularly with berm breakwaters, has been observed in the laboratory whereby smaller material fills voids within the berm resulting in a highly interlocked layer and increased stability. This process has, to some extent, been incorporated into the simulation model by checking the location of surrounding elements after a particle is relocated on the slope. If the particle is sheltered from the surface layer from the external flow, an increased coefficient of  $2C_n$  is applied to the particle weight which generally prevents further movement. If the surrounding elements are subsequently moved, the coefficient reverts back to its normal value and further displacement is possible. Particle nesting of undersize material was not found to be a dominant factor for stability of the reshaped slope which may be attributed to the relatively narrow material grading ( $D_{85}/D_{15}=1.42$ ).

### Application to Berm Breakwater

The berm breakwater illustrated in figure 3 was reshaped with the irregular wave conditions previously described. The numerically constructed breakwater was reshaped by regular waves with the same waveheight and period as the irregular wave parameters,  $H_s$  and  $T_M$ , therefore  $H=0.18\text{m}$  and  $T=1.93\text{s}$ . The damage was expected to be more extensive with the regular wave conditions as there will be few waves greater than  $H_s$  in the irregular wave series.

The main calibration factor required by the reshaping simulation model is the combined friction-interlocking coefficient,  $C_R$ . An artificially high value of  $C_R=5.0$  results in an almost statically stable structure whereas a low value,  $C_R=0.5$  produces a highly mobile structure for which all particles are unstable. In the absence of suitable data relating to the rock material, a trial and error procedure is required in order to determine a suitable value for which the predicted profile matches the experimental profile. Once established, reshaping under other wave conditions can be studied as the value of  $C_R$  is also expected to be a property of the packed material and independent of the wave conditions. The value of  $C_R$  is expected to be a function of the structure slope although the chosen constant value of  $C_R=1.6$  was found to be adequate for the simulation presented.

Results from the reshaping simulation, for the initial structure, are presented as an average reshaped profile. A measured and predicted reshaped profiles are shown in figure 6. An intermediate profile is also included although the simulation is not time-dependent and only included to provide an illustration of how the profile evolves.

Figure 6. Measured and Predicted Average Profiles

The predicted profile shows an increased degree of erosion from the upper part of the slope with a corresponding increased amount of accretion below SWL. The toe of the reshaped profile does not consist of material at its natural angle of repose but there is still some influence of the hydrodynamics which produces a relatively smooth transition to the horizontal bed. A section through the numerically reshaped structure is presented in figure 7.

Figure 7. Section Through Reshaped Berm Breakwater

After initial reshaping of the model breakwater, further tests were carried out in which individual stone displacements were observed as described by Tomasicchio (1992). By painting the reshaped profile in zones across the width of the flume, damage to the surface layer defined by the number of displaced stones was determined. Wave conditions with progressively increasing stability number,  $N_s$  ( $N_s = H / \Delta D_{n50}$ , where  $\Delta = (\rho_a - \rho_w) / \rho_w$ ), but constant wave steepness, were used and an assessment of the cumulative damage made after each test. Most of these tests were conducted with irregular waves although some data is available for displacements under regular waves. Due to the differences in the measured and predicted profiles, quantitative results from physical and numerical experiments are not compared. Figure 8 shows results from a typical simulation of displacements on the reshaped slope presented as a plan view of surface particles before and after exposure to regular waves with  $H = 0.166\text{m}$  and  $T = 1.86\text{s}$ . The particles are shaded according to their position on the reshaped slope before displacement.

Figure. 8 Surface Particle Displacements

### Conclusions

A reshaping simulation model, using a deterministic approach, which includes detail of individual armour displacements is shown to provide a qualitatively good prediction of profile development. Predictions of transport on the reshaped profile can also be made with the calibrated model although the results have not been validated against experimental data.

The influence of variability within the random structure of the armour layer can be investigated by repeating the numerical experiments on a modified structure. A different structure, with the same material grading and initial profile, can be numerically constructed by providing different seed values to the random number generator used to select particles for placement.

Modifications towards a more probabilistic model should include the variability of particle shape. This would require a distribution of projected area/volume, wave force and friction-interlocking coefficients rather than applying a single value as used in the present model.

Further improvements to the component models are possible although the associated increase in computational time should be taken into consideration. The simulation of initial reshaping with the present model can take up to 8 hours on a 50MHz 486 machine.

## CHAPTER 112

### THE BREAKING AND RUN-UP OF SOLITARY WAVES ON BEACHES

Ashwini Otta<sup>1</sup>, Ib A. Svendsen<sup>2</sup>, and S. T. Grilli<sup>3</sup>

#### ABSTRACT

A high accuracy boundary element method is used to compute the propagation of solitary waves from a constant depth region onto a plane slope. Initial wave heights range from  $H/h = 0.06$  to  $0.775$ , slopes between  $1:35$  and  $1:1.73$  ( $30^\circ$ ) have been investigated. The prebreaking shoaling shows very different characteristics on gentle slopes ( $1:20$  and less) and on steeper slopes.

A diagram constructed on the basis of a large number of numerical experiments gives a simple limit between which waves break on which slopes and which not. Typical examples of the range of wave behavior are shown. Waves that do not break at run up often break during run down. The velocity fields for the two types of breaking are compared and found to be very different. A simple explanation for this is offered.

#### 1. INTRODUCTION

The shoaling, run-up and breaking of solitary waves is of interest in connection with the analysis of the behavior of tsunamis in coastal regions.

A significant amount of literature has been published which analyses long wave propagation on slopes using the non-linear shallow water (NSW) equations or Boussinesq approximations. Thus, analytic solutions to periodic problems were obtained by Carrier & Greenspan (1958), Carrier (1966) and to the solitary wave problem by Synolakis (1987). Numerical solutions have been developed by Hibberd and Peregrine (1979), Pedersen & Gjevik (1983), and Zelt (1991). Furthermore, Kim et al. (1983) used a boundary integral formulation to analyze the problem. Experimental results for run-up were obtained by Ippen & Kulin (1954), Camfield & Street (1969) and recently, by Synolakis (1987). In particular

<sup>3</sup>The University of Rhode Island, Department of Ocean Engineering, Kingston, RI 02881

Synolakis, comparing results from the NSW equations with experimental run-up, finds some deviations in the surface profiles in the final stages when the waves get steep. Papanicolaou & Raichlen (1987) give a few results for breaker heights on very gentle slopes ( $< 1:50$ ). Finally, Svendsen & Grilli (1990) found using a high accuracy boundary element method (BEM) that when solitary waves of steepness up to 0.50 run-up on a relatively steep slope, the velocity profiles would differ quite significantly from the depth uniform velocity which is intimately linked with the NSW-equations. Similarly, the run-up of non-breaking waves, while in accordance with experimental results, would differ from the NSW predictions by as much as 75%.

Synolakis also developed a criterion for whether the waves would eventually break during the run-up and concluded that as the slope angle becomes small, the theory is only valid for small  $H/h$  whereas for steep beaches, he estimated the theory would be valid for relatively large  $H/h$ .

In the present paper we apply the version of the BEM method developed by Otta, Svendsen & Grilli (1992) to analyze the development of solitary waves on beaches. The wave heights initially (on the constant depth region in front of the slope) have height to depth ratios  $H/h$  from a moderate 0.10 to 0.775, the latter being almost equal to the steepest stable solitary wave on a horizontal bottom. The beach slopes are between 1.35 and  $1/1.73$  ( $30^\circ$ ). Both the shoaling behavior and the question of whether the waves break (and how) are addressed.

## 2. PROBLEM FORMULATION

The situation considered is described in Fig. 1. Solitary waves generated with initial height  $H_0$  in a region of constant depth  $h_0$  propagate towards a plane beach with slope angle  $s$ . Hence the only independent parameters of the problem are  $H_0/h_0$  and  $s$ . The motion is assumed irrotational and hence can be described by a velocity potential  $\phi$ . Hence the velocity field  $\vec{v}$  is given as

Figure 1: Definition Sketch

$$\vec{v} = \nabla\phi \tag{1}$$

and in the entire flow region  $\phi$  satisfies the Laplace equation

$$\nabla^2\phi = 0 \tag{2}$$

subject to the boundary conditions

$$\frac{\partial\phi}{\partial n} = 0 \text{ at the bottom } z = -h_0(x) \tag{3}$$

$$\frac{D\phi}{Dt} = \frac{1}{2}|v|^2 - g\eta \tag{4}$$

at the free surface  $z = \eta(x, t)$

$$\frac{D\eta}{Dt} = \vec{v} \tag{5}$$

where  $D/Dt = \partial/\partial t + (\vec{v} \cdot \nabla)$  represents the total derivative following a fluid particle. The geometrical quantities are shown in Fig. 1 and we have assumed a constant pressure along the surface.

To achieve the necessary accuracy in the computations, the solitary waves are generated initially by a method described by Tanaka (1986). At  $t = 0$ , we assume such a wave present in the computational wave tank with crest sufficiently far from the toe of the beach to be essentially undisturbed by the beach. Similarly, the seaward boundary is placed sufficiently far away not to disturb the computations with its reflection.

### 3. METHOD OF SOLUTION

The exact equations described in section 2 are solved by transforming the Laplace equation (2) into a Boundary Integral Equation which reads

$$\alpha(\vec{x}, t)\phi(\vec{x}, t) = \int_{\Gamma} \frac{\partial\phi}{\partial n} G(\vec{x}, \vec{x}_0) - \phi(\vec{x}_0) \frac{\partial G(\vec{x}, \vec{x}_0)}{\partial n} d\Gamma(\vec{x}_0) \tag{6}$$

$\Gamma$  represents the (closed) boundary of the computational domain given by the bottom and slope, the entire free surface and the seaward boundary (see Fig. 1).  $\vec{x}$  and  $\vec{x}_0$  indicate points on the boundary curve,  $\vec{x}_0$  being the point with respect to which the integral is performed. A free space Greens function is used for  $G(\vec{x}, \vec{x}_0)$ . (6) is an exact representation of the original equation (2) which was exact too.

The solution of (6) at each time step is found numerically at modal points on the boundary. These nodes divide the boundary  $\Gamma$  into  $M$  segments  $\Gamma_j$  each spanning over an element. Thus, (6) can be written

$$\alpha(\vec{x}, t)\phi(\vec{x}, t) = \sum_{j=1}^M \int_{\Gamma_j} G(\vec{x}, \vec{x}_0) \frac{\partial\phi}{\partial n} d\Gamma - \sum_{j=1}^M \int_{\Gamma_j} \phi(\vec{x}_0) \frac{\partial G(\vec{x}, \vec{x}_0)}{\partial n} d\Gamma \tag{7}$$

which is still exact. Hence, the solution is reduced to the question of expressing the two types of integrals in (7) in terms of  $\phi$  and  $\frac{\partial\phi}{\partial n}$  at the nodes.

The details of this technique, which also includes upgrading to the next time step the boundary values of  $\phi$  and  $\partial\phi/\partial n$  at each point using the boundary conditions (3) and (4) are described by Grilli et al. (1989), Grilli & Svendsen (1990a,b).

The approach used for the computations reported here differ from previous versions of the method in the way the derivatives along the boundary and integrals in (7) have been computed. A third order polynomial based on four nodes has been used, centrally positioned around each interval (termed midinterval approximation).

This turns out to yield a substantial improvement in accuracy over the spline approximations used earlier. Fig. 2 shows a comparison of results for  $H/h$  and the maximum error in the normal velocity  $\partial\phi/\partial n$  for the propagation of a very steep solitary wave ( $H/h = 0.775$ ) on a horizontal bottom. This is close to highest wave of  $H/h = 0.78$  that remains stable according to Tanaka (1986).

Ideally, we should expect each of the quantities in these computations to stay constant during the propagation. Initially, however, the wave undergoes minor changes before settling down to a largely constant value. These adjustments are caused by the fact that the numerical representation of the wave in our computations is based on different node position and also uses interpolation between nodes that differ (slightly) from the interpolation used in the computation of the initial wave (at  $t = 0$ ) by Tanaka's method.

In all, however, the constancy of the parameters in Fig. 2 shows the substantial improvement over previous versions of the method, which were not quite able to cover the propagation of waves with heights so close to the maximum stable wave height. The figure represents propagation over approximately 30 water depths.

#### 4. SHOALING OF SOLITARY WAVES

The tool thus developed has been used for numerical experiments with the shoaling and breaking of solitary waves on beaches with slopes varying from 1/35 to approximately 1/2.

Fig. 3 shows computations on a slope of 1/35 of waves with steepness between 0.10 and 0.40. The local value of  $H/h$  on the slope is plotted against  $x/h_0$ , the distance from the initial position of the wave crest.

The variation is essentially the same for all value of  $H/h$  and all waves in the figure end up breaking. Noticeable is the fact that the value of  $H/h$  at the breaking point almost independent of the initial height of the wave. The smaller waves just travel to smaller depths before they break. This pattern was already

Figure 2: Accuracy of Computations for Very Steep Solitary Wave ( $H/H = 0.775$ ) on a Constant Depth. 1) Quasi-spline interpolation. 2) Cubic mid-interval approximation.

Figure 3: Shoaling of Solitary Waves of Different Initial Height  $H_o/h_o$ , on a slope  $1/35$ .  $H/h$  on the Slope versus  $x/h_o$ . Slope Starts at  $x/h_o = 25$ .

Figure 4: Shoaling of Solitary Waves of Different  $H_o/h_o$  on Different Slopes.

observed experimentally by Ippen & Kulin (1954). It is also worth noticing that the  $H/h$  value of breaking for all the waves is 1.35–1.45, i.e., dramatically above the height 0.78 or 0.8 of the highest stable wave. The reason for this is of course that the (in)stability of a high symmetrical wave on a constant depth has little to do with unsymmetrical deformation to breaking of a wave on a gradually decreasing water depth.

The absolute change in the height of the waves can not be deduced from Fig. 3. Fig. 4, however, shows the variation of wave height  $H$  relative to the original height  $H_o$ . This figure also includes a sample of results for a number of steeper slopes (1/20, 1/8.25, 1/6.5). We observe in this figure a substantial difference in the behavior on different slopes of waves initially of the same height. Whereas the waves on a 1/35 slope studied in the previous figure increase in height by generally a factor of 2 ( $\log H/H_o \sim 0.3$ ), the same waves on the steeper slope of 1/8.25 or 1/6.5 propagate on the slope essentially without change in absolute height. It even turns out that on a slope with steepness 1/6.5, only the initially steepest of those waves reach breaking (see below).

The figure also shows that non of the two theoretical laws proposed in the literature for the variation of the height of shoaling long waves are particularly satisfactory. Green's law  $H \propto h^{-1/4}$  (represented by line G in Fig. 4) clearly has some merit during the initial stages of waves on the slope of 1/35 as one should expect from its derivation based on small amplitude waves on gentle slopes. More surprising perhaps is that the relation  $H \propto h^{-1}$  predicted by the Boussinesq theory (line B in Fig. 4) can be said to approximate the later part

of the wave height development towards breaking as judged from the fact that  $H/H_0$  curves for waves on a 1/35 slope have the same slope in that region. These features were discussed by Synolakis (1991) on the basis of experimental results. On the steeper slopes, however, even 1/20, none of these laws will apparently provide accurate predictions for the wave height variations. In fact, the steepest wave of 0.40 (curve g) on a 1/6.5 slope even decreases slightly in height as it climbs the slope.

## 5. WAVE BREAKING ON SLOPES

### Variation with slope angle and wave height

The second problem addressed in the present paper is the question of which waves break on which slopes.

Fig. 5 shows the propagation of the same wave, a very steep solitary wave with initial height  $H_0/h_0 = 0.75$ , on three different slopes,  $30^\circ$ ,  $7.12^\circ$  (1/8),  $3.81^\circ$  (1/15). The three figures illustrate the range of behavior described in section 4, and we particularly see that even a wave initially close to the maximum stable steepness does not break if the slope is too steep. It turns out that a wave of nearly maximum steepness will only break if the slope angle is smaller 1:4.

We also see the radical difference between the behavior of the same wave on a  $30^\circ$  and a  $7.12^\circ$  slope. Where the crest in the first case essentially rushes up the slope with a total runup of close to three times the initial wave height the wave on a  $7.12^\circ$  slope hardly changes height at all and mainly undergoes a rapid deformation that ends with breaking.

On a  $7.12^\circ$  slope, the front of the wave becomes an almost vertical wall at the point of breaking and the breaking occurs violently as the entire wall tumbles over. On the gentler slope of  $3.81^\circ$  the wave breaking is a classical plunging breaker although the size of the jet is relatively small.

In Fig. 6 is shown the influence (or lack of influence) of wave height on the breaking on a fairly gentle slope ( $3.81^\circ$ ). Each of the four waves with initial heights of  $H_0/h_0 = 0.3, 0.45, 0.6$  and  $0.7$  have shapes at the point of breaking that virtually are scaled versions of the others. Only the height to depth ratios  $H/h$  are slightly different as indicated in section 4 with the smaller wave reaching the largest  $H/h$ -value before it breaks.

### Breaking criterion

Based on a sufficient number of such calculations as numerical experiments, we are then able to construct the diagram shown in Fig. 7 which shows which waves break, which do not. The axes are  $\log 1/s$ , ( $s = h_x$  being the slope) and  $\log(H_0/h_0)$ ,  $H_0$  the original wave height on the constant depth  $h_0$ . The full line in the diagram separates the waves that break before or during run-up on

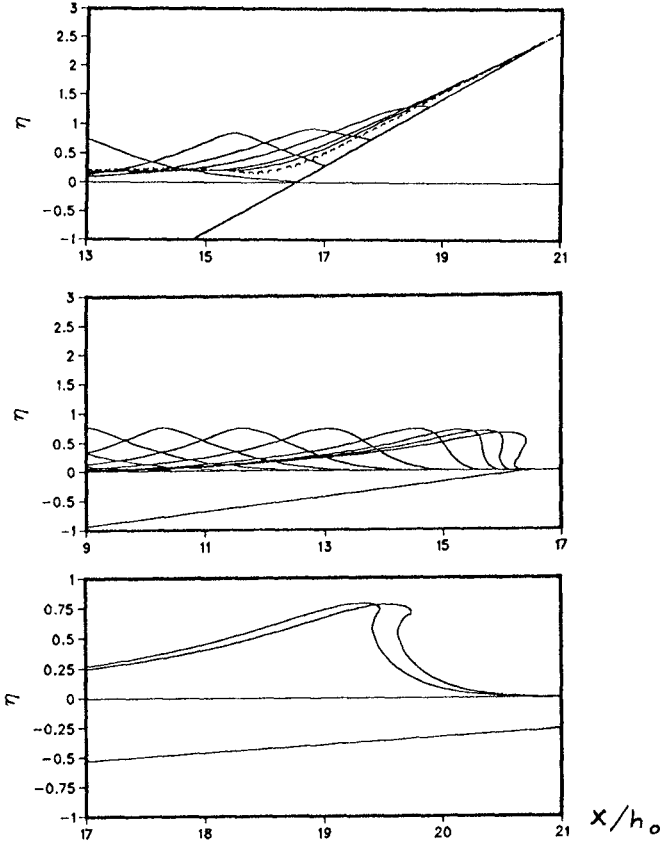

Figure 5: The Breaking of the Same Wave ( $H_o/h_o = 0.75$ ) on Three Different Slopes: a)  $30^\circ$ , b)  $7.18^\circ$  (1:8), c)  $3.81^\circ$  (1:15).

Figure 6: Breaking of Four Different Waves ( $H_o/h_o = 0.3, 0.45, 0.6$  and  $0.7$ ) on the Same (relatively gentle) Slope  $3.81^\circ$  (1:15).

a given slope. We see that the line indicates that waves with

$$\frac{H_0}{h_0} > 8.4 s^{15/9} \quad (8)$$

will break sometime during run-up on a slope.

The question of which waves break on a slope was also addressed by Synolakis (1987). Using the non-linear shallow water equations (NSW), he found that waves would eventually break on the slope if  $H_0/h_0 > 0.825^{10/9}$ . This criterion is indicated by the dashed line in Fig. 7.

We see that only for waves initially of noticeable steepness the NSW equations predict, that much smaller waves will break, than is found by the present more accurate method. Since run-up is greatly reduced if the waves break, this will also result in the NSW equations predicting much less run-up for the class of waves that actually do not break.

It could be argued that for waves initially of very small height (such as Tsunamis), the extrapolation of the two lines in the figure will meet. This happens for  $H_0/h_0 = 0.0078$  (corresponding to  $s = 0.015$ ), so that for that set of parameter values, the two methods give the same limit for which waves break and which do not.

However, in the first place it is not clear in advance that the formula (8) can be extrapolated to such small values of  $H_0/h_0$ . We have not at the present time performed any numerical experiments with so small wave heights on such gentle slopes.

Secondly, even such small waves will become quite steep when they approach breaking. The fact that the NSW equations fail to correctly predict breaking of the initially steeper waves may indicate that their prediction of the behavior of waves close to breaking is generally deficient, no matter how those waves start out. This would be in accordance with the general knowledge that near breaking the deviations from the hydrostatic pressure imbedded in the NSW equations is important.

#### Surging breakers

One of the interesting phenomena to look for in the numerical experiments is what happens to the waves that almost break, or only just break. Those are the waves around the full line in Fig. 7. If they break, this would presumably correspond to a so-called surging breaker. Fig. 8 shows computations for very steep waves on a slope of 1/4. The initial wave heights are 0.65, 0.68 and 0.75, and according to Fig. 7 these waves should not break but, particularly the 0.75 case should be very close to breaking. The figure is undistorted in scales so we can judge the development.

We notice that these waves show all the characteristics found from experi-

Figure 7: Wave Breaking Criterion

Figure 8: Waves Close to a Surging Breaking

ments for surging breakers. The front, with no water ahead of it, steepens to about  $75^\circ$  and the steepest surface slope is at very bottom of the front. At a certain point, the steepness stops, however, and the toe of the front shoots forward into a run-up while the wave crest behind collapses. Clearly, a very significant part of the potential energy plus the kinetic energy built into the wave crest at the instant of maximum slope is transferred into kinetic energy causing the run-up.

Though we have not tested this through more extensive experiments, we would expect this pattern to apply for a wide range of wave/slope combinations along the line given by (8). The question remains open however, how gentle the slope can be and how nearly breaking waves behave on really gentle slopes such as  $1/50$ .

#### Wave breaking in the backwash

It turns out that waves that do not break during run-up may still do so during run-down. This was already seen in the computations on steep slopes by Svendsen & Grilli (1990) and Grilli & Svendsen (1991) who also described the velocity fields.

Fig. 9 shows an example of the breaking of a wave during run-down. At the period following maximum run-up (approximately position 1), the water starts rushing down the slope at rapidly increasing speed. The water level nearly parallel to the bottom indicates the acceleration is close to  $g \sin \alpha$  where  $\alpha$  is the slope angle. Close to the slope, the water level drops well below undisturbed SWL while staying well above SWL a little further out. This creates a front, as of a new incoming wave, which rapidly breaks shoreward. The whole sequence, in particular the breaking, takes place so swiftly that under laboratory conditions it can hardly be followed with the naked eye. After the breaking, the SWL is restored at the shoreline while smaller reflected wave propagates away. This phase can only be reproduced by the present method when the wave does not reach breaking in the downrush.

It is worth noticing that although it looks like the down-wash breaking is equivalent to a new incoming wave front, the velocity field in this breaker is radically different from the velocity field in an ordinary shoreward propagating breaker. Fig. 10 shows a comparison between the two situations. It seems that due to the strong downward water flow on the slope meeting the backward breaker, this wave is held in an almost stationary position while it turns over. The strong outward going particle velocities confirms this impression.

## 6. CONCLUSION

Summarizing the results described, we conclude that

- The wave height variation of solitary waves shoaling on plane slopes depends far more radically on the slope than on the initial wave steepness.

Figure 9: Breaking During Run Down.

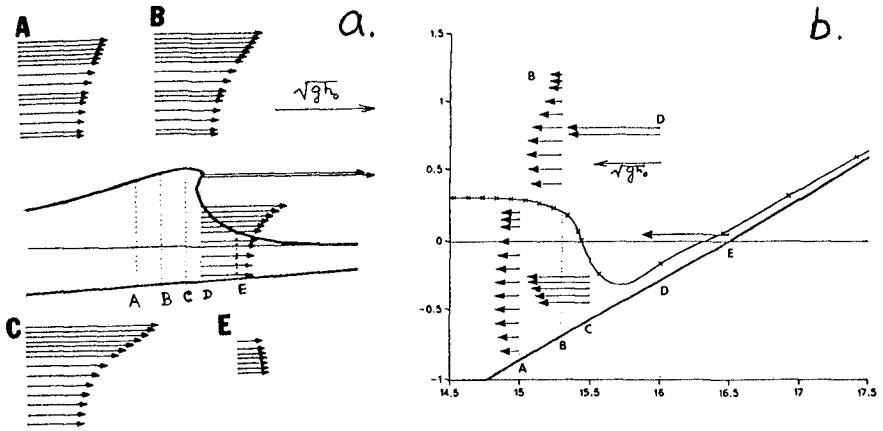

Figure 10: Velocity Profiles Under Forward & Backward Breaking Waves.

On gentle slopes ( $< 1:20$ ), the wave height grows monotonously, slowly at first, towards breaking nearly as  $h^{-1}$ .

On steeper slopes, the wave height stays almost constant over the slope.

- For all slopes investigated (1:35 being the gentlest), the wave height to water depth ratio at breaking is well above the limit of approximately 0.78 of the steepest stable wave on constant depth. For the moderately steeper slopes, the waves may break even at the shoreline (and the value of  $H/h$  then is infinite).
- No waves that can propagate stably on a constant depth break on slopes steeper than  $12^\circ$ .
- Waves that do not break during run up may still generate a (backward) wave breaking during run down. The velocity field in such a breaking is very different from the breaking of a progressive wave. It resembles the velocity field of a (second) shoreward moving wave which is arrested by the downrush. The wave deforms to breaking without propagating.

## Impact Loading and Dynamic Response of Caisson Breakwaters

### - Results of Large-Scale Model Tests -

H.Oumeraci<sup>1)</sup>, H.W. Partenscky<sup>2)</sup>, S. Kohlhas<sup>3)</sup>, P. Klammer<sup>4)</sup>

#### **Abstract**

The results of large-scale model tests on impact loading and dynamic response of a caisson breakwater are presented.

Hydraulic model tests are performed in which the impact loading is induced by breaking waves on the structure. Horizontal impact forces, uplift forces and the related overturning moments are determined. The transmissibility of the impact loads and the accelerations of the structure are investigated (dynamic response).

The hydraulic model tests are supplemented by pendulum tests on the same caisson breakwater model used in the hydraulic model tests in order to determine the characteristics of the structural model itself. The added mass of water oscillating with the structure, the stiffness of the foundation and the damping ratio are evaluated from these tests.

#### **Introduction**

Based on the lessons drawn from past failures and on a literature review, a research programme on monolithic structures subject to breaking waves has been established (OUMERACI et al, 1991). The main objective of this programme is the development of design guidelines as well as the evaluation of counter-measures for increasing the overall stability of the structure and its foundation. In fact, the stability of vertical and composite breakwaters has been yet approached by the existing codes of practice and design methods of different countries as a static problem (GODA, 1985). Therefore, the underlying philosophy of these investigations is to show that a caisson breakwater/foundation system is a purely dynamic problem which cannot be simply treated statically. For this purpose, large-scale hydraulic model tests and pendulum tests on a caisson breakwaters were performed, supplemented by a dynamic analysis of the structure. The paper is principally intended to present and discuss some of the most relevant results of the hydraulic and pendulum tests. The results of the dynamic analysis of caisson breakwater by using a simple numerical model, together with the experimental results, will be presented in a further paper (OUMERACI & KORTENHAUS, 1993).

### Experimental Set-up and Test Conditions

Hydraulic model tests and pendulum tests have been performed in the Large Wave Flume (GWK) in Hannover on a caisson breakwater, with a rubble mound foundation lying on a sand bed.

#### a) Hydraulic Model Tests

The hydraulic model tests were conducted by using regular and irregular waves with wave heights and periods up to 1.20m and 7s, respectively. The measurements were simultaneously performed on two independent caisson structures. Total forces were measured on the first caisson. The second caisson was installed on a rubble mound foundation lying on a 1.4 m-thick sand layer (Fig. 1).

FIG. 1: CAISSON BREAKWATER TESTED IN THE LARGE WAVE FLUME (GWK)

Simultaneous measurements of the following items were carried out:

(a) incident and reflected waves, (b) impact pressure on the caisson front, (c) uplift pressure, (d) wave-induced pore-water pressure in the foundation, (e) total wave-induced stress in the sand layer, (f) dynamic response of the caisson (accelerations) and (g) total forces.

Pressure and load transducers with high natural frequencies were used. Sampling rates up to 11kHz were adopted for impact pressures and forces.

**b) Pendulum Tests**

The hydraulic model tests were supplemented by pendulum tests (Fig. 2) using the same caisson/foundation model (Fig. 1) in different water depths.

\*) Same Model as shown in Fig. 1

FIG. 2: EXPERIMENTAL SET-UP FOR PENDULUM TESTS

The impulsive loads induced by the pendulum and the response of the structure and its foundation were simultaneously recorded. The main objective of these tests was to determine the hydrodynamic mass as well as the damping and the subgrade reaction coefficients to be considered in a dynamic analysis of the caisson/foundation system. Two test series were conducted on the caisson part lying on the rubble mound foundation: Tests under dry conditions and tests with different water depths.

**Discussion of Results of Hydraulic Model Tests**

**a) Impact Pressure Histories and Distribution**

The characteristics of the impact pressure histories simultaneously recorded at nine elevations of the caisson front are strongly related to the types and kinematics of the waves breaking on the structure (OUMERACI et al, 1993). Spatial pressure distributions on the caisson front for time steps as small as  $\Delta t = 0.1\text{ms}$  can be plotted from the measured data, and the related total forces are calculated from pressure integration. An example of such pressure distributions resulting from a breaking wave with  $H = 0.85\text{m}$  and  $T = 4\text{s}$  is given in Fig. 3 for  $\Delta t = 6.3\text{ms}$ .

FIG. 3: PRESSURE DISTRIBUTION ON CAISSON FRONT

These pressure distributions, together with the simultaneously measured pressure histories at different wall elevations not only give a complete picture of the impact process, but also allow us to identify the most relevant characteristics of the shape of the breakers impinging on the wall.

**b) Uplift Pressure Histories and Distributions**

Uplift pressures are subject to much less variation in time than the pressures on the caisson front (OUMERACI et al, 1991). For waves breaking on the caisson, the recorded uplift pressure histories exhibit a dynamic shape, even if much less sharper than that of the impact pressure on the caisson front. In this case, the uplift pressure is not linearly distributed and not equal to zero at the rear edge of the caisson, as usually assumed. This is shown for instance by Fig. 4 which represents the uplift pressure distribution at the instant of wave breaking ( $H = 0.85\text{m}$ ,  $T \approx 4.0\text{s}$ ).

FIG. 4: UPLIFT PRESSURE DISTRIBUTION FOR BREAKING WAVES

**c) Total Forces and Overturning Moments**

The total horizontal and uplift forces were obtained by spatially integrating the impact pressures measured on the caisson front (horizontal force  $F_h$ ) and the uplift pressure (vertical force  $F_v$ ). An example of the total horizontal force  $F_h$  and its overturning moment  $M_h$  around the rear edge of the caisson is shown in Fig. 5. It can also be seen that during the impact process, the location of the point of application of  $F_h$  is almost constant and slightly under still water level.

FIG. 5: HORIZONTAL FORCE AND INDUCED OVERTURNING MOMENT

The uplift force and related overturning moment which are caused by the same wave which induced the force and moment in Fig. 5 are also shown in Fig. 6. It can be seen that the point of application of the uplift force during impact is located rather at  $\frac{1}{4}$  than  $\frac{1}{3}$  of the caisson width from the seaward edge, due to the non-linear uplift pressure distribution as shown in Fig. 4. This will result in a larger contribution of the uplift force to the total overturning moment. In fact, depending on the caisson size, the water depth, the thickness of the rubble mound foundation, the breaker type and the magnitude of the horizontal force, this contribution may be higher than that of the horizontal impact forces (Fig. 7).

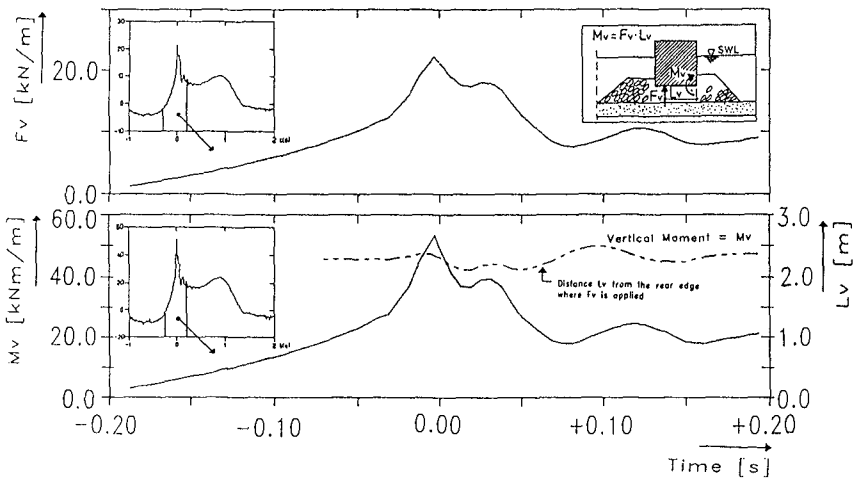

FIG. 6: UPLIFT FORCE AND INDUCED OVERTURNING MOMENT

FIG. 7: CONTRIBUTION OF UPLIFT FORCE TO THE TOTAL OVERTURNING MOMENT

#### d) Dynamic Response of the Structure

##### Transmissibility of Impact Loads

The dynamic response of the first part of the model caisson behind which the total horizontal reaction force was measured is described by the transmissibility of the impact load. This transmissibility is defined as the ratio of the reaction force measured behind the caisson to the total impact force on the caisson front obtained by pressure integration over the front area. An example of the results obtained is given in Fig. 8.

This and further similar results show that for the conditions tested, the transmissibility of the impact forces is in the range of 0.10 to 0.80 whereas the transmissibility of the force impulses is about twice the transmissibility of the related peak forces. This, however, strongly depends on the shape of the impact force history which is known to be primarily determined by the shape of the breaker impinging on the wall (OUMERACI & KORTENHAUS, 1993).

FIG. 8 TRANSMISSIBILITY OF IMPACT FORCES

Accelerations of the Structure

The response of the second caisson part is described by the accelerations of the caisson (vertical and horizontal direction at the rear top and horizontal direction at the front top of the caisson). A typical horizontal acceleration trace is given in Fig.9, showing that accelerations in the order of some decimeters/s<sup>2</sup> may occur. It is also seen that the structure oscillates with periods  $T_s \approx 0.06 - 0.08\text{s}$ .

Pore Water Pressure in Rubble Mound Foundation and Sand Layer

Pore-water pressure in the foundation and total stress in the sand layer induced by waves and wave impacts on the caisson represent further means to characterize the response of the foundation. The pore pressures in the rubble mound foundation are found to have peak values which are an order of magnitude lower than those of the impact pressure on the caisson front (OUMERACI, 1991).

FIG. 9: HORIZONTAL ACCELERATIONS AT THE REAR TOP OF THE CAISSON

The pore pressure histories in the sand foundation exhibit a shape which is almost similar to that of the pressure induced by a partial clapotis. The corresponding total stress is characterized by the sharp peaks at both the seaward and shoreward bottom edges and by low frequency oscillations after the peak which correspond to the rocking motions of the caisson recorded by the accelerometers.

**Results of Pendulum Tests**

**a) Tests under Dry Conditions**

An illustrative example for the results related to the rocking motions of the caisson subject to pendulum impact under dry conditions (without any water in the flume) is given in Fig. 10a showing the time series, and Fig. 10b showing the corresponding spectral representation. This means that the natural frequency of the structure under dry conditions is  $f_n^* \approx 15\text{Hz}$ .

a) Time Series

b) Spectral Representations

FIG. 10: ACCELERATION OF STRUCTURE OSCILLATIONS (DRY CONDITIONS)

The damping of the structure oscillations under dry conditions is shown by Fig. 11 where the oscillation amplitude  $A$  is plotted against dimensionless time corresponding to the number of oscillation cycles.

FIG. 11: DAMPING OF STRUCTURE OSCILLATIONS (DRY CONDITIONS)

From Fig. 11 and further similar results, the logarithmic decrement

$$\delta = \frac{1}{n} \left[ \frac{A(t)}{A(t+n \cdot T)} \right] = \frac{2 \pi D}{\sqrt{1-D^2}} \quad (1)$$

has been determined to  $\delta = 0.446$  which leads to a damping ratio  $D = 0.071$ . Since:

$$f_n = f_n^* \left[ \sqrt{1-(D)^2} \right] \quad (2)$$

where  $f_n^*$  is the natural frequency of the undamped oscillations, it can be assumed that  $f_n = f_n^*$  and that the logarithmic decrement  $\delta = 2\pi D$ .

### b) Tests with Different Water Depths

The pendulum tests were conducted for different water depths under the same loading conditions as for the tests under dry conditions.

As already mentioned, the main objective of these tests was to determine the dynamic parameters needed for dynamic analysis, namely :

- the added mass of water which is forced to oscillate with the structure subject to impact loads,
- the damping ratio of the oscillating structure,
- the stiffness of the foundation.

Added Mass of Water

The hydrodynamic mass is generally calculated by using the following formulae derived on the assumption of an incompressible and irrotational potential flow (OUMERACI & KORTENHAUS, 1993):

$$m_{ad,hor.} = 0.543 \cdot \rho_w \cdot d_w^2 \tag{3}$$

$$m_{ad,rot.} = 0.218 \cdot \rho_w \cdot d_w^2 \tag{4}$$

where:

$m_{ad,hor.}$ ,  $m_{ad,rot}$  = added mass of water for horizontal and rotational motion of the structure, respectively  $[kg/m]$

$\rho_w$  = density of water  $[kg/m^3]$

$d_w$  = water depth at the wall  $[m]$

Since the frequency of oscillations  $f_n$  of the structure is directly related to the total mass of the oscillating system  $M_t = M_c + m_{ad}$  ( $M_c$  = caisson mass /m), the added mass of water for each water depth  $d_w$  can be determined from the corresponding measured frequency  $f_n$  by the following relationship:

$$\frac{M_c + (m_{ad})_2}{M_c + (m_{ad})_1} = \left( \frac{f_{n1}}{f_{n2}} \right)^2 \tag{5}$$

where indices 1 and 2 are related to water depth  $d_{w1}$  and  $d_{w2}$ , respectively.

The variations of the frequency of oscillations for which the relative water depth  $d_w/d_h$  obtained from the pendulum tests is shown in Fig. 12. By using Eq. (5), the relationship between the added mass and the water depth can be found.

FIG. 12: EFFECT OF WATER DEPTH ON OSCILLATION FREQUENCY

Generally, the added mass calculated by using Eqs. (3) & (4) are slightly underestimated as compared to the experimental results (OUMERACI & KORTENHAUS, 1993).

Stiffness of Foundation

The stiffness coefficient related to the horizontal motions ( $K_x$ ) and to the rotational motions ( $K_\phi$ ) have also been determined from the results of the pendulum tests for different water depths. These results are compared to the approximate method of SAVINOV in Fig. 13 ( see MARINSKI & OUMERACI, 1992).

FIG. 13 - STIFFNESS COEFFICIENTS VS. WATER DEPTH

It is seen from Fig. 13 that the experimental results do not exhibit any variation with water depth, but show a relatively good agreement with the approximate method of SAVINOV.

**Damping Ratio**

The damping ratio  $D_x$  and  $D_\phi$  (for horizontal and rotational motions, respectively) have been determined for different water depths  $d_w$  at the caisson front by using the following relationships:

$$D_{x,\phi} = \sqrt{\left(\frac{\delta_{x,\phi}}{4\pi^2 + \delta_{x,\phi}^2}\right)} \tag{6}$$

where:

$\delta_x, \delta_\phi$  = logarithmic decrement for the horizontal and rotational motion, respectively:

$$\delta_x = \ln\left[\frac{x(t)}{x(t+T_x)}\right] \tag{7}$$

$$\delta_\phi = \ln\left[\frac{\phi(t)}{\phi(t+T_\phi)}\right] \tag{8}$$

$x(t), \phi(t)$  = amplitude of horizontal and rotational oscillations, respectively

$T_x, T_\phi$  = period of horizontal and rotational oscillations, respectively

$t$  = time

FIG. 14: DAMPING COEFFICIENT VS. WATER DEPTH

The damping ratio  $D_x$  and  $D_\phi$  obtained from the pendulum tests are plotted in Fig. 14 against water depth  $d_w$ .

It can be seen that the experimental D-values show a large scatter, but there is a clear tendency for the damping coefficient to increase with water depth.

### **Summary of Results, Concluding Remarks and Perspectives**

The results achieved so far in the hydraulic model tests, supplemented by the pendulum tests on the same model may be summarized as follows.

The suggestion commonly found in the literature that the effect of impact pressures on the stability of caisson breakwaters is not significant, could not be confirmed by the present study. In fact, the occurrence of a sharp force peak followed by a quasi-static load generally leads to a higher response of the structure than that of the quasi-static force alone (MARINSKI & OUMERACI, 1992).

The shape of the wave breaking on the structure primarily governs the characteristics of the impact load. Double-peaked impact forces which are induced by well-developed plunging breakers are found to be the most critical loads (OUMERACI et al, 1992).

Dynamic uplift pressures caused by wave impacts are not linearly distributed and appear to be important for the dynamic stability analysis of the structure.

Free damped nonlinear oscillations of the structure foundation system are essentially induced by the impulsive load due to breaking waves. This nonlinearity is probably due to the plastic deformations of the foundation as well as the hydrodynamic mass and geodynamic mass which both increase with the amplitudes of the oscillations of the structure.

The oscillations of the structure are transmitted to the foundation. The total stress recorded in the foundations shows a sharp peak, followed by smaller oscillations corresponding to the free rocking oscillations of the structure.

The total stresses recorded in the sand layer beneath the caisson structure and its rubble mound foundation are of two types: one is caused by the shock wave propagation into the soil foundation and the other one by the free oscillations of the structure following the impact.

The logarithmic decrement of the free oscillations of the structure-foundation system subject to breaking wave impact loads ranges from  $\delta = 0.35$  to 1.1 (average value of  $\delta$  is 0.62).

Accounting for the added mass of water oscillating with the structure may result in an increase up to 25 % of the natural frequency of the rocking motions, depending on the loads, the water depth and the size of the structure.

The stiffness coefficients ( $K_x$  and  $K_\phi$ ) determined by the pendulum tests agree relatively well with those determined by the approximate method of SAVINOV.

The damping coefficients determined by the pendulum tests exhibit a wider variation ( $D= 0.08 - 0.16$ ) than the subgrade reaction coefficients.

The results of these investigations can be used, together with a numerical model for the simulation of the dynamic response of the structure, in order to perform a sensitivity analysis of the most relevant parameters (shape and different characteristics of the loading, added mass, damping and stiffness coefficients etc.) of the system (OUMERACI & KORTENHAUS, 1993).

In the ongoing further analysis of the data from both hydraulic and pendulum tests, more effort is being concentrated on :

- the dynamic response of the foundation as related to the caisson oscillations;
- scaling problems related to the loading and response of the structure;
- providing a complete set of reliable data for the validation of numerical models.

### **Acknowledgements**

This study is part of an extensive research programme within the Coastal Engineering Research Unit "SFB 205" which is supported by the German Research Council (DFG), Bonn. Additional support is provided by the European Community within the Research Program MAST G6-0032.

## CHAPTER 114

# WAVE FORCES ON CROWN WALLS

Jan Pedersen<sup>1</sup>

Hans F. Burcharth<sup>2</sup>

### Abstract

This paper presents some of the results from a large parametric laboratory study including more than 200 long-duration model tests. The study addresses both the wave forces imposed on the breakwater crown wall as well as the performance of the structure in reducing the wave overtopping. The testing programme includes variations of the sea state parameters and of the geometrical configuration of the breakwater and crown wall. Basic relations between forces/overtopping and the varied parameters are examined and preliminary design guidelines for structures within the tested range of variations are proposed.

### Introduction

A rubble mound breakwater is very often constructed with a crown or parapet wall at its crest, since such a superstructure contributes to the effectiveness of the breakwater in reducing the amount of overtopping water. Furthermore, a wall will in most cases reduce the necessary crest height of the rubble structure and thereby decrease the amount of rubble material. The superstructure often functions also as service and traffic road.

Although crown walls are very popular and have been used worldwide for decades, there still does not exist any general applicable guidelines or design criteria for these structures. This is in sharp contrast to some of the other modes

<sup>2</sup>Prof. of Marine Civil Engineering, Department of Civil Engineering, Aalborg University, Sohngaardsholmsvej 57, DK-9000 Aalborg, Denmark

of failure for rubble mound breakwaters where today's design procedures includes fairly reliable calculations of the probability of failure within the lifetime of the structure, see fx. [2, Burcharth 1991a] and [3, Burcharth 1991b]. Such calculations requires as basis a well documented design equation which for example for failure of the main armour layer is fulfilled by the Hudson formula or the stability formulae by [10, v.d. Meer 1988]. The uncertainties related to existing general formulae for wave wall stability and overtopping are very large. The design of crown walls therefore relies on site specific hydraulic model studies or careful extraction and interpretation of the research results presented in the literature, see fx. [1, Bradbury et. al. 1988], [7, Jensen 1983] and [8, Jensen 1984].

Looking at the stability of the crown wall, several modes of failure have to be considered as shown in Fig. 1.

Fig. 1 - Possible failure modes for crown walls. From [4, Burchart 1993]

Only the failure modes a) and b) depends exclusively on the strength of the superstructure and the wave loading, whereas failure modes c), d) and e) are much more complex involving the properties of the underlying soil and failures of other parts of the structure. The problem of stability must in all cases be treated dynamically due to the dynamic behaviour of the wave loading. This imposes other problems since the transmissibility or relative amount of load transmitted to the rubble structure may be very different for the different failure modes. In the present investigations this dampening effect is not studied. All results relates to the pressures recorded on the stiff wave wall. The corresponding forces might be very conservative design measures especially for failure modes

c) and d), since these combined structure-soil failure mechanisms have relatively low transmissibility coefficients for short duration force actions. For a caisson breakwater [9, Oumeraci 1991] found a transmissibility coefficient in wave impact tests of 0.2-0.6 depending on the actual force history applied.

Model Tests

Fig. 2 - Experimental setup and parameter ranges.

Figure 2 shows the experimental setup used in the parametric laboratory study in one of the wave channels at Aalborg University. The channel is 1.6 m wide, 26 m long and is equipped with a piston type wave paddle. For the present study the wave channel was divided into a mid-section of 1 m width and two small side channels each of a width of 0.3 m. All varied parameters and their ranges

are given in Fig. 2. Waves are generated using a white noise filtering technique where it has been verified that the random number generator does not repeat itself, which is essentially for the probabilistic estimates of the measurements. Each of the over 200 performed test-runs consists of 4000-10000 waves, corresponding to 2-4 hours of run, in order to reach low exceedence probability levels with a high degree of reliability. Wave conditions are measured just in front of the breakwater and are separated in incident and reflected waves by a combination of the methods suggested by [6, Goda 1974b] and [5, Funke & Mansard 1980]. This separation is important since reflection amplitude coefficients of 20-30 % are registered.

The wave forces on the crown wall are measured using 16 Phillips P13 OEM 18 mm diameter pressure transducers mounted into the front face of the crown wall. In order to minimize the influence from local pressure disturbances the pressure cells are placed in 2-4 columns, dependent on the height of the used wave wall. Each column is displaced one diameter or less from the adjacent transducer columns, to get the best possible vertical resolution of the pressure field.

The wall itself consists of a 5 mm thick steel plate, supported several places along the width to ensure a stiffness large enough to prevent dynamic disturbances from movements and deformations. Preliminary tests using a strain gauge instrumented force table showed that this setup was unable to register the high frequent parts of the loading without introducing dynamic amplification and thereby blurring the measurements with signals from natural oscillations of the force table itself.

Sampling rates of 128 and 256 Hz were used depending on the actual geometric configuration. Only wave pressures on the front face of the wall were measured. The uplift pressure at the base plate was not recorded because of the uncertainty in correct scaling of the pore pressure in the underlying core material. Also, the forces from the armour units being in contact with the wall are not included in the present study.

From the pressure records the following force components (cf. Fig. 3) were calculated:

- The total horizontal force  $F_h$ .
- The base pressure  $P_b$  in the front base point.
- the overturning moment  $M_h$  around the front base point.
- The second order moment of pressures  $m_2$  around the front base point.

Fig. 3 - Calculated force components.

Forces

A typical example of the measured pressures on the crown wall is shown in Fig. 4. From left to right the figure illustrates the pressure evolution when a wave approaches the breakwater slope, hits the wall and starts to rush down. The timestep between each frame is 7.8 ms.

Fig. 4 - Example of typical pressure evolution on crown wall.  
Timestep between each frame is 7.8 ms.

High local pressures are observed in a narrow region just above the crest of the armour in the same moment the water hits the wall. This phenomenon happens because the water velocities outside the porous stone layers are higher than inside. The maximum loading occurs a little later when the porous layers are fully saturated and the water pressure is acting over the full height of the wall. The pressure decay during the down-rush has a much longer duration (in the order of half a wave period) than the pressure rise which occurs within 0.02-0.05 seconds, i.e. in the order of 1-3 % of the wave period.

By spatial integration of the pressure recordings the horizontal force and the overturning moment are obtained. Examples of time series of these force

components are shown in Fig. 5, which also illustrates the afore mentioned time scales for pressure rise and decay.

Fig. 5 - Examples of typical time series of force components. Obtained for lowest wall ( $h_f = 0.15$  m).

For the further processing the time series are analysed and probabilistic estimates for each of the force components are extracted. For simplicity only  $F_{0.1\%}$ , being the horizontal force which has an exceedance probability of 0.1%, will be used in the following. Also, unless otherwise stated, all results discussed in the following are obtained for a high wall, where practically no overtopping occurs.

#### Influence of parameters

To represent the sea state conditions the significant wave height  $H_s$  and the spectral peak period  $T_p$  (or the corresponding wave length  $L_p$ ) are used. For changes in water level [8, Jensen 1984] used the vertical distance  $A_c$  from the still water level to the armour crest and he showed that together with  $H_s$  it constitutes an important dimensionless parameter in predicting the wave forces on the crown wall. The influence of the width  $B$  of the armour crest and the height of the wave wall have also been examined. In Figs. 5-8 these different parameters are plotted against  $F_{h,0.1\%}$ .

Since the maximum forces are impulse forces (fig. 4 and 5) which are proportional to  $mv^2$ ,  $m$  being the mass of water hitting the structure and  $v$  the water velocity in the up-rush, which is proportional to  $\sqrt{gH}$ , it must be expected that the loading is proportional to  $H$ . The test results verify this, showing a clear linear dependency between  $H_s$  and  $F_{h,0.1\%}$ , Fig. 6. This is also in agreement with results by [1, Bradbury et. al 1988].

Like for  $H_s$  an increase in wave period and thereby wave length gives an increase in the wave load on the structure. Although the scatter is larger than for  $H_s$  Fig. 7 shows that the horizontal force is proportional to the wave length  $L_p$ . This result was also obtained by [8, Jensen 1984] whereas [1, Bradbury et. al 1988] found proportionality between the mean zero upcrossing wave period and the loading.

The parameter  $\frac{H_s}{A_c}$ , which incorporates variations in both wave height, water level and armour crest elevation, is in fig. 8 plotted against  $F_{h,0.1\%}$ , showing excellent linear dependency with nearly no scatter around the fitted lines.

In fig. 9 the results for different widths  $B$  of the crest berm are shown. Compared to the other investigated parameters, the influence of  $B$  is surprisingly small. As expected, the overall tendency is that the wave load on the wall decreases with increasing berm width, though when extending the width from  $3d_{n,50}$  to  $4d_{n,50}$  a small increase in the load is observed. No general conclusions of the influence of  $B$  on  $F$  can be drawn without examining the conditions for various force probability exceedence levels and various wave periods.

The last investigated parameter is the crown wall height  $h_f$ . From Fig. 10, where  $h_f$  is plotted against  $F_{h,0.1\%}$  for five different values of  $\frac{H_s}{A_c}$ , it is seen that for small values of  $h_f$  and relative large values of  $\frac{H_s}{A_c}$  an increase of the wall height results in an increase in the wave loading. Unfortunately, only two wall heights are situated in this part of the figure, but by using the point  $(h_f, F) = (0,0)$  it is possible to get an idea of the relation between  $h_f$  and  $F_{h,0.1\%}$ . As seen in Fig. 10 this relation is quite non-linear. When the wave wall height is extended above a certain level, an upper limit, exclusively depending on sea state and water level, is reached. From this upper limit the wave force will no longer depend on  $h_f$ . For very low walls the influence of the sea state more or less vanishes and the horizontal force only depends on the height of the wave wall. This situation is caused by excessive overtopping where a large part of the up-rushing water spills over the structure without causing significant impulse loads.

Fig. 6 - Influence of  $H_s$

Fig. 7 - Influence of  $L_p$

Fig. 8 - Influence of  $\frac{H_s}{A_c}$

Fig. 9 - Influence of berm width  $B$

Fig. 10 - Influence of  $h_f$

Guidelines for calculation of horizontal wave force

At present the only way to determine the horizontal wave loading on a crown wall accurately is by means of physical model tests. Based on such tests [8, Jensen 1984] proposed the following empirical relationship between  $F_{h,0.1\%}$  and some of the parameters also examined in the present study :

$$\frac{F_{h,0.1\%}}{\rho g h_f L_p} = a \left( \frac{H_s}{A_c} + b \right) \tag{1}$$

where  $\rho$  is the water density and  $a$  and  $b$  are dimensionless empirical coefficients. Although the method by which the different parameters have been non-dimensionalised is not fully correct, the main features of the formula are verified by the current study. Figs. 6 and 7 show the same linear influence of  $H_s$  and  $L_p$  respectively as expressed in eq. 1. The influence of the wall height  $h_f$  however, which in eq. 1 also is expressed as proportional to  $F$ , can not be confirmed. Although slightly unreliable due to the relative few wall heights tested the current study shows that  $h_f$  should enter the formula in a power larger than 1. Assuming that the major part of the load is caused by hydrostatic water pressure, one finds that the horizontal force is a function of  $h_f^2$  which, although the forces are merely caused by impact pressures, supports the present observations.

In Fig. 11 the ratio  $\frac{H_s}{A_c}$  is plotted against the left hand side of equation 1 for model test results obtained from [8, Jensen 1984], [1, Brabury et. al 1988] and the present study.

Fig. 11 - Different model test results plotted according to eq. 1.

Although not fully explaining the influence of all relevant parameters, and showing quite a lot of scatter compared to the model test results, eq. 1 still provides a satisfactory first estimate on the wave loading on the crown wall.

## Overtopping

In all model tests performed also the mean overtopping rate  $Q_m$  was measured. An 0.5 m wide tank for collection of the water discharged over the crown wall was installed in the middle of the test section and fitted to the top of the wall. From the tank the water was automatically pumped through a flow meter and back into the flume. Reading of the flow meter was taken after each test. Fig. 12 illustrates the used setup.

*Fig. 12 - Sketch of setup for overtopping measurements.*

Like for the study of the wave forces the overtopping results are used to examine the influence of the different sea state and geometrical parameters on  $Q_m$ .

## Influence of parameters

Fig. 13 shows the significant wave height plotted against  $Q_m$  for fixed wave period, wall height and berm width but for different water levels. As seen the influence from  $H_s$  on  $Q_m$  is very large.  $Q_m$  is approximately proportional to  $H_s^5$ . In Fig. 14 the influence of changes in water level and wall height is shown.  $R_c$  being the distance from the still water level to the top of the wave wall, is able to incorporate the variations of both parameters. The ratio  $\frac{H_s}{R_c}$  is seen to constitute an important dimensionless parameter expressing the influence of both the wave height and the vertical distance to the top of the structure.

Several examinations of how the wave period alters  $Q_m$  were carried out, showing no general dependency for nor  $T_p$  or  $L_p$ . The ratio  $\frac{L_m^2}{T_m^2}$  (or  $c_m L_m$ ) where  $T_m$  is the mean zero upcrossing period and  $L_m$  and  $c_m$  the corresponding wave length and wave celerity, offers a very fine expression for the influence of the period cf. Fig. 15. This figure shows, with nearly no scatter around the fitted lines, that

$Q_m$  depends linearly on  $\frac{L_m^2}{T_m}$ .

Finally also the influence of the armour berm width  $B$  on the mean overtopping rate has been investigated. As expected Fig. 16 shows that when  $B$  increases the amount discharged over the wall decreases.  $Q_m$  is approximately proportional to  $\frac{1}{B}$ .

Fig. 14 - Influence of  $\frac{H_s}{R_c}$

Fig. 13 - Influence of  $H_s$

Fig. 16 - Influence of berm width  $B$

Fig. 15 - Influence of  $\frac{L_m^2}{T_m}$

Guidelines for calculation of mean overtopping rates

Several researchers have studied the subject of overtopping of coastal structures. Probably the most comprehensive work concerning crown walls on rubble mound breakwaters is found in [1, Bradbury et. al 1988]. Based on a large model study the authors suggest the following expression for calculation of the mean overtopping rate :

$$Q^* = \alpha (F^*)^\beta \quad (2)$$

where

$$Q^* : \text{dimensionless discharge} = \frac{Q_m}{T_m g H_s}$$

$$F^* : \text{dimensionless freeboard} = \left( \frac{R_c}{H_s} \right)^2 \sqrt{\frac{s_p}{2\pi}}$$

$\alpha, \beta$  : empirical coefficients depending on breakwater  
and wave wall geometries

In Fig. 17  $\ln(F^*)$  is plotted against  $\ln(Q^*)$  for the model test results obtained in the present study. For all results shown the armour berm width was kept constant at 0.18 m ( $3d_{n,50}$ ). Though some scatter is observed eq. 2 generally predicts the overtopping rates very well. For the actual case  $\alpha$  and  $\beta$  was fitted to  $7.4 \cdot 10^{-8}$  and  $-2.58$  respectively.

Based on the analysis of the influence of the different examined parameters on  $Q_m$  (cf. Figs. 13-16) the following alternative relationship for prediction of the overtopping rates was developed :

$$\frac{Q_m T_m}{L_m^2} = \alpha \left( \frac{H_s}{R_c} \right)^\beta \quad (3)$$

where  $\alpha$  and  $\beta$  are empirical dimensionless coefficients.

As in eq. 2 the influence of the armour berm width must be included in  $\alpha$  and  $\beta$ , since a general non-dimensional expression for this parameter has not yet been found. Also, the effects of permeability, slope angle and slope roughness have to be included in  $\alpha$  and  $\beta$  just as for eq. 2. In Fig. 18 logarithmic values of both sides of eq. 3 are plotted for a fixed armour berm width of 0.18 m ( $3d_{n,50}$ ). Compared to Fig. 17 the scatter around the fitted line is a little smaller.  $\alpha$  and  $\beta$  are fitted to  $1.26 \cdot 10^{-5}$  and 5.2 respectively.

It must be concluded that both models, eq. 3 slightly better than eq. 2, are able to predict the amount of water overtopping the wave wall with quite good accuracy.

Fig. 17 - Plot of  $\ln(F^*)$  against  $\ln(Q^*)$  from eq. 2.

Fig. 18 - Plot of  $\ln\left(\frac{Q_m T_m}{L_m^2}\right)$  against  $\ln\left(\frac{H_s}{R_c}\right)$  from eq. 3.

### Conclusions

Some of the results obtained from an extensive parametric model study concerning wave forces and overtopping on rubble mound breakwater crown walls have been presented.

The analyses more or less confirm the relationship suggested by [8, Jensen 1984] for prediction of the horizontal wave forces, though some discrepancies are observed. Until more work has been carried out on this subject the formula by

Jensen serves well as a first estimate in assessing the wave load.

Concerning wave overtopping a new formula has been developed, which, although not fully complete, is able to predict the mean overtopping rate on the wave wall with quite good accuracy. The relationship proposed by [1, Bradbury et.al] has also been analysed and shows an almost similar accuracy in estimating the amount of water discharged over the crown wall.

## CHAPTER 115

### Optimal Design of Rubble Mound Structures under the Irregular Wave

Cheong-Ro Ryu<sup>1</sup>, Yoon-Koo Kang<sup>2</sup> and Jong-Wook Kim<sup>3</sup>

#### Abstract

A design algorithm for the optimal cost effective rubble mound structures is developed considering extreme wave statistics and wave control functions as well as the stability under the irregular wave attack. In the algorithm, the conventional deterministic design method and the optimization technique, SUMT (Sequential Unconstrained Minimization Techniques) are used to evaluate the minimum cross section of the structure.

The applicability and design sensitivity of the algorithm is examined using experimental data on stability, run-up / overtopping and reflection under the various irregular waves that have different wave grouping characteristics. The field conditions not only the construction method but also the costs can be introduced in the cost estimation subroutine.

#### 1. Introduction

Cost effectiveness is an important factor in the optimal design concept of coastal structures as well as the stability and wave control functions of the structures are. In the design, uncertainty of extreme waves and/or design waves, allowable damage considered destruction process, and various wave control functions of the structures in irregular wave field should be considered, however, these effects were not introduced systematically in the conventional design process (Hudson, 1959; CERC, 1984; Ryu and Sawaragi, 1986; Smith, 1987; Van der Meer, 1987).

In this study, conventional deterministic design method and a new optimization technique, SUMT are used simultaneously and/or as a dual system to develop a systematic design algorithm for the rubble mound structures considering those effects and cost effectiveness. In the construction of the algorithm, previous experimental works on stability, run up / overtopping and reflection by irregular waves with different wave

<sup>3</sup> Researcher, Maritime Research Institute, Hyundai Heavy Industries Co., Ulsan 682-792, Korea

grouping characteristics are applied to the present problem of setting up the modules for design constraints.

To discuss some aspects of the usefulness of the algorithm, we first analyze the reliability of the well known conventional design methods for regular and irregular waves. Next, check the design sensitivity due to the irregularity and the uncertainty of extreme waves, as well as construction field conditions and by introducing design concept of allowable damage and wave control functions.

## 2. Construction of the Optimal Design Algorithm

The algorithm is constructed with the modules for 1) extreme wave probability analysis, 2) structural stability analysis, 3) considering of wave run up, overtopping and reflection problems for wave-structural interaction analysis as the wave control functions, 4) total cost minimizing during life time, 5) drawing the structural dimensions.

In the construction of each module, the up-to-date research results including experimental results carried out in the study and conventional well known results are used simultaneously to study comparatively. In the design process, the conventional deterministic and the optimal design methods are used to calculate the structural dimensions and the total cost.

Figure 1 shows the flow of the optimal cost effectiveness design process. As shown in the figure, the calculation starts with the defined initial total cost ( $TCM_{max}$ ), allowable damage steps (N), return period steps (NN). The total cost for every step can be estimated in the every iteration step, and the cross sectional dimensions for the minimum total cost condition is found as the optimal cost effective design.

## 3. Optimization of the Cross-Section of Structures

### 3.1 Design Variables

Design variables for rubble mound structures with uniform and composite slopes defined as following equation in relation to Figure 2 and Figure 3.

$$X = (X_1, X_2, X_3, X_4, X_5, X_6, X_7, X_8, X_9, X_{10})^T \quad (1)$$

where  $X_1, X_2, \dots, X_n$  are the characteristic length scales of the structure as shown in Figure 2, 3,  $X_5$  in the uniform slope and  $X_8$  in the composite slope are the specific length of the revetment armor, and  $h$  the water depth.

### 3.2 Application of the Optimization Technique

In the development of design algorithm, to minimize the cross-sectional area efficiently, the conventional deterministic design method is applied to calculate initial design variables, and the optimization technique such as Sequential Unconstrained Minimization Techniques (SUMT) are used shown as Figure 1.

The optimal design concept can be expressed as the finding problem of design variables under the condition of minimizing the objective function and satisfying the constraint functions as;

$$\text{Find } X = (X_1, X_2, \dots, X_n)^T \quad (2)$$

$$\text{Minimize : } f(X) \quad (3)$$

$$\text{Subject to : } g_j(X) \leq 0, \quad j=1, \dots, m \quad (4)$$

$$h_k(X) = 0, \quad k = 1, \dots, l \quad (5)$$

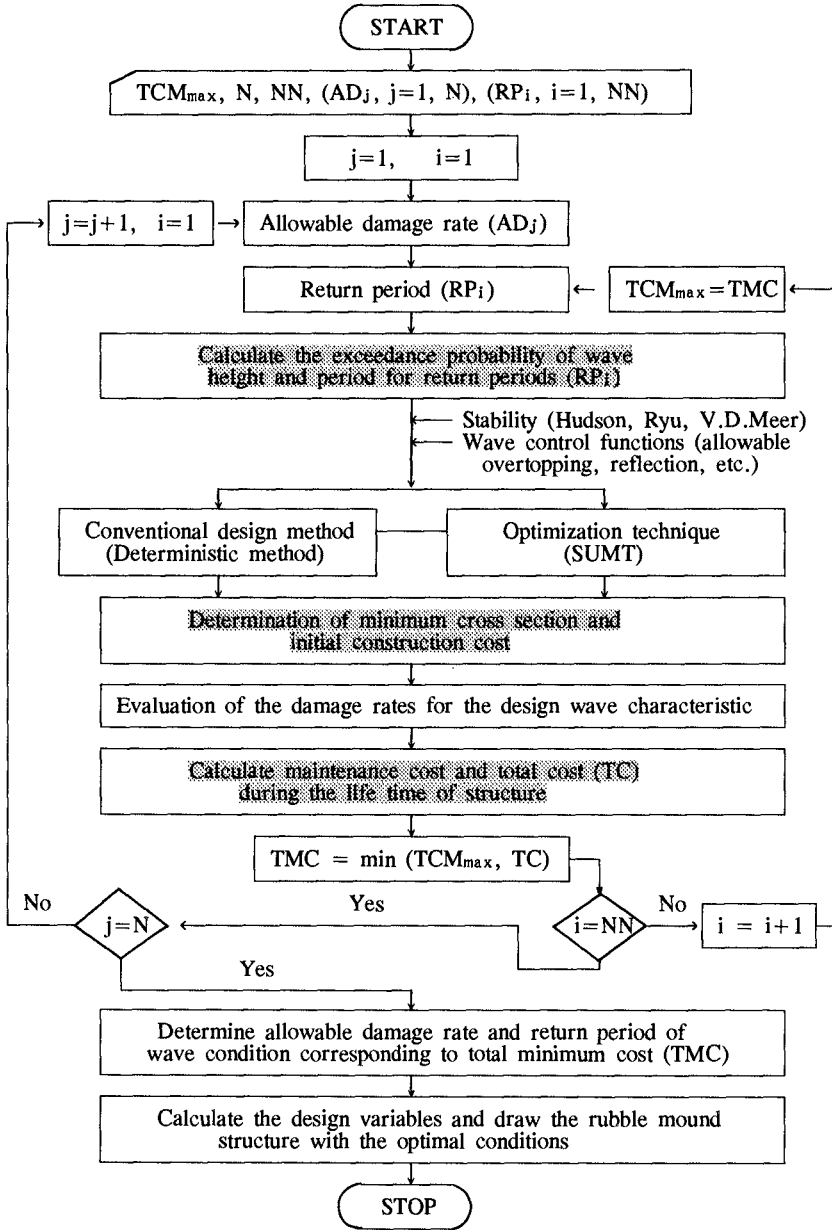

Figure 1. The flow of the optimal design process.

where  $f(X)$  is objective function,  $X$  design variable vector,  $g_j(X)$  the inequality constraints functions, and  $h_k(X)$  the equality constraint functions.

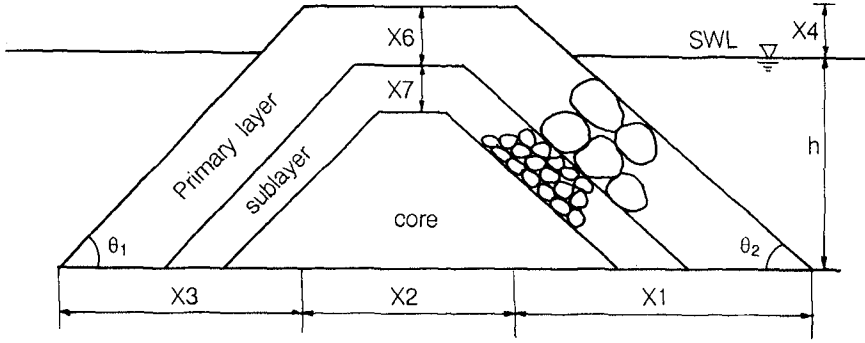

Figure 2. Definition of design variables and sectional area of the rubble mound breakwaters with uniform slope.

Figure 3. Definition of design variables and sectional area of the rubble mound breakwaters with composite slope.

3.2.1 Objective function

The objective function of cross-sectional area is estimated by following equations for the uniform slope.

$$\begin{aligned}
 f(X) &= A + B + C \\
 &= A_1 + A_2 + A_3 + B_1 + B_2 + B_3 + C_1 + C_2 + C_3
 \end{aligned}
 \tag{6}$$

where,

$$\begin{aligned}
 A1 &= X6 / \sin\theta1 * (h + X4 - X6) \\
 A2 &= (X2 + X2 + X6 / \tan\theta1 + X6 / \tan\theta2) * X6/2 \\
 A3 &= X6 / \sin\theta2 * (h + X4 - X6) \\
 B1 &= X7 / \sin\theta1 * (h + X4 - X6 - X7) \\
 B2 &= [(X2 + X6 / \tan\theta1 + X6 / \tan\theta2 - X6 / \sin\theta1 - X6 / \sin\theta2) \\
 &\quad + (X2 + X6 / \tan\theta1 + X6 / \tan\theta2 - X6 / \sin\theta1 - X6 / \sin\theta2) \\
 &\quad + X7 / \tan\theta1 + X7 / \tan\theta2)] * X7/2 \\
 B3 &= X7 / \sin\theta2 * (h + X4 - X6 - X7) \\
 C1 &= (h + X4 - X6 - X7) * (h + X4 - X6 - X7) / (2 * \tan\theta1) \\
 C2 &= [X2 - (X6 / \sin\theta1 - X6 / \tan\theta1) - (X7 / \sin\theta1 - X7 / \tan\theta1) \\
 &\quad - (X6 / \sin\theta2 - X6 / \tan\theta2) - (X7 / \sin\theta2 - X7 / \tan\theta2) \\
 &\quad * (h - X6 - X7) \\
 C3 &= (h + X4 - X6 - X7) * (H + X4 - X6 - X7) / (2 \tan\theta2)
 \end{aligned}$$

The cross-sectional area for the composite slope can also calculate by the same conception in relation to Figure 3 as

$$\begin{aligned}
 f(X) &= A + B + C \\
 &= A1 + A2 + A3 + A4 + A5 \\
 &\quad + B1 + B2 + B3 + B4 + B5 \\
 &\quad + C1 + C2 + C3 + C4 + C5
 \end{aligned} \tag{7}$$

where  $A$ ,  $B$  and  $C$  are the area of cover layer, sublayer and core layer respectively.

### 3.2.2 Design Constraint Functions

#### (1) Estimation of Extreme Wave Conditions

Using the relation between the return period (RP) and non-exceedance probability,  $P(X \leq x)$  and considering Weibull distribution for the extreme storm wave heights and wave periods for design can be estimated by the following equations.

$$RV = [ - \ln\{ 1 - P( X \leq X_{m, n} ) \} ]^{1/k} \tag{8}$$

$$X = a_0 RV + b_0 \tag{9}$$

where  $RV$ : transformed variable for the non-exceedance probability,  $m$ : order of data,  $n$ : number of data,  $X$ : variables (wave height & period),  $k$ : parameter of extreme value distribution function,  $a_0$ ,  $b_0$ : regression constants.

The uncertainties of the extreme waves are defined by the reliability analysis, and the design waves with confidence interval can be expressed as

$$H_{1/3} = H_{1/3}' \pm \sigma H_{1/3} \tag{10}$$

$$T_{1/3} = T_{1/3}' \pm \sigma T_{1/3} \tag{11}$$

in which  $H_{1/3}$  is the significant wave height,  $T_{1/3}$  is the significant wave period, superscript ' denotes the value from the regression formular equation (2),  $\sigma H_{1/3}$  and  $\sigma T_{1/3}$  are the uncertainty parameter for extreme wave height and period respectively, and (+) and (-) signals denote the upper and the lower confidence level.

The extreme / design wave characteristics for the return periods ( $RP_i$ ;  $i=1, NN$ ) can be estimated from the equations (9), (10), (11).

## (2) Stability Analysis of Rubble Mound Structure

Among the many well known conventional design formulas, Hudson (1959) and CERC (1984) for the regular wave, and Ryu & Sawaragi (1986) and Van der Meer (1987) for the irregular waves are applied for the stability check in the algorithm.

For the uniform slope structures:

$$W_H = \frac{\gamma_r H^3}{K_D \cot \theta (S_r - 1)^3} \quad (12)$$

by Hudson (1959) & CERC (1984)

$$W_R = \left[ \frac{\gamma_w (6.15 Q_p + 20.0) \tan \theta}{\gamma_r^{1/3} (D_R + 30.1) \tan \phi} \right]^{3/2} H_{1/3}^3, \quad (13)$$

by Ryu and Sawaragi (1986)

$$W_V = \frac{\xi_z^{3/2}}{\{6.2 P^{0.18} (D_V / \sqrt{N})^{0.2} \xi_z^{0.5}\}^3} \frac{H_{1/3}^3 \gamma_r}{(S_r - 1)^3} \quad (14)$$

for plunging wave

$$= \frac{1}{\{P^{0.13} (D_V / \sqrt{N})^{0.2} (\cot \theta)^{0.5} \xi_z P\}^3} \frac{H_{1/3}^3 \gamma_r}{(S_r - 1)^3} \quad (15)$$

for surging wave by Van der Meer (1987)

For the composite slope structures:

$$W_R = \left[ \frac{\gamma_w (5.46 Q_p + 17.73) \tan \theta'}{\gamma_r^{1/3} (D_R + 36.3) \tan \phi} \right]^{3/2} H_{1/3}^3 \quad (16)$$

by Ryu and Sawaragi (1986)

where  $W$  is the rubble unit weight, subscripts  $H$ ,  $R$  and  $V$  are the weight by Hudson, Ryu and Sawaragi, and Van der Meer respectively,  $H$  the design wave height,  $K_D$  the empirical stability coefficient,  $\theta$  the angle from horizontal of seaward slope of the structure,  $\gamma_r$  the unit weight of armor unit,  $S_r$  the specific gravity of armor unit,  $Q_p$  the wave spectrum peakedness parameter,  $\tan \phi$  the friction coefficient,  $D_R$  the allowable damage level by Ryu's definition,  $D_{n50}$  the nominal diameter,  $T_z$  the average wave period,  $D_V$  the damage level by Van der Meer's definition,  $P$  the permeability of core,  $\xi_z$  the surf-similarity parameter with average wave period, and  $\theta'$  the equivalent slope of the composite structures.

These stability equations can rearrange to inequality constraint functions for the optimization formulation as

$$g_1(X) = X_5^3 \gamma_r - [ \gamma_r / \cot \theta (K_D (S_r - 1)^3) ] H_{1/3}^3 \geq 0 \quad (12')$$

$$g_1'(X) = X_5^3 \gamma_r - \left[ \frac{\gamma_w(6.15 Q_p + 20.0)}{\gamma_r^{1/3} (D_R + 30.1)} \frac{\tan\theta}{\tan\phi} \right]^{3/2} H_{1/3}^3 \geq 0 \quad (13)'$$

$$g_1''(X) = X_5^3 \gamma_r - \frac{\xi_z^{3/2}}{\{6.2P^{0.18}(D_V/\sqrt{N})^{0.2}\xi_z^{0.5}\}^3} \frac{H_{1/3}^3 \gamma_r}{(S_R - 1)^3} \geq 0 \quad (14)'$$

for plunging wave

$$= X_5^3 \gamma_r - \frac{1}{\{P^{0.13}(D_V/\sqrt{N})^{0.2}(\cot\theta)^{0.5}\xi_z^P\}^3} \frac{H_{1/3}^3 \gamma_r}{(S_R - 1)^3} \geq 0 \quad (15)'$$

for surging wave

$$g_1'''(X) = X_8^3 \gamma_r - \left[ \frac{\gamma_w(5.46 Q_p + 17.73)}{\gamma_r^{1/3} (D_R + 36.3)} \frac{\tan\theta'}{\tan\phi} \right]^{3/2} H_{1/3}^3 \geq 0 \quad (16)'$$

### (3) Wave Control Functions

In considering with function and purpose of the structures, the following equations are used as the design constraints for wave control functions in relation to wave overtopping and reflection (Takada, 1973; Ryu and Kang, 1990; Ryu, 1984).

$$g_2(X) = AQ - Q \geq 0 \quad (17)$$

$$g_3(X) = AR - K_r \geq 0 \quad (18)$$

$$Q = 0.5a(R_u - H_c)^2 (X_0/R_u - \cot\theta) \quad (19)$$

$$a = 7.6 (\cot\theta)^{0.73} (H_0/L_0)^{0.83} \quad (20)$$

$$R_u = [1.17 \xi_{1/3}/(1 + 0.8 \xi_{1/3})] \times H_{1/3}, \text{ for the uniform slopes} \quad (21)$$

$$K_r = 0.5 \left[ \frac{(\xi_{1/3} - 2.65 \tan\theta)}{4.3} \right]^{0.7}, \text{ for the uniform slopes} \quad (22)$$

where  $AQ$  is the allowable overtopping rate,  $Q$  the overtopping rate,  $AR$  is the allowable wave reflection and  $K_r$  the wave reflection coefficient,  $R_u$  is run-up height,  $\xi_{1/3}$  is significant surf-similarity parameter,  $H_c$  is the crest height,  $X_0 = L_0/4$ , and  $L_0$  and  $H_0$  are deep sea wave length and height respectively.

For the composite slopes, the same inequality constraints are used as equations (17) and (18), however the run-up and the wave reflection characteristics on the composite slope are considered referred to the analysis results with phase interaction mechanism on the composite slope face by Ryu et al. (1986) instead of equations (21) and (22).

Crest width, slope stability and other design constraints can also be included from necessity.

## 4. Optimal Cost Effectiveness

### 4.1 Initial Construction Cost (ICC)

Initial construction cost is very different by field by field, however, the cost changes can be defined to be proportional to the cross-sectional area and material scales. The relation simply can express as following equation.

$$ICC = \alpha_a A + \alpha_b B + \alpha_c C \quad (23)$$

The weight functions  $\alpha_a$ ,  $\alpha_b$  and  $\alpha_c$  should be change with the field conditions, construction facilities and techniques, and other a lot of constraints. Where  $A$ ,  $B$ , and  $C$  are the unit costs of the cover layer, sublayer and core layer respectively.

#### 4.2 Maintenance Cost

To estimate the maintenance cost, the probability of failure occurrence should be considered as denoted as following equation.

$$dF = (1 - (1 - \Delta P))^\lambda \quad (24)$$

where  $dF$  denotes the probability of failure occurrence per a year,  $\Delta P$  is the exceedance probability of wave conditions, and  $\lambda$  the total number of wave events per a year to destruct. If it can be assumed that the maintenance work will be immediately made after damage is accrued, the total maintenance cost during life time of structures ( $TMY$ ) is given by

$$TMY = \int_L^U [\alpha_f (EDR \times ICC)] dRP \quad (25)$$

where  $dRP$  is considered interval of the return period,  $U$  and  $L$  are the upper and lower limit of the return period,  $EDR$  is the equivalent damage rate, and  $\alpha_f$  the weighting value for repair compare to the initial construction cost.  $\alpha_f$  in the equation is one of the sensitive constant in the maintenance cost estimation. It is very changeable parameter by field by field, and the value in the  $[\alpha_f (EDR \times ICC)]$  means the maintenance cost per a year.

#### 4.3 Total Cost (TC) Minimization

Total cost during the life time ( $TC$ ) can be written as the sum of initial construction cost ( $ICC$ ) and total maintenance cost ( $TMY$ ). The maintenance cost  $TMY$  is required every year, and the cost can be changed to the present value considering interest / discount rate and the other effects.

The typical total cost change is shown in Figure 4, and it can be written as

$$TC = ICC + P_{wf} (TMY) \quad (26)$$

$$P_{wf} = \frac{(1+i)^n - 1}{i(1+i)^n} \quad (27)$$

where  $P_{wf}$  denotes the present value exchange rate,  $i$  the discount rate,  $n$  the life time of the structure. In the above equation,  $i$  is an important and effective parameter in the  $TC$  calculation, and it is changeable by the economic conditions.

Figure 4. Construction, maintenance, and total costs as functions of wave conditions.

If those effective parameters such as  $i$ ,  $\alpha_f$ ,  $\alpha_a$ ,  $\alpha_b$  and  $\alpha_c$  can be introduced reasonably in the cost estimation, the minimum cost condition can be found easily by the conception as shown in Figure 4.

## 5. Application of the Design Algorithm

### 5.1 Variation of the Cross-Section for Uniform Slope

Using the wave observed data at the east coast of Korean Peninsula, the extreme wave characteristics can be derived as

$$\left. \begin{aligned} H_{1/3} &= 1.01 RV + 1.93 \\ T_{1/3} &= 2.50 RV + 6.66 \end{aligned} \right\} \quad (28)$$

where the symbols are same as equations (8) and (9). The unit construction cost and other design constraints are also referred to G-port in Korea

From the equation (28), extreme / design wave characteristics by return periods can be easily estimated, and can get the cross-sectional dimensions by the algorithm. Figure 5(a) shows the cross-sectional variation characteristics due to the select of return period for the design waves. Figure 5(b) indicates the effect of allowable reflection of waves on the cross-section. The detail dimensions are illustrated in the Figures. From the Figures, it can be remarkably said that the allowable reflection very sensitively affect to the slope angle and total cross-sectional area, and the change of design waves

Figure 5. The cross-sectional variation characteristics due to the select of return period for the design waves and the effect of allowable reflection of waves on the cross-section.

affects to the weight of cover layer armor unit. Figure 6 shows the cross-sectional and the crest height changes as well as the rubble weight and the slope angle variations due to the allowable overtopping rate as a function of return period of design waves.

In the calculation the allowable reflection coefficient  $AR$  is considered to  $0.3$ , and Ryu and Sawaragi's formula is applied to the stability analysis with allowable damage rate  $D_R = 60\%$  and spectral peakedness parameter of irregular wave  $Q_p = 2.0$ . From the figures it can be concluded that allowable overtopping rate affects sensitively on the change of crest height. As the result the cross-sectional area is also changed by the rate as a function of the return period.

Figure 7 shows the effects of the spectral peakedness parameter of irregular design waves. In the figure, it is also found that the effects can not be neglected in the design as neglected in a lot of conventional design formulas.

### 5.2 The Cross-Section Changes of Composite Slope

The optimal design results for the composite slope structures are listed in Table 1. In this case, the reflection control functions are considered with the reflection coefficient at boundary 1, berm front, to be less than  $0.4$ , and the overtopping is not allowed. In the table, it can understand that the design variables are sensitively affected by the extreme wave statistics (RP). The berm width and depth are especially sensitive with a small change of design waves. These may will be more changeable if the allowable reflection is considered as a function of the wave statistics with a conception of environmental wave control in a sea area.

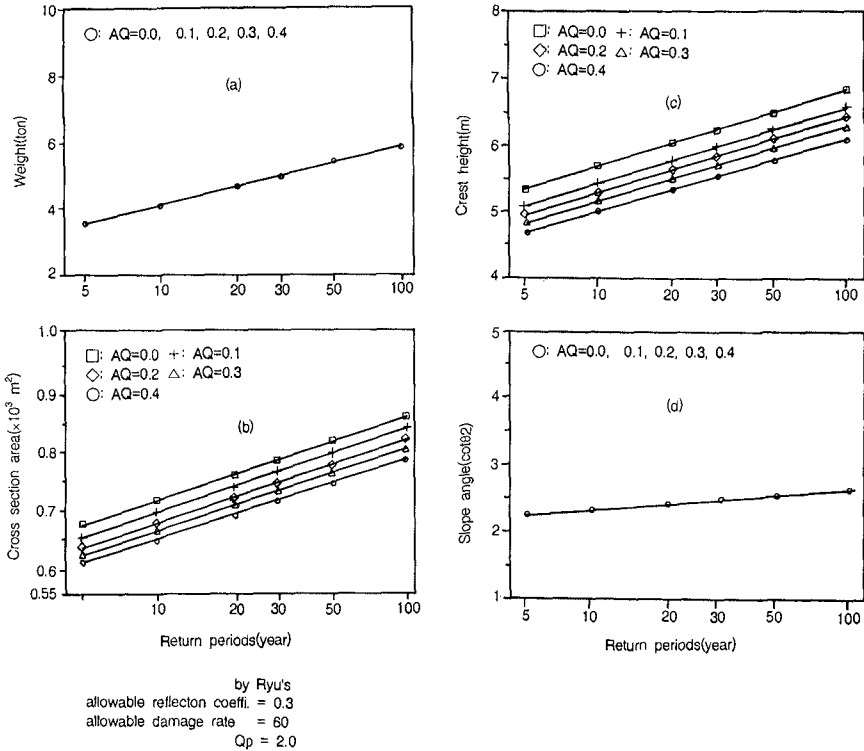

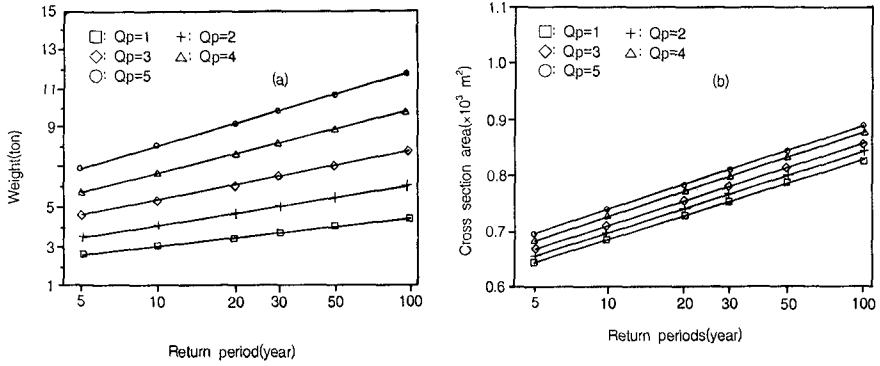

Figure 6. The variations of design variables according to the allowable overtopping rates.

Table 2 shows the results of the design variables change due to the allowable damage. The rubble weight, X8 has a decreasing tendency with increasing of allowable damage  $D_R$ , however, we can not find a typical cross sectional area in the table.

From these results, it is emphasized that the algorithm can be applied to the design of composite slope structures.

### 5.3 Total Cost Variations

Figure 8 is the final results on unit total cost calculation by the algorithm. It changes according to the return period and the other design constraints listed in the figure, and we can easily find the minimum cost point by the design conditions. Although, it is a special application example and the result can be changed by field by field, it can be emphasized that the minimum point take place in some region of medium return periods shorter than 50 years. It means that the optimal design concept is a reasonable design method for the systematic and cost effective coastal developments.

by Ryu's  
 allowable overtopping rate = 0.3  
 allowable reflection coeff. = 0.3  
 allowable damage rate = 60

Figure 7. The effects of the spectral peakedness parameter of irregular design waves.

## 6. Conclusions

The conclusions obtained herein are as follows:

A cost-effective design algorithm of rubble mound structure with various slope shapes has been developed considering the uncertainty and irregularity of design waves / the return period of extreme waves, allowable damage ( $D_R$ ), and wave control functions.

The reliability of the design results can be directly estimated using the algorithm. It means that the design algorithm can overcome the design fault because of the design wave selection problems in the extreme waves. In considering the allowable ranges of the design constraints and irregularity of the design wave, the design sensitivity can easily be checked also by using the algorithm.

In order to examine the applicability of the algorithm, the design sensitivity for the structural dimensions and total costs are analysed and compared with those of conventional methods using design examples. From the results of comparative studies, the algorithm is found to be applicable, and it will be more useful and powerful algorithm for the design of rubble mound structures under the more complex design conditions, design constraints, and cost functions.

## CHAPTER 116

### Numerical simulation of nonlinear wave interacting with permeable breakwaters

T.Sakakiyama<sup>1</sup> and R.Kajima<sup>2</sup>

#### Abstract

A fully nonlinear simulation model was developed to predict the wave transformation interacting with a permeable breakwater. The present model was applied to simulate wave transformations due to a rubble-mound breakwater and due to a caisson breakwater covered with armor units and verified by hydraulic model tests. Numerical experiments were also performed to interpret the stability of armor units and the wave-induced pressure on the caisson through the pile of armor units.

#### 1. INTRODUCTION

Numerical models to predict wave motions near and inside of a rubble mound breakwater have been recently developed. Since some models are based on the linear wave theory (Hölscher *et al.*, 1989), they provide only a change of amplitude of a sinusoidal wave. Others are nonlinear but one-dimensional models, *i.e.*, they are based on the depth-integrated equations (Wurjanto and Kobayashi, 1992). Ohyama and Nadaoka (1991) developed a fully nonlinear model to simulate wave transformation on an impermeable bottom based on the potential theory. No fully nonlinear model including the effect of permeability is developed yet.

The purpose of this paper is to develop a fully nonlinear two-dimensional numerical model to predict the wave transformation in the field which is partially occupied by a permeable structure. The interaction between waves and structures is expressed by the resistance forces in the structures, the drag and inertia forces. In this paper, analyzed are the wave transformations due to a rubble-mound breakwater and due to a caisson breakwater covered with armor units both in

<sup>2</sup> Senior research fellow, ditto.

front and at back. The computations are compared with hydraulic experimental results. Numerical experiments are also carried out to investigate the wave force acting on the armor units and the wave-induced pressure on the caisson through the pile of armor units.

## 2. Numerical simulation method

### 2.1 Governing equation

Sha *et al.*(1977) derived the quasi-continuum governing equations for conservation of mass, momentum and energy called the porous body model(PBM). Their purpose was to apply these equations to the flow in a class of systems, such as heat exchangers and fuel-rod bundles in a nuclear reactor.

The governing equations of PBM for incompressible two-dimensional flow are modified to apply it to the wave field(Sakakiyama,1991). The inertia and the drag forces are introduced into the horizontal and vertical components of the momentum equations, and rearranging them yields the following equations:

Continuity equation

$$\frac{\partial(\gamma_x u)}{\partial x} + \frac{\partial(\gamma_z w)}{\partial z} = 0, \quad (1)$$

Momentum equation

$$\lambda_v \frac{\partial u}{\partial t} + \lambda_x u \frac{\partial u}{\partial x} + \lambda_z w \frac{\partial u}{\partial z} = -\gamma_v \frac{\partial \phi}{\partial x} - R_x + \frac{1}{\rho} \left\{ \frac{\partial(\gamma_x \tau_{xx})}{\partial x} + \frac{\partial(\gamma_z \tau_{zx})}{\partial z} \right\}, \quad (2)$$

$$\lambda_v \frac{\partial w}{\partial t} + \lambda_x u \frac{\partial w}{\partial x} + \lambda_z w \frac{\partial w}{\partial z} = -\gamma_v \frac{\partial \phi}{\partial z} - \gamma_v g - R_z + \frac{1}{\rho} \left\{ \frac{\partial(\gamma_x \tau_{xz})}{\partial x} + \frac{\partial(\gamma_z \tau_{zz})}{\partial z} \right\}, \quad (3)$$

where

$$\left. \begin{aligned} \lambda_v &= \gamma_v + (1 - \gamma_v) C_M \\ \lambda_x &= \gamma_x + (1 - \gamma_v) C_M \\ \lambda_z &= \gamma_z + (1 - \gamma_v) C_M \end{aligned} \right\} \quad (4)$$

and  $\lambda_v$  is the volume porosity and  $\lambda_x$ ,  $\lambda_z$  the horizontal and vertical components of the surface permeability, respectively.  $\phi = p/\rho$  is the ratio of the pressure  $p$  to the density of the fluid  $\rho$  and  $u$ ,  $w$  the velocity components in the  $x$ - and  $z$ -direction respectively,  $g$  the acceleration due to gravity,  $\tau$  the viscous stress acting on the surface of the control volume. The drag forces are modeled by Eq. (5) and Eq. (6),

$$R_x = \frac{C_D}{2\Delta x} (1 - \gamma_x) u \sqrt{u^2 + w^2} \quad (5)$$

$$R_z = \frac{C_D}{2\Delta z} (1 - \gamma_z) w \sqrt{u^2 + w^2} \quad (6)$$

Unknown are the inertia and drag coefficients  $C_M$ ,  $C_D$ , which are experimentally determined.

### 2.2 Boundary conditions

The continuity equation Eq. (1) and the momentum equations (2) and (3) are numerically solved with appropriate boundary and initial conditions.

A kinematic boundary condition on the free surface is expressed as:

$$\frac{\partial \eta}{\partial t} + u_s \frac{\partial \eta}{\partial x} = w_s \tag{7}$$

where  $\eta$  is the free surface displacement,  $u_s$  and  $w_s$  are the horizontal and vertical components of the velocity on the free surface  $\eta$ , respectively.

A dynamic boundary condition at the free surface is represented by the following:

$$p = 0 \quad \text{on} \quad z = \eta \tag{8}$$

At a bottom boundary, a free slip condition is imposed. When a water depth is uniform, the slip conditions for the velocity  $u$ ,  $w$  and the pressure  $p$  are expressed as follows:

$$\frac{\partial u}{\partial z} = 0 \tag{9}$$

$$w = 0 \tag{10}$$

$$\frac{\partial p}{\partial z} = -\rho g \tag{11}$$

The boundary condition on the pressure given by Eq. (11) is led by substituting Eq. (10) into the vertical component of the momentum equation, Eq. (3). In the case that a boundary contains an impermeable vertical wall, the similar free slip condition is imposed at the impermeable boundary.

An inflow boundary works as a wavemaker. Perturbation solutions of the nonlinear wave theory by Isobe *et al.*(1978) are used to give the inflow boundary conditions. The nonlinear wave theory applied to the inflow boundary condition depends on the following wave condition:

$$\left. \begin{array}{l} \text{Stokes wave 5th-order solution} \\ \text{cnoidal wave 3rd-order solution} \end{array} \right\} \begin{array}{l} U_s \leq 25 \\ 25 < U_s \end{array} \tag{12}$$

where  $U_s$  is the shallow water Ursell parameter defined with the long wave length  $L = T\sqrt{gh}$  in the Ursell parameter  $U_r = HL^2h^3$ ;

$$U_s = \frac{gHT^2}{h^2}. \tag{13}$$

At an outflow boundary, Sommerfeld's radiation condition is imposed:

$$\frac{\partial F}{\partial t} + C \frac{\partial F}{\partial x} = 0 \tag{14}$$

where  $C$  is the wave celerity and  $F$  denotes the variable  $\eta, u, w$  or  $p$ . Eq. (14) indicates that the variable  $F$  progresses with the phase speed  $C$ .

Fig. 1 Rubble-mound breakwater( $\lambda = 1/60$ )Table 1 Experimental conditions for rubble-mound breakwater( $\lambda=1/60$ )

wave period $T$ (s)	wave height $H$ (m)	water depth $h$ (m)	Tetrapod		
			$W$ (kg)	$b$ (m)	$\epsilon$
1.50	0.015-0.275	0.417	0.13	0.059	0.53

The initial condition is set as the still water state. The surface displacement  $\eta$  at  $t = 0$  is null for a whole computational region as well as  $u = w = 0$ . The pressure  $p$  at  $t = 0$  is given by the hydrostatic pressure.

The Poisson equation for the pressure is iteratively solved by the successive over-relaxation(SOR) method with the given boundary and initial conditions mentioned above. The dynamic boundary condition on the free surface given by Eq. (8) is exactly satisfied in an iterative process of the pressure computation by applying the "irregular star" method(Chan and Street,1970).

### 3. Rubble-mound breakwater

#### 3.1 Experiments

The experiments were performed by using a laboratory wave flume (78m long, 1.2m high and 0.9m wide). The model breakwater was a conventional trapezoidal rubble-mound breakwater as shown in Fig. 1. The rubble-mound breakwater consists of single size of Tetrapods(weight  $W = 0.13$ kg) for the simplicity to analyze experimental results. The *In Situ* porosity of the breakwater is  $\epsilon = 0.53$ . Slopes of the breakwater surface are 1 on 1.5 for both the seaward and landward side surfaces. Table 1 shows the experimental conditions. The model scale is supposed as  $\lambda = 1/60$ . Water depth at the breakwater is  $= 0.417$ m in the model scale and uniform depth  $h = 0.737$ m. Wave period was  $T = 1.5$ s. Wave height ranges from  $H = 0.015$ m to  $0.275$ m. The maximum ratio of the wave height to the water depth  $H/h$  was up to about 0.65. The nonlinearity of the waves generated was remarkable but wave breaking was not included in the present experimental conditions.

The reflection coefficient was estimated with the method for resolving incident and reflected waves proposed by Goda(1985). The displacements of a transmitted wave were measured at five locations. The averaged values of the five transmitted wave heights are used in the following analysis.

Fig. 2 Reflection and transmission coefficients of rubble-mound breakwater

Table 2 Calculation condition for rubble-mound breakwater

$H(\text{m})$	$T(\text{s})$	$h(\text{m})$	$L_I(\text{m})$	$\Delta x/L_I$	$\Delta z/h$	$\Delta t/T$	cal. region
0.15	1.5	0.417	3.20	1/71.1	1/13.89	1/200	$8.63 \times L_I$

In Fig. 2, the experimental results of the reflection coefficient  $K_R$  and the transmission coefficient  $K_T$  are shown as a function of the wave steepness  $H/L$ , where  $L$  is the wave length at the breakwater ( $h = 0.417\text{m}$ ) estimated by the linear wave theory. As the wave steepness  $H/L$  increases, the transmission coefficient  $K_T$  decreases remarkably but the reflection coefficient  $K_R$  is almost constant. Basically, the wave reflection depends on the porosity and slightly on the inertial resistance. The wave transmission depends on the energy dissipation in the permeable structure. An amount of the energy dissipation is proportional to the product of the friction factor and the velocity squared.

### 3.2 Simulation of wave transformation

The computation was carried out under the wave condition as shown in Table 2. The wave period is  $T = 1.5\text{s}$  and the progressive wave height at the breakwater  $H = 0.15\text{m}$  ( $H/h = 0.36$ ). The horizontal distance of the calculation region was  $8.63 \times L_I$ , where  $L_I$  is the incident wave length at the uniform depth ( $h_I = 0.747\text{m}$ ) obtained from the nonlinear wave theory. The wave lengths are  $L_I = 3.20\text{m}$  at the uniform depth and  $L = 2.68\text{m}$  at the breakwater. The space increments are  $\Delta x = 0.045\text{m}$  ( $\Delta x/L_I = 1/71.1$  and  $\Delta x/L = 1/58.9$ ) horizontally and  $\Delta z = 0.03\text{m}$  ( $\Delta z/h = 1/13.89$ ) vertically. The time increment is  $\Delta t = T/200$ . It took about one hundred minutes with the main frame computer HITAC 680H to calculate 4000 time steps (20 cycles  $\times$  200 steps per wave period) to reach steady state wave motion near the rubble-mound breakwater.

The inertia coefficient  $C_M$  and the drag coefficient  $C_D$  were estimated so that

Fig. 3 Simulated result of wave transformation due to rubble-mound breakwater

the reflection and transmission coefficients obtained in the computation might agree well with those in the experiment, respectively. The reflection and transmission coefficients obtained in the computation are  $K_R = 0.15$  and  $K_T = 0.14$ . The corresponding experimental results are  $K_R = 0.18$  and  $K_T = 0.14$ , respectively. The values of  $C_D = 1.2$  and  $C_M = 1.7$  are obtained by best fitting the computation to the experimental result.

Fig. 3 shows one of the computed wave velocity fields near and within the rubble-mound breakwater. Although a partial standing wave is formed at the windward side of the breakwater, the wave profile and its velocity field are rather similar to those of a progressive wave. It is because of a small reflection coefficient ( $K_R = 0.15$  in the computation). Comparing with the profile of partial standing wave, that of wave run-up on the breakwater slope is deformed and becomes steep. The wave attenuation in the permeable breakwater and the wave propagation through it are reasonably simulated.

### 3.3 Wave force acting on armor units

One of the most important physical phenomenon to investigate the stability of armor units is the movement of wave run-up on a breakwater slope. However, it is quite difficult to measure the velocity and acceleration along the slope during the wave run-up and -down in a hydraulic experiment. Numerical simulation is one of the most useful tools to investigate the wave run-up cooperating with hydraulic experiments. A well-calibrated numerical simulation method helps us interpret that phenomenon.

Fig. 4 shows the hodographs of the wave run-up velocity at the two elevations along the armor layer. The vertical heights of the wave run-up and run-down are  $R_{max}/h = 0.209$  and  $R_{min}/h = -0.128$ , respectively. The circles on the curves are time scale, which indicate the moments at every one eighth of the wave period. Arrows show the mean velocity vectors of the wave run-up velocity. The slope of armor layer of the breakwater is indicated with the dashed line. Above the elevation of the wave run-down, the hodographs are not closed. The direction of the mean flow at  $z/h = 0.043$  is into the body of the permeable

Fig. 4 Velocity hodograph

breakwater. The positive(upward) velocity perpendicular to the slope of the breakwater occurred below  $z/h = -0.101$ . Below the level of the wave run-down,  $z/h < R_{min}/h = -0.128$ , velocity hodographs are closed and make ellipses as shown in Fig. 4(b)  $z/h = -0.245$ , and the apsis of the velocity hodograph is parallel to the slope of the breakwater. Getting close to the bottom, the ellipse becomes flat. The velocity hodograph is affected by the impermeable flat bed.

With the results of the numerical simulation, we discuss wave force action on armor units placed on the slope of the rubble-mound breakwater. Wave force acting on the armor units are estimated by using the Morison equation given by Eq. (15) with the velocity field near the armor layer.

$$\begin{aligned}
 F(x, z, t) &= F_D(x, z, t) + F_I(x, z, t) \\
 &= \frac{1}{2} \rho C_D A u_s(x, z, t) |u_s(x, z, t)| + \rho C_M V \alpha_s(x, z, t) \quad (15)
 \end{aligned}$$

where  $F_D$  is the drag force and  $F_I$  the inertia force. The drag and inertia coefficients  $C_D$ ,  $C_M$  of the single Tetrapod were obtained by Sakakiyama and Ka-

Fig. 5 Time histories of total wave force  $F$ , inertia force  $F_I$  and drag force  $F_D$

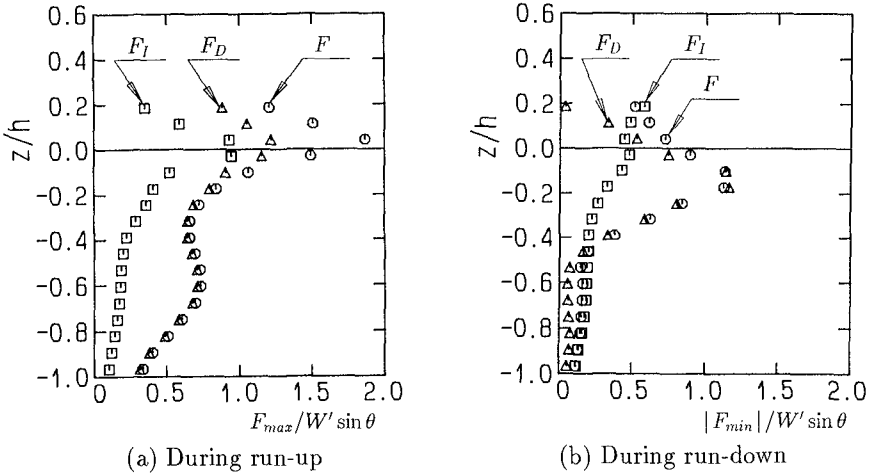

Fig. 6 Vertical profile of wave force on armor units

jima(1990). They show the relationship between  $C_D$ ,  $C_M$  and the Reynolds number with a parameter of  $KC$  number.

Fig. 5 shows the time histories of the wave forces. The drag and inertia coefficients are determined as  $C_D = 1.0$  and  $C_M = 1.0$ , respectively referring to the results by Sakakiyama and Kajima(1990). The time history of the total wave force is very similar to the measured one obtained by Sakakiyama and Kajima(1990) except that the total wave force in Fig. 5 does not contain the buoyant weight of the armor unit. From the time history of the calculated wave force, the inertia force  $F_I$  works for a short time with a large peak behaving like a slamming force. The drag force  $F_D$  has longer duration than the inertia force. It is considered that the slamming force is not dangerous for the stability of the armor units because that force works into the body of the breakwater. However, the breakage of slender and fragile concrete armor units is due to this type of wave force causing the armor units to be rocking (Burcharth *et al.*,1991).

Fig. 6 shows the profiles of the wave force along the slope of the breakwater. The symbols indicate the peak values of the inertia, drag and total forces both

Fig. 7 Caisson breakwater( $\lambda = 1/60$  and  $1/15$ )

Table 3 Experimental conditions for caisson breakwater in prototype

wave period $T(s)$	water depth $h(m)$	wave height $H(m)$	
		$\lambda = 1/60$	$\lambda = 1/15$
15.5	25.0	1.08-17.64	1.08-16.92

during the wave run-up in Fig. 6(a) and during run-down in Fig. 6(b). The axis of abscissa indicates the ratio of the wave force to  $W' \sin \theta$ , where  $W'$  is the buoyant weight of an armor unit,  $\theta$  the angle of breakwater slope. The ratio of the value of unity means the incipient condition of the armor unit when the friction force between armor units is neglected. The computational results shows that the profiles of the drag, inertia and total forces have the maximum values near the still water level during the wave run-up. During the wave-run down, the maximum value of the total wave force is found close to that of the drag force at  $z/h \simeq -0.2$ . It agrees with the fact that the armor units near the still water level are the most unstable as we have experienced in hydraulic experiments.

## 4. Caisson breakwater covered with armor units

### 4.1 Experiments

The experiments on a caisson breakwater covered with armor units were performed by using both a large wave flume(205m long, 6.0m deep and 3.4m wide) and a small one(78m long, 1.2m deep and 0.9m wide). The model scales were  $1/15$  and  $1/60$ , respectively. Fig. 7 shows the prototype breakwater of which models were used in the scale model experiments. A narrow caisson is placed in the breakwater body to reduce transmitted waves. The core material consists of stones( $W = 50\text{kg}$  to  $200\text{kg}$  in prototype scale) of which porosity is estimated as  $\epsilon = 0.4$ . The weights of armor units are  $W = 80\text{t}$  in the armor layer at the windward side,  $W = 11\text{t}$  in the filter layer and  $W = 28\text{t}$  in the armor layer at the leeward side. The corresponding weights of the armor units in the  $1/15$ -scale experiment were  $20\text{kg}$ ,  $6.8\text{kg}$  and  $10.0\text{kg}$ . Those used in the  $1/60$ -scale experiment were  $0.37\text{kg}$ ,  $0.054\text{kg}$  and  $0.13\text{kg}$ . The *In Situ* porosity of armor and filter layers in the breakwater is  $\epsilon = 0.50$ . The armor layer at the leeward side is placed to reduce multi-reflected waves in a harbor.

Table 3 shows the experimental conditions indicated in equivalent prototype

Table 4 Calculation condition for caisson breakwater

values. The reflection and transmission coefficients for various wave conditions (prototype wave conditions of incident wave height  $H = 1\text{m}$  to  $17\text{m}$ , period  $T = 15.5\text{s}$  and water depth  $h = 25.0\text{m}$ ) were obtained in the same way.

Measurements include also wave pressures on the seaward wall of the caisson covered with the permeable structures at 10 points in the large-scale experiments and at 6 points in the small-scale experiments.

#### 4.2 Simulation of wave transformation

The computation was carried out under the wave conditions of the small scale-experiment such as the wave period  $T = 1.5\text{s}$ , the wave height at the breakwater  $H = 0.15\text{m}$  ( $H/h = 0.36$ ). Difference between the small- and large-scale conditions is the values of the inertia and drag coefficients which are functions of the Reynolds number and by which the scale effect is considered in the numerical simulation.

The computational condition is shown in Table 4 indicated in the prototype values. The horizontal distance of the calculation region was  $8.48 \times L_I$ , where  $L_I$  is the incident wave length at the uniform depth ( $h_I = 44.2\text{m}$ ) obtained from the nonlinear wave theory. The wave lengths are  $L_I = 191.24\text{m}$  at the uniform depth and  $L = 161.16\text{m}$  at the breakwater. The space increments are  $\Delta x = \Delta z = 1.667\text{m}$  ( $\Delta x/L_I = 1/114.7$  and  $\Delta x/L = 1/96.7$  horizontally,  $\Delta z/h = 1/15.0$  vertically). The time increment is  $\Delta t = T/200$ . It took about four hours with the main frame computer HITAC 680H to calculate 4000 time steps (20 cycles  $\times$  200 steps per wave period) to gain the steady state wave motion near the caisson breakwater.

The reflection and transmission coefficients obtained in the calculation for the

Fig. 9 Comparison of wave pressure between calculation and experiment

small-scale model are  $K_R = 0.18$  and  $K_T = 0.010$ . The corresponding small-scale experimental results are  $K_R = 0.21$  and  $K_T = 0.015$ , respectively. The computation which reproduced the experiment best gives  $C_M = 1.2$  and  $C_D = 0.9$ .

Fig. 8 shows the computed wave velocity field and the surface profile for the small-scale model when the wave runs up on the slope at the windward side of the permeable breakwater. The wave surface profile is deformed on the slope of the armor layer resulting in a steeper surface at the leeward side than that at the windward. Velocity of the wave front just outside the armor layer is increased according to the wave deformation. The velocity inside the armor layer is small and discharge also smaller than that outside the armor layer. The difference of the velocity between inside and outside the armor layer is large and the flow is concentrating to the surface of the armor layer. It is concluded that the velocity field is reasonably simulated as a whole.

The inertia and drag coefficients  $C_M$  and  $C_D$  in the computation were estimated so that the reflection and transmission coefficients obtained by the experiment might agree well with the those obtained by the computation, respectively. In order to verify the present method, it is necessary to compare other values between the experiment and the computation. Thus a wave-induced pore pressure is compared between the computed and measured results as shown in Fig. 9, where  $w$  is the specific weight of fluid. It is found that the quantitative agreement of the computed pressure profile with the measured one is very good for the small-scale experiment. The large-scale experimental result is also shown in Fig. 9. The scale effect on the pressure will be discussed in the following subsection.

#### 4.3 Scale effect of wave transformation and pressure

Fig. 10 shows the results of the reflection and transmission coefficients obtained through the large- and small-model scale experiments. The factor of the model scale according to the Froude law is 4 (the large-model scale is 1/15 and the small

Fig. 10 Scale effect of reflection and transmission coefficients

one 1/60). It is found that the reflection coefficients of the large-scale experiments are larger than the small ones. The transmission coefficients of the large-scale experiments are larger than small-scale one, although the difference is very small. Consequently, the energy dissipation rate of the large-scale experiments is less than that of the small-scale ones.

The tendency of the scale effect on the wave pressure is opposite to that on the wave reflection as shown in Fig. 9 on the pressure profiles comparing between the experimental results with the large- and small-scale models. That is, the wave pressures in the small-scale hydraulic experiments are larger than those in the large-scale one.

It is concluded from the results of the scale effects on the wave reflection and the wave pressure that the wave pressure is small when the wave reflection is large. It is very natural and explained as follows: When the reflection coefficient is large, a small amount of wave penetrates in a permeable structure and onto the caisson. As the result, the wave pressure becomes small.

The scale effects on the wave reflection and wave pressure mentioned above is explained with the following numerical experiments. Fig. 11 shows the effect of the inertia coefficient on the wave pressure, when the drag coefficient is constant as  $C_D=0.9$ . The computation are performed by varying the inertia coefficient  $C_M$  with 1.2, 1.5 and 1.7. As the inertia coefficient  $C_M$  increases the wave pressure decreases. On the other hand, the reflection coefficient increases as the inertia coefficient  $C_M$  increases. The transmission coefficient decreases very slightly. The reflection and transmission coefficients are less sensitive to the change of the inertia coefficient  $C_M$  than the wave pressure.

As the inertial resistance described by the factor  $\lambda_v = \gamma_v + (1 - \gamma_v)C_M$  defined as Eq. (4) increases, the wave reflection from the armor and filter layers increases. Consequently, the less part of wave transmits in the permeable structure and the wave pressure decreases. As the Reynolds number increases under the condition

that  $KC$  number is constant, the inertia coefficient increases according to the Froude law for scaling.

Fig. 12 shows the effect of drag coefficient on the wave pressure, while the inertia coefficient is constant as  $C_M = 1.5$ . The drag coefficient  $C_D$  is selected as  $C_D = 0.3, 0.6$  and  $0.9$ . As the drag coefficient increases, the wave pressure decreases. It is caused by an increase of the wave energy dissipation in the permeable structure.

As explained above, both the drag and inertia coefficients influence the scale effect on the wave reflection, transmission and also the pressure. These scale effects are reflected to the numerical model through  $C_M$  and  $C_D$  which are functions of the Reynolds number.

Fig. 12 Wave pressure depending on drag coefficient ( $C_M = 1.5$ )

## 5. Conclusions

A fully nonlinear numerical model has been developed to simulate the wave motion near and in a permeable breakwater. The simulated results were compared with hydraulic experimental ones using two types of permeable breakwaters, a rubble-mound breakwater and a caisson breakwater covered with armor units. The present model can reproduce the wave reflection and transmission, and also the pressure on the caisson. Wave profiles and velocity fields near and in the permeable breakwaters were realistically simulated. Wave force acting on armor units was estimated by Morison equation with the computed velocity. The maximum wave force was found near the still water level during wave run-up.

The scale effects on the wave reflection, transmission and wave-induced pore pressure were demonstrated by the hydraulic experiments. Computation interprets these scale effects. As model scale increases the drag coefficient decreases and the inertia coefficient increases. As the result, the wave energy dissipation due to the drag force decreases while the wave reflection increases due to the inertial resistance. Consequently, the scale effect on the wave-induced pore pressure is canceled by two opposite effects of fluid resistance.

The drag and inertia coefficients were determined so that the reflection and transmission coefficients of the experiment fit with those of the computation, respectively. A fundamental experiment, an oscillation flow test using U-tube tank, for instance will be required to estimate the inertia and drag coefficients.

## CHAPTER 117

### WAVES ON PERMEABLE LAYERS

Toru Sawaragi<sup>1)</sup> and Ichiro Deguchi<sup>2)</sup>

#### **Abstract**

To analyze a wave attenuation on a permeable layer, we first examined the applicability of Forchheimer type equation to the fluid motion in the permeable layer through permeability tests in steady and unsteady flows. Then, we investigated the effects of a boundary shear on the surface of the permeable layer on the wave attenuation by solving boundary layer equations around the surface of the layer.

It is found that the permeability and the turbulent drag coefficient in the Forchheimer type equation in the unsteady flow are different from those in the steady flow. We showed that the Forchheimer type equation could linearize by using an equivalent linear drag coefficient formulated empirically through the permeability test. The effect of the boundary shear on the wave attenuation on the permeable layer was small compared with the effect of energy loss in the permeable layer if the thickness of the layer was relatively large.

It is also found that we can predict the wave attenuation on the permeable layer exactly when the incident wave has a strong linearity.

#### **Introduction**

When we analyze a wave deformation through a structure with permeability, we often apply a Forchheimer type equation to a fluid motion in the permeable layer. A non-linear turbulent resistance term in the equation is usually replaced by a linear resistance term based on a so-called Lorentz's law of equivalent work. Also we can linearize the equation by using a newly defined equivalent linear drag coefficient through permeability tests.

However, the wave deformations on the permeable layer that were analyzed by these methods do not always agree well with the measured wave deformation. The followings are the conceivable reasons for this disagreement:

1) Errors in the evaluation of empirical coefficients in the Forchheimer type equation in unsteady flow. Several experimental results were reported about the permeability, an additional mass coefficient and a turbulent drag coefficient of a constitution material of the permeable layer in unsteady flow. Those are obtained from the experiments under very limited conditions.

1) Professor and 2) Associate Professor, Dept. of Civil Engineering, Osaka University, Suita-city, Osaka 565, Japan

2) Disregard of the boundary shear on a surface of the permeable layer. The continuity of vertical velocity on the surface of permeable layer is satisfied in the analysis of the wave deformation of conventional potential approach. However, the continuity of horizontal velocity is not satisfied and we can not evaluate exact boundary shear.

3) Non-linear behavior of incident waves.

Objectives of this research are as follows:

- 1) To investigate the influence of unsteady property of fluid motion on coefficients in the Forchheimer type equation through unsteady and steady permeability tests. Based on the experimental results, we formulate an equivalent linear drag coefficient.
- 2) To evaluate boundary shear on the permeable layer by using a horizontal water particle velocity that is a solution of a boundary layer equation near the surface of permeable layer. We examine the influence of the boundary shear on wave attenuation.
- 3) To examine the effect of nonlinear property of incident waves on wave attenuation by carrying out a Fourier analysis of surface displacement measured on the permeable layer.

**Waves on permeable layer**

First of all, we give brief explanation of an expression of wave on the permeable layer based on the potential approach. We suppose the wave of a period  $T$  and height  $H$  propagating in the positive  $x$  direction on the permeable layer. Figure 1 illustrates a definition sketch where  $D$  is the thickness of the permeable layer,  $h$  is the depth on the permeable layer,  $(u, w)$  are the water particle velocity in  $x$  and  $z$  directions,  $\phi$  and  $p$  is the velocity potential and the pressure. We attach a subscript  $d$  to the quantity in the permeable layer.

Fig.1 Definition sketch of wave on permeable layer

We can treat a fluid motion on the permeable layer as a potential flow. If we apply Forchheimer type equation to the fluid motion in the permeable layer that is expanded to the unsteady flow by Sollitt et al.(1970), we can express the fluid motion in the permeable layer as follows:

$$S \frac{\partial q}{\partial t} = -\frac{1}{\rho} \nabla p - \frac{v}{K_p} q - \frac{C_f \lambda}{\sqrt{K_p}} q^2 \tag{1}$$

$$S = \{1 + (1 - \lambda) C_m\} / \lambda$$

where  $q$  is the sectional averaged infiltration velocity (macroscopic velocity) in the permeable layer,  $\nabla p$  is the pressure gradient,  $K_p$  is the permeability of the permeable layer,  $g$  is the gravity acceleration,  $\nu$  is the kinematic viscosity of the fluid,  $C_m$  and  $C_f$  are the added mass and the turbulent drag coefficients of the rubble of the permeable layer, and  $\lambda$  is the void ratio of a permeable layer.

There are two methods to linearize the non-linear resistance term in Eq.(1). One is to determine an equivalent linear permeability by applying the Lorentz's law of equivalent work to the each layer of the horizontally divided permeable layers. We can determine a unique equivalent linear permeability  $K_{pe}$  through the whole sublayer by iterative calculations so that the total energy loss during one wave period becomes the same as that of the non-linear resistance term. However, we have to determine the values of  $C_m$ ,  $C_f$  and  $K_p$  before we find out the equivalent linear permeability and linearize Eq.(1). This method also requires large CPU time.

Another method is to use an equivalent linear drag coefficient  $f$ , which brings the same energy dispersion as that of Eq.(1) in one wave period, instead of the permeability and the turbulent drag coefficients to evaluate drag force in Eq.(1). We have to determine the value of  $f$  before we linearize Eq.(1) through the unsteady permeability test which I will mention later in detail in a next section. Anyway, in both methods, we can linearize Eq.(1) as Eq.(2) with the relation between  $K_{pe}$  and  $f$  given by Eq.(3):

$$S \frac{\partial q}{\partial t} = -\frac{1}{\rho} \nabla p - f \sigma q \quad \text{or} \quad S \frac{\partial q}{\partial t} = -\frac{1}{\rho} \nabla p - \frac{\nu}{K_{pe} \sigma} q \quad (2)$$

$$f = \gamma / (K_{pe} \sigma) \quad (3)$$

We normalize the quantities in the following manner:

$$\begin{aligned} (x', z', h', D') &= (\sigma^2/g)(x, z, h, D), \quad t' = \sigma t, \quad K_p' = \sigma K_p / \nu \\ (u', w, 'u_d', w_d') &= (1/\alpha a_0)(u, w, u_d, w_d) \\ (p', p_d') &= (1/\rho g a_0)(p, p_d), \quad (\phi', \phi_d') = (\sigma/g a_0)(\phi, \phi_d) \end{aligned} \quad (4)$$

where,  $\sigma$  is the angular frequency and  $a_0$  is the amplitude of surface displacement of a fundamental frequency component.

Then the fundamental equations to be solved are shown below.

On the permeable layer:

$$\nabla^2 \phi' = 0 \quad (5)$$

$$\text{where, } u' = \partial \phi' / \partial x', \quad w' = \partial \phi' / \partial z' \quad (6)$$

In the impermeable layer:

$$\nabla^2 \phi_d' = 0 \quad (7)$$

$$\text{where, } u_d' = \xi (\partial \phi_d' / \partial x'), \quad w_d' = \xi (\partial \phi_d' / \partial z') \quad (8)$$

$$\text{and } \xi = K_{pe} \sigma / \nu = 1 / f \quad (9)$$

The pressure on and in the permeable layer is expressed as follows:

$$p' = - \left[ \frac{\partial \phi'}{\partial t'} + \frac{g}{\alpha a_0} z + \frac{\sigma^2 a_0}{2g} \left\{ \left( \frac{\partial \phi'}{\partial x'} \right)^2 + \left( \frac{\partial \phi'}{\partial z'} \right)^2 \right\} \right] + \frac{C_1}{g a_0} \quad (10)$$

$$p_d' = -\phi_d' - \xi S \frac{\partial \phi_d'}{\partial t'} + C_2 \quad (11)$$

where,  $C_1$  and  $C_2$  are the constant.

The velocity potential in and on the permeable layer has to satisfy the following boundary conditions:

Kinematic boundary condition on the free surface:

$$\frac{\partial \eta'}{\partial t'} = -\frac{\sigma^2 a_0}{g} \frac{\partial \phi'}{\partial x'} \frac{\partial \eta'}{\partial x'} + \frac{\partial \phi'}{\partial z'} \quad : z' = \eta \quad (12)$$

Dynamic boundary condition on the free surface:

$$\eta = -\frac{\partial \phi'}{\partial t'} - \frac{\sigma^2 a_0}{2g} \left\{ \left( \frac{\partial \phi'}{\partial x'} \right)^2 + \left( \frac{\partial \phi'}{\partial z'} \right)^2 \right\} \quad : z' = h' \quad (13)$$

Continuity of the pressure on the surface of permeable layer:

$$p' = p_d' \quad : z' = -h' \quad (14)$$

Continuity of the vertical (macroscopic) velocity on the surface of permeable layer:

$$w' = w_d' \quad : z' = -h' \quad (15)$$

No vertical flux from the bottom:

$$w_d' = 0 \quad : z' = -(h' + d') \quad (16)$$

These equations are solved by the same way as finding the solution of Stokes waves. The author et al.(Deguchi,1988) have already derived the 2nd order solution corresponding to the Stokes 2nd order theory of the order of  $(\sigma^2 a_0/g)$ . Here we show the result of the 1st order solution for the sake of restricted space.

The dispersion relation for a sinusoidal wave with an amplitude  $a_0$ , which is expressed by Eq.(17) is given by Eq.(18).

$$\eta = \exp\{i(k' x' - t')\} \text{ or } \eta = a_0 \exp\{i(kx - \sigma t)\} \quad (17)$$

$$\sigma^2 = gk \frac{(\xi S + i) \sinh kh \cosh kd + \xi \cosh kh \sinh kd}{(\xi S + i) \cosh kh \cosh kd + \xi \sinh kh \sinh kd} \quad (18)$$

Equation (18) is correct to the 2nd order and is expressed here in a dimensional form. When the angular frequency  $\sigma$ , the water depth on permeable layer  $h$  and the thickness of permeable layer  $d$  are given, we can find the wave number on permeable layer from Eq.(18). If the wave number is a complex with a positive imaginary part, i.e.  $k = \alpha + i\beta$  and  $\beta > 0$ , the value of  $\beta$  becomes an attenuation factor of the wave on the permeable layer and we can express the surface profile of the wave as follows:

$$\eta = a_0 \exp(-\beta x) \exp\{i(\alpha x - \sigma t)\} \quad (19)$$

Figure 2 illustrates the dependency of the attenuation factor  $\beta$  on the non-dimensional permeability  $\xi$  and the value of  $d/h$ . These results are calculated by applying Lorentz's law of equivalent work to Eq.(1). The values of the coefficients in E(1) are shown in the figures.

We can see from Fig.2(a) that the attenuation factor becomes the maximum when the value of  $\xi$  is in the range of 0.2 and 0.4. This means that the optimum permeability exists to attenuate incident waves on the permeable layer. Figure 2(b) shows that the attenuation factor increases with the increase of the relative thickness of the permeable layer  $d/h$ . However, the rate of increase of the attenuation factor is small when  $d/h > 1$ . It is also found that the turbulent drag coefficient  $C_f$  also gives influence on the attenuation factor.

From these results, we can judge that the values of the coefficients in Eq.(1) (or Eq.(2)) play very important roles in the attenuation of wave on the permeable layer.

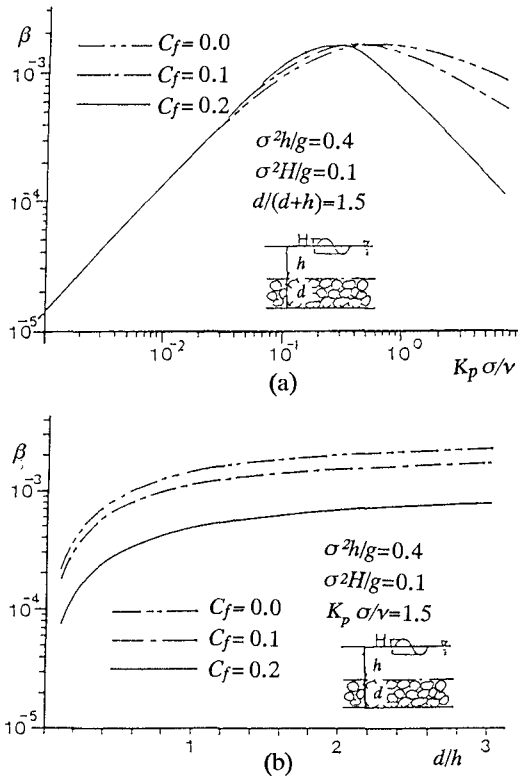

Fig.2 Dependency of attenuation factor  $\beta$  on nondimensional permeability  $\xi$  (Fig(a)) and  $d/h$  (Fig.(b)).

**Unsteady permeability test**

The author et al.(1988) have already carried out the unsteady permeability tests of rubble stones of mean grain diameter  $D=3.18cm$  and  $1.35cm$  under various flow conditions of velocity amplitude  $\hat{q}$  and period  $T$ . We found from the results that the value of  $f$  increases with the increase of K-C number ( $KC=\hat{q}/(\sigma D)$ ) and proportional to  $-1/2$  power of Reynolds' number ( $R_d=\hat{q}D/\nu$ ) when K-C number is small. It is also found that the permeability  $k_p$  in unsteady flow is almost the same as that in steady flow. However, a turbulent flow drag coefficient consists is even more small a value in unsteady flow. The added mass coefficient becomes 0 to 1.8.

However, a wave height attenuation on the permeable layer depends deeply on these coefficients. Therefore, we conducted another series of steady and unsteady permeability tests under a more extensive conditions by using rubble stones ( $D=4.50cm, 3.07cm,$  and  $1.80cm$ ). We measured a permeability  $K_p$ , added mass coefficient  $C_m$ , turbulent drag coefficient  $C_f$  and equivalent linear drag coefficient  $f$ . We also examined their dependencies on the values of  $KC, R_d$  and so on.

The equivalent linear drag coefficient is determined from the following equation by using measured pressure gradient  $\nabla p(t)$  and sectional averaged velocity  $q(t)$  in the unsteady permeability tests:

$$f = \frac{\rho \int_t \left( -S \frac{\partial q}{\partial t} - \frac{\nabla p}{\rho} \right) q dt}{\rho \sigma \int_t q^2 dt} \quad (20)$$

An experiment was carried out by using a U-tube wave tunnel that has a straight part of 3m (0.2m wide and 0.3m high). We filled up rubbles in the middle of the straight part for 1.2m length. The amplitude of depth-averaged velocity  $\hat{q}$  and the period  $T$  of generated oscillatory flow were  $2\text{cm/s} < q < 10\text{cm/s}$  and  $5\text{s} < T < 12\text{s}$ . The corresponding ranges of  $KC$  and  $R_d$  were  $0.4 < KC < 10$  and  $360 < R_d < 4500$ .

The results are summarized as follows:

- 1) The permeability in Eq.(1) obtained from unsteady test is not always coincides with that obtained from the steady test in the region where the value of is large ( $KC > 4$ ). The former is usually larger than the latter by 20 to 50%.
- 2) The turbulent drag coefficient becomes 0 to 0.2 in the unsteady flow. This value is smaller than that in the steady flow.
- 3) The added mass coefficient becomes the maximum (1.8) when the relative acceleration defined by  $\hat{q}\sigma/g$  is about 0.01. In the region where  $\hat{q}\sigma/g$  is nearly 0 and greater than 0.04, the added mass coefficient can be regarded to be almost 0.
- 4) An equivalent linear drag coefficient does not rely on the value of  $R_d$  when the value of  $KC$  is larger than 2. The result is shown in Fig.3. It can be expressed by a unique function of  $KC$ . We can find the following empirical relation between  $f$  and  $KC$  from Fig.3.

$$f = 0.1 + 1.8 \{ \hat{q} / (\sigma D) \} \quad (21)$$

Fig.3 Relation between equivalent linear drag coefficient and K-C number

As I mentioned before, if we intend to evaluate fluid motion in the permeable layer more precisely, we should use Eq.(1) by applying the Lorentz's law of equivalent work. However, this procedure requires large CPU time until we find the

equivalent linear permeability coefficient. Also, we cannot formulate the permeability and the turbulent drag coefficient in the unsteady flow. Therefore, we use Eq.(2) together with Eq.(21) to construct boundary layer equation on and inside the permeable layer.

**Boundary shear stress on the surface of permeable layer**

(1) Boundary layer equation on and inside the permeable layer

The former analysis of the wave deformation on a permeable layer is based on a potential wave theory. Accordingly, the continuities of the pressure and vertical discharged velocity are satisfied by the imposed boundary conditions. However, the continuity of horizontal velocity is not satisfied. On the surface of the rubble on the permeable layer, a so-called non-slip condition has to be applied. A Hell-Shaw approximation is usually applied in the analysis of the steady flow on the permeable layer. However, there is no guarantee that the same approximation can apply to the unsteady fluid motion on the permeable layer.

Here, we suppose the existence of the boundary layer on and inside the permeable layer where the macroscopic horizontal velocity and the vertical gradient of horizontal velocity continue smoothly. We construct the boundary layer equations by applying Couette flow approximation in the boundary layer. Based on the analyzed results, we evaluate the boundary shear on the surface of the permeable layer and examine their effect on the wave attenuation on the permeable layer.

Figure 4 illustrates the coordinate system where,  $u_p$  and  $u_{dp}$  are the potential velocities on and in the permeable layer,  $u$  and  $u_d$  are the horizontal velocities inside the boundary layer.

Fig.4 Coordinate system

We also assume that the thicknesses of the boundary layers on and in the permeable layer are  $\delta_w$  and  $\delta_{dw}$ , respectively and that the zero adjusting height is  $z_0$ . We need not adjust velocity distribution on the surface of the permeable layer. However, we use the expression of  $z_0$  considering the contrast of a rough turbulent boundary layer on an impermeable layer.

Then the boundary layer equations on and inside the permeable layer are expressed as follows:

The upper boundary layer,  $z_0 < z < \delta_w$ :

$$\frac{\partial U}{\partial t} = K_z \frac{\partial^2 U}{\partial z^2} \tag{22}$$

The lower boundary layer,  $-\delta_{dw} < z < z_0$ :

$$S \frac{\partial U_d}{\partial t} = -f \sigma U_d + K_{dz} \frac{\partial^2 U_d}{\partial z^2} \tag{23}$$

$$U = u - u_p, U_d = u_d - u_{dp} \tag{24}$$

where,  $K_z$  and  $K_{dz}$  are the eddy viscosity on and inside the layer.

Boundary conditions for these boundary layer equations are given by the following equations:

$$U = 0 \text{ or } u = u_p \text{ at } z = \delta_w \tag{25}$$

$$U_d = 0 \text{ or } u_d = u_{dp} \text{ at } z = \delta_{dw} \tag{26}$$

$$\partial U / \partial z = \partial U_d / \partial z \text{ or } \partial u / \partial z = \partial u_d / \partial z \text{ at } z = z_0 \tag{27}$$

$$U - U_d = u_{dp} - u_p \text{ or } u = u_d \text{ at } z = z_0 \tag{28}$$

We borrow the following expression for the kinematic eddy viscosity in Eq.(22) from the rough turbulent boundary layer theory:

$$K_z = \kappa u^* z \text{ in } z_0 < z < \delta_w \tag{29}$$

where  $u^*$  is the shear velocity on the permeable layer and  $\kappa$  is Karman's constant.

On the other hand, we express the kinematic eddy viscosity in the lower boundary layer assuming that the mixing length in the permeable layer is regulated by the scale of the void (Yamada et al.,1982):

$$K_{dz} = \gamma Du^* \text{ in } -\delta_{dw} < z \leq z_0 \tag{30}$$

where,  $\gamma$  is an empirical constant.

Through the continuity of the kinematic eddy viscosity, the order of  $\gamma$  is estimated to be as follows from Eqs.(29) and (30):

$$\gamma = \kappa z_0 / D \sim 0.4/30 \approx 0.0133 \tag{31}$$

Also, we assume that the boundary layer thicknesses of upper and lower boundary layer are expressed as follows based on the analogy of the rough turbulent boundary layer on the impermeable layer:

$$\delta_w = \delta_{dw} = \alpha \kappa u^* / \sigma \tag{32}$$

We conducted preliminary calculation as for the empirical constant  $\alpha$  and it is found that the border shearing stress becomes almost constant in the region where  $\alpha > 3$ . Therefore, we use the value  $\alpha = 4$  in the following calculation.

(2) Velocity distribution and boundary shear stress

The horizontal water particle velocities obtained as solutions to the upper and lower boundary layer equations are expressed as follows:

$z_0 < z$ :

$$u = \left[ -\beta_1 \left\{ \frac{\ker q_w + i \keiq_w}{\ber q_w + i \beiq_w} (\ber q + i \beiq) - (\ker q + i \keiq) \right\} + \beta_2 \right] \exp(-i\sigma t) \tag{33}$$

$z < z_0$ :

$$u_d = \left[ \beta_3 \exp \left\{ \frac{(a^2 + \sigma^2)^{1/4}}{b^{1/2}} \exp \left( \frac{i}{2\theta} \right) z \right\} + \beta_4 \right] \exp(-i\sigma t) \tag{34}$$

Where,

$$q_w = 2\{\delta_w \sigma / (ku \cdot)\}^{1/2}, \quad q = 2\{z \sigma / (ku \cdot)\}^{1/2}$$

$$a = f \sigma / S, \quad b = \gamma Du \cdot / S, \quad \theta = \tan^{-1}(-\sigma / a).$$

(ber, bei) and (ker, kei) are the real and the imaginary parts of the 1st and 2nd kinds of Bessel function. The integral constants  $\beta_1$ - $\beta_4$  are determined from the boundary conditions Eqs.(25) to (28).

The boundary shear stress on the surface of the permeable layer  $\tau(t)$  and the amplitude of the shear velocity  $u^*$  corresponding to the maximum shear stress  $\tau_{max}$  are evaluated by using the results.

$$\tau(t) = \rho \kappa u \cdot z_0 \frac{\partial u}{\partial z} \Big|_{z=z_0} \quad (35)$$

$$u \cdot = (\tau_{max} / \rho)^{1/2} \quad (36).$$

We can decide the water particle velocity in the boundary layers and the shear stress on the permeable layer by carrying out the same iterative calculation as in the boundary layer theory on the impermeable bed using these relations.

Figure 5 shows an example of the calculated phase variation of vertical distribution of horizontal water particle velocity in the case of J-6 that will be mentioned latter. The calculation conditions are shown in the figure.

Fig.5 Example of the calculated velocity distribution

Figure 6 illustrates the effects of nonlinearity on incident waves and permeability of the layer on the boundary shear stress. The horizontal axis  $gHT^2/h^2$  of Fig.6(a) is the nondimensional parameter proposed by Shuto(1976) to show the nonlinearity of the waves of height  $H$  and period  $T$  at the depth of  $h$ . The horizontal axis of Fig.6(b) is the nondimensional permeability  $K_{pe} \sigma / \nu = 1/f$ . A calculation condition is shown in figures.

From Fig.6(a) it is found that the boundary shear stress increases in proportion to the increase of  $gHT^2/h^2$ . However, it decreases with the increase in  $1/f$  (or  $K_{pe} \sigma / \nu$ ) and becomes constant in the region of  $1/f = K_{pe} \sigma / \nu > 3$ . This region of  $1/f$  corresponds to the region where the influence of the permeability on wave attenuation decreases rapidly (see Fig.2(a)).

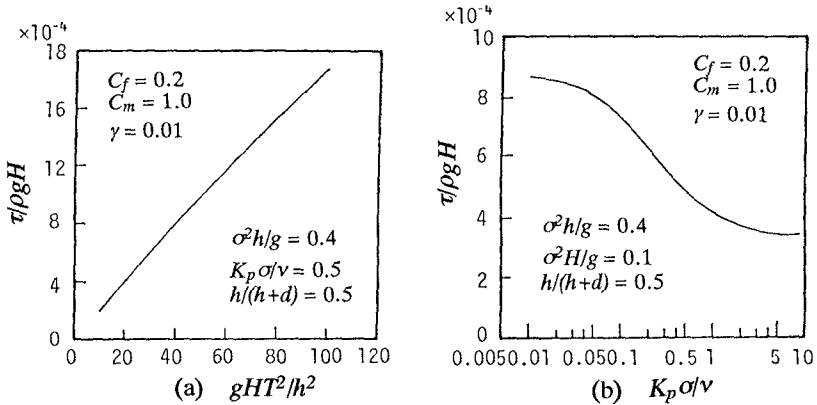

Fig.6 Effect of nonlinear property of incident wave (a) and permeability (b) on boundary shear stress

Furthermore, we examined the influence of the turbulent drag coefficient and the added mass coefficient on the boundary shear stress. As a result, the non-dimensional shear stress increases with the increases of the turbulent drag coefficient and the added mass coefficient. As for the rate of increase one of the former is big. Accordingly, that border shearing force is relying strongly on a turbulent flow drag coefficient more an addition mass coefficient was understood.

### Effect of boundary shear stress and nonlinearity of incident waves on wave attenuation on permeable layer

#### (1) Experiment on wave attenuation and velocity distribution on permeable layer

We carried out experiments concerning attenuation of waves propagating on the permeable layer to investigate the effects of the boundary shear and nonlinear effect of incident waves on wave transformation on the permeable layer. The experiments were carried out on the permeable layer in the two-dimensional wave tank of 30m long, 0.7m wide and 0.9m high. The permeable layer was made on the horizontal bottom in the wave tank and the length was 3.5m and the thickness was 15cm. The water depth on the permeable layer was 15cm. Two kinds of rubble stone whose mean diameter were 3.07cm and 1.80cm were used to construct the permeable layer. Experimental conditions are summarized in Table-1.

In the experiment, We measured the water height attenuation through the permeable layer and particle velocity at the center of the permeable layer. Wave height was measured by capacitance type wave gauges at the interval of 25cm and water particle velocity was measured by an electromagnetic current meter and a hydrogen bubble method. The measured time series of surface displacement was analyzed by FFT to investigate the frequency component of wave motions. We also measured the phase difference of the water particle velocity near the boundary at the center of the permeable layer by a tuft method in 6 cases. Vertically distributed 6 pieces of silk yarn glued on the side wall of the wave tank were used as tufts.

Table-1 Experimental conditions

Case	$d$ (cm)	$h$ (cm)	$T$ (s)	$H$ (cm)	$gHT^2/h^2$

M-5			1.00	6.33	10
M-6				3.45	5

(2) Change in wave height on permeable layer

We calculated the deformation of the waves that were propagating on the permeable layer in the positive  $x$  direction by the following method: Let the wave heights at  $x=j\Delta x$  and  $(j+1)\Delta x$  be  $H_j$  and  $H_{j+1}$ , respectively. The wave attenuation rate  $k_p$  between  $x=j\Delta x$  and  $(j+1)\Delta x$  caused by the permeability of the permeable layer is expressed as follows:

$$k_p = \exp(-\beta\Delta x) = H_{j+1}/H_j \tag{37}$$

where,  $\beta$  is the imaginary part of the complex wave number that is the solution to the dispersion relation Eq.(18).

On the other hand, the wave attenuation rate at the same distance  $\Delta x$  caused by the boundary shear stress ( $K_t$ ) is calculated from the following equation:

$$K_t = \left[ \frac{E_t \Delta x}{H_j} \left\{ \frac{1}{16} \left( 1 + \frac{2kh}{\sinh 2kh} \right) \frac{\rho g \sigma}{k} \right\} + 1 \right]^{1/2} \tag{38}$$

where,  $E_t$  is the energy dissipation that is evaluated by using the boundary shear stress on the surface of the permeable layer as follows:

$$E_t = \frac{2}{T} \int_0^{T/2} \tau u|_{z=z_0} dt \quad (39)$$

Wave height at  $x=(j+1)\Delta x$  is calculated by using  $K_p$  and  $K_t$  from the wave height at  $x=j\Delta x$  by the following relation:

$$H_{j+1} = k_p k_t H_j \quad (40)$$

Figure 7 shows two examples of comparisons of measured and calculated wave attenuation in different cases. A full line is the result calculated by considering only the influence of the permeable layer by using the equivalent linear drag coefficient ( $Kt=1$ ). A broken line is the calculated result that includes both effects of the boundary shear and the permeability.

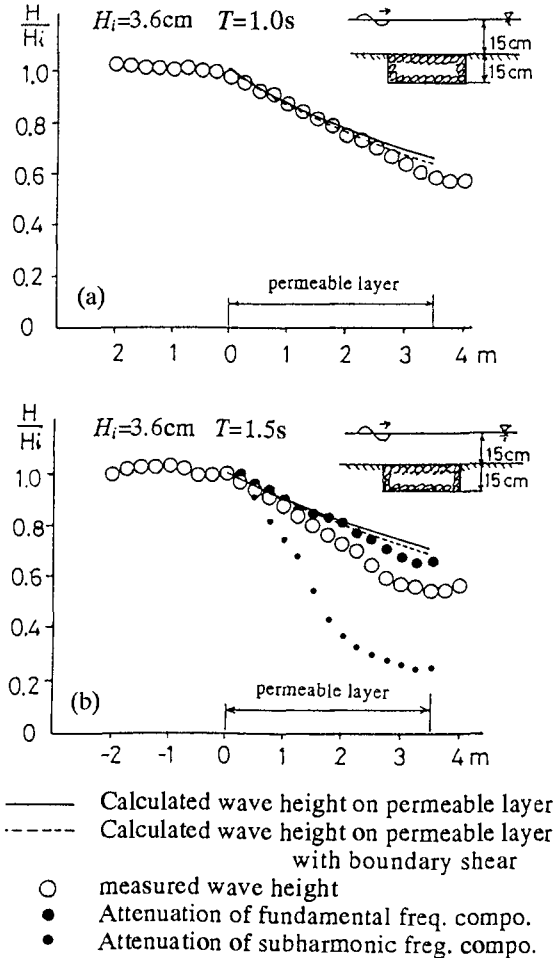

Fig. 7 Wave attenuation on a permeable layer((a):Case J-5,(b):CaseJ-2)

Figures 7(a) and (b) are the results of Case J-6( $T=1.0s$ ) and Case J-2 ( $T=1.5s$ ). Experimental conditions are shown in each figure. We used the value of the added mass coefficient in Eq.(22) obtained from the unsteady permeability tests.

First, the influence of the boundary shear on the wave attenuation, that is shown by the difference of the solid and broken lines in the both figures, is very small and can be negligible as compared with the effect of the permeability.

From Fig.7(a), it is found that measured wave height on the permeable layer (shown by the open circles) coincides fairly well with the calculated wave height when the wave period of incident waves is somewhat short. When the period is relatively long, the results of which is shown in Fig.7(b), the decrease of measured wave height on the permeable layer is larger than that of calculated one.

We investigated this reason by examining fundamental frequency and subharmonic frequency components obtained from a Fourier analysis of the measured surface displacement around the permeable layer. The energy of the subharmonic component at the offshore side of the permeable layer was less than 5% of that of the fundamental frequency component in Case J-6. On the other hand, the energy of the subharmonic component in Case J-2 was more than 30% of that of the fundamental frequency band at the offshore of the permeable layer.

In Fig.7(b), the decrease of the amplitudes of fundamental frequency and subharmonic frequency components obtained from the Fourier analysis are shown by large and small closed circles. The decrease of the amplitude of fundamental frequency component on the permeable layer agrees well with the calculated wave attenuation based on the linear wave theory. However, the decrease of the subharmonic component is larger than the predicted wave attenuation. Therefore, the difference of the measured and calculated wave heights of case shown in Figure 6 comes from the fact that a large subharmonic component was included in the incident waves.

We have already reported that the decrease of the subharmonic component in a bound wave like Storks 2nd order wave is twice as first as the decrease of the fundamental frequency component (Deguchi, et al.,1988). However, the incident waves in the case of J-2 included a larger subharmonic component that cannot be explained by the Stokes wave theory. Also, the analysis method of the wave deformation on the permeable layer based on a non-linear wave theory has been proposed (Isobe, et al.,1991). Here, we examine applicability of the linear wave theory to the wave transformation on the permeable layer.

Figure 8 illustrates errors of the calculated wave heights in the 24 cases shown in Table 1.

Fig. 8 Estimated error of wave attenuation on permeable layer

The horizontal axis is the parameter  $gHT^2/h^2$  concerning the nonlinearity of incident waves (Shuto, 1973). The error was defined by using the difference of measured and calculated wave attenuation rate,  $K_m$  and  $K_c$ , at the onshore end of the permeable layer as follows:

$$\delta = |K_m - K_c|/K_c * 100 \quad (26)$$

It can be seen from Fig.8 that the error becomes more than 10% when the value of  $gHT^2/h^2$  is larger than 30, i.e., the nonlinear property of incident waves is large. When the value of  $gHT^2/h^2$  is less than 10, the error remains within 5%.

## **Conclusion**

The main results obtained in this study are summarized as follows:

- 1) The turbulent drag coefficient and the permeability in the Forchheimer type equation in the unsteady flow are different from those in the steady flow. In the unsteady flow, they depend on K-C number, and the relative acceleration. We proposed the empirical relation between the equivalent linear drag coefficient and K-C number through the unsteady permeability tests.
- 2) The wave attenuation on the permeable layer is caused mainly by the energy loss in the permeable layer. The effect of the boundary shear on the surface of the permeable layer on the wave attenuation is negligibly small when the thickness of the layer is relatively large.
- 3) The linear wave theory can apply to the analysis of wave decay on the permeable layer when the value of  $gHT^2/h^2$  is smaller than 10. When the value of  $gHT^2/h^2$  is greater than 30, the non-linear property of the incident waves becomes significant. In such case, the wave attenuation on the permeable layer is larger than that predicted by the linear wave theory. We can explain this reason by the fact that the amplitude of subharmonic component included in the incident waves is faster than that of the fundamental frequency component.

## CHAPTER 118

### IMPACT LOADS INDUCED BY PLUNGING BREAKERS ON VERTICAL STRUCTURES

Schmidt, R.<sup>1)</sup> ; Oumeraci, H.<sup>2)</sup> ; Partenscky, H.-W.<sup>3)</sup>

#### Abstract

Results of large-scale model tests on impact loading of a vertical wall by using waves up to 2 m height and 9.4 s period are presented. A classification of the breaker types tested and breaking criteria for waves in front of a vertical wall are suggested. Impact pressure distributions, forces and force impulses induced by plunging breakers on a vertical wall are discussed. The statistical distributions of the impact pressures and forces for different breaker types are also given. Some aspects of the generation mechanisms of impact pressures and the role of air content and its statistical distribution in the impact process are outlined.

#### Introduction

It has often been suggested in the literature that impact pressure induced by breaking waves has no structural significance, and hence should not be used for design purposes. One of the main reasons for this view point may certainly be explained by the static approach yet used to study the stability of vertical structures. The results of a study on vertical breakwater failures (OUMERACI et.al., 1991) together with the results of more recent investigations on the effect of impact loads on a vertical breakwater (OUMERACI et.al., 1992; TAKAHASHI et.al., 1992) have shown that impact pressure has not only a very localized effect, but may also be detrimental for the stability of the structure components as well as for the overall stability of the structure, including the foundation; i.e. the stability

3) Prof. Dr.-Ing. Dr.-Phys., Formerly Managing Director Franzius-Institut

of monolithic structures subject to breaking waves is of purely dynamic nature and cannot be simply reduced to a static problem.

For the dynamic stability analysis, detailed spatial and temporal pressure distributions with the corresponding force histories are required. However, reliable laboratory measurements in the impact area generally represent a very difficult task due to the highly transient and complex nature of the two-phase flow and pressure field involved, as well as to the scale effects related to air entrainment/entrapment. Therefore, a detailed large-scale model study on impact pressures due to breaking waves on a vertical wall has recently been performed in the Large Wave Flume (GWK) of Hannover. It is the main purpose of the paper to discuss some of the results of this study.

**Experimental Set-Up and Test Conditions**

The hydraulic model tests were performed in the Large Wave Flume of Hannover (320x5x7 m) by using regular and irregular waves up to 2 m height and 9.4 s period. The experimental set-up is given in Fig. 1, showing a) a sloping seabed 1:20 terminated by a vertical stiff wall of 6 m height instrumented with 28 high resolution pressure transducers ( $f_N > 35$  kHz), and b) the locations of eleven wave gauges installed in front of the wall.

Fig. 1. Experimental Set-Up in the Large Wave Flume (GWK)

Water depths in the flume up to 3.0 m (1.6 m at the wall) were used for the tests. Most of the waves used in the tests arrive at the wall as plunging breakers, the maximum breaker heights obtained are in the range of  $H_b = 1.15 \cdot d_b$ , where  $d_b$  is the breaking depth measured from SWL.

**Breaker Types and Kinematics**

*Breaker Types*

A strong correlation exists between the shapes of the breaking waves at the vertical wall and the trapped air. On the other hand, the latter is known to considerably affect the magnitude as well as the spatial and temporal distribution of the impact pressure. Therefore, an attempt was first made to classify the breaker types obtained for the conditions tested, before any further analysis of the results was undertaken. In fact, different breaking wave conditions in comparison to those on an unobstructed beach are expected (GALVIN, 1968). For this purpose, video records as well as wave profiles obtained from wave gauge measurements were used. Depending on the value of  $H_b/d_w$  and on further parameters, seven types of breaking and broken waves – five for the plunging and two for the spilling breaker – in front of the vertical wall were obtained (Fig. 2). The water depth  $d_w$  directly at the vertical wall corresponds to the breaking depth  $d_b$  measured from SWL by the linear relationship  $d_w = 0.80 \cdot d_b$  (average from 705 breaking waves and correlation coeff. of 0.84).

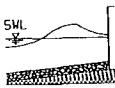

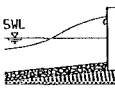

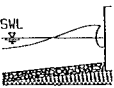

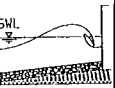

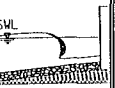

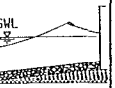

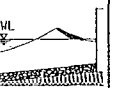

Plunging breaker					Spilling breaker	
upward deflected	well developed		broken		well developed	broken
$\frac{H_b}{d_w} = 0,92$	$\frac{H_b}{d_w} = 0,99$	$\frac{H_b}{d_w} = 1,06$	$\frac{H_b}{d_w} = 1,14$		$\frac{H_b}{d_w} = 0,99$	$\frac{H_b}{d_w} = 1,14$
						
Type 1	Type 2	Type 3	Type 4	Type 5	Type 6	Type 7

Fig. 2. Breaker Types Observed during Tests in GWK

In the following, however, special emphasis was put on the analysis of the results related to plunging breakers.

*Breaking Criteria*

Existing formulae for the prediction of the maximum breaker height  $H_b$  (or of the breaking depth  $d_b$ ) as a function of the wave period  $T$  and the beach slope  $m$  (see for instance Eq. (2.92) in C.E.R.C., 1984) are related to waves on an unobstructed beach slope. Due to a full obstruction by a vertical wall in the flume, waves with  $H_o/L_o = 0.0075 - 0.013$  were found to break in a depth  $d_b$  which is about 30 % higher than those predicted by the C.E.R.C. - formula. This is shown for instance by Fig. 3 in which the results of WEGGEL (1968) have also been plotted for comparison.

Fig. 3. Maximum Breaker Heights in Front of a Vertical Wall

It is seen that in the presence of a vertical wall, a maximum breaker height  $H_b$  may occur which is almost 20 % larger than the breaking depth  $d_b$ . The corresponding deep water wave steepness is about 0.009.

*Velocity and Volume of Wave at Breaking*

The wave profiles in front of the vertical wall recorded by the wave gauges and video are shown for different time steps in Fig. 4. The

Fig. 4. Wave Profiles in Front of a Vertical Wall at Different Time Steps

velocities and the volume of the wave at the instant of breaking are determined from such wave profile developments like those in Fig. 4 and compared to those predicted by different wave theories (linear wave theory, modified linear wave theory by GODA (1964) and solitary wave theory). It was found that for both the velocities  $u_s$  and the volume of the wave  $V_s$  at breaking, the solitary wave theory provides the best approximation:

$$u_s = \sqrt{g \cdot (d_b + H_b)} \quad (1) \qquad V_s = \sqrt{\frac{16}{3} \cdot H_b \cdot d_b^3} \quad (2)$$

where  $d_b$  is the breaking depth measured from SWL and  $H_b$  the breaker height, respectively. This is an important result as the momentum transferred by a breaking wave to the wall may be approximately evaluated directly by using Eqs. (1) and (2). A comparison of such an approximation with the related force impulse obtained from pressure measurements will be shown later in Fig. 10.

## **Impact Loads**

### *Influence of Sampling Frequency on measured Impact Loads*

The first step when measured highly dynamic processes generally consists in evaluating the proper sampling rate. Therefore, the effect of the sampling frequency  $\Delta f$  on the peak pressures, peak forces and impulses has been investigated for  $\Delta f = 0.1 - 11$  kHz. The results obtained show particularly that:

- a) For the pressure peaks, sampling rates of  $\Delta f = 2, 1$  and  $0.175$  kHz result in a reduction of 2, 7 and 50 %, respectively;
- b) For the force peaks, sampling rates of  $\Delta f = 2, 1, 0.175$  and  $0.1$  kHz result in a reduction of 2, 3, 20 and 37 %, respectively;
- c) For the force impulses, no significant changes results even if the sampling rate is reduced to  $0.1$  kHz.

### *Impact Pressures and Forces*

For each of the breaker types in Fig. 2, the following results can be obtained:

- a) Simultaneous pressure histories at the 28 wall elevations by using a sampling frequency of  $11$  kHz;
- b) Pressure distributions along the wall for time steps  $\Delta t = 0.09 - 10$  ms.

For instance, some pressure distributions are given in Fig. 5 (breaker height  $H_b = 1.57$  m and wave period  $T = 6.75$  s) at eleven different time steps. The horizontal force  $F_h$  per linear meter obtained from pressure integration is also given. Fig. 5 also illustrates that impact pressures are not only limited to small local areas but may also occur simultaneously over a large height (in a range up to the wave height!) of the vertical wall.

Particularly in the case of well-developed plunging breakers with large entrapped air pocket, the spatial integration of the impact pressures generally leads to a total force with a duration which may be much larger than usually assumed. In fact, the duration of total impact forces may reach 5 to 10 times that of the corresponding impact pressures. Since the latter is generally in the range of 0.05 – 0.02 s (in the model), the duration of the total impact force may reach values in the range of 0.05 – 0.2 s corresponding to values of 0.15 – 0.6 s in prototype; i.e. values which may be in the same range or higher as the natural period of oscillations of common prototype caisson breakwaters:  $T_N = 0.2 - 0.4$  s (MURAKI, 1966).

Fig. 5. Pressure Distributions at Different Time Steps ( $H_b=1.57$  m ;  $T=6.75$  s)

The origin of negative pressure (see Fig. 5, steps 6–10) can also be explained by the fact that the trapped air is compressed so much that in re-expanding it throws the water mass back with such a velocity that the pressure drops below the atmospheric pressure value. The pressure distributions in Fig. 5 clearly characterize the impact of a plunging breaker with a large air pocket entrapped between the breaker front and the wall.

Fig. 6. Horizontal Force History Resulting from Pressure Integration

Typically, two force peaks (time step 1+4) occur which are also seen in the related force history shown in Fig. 6. A further important characteristic of this type of impact (well-developed plunging breaker with entrapped large air pocket) is the presence of the relative low frequency oscillations after the force peak (see Fig. 6). The latter are caused by the cyclic compressions and expansions of the entrapped air pocket under the highly transient pressure fields, and are hence related to the size of the entrapped air pocket. The equivalent diameter  $D_o$  of the air pocket at its initial stage can be determined from the period  $T_{osc}$  of the force oscillations by the following relationship (OUMERACI et.al., 1992):  $D_o = k_a \cdot T_{osc}$  where  $k_a = 5.35$  m/s. This means that the force oscillations with  $T_{osc} = 0.075$  s in Fig. 6 corresponds to a trapped air pocket of  $D_o = 0.40$  m in the large-scale model. The period of the force oscillations transferred to prototype conditions may also lie in the range of the natural period of prototype caisson breakwaters:  $T_N = 0.2 - 0.4$  s (MURAKI, 1966). These force oscillations may lead to near resonance excitation.

Fig. 7. Characteristics of Impact Forces and their Origin

The typical features of a force history caused by the impact of a breaker plunging on a vertical wall and entrapping a large air pocket are schematically summarized in Fig. 7 which also illustrates the origin of each of these characteristics.

Fig. 8. Duration of Impact Force

#### *Duration of Impact Forces*

Since the duration of the total impact force  $t_{dyn}$  constitutes an important characteristic of the dynamic loading, a relationship between  $t_{dyn}$  (related to wave period  $T$ ) and the dimensionless maximum peak force  $F_{max}$  (related to the squared breaker height  $H_b$ ) has been determined in Fig. 8, showing that  $t_{dyn}$  is almost inversely proportional to  $F_{max}^2$ . The extreme values of  $F_{max}$  generally occur for a deep water wave steepness  $H_o/L_o \approx 0.005$ . For lower or larger values of  $H_o/L_o$ ,  $F_{max}$  decreases abruptly. For the force impulse, however, the extreme values occurs for  $H_o/L_o \approx 0.0075$ .

#### *Force Impulses*

The "dynamic" and "quasi-static" components  $I_{dyn}$  and  $I_{stat}$  of the force impulse have been determined separately. These are defined in Fig. 9 where the point  $M$  of maximum wave run-up is also shown. By assuming the conservation of momentum, the force impulse  $I_w = I_{dyn} + I_{stat}$  should be equal to the momentum of the wave with a mass  $m_w = \rho \cdot V_s$  impinging on a wall with a horizontal velocity  $u_s$ . The momentum of the wave was also

Fig. 9. Force-Impulse Definition Sketch

calculated by using Eqs. (1) and (2) and compared to the force impulse  $I_w$  in Fig. 10. It is seen that despite the large scatter, the solitary wave theory still represents a good mean for the approximate evaluation of the loading of vertical structures induced by breaking waves. In average, the wave momentum was slightly larger (7%) than the force impulse  $I_w$  ( correlation coeff. = 0.83 ).

Fig. 10. Force Impulse vs. Wave Momentum

*Statistical Analysis of Impact Pressures and Forces*

A statistical analysis of the impact pressures and forces recorded for the different loading cases defined in Fig. 2 has been performed for almost 1000 breaking wave impacts. Although this analysis still proceeds, some of the first results may already be discussed below.

a) Impact Pressures: Relative Frequency of Occurrence (36 Classes)

b) Impact Forces: Relative Frequency of Occurrence (30 Classes)

Fig. 11. Statistical Distribution of Impact Pressures and Forces for the Different Loading Cases of the Plunging Breaker (see Fig. 2)

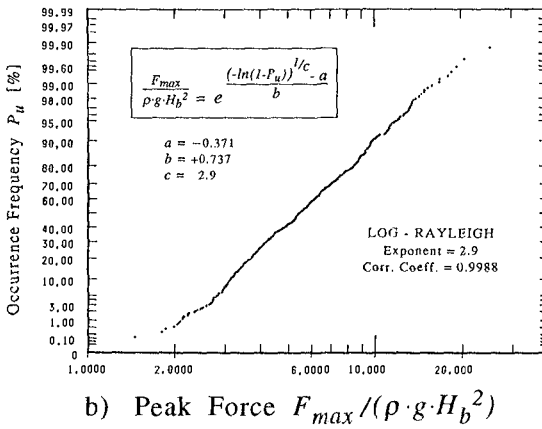

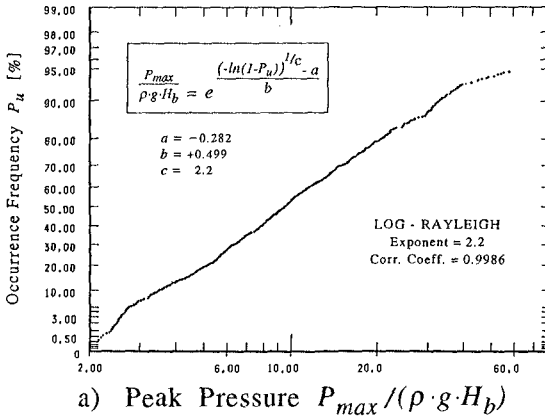

Fig. 12. Statistical Distribution of Impact Loads (n=717 Breaking Waves)

In Fig. 11 the frequency of occurrence of the dimensionless peak pressures and forces is plotted for the different loading cases of the plunging breaker shown in Fig. 2. It is clearly seen that the highest impact pressures occur for loading case 3. On the other hand, the differences between the loading cases are more pronounced for the distribution of impact pressures (Fig. 11a) than for that of the impact forces (Fig. 11b). Further results have also shown that the maximum impact pressures, forces and overturning moments are best described by a LOG-RAYLEIGH distribution whereas the corresponding impulses follow a LOG-GUMBEL distribution (Fig. 12).

### Air Content

The air content of the air-water mixture and the air dynamics involved

Fig. 13. Statistical Distribution of Sound Velocities in Air-Water Mixture during Impact

ward the wall) of a perturbation in the impact pressure traces and distributions (Fig. 5). The identification of the same perturbation at different pressure cells and the phase shifts have been determined from the detailed pressure histories (sampled at 11 kHz) of the pressure gauges under still water level by using FFT-techniques (SCHMIDT, 1993).

The results obtained by using this procedure for 201 breaking waves impacting directly on the wall are given in Fig. 13 showing the statistical distribution of the investigated sound velocity  $c_w$ , i.e.  $c_w$  values between 100 m/s and 450 m/s with an average value of  $\bar{c}_w = 212$  m/s occur,

in the impact process represent a further important factor in the generation mechanisms of impact pressures. However, the entrained air could not be directly measured in the model tests. Nevertheless, an attempt is made to use the detailed impact pressures measured at 28 different elevations along the wall for the approximate statistical evaluation of the air content involved in the impact process. This has been done through the sound velocity  $c_w$  in the air-water mixture which is evaluated by following the propagation (down-

corresponding to air contents  $\alpha = 0.04 - 1.0 \%$  ( $\bar{\alpha} = 0.2 \%$ ). These velocities actually correspond to speeds at which a perturbation propagates downwards within the air-water mixture. Detailed shock pressure measurements performed by HATTORI and ARAMI (1992) have also shown that this propagation essentially develops within the air-water mixture.

### **Concluding Remarks**

Despite more than 80 years of research work on impact loading of vertical structures subject to breaking waves there are still two basic attitudes related to the design of such structures.

The first attitude consists in simply assuming that impact pressures are not important and thus should not be adopted in the design. The inadequacy of this approach has been demonstrated by the results of the more recent investigations (OUMERACI et.al., 1992; TAKAHASHI et.al., 1992).

The second attitude is to skip the problem of evaluating the design impact load by assuming that the structure can be designed in such a way that impact pressure will not occur. The existing standard design pressure formulae implicitly reflect this attitude. However, it is not advisable to design vertical breakwaters only by applying such formulae, since most of vertical structures will certainly be subject to all conditions of breaking waves during their lifetime.

In fact, the worst loading case for a vertical structure and its foundation is induced by a well-developped plunging breaker. In this respect, the results to be presented in this paper intend to help in assessing the worst impact loads to be considered in a dynamic analysis of the structure and its foundation.

## CHAPTER 119

### PROFILE CHANGES OF ROCK SLOPES BY IRREGULAR WAVES

W. Gray Smith<sup>1</sup>, Nobuhisa Kobayashi<sup>2</sup>, Shuji Kaku<sup>3</sup>

#### Abstract

Experimental data has been obtained to test the abilities and limitations of existing and new empirical predictive methods for breakwater profile changes under random waves. The thirty data points obtained within this study describe a structure that is neither solely statically nor dynamically stable, and have indicated the difficulties of empirical formulas in accounting for the complex wave and structural interactions affecting breakwater profile development. Data analyses have indicated that current empirical formulas are not able to predict the profile changes very accurately for the data obtained herein. However, qualitative understanding can be obtained based upon the application and adjustment of the formulas to the structure tested herein.

#### Introduction

Design of conventional and berm breakwaters requires the prediction of structural profile changes caused by irregular waves. These changes can be defined by the damage suffered by a statically stable structure or through the description of the structural profile evolution experienced by a dynamically stable structure. This paper examines experimental profile changes for structures overlapping the dynamic/static stability boundary, and evaluates the predictive capabilities of existing and new empirical formulas tested in comparison to profile change data obtained through specific model tests. The new data set is used to clarify the abilities and limitations of the current design methods, and possibly lend insight into the development of an improved method of design for the structures of interest. An attempt is also made to elucidate similarities and differences existing between rock slopes and sand beaches since different formulas

proposed for different sizes of cohesionless materials should be synthesized and generalized.

### New Static Stability Formula

van der Meer (1987) conducted extensive irregular wave tests and proposed an empirical formula for the static stability of uniform rock slopes, for which only minor profile changes are allowed under design wave conditions. This formula yields a prediction of the damage suffered by a structure under a given wave climate, where damage is qualitatively described as the displacement of armor stones. This damage level,  $S$ , is defined as the cross-sectional eroded area,  $A$ , normalized by the square of the nominal armor unit diameter based on a median stone mass,  $D_{n50}$ , as  $S=A/D_{n50}^2$ . van der Meer's formula can be arranged to express the structural damage level,  $S$ , as a function of  $\cot \alpha = \cotangent$  of the structural slope angle  $\alpha$ ,  $N = \text{number of individual waves}$ ,  $P = \text{empirical permeability coefficient}$ ,  $\xi_m = \text{surf similarity parameter based on the significant wave height, } H_s$ , and the mean wave period,  $T_m$ , and  $N_s = \text{stability number defined as } N_s = H_s/[(s-1)D_{n50}]$  where  $s = \text{specific density of the armor unit}$ . This stability number may be used to classify structures as either statically or dynamically stable, where  $N_s = 1 - 4$  was the range van der Meer prescribed for his static stability formula. It is noted that this classification system contains a transition from static to dynamic stability, where dynamic stability was defined with  $N_s \geq 3$ . It is evident, therefore, that for certain structural types such as berm breakwaters it can be difficult to select design methods, specifically whether to design the structure as dynamically or statically stable. This formula for static stability assumes that  $S$  is proportional to  $N^{0.5}$  and  $S > 0$  as long as  $N_s > 0$ . This implies that the damage level does not approach an equilibrium value,  $S_e$ , with the increase of the duration,  $NT_m$ , of the wave action. This is in disagreement with the evolution of the berm breakwater which is initially dynamic, but may eventually reach a stage of static stability similar to sand beaches approaching equilibrium for given wave conditions. Moreover, the formula does not account for the threshold condition of initiation of armor movement.

Kaku *et al.* (1991) found that van der Meer's static stability formula provided reasonable estimates of the stability number for specified damage levels, but failed to yield predicted damage levels with an adequate level of confidence. Therefore, using the data sets of van der Meer (1988), and Ryu and Sawaragi (1986), Kaku *et al.* (1991) proposed a new empirical formula to estimate the damage level of a statically stable structure under design conditions. This data set included 665 data points with the stability number,  $N_s$ , ranging between 0.9 - 3.9. By assuming that the damage level approaches an equilibrium value,  $S_e$ , asymptotically with time, the damage level,  $S$ , is expressed as (van der Meer, 1988)

$$S = S_e(1 - e^{-KN}) \quad (1)$$

where  $S_e = \text{equilibrium damage level}$  and  $K = \text{empirical parameter related to the number of waves required to establish an approximately equilibrium slope profile}$ . For example,  $S = 0.95S_e$  at  $N = 3/K$ . A similar equation was employed by Kriebel and Dean (1985) to express time-dependent beach and dune erosion.

The data sets used in the development of the formula suggest that  $K$  be given by

$$K \approx \frac{a_1}{S_e^{b_1} + c_1} \quad (2)$$

where  $a_1 = 0.01$ ,  $b_1 = 0.8$ , and  $c_1 = 7$  are empirical constants. The similarity between the stability number,  $N_s$ , and the Shields parameter used for sediment transport allowed Kaku *et al.* to include the initiation of armor movement in their formula. A critical stability number,  $N_c$ , was defined by modifying van der Meer's formula for very small damage levels, with the structure assumed to be totally stable below this critical value. This critical stability number was given as

$$N_c = C \frac{6.2P^{0.18}}{\sqrt{\xi_m}} \quad \xi_m < \xi_c \quad (3a)$$

$$N_c = C \xi_m^P \frac{\sqrt{\cot \alpha}}{P^{0.13}} \quad \xi_m > \xi_c \quad (3b)$$

with  $C = 0.4$ , the surf similarity parameter  $\xi_m$ , and the critical value  $\xi_c$ , given as

$$\xi_m = \frac{\tan \alpha}{\sqrt{\frac{2\pi H_s}{gT_m^2}}} \quad \xi_c = [6.2P^{0.31} \sqrt{\tan \alpha}]^{\frac{1}{P+0.5}} \quad (4)$$

The equilibrium damage level was then expressed as

$$S_e = a_2(N_s - N_c)^{b_2} \quad N_s > N_c \quad (5a)$$

$$S_e = 0 \quad N_s \leq N_c \quad (5b)$$

with  $a_2 = 12$  and  $b_2 = 1.3$ .

van der Meer's formula and the new stability formula are compared with the data sets used to develop these formulas in Figures 1a and 1b, where the comparison is the measured damage level against the empirical damage level. The predicted and measured damage levels can vary by a factor of two for these data sets with significant scatter evident for higher damage levels, which indicates a structure approaching a more dynamic classification. Consequently, larger errors would be expected for other data sets.

## Experiment

The experiment was organized to obtain detailed data on macro-scale armor unit

Figure 1a: Comparison with van der Meer's Formula (1987)

Figure 1b: Comparison with New Formula

movement in the laboratory by measuring altered breakwater profiles under random wave action. A concise summary of the experimental results and analyses from Smith (1991) is presented in the following. The experiment was conducted in a wave tank using a 20 cm thick layer of gravel,  $D_{n50} = 1.8$  cm and a specific density of  $s = 2.7$ , placed on top of a 1:3 glued gravel slope (Figure 2a). Evaluation of the armor unit distribution showed an essentially uniform gravel distribution, where the gradation ratio,  $D_{85}/D_{15}$ , was approximately equal to 1.25. The wave generation was conducted using a piston-type paddle driven by a hydraulic system, and made use of a TMA spectrum as explained by Kobayashi *et al.* (1990). The random signal typically repeated itself after approximately 200 waves. Six irregular wave signals were prepared by varying  $H_s$  and  $T_m$ .

Free surface displacement measurements taken at three locations seaward of the slope were separated into incident and reflected wave trains, where the setup of the

gages is shown in Figure 2a. A surface profiler, shown in Figures 2a and 2b, was constructed to measure the structural profile automatically using three vertically mounted survey probes, located relative to the structure as shown in Figure 2b. The horizontal and vertical motion of the profiler was controlled automatically and produced structural changes relative to the initial profile. It is also noted that the lateral variability of the profile response was negligible and profile change was essentially two-dimensional.

Figure 2a: Experimental Setup

Figure 2b: Plan View of Wave Gage and Surface Profiler Locations

Six tests were performed, with each test consisting of six structural profile measurements at  $N = 0$  and  $N = 200, 400, 600, 800,$  and  $1000$ , where  $N$  is the number of individual waves from the beginning of each test. Each of the six tests hence consisted of five runs with the measured incident and reflected waves as well as the slope profile relative to the initial profile for each run. The data from the thirty runs are summarized in Table 1. Figure 3 depicts a typical result obtained for the wave measurements. Figure 3 shows the incident versus reflected wave spectrum, where wave reflection from the structure was minimal. It was also observed that the incident wave

train proved reproducible and that the reflected waves during each test were observed to remain essentially the same, thus being insensitive to profile changes. The measured average reflection coefficient,  $r$ , as defined by Kobayashi *et al.* (1990), is listed for each run in Table 1.

Figure 3: Incident and Reflected Spectrum

The slope geometry of the breakwater structure was obtained for each of the thirty test runs. Figure 4 depicts a typical measured altered profile, where the initial slope is included in an effort to indicate the degree of profile change. Qualitative assessment of the data showed erosion of the profile near the still water level (SWL) at profile elevation zero, with areas of deposition located both above and below the erosional area, corresponding to the transition between accretional and erosional profiles for sandy beaches. The increase of  $S$  with the increase of  $N$  followed the assumed exponential form as given by Eq. 1 fairly well, where significant alteration of the profile occurred during the first few hundred waves with much less profile change associated with the later stages of each test run. This implies that the profile change is sensitive to the degree of profile deviation from the equilibrium profile. It is also noted that the effects of the wave period proved important as shown in Table 1. In summary, the test runs with  $N_s = 2.69 - 3.67$  and  $S = 6.3 - 38.1$  were close to the upper limit of applicability of the static stability formulas.

### Comparison with Static Stability Formulas

The static stability formula proposed herein and that of van der Meer (1987) are compared with the thirty new data points obtained from the present experiment. Before the comparison was completed the validity of the application of the formulas was ensured using the parameter ranges described by van der Meer (1988), including the stability number, wave steepness, surf similarity parameter, and initial profile slope. It was found that the values for the present experiment were within the ranges established by van der Meer (1988) for his static stability formula.

Figure 4: Typical Measured Altered Breakwater Profile

Figures 5a and 5b graphically depict the accuracy of van der Meer's formula, where different permeability coefficients are used in an effort to improve the agreement. The permeability of a structure has been shown to affect the structural response, where in general impermeable structures suffer greater erosion than do permeable structures subject to the same wave conditions. Examining the structure studied herein, a permeability coefficient  $P = 0.4 - 0.5$  seemed appropriate based on van der Meer's recommendations. However, calculations have been conducted using a range of permeability coefficients. Figure 5a indicates that the damage level is being underestimated by roughly a factor of two, using the permeability coefficient,  $P = 0.4$ , with the error increasing for the higher levels of damage. Decreasing  $P$  to a value of 0.1 caused the predicted damage level to increase as shown in Figure 5b. It can be seen from Figures 5a and 5b that the damage prediction improves for the lower permeability coefficient. However, the lower permeability coefficients are unrealistic for the structure used in the experiment. These observations seem to be in agreement with the data analyses presented by Kaku *et al.* (1991), where it was shown that the formula predicted poorly for higher damage levels. Interpretation of these results indicate that this formula might be sufficient when applied to structures with low stability numbers, but is not accurate enough for structures approaching dynamic stability.

Figures 6a and 6b depict the capability of the new formula in predicting the damage levels, using various empirical coefficients in an attempt to improve the agreement. Figure 6a represents the new formula, using the empirical coefficients as fitted to the data sets of van der Meer (1988), and Ryu and Sawaragi (1986), and displays results similar to those shown in Figure 5a. It is noted that the permeability coefficient was again adjusted for this new formula, however, it provided relatively insignificant improvement in the formula's prediction. Hence  $P = 0.4$  is assumed for the new formula. Two alternative approaches were undertaken toward the improvement of the agreement for Kaku *et al.*'s formula. First, it was observed that the equilibrium damage level, predicted by Eq. 5, was only slightly higher than most of the damage levels

Figure 5a: Comparison with van der Meer's Formula ( $P = 0.4$ )

Figure 5b: Comparison with van der Meer's Formula ( $P=0.1$ )

suffered by the structure following 1000 waves. It was not anticipated that the structure would reach equilibrium over this amount of time, therefore, the value of the equilibrium damage level was increased in an effort to obtain higher damage level estimates. This increased equilibrium damage level caused a decrease of the exponential growth factor,  $K$ , as predicted by Eq. 2. The lower value of  $K$  in Eq. 1 offset the increase of the equilibrium damage level and little improvement was obtained from this adjustment.

Figure 6a: Comparison with New Formula ( $a_1 = 0.01$  &  $b_2 = 1.3$ )

Figure 6b: Comparison with New Formula ( $a_1 = 0.08$  &  $b_2 = 1.5$ )

Secondly, it was observed that approximately half of the damage was occurring during the first 200 waves, thus indicating that this profile would possibly approach equilibrium more rapidly than anticipated. Kaku *et al.*'s formula, however, predicts a much smoother rise towards equilibrium, with the initial damage level increase much less than that observed during the experiment. Adjustment of the exponential growth

parameter  $a_1$  for  $K$  in Eq. 2 caused the damage levels to be predicted more accurately, while the increase of the equilibrium damage level by adjusting the parameter  $b_2$  in Eq. 5 also allowed for improved prediction of the higher damage levels. These two empirical parameters,  $a_1$  and  $b_2$ , were fitted to the present data set. Figure 6b depicts the improved results of the new formula, where  $a_1 = 0.08$  and  $b_2 = 1.5$  are the parameters fit to the new data set. This adjustment has improved the performance of Kaku *et al.*'s method for the data described herein. However, any conclusive results will require more data in order to properly calibrate the parameters. Nevertheless, better agreement is achieved with the adjusted formula of Kaku *et al.* in comparison with van der Meer's formula. Also, it is important to point out the adjustment of van der Meer's formula required unrealistic permeability coefficients. The framework of Kaku *et al.*'s formula may be more realistic, for it adjusts the time scale of profile development, which is not fully defined by any previous work.

In summary, the damage levels predicted by the empirical formulas of van der Meer (1987) and Kaku *et al.* (1991) failed to accurately predict the damage suffered by the structure in this experiment. However, it is expected that the formula due to Kaku *et al.* is more adjustable to various conditions. Moreover, the necessity of the adjustments of the empirical parameters suggest that these simple formulas are not sufficiently accurate partly because they do not account for detailed irregular wave and structural characteristics.

#### Comparison with Dynamic Stability Formulas

In addition to the previous static stability approach to profile evolution prediction, the range of  $N_s = 2.69 - 3.67$  associated with the new data set may allow for the evaluation of dynamic profile prediction methods. Dynamic stability allows for significant alteration of the structure from the initial profile configuration, thus requiring the prediction of the actual evolved profile shape. van der Meer and Pilarczyk (1986) studied the dependency of the evolved profile on various wave and structural parameters, and developed an empirical formula that predicts the locations of abrupt profile changes on an assumed profile shape. This formula connects these points with straight lines and curves, which are described by power functions similar to those used to express the equilibrium profile for sandy beaches. Their formula is applicable to structures with  $N_s$  between 3 and 200 with arbitrary initial profile configurations, and the new data set corresponds to the lower limit of applicability for this dynamic stability formula.

A typical result of van der Meer and Pilarczyk's formula is shown in Figure 7, where the predicted profile is plotted with the measured altered structural slope. It is evident that the formula overpredicts the response of the breakwater. It is noted that this result was anticipated due to the low stability associated with the data set in relationship to the data used to develop the dynamic stability formula. It can be seen that the accretion of the berm was greatly overpredicted, and that a large area of erosion was predicted below the SWL. In general, the formula predicts accretion above the SWL and erosion below, which is in contrast to the data which depicts more of an S-shape, where erosion is restricted to the area around the SWL with areas of accretion both above and below the SWL as shown in Figure 4. The damage levels associated with the predicted profiles were also calculated in order to quantify the predictive capabilities

of the formula when applied to the structure tested herein. It was found that the damage level obtained for the predicted profiles is overestimated by roughly a factor of two as shown in Figure 8, where application of this method might be used to define an upper limit of damage for a static/dynamic structure.

Figure 7: Predicted Dynamic Profile(van der Meer and Pilarczyk, 1986)

Figure 8: Comparison with Formula of van der Meer and Pilarczyk (1986)

van der Meer (1992) reanalyzed the data set used previously to develop the dynamic stability formula of van der Meer and Pilarczyk (1986), with emphasis placed on berm breakwaters which pass through stages of dynamic stability and eventually develop an essentially stable profile. The data set contained structures with  $N_s$  between 3 and 500, but a new formula was developed for the data set concentrating on structures with  $N_s < 6$ . The modified method notes the probability of a more rapid increase in the damage

level than that predicted for statically stable structures and may be applied for  $N = 250 - 10,000$  with alterations to the profile taking place even after significant durations. The effects of the initial slope are discussed by van der Meer (1992) where it is noted that for  $N_s < 10$  the initial slope largely affects the final profile, much as is the case with statically stable structures. This lead to the inclusion of a definition of an equivalent slope profile to be used with the modified formula, which would prove important for a typical berm breakwater profile. The present experiment, however, used a uniform slope of approximately 1:3, and the qualitative assessment of the profile development as discussed by van der Meer (1992) agrees with the observed profile evolution within the experiment.

The modified formula has been applied to the new data set described herein, where comparisons are made between the measured and predicted slope profiles and corresponding damage levels. A typical result of the new formula is shown in Figure 9. Figure 9 depicts that the predicted slope underestimates the berm accretion both in volume and in the height to which the berm is developed, also the erosion around the SWL and the accretion below the SWL are poorly predicted. van der Meer (1992) encountered similar problems with the prediction of the size of the structural crest when the formula was applied to the data of Ahrens and Heimbaugh (1989), and suggests that the limited data did not allow for calibration of the parameter related to this structural feature. However, the trend of the profile seems to agree with the present data, because the formula predicts accretional areas both above and below the SWL, and an erosional area near the SWL. Despite the appropriate profile shape, profile development is insufficient due to the relatively small alteration of the initial profile as predicted by the formula. This observation was also noted quantitatively when calculating the damage levels of the predicted profiles, where the damage was found to be underpredicted by roughly a factor of two as shown in Figure 10. In analyzing the results it is anticipated that an improved prediction of the berm crest would allow better agreement to be realized since this would in turn upgrade the erosive portion about the SWL, thus improving overall results for the entire predicted profile.

Figure 9: Predicted Dynamic Profile(van der Meer, 1992)

Figure 10: Comparison with Formula of van der Meer (1992)

## Conclusions

It has been shown that for the new data set with a structural classification that is neither strictly statically or dynamically stable, current design methods are insufficient in predicting profile response with any consistent accuracy. The static stability formulas of van der Meer (1987) and Kaku *et al.* (1991) failed to accurately predict the damage suffered by the structure, where the formulas underestimated the damage. This result is not surprising in that the formulas were developed with data that included numerous structures with low damage levels. The flexibility of the static stability formulas was tested for the new data set with the adjustment of the empirical permeability coefficient and the empirical parameters contained within the formula due to Kaku *et al.* (1991). van der Meer's formula improved with the decreasing permeability coefficient, however, the results were dependent on what appears to be an unrealistic value for the permeability coefficient. Kaku *et al.*'s formula showed improved accuracy with the adjustment of the time scale for profile development, which occurred at a higher rate for the more dynamic structure studied herein. It appears, therefore, that the formula due to Kaku *et al.* is more versatile and allows for adjustments to be made dependent upon the structural type of interest. More data will be required to properly calibrate this formula. It seems that the previous investigators tried to describe too varying a range of structural types with simple formulas, where it is not plausible given the wide variety of influences to which different structural types are subjected.

Secondly, the dynamic stability formulas of van der Meer (1992), and van der Meer and Pilarczyk (1986) were evaluated using the new data set. The data tested the ability of the formulas to predict the actual profile response and damage levels suffered. van der Meer (1992) revised the stability formula for structures close to the static stability boundary. The revised formula provided good qualitative results in that the profile shape was predicted relatively well despite a repeated underprediction of the amount of actual profile response. It is anticipated that this formula is a step in the right

direction, but requires additional data in order to produce more accurate results. van der Meer and Pilarczyk's (1986) dynamic stability formula repeatedly overpredicted profile response. In summary, the existing dynamic formulas seem to be insufficient for the specific structures studied within this study.

## CHAPTER 120

### Wave-Induced Uplift Characteristics on Concrete Block Slope Revetments

Uwe Sparboom<sup>1</sup> and Wolf Debus<sup>2</sup>

#### Abstract

The paper deals with full-scale wave attack on concrete block slope revetments. The tests were carried out in the research facility LARGE WAVE CHANNEL, Germany. The blocks were placed on a filter layer (granular and/or geotextile) preventing the failure of the sandy sub-soil. Stability results are reported. Pressure measurements at special testblocks were used to investigate uplift characteristics of the blocks. Furthermore, the measurements were applied for verifying analytical design procedures.

#### Introduction

Permeable dyke revetments are preferably applied for coastal protection works at the German coast. An economical solution for the sloping cover layer on dykes with a sandy core can be realized by the use of prefabricated concrete blocks placed on a filter layer preventing failure of the sandy sub-soil. The filter layer can be constructed by a quasi three-dimensional granular filter, by a quasi two-dimensional geotextile filter or by a combination of both filter types. In the past, wave attack at storm surge conditions frequently caused failures of such dyke revetments. With the new full-scale laboratory LARGE WAVE CHANNEL a fundamental research project was started in order to investigate dyke revetments under prototype conditions. The main dimensions of this research facility are: depth 7.0 m, width 5.0 m and length 324 m. Regular waves and random seas are produced mechanically by a wave generator. The maximum wave height is 2.5 m. Details about the channel were published by Grüne and Führböter (1975); design criteria and technical works were reported by Grüne and Sparboom (1982).

### Test Set-Up

The core of the 1 to 4 sloping sea dyke was made by sand with a mean diameter of  $d_{50} = 250 \mu\text{m}$ . The area of the highest expected wave attack was subdivided into two testfields each of 10 m in length and 2.5 m in width. Both testfields were separated by a concrete wall of 1 m in depth. A cross-section of the revetment is given in Figure 1. The whole prototype revetment can be seen in Figure 2. The testfields are shown in Figure 3. The concrete blocks were placed in stretcher-bond equivalently to usual method in practice. The investigated structure types are drawn in Figure 4.

Figure 1. Cross-Section of the Prototype Dyke Revetment

Figure 2. 1 to 4 Sloping Dyke Revetment in the Large Wave Channel

Figure 3. Testfields of the Prototype Dyke Revetment

Figure 4. Investigated Structure Types of the Prototype Dyke Revetment

The testblocks which contained measuring devices were installed nearly 0.5 m below SWL in each teststructure or testfield. The measuring equipment was designed to registrate the following electrical signals synchronously:

- wave parameters (height and period) at the toe of the dyke revetment and
- wave pressures acting on the testblocks at the top and bottom side.

The waves were generated regularly applying an integrated absorption control system. The minimum wave number for each test was 200. After very first block failure which was observed by visual control the test was interrupted. A damaged teststructure was replaced by a more stable one being able to increase the wave parameters as far as the second teststructure was damaged. This is the reason why synchronous measurements at both structures (Type A and B) are only available for testserie 1. Testserie 2 was carried out with the structure of Type B only.

### Stability Investigations

Designing blocks of sea dyke revetments it is very useful to consider the breaker parameter which contains the influence of the wave period (as part of the wave steepness) and the slope angle (Bruun,1985). The stability parameter proposed by Pilarczyk, 1987 is given with a non-dimensional quantity which is calculated by the ratio wave height to block thickness multiplied with the relative block density.

Breaker Parameter  $\xi_0 = \frac{1}{n \cdot \sqrt{H_M / L_0}} ; L_0 = \frac{g T_M^2}{2 \pi}$  (1)

- $\xi_0$  (-) breaker number in deep water
- $n$  (-) front slope 1 : n
- $L_0$  (m) wave length in deep water
- $T_M$  (s) wave period (regularly generated)
- $H_M$  (m) wave height (regularly generated)
- $g$  (m/s<sup>2</sup>) acceleration due to gravity

Stability Parameter  $\chi = \frac{H_M}{\Delta d_B} ; \Delta = \frac{\rho_b - \rho_w}{\rho_w}$  (2)

- $\chi$  (-) stability parameter
- $H_M$  (m) wave height (regularly generated)
- $\Delta$  (-) relative block density
- $\rho_b$  (kg / m<sup>3</sup>) density of concrete blocks
- $\rho_w$  (kg / m<sup>3</sup>) density of water
- $d_B$  (m) block thickness

In Führböter and Sparboom, 1988 there can be found stability results for various types of block structures. In this paper tests with wave parameters very close to failure conditions are focussed. In testserie 1 the failure - very first block lifting out of the revetment - occurred at wave parameters  $H_M = 0.8$  m and  $T_M = 6.0$  s (Type A, Figure 5) whereas in testserie 2 the failure

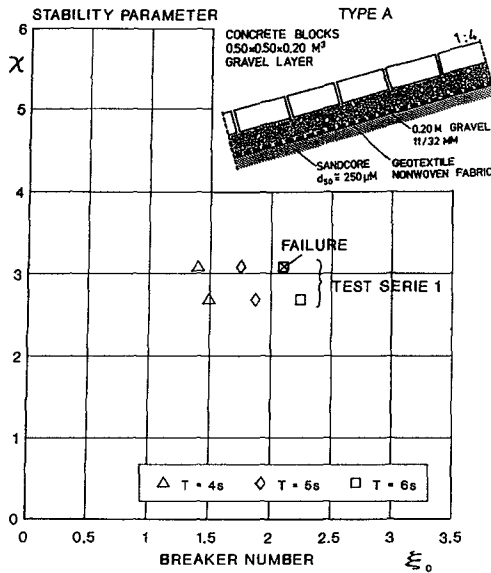

Figure 5. Stability Results Under Critical Wave Conditions - Granular Filter (Testserie 1)

occurred at wave parameters  $H_M = 1.2$  m and  $T_M = 5.0$  s (Type B, Figure 6). The structure of Type B remained stable under test conditions of testserie 1.

For both structure types the failure position was found nearly  $0.5 H$  beneath SWL. The very first block lifting occurred just before wave breaking (foto Figure 7).

Figure 6. Stability Results Under Critical Wave Conditions - Geotextile Filter (Testseries 1 and 2)

Figure 7. Very First Block Failure

Block Lift Forces

In order to investigate pressure variations causing block lifting special testblocks (see Figure 3) were supplied with pressure transducers at top and bottom side. An example of these measurements is plotted in Figure 8. The pressure differences  $\Delta p$  of top and bottom side just before wave breaking were evaluated. Additionally, the reaction times  $T_{pos}$  with uplift characteristic (from zero to maximum) were recorded.

Figure 8. Example of Synchronous Pressures Acting on the Testblocks (Testserie 1)

Estimating the uplift forces (Sparboom and Debus, 1990) the uplift pressures were integrated over the plane of the testblock. For the critical damage tests the development of the uplift forces - evaluated for several waves in each test - can be seen in Figures 9 and 10. Both structure types were damaged in nearly 10 minutes. The maximum uplift force amplitudes are of nearly equal amount for both structure types.

Figure 9. Block Failure Testserie 1; Waves:  $H_M = 0.8$  m,  $T_M = 6.0$  s

Figure 10. Block Failure Testserie 2; Waves:  $H_M = 1.2$  m,  $T_M = 5.0$  s

For the testseries 1 and 2 a representative set of parameters defined in Figure 8 were evaluated. The uplift forces  $F_p$  were found by integrating the pressure differences over the testblock. These force values  $F_p$  were related to the block weight under water  $F_w$  (weight force minus buoyant force). The reaction times  $T_{pos}$  were related to the wave period  $T_M$  of the corresponding test. In the case of a granular filter the uplift force works in the range 0.10 to 0.45 of the period ratio (Figure 11). For comparison in the case of a geotextile filter the main range lies between 0 and 0.15 (Figure 12). But there are also period ratios in the range 0.3 to 0.4. It can be assumed that uplift forces acting under such conditions cause block failures.

Figure 11. Uplift Forces vs. Reaction Time for Testserie 1 - Granular Filter

Figure 12. Uplift Forces vs. Reaction Time for Testserie 2 - Geotextile Filter

From Figures 11 and 12 it may be assumed that block failures occur if the uplift forces are acting in a time interval with a duration of at least 1/3 of the wave period (Führböter and Sparboom, 1988). Uplift forces causing block movements roughly amount 2 to 4 times of the block weight force under water.

Verification Analysis

Experimental full-scale data on block revetments are especially helpful verifying theoretical evaluations. Burger et al., 1990, Bezuijen et al. 1990 and Klein Breteler and Bezuijen, 1991 published analytical procedures for the design of block revetments placed on a granular filter layer. In Figure 13 a definition sketch of the used parameters is given.

Figure 13. Definition Sketch of the Analytical Solutions on Waves Acting on Block Revetments

It was assumed that - with respect to full-scale failure mechanism - the maximum pressure over the revetment occurs just before wave breaking. The following equations were used (see also Figure 13):

BURGER et al., 1990 and BEZUIJEN et al., 1990

$$\Phi_w = \left[ \frac{\lambda}{2 \tan \alpha \tan \beta} * \left( 1 - e^{-\tan \alpha \tan \beta \Phi_B / \lambda} \right) + \frac{\lambda}{2} \right] * \left[ 1 - e^{-2 Z_1 / \lambda} \right] \quad (3)$$

- $\Phi_w$  (m) maximum uplift pressure over the revetment
- $\lambda$  (m) vertical leakage factor
- $\alpha$  ( $^\circ$ ) slope angle
- $\beta$  ( $^\circ$ ) angle of the wave front
- $Z_1$  (m) height of the phreatic surface in the filter layer
- $\Phi_B$  (m) height of the wave pressure front

$$\lambda = \sin \alpha * \sqrt{\frac{k * b * D}{k'}} \quad (4)$$

- $k$  (m/s) permeability of the filter layer
- $k'$  (m/s) permeability of the cover layer
- $b$  (m) thickness of the filter layer
- $D$  (m) thickness of the cover layer

BURGER et al., 1990

$$\Phi_B = H * ( 0.17 * \cot \alpha + 0.07 ) * \xi^{(-0.125 * \cot \alpha + 1.22)} \quad (5)$$

- $H$  (m) incoming wave height (regularly generated)
- $\xi$  (-) breaker number

$$\beta = ( 26.6 + 2.45 \cot \alpha ) * \xi^{(-0.215 * \cot \alpha + 0.73)} * \left( \frac{d}{H} \right)^{( 0.05 * \cot \alpha + 0.06 )} \quad (6)$$

$d$  (m) water depth

BEZUIJEN et al., 1990

$$\Phi_B = 0.36 H \left( \frac{\tan \alpha}{H / L_0} \right)^{0.5} ; \frac{\tan \alpha}{H / L_0} \leq 37 \tag{7}$$

- H (m) incoming wave height (regularly generated)
- L<sub>0</sub> (m) wave length in deep water ( $g * T^2 / 2\pi$ )
- g (m/s<sup>2</sup>) acceleration due to gravity
- T (s) wave period (regularly generated)

$$\tan \beta = \frac{0.17}{\sqrt{H / L_0}} \tag{8}$$

KLEIN BRETELER, BEZUIJEN, 1991

$$\Phi_W = \Lambda * [ 0.43 * (H / \Lambda)^{0.6} * (H / L_0)^{-0.2} * (\tan \alpha)^{0.5} ] \tag{9}$$

- Φ<sub>W</sub> (m) maximum uplift pressure over the revetment
- Λ (m) leakage factor

$$\Lambda = \sqrt{\frac{k * b * D}{k'}} \tag{10}$$

The relative uplift pressures evaluated for waves of testserie 1 are plotted in Figure 14. Since these measured uplift pressures belong to the structure type with a granular filter layer they are comparable to calculated uplift pressures using the formulae (3) to (10).

As also remarked by Bezuijen et al., 1990 it was very difficult to estimate real cover layer permeabilities. The joint width between the blocks of the investigated revetment differed from close contact to 10 mm wide gaps (mean 5 mm). For comparison, three various cover layer permeabilities were

Figure 14. Measured Uplift Pressures With Wave Parameters of Testserie 1; Structure Type A With a Granular Filter Layer

estimated. It was assumed that the relative reaction time of the calculated uplift pressures would have been as long as in the experiments. Results of the calculations are shown in Figure 15.

Comparing the results of Figures 14 and 15 it can be seen that theoretically calculated uplift pressures are much smaller than the highest pressures measured in full-scale. In the case of 5 mm joint width the maximum measured pressure is nearly 75 % underestimated. On the one hand the analytical approach seems to be affected by semi-empirical assumptions based on small-scale modelling, especially the description of the pressure due to the breaker process and the description of the permeabilities of the cover layer as well as of the filter layer. On the other hand real uplift pressures are larger due to friction or clamping forces between single blocks. It is very difficult to estimate these resistant forces theoretically. It is proposed to combine the theoretical design for loose block revetments with results of full-scale experiments with naturally placed blocks using transfer factors from theoretical to prototype conditions. In Figure 16 theoretically calculated uplift pressures of the different procedures are compared with measured uplift pressures. For the special structure considered here such transfer factors could be expected in the range between 2 (small gaps) and 4 (wide gaps). This means that theoretically calculated maximum uplift pressures for a loose block should be increased at least 2 to 4 times being able to estimate the total uplift pressure causing block failure.

### Concluding Remarks

According to earlier results reported by Führböter and Sparboom, 1988 it is expected that placed concrete blocks (relative density  $\Delta = 1.3$ ) protecting a slope 1 to 4 remain stable under the following assumptions:

$d_B \geq 1/3 H$  case of granular filter on sandy sub-soil,

$d_B \geq 1/5 H$  case of geotextile filter on sandy sub-soil.

Failure occurrence of such structures is expected at breaker numbers  $\xi_0$  ranging from 1 to 2. The failure location was found nearly  $0.5 H$  below SWL.

From time history records of pressure measurements at top and bottom side of testblocks it was found that block movements occur if uplift forces are acting at least  $1/3$  of the wave period. Uplift forces may cause block movements if the amplitude is 2 to 4 times higher than the block weight force under water.

Figure 15. Calculated Uplift Pressures for Various Cover Layer Permeabilities Related to Wave Parameters of Testserie 1, Structure Type A With a Granular Filter Layer

Figure 16. Measured Versus Calculated Relative Uplift Pressures for Joints With a Width of 1, 5 and 10 mm

For an economical design on placed block revetments it is recommended to select structural permeabilities increasing from sub-soil to filter layer and from filter layer to cover layer.

Verifying analytical approaches on placed block revetments it was found that calculated uplift pressures in the case of loose blocks are definitely smaller than measured uplift pressures in the naturally placed revetment. The physical mechanism of wave breaking together with the response of a more or less permeable and flexible block revetment is a very complex domain. In the opinion of the authors full-scale laboratory experiments as well as field investigations are inevitably necessary to study breaking wave attack of sea dykes and revetments. Results of such experiments are especially useful to verify theoretical solutions or to calibrate numerical models.

# CHAPTER 121

## FIELD MEASUREMENTS ON PLACED BLOCK REVETMENTS

Theo Stoutjesdijk, MSc<sup>1</sup>  
Ben Rigter, MSc<sup>2</sup>  
Adam Bezuijen, MSc<sup>1</sup>

### Abstract

A report is given on a field measurement campaign on placed block revetments. Four types of measurement are described. Typical results are presented and discussed. The entire campaign shows a consistent image of changing physical properties in the field.

### Introduction

Placed block revetments are a type of coastal protection commonly used in the Netherlands and Germany. Extensive research has been carried out on this type of construction, including small and large scale model tests (Burger et al, 1990, Sparboom and Führböter, 1990). Analytical and numerical design methods are available (Burger et al, 1990 and Bezuijen et al, 1987). However, until recently little field data of this type of construction in marine conditions has been reported. Therefore, Rijkswaterstaat, the Dutch Ministry of Public Works, has initiated a field measurement campaign. The scope of this work was to compare the results of model tests and calculation models with the physical behaviour of revetments in the field.

### Some theory on placed block revetments

Shown in figure 1 is a common construction in the Netherlands. You see a top layer of carefully placed blocks and a permeable filter layer underneath.

The theory behind this type of revetment can be simplified into four statements:

- first, wave action causes pressures on the top layer.
- in the filter layer a reaction to these pressures takes place. This reaction depends largely on the permeabilities of top layer and filter layer. This can be characterized by one

---

<sup>1</sup>DELFT GEOTECHNICS, P.O. Box 69, 2600 AB Delft, The Netherlands

<sup>2</sup>RIJKSWATERSTAAT, P.O. Box 5044, 2600 GA Delft, The Netherlands

Figure 1 Placed block revetment

parameter; the leakage length. This parameter can be expressed as:

$$\Delta = \sqrt{\left(\frac{b \cdot D \cdot k}{k'}\right)} \quad [1]$$

with:  $\Delta$  = leakage length [m]  
 $b$  = thickness of filter layer [m]  
 $D$  = thickness of top layer [m]  
 $k$  = permeability of filter layer [m/s]  
 $k'$  = permeability of top layer [m/s]

- the load on the top layer is the difference in pressures on top and underneath the top layer.
- the load on the top layer can be compared to the strength. A certain force is required to push a block out of the revetment.

In the analytical and numerical models wave pressures, permeabilities and leakage length are used to calculate the reaction in the filter layer and consequently the load on the top layer. The load is compared to the strength, which is expressed in terms of one or more times the block weight.

#### Overview of performed measurements

The same factors as mentioned above return in the overview of performed measurements. Four types of measurement are discussed, respectively:

1. Permeability tests  
It is clear that the permeability of the top layer is an important factor. This can be measured directly in the permeability test. The amount of water that disappears from a reservoir is measured. This can be linked to the permeability of the top layer.
2. Infiltration tests  
The reaction in the filter layer to an imposed water-column is measured in the infiltration test. As this reaction is a function of the leakage length, the leakage length can be predicted.
3. Wave and pore pressure tests  
In the wave and pore pressure test the wave pressure on the top layer and the pore pressure beneath the top layer are measured simultaneously. The difference is the load on the top layer. The results are used to hindcast the leakage length.
4. Pull-out tests  
Blocks are pulled out of the revetment. The force required to do this is measured. This gives an impression of the strength of the top layer.

#### Permeability test

Figure 2 Set-up of permeability test

As shown in figure 2, the permeability of the top layer is measured by placing a reservoir with a known surface of the open bottom on the top layer. Leakage through the gaps between the top layer and the reservoirs is reduced to a minimum by applying foam around the sides. A second reservoir is placed around the inner reservoir to make sure that the flow through the top layer is as one

dimensional as possible. Next, the reservoirs are both filled with water. The amount of water disappearing in a fixed period of time from the inner reservoir through the top layer is measured. This can be linked to the permeability of the top layer.

#### Results of permeability test

Measurements of the permeability of the top layer are performed at different heights.

Roughly, three zones can be distinguished:

- the tidal zone with a permeability of  $5 \cdot 10^{-7}$  m/s.
- the zone between high water level and high high water level, with a permeability 100 times higher than in the tidal zone.
- the storm surge level, again with a permeability which is again 100 times higher than the zone below.

The conclusion is, that the permeability in the tidal zone has decreased with a factor 10,000 during the lifetime of the construction. This permeability is also much lower than normally found in model tests. The reason for this sharp decrease in permeability was found when some blocks were lifted. The joints between the blocks are completely filled with sand and other fine material. Especially in the tidal zone, biological growth can influence the permeability. The filter layer, which originally consisted of gravel, is now a mixture of gravel and sand. However, as the decrease in permeability of the filter layer is less dramatic than the decrease in permeability of the top layer, inevitably the leakage length increases. As a large leakage length yields larger loads this is unfavourable.

#### Infiltration test

Figure 3 Infiltration test, measurement set-up

The next type of test presented here is the infiltration test. This test is used to determine the leakage length. The state of the art in modelling allows us to calculate the reaction in the filter layer to a given load, if only the leakage length is known. Therefore, some elements of the top layer are removed and a box of 1 m height is placed in the hole. Water is pumped into the box to a certain, constant, level, so that the local load on the filter layer is known. The decrease in pore pressure, as a function of distance from the location where the load is applied is measured.

A long leakage length means that the permeability of the top layer is relatively small compared to the permeability of the filter layer (see also equation [1]). Therefore the decrease in pore pressure with increasing distance from the infiltration point is small. A short leakage on the other hand means that the permeability of the top layer is relatively large. The decrease in pore pressures takes place over a limited distance.

Figure 3 shows the measurement set-up. An infiltration reservoir is placed on the top layer. Bore holes are made through the top layer. This enables the placement of pore pressure transducers in the filter layer. Next, the reservoir of 1 m height is filled to overflow level and kept there until a stationary situation is obtained. At that moment the pore pressures in the filter layer are determined.

#### Results infiltration test

Shown in figure 4 is the measured decrease in pore pressure as a function of height. Schematically drawn are also the revetment, the infiltration reservoir, and the measured pore pressures. In a one-dimensional situation, that can be reached with several infiltration points in a horizontal row with laminar flow, an analytical solution is possible.

Figure 4 Result of infiltration test

In practice however, only one or two infiltration points are used, and around the infiltration points turbulent flow is dominant. This means two dimensional flow has to be dealt with to determine the leakage length. Calculations are performed with the same numerical model that is used to investigate the influence of oblique wave attack on revetments (Bezuijen et al, 1992). The result of a calculation with this model can be seen in figure 5.

Shown is the calculated piezometric head for a two dimensional situation. The leakage length in this case is relatively short, about 0.8 m. The drawn lines are lines of equal pore pressure. Vertically is set out the height on the revetment (not the distance along the surface of the slope), horizontally the horizontal distance. The calculation is performed on a dry slope; the tidal level is below the toe of the revetment.

Figure 5 Result of calculation model

Around the infiltration point the water flows down the slope in a kind of umbrella shape. If the pore pressure is measured in several points, this can be compared to the calculated piezometric head in figure 5. Shown is the difference in piezometric head over the cover layer. A negative value means, that the water level lies below the cover layer at that position. Only if this value is positive, water will flow through the cover layer out of the construction. The minus 0.15 m-line represents the phreatic surface in the filter layer. The positive values on the bottom of the graph represent a build-up of difference in piezometric head that is caused by an impermeable toe construction. Good agreement is found, provided the right leakage length is chosen.

#### Wave and pore pressure test

In the wave and pore pressure test, a measuring beam with a length of six to nine metres is placed on the top layer, as shown in

figure 6. On top of the measuring beam 12 wave pressure transducers are fixed. Along the measuring beam 3 bore holes are made through the top layer. Through the bore holes pore pressure transducers are placed in the filter layer.

Measurements are only useful when there is enough wind to generate waves of some height. Measurements are possible up to Beaufort 7 to 8. During fairly stormy weather the wave pressures on the top layer and the pore pressures beneath the top layer are measured simultaneously. The difference between them is the load on the top layer. Therefore, the wave and pore pressure test is a direct measurement of the load on the top layer.

Figure 6 Measurement beam and bore holes

#### Results of wave and pore pressure test

Shown in the graph in figure 7 are the measured wave pressure, the measured pore pressure and the difference between these two, which is the load on the top layer.

The wave height on the spot of the pore pressure transducers is some 20 cm, the reaction in the filter layer is about 2 cm. This reaction in the filter layer is much smaller than expected, because the permeability of the cover layer in the tidal zone is much lower than expected. The result of such a small reaction in the filter layer is, that a wave height of one fifth of the design wave height will be sufficient to cause a load on the top layer that is equal to the weight of the blocks. The same theory, however, also explains that with permeabilities that are very low, little water can reach

the critical point. A much higher load is required to actually cause damage.

According to the theory on placed block revetments the reaction of the pore pressures to the wave pressures is determined by the leakage length. The wave and pore pressure test therefore can also be used to make a hindcast of the leakage length.

Figure 7 Result of wave and pore pressure test

Figure 8 Simulation of pore pressures

This hindcast is performed done with a numerical calculation model STEENZET/1. The measured wave pressures are used as input for

the model. The pore pressures in the filter layer are calculated and compared to the measured pore pressures. A good correspondence between measured pore pressures and calculated pore pressures can be found, provided the right leakage length is chosen. In figure 8 both these properties are given.

The leakage length used for this simulation is 13 m. This is 10 to 20 times larger than usually found in model tests. As a long leakage length yields large loads, this is unfavourable.

A different aspect is found when we take a look at the phreatic surface in the filter layer. The test is repeated at different tidal levels. This information can be used to compare the phreatic surface in the filter layer with the mean sea water level. Because of the small permeability of the top layer, the phreatic surface does not respond instantaneously to a change in tidal level. This difference in water levels can cause a considerable extra load on the top layer if the tidal level drops and the phreatic surface does not react accordingly, as shown in figure 9.

Figure 9 Phreatic surface and tidal level

So far this phenomenon has never been observed in model tests, simply because these tests are performed on newly made constructions. Therefore, also in calculation models it is always assumed that the mean water level in and outside the construction is more or less equal. This proves to be a dangerous assumption.

#### Pull-out test

So far only the load on the top layer has been considered. As it is shown in the previous paragraphs that this load can be much larger than expected, it is important to compare this load to the strength of the top layer.

An impression of the strength of the revetment can be obtained by pulling blocks out of the revetment and registering the force required to do this.

Shown in figure 10 is a pulling unit, consisting of a trailer which is fixated on the top layer with four supports. On board of the trailer a computer-controlled system is mounted that is able to lift a block over a vertical distance of 2.5 cm by exerting a

hydraulically controlled pulling force of about 6 times the block weight. The maximum pull-out force is about 10 kN.

A large number of blocks (over one thousand) was pulled out, ensuring that a statistical evaluation of the results is valid. The aim of the test was to answer the question how many blocks are loose blocks that can be lifted easily during wave attack.

Figure 10 Pulling unit

#### Results of pull-out tests

Shown in figure 11 are the results of pull-out tests on three different levels.

Three things can be read from this graph:

- the influence of the height is evident: the lower on the revetment the higher the strength of the construction.
- at a pull-out force equal to the block weight less than one percent of all the blocks is pulled out
- the percentage of blocks that is not pulled out of the revetment, even at a pull-out force of 6 times the block weight is considerable. Depending on the level, only 15, 30 or 70 percent of the blocks was lifted.

Figure 11 Results of pull-out tests

Not shown in this graph is the fact that in the tidal zone no blocks could be pulled out. In general, the required pull-out force is higher than expected. This is caused by friction forces and clamping forces in case of a slight rotation of the block. It is stressed that, during wave attack, the load on the blocks can be different than the schematized load of the pull out tests. Also, it is possible that more than one block at a time will move. Still, the strength of older placed block revetments with a low permeability of the cover layer can be considered higher than the strength of loose blocks.

### Conclusions

The entire campaign of field measurements shows a consistent image from which the following conclusions can be safely made:

- first, it is clear that physical properties in the field, especially permeabilities, can differ dramatically from properties in model tests. This means that existing revetments can show physical behaviour that differs from the behaviour found in model tests.
- in time permeabilities decrease due to biological activity and migration of sand and fine material.
- in the tidal zone this influence is larger than in the zones above it. Properties vary with height.
- if the permeability of the cover layer decreases more than the permeability in the filter layer, the load on the top layer increases. At the same time however, also the strength seems to increase.

Existing design methods are based on the concept of loose blocks. The methods have been verified in model tests, and therefore they are valid for revetments with relatively large permeabilities

and short leakage length. Usually, a revetment is designed on the properties as expected directly after construction.

In the measurement campaign it is shown, that the concept of loose blocks is valid at storm surge level, but not necessarily in the tidal zone. Also, it is shown, that permeabilities decrease, the leakage length grows and consequently the load on the top layer increases. Permeabilities in the tidal zone can decrease to a degree that, even if there is a large uplift pressure, still no block movement will occur, as no water can flow towards the attacked block. In practice, also the pull-out force can be much higher than expected.

As a consequence for the design of placed block revetments the change in physical behaviour with time should be anticipated for the entire lifetime of the construction.

## CHAPTER 122

# Numerical determination of wave induced flow in rubble mound breakwaters.

Sun ZC<sup>1</sup>, Williams AF<sup>2</sup>, Allsop NWH<sup>2</sup>

### 1 ABSTRACT

This paper describes a numerical model of wave action onto and into a rubble mound breakwater. The model is constructed of two parts, the wave action on the exterior of the mound in which a boundary element method is used and flow inside the rubble mound in which a finite element method is used. The two parts of the model are coupled by demanding continuity of flow through the front face of the breakwater. The predicted pressures within the core of the rubble mound are compared with data collected from physical model tests.

### 2 INTRODUCTION

The problem is that of wave action onto and into a rubble mound breakwater as illustrated in Fig(1). External wave action on the breakwater induces wave action within the porous material of the rubble mound. The stability of both the rubble mound core and the external armour layers is dependent on the pore water pressures within the structure. Our aim is to model the wave motion within the rubble mound, and calculate the instantaneous pore pressures as they change under wave action.

A complete model needs to incorporate all of the following physical processes: Random wave motion external to the breakwater and uprush onto the breakwater face. Energy dissipation caused by wave breaking and friction at the breakwater surface. The transport of water through the front face of the breakwater. The flow of water through the porous material of the breakwater core. Here the flow is non-Darcy or turbulent and the flow rate is unsteady. The effect of entrained air in the flow of water through the porous material. A complete model must also be able to deal with complex breakwater geometries, such as berms and layers of armour and filter

<sup>2</sup>Coastal Structures section, Hydraulics Research, Wallingford, OX10 8BA, UK.

**Figure 1** Wave action on a rubble mound breakwater.

materials.

No model is presently able to incorporate all of these processes. Analytical solutions such as that proposed by Sollitt & Cross (1972) by necessity require the geometry to be simplified to a homogeneous rectangle with vertical faces. Madsen & White (1976) also developed an analytical solution which uses assumptions of rectangular geometry and linear periodic wave theory. They improved the range of application of their model by representing multi-layered trapezoidal breakwaters with a "hydraulically equivalent" homogeneous rectangular structure. Predictions of wave reflection and transmission can be made using analytical models of this type. Unfortunately the simplifying assumptions and averaging processes necessary to arrive at an analytical solution make it impossible to calculate local instantaneous water velocities or pressures.

To find the local instantaneous velocities and pressures required for the investigation of breakwater stability, a method is required that does not make gross assumptions about the structure geometry or involve integration of the solution over a wave period. These requirements may only be met by use of a numerical model. McCorquodale & Nasser (1974), Nasser (1974) and Hannoura (1978) have all developed numerical models for flow with the porous material of the breakwater. A hybrid finite element/difference model is described by Hannoura & McCorquodale (1985), in which the time integration is carried out by a finite difference method and the space integration is solved by use of a finite element method. The model is restricted in its application as it only simulates the flow within the breakwater, and requires the boundary condition on the seaward face of the breakwater to be supplied from empirical data or an alternative numerical model.

A more comprehensive model is at present in development under the European MAST G6-S project (Meer et al. (1992)). This model utilises the

volume of fluid (VOF) technique similar to the SOLA-VOF developed by Nicholas, Hirt & Hotchkiss (1980). VOF methods are the most promising way forward to a complete model which includes the effects of wave runup and breaking. Unfortunately VOF models are computationally intensive and at present a main frame computing facilities are required for implementation. The model being developed under MAST still requires further work and it may be several years before a fully working VOF model is available.

At Wallingford we have developed an intermediate numerical model which divides the problem into two parts:- a). The external wave action which produces pressures on the outer surface of the breakwater. (The external flow field). b). The internal flow within the breakwater driven by the pressures induced by the external flow field. (The internal flow field). The internal flow field (b) is modelled by the use of a finite element method. The external flow field (a) is calculated by use of a boundary element method. These two models are then coupled by allowing water to flow through the shared boundary. The ability to model the wave action on the exterior face of the breakwater means that support from physical model tests, as is necessary for the implementation of the Hannoura & McCorquodale (1985) model, is not required.

### 3. THE EXTERNAL FLOW FIELD

Here the wave motion is calculated in two dimensions by use of a boundary element method. The program used is a variation of the program developed by Shih (1989), from the method described by Vinje & Brevig (1981).

#### 3.1 GENERAL PRINCIPLES

The fluid is assumed to be both incompressible and irrotational. Such a two dimensional flow field can be described by either one of the pair of orthogonal functions termed the velocity potential  $\phi$  and stream function  $\psi$ . Both the velocity potential and the stream function are solutions of the Laplace equation with some specified boundary condition. In this way the Laplace equation relates the values of these functions in the interior of the computational domain to values at the boundary of the domain. If the stream function or the velocity potential is specified at all points on the boundary, then the stream function inside the boundary can be found and hence the complete flow field computed. This is convenient as in our problem the boundary condition at the free surface of the material is most easily phrased in terms of the velocity potential  $\phi$ , while the conditions at the other boundaries of the domain are most easily specified by the stream function  $\psi$ . For the purposes of the numerical model the boundary is specified at discrete points  $z_k$  as shown in Fig (2).

If suitable boundary conditions can be specified for the whole domain, then the complete flow field may be calculated. The only remaining problem is that of finding the position of the free surface. The position of the free surface is continually re-calculated by tracking the movements of points on the surface. The motion of these points is given by the most recently computed values of the flow field at these points.

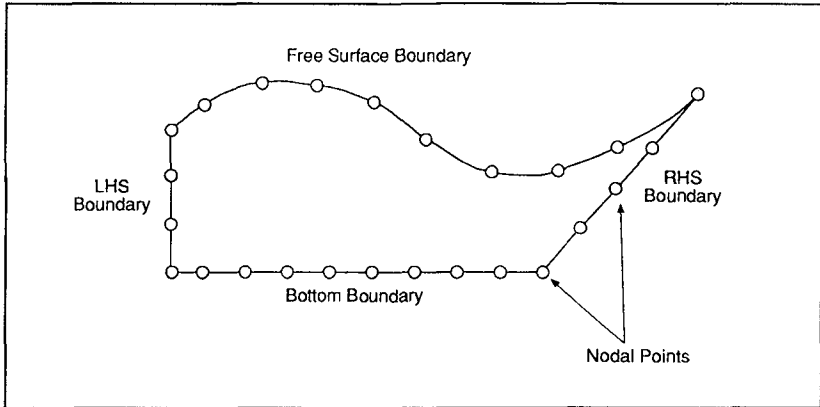

Figure 2 The computational domain.

### 3.2 MATHEMATICAL FORMULATION

The orthogonal function defined by the velocity potential  $\phi$  and stream function  $\psi$  may be combined to form the complex potential;

$$\beta(z, t) = \phi(z, t) + i\psi(z, t) \quad (1)$$

In which  $z$  is a complex variable which describes the position in the computational domain;  $z = x + iy$  and  $t$  is the time variable.

As  $\phi$  and  $\psi$  both satisfy the Laplace equation,  $\beta$  must be an analytical function within the boundary of the fluid. For such an analytical function the value of  $\beta$  within the boundary can be related to the values of  $\beta$  at the boundary by use of the Cauchy integral theorem. If  $z_k$  is some point inside the boundary  $C$  then:

$$f(z_k) = \frac{1}{2\pi i} \oint_C \frac{f(z)}{z - z_k} dz \quad (2)$$

We are interested in the case when  $z_k$  also lies on the boundary. In this case if the boundary  $C$  is smooth, then  $z_k$  is related to all other points on the boundary by:

$$-i\pi\beta(z_k, t) + \oint_C \frac{\beta(z, t)}{z - z_k} dz = 0 \quad (3)$$

Equating the real and imaginary parts of Equ(3) produces two equations for the conditions where either  $\phi$  or  $\psi$  is known at the boundary point  $z_k$ :

$$\pi \psi(z_k, \hat{t}) + \operatorname{Re} \oint_C \frac{\beta(z, \hat{t})}{z - z_k} dz = 0 \quad (4)$$

for  $z_k$  lying on the boundary for which  $\phi$  is known

$$\pi \phi(z_k, \hat{t}) + \operatorname{Re} \oint_C i \frac{\beta(z, \hat{t})}{z - z_k} dz = 0 \quad (5)$$

for  $z_k$  lying on the boundary for which  $\psi$  is known

For purposes of the numerical calculation, the boundary is divided into discrete points. By assuming a linear variation of  $\beta$  between the points, the integral around the boundary can be expressed in terms of a summation over an influence function. The set of equations formed by this summation for each point is then assembled into a matrix. The matrix is solved by Gaussian elimination to produce  $\phi$  and  $\psi$  at each point on the boundary.

### 3.3 BOUNDARY CONDITIONS

There are four boundaries on which conditions must be specified.

**THE IMPERMEABLE BOTTOM BOUNDARY:** Here the condition is no flow normal to this boundary, which results in:

$$\psi = \text{constant}$$

In our case the constant = 0

**THE LEFT HAND BOUNDARY:** This boundary condition is supplied by the wave maker and the simple theory of wave generation proposed by Galvin (1964) is used. The wave maker is simulated as a piston that produces flow normal to this boundary, hence at this boundary  $\psi$  is specified. In addition to the original model developed by Shih, this boundary has been modified to allow wave energy to exit the computational domain.

**THE RIGHT HAND BOUNDARY:** This is the interface with the internal flow model. Flow normal to the boundary is given by the seepage flow from the internal model at this interface. Here  $\psi$  is again specified.

**THE FREE SURFACE BOUNDARY:** At this boundary two conditions are required, one to specify the velocity potential and another to describe how this boundary should move between time steps.

The velocity potential is given by the dynamic condition:

$$\frac{\partial \phi}{\partial t} = ww^* - gy - \frac{p_s}{\rho} \quad (6)$$

Where  $w = u - iv$  the conjugated complex velocity,  $g$  = acceleration due to

gravity,  $y$  = the vertical position of the boundary point,  $p_s$  = the pressure at the surface (in most cases  $p_s = 0$ ),  $\rho$  = density of the fluid

Hamming's fourth order predictor-corrector method is used to determine  $\phi$  from Equ(6) with the exception of the first three time steps of a calculation when the Runge-Kutta method is used.

The new position of the boundary is calculated from the kinematic condition:

$$\frac{Dz}{Dt} = \frac{D}{Dt}(x+iy) = w^* \quad (7)$$

Where  $z$  = the complex position of the boundary point (which has coordinates  $x$  and  $y$ ). This allows the new position  $z$  of the boundary to be calculated for the next time step by an integration over time  $t$ .

#### 4. THE INTERNAL FLOW FIELD

As in the external flow model the internal flow model is two-dimensional, with the breakwater cross section forming the computational domain. Wave motion is caused by the variation of the pressure on the seaward face of the structure and fluid flow through the structure. The front face of the breakwater forms the interface of the two models. The pressures on this external face are supplied by the external flow model.

##### 4.1 THE GENERAL PRINCIPLES

The problem is one of seepage flow through a porous granular medium, with a free surface within the medium. The granular material of the breakwater is of sufficient size that the flows within the medium are turbulent and may not be described by Darcy's linear law. The existence of an exact relationship between hydraulic gradient  $i$ , and the bulk flow velocity  $u$ , is in this case uncertain, however recent research by Williams, Burcharth, & den Adel (1992) indicates that the Forchheimer equation forms the best fit to the empirical data available at present. The unsteady flow form of the Forchheimer equation is:

$$i = au + bu^2 + \frac{(1+C)}{g} \frac{\partial u}{\partial t} \quad (8)$$

Where  $a$  and  $b$  are the Forchheimer coefficients which are dependent on the granular material. Separate layers of filter material within the breakwater result in  $a$  and  $b$  being functions of position.  $C$  is the virtual mass coefficient and is also dependent on the material. Means of determining values for  $a$ ,  $b$  and  $C$  are discussed in the paper by Williams et al. (1992).

The assumption that the fluid is incompressible provides the continuity equation in the form

$$\nabla u = 0 \quad (9)$$

The Forchheimer equation and the equation of continuity with adequate boundary conditions are sufficient to allow the flow field to be solved uniquely.

The flow field is calculated by use of a finite element method where the computational domain is defined by the breakwater cross section and the phreatic surface of the water. The phreatic surface rises and falls with the wave motion. As a result the size and shape of the computational domain is also a function of time. The position of the phreatic surface must therefore be calculated at each time step and the finite element mesh re-fashioned to fit the new computational domain.

## 4.2 MATHEMATICAL FORMULATION

It is useful to phrase the Forchheimer equation in terms of the piezometric head  $P_p$ .

$$-\nabla P_p = (a+b|\bar{u}|)\bar{u} + \frac{(1+c)}{g} \frac{\partial \bar{u}}{\partial t} \quad (10)$$

the piezometric head is related to the pressure  $p$  by:-

$$P_p = \frac{p}{\gamma} + y \quad (11)$$

where  $y$  is the some vertical coordinate.

The time domain is dealt with by the use of finite differences. Writing:

$$\frac{\partial \bar{u}}{\partial t} = \frac{(\bar{u}|_{t+\Delta t} - \bar{u}|_t)}{\Delta t} \quad (12)$$

Substituting Equ(12) into Equ(10) gives:

$$\bar{u}^{t+\Delta t} = K \left( \Delta(P_p)|_{t+\Delta t} - \frac{1+c}{g\Delta t} \bar{u}^t \right) \quad (13)$$

where

$$K = \frac{1}{a+b|\bar{u}| + \frac{(1+c)}{g\Delta t}} \quad (14)$$

is the conductivity of the rubble material. Note that  $K$  is a function of  $u$ .

Substituting Equ(14) into the continuity equation (Equ(9)) yields the governing equation for the piezometric head:

$$\Delta( K \Delta P_p ) = 0 \quad (15)$$

For the purposes of the numerical simulation this equation is re-phrased as the requirement that:

$$\chi = \iint_A K \left[ \left( \frac{\partial P_p}{\partial x} \right)^2 + \left( \frac{\partial P_p}{\partial y} \right)^2 \right] dx dy \quad (16)$$

should be a minimum for the given boundary conditions and the integration is carried out over the whole of the computational domain. Finite element discretization of this equation is carried out using triangular mesh elements. The minimisation technique produces a set or matrix of equations that can be solved to give the piezometric head and flow velocities for the specified boundary conditions.

### 4.3 BOUNDARY CONDITIONS

For the internal flow the boundary conditions are specified in terms of the piezometric head  $P_p$ . There are four relevant boundaries:

**THE BOTTOM BOUNDARY:** This boundary is impermeable so the condition of no flow normal to this boundary gives:

$$\frac{\partial P_p}{\partial y} = 0 \quad (17)$$

where  $y$  is the vertical coordinate.

**THE HARBOUR SIDE BOUNDARY:** At present, this boundary has been kept simple by specifying that the water level behind the breakwater remains constant at  $y=d$ . Hence:

$$P_p = d \quad (18)$$

**THE SEAWARD BOUNDARY:** This is the interface between the internal and external models. Here the boundary condition is supplied by the pressure distribution given by the external model.

$$P_p = \frac{\rho}{\gamma} + y \quad (19)$$

Continuity of flow through this boundary is achieved by the coupling technique described in the next section.

THE PHREATIC SURFACE BOUNDARY: Since this boundary moves, two boundary conditions are required.

The kinematic boundary condition:

$$\frac{Dx}{Dt} = u, \quad \frac{Dy}{Dt} = v \quad (20)$$

where  $x$  and  $y$  are the coordinates of the boundary point and  $u$  and  $v$  at the flow velocities at these points.

The dynamic boundary condition:

$$P_p = \gamma \quad (21)$$

At time  $t = 0$ , the initial conditions are:

$$P_p = \text{const.} \quad \bar{u} = 0 \quad (22)$$

## 5 COUPLING OF THE INTERNAL AND EXTERNAL FLOW MODELS

The external flow model is coupled to the internal flow model by demanding continuity of flow and pressures through the shared boundary. This is achieved by use of a trial and error technique as shown in the flow chart in Fig(3).

It is this coupling of the external and internal flow regimes that makes the completed model unique. This technique allows the wave motion onto and through the breakwater to be simulated without the need for additional data to be supplied from physical model tests.

## 6 PHYSICAL MODEL TESTS

Work carried out at Wallingford for the Single Layer Armour Unit Research Club has provided an excellent opportunity to obtain empirical data against which the numerical model can be tested. The study involved the construction of a model rubble mound which was armoured with model units.

The rubble mound was constructed with the geometry as shown in Fig (4). The core material was crushed limestone ranging in size from 4-6mm, the underlayer consisted of 10-14mm limestone. The armour units were simulated by a plastic frame work of the appropriate porosity or by model units of the correct density. During construction care was taken to carefully weigh all the core and filter material used in the model so that the porosity of the relevant layers could be determined. These porosities must be known to allow the correct determination of the Forchheimer coefficients  $a$  and  $b$  used in the numerical model.

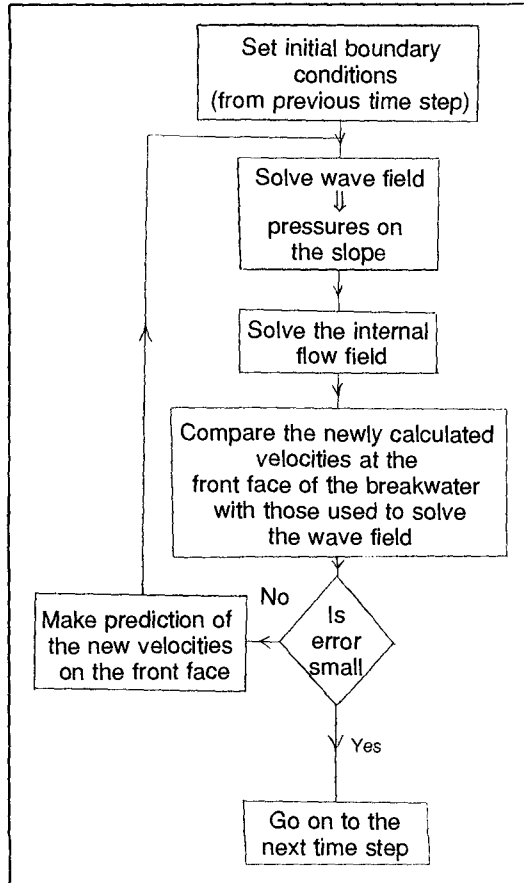

During the construction the pressure transducers were buried in the positions

shown. The cables of these transducers exited the rear of the mound and connected to the appropriate equipment to allow the pressures to be monitored by computer.

In order to make the comparison of the numerical simulation and the physical model test data as simple as possible, only data from regular wave conditions have been investigated. The wave conditions tested ranged in height from 0.11 to 0.2m and in period from 1.6 to 2.8s. The piezometric heads measured by the pressure transducers were logged by computer for each test condition.

The numerical model was run for a structure with the same geometry and material properties as the physical model. The values of the Forchheimer coefficients  $a$  and  $b$  were determined by comparison of the core and filter material with material whose permeability had previously been measured at HR, (see Williams et al. (1992)). The piezometric head at the positions of the pressure transducers was determined from the internal flow model and compared to the physical model data as described in the next section.

**Figure 3** Linkage of Wave and Internal Flow Models.

## 7 RESULTS

The flow of fluid within the mound is illustrated as a velocity plot in Fig. (5.a-d). The wave height is 0.14m with a period of 2.4s. It is seen that the majority of the fluid flow occurs within the armour and filter layers. This is expected as the armour and filter layers are several orders of magnitude more permeable than the core of the breakwater. Points on the phreatic surface are marked  $\circ$ .

In Fig.(6.a-e) show the predicted and observed pressures at the positions of

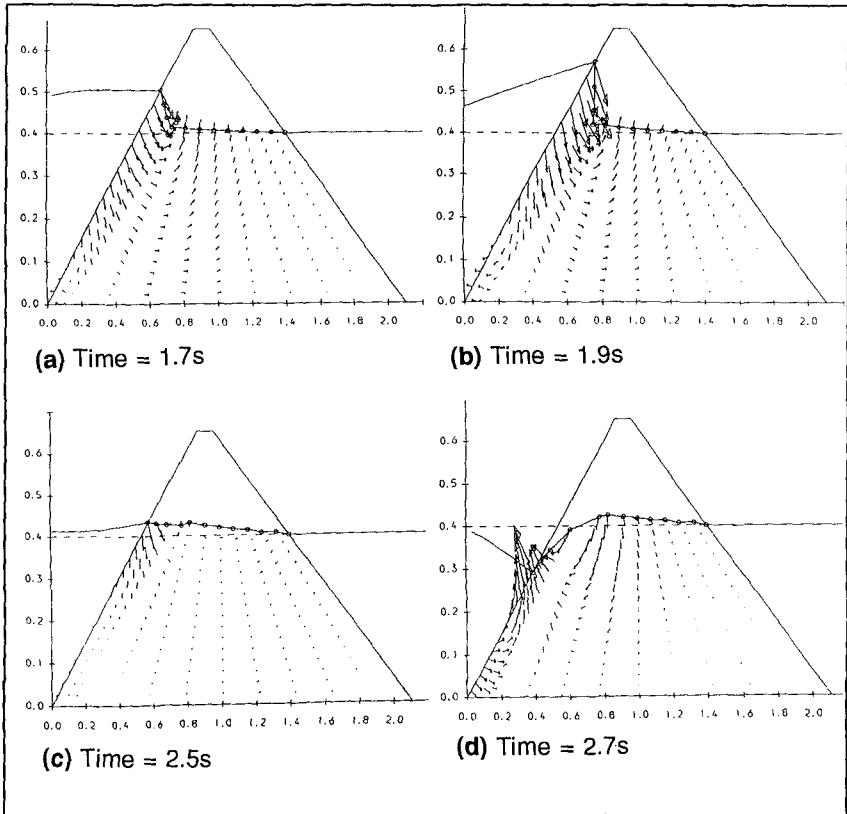

**Figure 4** Locations of the pressure transducers.

the pressure transducers within the mound. The close match between the empirical data and numerical results is very encouraging. The discrepancy between the observed and predicted pressures for positions deep within the mound is probably the result of the boundary condition, of constant water level behind the mound imposed on the internal flow model. Replacement of this boundary condition would allow wave motion behind the breakwater, and reduce the amount of predicted of wave attenuation within the mound. It may be possible to model the wave motion behind the breakwater, by applying the boundary element method to this region and demanding continuity of flow through the rear face of the breakwater as for the front face.

The discrepancies between observed and predicted pressures for high wave conditions may be the result of the effects of wave breaking that cannot be modelled with the boundary element technique described. The use of empirically derived correction factors might be of use in reducing this error, however this would require an extensive series of physical model tests. Such a series of tests would circumvent the advantages of this model over the internal flow model developed by Hannoura & McCorquodale (1985).

The model at present is sometimes unstable. Problems may be encountered in establishing continuity of flow across the external/internal interface with sufficient accuracy. This may be due to the fundamental differences in the models used to calculate the external and internal flows, and the assumptions that these models are based upon. The boundary element model used for the external flow requires the assumption that the flow is irrotational. No such restriction is placed on the internal finite element model. Such inconsistencies of formulation may well be the source of the observed inability to match the

**Figure 5** Velocities within the mound

flow through the interface. The nature of the instability requires further study so that the conditions that lead to it may be predicted. Until this time the model must be used cautiously and the results interpreted with care.

## 8 CONCLUSIONS

There is a good agreement between predicted and observed pressures near the front face of the breakwater mound for waves of moderate height. The accuracy of the model declines when significant a degree of wave breaking and air entrainment occurs.

The model under predicts the amount of wave action deep within the mound. This is almost certainly due to the effects of an unrealistic boundary condition applied to the harbour side of the breakwater. Correction of this boundary condition should significantly improve this aspect of the model.

The full modelling of wave action that includes wave breaking and the

Figure 6 Predicted • and observed pressures within the mound.

entrainment of air must wait for the development of volume of fluid methods as described in the introduction. Until VOF models are available for implementation on small computers, composite models such as this will continue to provide valuable insight into the nature of flows within the cores of rubble mound breakwaters.

## 9 ACKNOWLEDGEMENTS

The collection of physical modelling data and the comparison of this data with the numerical model described in this paper was supported by Single Layer Armour Unit Research Club, co-funded by the Department of the Environment Construction Industry Directorate. Work on the development of the numerical model was funded by Dalian University Of Technology, the British Council and HR Wallingford. The presentation of this paper was supported by HR Wallingford.

#### **Abstract**

A flexible submerged breakwater called "flexible mound", made of an elastic membrane bag filled with water, has been developed for wave control in shallow water as an advanced alternative to the conventional rigid submerged design. Experimental studies were carried out to compare the characteristics of the wave dissipation by flexible mound with those by rigid models. The appropriate ranges of important parameters affecting the efficiency of the flexible type were identified. Numerical studies were also conducted to investigate the mechanism of wave absorption by the flexible structure. To verify the stability and utility of the flexible mound, additional experimental studies were performed using a prototype model. A design concept involved in an actual field construction of the flexible breakwater is also presented.

#### **Introduction**

With more than 30,000 km of coastlines surrounded by rough seas, detached breakwaters, made of concrete blocks, are commonplace in the coastal scenery of Japan. Although these structures serve the intended purpose of shore protection, their undesirable effects on the scenic value of shorelines have been questioned recently. For development of marine recreational zones, there is a particularly strong demand for invisible yet safe and effective wave control methods. Conventional submerged rigid dikes could partially meet this need if it is made very wide with its height close to the water surface. However, it is often too massive for general

2) Ohsaki Research Inst., Shimizu Corp., Chiyoda-ku, Tokyo 100, Japan

3) Public Works Research Inst., the Ministry of Construction, Tsukuba, Ibaraki 305, Japan

applications, and breaking waves and fast currents around the structure could be dangerous to swimmers and small boats. In response to this demand, and as an alternative to the rigid submerged design, the authors have devised a submerged flexible breakwater called "flexible mound", made of an elastic membrane bag filled with water. Earlier studies by Tanaka et al. (1987) and Kiyokawa et al.(1987) have shown that characteristics of wave dissipation by the flexible mound are substantially different from those by a rigid model, and that the flexible mound can effectively dissipate waves even when the submergence ratio is greater than 0.4. The authors have also identified some important parameters and their appropriate ranges for optimum performance of the flexible design.

The objective of the present study is to investigate the mechanism of wave absorption by the flexible mound by physical and numerical model analyses. Experimental studies using a prototype model are also carried out to verify stability and utility of the flexible submerged breakwater.

**Modeling Approach**

The concept of the flexible mound and the definition of parameters used in the present study are shown in Figs.1 and 2, where  $p_0$  is the static internal added pressure;  $\rho$  : the fluid density;  $g$  : the gravitational acceleration;  $\rho_m$  : the membrane density;  $e$  : the membrane thickness; and  $E$  : Young modulus of the membrane.

Fig.1 Concept of Flexible Mound (FLM)

Fig.2 Definition sketch & modeling using lumped-mass method

Since numerical model has been described in detail by Ohyama et al. (1989), only an outline of the numerical analysis is presented here. In this modeling approach, the elastic membrane is discretized into small elements using the lumped-mass method as shown in Fig.3. Forces acting on  $j$ -th nodal point are shown in Fig.4; where  $F_j$  is the hydrodynamic force caused by the pressure difference between the interior and the exterior of the membrane,  $f_j$  and  $f_{j-1}$  are the tensions acting on  $j$ -th and  $j-1$ -th spring, and  $f_0$  is the net weight of the mass in the water. These forces can be represented by using the velocity potentials on the surfaces of the membrane and amplitudes of the membrane motions for all elements. In addition to the assumption inherent in the velocity potential, the motions of the fluid and the membrane are assumed to be sufficiently small, so that the linear theory can be applied. The boundary value problem for the potentials can be transformed into boundary integral equation by applying Green's function and Green's formula. Discretizing the integral equations into finite elements, linear equations for the velocity potentials and the amplitudes of the membrane are obtained.

Wave transmission coefficient,  $K_T$ , and reflection coefficient,  $K_R$ , are obtained from the potential values on the free surface sufficiently apart from the structure.

## Experiments

Physical model experiments were carried out in a wave tank, 40 m long, 0.6 m wide and 1.3 m deep as shown in Fig.5. Two models of the flexible mound were made of reinforced rubber membrane fiber with Young modulus,  $E=5800 \text{ N/cm}^2$ , density,  $\rho_m=1.2 \text{ g/cm}^3$ , and thickness,  $\epsilon=1.5 \text{ mm}$ . The models were then hermetically sealed, filled with water and installed on the bottom of the wave tank. A rigid model was also examined for comparison of mobility effects on wave dissipation. The model configuration and the wave conditions are listed in Tables 1 and 2. During the experiments, it was observed that the stationary component of the internal pressure  $p_0$  shifts steadily upward by  $\Delta p_0$  as a train of waves traverses over the flexible model. Therefore,  $p_0' = p_0 + \Delta p_0$  is the virtual internal pressure during experiments.

A comparison between the experimental and the numerical results for the frequency dependence of the transmission and the reflection coefficients,  $K_T$  and  $K_R$ , is shown in Fig.6, in which  $B$  is the base width of the model, and  $L$  is the incident wave length. Some discrepancies between the numerical and the experimental results are attributable to the fact that the energy loss by the structure's motion in the experiments was not taken into account in the numerical analysis. Nonetheless, this numerical model can qualitatively evaluate governing parameters and their effects on wave dissipation by the flexible mound.

Fig.6 Comparison between numerical and experimental results for wave transmission and reflection characteristics (Case A - 1 : R/h = 0.4, B/h = 2.34, p<sub>0</sub>/ρgh = 0.1)

**Characteristics of wave dissipation**

According to the customary dimensional reasonings, K<sub>T</sub> and K<sub>R</sub> may be expressed by the following dimensionless parameters:

$$K_T, K_R = f(B/L, B/h, R/h, R/H_1, p_0/\rho gh, E/\rho_m gh, \rho_m/\rho, \epsilon/h) \tag{1}$$

A preliminary study (Ohyama et al., 1989) has indicated that, among the eight dimensionless parameters in the group, three parameters, E/ρ<sub>m</sub>gB, ρ<sub>m</sub>/ρ, and ε/h are insignificant in the practical range of application. The rest of the parameters, dimensionless frequency, B/L; width to water depth, B/h; submergence ratio, R/h; relative internal added pressure, p<sub>0</sub>/ρgh; and crown depth to incident wave height, R/H<sub>1</sub>, have influence on the performance of wave control by the flexible structure.

A previous study (Tanaka et al., 1990) has shown that the appropriate ranges of the

parameters,  $B/h$ ,  $R/h$  and  $p_0/\rho gh$ , in order to obtain good performance for a wide range of  $B/L$  are  $B/h : 1.5 \sim 3.0$ ,  $R/h : 0.3 \sim 0.5$ , and  $p_0/\rho gh : 0.03 \sim 0.1$ . These values are used in the subsequent discussion.

Significant factors in the wave dissipation by the flexible mound are found to be 1) interaction between radiation waves and scattering waves, 2) breaking waves over the structure, and 3) energy loss other than the breaking waves. Since the mechanism of the energy loss has not been analyzed in detail, the first two factors are investigated by comparison with the characteristics of wave dissipation by a rigid breakwater. Fig.7 shows the numerical results of the transmission and the reflection coefficients,  $K_T$  and  $K_R$ , versus the parameter,  $B/L$ , for the rigid and the flexible models. The flexible mound can markedly reduce the transmitted wave heights because of the phase interaction between the radiated and diffracted waves, whereas the transmission coefficient is nearly 1.0 in the case of the rigid model. In Fig.7, there

Fig.7 Comparison of  $K_T$  characteristics between for a rigid model and a flexible model

Fig.8 Amplitude ratio and phase differences of radiation wave to scattering wave.

are wave periods, A, B and C, at which  $K_T=0.0$ . At these points, the scattering and the radiation waves have the same height but are in the inverse phase as seen in Fig.8. Thus, it is concluded that the phase interaction between the radiation and the scattering waves plays the primary role for wave dissipation by the flexible mound. The points where no waves transmit may be related to the natural periods of the flexible mound.

Fig.9 shows the experimental results of  $K_T$  versus  $B/L$  for the rigid and the flexible models under breaking wave conditions. The parameters,  $R/H_1$  and  $B/L$ , are important for the wave dissipation for the rigid model. As is well-known, when  $R/H_1$  is greater than 2.0 or  $B/L$  is less than 0.3, a rigid model cannot reduce the transmitted wave heights because the incident waves propagate over the structure without breaking (Nagai et al., 1977). The breaking waves may also play an important role in wave dissipation by flexible dikes when  $R/H_1$  is small. As shown in Fig.9, however, the characteristics of wave dissipation for the flexible model are different from those for the rigid model under the condition of wave breaking. This indicates that the transmitted waves for the flexible model may be reduced not only by the wave breaking but also by the wave interaction.

Fig.9 Effect of wave breaking on transmission coefficients by experiments  
 (Case A - 2 :  $R/h = 0.4$ ,  $B/h = 2.34$ ,  $p_0/\rho gh = 0.5$ , Case B - 1 :  $R/h = 0.46$ ,  $B/h = 2.29$ ,  $p_0/\rho gh = 0.5$ , Case C - 1 :  $R/h = 0.2$ ,  $B/h = 3.56$ )

Since a flexible mound is a kind of multi-degree-of freedom oscillation system, it is expected to respond sensitively to the wave periods. Therefore, it is important for practical design of the flexible breakwater to evaluate the effects of irregularity of wave field on the wave dissipation. Fig.10 shows the experimental results for regular and irregular waves for which the incident wave heights,  $H_1$  and  $H_{1/3}$ , are 8cm and between 6.2 and 8cm, respectively. Bretschneider-type spectra (Bretschneider, 1968), with the significant periods, 1.24, 1.43 and 1.63, were used for irregular waves. The performance of  $K_T$  for irregular waves is insensitive to  $B/L$  compared to the results for the regular waves, a desirable feature for practical applications.

Fig. 10 Comparison between regular & irregular waves (exp.)

**Utility and Application of the flexible mound**

A prototype model of the flexible mound, which has a 4 m-wide base and is 1.2 m high, was designed according to the aforementioned experimental and numerical studies. The layout of the setup is shown in Fig.11. Experimental study was carried out to verify the effectiveness of wave control, the durability of the membrane, and the stability of the seabed around the structure under the conditions;  $h = 2\text{ m}$ ,  $R/h = 0.4$ ,  $p_0/\rho gh = 0.05$  and  $B/h = 2.0$ . Fig.12 indicates an example of the characteristics of  $K_T$  versus  $B/L$  when  $R/H_I$  varies from 0.89 to 3.1. The prototype model achieved transmission coefficients of less than 0.5 in broad ranges of  $R/H_I$  and  $B/L$ . Figs.13 and 14 show experimental results of scouring around the structure and evolution of beach profile behind the structure. The maximum depth of scouring around the structure is about 30% of incident wave height even under storm surge condition, an insignificant factor in general application. The evolution of beach profile behind the flexible mound is also the same level as those of conventional submerged breakwaters. The durability of the membrane and the stability of the structure's base have also been verified in this experiment.

Fig.13 The scoring profile around the flexible mound

Fig.14 The evolution of the beach profile behind the flexible mound

The flexible mound is not only useful as an improved alternative to the ordinary submerged breakwaters but is also effective as an emergency breakwater, that can be inflated only during a storm passage. Two units of the flexible mound, 9 m wide, 40 m long and 3 m high, have been installed recently at an entrance of a small harbor shown in Fig.15. The units are normally deflated, flush with the sea floor with water-supply-drainage system so that passenger liners can pass over the structure. During a storm surge, the mounds are inflated by the water and serve as emergency breakwaters. Photo.1 shows a inflated membrane at a construction yard. Before the installation, it has been verified by 3-dimensional model tests that the flexible structures can reduce transmitted wave heights to less than 50 % of incident wave on average.

## **Conclusions**

A flexible submerged breakwater, composed of a thin membrane bag filled with water, has been developed for wave control in shallow water as an alternative to the conventional rigid type. The flexible dike can be made more compact compared to the rigid type, and controls waves without sacrifice to the scenic value of the coastal landscape. A noteworthy feature of the flexible design is that it utilizes the interaction of incident and scattering waves with radiation waves generated by the membrane's motion.

Major findings are summarized as follows:

- (1) Three factors, 1) wave interaction, 2) wave breaking over the structure and 3) energy loss other than breaking waves, are related to the mechanism of wave dissipation by the flexible breakwater. The interaction of the scattering waves with the radiation waves, generated by the membrane's motion, plays the most important role in wave dissipation. The performance of the wave interaction is effective when the scattering and the radiation waves have the similar height but in the inverse phase. In addition to the interaction, the wave breaking is also important for the dissipation of the wave energy when the crown depth to incident wave height,  $R/H_1$ , is small. The energy loss excluding wave breaking also has some significance. Its mechanism is currently being investigated by writers.
- (2) Although the flexible dike consists of a multi-degree-of freedom oscillation system, characteristic of wave dissipation for irregular waves is not sensitive to wave periods.
- (3) The effectiveness of wave dissipation by the flexible mound, the durability of the membrane and the stability of the structure were verified by a prototype model test for a wide range of wave conditions.

- (4) The flexible mound is not only useful as an improved alternative to the conventional submerged breakwaters but is also effective as an emergency breakwater, that can be inflated only during a storm passage. Two units of flexible mound have been installed at an entrance of a harbor as a emergency dike, recently.

## CHAPTER 124

### FIELD EXPERIMENTS ON A DUAL CYLINDRICAL CAISSON BREAKWATER

\* Katsutoshi TANIMOTO\*, Hiroshi ENDOH\*\*, Shigeo TAKAHASHI\*\*\*

#### INTRODUCTION

A deepwater caisson breakwater as shown in Fig.1 has been developed by the Ministry of Transport, Japan. The new breakwater is a composite breakwater with a cylindrical caisson named as dual cylinder caisson. The caisson has dual cylindrical walls and its outer cylinder has a perforation in the fore half of the upper portion, forming a wave chamber of a doughnut shape bounded by its inner impermeable cylinder.

A series of laboratory experiments had been carried out at the Port and Harbour Research Institute from 1985 to 1988<sup>1)3)</sup>. According to the laboratory experiments, the caisson was found to have advantages of low reflection and high stability. The design method of the caisson was proposed through intensive laboratory studies in 1988.

Prototype experiments of the dual cylindrical caisson breakwater have been conducted in order to verify its proposed design method against waves at Sakai Port by the Third District Port Construction Bureau, since 1989. A distinguished attempt in the field experiments was tried to measure the displacement of caisson as well as wave pressures during sliding due to high waves. This attempt was accomplished by a storm occurred on February 17, 1991.

Photo 1 shows a scene of the test breakwater after the storm. The middle caisson was slid and fallen down from the rubble mound. The middle caisson is the test caisson which was designed against a

Photo. 1 Slid Caisson in Sakai Port

design wave with one year return period, while the other two caissons were designed with the 50-years return period wave.

After the field test of sliding, model experiments with a scale of 1/21 were performed in a wave basin to reproduce the field situation and investigate the details of the phenomena. The present paper describes both results of field and laboratory experiments, especially on the wave forces and the sliding stability of the caisson in comparison with the proposed design method<sup>4</sup>).

#### DESIGN OF TEST CAISSON AND MEASURING SYSTEM

##### Calculation Method of Design Wave Force

The proposed method to calculate design wave forces and the design of the test caisson for the sliding test are explained here before showing the experimental results.

Fig. 2 Three Phases of Wave Action

Fig. 3 Distribution of Wave Pressure

Figure 2 demonstrates three phases of wave action which must be considered in the caisson design against waves. The phases I indicates the phase when the wave force on the front side of the outer cylinder peaks. At this phase the resultant upward vertical force  $F_V$  mostly has its peak during one cycle of wave action and the horizontal wave force on the caisson  $F_H$  is large. Consequently, the stability against sliding is most critical at this phase.

The phase II indicates the phase when the wave pressure in the wave chamber is predominant. At this instant, the horizontal wave force  $F_H$  peaks, but the vertical force  $F_V$  is generally small due to a large amount of seawater in the wave camber. The phase III is when the water surface in front of the caisson is the lowest. The horizontal force has its negative peak (maximum to the showered) at this phase. The phase II and III are important for the design of the structural strength of the caisson.

A general distribution of the design wave pressure for the phase I and II is shown in Fig. 3. The intensity of wave pressure on each structural member can be obtained from the Goda pressure formula<sup>1)2)</sup> with each modification factor, which had been obtained from the model experiments<sup>3)</sup>. It should be noted that the pressure on the upper half of the outer cylinder in Fig.3 is defined as the difference between the pressures of outer and inner faces of the perforated wall and that the wave pressure is assumed to exert up to the elevation of  $0.75 \eta_{G^*}$  above the still water level.

The basic pressure distribution is calculated by the Goda pressure formula with  $\alpha_2 = \theta$  as follows:

$$\eta_{G^*} = 0.75(1 + \cos \beta) H_D \tag{1}$$

$$p_{G1} = 0.5(1 + \cos \beta) \alpha_1 W_0 H_D \tag{2}$$

$$p_{G3} = p_{G4} = \alpha_3 p_{G1} \tag{3}$$

where  $\alpha_1 = 0.6 + 0.5 \left[ \frac{4\pi h}{L_D} / \sinh(4\pi h / L_D) \right]^2$  (4)

$$\alpha_3 = 1 - (h'/h) [1 - 1/\cosh(2\pi h / L_D)]$$
 (5)

Fig. 4 Wave Pressure Distribution in Horizontal Sections at Phase I

Fig. 5 Wave Pressure Distribution in Horizontal Sections at Phase II

$\beta$  : the angle of wave approach measured from a line normal to the breakwater alignment,  $H_D$ ,  $L_D$  : the wave height and length applied to the calculation of design wave forces,  $w_0$  : the specific weight of seawater,  $h$  : the water depth in front of the breakwater,  $h'$  : the distance from the design water level to the bottom of the caisson.

The wave pressure distribution in the horizontal sections and values of the modification factors are shown in Fig. 4 for the phase I. The wave pressure is assumed to act uniformly on the fore half of cylinders for the action of non-breaking waves. The modification factor  $\lambda_{OF}$  for the perforated wall is 0.65, and the modification factor  $\lambda_{OF}$  for the lower impermeable part of the outer cylinder is 0.9. The modification factor  $\lambda_{IF}$  for the front half of the inner cylinder is 0.15. The modification factors at the phase II are similarly shown in Fig. 5.

The negative wave pressure at the phase III can be obtained appropriately according to the fourth order approximation of a finite amplitude standing wave theory. The residual water level in the wave chamber, however, must be separately given as  $\eta^- = 0.25 H_D$ . The pressures in the wave chamber is the hydrostatic water pressure corresponding to the difference between the water level and the still water level.

#### Design Condition and Safety Factor Against Sliding

The design wave with a return period of one year was selected for the sliding test caisson. The design conditions are as follows:

$$\begin{aligned} H_1/3 &= 2.6 \text{ m}, H_D = H_{MAX} = 4.7 \text{ m}, \\ \beta &= 0, \text{ Design tidal level} = + 0.4 \text{ m} \end{aligned}$$

Figure 6 shows a cross section of the sliding test caisson. The caisson is a reinforced concrete caisson with the outer diameter of 16.2 m and the height of 10.4 m. The opening ratio of the perforated wall is 0.25. The inside of caisson is filled with only water to reduce the caisson weight for the sliding test. The caisson weight deducted the buoyancy in seawater is 860 tf.

Fig. 6 Cross Section of Sliding Test Caisson

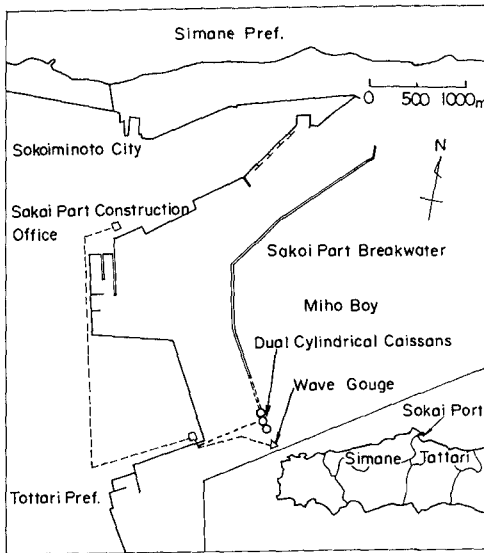

Fig. 7 Test Caissons in Sakai Port

The safety factor  $SF_s$  against sliding is defined by the following relation:

$$S F_s = \mu (W_0 - F_v) / F_H \quad (6)$$

where  $\mu$  is the friction coefficient between the bottom slab of caisson and the rubble mound foundation, and it is taken as 0.6 according to the design standard of breakwaters. The safety factor of the test caisson is 0.98 against the calculated wave force.

### Measuring System

Figure 7 shows the plan of Sakai Port and the location of the test breakwater. The test breakwater is isolated one consisting of three units of caissons. The middle caisson is the sliding test caisson.

The wave profile and wave direction were measured by a set of wave gauges and velocity meters which located at the position 250 m away from the test breakwater as in the figure. Thirty four pressure transducers were attached to the sliding test caisson to measure the wave pressure distribution and to calculate the resultant wave force. Six displacement meters of wire type were equipped at the top and the bottom of the caisson. They were fixed on the neighboring caissons and on armor concrete blocks for the rubble mound foundation. The data of the pressures and displacements were recorded continuously during storms by a computer in an on-land observation house.

## SOME RESULTS OF FIELD EXPERIMENTS

Example of Analogue Records

Figure 8 shows an example of field records obtained during the storm in February 17, 1991. The top record indicates the water surface oscillation measured by the wave gage. The middle record indicates the wave pressure profile at the impermeable front wall. It is noticed that the time profile of the pressure is well correlated to that of the water surface elevation. This is because the incident waves to the breakwater are diffracted waves by a peninsula (Zizou-misaki Cape of Shimane Peninsula) and have relatively long crests and the wave angle is almost zero. The bottom record shows the horizontal displacement of the caisson measured at the bottom. The first sliding is not included in this figure and the displacement from the second to the fifth sliding is shown in the figure. The capacity of the displacement meters was

Fig. 8 Sample Record during the Storm on the 17th of February 1991

Table 1 Waves and Sliding Distances

TIME	$H_{max}$ (m)	$H_{1/3}$ (m)	$T_{1/3}$ (s)	$S_a$ (m)	$\Delta S$ (m)	
2:45-3:00	3.15	2.05	14.1	1.06	1.06	once
3:00-3:15	2.77	1.72	13.1	1.06	0	no

3:45-4:00	3.17	2.23	13.4	>5		

5 m and therefore, the wires of the meters were cut off when the sixth sliding occurred.

Wave Conditions and Sliding Distances

The first sliding was recorded at 02:50:40 on February 17 and the sixth sliding was occurred at 03:53:47 on the same day. Observed waves were analyzed for every 15 minutes from 02:45:00 to 04:00:00. The results are shown in Table 1 together with data of the sliding distances, in which  $S_A$  denotes an accumulated sliding distance and  $S$  denotes the sliding distance during each 15 minutes. For the first 15 minutes, the maximum wave height is 3.15 m, the significant wave height and period are 2.05 m and 14.1 s, and the first sliding occurred which distance was 1.06 m. The tidal level is observed as 0.31 m above the datum level at this time. This sliding distance by one wave is considerably large due to the non breaking wave action having a relatively long wave period in this case.

Measured Wave Pressure Intensity

Figure 9 demonstrates the order of the magnitude of the wave pressure measured at several points of the caisson. In this figure, the representative positive wave pressure intensities like  $P_{max}$ ,  $P_{1/10}$ , and  $P_{1/3}$  are plotted against the corresponding representative wave heights like  $H_{max}$ ,  $H_{1/10}$ , and  $H_{1/3}$ . Relatively large pressure intensities appear at the most rear part in the wave chamber, but the intensity is less than  $1.0 w_0H$ .

Fig. 9 Pressure Intensities in the Field Experiments

## LABORATORY EXPERIMENTS AND COMPARISON WITH FIELD DATA

Wave Conditions

Laboratory experiments were carried out to reproduce the field experiment in a wave basin with a model scale of 1/21 using uni-directional irregular waves. Seven kinds of laboratory waves having different wave heights and periods were used in the experiments. Two of them are corresponding to the November storm waves and others are corresponding to the February storm waves, which wave conditions are listed in Table 1. The November storm is a short and small storm just after the completion of the caisson installation. For each of them five different wave trains were prepared. Representative wave parameters according to the zero-upcrossing method are presented in Table 2 with the mean value and the standard deviation for five wave trains. The duration time of one wave train is 15 minutes. The wave direction is perpendicular to the breakwater alignment.

The wave spectra for the November storms are represented by the Modified Bretschneider-Mitsuyasu (MBM) spectrum. For the February storm, however, the MBM spectrum is not applicable, because the observed spectrum is very sharply peaked. Therefore, the JONSWAP type is applied as the target spectrum of the February storm. The peak parameter in the JONSWAP spectrum can be selected so that the realized spectrum coincides with the spectrum observed in the field as much as possible. Figure 10 shows the comparison of the wave spectra in the field and in the laboratory.

Fig. 10 Wave Spectra in the Field and Laboratory

Fig. 11 Measured Instantaneous Pressure Distribution

Wave Pressure Distribution

Figure 11 shows an example of the instantaneous distribution of wave pressures when the wave force at the phase 1 is the largest during the action of random waves. Both data measured in the field and the laboratory are shown together with the distribution calculated by the proposed method. Although the measured wave pressure are considerably larger than the calculated ones at the front of the inner cylinder, it can be said that the proposed method predicts well the wave pressure distribution as a whole. The resultant wave forces are calculated from such an instantaneous distribution of the wave pressures by considering application areas of caisson walls shared by respective measuring points.

Horizontal and Vertical Wave Forces

Peak values of measured and calculated wave forces for the

phase I are compared in Figs. 12 and 13. In the figures, the ordinate indicates the measured force and the abscissa indicates the calculated force. The horizontal wave forces are shown in Fig. 12, where the measured wave forces in the laboratory experiments are generally larger than the calculated ones, but the laboratory data agree well the field data. Data of the vertical wave forces in Fig. 13 are widely scattered. The main reason is that the amount of water in the wave chamber at the phase I varies considerably depending on the wave periods and wave trains.

Fig. 12 Horizontal Wave Forces Fig. 13 Vertical Wave Forces

Fig. 14 Equivalent Sliding Forces

Figure 14 shows the peak values of calculated and measured equivalent sliding forces which are equal to  $(F_H + \mu F_V)$ . The ordinate indicates the measured force and the abscissa indicates the calculated force. The equivalent sliding forces in the laboratory experiments are generally larger than the calculated ones, as the horizontal forces in Fig. 11. However, it should be noted that the equivalent sliding forces measured in the field are a little lower than those in the laboratory and are almost the same as the calculated ones. The measured wave forces scatter significantly in the figures. This is because the wave profile varies even though the wave height is the same. Therefore, this may be the reason of the difference between the values in the laboratory and the field.

Relation between Safety Factor and Sliding Distance

In the laboratory experiments, the horizontal displacement was measured for two possible weights of the sliding test caisson. The one is corresponding to the design weight, and the other is the weight assumed that the water level inside the inner caisson lowers to the tidal level. They are denoted by  $W_1$  and  $W_2$ , respectively.  $W_2$  is calculated as 781 tf in a still water and is 90% of  $W_1$ . Because it is difficult to prevent the leakage of water from the inner cylinder, the weight  $W_2$  is presumably the weight during sliding.

Fig. 15 Safety Factor and Sliding Distance

In the laboratory experiments, the friction coefficient was also measured. Since the sliding in the field occurred only three months after its installation and no large storms attacked the caisson until the sliding occurred, the compaction of the rubble mound by the caisson movements was not enough to get the ordinary friction factor of 0.6. The measured friction coefficient without the compaction of the rubble mound were about 0.55 in the laboratory experiments.

Figure 15 shows the results of sliding tests in the laboratory. The ordinate indicates the maximum sliding distance by one wave during the action of irregular waves. The abscissa indicates the safety factor against sliding, which is calculated for the measured wave forces, the caisson weight ( $W_1$  or  $W_2$ ), and the friction coefficient of 0.55. The results shows that the caisson slides in most cases having the safety factor less than 1.0. Thus, the results of laboratory experiments suggests that the occurrence of the sliding can be judged by the safety factor.

#### Safety Factor against Sliding for the Field Data

The safety factor against sliding which is calculated according to the measured wave forces is shown in Table 3 for the condition of the first sliding in the field. The caisson slid by 1.06 m during the first sliding. The safety factor is 0.93, less than 1.0, when the friction factor is assumed to be 0.55 and the caisson weight is  $W_2$ . Even if the caisson weight is  $W_1$  and the friction factor is 0.6, the safety factor is less than 1.2. Therefore, it can be concluded that the caisson sliding can be judged by its safety factor also in the field experiments.

Table 3 Safety Factor against Sliding

$w_0$ (tf)	$\mu$	S. F.
895	0.60	1.19
895	0.55	1.10
781	0.60	1.01
781	0.55	0.93

The safety factor using the calculated wave forces, the caisson weight of  $W_2$  and the friction coefficient of 0.55 is 0.87. Because the measured wave forces in the field are almost the same as the calculated wave forces, the safety factor against sliding using the calculated wave forces is close to that using the measured wave forces.

#### CONCLUDING REMARKS

Slidings of a prototype dual cylinder caisson were successfully measured in the field verification experiments. The slidings of the caisson were reproduced in laboratory experiments. The major conclusions in this study are as follows:

1) The sliding of the caisson can be judged by its safety factor

- using the measured wave forces, the caisson weight and the friction factor both in the field and in the laboratory.
- 2) The measured wave forces acting on the caisson in the field were almost the same as the calculated wave forces. Therefore, the sliding of the caisson in the field can be judged also by the safety factor using the calculated wave forces.
  - 3) The measured wave forces in the laboratory are larger than those in the field as a whole. However the difference is not significant and this is because of the wide variation of the laboratory data.

#### ACKNOWLEDGMENTS

The field experiments have been conducted under the guidance of the advisory committee chaired by professor Y. Goda. The experiments were carried out by the collaboration with many engineers especially of the Sakai Port Construction Office and the Kobe Design and Investigation Office of the Third District Port Construction Bureau, MOT. The authors wish to express their sincere gratitude to all the people.

## CHAPTER 125

# Pressure Oscillations during Wave Impact on Vertical Walls

M.E.Topliss\*    M.J.Cooker†    D.H.Peregrine‡

### Introduction

This area of study concerns wave impact pressure on vertical structures. Severe damage can be inflicted on coastal defences during storms and numerous laboratory experiments have been undertaken to gain an understanding of the physical processes. This paper gives a mathematical description of high frequency pressure oscillations which are observed in measurements of water-wave impacts; particularly impact against a vertical wall. Our ultimate aim is to trace the physical origins of the pressure fluctuations which are related to the understanding of the role of fluid compressibility in breaking wave impact pressure. It has been suggested by some authors that the recorded pressure oscillations are due to the vibrations of air-filled gas bubbles, for example Weggel & Maxwell (1970) model some details of acoustic wave propagation. In addition, it is well known that the compressibility of a small volume fraction of air in water dramatically reduces the velocity of sound in the mixture. We investigate possible cases by simplifying the geometry and finding the frequency of free oscillations. We ignore the main flow of water since it has a longer time-scale. Our initial model considers compressible aerated water near the wall and compressible non-aerated water with a much higher sound speed further away. This is compared with a simple example of an air pocket trapped against a wall in incompressible water. Comparisons with three experimental results are encouraging.

### Bubbly mixture near a wall

This model applies to the instances when a wave has broken creating a volume of water with many small bubbles next to the impact wall. This is now a compressible mixture.

Consider a region of uniform bubbly mixture (region 1) with a gas fraction  $\alpha$  next to a vertical wall, and non-aerated water on the other side (region 2) as shown in figure 1.

We treat the solid wall and solid bed as rigid so that the component of displacement normal to these boundaries vanishes. As there is a large density contrast between the fluid and the air above, we take the pressure to vanish at the free surface. For linearised theory and sinusoidally varying velocity potential  $\phi(x, y) e^{i\omega t}$  this implies  $\phi$  may be taken to be zero on the free surface.

Figure 1. Limited volume of bubbly water

Sound waves are weak pressure disturbances which propagate at high speed through a fluid. The sound velocity in air is approximately 340 metres per second; that in water is approximately 1500 metres per second. In a mixture of air and water however, the speed of sound is dramatically reduced. The density in region 1 is taken to be  $\rho_1 = (1 - \alpha)\rho_2$  where  $\rho_2$  is the density in region 2. We have taken the speed of sound in region 1 as derived by Hsieh & Plesset (1961) to be

$$c_1^2 = \frac{\gamma p}{\rho_1 \alpha (1 - \alpha)},$$

where  $p$  is the atmospheric pressure,  $\rho_1$  is defined above,  $\gamma$  is the ratio of specific heats,  $\alpha$  is the gas fraction. For example 1 percent, 4 percent and 10 percent aeration give sound speeds of 120 m/s, 60 m/s and 40 m/s respectively, and this accords with experimental measures. The expression for  $c^2$  is a good empirical rule provided  $\alpha$  is not too near 0 or 1.

Viscosity and gravitational effects will be ignored. The reduced wave equation,

$$(\nabla^2 + k_i^2) \phi_i = 0$$

where the subscripts  $i = 1, 2$  refers to regions 1, 2 respectively and  $k_i = \omega/c_i$  where  $\omega = 2\pi f$ , is solved by separation of variables.

As the free surface and the rigid bed are totally reflecting surfaces the fluid can be considered as an acoustic plane waveguide and a standing wave field results, which has a cut-off frequency  $\omega_n$  for each mode of oscillation, below which no propagation occurs. In region 2 the sound speed is very much higher and therefore  $\omega$  maybe less than the cut-off frequency and there is no propagation. The velocity potential for the bubbly mixture in this instance is:

$$\phi_1 = A_1 e^{\sqrt{k_1^2 - \gamma_n^2} L} \cos(\gamma_n y) \cosh \left[ \sqrt{k_1^2 - \gamma_n^2} (x + L) \right] e^{i\omega t}$$

and for the non-aerated water outside the bubbly mixture is

$$\phi_2 = A_1 e^{\sqrt{k_1^2 - \gamma_n^2} L} (1 - \alpha) \cos(\gamma_n y) \cosh \left[ \sqrt{k_1^2 - \gamma_n^2} L \right] e^{-\sqrt{\gamma_n^2 - k_2^2} x} e^{i\omega t}$$

where  $c_2 =$  the speed of sound in non-aerated water,  $\gamma_n = n\pi/2H$ ,  $n = 1, 3, 5, \dots$ ,  $H$  is the depth of the fluid,  $L$  is the width of the bubbly layer,  $A_1$  is a constant.

Assuming pressure and normal velocity are continuous across the interface between region 1 and region 2, we find an expression for the frequency of modes of oscillations trapped in region 1:

$$(1 - \alpha) \sqrt{\gamma_n^2 - k_2^2} = \sqrt{k_1^2 - \gamma_n^2} \tan \left[ \sqrt{k_1^2 - \gamma_n^2} L \right]$$

For a fixed width and air content, a high free surface will give a low frequency as illustrated in figure 2. Figure 3 shows that, for a fixed amount of air and depth, a wider region will have a lower frequency. Conversely a very narrow band of bubbles against a rigid wall will produce very high frequencies. Both figures show higher frequencies with a lower aeration level.

Figure 2. Variation of  $f$  with  $H$

Figure 3. Variation of  $f$  with  $L$

### A trapped air pocket

To model of a trapped air pocket against a vertical wall we now have to take into account a) the presence of the free surface, b) the cylindrical geometry of the gas pocket, c) the presence of the rigid wall.

Suppose the bubble contains air at atmospheric pressure and that it's centre is submerged a distance  $h$  below the free surface and lies a distance  $d$  above the seabed as shown in figure 4. The water is taken to be incompressible.

Figure 4. Trapped air pocket at the wall

We model the vibrations of the trapped air pocket by considering the radial oscillations, translation and shape oscillations of a single two dimensional bubble with semi-circular cross-section of radius  $r$ . As this study concerns only relatively large bubbles, surface tension effects can be neglected as they are only significant for small radii. During the short time in which the bubble oscillates regularly we suppose that the free surface moves very little so that we may again ignore the flow in the impacting wave. We take an image of the bubble above the free surface to be oscillating in anti-phase with respect to the bubble, an image below the rigid bed to be oscillating in phase, and a third image below, oscillating in anti-phase, to ensure symmetry as shown in figure 5. These images then extend above and below to produce an infinite series which is summed analytically. The potential for this model is

$$\phi = -\alpha_0 \log \left[ \frac{\cosh(\lambda z) - \cos(\lambda d)}{\cosh(\lambda z) + \cos(\lambda d)} \right] + \frac{\alpha_1}{(z - z_0)} + \frac{\alpha_2}{(z - z_0)^2}$$

where  $\lambda = \pi/2(d + h)$ ,  $z_0$  = the position of the bubble,  $i = \sqrt{-1}$ ,  $\alpha_0, \alpha_1, \alpha_2$  are constants. Figure 6 shows the pressure contours from a two dimensional bubble.

The logarithmic term, which is the dominant term, represents the radial oscillations. The second term, evaluated on the bubble surface,

$$\frac{\alpha_1}{(z - z_0)} = -\alpha_0 \frac{\lambda r}{2} [\cot \lambda d + \tan \lambda d] \sin \theta ,$$

represents translational motion and the third term, evaluated on the bubble

surface,

$$\frac{\alpha_2}{(z - z_0)^2} = \alpha_0 \frac{\lambda^2 r^2}{8} [4 + \tan^2 \lambda d - \cot^2 \lambda d] (2 \cos^2 \theta - 1) ,$$

represents a first approximation to shape oscillations.

We calculate the time-harmonic irrotational flow induced by the semicircular two dimensional bubble and the frequency of the small oscillations is given by

$$\omega^2 = - \frac{2\gamma p [1 + \frac{1}{2}\lambda^2 r^2]}{\rho r^2 [\log(\frac{1}{2}\lambda r \tan \lambda d) + \frac{1}{4}\lambda^2 r^2]}$$

$p$  is the atmospheric pressure,  $\rho$  is the density of water. As figure 7 shows, for fixed  $h + d$ , an air pocket nearer the rigid bed will have a lower resonant frequency than an air pocket nearer the free surface. The size of the air pocket is inversely proportional to the frequency as illustrated in figure 8. This corresponds to the previous model for the bubbly mixture which showed high frequencies are obtained for lower aeration.

i) as  $h$  becomes large,

$$\omega^2 = - \frac{2\gamma p}{\rho r^2 \log [2rd/R]},$$

the frequency for a single two dimensional bubble in the vicinity of a rigid boundary, where  $R$  is a large number representing a boundary far away. This is to ensure boundary conditions in the far field are satisfied.

ii) as  $d$  becomes large,

$$\omega^2 = - \frac{2\gamma p}{\rho r^2 \log [r/2h]},$$

the frequency for a single two dimensional bubble in the vicinity of a free boundary (Topliss 1991).

## Comparisons with experiments

We have considered three experimental studies for comparison with these theoretical results:

I) Hattori & Arami (1992); Chuo University, Japan

Hattori & Arami have provided us with many details of their experiments which investigate the importance of an air pocket between the breaking wave and the wall. The experiments were undertaken in a small wave tank (still water depth at the wall of five centimetres) and high-speed video frames were taken of waves as they impact on a vertical wall and some waves appear to trap a cylinder of air against the wall. Records from six pressure gauges of one centimetre diameter are available.

The histories of the pressure, measured at the wall, for these waves exhibit three stages. Initially the pressure rises to a peak value and is followed by an interval of regular smooth oscillations, of decreasing amplitude. These oscillations are displayed with the same frequency in all six pressure gauges. Clearly this decay requires further modelling. This finally develops into a more confused signal, consisting of higher frequencies with lower amplitudes, and which carries on for an indefinite time.

As the wave advances towards the impact structure, it begins to curl over, entrapping an air pocket against the wall. In the video frames following the impact, it can be seen that the free surface rises and a thin jet of water shoots up the wall. We neglect this since it is usually much thinner than the bubble until a later stage and assume a flat surface in our models. For each experiment we have considered, we have taken measurements from the first three frames at the beginning of the oscillations and compared the frequency calculated for that geometry with the frequency given by the pressure gauges. The theory compares particularly well for large air pockets, see table 1.

II) Witte (1988); Leichtweiss-Institut, Germany

Witte describes a wave impact against a vertical wall and observed an air pocket trapped against the impact wall. The wave tank had a still water depth at the wall of sixteen centimetres and fourteen pressure cells. Full details are given of one case (example no.13, figure 6.3, type II). Regular oscillations are recorded in all cells of period 12 milliseconds, or a frequency of 83.3 Hertz. If we choose  $h = 0.22$  m and  $d = 0.05$  m (no photographs are given but the description given by Witte suggests that the air pocket is nearer the bed than the free surface) then, from figure 9 below where the variation of frequency with size of air pocket is presented, a bubble of radius 0.0155 m would give a frequency of 83 Hertz. Although no photos are available, the statistics presented in Witte (1988) for this type of impact give scope for further study.

## III) Graham &amp; Hewson (1992); Plymouth University, England

Graham & Hewson have carried out model-scale experiments of waves breaking against a vertical wall, with three pressure transducers and one aeration gauge in order to investigate aeration levels of a wave impacting upon structures. No previous work (to our knowledge) has been carried out on aeration measurements and with the kind permission of Graham & Hewson we are able to compare our theoretical work with the preliminary work carried out at Plymouth. Video frames are not yet available.

After impact the pressure transducers show both rapid fluctuations and an underlying frequency of approximately 30-40 Hertz. Although we have been unable to find an example which would give a frequency this low, the rapid fluctuations are in the range of 100-300 Hertz which is consistent with other experiments. The levels of aeration shown range between 4 percent and 20 percent. If we estimate the depth of the water at the wall to be 0.1 metres and the width of the bubbles to be 0.04 metres we can expect frequencies of between 100 and 260 Hertz, as illustrated in figure 10. These are within the range of frequencies measured in the experiments.

## Discussion

We have not yet been able to compare the theory with large scale experiments, although studies are been undertaken in Hannover (Schmidt, Oumeraci & Partensky 1992), where double peak forces have been recorded along with negative pressures. Table 2 gives examples of how scale effects could vary the frequencies according to the size and position of an air pocket trapped. We have taken an example from table 1 (data No.132-3) and altered the geometric parameters.

	radius $r$ (metres)	distance $d$ (metres)	distance $h$ (metres)	frequency $f$ (Hertz)
	0.008	0.031	0.040	207
x 5	0.04	0.155	0.2	42
x 10	0.08	0.31	0.4	21
x 50	0.4	1.55	2.0	4.2
x 100	0.8	3.1	4.0	2.1

Table 2. Variation of geometries for a trapped air pocket

For a wave which breaks giving a bubbly mixture, table 3 gives examples of frequencies which could be obtained in a larger volume. Here we have taken the gas fraction to be 0.1.

	height H (metres)	width L (metres)	frequency $f$ (Hertz)
	0.1	0.04	146
x 5	0.5	0.2	106
x 10	1.0	0.4	14.6
x 50	5.0	2.0	10.6
x 100	10.0	4.0	1.46

Table 3. Variation of geometries for a bubbly mixture

Table 2 and 3 show that the frequency varies linearly with the geometric parameters, a property easily deduced from the equations. For the lowest frequency shown above, a typical compressible length = wavelength /  $2\pi$  which is approximately 160 metres in pure water but only 5 metres for 10 percent aeration indicates that for the largest waves that trap air, sound propagation is important as has been noted by Schmidt, Oumeraci & Partenscky.

This work has only studied free oscillations. The initial forcing, amplitude and damping of the oscillations all require further study. The decay of the regular oscillations, well illustrated by the experiments of Hattori & Arami (1992), are due to damping which could be the result of several mechanisms: viscous damping, thermal damping or acoustic radiation. There are also radiating modes which need investigation.

The financial assistance of SERC is gratefully acknowledged.

## CHAPTER 126

### WATER PARTICLE VELOCITIES ON A BERM BREAKWATER

Alf Tørum <sup>1</sup> and Marcel van Gent <sup>2</sup>

#### ABSTRACT

Water particle velocities in waves running up and down a berm breakwater have been measured for several wave heights and wave periods with a Laser Doppler Velocimeter (LDV).

The measured water particle velocities have been compared with velocities computed with the numerical model ODIFLOCS. There is a fair agreement between the calculated and measured velocities.

#### 1 INTRODUCTION

It is the velocity field on a breakwater front that is the main governing factor with respect to the stability of the armour cover blocks. This velocity field and the forces on a cover block have been poorly known.

The different formulae that have been presented on the required block weight, e.g. Iribarren (1938), Hudson (1985) and Hedar (1960) have been based on some approximate concept of the velocities and the forces, leading to formulae with a single unknown coefficient. The value of this coefficient has been determined from model tests.

One of the first attempts to calculate and measure the velocities for downrush on a rubble mound breakwater model was made by Brandtzæg and Tørum (1966), Brandtzæg, Tørum and Østby (1968). They measured velocities

with a micro propeller. The measurements were made at one height above the slope and gave no details about the velocity variation from the slope face and up towards the water surface. There was a fair agreement between the measurements and the simple mathematical model that was derived to calculate the velocities in downrush.

Sawaragi et al. (1982) measured particle velocities on the breakwater slope by filming particles made of sponge with the same specific mass as water introduced in the water. The point to point movement of the particles was recorded on 16 mm colour films taken by a high speed film camera (50 frames per sec). From the film the particle velocities were obtained by superposition of projected film frames to give a distance and a time interval of movement. Sawaragi et al. found that the non-dimensional maximum velocity was a function of the surf similarity parameter and the ratio of the wave height to the water depth. Sawaragi et al. did not compare their velocity measurements with any theoretical results.

Kobayashi et al. (1987) and Kobayashi and Wurjanto (1989) developed a numerical model for the computation of the water particle velocities on an impervious rubble mound slope. This model is based on the finite amplitude shallow water wave equation. By use of this model they can calculate the vertically averaged horizontal velocities as well as run up and run down. They compared the calculated run up with measurements, which showed fair agreement, but did not make any comparisons between calculated and measured velocities.

Breteler and van der Meer (1990) report the measurement and computation of wave induced velocities on a smooth slope. The measurements were made with an electromagnetic current meter. The computations were made with the computer program developed by Kobayashi and Wurjanto (1989). Breteler and van der Meer concluded that there was a fair agreement between the measurements and the computations with respect to run up levels and run down velocities, the results for run up velocities were a little worse and the results for pressures and run down levels were bad.

Laser doppler velocity meters (LDV) offers the possibility to make good velocity measurements without any interference with or disturbance of the fluid. Since no detailed velocity measurements have been carried out as the waves run up and down a berm breakwater slope it was decided to carry out such measurements. The results have been compared with results obtained by the computer program ODIFLOCS, van Gent (1992).

## **2 TEST SET UP AND MEASUREMENT SYSTEMS**

### **2.1 Wave flume and berm breakwater model**

The measurements were carried out in a wave flume with the berm breakwater

as shown in Figure 1. The width of the flume was 1.0 m.

Figure 1 The wave flume with the breakwater model.

The breakwater cross section is shown in Figure 2. The shown section of the reshaped breakwater was obtained by using waves with heights up to 0.25 m.

Figure 2 Berm breakwater cross section.

## 2.2 Laser Doppler Velocimeter (LDV)

The water particle velocities were measured with a Laser Doppler Velocimeter (LDV). The LDV system is a two component system based on the forward scatter mode. This LDV system was built in-house for a study of the kinematics of irregular water waves (potential flow). The noise to signal ratio was too large for this instrument to give any meaningful measurements of turbulence. The measurements were taken with a rate of 100 samples per second. In the analysis the data have been smoothed by using a gliding average of 11 data points.

The velocities were taken at several of the points shown in Figure 3. The main reason for concentrating the velocity measurement points in the area shown in Figure 3 was that less air entrainment due to breaking waves was expected in this area

Figure 3 Velocity measurement points.

than closer to the breakwater crest. Air entrainment causes drop outs of the LDV measurements. Another reason is that it may be expected that the destructive velocities and forces downslope are largest in this region where the breakwater slope is flattest.

The berm breakwater profile shown in Figure 3 gives an average profile along the glass panel wall of the flume. The distance between this profile and the lowest measuring point is not necessarily representative for the distance between the measurement point and the closest stone. The measurement points are located approximately in the middle of the wave flume. The LDV system was orientated such that the velocities in horizontal and vertical direction was measured. However, during the analysis the instantaneous velocities in any direction could be obtained. In this paper velocities parallel and normal to the breakwater slope are given. Positive parallel velocities mean uprush while positive normal velocities mean velocities away from the slope.

### 2.3 Wave measurements

The waves were measured with wave gauges of the conductivity type. Prior to the velocity measurement runs the waves were calibrated in the wave flume. During the wave calibration runs the waves were measured in an area approximately 5 m ahead of the breakwater model. All the tests during the water particle velocity measurements were carried out with regular waves. Hence the waves were calibrated by moving a wave gauge along the wave flume to obtain the maximum and minimum wave heights. The height of the incoming wave was then set as the average of the maximum and minimum wave height.

During the velocity measurement runs the waves were measured close to the velocity measurement points, Figure 3. The main purpose of this gauge is to give phase information between the wave elevation and the velocity measurements. The wave elevation measurements at this gauge may be inaccurate, partly because of the shallow water and partly by air entrainment during the breaking of the largest waves.

### 3 VELOCITY MEASUREMENTS - ANALYSIS AND RESULTS

Water particle velocities have been measured primarily at the measurement points, see Figure 3: 08, 09, 10, 11, 13 and 22 for the three wave periods  $T = 1.5, 1.8$  and  $2.1$  s for several wave heights for each wave period. Not all data have been analysed, but we will present some main features of the analysis. Figure 4 shows waves measured at the location of the reference wave gauge shown in Figure 3. Figures 5 and 6 show parallel and normal velocities in point 08 measured simultaneously with the waves. Figure 7 shows a time expanded diagram of the wave and the parallel and normal velocity at point 08. The time reference is the same as in Figures 4, 5 and 6. Further details on the measurements are given by Tørum (1992).

Figure 4 Measured wave at the location of the reference wave gauge shown in Figure 3.

Although the waves are "regular" there are slight variations in their heights at the reference gauge. In this case the waves broke after they passed the wave gauge and the measurements are not influenced by any air entrainment.

There are also slight variations in the parallel velocities. It is though not necessarily such that a high wave generate a large uprush velocity. The normal velocities are more irregular than the parallel velocities.

The maximum, mean and minimum velocities measured in the points 08, 09, 10, 13 and 22 are shown in Tables 1 and 2 for uprush and downrush. Point 9 "went dry" during downrush. Hence no "maximum" downrush velocities were taken for this point.

Figure 5 Measured parallel velocity at point 08. Positive velocity means uprush.

Figure 6 Measured normal velocity at point 08. Positive velocity means velocity away from the slope.

There is a tendency that the maximum parallel velocities in uprush are largest closest to the berm breakwater slope. This might be due to amplification effects close to cover stones or overshoot effects in the wave boundary layer.

Since the velocities were not measured simultaneously in the different points it is not possible to draw a "true" velocity profile through the measurement points 09, 10 and 13. An order of magnitude analysis indicates that the boundary layer thickness is 0.01 - 0.015 m during maximum velocities.

Figure 7 Measured velocities in point 08 and wave at reference wave gauge. Positive velocity means uprush.

## 4. COMPARISON OF MEASUREMENTS WITH THE NUMERICAL MODEL ODIFLOCS

### 4.1 Description of the numerical model ODIFLOCS

The model ODIFLOCS (One Dimensional Flow on and in Coastal Structures) describes the wave motion on and in several types of structures. The model takes various phenomena into account. For instance reflection, permeability, infiltration, desorption, overtopping, varying roughness along the slope, linear and non-linear porous friction (Darcy- and turbulent friction), added mass, internal set-up and the disconnection of the free surface and the phreatic surface are all implemented. The model couples a hydraulic model to a porous flow model. Kobayashi et al. (1987 and 1989) proved that long wave equations can be used for the description of the external flow. The way in which the wave front is treated is also done in a similar way as by Kobayashi et al. (1987 and 1989). In the model ODIFLOCS long wave equations are applied for the internal flow as well. Long wave equations use hydrostatic pressures and imply a simulation of a breaking wave like a bore. The external flow and the internal flow are computed in two layers, a hydraulic layer and a porous layer, that partially overlap. The flow between both layers is determined by the pressure gradients. This flow has a maximum caused by the equilibrium of the pressure gradient and the friction. The pressure gradient in the vertical direction is assumed not to be larger than one. For a detailed description of this aspect and the model in general, see Van Gent (1992).

### 4.2 Comparison of measurements with the numerical model ODIFLOCS

The model can deal with only one porous layer. For a berm breakwater with a core, the choice has to be made whether the breakwater will be modelled as a homogeneous structure or as a structure with an impermeable core. The permeability of the core was very much the same as the material of the berm itself. Therefore, modelling as a homogeneous structure has been applied. The friction factor, depending on the roughness of the surface and the flow characteristics, was derived by using the empirical formula for fully rough turbulent flow on a uniform sloping breakwater by Madsen and White (1975):

$$f_w = 0.29 \left( \frac{d}{d_s} \right)^{-0.5} \left( \frac{d}{R \cot \alpha} \right)^{0.7}$$

The depth in front of the structure  $d_s$  was 0.79 m; for the size of the armour unit,  $d$ , the  $D_{n50}=0.034$  m was taken; the run-up  $R$  is about equal to the

wave height for which 0.175 was used and for the angle of the slope, the angle from the berm section was taken ( $\cot\alpha=5$ ). This gives a friction factor  $f_w=0.15$ . For the porosity, 0.35 was used. For the simulation added mass was not included. It might be inappropriate to compare calculated depth-averaged velocities with measured velocities in one point. However, an approximation of the maximum boundary layer thickness gives 0.01-0.015 m. This is rather low compared to the local water depth. Measured velocities in points above the boundary layer are assumed to be representative for the depth-averaged velocities. Measured velocities in different points above the slope, but in the same cross section, show differences in the order of magnitude of 20%.

For comparisons, two measuring points have been selected. The velocities measured in point 8 and 10, both above the berm and about 0.1 m away from each other, were used. Point 8 was positioned very close to the bottom and point 10 was about 0.07 m above the slope. Wave heights were measured above the berm and a comparison of those wave heights has been made as well, although the measured wave heights may be inaccurate as explained before. The simulated wave conditions were the nine combinations of wave heights of about 0.10, 0.15 and 0.20 m and wave periods of 1.5, 1.8 and 2.1 s. The combination  $H=0.175$  m and  $T=1.8$  s was added. Measuring point 8 is about at the level of the boundary thickness for these wave conditions. Point 10 is assumed to be above the boundary layer.

The calculated velocities are the horizontal velocities while the given measured velocities are the velocities along the slope. In principle the given measured velocities should be slightly larger than the calculated velocities.

The calculated velocities are the depth averaged velocities while the given measured velocities are velocities in a point. It is though believed that the measurement points are outside the boundary layer, except point 8.

The results of the comparisons of measured surface elevations with output from the numerical model, are summarized in Table 3.

The differences are rather low. A comparison between the maximum and minimum surface elevation is made to exclude the influence of a slightly different water level. The numerical model underestimates the fluctuation of the surface elevation with an average of 12.6 % difference (about 0.02 m) with the measured elevations. The wave condition  $T=1.5$  s and  $H=19.5$  cm gives a difference (10.9%) in the same order of magnitude as the average difference (12.6%). Therefore this computation is supposed to give a representative impression of the differences, see Figure 8.

Table 3 Differences between measured and calculated surface elevations.

Surface elevation (H in cm)		Measured		ODIFLOCS		Difference (in %)
		max	min	max	min	
T=1.5	H=11.7	32.0	14.9	28.8	14.7	17.5
	H=15.0	35.0	15.0	31.0	14.5	17.5
	H=20.8	36.0	13.5	37.0	13.0	-6.7

Average						12.6

Figure 8 Comparison of the measured surface elevation with ODIFLOCS results.

The comparison of simulated depth-averaged velocities with the measured (point) velocities are summarized in Table 4 and Table 5. Two measurements in point 8 were not carried out. Differences for point 8 were to

be expected because this point is so close to the bottom that the influence of the boundary layer is present here. However, an underestimation of the measured velocities with an average of 15.3% (maximum uprush velocity + maximum downrush velocity) is not so bad regarding the assumptions made for comparisons. The velocities in the direction of the breakwater (max) show an average underestimation of 18.4%. The velocities in the opposite direction give an average underestimation of 8.4%.

Table 4 Differences between measured and calculated velocities in point 8.

VELOCITIES point 8 (H in cm)		Measured		ODIFLOCS		Difference (in %)		
		max	min	max	min	mx-mn	max	min

Average						15.3	18.4	8.4

Table 5 Differences between measured and computed velocities for point 10.

VELOCITIES point 10 (H in cm)		Measured		ODIFLOCS		Difference (in %)		
		max	min	max	min	mx-mn	max	min
T=1.5	H=11.7	0.38	-0.43	0.42	-0.40	-1.2	-10.5	7.0
	H=15.0	0.55	-0.55	0.52	-0.60	-1.8	5.5	-9.1
	H=20.8	0.90	-0.83	0.73	-0.88	6.9	18.9	-6.0
T=1.8	H= 9.7	0.34	-0.34	0.47	-0.33	-17.6	-38.2	2.9
	H=14.0	0.58	-0.56	0.64	-0.55	-4.4	-10.3	1.8
	H=19.8	0.94	-0.83	0.92	-0.90	-2.8	2.1	-8.4
T=2.1	H= 9.9	0.52	-0.54	0.57	-0.38	10.4	-9.6	29.6
	H=14.2	1.05	-0.90	0.77	-0.60	29.7	26.7	33.3
	H=19.5	1.42	-1.20	1.05	-0.90	25.6	26.1	25.0
Average						5.0	1.2	8.5

Comparisons with data from measuring point 10 give better results than for point 8. As mentioned before, the relatively higher differences for point 8 are probably due to the overshoot effect in the boundary layer. The average underestimation is now 5% (average of max. uprush velocity + max. downrush velocity) of the measured velocity. The average difference independent of whether an underestimation or an overestimation is found, is higher than 5%. The average (absolute) deviation of the sum of the maximum velocities in both directions is 11.1% (max-min). The average deviation is 16.4% in the direction towards the breakwater and 13.7% in the direction away from the breakwater. Table 4 shows that the underestimation is relatively high for the combination with high wave heights and long wave periods. For these cases, the boundary layer may be relatively thick. Measuring point 10 may be influenced by the higher velocities of the boundary layer. In general, the predicted velocities show differences with the measured velocities in the same order of magnitude as the differences which appear between measured velocities at different positions above the slope in the same cross section. The results prove that the numerical model ODIFLOCS predicts velocities rather good although differences of about 35% occurred sometimes. Figure 9 and 10 show the results of two comparisons. Figure 11 shows differences for a wave height of 0.099 m and a period of 2.1 s in measuring point 10. This combination gives a difference with the measurement of 10.4% which gives a representative impression of the deviations.

Figure 9 Comparison of the measured velocity with ODIFLOCS results - point 10.

Figure 10 Comparison of the measured velocity with ODIFLOCS results - point 10.

### 4.3 Calculated extreme velocities

The comparison between the measured velocities and the calculated velocities give a fair agreement. Therefore, it is interesting to compute the

MAXIMUM VELOCITIES					
T	H	U <sub>max</sub>	U <sub>min</sub>	x-U <sub>max</sub>	x-U <sub>min</sub>
1.5	0.117	1.33	-0.52	-0.03	-0.03
	0.150	1.61	-0.69	-0.03	0.00
	0.208	2.01	-0.92	-0.03	-0.48
1.8	0.097	0.94	-0.50	-0.03	-0.09
	0.140	1.55	-0.71	-0.09	-0.06
	0.198	2.02	-0.93	-0.06	-0.69
2.1	0.099	0.87	-0.49	0.03	-0.12
	0.142	1.53	-0.70	-0.12	-0.09
	0.195	2.02	-0.95	-0.12	-0.81

Table 6 Maximum velocities with the positions along the slope.

found further down the slope. For these three cases local maximums occurred just below still water level.

maximum velocities appearing somewhere along the slope. The calculated maximum velocities show that the maximum upward velocities (U<sub>max</sub>) are higher than the maximum downward velocities (U<sub>min</sub>). These extreme velocities appeared to be just below the still water level. Only for the computations with the relatively high wave heights, the extreme velocities U<sub>min</sub> were

## 5 CONCLUSIONS

Although the measurements were carried out for "regular" waves, there were variations in the heights of consecutive waves and also in the maximum velocities for each wave.

On this background the conclusion from the few comparisons we have made between the ODIFLOCS calculations and the measurements are that there is a fair agreement between the measurements and the calculations except in measurement point 08. The velocities in measurement point 08 are as previously remarked possibly influenced by proximity to the stone cover layer.

## ACKNOWLEDGEMENT

This project was carried out under the European Communities Research Programme Marin Science and Technology, EC MAST. More specifically the project was a subproject under EC MAST Coastal Structures. The project was funded partly by EC and partly by the Norwegian Coast Directorate. We appreciate very much this financial support.

The authors are also grateful to the participants of the EC MAST - Coastal Structure project for discussions and comments during workshops.

### ABSTRACT

When the construction of the Zeebrugge Outer Harbour was finished a full scale monitoring system was realized as a part of the global monitoring and inspection programme.

The monitoring system was designed to follow the water level- and the water pressure fluctuation inside and in front of the breakwater.

A general description is given of the instrumentation of a section of the NW-breakwater followed by a global overview of the data-acquisition system and off-line data processing.

Results from the primary analysis of the raw data of relevant storm measuring sessions are presented.

### 1. INTRODUCTION

In 1989 the construction of the breakwaters of the Zeebrugge Outer Harbour was finished. The breakwaters are of the rubble-mound type with open crest (without a concrete parapet wall). Figure 1 shows a typical cross-section. Some quantities involved in the construction of the breakwaters are approximately : willow mattresses : 1.1 Mm<sup>2</sup> ; quarry stones : 11 Mtons ;

---

<sup>2</sup> Harbour and Engineering Consultants HAECON N.V., Ghent - Ghent University, Belgium

<sup>3</sup> Harbour and Engineering Consultants HAECON N.V., Ghent, Belgium

concrete cubes 25 t - 30 t : 60,000 units ; Haros®  
15 ton : 11,000 units.

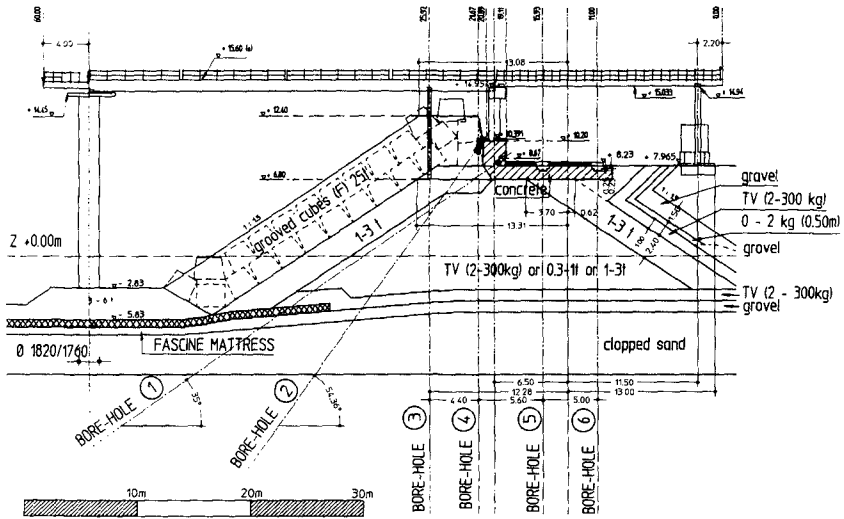

Figure 1. Cross-section of the breakwater

Once the construction of the breakwaters was finished, the principal organized an inspection, monitoring and maintenance programme of the new breakwaters. Such a programme is a standard rule in the management policy of the Ministry of the Flemish Community regarding major infrastructure works.

The monitoring and inspection programme is based on a complete design file and is composed of the following parts :

- (a) visual control of the armour layer, the crest of the breakwater and the filter construction next to the road ;
- (b) topographic measurements ;
- (c) bathymetric soundings of the different zones surrounding and inside the harbour ;
- (d) aerial remote sensing of the armour units ;
- (e) side scan sonar recordings of the underwater armour layer and the wave breaking carpet and berms ;
- (f) evaluation of the hydraulic design conditions on the basis of data collected by five measurement

- stations and seven wave-buoys in the surroundings of the harbour ;
- (g) evaluation of some design hypothesis by means of an instrumentation of a section of the NW-breakwater.

The last item of this programme, the NW-breakwater instrumentation, makes it possible to collect reliable prototype measurement-data. As such, it is an important step forward to a more reliable design of rubble-mound breakwaters.

## 2. AIM OF THE NW-BREAKWATER INSTRUMENTATION PROGRAMME

The whole infrastructure was designed to measure, to follow the water level- and water pressure fluctuation inside and in front of the breakwater. Knowledge of these phenomena are important on the one hand with regard to the stability of the armour layer and on the other hand with regard to the overall slope stability of the breakwater.

At several occasions the importance of water pressures inside the armour layer on the hydraulic stability of the armour units has been emphasized. To our knowledge less attention has been paid to the influence of the water pressure fluctuation on the overall slope stability. We will focus our attention to this item.

With regard to the water level fluctuation and especially the influence on the slope stability one has to distinguish between two loading situations :

- A. slope only subjected to tides (e.g. inner slope of a breakwater)
- B. slope subjected to tides and waves.

For case A one can assume that the pore pressure is hydrostatic with regard to the still water level (S.W.L.). Regarding the high permeability of the breakwater material the S.W.L. in the core will be the same as in front of the breakwater. The low water situation is the most critical one.

For case B (tide and waves) the water level in front of the breakwater varies over several meters in a few seconds. As a result hydrodynamic pore-pressures will be generated in the armour layer, under-layer and breakwater core. Harlow E.H. (1980), Barends F.B.J. et al. (1983) and others state that these hydrodynamic pressures played an important role in the destruction of some bigger rubble-mound breakwaters (such as Sines, Bilbao, Tripoli, Arzew, ...).

Literature review revealed only limited information with regard to research work on the water pressure fluctuation inside the breakwater : some researchers have tried to solve the problem using mathematical modelling, others worked on physical models.

Before discussing in more detail the results of the modelling we draw the attention on the set-up which occurs in the breakwater core (fig. 2). This set-up is predominantly caused by the geometry of the slope : inflow of water through AC (at maximum run-up), outflow through AB (at maximum run-down). This difference in surface, together with the longer way which has to be passed through by the water particles during outflow cause a surplus of water with an internal set-up of the water level as a consequence.

Figure 2. Internal set-up due to wave action (Barends, 1985)

#### a) Mathematical models

The water level fluctuation inside a breakwater is determined by the still water level S.W.L., the internal set-up and an internal wave. The S.W.L. is defined by the design conditions.

The internal set-up depends on the permeability of the materials and the width of the breakwater at the S.W.L. Barends F.B.J. (1985) finds a set-up up to 0.25 D (D = water depth in front of the breakwater). The set-up becomes important, especially when a sand fill has been placed at the inner side of the breakwater. Barends F. B.J. et al. (1983 and 1985) and Hannoura A.A. et al.

(1985) present the model HADEER : this model calculates the horizontal water movement in and through the coarse core-material, caused by regular waves acting on the seaward slope of the breakwater. The main results of the published data are :

- the finer the core material, the higher the set-up and the higher the damping (= the lower the wave amplitude at the leeside) ;
- the higher the incoming wave, the higher the set-up ; the damping is not influenced by the magnitude of the incident wave.

#### b) Physical models

Depending on the scale of the physical model one can distinguish models with normally applied scale (scale model less than 1,0 m high) and the so-called big scale models.

Considering scale models with normally applied scale, the most relevant results were found in Günbak A.R. (1976) and Simm J.D. et al. (1988).

The main results of Günbak's experiments are :

- mean water level inside the breakwater core is clearly higher than S.W.L. .
- the water level fluctuation decreases while moving to the centre of the core;
- the water pressure inside the core increases when finer core material has been used.

Simm J.D. et al. find :

- the set-up is proportional to  $H^2T$ , so closely related to the wave energy ;
- the damping of the fluctuation inside the core ;
- the pore pressure in the middle of the breakwater varies almost hydrostatically.

Considering the so-called big scale models, Burger W. et al. (1988 and 1990) report the results of tests carried out in the Groszen Wellen Kanal (G.W.K.) at Hannover. In the G.W.K. they have built a breakwater of ca. 4.00 m high on a sandbed of ca. 1,50 m thick.

When analyzing into detail one finds that the results of Burger et al. confirm some results of Simm et al. : the water pressure varies almost hydrostatically in the centre of the breakwater core.

To our knowledge only few attempts have been made to measure the pore water pressure fluctuation in a breakwater on site, e.g. Hakimi et.al. (1984) describe the instrumented breakwater at Jorf Lasfar (Morocco).

Only preliminary results are available. They find a rather high damping even in the seaward borehole, which is located close to the axis of the breakwater. However they have used open pipes instead of pressure transducers.

The foregoing emphasizes the lack of results, especially full-scale results, with regard to the water level and pore water pressure fluctuation inside a breakwater. By reviewing some literature we focussed on data which are useful to analyze the overall slope stability. We assume that a review focussed on the armour layer stability will lead to a comparable conclusion.

Yet, in 1983, at the opening session of the "Coastal Structures Conference" held in Washington D.C., A.W. Price stated that the common approach for the design of rubble mound breakwaters (based on mathematical and physical modelling) was not sufficiently funded on measurements on full scale operational breakwaters and that there was a serious lack of knowledge about the real phenomena of energy dissipation inside the different parts of the rubble-mound breakwater.

The main final objectives of the herein presented instrumentation programme are :

- 1) Acquire a better understanding of the geo-hydraulic phenomena and parameters affecting the overall stability and behaviour of the armour layer of rubble-mound breakwaters subjected to random wave attack.
- 2) Development of simulation techniques of these phenomena on physical models, leading to higher reliability in model tests.
- 3) Particular attention will be paid to the determination of the real forces acting on the amour units and the real hydraulic pressure set-up in the breakwater core and foundation layers.

These goals can't be achieved all at once. So in a first phase, we intend to collect data, interpret and implement these data in order to be able to provide basic full scale data for :

- the calibration of mathematical models ;
- the elaboration of a more comprehensive and adequate scaling method in physical modelling.

### 3. INFRASTRUCTURE

A measurement jetty of ca. 70 m long has been built on a steel pile at the toe of the breakwater and on a support on top of the breakwater (fig. 1).

Six boreholes have been drilled : four vertical boreholes (3, 4, 5 and 6) in the core and partially in the armour layer and two oblique boreholes (1 and 2) in the core, underneath the armour layer. Galvanized steel casings are placed in these boreholes. These casings are perforated in order not to disturb the overall permeability. In these casings part of the instruments are placed.

The casings reach the clapped sand. Doing this way it is possible to place pore water pressure transducers in the clapped sand underneath the breakwater toe. Knowledge of the variation of the pore water pressure in this area is very important for the overall slope stability.

The results of a measurement campaign and an evaluation of their influence on the overall slope stability can be found in De Rouck (1991).

A data acquisition system confined in an airconditioned 20' container is placed on the lee-side of the jetty at the landward side of the service road.

The steel pile and the bridge over the armour layer, is used to install measuring equipment.

#### 4. MEASURING EQUIPMENT

The main considerations kept in mind during the selection of instrument layout and instruments themselves were :

- good reliability to marine environment and wave action ;
- good accessibility for instrument installation and maintenance ;
- provision of reliable power supply.

The instrumentation was directed to the measurement and observation of the following phenomena :

- wave characteristics in front of the breakwater up to 250 m seaward, and at greater distances (ca. 3 km) ;
- tidal currents and orbital velocity (3 axes) at the toe of the armour layer ;
- water level and water pressure fluctuation at several points in front of the breakwater, in the armour layer and in the core ;
- air pressure in the upper part of the boreholes underneath the service road of the breakwater ;
- impact pressure on all faces of armour units ;
- video observation of the uprush and downrush of the waves on the armour layer.

The following equipment has been installed :

- wave-rider buoys : 2
- infra-red wave height sensor : 1
- pressure transducers : 11
- electrical analog step-gauge : 3
- electrical digital step-gauge : 1
- video camera : 2
- 3D ultrasonic current meter : 1
- temperature meter : 1

The location of the sensors is indicated on fig. 3.

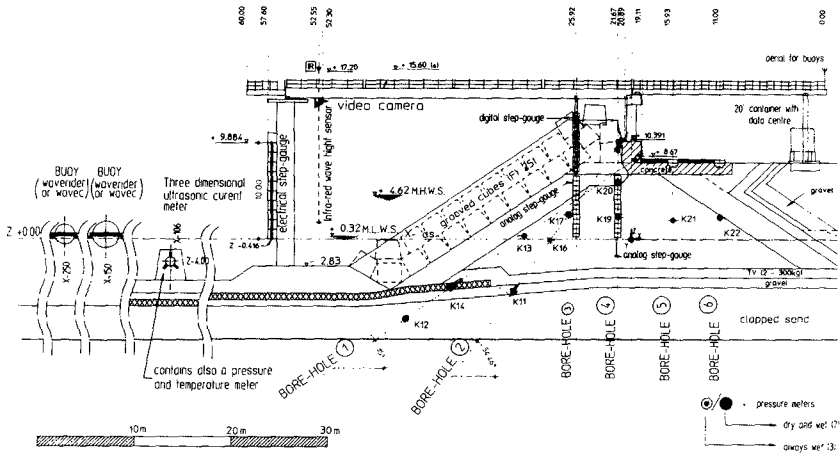

Figure 3. Location of the sensors in the measurement jetty

All instruments are controlled by a data acquisition system and scanned at variable frequencies, with a maximum of 50 for the dynamic wave impact on the armour units. The system permits a visual control of the signals and dumps the accumulated data into a hard disc memory. After a measuring session the data are transferred to tape cassettes for further off-line data processing.

Fig. 4 is giving a global overview of the data-acquisition system and the off-line data processing.

DATA-ACQUISITION  
SYSTEM FOR  
MEASUREMENTS IN-SITU

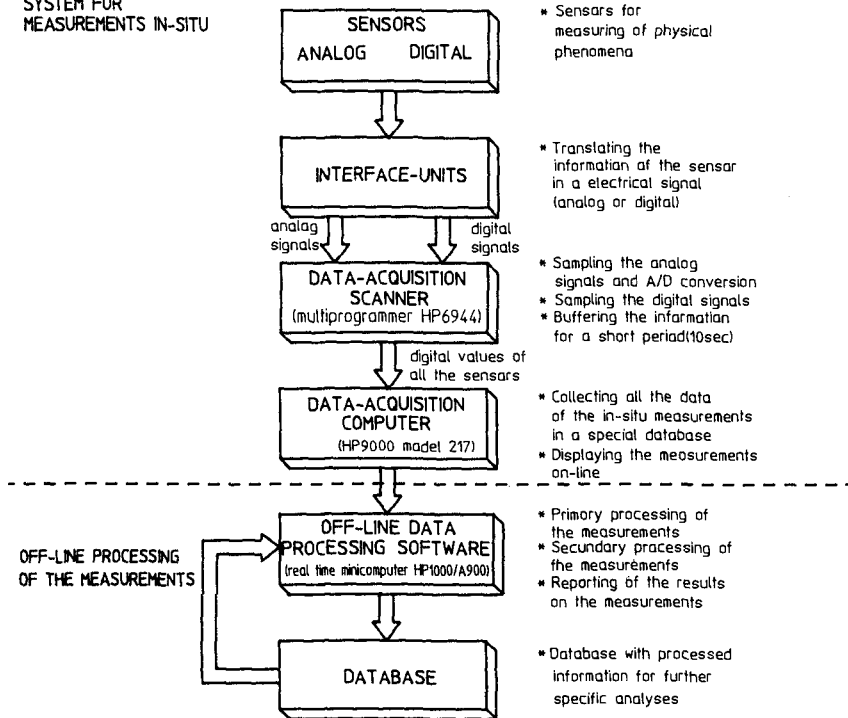

Figure 4. Global overview of the data-acquisition system and off-line processing

A basic software package has been established to reorganize the data in an appropriate database, to calibrate and scale the raw data, to produce graphical output (time plots and instant profiles) and to perform the specific analysis of some variations in selected significant time intervals. Experience has shown that this basic package has to be revised and upgraded continuously in parallel with the interpretation, further analysis of the results and orientation of the research.

In normal weather conditions a watch-dog programme is running continuously on the computer system to check all sensors. In order to be aware of major storm weather conditions a special prewarning procedure has been elaborated. The oceanographic hydro-meteo station at Zeebrugge is making special forecasts with a preavis

(stand-by) of 48, 24, 12 and 6 hours to the responsible scientist. At this moment the decision is taken to measure or not. In the positive case the programme is loaded for the start of a continuous measuring session during maximum 17 hours.

## 5. RESULTS

Relevant storm measuring sessions were performed during the storm periods of March 1988, March-April 1989 and January-February 1990.

These sessions did provide the raw data for a primary analysis which revealed very promising results. All data and results were stored in a well structured database and are partially reported. A primary interpretation did reveal some interesting phenomena, e.g. about the components of the waves in front of the rubble-mound breakwater and the damping of these waves in the core.

As an example : on 26.01.1990 measurements were carried out for several hours during a storm. An excerpt of the measurements is given on fig. 5. The wave height of the incident wave was 3.30 m. From this figure it can be concluded that the incoming wave is propagated into the core of the breakwater at least to sensor K19 which is installed in borehole 4. Even the signals registered by sensor K21 (borehole 5) and K22 (borehole 6) show some damped wave action.

To detect any damping of the waves with increasing distance from the slope of the breakwater the double amplitudes  $A_{Ki}$  of the measured waves at each location are compared with the wave height of the incident wave  $A_{inc.w}$ . The mean results are given in table 1 and are represented on fig. 6.

Sensor	$A_{Ki}$ (m)	$\frac{A_{Ki}}{A_{inc.w}}$
K13	1.90	0.58
K16	1.30	0.39
K17	1.27	0.38
K19	0.50	0.15
K21	ca. 0.30	0.09
K22	ca. 0.20	0.06

Table 1 : Damping ratio of sensors placed in the six boreholes

Figure 5. Example of propagation of an incident wave into the core of the breakwater

Figure 6. Cross-section of instrumented breakwater and example of wave damping

Pressure meter K13 is placed at the LW-level and approximately on the interface between the 1-3 ton filter layer and the core. At the location of K13 the amplitude has decreased to ca. 1.90 m, due to damping in the armour layer and underlayer.

## 6. CONCLUSIONS AND PERSPECTIVES

The first results of the breakwater instrumentation have proved the reliability of the system to collect full scale data. However more elaboration and interpretation is needed to clearly identify and extract the basic information.

The complexity of the phenomena and the considerable investments involved make it necessary to look for future international cooperation.

As the available infrastructure in Zeebrugge is unique, it can also be used for testing of marine instruments and measuring sensor packages actually under development.

#### Abstract.

Three-dimensional physical models of detached rubble-mound breakwaters have been built with separate Total Section, Front Slope, Crest and Back Slope sections. The stability responses of the armor units of this sections have been tested using irregular waves and different freeboards.

The stability curves relating the level of damage, the stability number,  $N_s$ , and the freeboard, have been obtained for each one of the different sections defined on the breakwaters. A distinct behaviour of the different sections have been found. The curves that plot the stability number against the freeboard for a given level of damage shows a minimum for an intermediate freeboard for the Crest and Back Slope sections. The total section stability response is a combination of the response of each one of its components. As a consequence, relative minimums of stability may appear for intermediate freeboards, due mainly to the contribution of the Crest failure to the total stability.

## Introduction.

Low-crested and submerged breakwaters are designed to allow the transmission of a significant amount of wave energy due to overtopping. Conventional breakwaters have the traditional multi-layer cross-section. Reef breakwaters are low-crested or submerged breakwaters composed by a homogeneous rubble.

Because of the overtopping, the flow over the front slope section of the breakwater attenuates as the freeboard decreases and the weight of the armour stones on the front slope can be significantly reduced, as proposed by Van der Meer (1988). However, the crest and back slope armour units may need increased weight to withstand the wave forces caused by overtopping. The combination of increasing stability on the front slope and the decreasing stability on the crest and back slope can lead to stability minimums in intermediate positive freeboards, as suggested by Ahrens et al. (1990). Losada et al. (1992) used experimental velocity data and analytical values, obtained from Kobayashi et al. (1987, 1990), to show that the minimum stability of crest units occurs when the crest is at the mean water level. Experimental studies of the U.S. Army (1965), Raichlen (1972), Magoon et al. (1975) and Walker et al. (1976), suggested that the Back Slope section of low-crest breakwaters is more susceptible to damage than the seaward slope.

The aim of this paper is to establish that the different sections of the breakwater trunk have very diverse stability response to a sea state condition and that the behavior of the Total Slope section, (generally the only probed in two-dimensional model tests), reflects the stability response of each section component of the breakwater trunk. A complete description of this study is described in Vidal et al. (1992).

## Damage criteria.

The average erosion area,  $A_e$ , and the number of displaced units,  $N$  are usually used to describe the damage in the breakwater tests. The values of these variables do not give complete information of the state of damage of the breakwater, because they depend upon the geometry of the study sections. To relate the state of damage of a section of the structure with the values of these variables, it is necessary to define some general damage criteria.

Losada et al. (1986) defined three different degrees of armour damage that can be recognized by visual

assessment. These are: Initiation of Damage, (ID), Iribarren's Damage, (IR) and Destruction, (D). Recently, Vidal et al. (1991) proposed an additional damage level called Start of Destruction, (SD). These global damage definition will be used in the following. Relations between the S parameter and the damage level will also be given (see Table 3) in this paper for the different sections tested.

### Experimental set-up and data analysis.

#### Experimental set-up.

The physical tests were carried out at the Hydraulics Laboratory of the National Research Council, Ottawa, Canada.

Figure 1.

The net area used in the facilities was  $34 \times 14 \text{ m}^2$ . Figure 1 shows a plan view of the experimental set-up. A 1.5 meter-wide channel was constructed on one of the sides of the basins. In the side walls near the model heads, five modules of upright wave absorbers were placed in order to dissipate the diffracted energy from the model. On the side opposite the wave board, a 1/15 sloped gravel beach was built in order to ensure an efficient dissipation of wave energy. Excluding the gravel beach, the bottom in all the testing area was kept horizontal. The models were placed with their longitudinal axis parallel to the wave board. A distance of approximately 5 m between the rear toe of the

breakwater and the front toe of the rear gravel beach was available to monitor the transmitted and diffracted wave energy.

Figure 2. shows a plan view of the models. A steel frame covering the upper 0.35 m of the breakwater was built. Using this frame, the structure was subdivided into six components, four trunk- and two head-sections. The trunk sections, 0.5 m long each, were: Front Slope, (FS), Back Slope, (BS), Crest, (C) and Total Slope, (TS). The remaining parts of the breakwater sections, which were not included in these sectors were covered with a steel mesh having square openings of 1x1 cm in size. This prevented any motions or damage to these parts without changing the flow characteristics through and over the structure.

Figure 2.

The breakwater cross-section was composed of a permeable core armoured with two layers of rocks which were carefully selected in term of weight. Some main characteristics of the armour and core stones are provided in Table 1. In order to assure easy tracking of the armour units displacement, a colour coding was deployed. All the slopes of the trunk and heads were 1:1.5 and the crest width was equivalent to  $6 \cdot D_{h50}$  and therefore, approximately 0.15 m. The water surface elevations of sea states were measured at eleven different locations as shown in Figure 1.

Before and after every test profiling, VCR pictures and color photographs were taken in order to assess the

damage. During the wave generation period of each test, VCR pictures were taken to survey the evolution of the damage. The profiling of the breakwater cross-sections was performed using an electro-mechanic profiler. Nine profiles, 0.05 m apart, were taken for each trunk sector.

PARAMETER	ARMOUR	CORE
$D_{n15}$ cm	2.37	1.64
$D_{n50}$ cm	2.49	1.90
$D_{n85}$ cm	2.64	2.24
$\rho_r$ g/cm <sup>3</sup>	2.65	2.65
$P_s$	0.45	0.44

**TABLE 1: Model rubble characteristics**

The one hour time series were synthesized using the Random Phase Spectra Method. The synthesized time series had JONSWAP spectra with two different peak periods ( $T_p = 1.4$  and  $1.8$  s) having a peak enhancement factor of  $c = 3.3$  and variable zero-moment wave height  $H_{m0}$ .

TEST NUMBER	$d_s$ cm	$h_c$ cm	$T_p$ sec	$H_{m0}$ cm

34, 35	54	60	1.8	8, 11

**TABLE 2: Target parameters for the stability tests.**

A total of 35 tests were carried out. The relevant target parameters of these tests are summarized in Table 2. The damaged breakwater sections were rebuilt after each test.

#### Data analysis.

The wave data from the probes was subjected to spectral, SIWEH, zero crossing and probability distribution analysis. The data collected from the three probes in front of the sea side of the test structure was subjected to reflection analysis.

The global damage figure for each part of the breakwater was obtained from the visual inspection of the model after the test. The final figures for the relation between the global damage levels and the S parameter was obtained after the tests and is given in Table 3. To assess the number of units displaced during each test, still colour photographs and video pictures were taken before and after the test.

SECTION DAMAGE	TS	C	BS	FS
ID	1.5	1.0	0.5	1.0
IR	2.5	2.5	2.0	2.5
SD	6.5	5.0	3.5	4.0
D	12.0	10.0	---	9.0

**TABLE 3: Approximate 'S' minimum threshold values for the different definitions of damage and breakwater trunk sectors.**

If  $N_{ex}$  is the number of units displaced in a trunk sector of length  $X$  and porosity  $P_s$ , the following expression, was used to translate this number into an equivalent visual damage parameter,  $S_v$ :

$$S_v = N_{ex} \cdot D_{n50} / ((1 - P_a) \cdot X) \quad (1)$$

Using the data from the mechanical profiler the average profile for each section of the breakwater before and after each test was calculated and the eroded average area,  $A_e$ , was derived. The adimensional damage parameter ' $S_p$ ' was evaluated from this eroded area,  $A_e$ , using the expression:

$$S_p = A_e / (D_{n50})^2 \quad (2)$$

Using the indicated procedure, four values of  $S_p$  and  $S_v$ , corresponding to the four trunk sectors were obtained for each test.

### Discussion of stability results.

To represent an overall dimensionless sea state parameter, the stability number,  $N_s$ , was used:

$$N_s = H_s / (\Delta \cdot D_{n50}) \quad (3)$$

Where  $\Delta = (\rho_r - \rho) / \rho$ . It was decided to classify the results according to the values of the adimensional freeboard,  $F_d = F / D_{n50}$ , where  $F$  is the breakwater freeboard,  $F = h_c - d_s$ . For a given breakwater, water depth, time domain characteristics of incident waves and sea state duration, the damage should be a function of the stability number and the adimensional freeboard:

$$S = f(N_s, F_d) \quad (4)$$

For fixed damage levels,  $S = S_o$ , this function can be represented in a bidimensional plot relating the stability number for this damage level,  $N_{so}$ , with the freeboard:

$$S = f_o(F_d) \quad (5)$$

If this function has a minimum for a given freeboard, this freeboard will give the minimum stability for the corresponding section of the breakwater.

### **Comparison between damage levels.**

In the following plots of the stability results  $F_d - N_s$  for each one of the trunk sections will be presented. Each set of data will be related to a global damage level.

#### **- Front slope section 'FS':**

Figure 3 plots the stability results for the 'FS' section. The lines drawn at the right correspond to the limiting  $N_s$  values for each line, taken from Van der Meer's (1988) data of non-overtopped breakwaters.

The curves fitted to each set of data in Figure 3 are straight lines suggesting a linear relation between the freeboard and the stability number for each damage level. The minimum value for a given damage level always corresponds to the non-overtopped breakwater. The values of  $N_s$  for initiation of damage and destruction are closer for the positive than for the negative freeboard or that the section is more brittle for the positive freeboards. The

freeboard of minimum stability increases as the level of damage increases. This is because the minimum stability corresponds to the non-overflowing condition and if the wave height increases to attain bigger damages, the freeboard for non-overflowing must also increase.

### FRONT SLOPE SECTOR

Figure 3.

Any damage in the breakwater that decreases the freeboard will cause better stability conditions in the 'FS' section. As the deformation of the 'FS' section due to damage also improves its stability, the result is that the 'FS' section in low-crested breakwaters is always in a stable condition (any damage increases the stability of the section).

#### - Crest section, 'C'.

Figure 4 depicts the results for the 'C' section. The curves that fit the data are 2<sup>nd</sup> order parabolas.

For a given damage level, the freeboard of minimum stability is found slightly below the zero freeboard. The minimum of stability moves somewhat to the negative freeboards as the damage level increases, indicating the effect of the increasing wave height. The slope of the curves for positive freeboard is higher than for negative freeboard. That implies that the 'C' section increases its stability faster with the increase of positive freeboard than with the decrease of the negative freeboard. When the freeboard is positive, the armour units removed from the

Crest section by the waves are mainly carried with the forward movement of the waves to the 'BS' section. When the freeboard is negative, a higher proportion of armour units are carried to the front slope with the backward movement of the waves, due to the increase of the symmetry of the flow over the crest as the freeboard decreases. The proportion of units that moves to the FS or to the BS depends also on the wave height.

Figure 4.

Taking into account only the freeboard, the Crest section is in an unstable situation for positive freeboards: when the damage reduces the freeboard, the stability decreases. Figure 4 shows that the crest section is not more brittle for positive than for negative freeboards. The factors that compensate the decrease in stability due to de reduction of the crest height should be the increase of the width of the crest and the change in the crest slope that results from this reduction of crest height.

- Back slope section, 'BS'.

Figure 5 plots the results for the 'BS' section. Due to the high stability of this section, only the Initiation of Damage has enough information to show the complete trend. The fitted curve is a 2<sup>nd</sup> order parabola that has its minimum in a  $F_d$  value between 1 and 2. The other curves for higher levels of damage must have their minimums for higher freeboards and stability numbers. Extrapolating the trend

of the curves for Iribarren's Damage and Starting of Destruction, and assuming that they are parabolas it can be concluded that the a high brittleness could be expected.

The behavior of the 'BS' section can be explained by the characteristics of the flow over the armour. For negative freeboards, the waves go over the crest and break (backward and forward) on the water that protect the back slope armour units. When the crest emerges, the water jet starts to impinge over the back slope armour units and the stability continues to decrease because the flow works with gravity to move the armour units. With the crest emerged, a minimum  $N_s$  is necessary for the initiation of overtopping and the origin ( $S=0$ ) of the line  $N_s-S$  moves to higher  $N_s$ .

**BACK SLOPE SECTOR**

Figure 5.

The distribution of damage in the 'BS' section is more irregular than in the other sections. The shape and concentration of the water jet that impinges over the 'BS' creates areas where the damage is concentrated. Because of that, the values of  $S$  for a given damage level are smaller in this section than in the others (see Table 3).

**- Total slope section, 'TS'.**

Figure 6 shows the results for the 'TS' section. The horizontal lines at the right of the figure indicates the values of  $N_s$  for the different damage levels corresponding to the non-overtopping case, obtained from Van der Meer (1988). Instead of the straight lines of the 'FS' section

(Figure 3), the best fits are 2<sup>nd</sup> order parabolas with a minimum corresponding to the freeboard of non-overtopping. The interaction between the damage on the sections, particularly between the Crest and the Front Slope, produces relative minimums in the curve  $F_d-N_s$ . This complex behavior is the cause of controversy about which is the  $F_d$  of minimum stability.

TOTAL SLOPE SECTION

Figure 6.

The separation between the curves for the different damage levels is slightly minor in the positive freeboard range. This is due to the increase of brittleness for the positive freeboards in the Front Slope section. This brittleness is maximum for the non-overtopping case.

Comparison between sections.

The comparison between sections can be performed for fixed damage levels. As a representative example, the comparison for Iribarren's damage is discussed here.

Figure 7 plots the stability results  $F_d-N_s$  for Iribarren's Damage. Each set of data represents a different breakwater trunk section. The fitted curves are the same as used in Figures 3 to 6.

The 'FS' section is the least stable for  $F_d \geq 0.5$ . For  $F_d \leq 0.5$ , the 'C' section is the least stable of the trunk sectors. The Back Slope section is the most stable section of the breakwater for  $F_d \leq 2.0$ . For  $F_d \geq 2.0$ , the Crest section

is the most stable. For this reason, if the freeboard is high and the armour of the Crest is the same as the Back Slope, the damage can start in the Back Slope and desegregate the Crest.

### IRIBARREN'S DAMAGE

Figure 7.

The curve corresponding to the 'TS' section reflects the influence of the damage in all its components: for high positive freeboards, it behaves like the 'FS' section and for negative freeboards, it approaches the 'C' curve. Because the Crest section is more stable than the Front Slope for  $F_d \geq 0.5$ , the damage produced on the crest region of the 'TS' section is mainly caused by the spreading of the damage from the seaward slope to the crest. Several tests with positive freeboards have reported Destruction of the crest region of the 'TS' section while the Crest section had only Initiation of Damage. This damage on the crest region of the 'TS' was also attained for high positive freeboards due to the spread of the damage in the landward slope, because in these cases, the crest region is more stable than the back slope region.

### Conclusions and recommendations.

The damage in a low-crest or submerged breakwater is the response to the different flow and stability conditions that support the armour units in the different sections of the breakwater. The different sections of the breakwater have distinct stability responses to a sea state condition. The behavior of the Total Slope section, (generally tested

in conventional model tests), reflects the stability behaviour of each section component of the breakwater trunk. If the objective of the model tests is to optimize the armor weight to obtain a similar security condition in each part of the breakwater, the stability curves for each section should be determined.

The stability of low-crested rubble-mound breakwaters is very dependent on the freeboard. This implies that, any comparative evaluation of breakwater stability should be based on low levels of damage such as Iribarren's Damage or lower. Higher level of damage could affect the crest level of the structure, thereby, affecting the stability and performance characteristics.

More experimental and theoretical work is necessary to establish the influence of other variables held constant in these tests: slope angles, crest width, type of armour units, etc. The high stability of the Back Slope section has impeded the completion of the stability curves for high levels of damage.

#### **Aknowledgements.**

The authors are grateful to the Hydraulics Laboratory of the National Research Council of Canada for generously providing the facilities for these experiments and also to the Dirección General de Puertos y Costas, the University of Cantabria and the Dirección General de Investigación Científica y Técnica of Spain for their support of the work.

#### 1.0 INTRODUCTION

With the completion of the Eastern Scheldt storm surge barrier the Delta plan was realized. Herewith a period of the construction of large hydraulic engineering structures ended more or less. Therefore the interest in the optimal maintenance of the existing structures is growing and efforts are made to develop a theoretical basis for the planning of maintenance.

In the field of mechanical engineering considerable progress has been made. Maintenance is defined as consisting of two activities inspection and repair. Inspection implies the observation of the state of the structure and repair the restoration of the structure to it's original state.

Two main classes of maintenance are discerned: corrective and preventive maintenance. In this classification only the last subclass contains inspection besides repair. When a corrective maintenance strategy is applied, the structure will be repaired after failure. In a preventive maintenance scheme the structure will be repaired at specified intervals defined in time or operational hours before failure occurs. In a more refined strategy the state of the structure is inspected at such intervals. On the basis of the inspection result the decision to repair is taken.

The optimal cycle of inspection and repair is found by minimization of the present value of the sum of failure costs, inspection costs and repair costs. In these optimization models simple probability distributions for the time to failure as the exponential distribution are frequently applied. Some times this constant failure rate model is refined by the use of a "bathtub" curve for the failure rate.

Generally in mechanical engineering the failure rate is not related to the environmental conditions or loads. This paper studies if these theories can be applied directly to the maintenance of hydraulic structures like dikes, dunes, breakwaters, bottom protections or that further refinement is required.

## 2.0 THE MAINTENANCE OF HYDRAULIC STRUCTURES

The design of hydraulic structures is among others based on the analysis of the ultimate and the serviceability limit states (ULS and SLS respectively) that are typical for the structure at hand. Beside one class of ULS two classes of SLS can be discerned.

ULS models the failure of the structure under extreme loads  $S$

SLS describes the deterioration the resistance  $R$  of the structure under the ever present loads.

SLS analyses the functional performance of the structure under the ever present loads (e.g. limiting wave transmission for a breakwater.

When maintenance is studied the first mentioned type of SLS needs special attention. As the deterioration due to SLS leads in many cases to an increased likelihood of the occurrence of the ULS over the lifetime [3] and thus to failure. The deterioration may be regularly redressed by systematic repair. The regular heightening of dikes in the Netherlands to neutralize the effects of settlement and sea level rise is an example.

In hydraulic engineering the corrective maintenance strategy is generally not advised in view of the great risks involved when a dike, a breakwater or a bottom protection reaches an unsafe state due to ULS failure. The corrective maintenance strategy can only be applied to relatively unimportant parts of the structure that do not initiate overall failure. The maintenance of dike revetments in Holland gives an example. Every year during major storms minor parts of the dike revetment

are washed away. This poses no threat to the hinterland protected by the dike as a considerable reserve strength is hidden in the clay layers on which the revetments are mostly placed. After the storm the damage will be repaired before the next extreme high water occurs. In hydraulic engineering only preventive maintenance is advised in view of the high failure costs associated with the breach of a dike, the interruption of harbour activities due to breakwater failure.

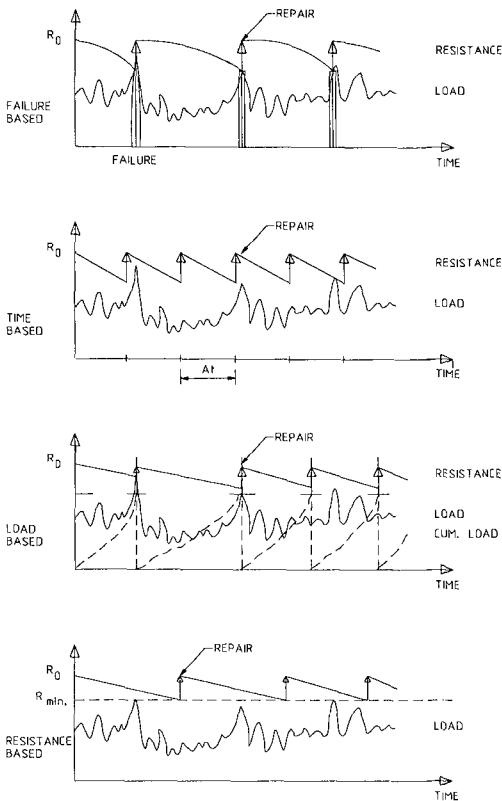

Fig. 1 Corrective maintenance and preventive maintenance governed by various triggers

Several types of triggering preventive maintenance can be imagined (Fig. 1). The simplest alternative is time based maintenance which implies that the structure is repaired at fixed intervals. Use based maintenance is a

second alternative. Here the structure is repaired after a certain number of uses. A spillway can be repaired after a specified number of spills.

Connected to this type is the load based strategy. Here repair is triggered if e.g. the sum or cumulative effect of the loads exerted on the structure over time exceeds a specified level. In the resistance based strategy the resistance or the state of the structure is inspected and repair is due when this variable falls below a specified minimum level.

Due to the spatial vastness of hydraulic structures, the high cost of inspection and the often poor resolution of the (underwater) observations a strategic approach to inspection is necessary. The decision to start a thorough inspection of the state of the structure is based on the outcome of an observation of variables that provide an indication of the state to be expected in case of a full inspection. The observation of these proxy-variables is called monitoring. Monitoring of the time, the use, the cumulative load or the state will precede an expensive and elaborate inspection of the exact state of the structure. This principle is shown in Fig.2.

Fig.2 Preventive maintenance with monitoring and inspection

The steel gates of the Eastern Scheldt Storm Surge Barrier provide an example. The cumulative effect of the wave loads is monitored on a continuous basis. When the cumulation exceeds a certain level the nodes of the steel frame, supporting the water retaining surface of the gates, are inspected to measure growth of fatigue cracks.

The way to choose between corrective and preventive maintenance and the various strategies comprised under the latter is depicted in Fig 3. If the consequences of failure are grave preventive maintenance is preferred. The second question is if a description of the deterioration process is known. Without such a

deterioration model continuous monitoring and subsequent inspection of the state is the only viable solution. If a good deterioration model is available and if it contains the effect of loading on the process, the monitoring of strategies the cumulative

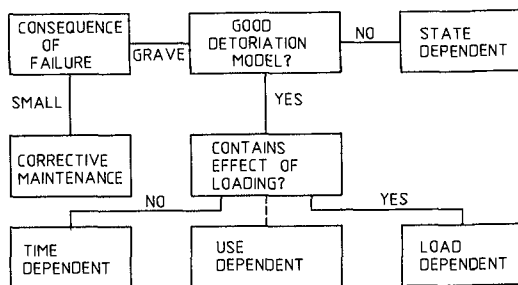

Fig. 3 Choice between maintenance strategies

the cumulative load as a precursor to full inspection of the state seems the right alternative. If there is no clear relation between the loads and the deterioration the monitoring of time forms the only basis for the scheduling of inspections. The use based inspection strategy lies between these extremes. Many specialists assume that deterioration models for various hydraulic structures do not yet exist. Some reflection however shows that with slight adaptation the equations used in the SLS analyses provide excellent deterioration models. The calculation of the settlement of a dike, of the erosion of a bottomprotection, of scour behind a structure, of long shore transport on a berm breakwater, provide examples. The scour behind the bottomprotection of a discharge sluice can be predicted as a function of time via the current velocity, the turbulence and the  $D_{50}$ , see [5]. The relatively slow scour process is however only a threat insofar it may cause an instability of the foundation of the discharge sluice via a slide flow (ULS). The slide flow is initiated by a steep upper slope of the scour hole as is shown in fig.'s 4 and 5. The steep upper slope may be redressed by the dumping of gravel or sand as a maintenance measure.

The value of inspection was analyzed for two types of SLS behaviour common in hydraulic engineering (Fig.6). The first type is characterized by a deterioration of the resistance  $R$  linear with time, as is the case with settlement and sea level rise. The derivative with respect to time is constant but uncertain. If an inspection is performed the derivative can be accurately estimated and a precise prediction of the resistance  $R(t)$  at some moment in the future can be provided. The value of the inspection is that the wide p.d.f. of  $R(t)$  existing before changes into a very narrow one after.

The behaviour of a dune under the continuous action of waves and wind, that is conveniently described by a random walk model [3], constitutes the second type. Now the inspection provides the position of the dunefoot at  $t_i$ . Due to the random walk character of the process the position of the dune foot at some future moment can only be predicted in terms of a fairly wide p.d.f.

Fig. 4 Scour hole (SLS) leading to a flow slide (ULS) threatening the foundation

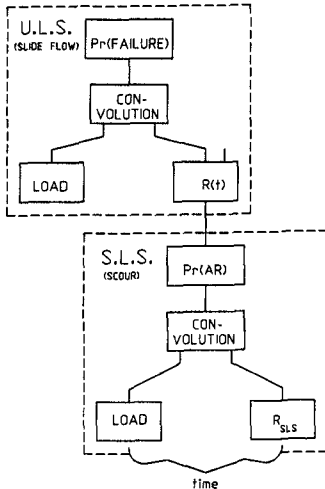

Fig. 5 Relation SLS-ULS

Quite narrower however than before inspection. So generally speaking inspection reduces the standard deviation of the prediction of the state of the structure in the future, for instance the planned moment of repair.

The optimal intervals of inspection and repair can be evaluated by minimizing the expected value of the present value of the total cost. The total cost comprises the cost of inspection, the cost of repair and the risk defined as the product of the probability of failure and the consequential damage  $D$ . Moreover the

expected value of the present value of the total cost has to be taken as the various costs are stochastic variables. In the literature decisions are based on

expected values neglecting the variance of the total cost. Most decisionmakers are however risk averse. Therefore the study of the variance might be of interest for future studies.

Fig. 6 The value of inspection for two types of degradation processes

### 3.0 EXAMPLES

Some examples that were solved successfully elsewhere where already mentioned. The linear degradation of the dikeheight by sea level rise and the regular heightening was studied in [2]. For the settlement of the dike, a logarithmic function of time, an analysis is given in [6]. The optimal interval of beach nourishment to combat the erosion of a dune, that can be modelled as a random walk process was studied in [3] and [7].

A fourth type describes the gradual deterioration of a bed protection or a berm breakwater that loses once in every year an uncertain amount of material due to the extreme load. Given the threshold character of the transport relation the transported amount is in many years zero and has some years a positive value causing erosion. The p.d.f. of the significant wave height and

the consequent p.d.f. of longshore transport is given in Fig. 7.

Fig. 7 Longshore transport  $T$

In this paper a similar process leading to the degradation of the bottom protection (BP) behind a discharge sluice will be studied. The BP consists of a sand tight cloth ballasted by a layer of rock. The layer of rock is gradually eroded over time by extreme discharges. This leads in due time to one of two failure modes (Fig.8): either the cloth is exposed to the current and fails or the weight of the rock layer becomes insufficient to withstand the uplift pressure, that is a fraction of the head difference, when the sluice is closed.

The uplift pressure follows a Gumbel-distribution with parameters of 1.55 and 0.78 kN/m<sup>2</sup> for mode and width.

The maximal current velocity  $U$  is normally distributed with a mean of 2 m/s and a standard deviation (s.d.) of 0.4 m/s.

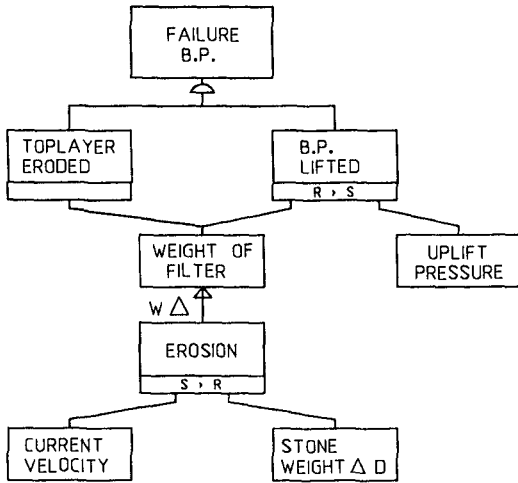

Fig. 8 The two failure modes of the bottom protection

The transport relation has the following form  $T = 1260 (U - 2)^2$  kg/m<sup>2</sup> per year for  $U > 2$  m/s and  $T = 0$  elsewhere.

The conditional p.d.f. of the transport per year if transport occurs is derived as:

$$f_T(X|X>0) = \frac{1}{\sqrt{5040 * X}} * e^{\frac{-X}{403.2}}$$

The probability of transport is 0.5 and equal to the probability of no transport. Numerically the mean and the s.d. of the transport per year are calculated at 101 and 226 kg/m<sup>2</sup>. The degradation as a function of time is the sum of the yearly erosion. The p.d.f. of the degradation after 5, 10, 20 and 40 year is given in Fig. 9.

Next the probability of uplift is calculated for every year and the probability of total erosion leading to the exposure of the filter cloth. In the area (I) near the sluice the latter is the deciding mechanism and in the areas further away (II & III) erosion forms the main failure cause. The  $p_f$  is given as a function of time in Fig. 10.

Fig. 9 The p.d.f. of degradation of the B.P. after 5, 10 20 40 years

$f(t)$  [1/year]

Fig. 10 The failure rate  $p_f$  as a function of time

The present value of the risk is written as follows:

$$\sum (D * f(t) * \frac{\Delta T}{(1+r)^t})$$

The cost of repair is based on the expected value of the erosion, which equals  $101 \cdot t$  kg/m<sup>2</sup> after  $t$  year for area I. The present value of the total cost of repair at  $t$  is given by:

$$\frac{C + c * (101 * t)}{(1+r)^t}$$

Now the present value of the cost of repairs and the risk between repairs has to be added over the life time of the structure. This defines the objective function that has to be minimised with respect to  $t$ , the repair interval.

For the numerical evaluation the following values have been assumed:

$$\begin{aligned} D &= 40 \text{ Mfl} \\ C &= 10 \text{ kfl} \\ c &= 100 \text{ fl.m}^2/\text{kg} \quad (\text{equal to } 50 \text{ fl/ton}) \\ r &= 0.04 \end{aligned}$$

The present value of the total cost as a function of the repair interval is given in Fig. 11. The optimal interval is 4 year if the three areas of the B.P. are repaired at the same time. The calculation was also performed for separate intervals for each of the three areas of the B.P. With the reasonable assumption that the mobilization cost  $C$  has to be paid only once when the repairs for the areas coincide and three times when not, the minimum cost is reached at 4 yearly interval for all areas. If inspection of the state of the B.P. is introduced the p.d.f. of the resistance  $R(t)$  will be replaced by the result of the inspection the deterministic value  $R_i$ . Ex ante the value of  $R_i$  is uncertain and follows the p.d.f. of  $R(t)$ . To find the value of the inspection under the assumption of instantaneous repair, we have to integrate over all possible results of the inspection with their respective probabilities given by the p.d.f. of  $R(t)$ .

Fig. 11 Total expected cost as a function of the repair interval

#### 4.0 CONCLUSIONS

The maintenance theory developed in mechanical engineering has to be adapted and refined to account for the typical problems of hydraulic engineering. A probabilistic approach proves to be highly effective and necessary in the approach of the problem. Moreover the serviceability limit state (SLS) equations used in the design of hydraulic structures may be easily adapted to serve as degradation models.

The advantage of the use of rigorous maintenance models is that the risk of deferred repair and the value of inspection can be objectively assessed. Therefore the theory can assist managers of coastal structures in the definition of optimal maintenance strategies.

However all decisions in the described model are based on expected values of the costs. The limitations imposed by the omission of the variance of the cost has to be further explored.

## CHAPTER 130

### Finite Element Simulation of Wave-Induced Internal Flow in Rubble Mound Structures

H. WIBBELER<sup>1)</sup> and H. OUMERACI<sup>2)</sup>

University of Hannover, Sonderforschungsbereich 205,  
Coastal Engineering, Hannover/Germany

#### Abstract

A Finite Element Model for the simulation of the wave-induced flow in a porous structure is presented and applied to three types of structures: homogeneous vertical structure, homogeneous trapezoidal structure and traditional multilayered rubble mound breakwater. The obtained results are related to the motion of the phreatic surface, the pore pressure histories and distributions within the structure as well as to the internal velocity field induced by wave action. The problems to be solved in order to get an improved numerical model are discussed.

#### Introduction

Rubble mound breakwaters still represent the most commonly used type of structure for the protection of coastal areas, harbours and further facilities against wave action. The traditional approach to study the stability of such structures still consists in the use of physical wave models with scales ranging from 1:30 to 1:50. For such scales the REYNOLDS numbers of the wave-induced flow in the core material of the model are generally smaller than the critical value  $Re_D = 10^4$ . For lower  $Re_D$ -values scale effects due to higher viscous forces start to occur. The latter will in turn affect the flow field in the armour and underlayer, so that the hydraulic stability may also be subject to scale effects. Due to the oscillatory nature of the flow and to the large variation of the hydraulic gradients, the tentative approach using distortion factors in the FROUDE scaling of the core material is not satisfactory. On the other hand, the performance of large-scale model tests in a wave flume is too costly and time consuming when used for design purposes or basic research including a large variation of the relevant parameters. For this reason, a research strategy has been adopted which consists in using numerical codes calibrated by experimental data obtained from a limited number of large-scale model tests (WIBBELER / OUMERACI, 1992).

2) Dr.-Ing., Senior Researcher, Franzius-Institut, SFB 205, Nienburger Str. 4  
3000 Hannover 1 / Germany

These calibrated codes are used as research tools for further parameter studies, the final objective being, however, the development of analytical solutions. Since the early seventies several models for the simulation of the wave-induced flow on and in rubble mound breakwaters have been developed. Both analytical solutions and numerical models were described. Despite the relatively high number of existing numerical models, no model exists which has been calibrated by reliable data covering all relevant flow phenomena involved. This paper will first briefly review some of the mathematical/numerical models available and then discuss the results of a Finite Element Model developed at the University of Hannover for the simulation of the wave-induced flow in a rubble mound breakwater.

### Review of Existing Mathematical/Numerical Models

An exhaustive review of the existing mathematical/numerical models for the simulation of wave-induced internal flow in rubble mound structures would be beyond the scope of this paper. Therefore, only a very brief review is given below. As illustrated by Fig. 1, one may distinguish analytical and numerical models. The latter are in turn divided in a) Finite Difference Models (FD), b) Finite Element Models (FE) and c) Hybrid Models using Finite Elements and Finite Difference Techniques (FD/FE).

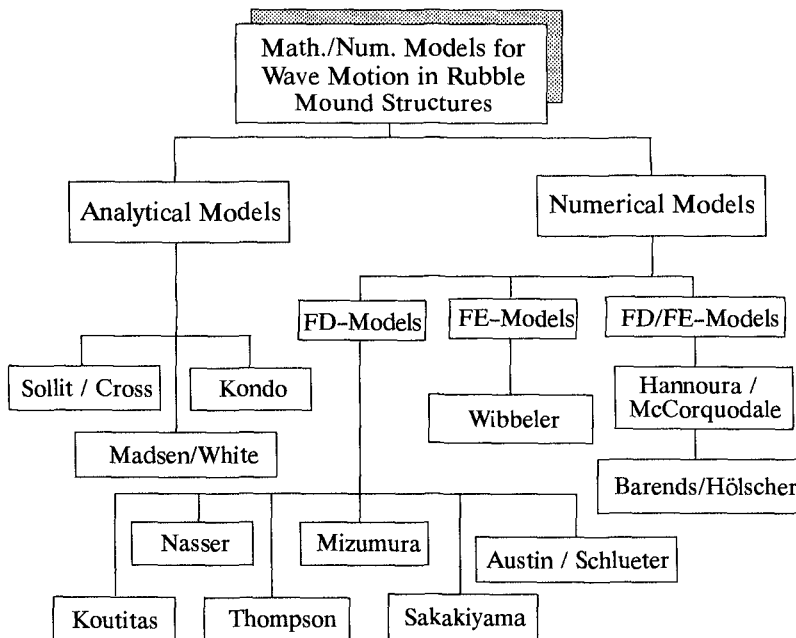

Fig. 1: Existing Models for Wave Motion in Rubble Mound Structures

However there are still a number of problems to be solved in order to come up with a reliable model which can properly simulate the interaction between waves and rubble mound structures, especially the wave-induced internal flow. Among these problems the following may be mentioned:

a) *Description of the external flow field:* The present knowledge on the wave kinematics in front of a rough permeable structure is almost nil.

b) *Interaction between external and internal flow:* Almost nothing is available on the physical processes involved at the boundary between two layers of different porous materials (discontinuities) and their mathematical formulation (coupling problem).

c) *Energy dissipation on the slope:* The question on how to account for this dissipation in case of breaking is still an unresolved problem.

d) *Porous flow equation:* It is still not clear whether a FORCHHEIMER-type equation will apply for the flow in the armour layer and filter layer.

e) *Air entrainment:* The air entrained by waves breaking on the structure is expected to strongly affect the internal flow. No attempt has yet been made to account for this effect in a numerical model.

f) *Internal stability of the porous medium:* Generally the porous matrix is assumed to be fixed. Actually, however, this is not the case.

As a conclusion, there is still a long way to go before a reliable numerical model can be developed which can account for all these aspects. Meanwhile, a relatively simple Finite Element Model for the simulation of wave-induced internal flow in a rubble mound breakwater has been developed at the University of Hannover. This model and some of the computational results obtained so far are discussed below.

### **Description of the Finite Element Model**

#### **Porous Flow Equations**

For the description of the fluid flow within the rubble mound structure non-linear constitutive equations of the FORCHHEIMER-type :

$$i = (a + b|v|) v \quad (1)$$

or of the exponential-type :

$$i = c |v|^{m-1} v \quad (2)$$

can be used, where :

- $v$  velocity vector
- $a$  FORCHHEIMER constants
- $b$  FORCHHEIMER constants
- $i$  hydraulic gradient ( $i = -grad h$ )
- $c, m$  constants of exponential law

The FORCHHEIMER constants and the constants of the exponential law are mainly dependent on the grain size and shape, the roughness of the grain surface and the porosity of the material. These constants have to be determined experimentally. Such experimental studies have been performed for instance by (SHIH, 1990) and (HANNOURA / McCORQUODALE, 1985). From the latter study the following equations can be evaluated:

$$a = 70.0 \frac{\nu}{g n \delta^2} \quad (3)$$

$$b = 0.54 \frac{(0.5 + 0.5f_r)}{g \sqrt{n} \delta} \quad (4)$$

$$\delta = \frac{n d}{6(1-n)S_f} \quad (5)$$

- $a, b$  FORCHHEIMER constants
- $d$  particle diameter
- $\delta$  effective pore hydr. diameter
- $f_r$  roughness factor
- $g$  acceleration due to gravity
- $n$  porosity
- $\nu$  kinematic viscosity
- $S_f$  particle shape factor

Fig. 2: Effect of Size and Shape of Grain Particles on FORCHHEIMER constants

Furthermore, the velocity vector  $v$  is expressed as a function of the permeability tensor  $K$ . Using a relative permeability coefficient  $k_r$ , the following general linearized constitutive equation is obtained which is used in the computations to evaluate the velocity in the porous media:

$$v = - k_r k_n K i \quad (6)$$

where  $k_n$  is a non-linear permeability coefficient.

### Finite Element Formulation and Evaluation of the Phreatic Surface

In the present Finite Element Model the piezometric heads  $h$  are used as degrees of freedom ( $h$ -model). The transient motion of the phreatic surface, which is defined by the condition  $p=0$  (pressure head), is described by the following differential equation:

$$\phi \gamma \frac{\partial S}{\partial p} \frac{\partial h}{\partial t} - k_r k_n \operatorname{div} ( K \operatorname{grad} h ) - q = 0 \quad (7)$$

$\gamma$	specific weight	$k_r$	relative permeability
$h$	piezometric head	$\phi$	porosity
$K$	permeability tensor	$q$	discharge
		$S$	saturation

A Finite Element formulation of Eq. (7) leads to following equation:

$$\left( \frac{1}{\Delta t} S_e + \Theta K_e \right) h_{n+1} = \left( \frac{1}{\Delta t} S_e - (1 - \Theta) K_e \right) h_n - Q \quad (8)$$

with:

		$B$	derivatives of shape functions
		$\Delta t$	time step
$K_e = \int_{\Omega} B^T K B \, d\Omega$	(9)	$K_e$	element matrix
		$N$	shape functions
$S_e = \int_{\Omega} S_0 N^T N \, d\Omega$	(10)	$Q$	vector of nodal flows
		$S_e$	saturation matrix

Eq. (8) is solved by using a  $\Theta$  - method.

The position of the phreatic surface must be evaluated by an iterative procedure. For these calculations, the domain of the structure is divided into two parts. These are the wet part beneath and the dry part above the phreatic surface. During the iteration, the permeability of the structure above the phreatic surface is set to a very small value, so that it behaves as almost impermeable. In each iteration step the element matrices must be calculated by using the new position of the phreatic surface. This procedure has to be continued until the position of the phreatic surface remains constant. The convergence of the iteration can be improved by use of a transition area between the permeable and impermeable domain (RANK / WERNER, 1986). This transition area is also used to calculate the saturation matrix  $S_e$ . Matrices of elements which are intersected by the phreatic surface have to be calculated by a special integration method (WIBBELER / MEISSNER, 1992).

### The Finite Element Mesh

One of the most important steps of a Finite Element calculation is the discretization of the structure. For the present model, an automatic mesh generator is available. This mesh generator is able to create meshes according to the different layers of the breakwater and the position of the phreatic surface. The reliability of the results can be controlled by the evaluation of an error estimator (MEISSNER / WIBBELER, 1990). The distribution of the approximation error allows the mesh generator to create an improved mesh either by a complete remeshing or by local refinements (adaptive discretization).

Fig 3: Adaptive Discretization of a Breakwater

### Simulation of Wave Motion

The wave motion in front of the structure and at the seaward slope of the breakwater can be described by using any wave theory or a numerical model as well as by using the wave data directly recorded from hydraulic model tests. The pressure at each boundary slope is prescribed by the function  $h(t)$  where  $h$  denotes the piezometric head (Fig. 4).

Fig.4: Simulation of Wave Motion

### Flowchart of the Finite Element Model

The main components of the present Finite Element Model are described by the flowchart in Fig. 5.

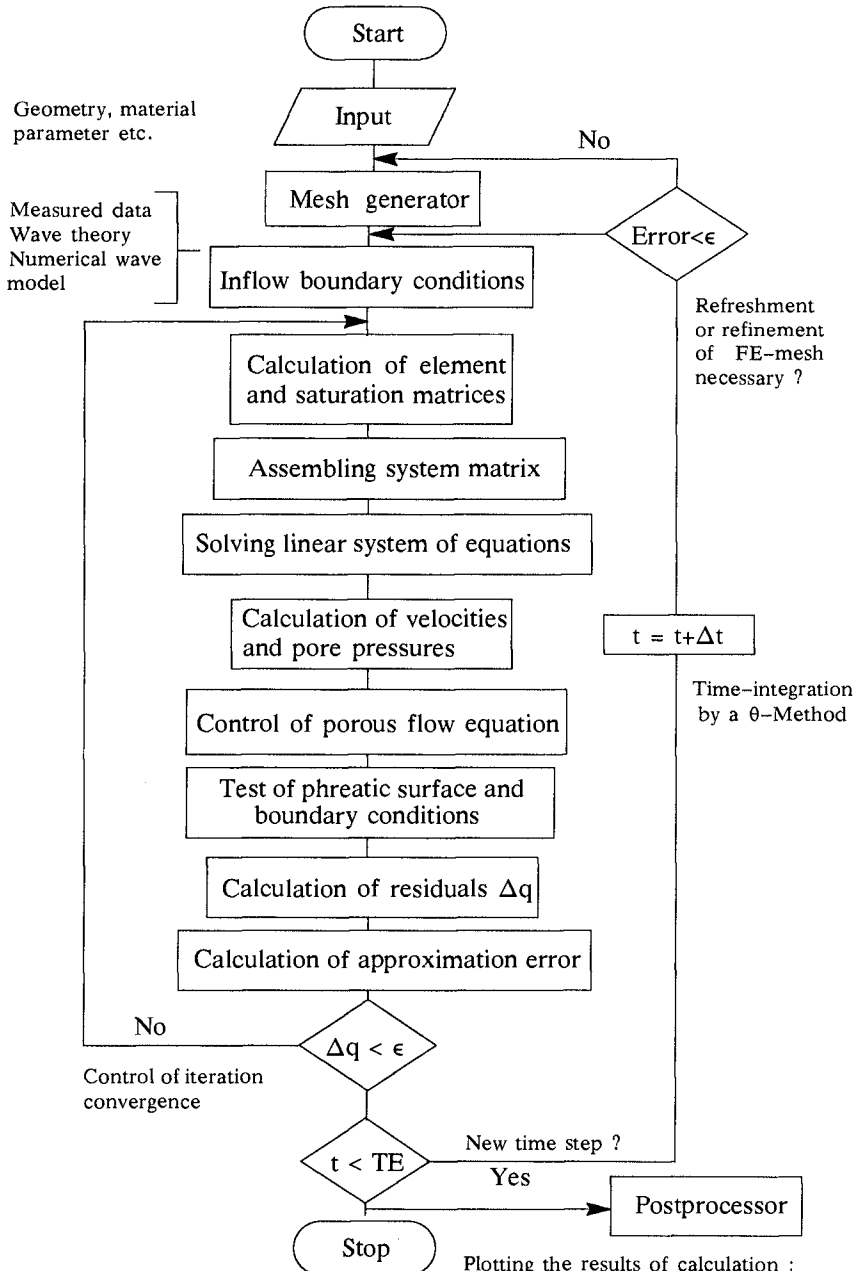

Fig. 5: Flowchart of the Numerical Model

Plotting the results of calculation : Velocity vectors, contours of pore pressure, pore pressure histories etc.

### Computational Results

The simulation using the FE-Model described above is demonstrated on three types of porous structures: on a homogeneous vertical structure, a homogeneous trapezoidal structure and a multilayered traditional breakwater.

#### a) Homogeneous Vertical Structure

The actual vertical structure and its FE-discretized counterpart are shown in Fig. 6.

Fig. 6: Homogeneous Vertical Porous Structure

The instantaneous velocity fields and isobars at four successive time steps  $\Delta t = T_w/4$  ( $T_w = \text{Wave Period}$ ) are shown in Fig. 7, providing a good insight in the flow processes within the structure during a wave cycle.

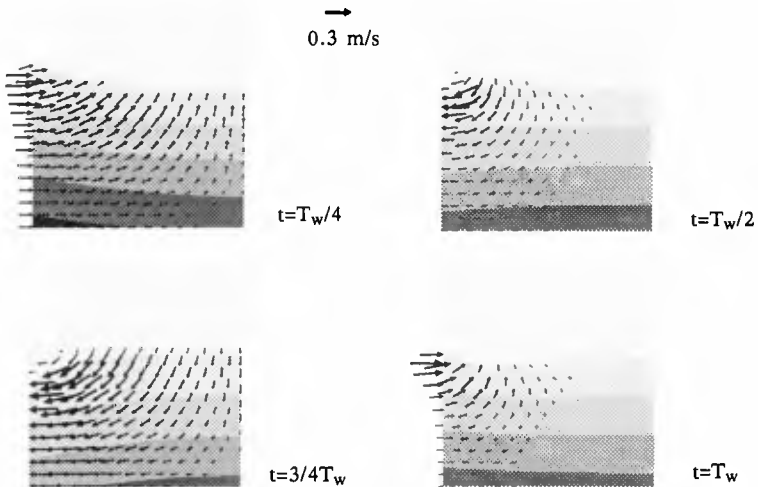

Fig. 7: Velocity Fields and Isobars within the Vertical Structure  
( Wave Conditions see Fig. 6)

Pore pressure histories at two different elevations under still water level are given in Fig. 8, showing a) the rate at which the wave motion is damped at different levels as the wave propagates into the structure and b) the phase shift of the pressure histories at different locations in the direction of wave propagation.

Fig. 8: Pore Pressure Damping and Phase Shift  
(Wave Conditions see Fig. 6a)

The spatial pore pressure distribution at section II-II during maximum wave run-up and maximum wave run-down are given in Fig. 9, showing the possible range of pressure variation within the structure during one wave cycle.

Fig. 9: Pore Pressure Distribution at Section II-II during  
Max. Wave Run-Up and Max. Run-Down

**b) Homogeneous Trapezoidal Breakwater**

Both the actual and discretized homogeneous trapezoidal breakwater are shown in Fig. 10 where also the incident wave conditions used for the computation are given.

Fig. 10: Homogeneous Trapezoidal Breakwater

In the same manner as for the homogeneous vertical structure, instantaneous velocity fields and isobars at different time steps of the wave cycle can be determined (Fig. 11).

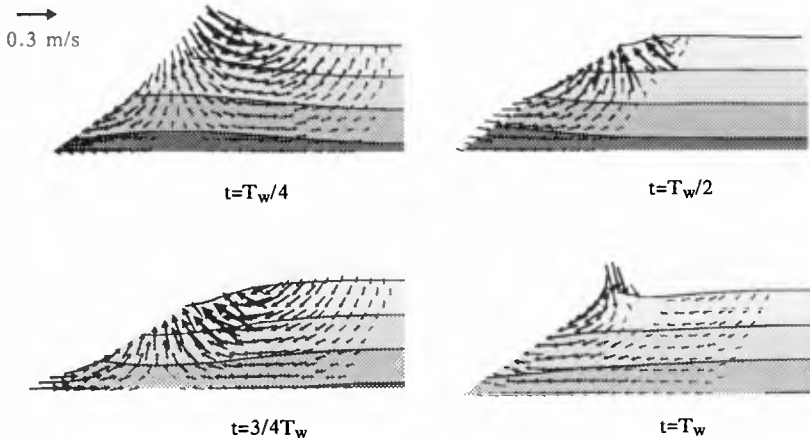

Fig. 11: Velocity Fields and Isobars within the Homogeneous Trapezoidal Structure (Wave Conditions see Fig. 10)

This kind of results is particularly important for the study of the flow-induced forces on the armour units as well as for the stability of the armour layer and breakwater toe. For instance, it is seen from Fig. 11 that not only run-down but also run-up may exert large forces on the armour units. A number of results of numerical tests of this kind can be analysed in order to improve the understanding of the flow processes leading to failures and to enable an analytical description of the forces involved.

The simultaneous pore pressure histories obtained at the three different locations (79,83 and 300 in Fig. 10b) in the breakwater also well illustrate the damping of the wave motion and the phase shift of the pore pressure histories at the different locations in the direction of wave propagation (Fig.12).

Fig. 12: Simultaneous Pore Pressure Histories  
(Wave Conditions see Fig. 10)

The relative pore pressure  $p(x)/p_0$  distribution in a horizontal plane located slightly below SWL is given for instance in Fig. 13, showing a relative good agreement with the results of large-scale model tests and the analytical solution given by (OUMERACI/PARTENSKY, 1990).

- $p_0$  : pore pressure at the seaward slope ( $x=0$ )
- $L'$  : wave length in the breakwater
- $\beta$  : damping coefficient which is strongly depth dependent

Fig. 13: Horizontal Distribution of Wave-Induced Pore Pressure

**c) Traditional Multilayered Breakwater**

The actual structure which has been tested in the Large Wave Flume (GWK) in Hannover and its discretized counterpart are given by Fig. 14,

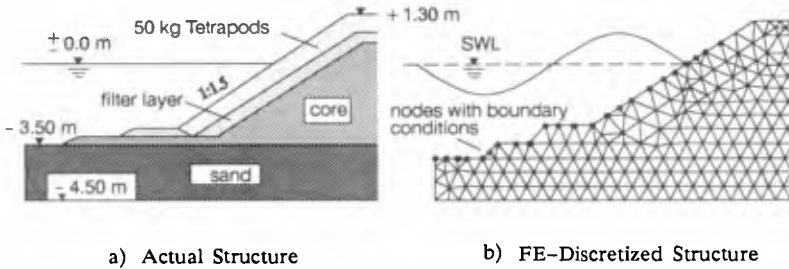

Fig. 14: Traditional Multilayered Breakwater

where only half of the structure is represented (second half is symmetrical to the represented part). In the same manner as for the previous homogeneous structures, the velocity fields in the structure during four steps ( $t=T_w/4$ ,  $T_w/2$ ,  $3/4T_w$ , and  $T_w$ ) of the wave cycle  $T_w$  are obtained in Fig. 15,

Fig. 15: Velocity Field and Isobars in the Multilayered Structure  
(Wave Conditions see Fig. 14)

which may give some indications on possible critical locations for the stability of the armour layer and the toe of the structure.

Further results of the computation as compared to the experimental data from the large-scale model tests are given in a further paper (WIBBELER / OUMERACI, 1992 ) showing a relatively good agreement between computed and measured wave-induced pore pressures within the structure.

### **Concluding Remarks and Perspectives**

The results of the FE-Model applied to three types of porous structures subject to wave action have shown that:

- a) the wave-induced pore pressure histories at different locations within the structure,
- b) the motion of the internal water table,
- c) the internal velocity field during a wave cycle

can be satisfactorily simulated, despite the simplicity of the model used. This has also been shown more clearly in a further paper (WIBBELER / OUMERACI, 1992 ).

The reasons for some discrepancies between numerical and experimental results are essentially due to air entrainment, singularities due to abrupt changes, unsteadiness of the flow and high turbulence within the first layers. Although the computation yields acceptable results for engineering purposes, there is a considerable need to improve and extend the FE-Model. This concerns particularly the coupling of the internal and external flow field, the improvement of the inflow boundary conditions, the consideration of the virtual mass effects and the simulation of the two-phase flow.

The research within the next years will be directed toward the development of an integrated numerical model for the simulation of the wave-induced flow processes on, at and in the rubble mound structure. The final result will be a reliable research tool for the study of the hydraulic stability of rubble mound structures, including all hydrodynamic effects of internal and external flow.

## CHAPTER 131

# The permeability of rubble mound breakwaters. New measurements and new ideas.

Williams AF<sup>1</sup>, Burcharth HF<sup>2</sup>, den Adel H<sup>3</sup>

### 1 ABSTRACT

The results of an extensive series of permeability experiments originally analysed by Shih (1990) are reinterpreted in the light of new experiments. It is proposed that the Forchheimer equation might not fully describe flow at the high Reynolds numbers found in the interior of rubble material. A new series of tests designed to test for deviations from the Forchheimer equation and investigate the effects of material shape are described. While no evidence can be found to indicate a deviation from the Forchheimer equation a dependency of permeability and the surface roughness the material is demonstrated.

### 2 INTRODUCTION

This work forms part of a study under the MAST project G6 Coastal Structures, funded by the European Community, to develop a package of techniques to model wave action on rubble mound breakwaters. An important parameter necessary for such models is the permeability; HR Wallingford of the UK, Aalborg University of Denmark and Delft Geotechnics of the Netherlands. The major part of the testing has been carried out at HR Wallingford, by Williams, while contributions to the analysis have been made by Burcharth and den Adel.

Traditionally, permeability of the material in rubble mounds has been a difficult

---

<sup>2</sup>Department of Civil Engineering, University of Aalborg, Denmark.

<sup>3</sup>Department of Marine Structures, Delft Geotechnics, The Netherlands.

parameter to measure. Prototype size experiments are not feasible due to the large scale of the material involved. The problem is compounded by uncertainties about the way small scale experiments may be scaled to prototype size. Before the start of this study a large amount of work had already been carried out on permeability at Wallingford. A large range of material sizes (4-60mm) were tested so that the effects of material size could be investigated. Shih (1990) carried out the first analysis of the results and looked for the desired scaling effects. Here further ideas about the interpretation of these experiments are discussed and a further set of measurements designed to look at the effects of material shape are described.

Following the analysis by Shih and similar work carried out at Aalborg, it became apparent that there were uncertainties about the interpretation of the data. Burcharth & Christensen (1991) suggested that there might be several distinct flow regimes possible in rubble material and that the transition from a laminar flow pattern to a turbulent flow pattern would be described by a Reynolds number. If this was the case then it would effect attempts to scale permeability measurements made at model scale to prototype size.

Further experiments were required to investigate the transition from laminar to turbulent flow regimes. In order to do this the permeameter at Wallingford was modified to increase the maximum possible flow rate and, thus enable a wider range of Reynolds number, for each single material size, to be investigated.

In addition to looking for flow regime changes, these new tests also provided the opportunity to investigate the effects of material shape on permeability. It was possible to obtain samples of material that had been carefully prepared according to shape. This material had been analysed using an image processing technique, by Latham et al. (1988).

### 3 FLOW EQUATIONS

The most common interpretation of permeability of a material is as a measure of the pressure gradient required to produce a given flow rate of fluid through the material. This was formulated into an equation by Darcy,

$$u = ki \quad (1)$$

where  $u$  is the discharge velocity, and  $k$  is the effective permeability

The linear form of Darcy's law makes it easy to deal with, and has proved very successful in the modelling flows through pores materials when the flow

rate or Reynolds number is low. However, at higher Reynolds number the inertia of the fluid becomes important and the relationship between  $i$  and  $u$  can no longer be expressed in this linear form. The size of the rubble material within a breakwater and the flow rates induced by wave action result in flows with typically large Reynolds numbers (>500). This means that to model correctly the breakwater behaviour requires a non-linear expression within the flow equation.

The exact form that such a non-linear flow law should take is at present unclear, for the purposes of these experiments the equation suggested by Forchheimer (and described by Engelund (1953)) shall be used.

$$i = au + bu^2 \quad (2)$$

In this equation the permeability is described by the two coefficients  $a$  and  $b$  which are intended to be independent of the discharge rate  $u$ .

It is generally considered that the two terms on the right hand side of Equ(2) independently describe the laminar and turbulent flow regimes. The first term  $au$  describes the laminar flow and is dominant at small values of  $u$ . In laminar flow the viscous terms in the Navier stokes equation dominate and hence the coefficient,  $a$  should be dependent on the viscosity of the fluid  $\nu$ . Conversely the second term,  $bu^2$  is dominant at large values of  $u$  and is attributed to the turbulent flow regime, indicating that  $b$  must be independent of the fluid viscosity.

The Forchheimer equation is the most widely used in the analysis of permeability data, however it may not fully describe the complex flows that occur in the large porous material of a rubble mound. If the Forchheimer equation is our chosen flow equation, the question is now one of determining the form of the coefficients  $a$  and  $b$ .

#### 4 THE $a$ AND $b$ COEFFICIENTS

Engelund (1953) suggests that the relevant parameters are the porosity of the porous medium  $n$ , and some measure of the grain size  $D$ . By demanding that the coefficients remain dimensionally correct he obtained the best fit to his data with the expressions:-

$$a = \alpha \frac{(1-n)^3}{n^2} \frac{\nu}{gD^2} \quad (3)$$

These expressions provide the permeability in terms of only two simply-determined parameters, by the incorporation of the two dimensionless

$$b = \beta \frac{(1-n)}{n^3} \frac{1}{gD} \quad (4)$$

coefficients  $\alpha$  and  $\beta$ . Ideally  $\alpha$  and  $\beta$  would be constants however even Engelund recognised that they may be dependent on other properties of the material, such as shape or grain size distribution. This means that there is a wide range in the possible values for  $\alpha$  and  $\beta$  which must be determined for the material under consideration.

Engelund chose his coefficients to provide the best possible fit to his data. It has been pointed out by Burcharth & Christensen (1991), that Engelund's data set is restricted to results from material with very small particle sizes, and hence low Reynolds number flows. Burcharth goes on to suggest a new formula for the laminar coefficient,  $a$ , based on arguments of dimensional analysis and geometry of the voids in a porous material. Burcharth's new coefficient takes the form:-

$$a = \alpha_B \frac{(1-n)^2}{n^3} \frac{v}{gD^2} \quad (5)$$

This results in the new dimensionless coefficient  $\alpha_B$ . It should be noticed that in the range of experimental observation of  $n=0.3$  to  $n=0.45$  the general form of Engelund's laminar coefficient and Burcharth's new coefficient are so similar as to be indistinguishable.

Shih (1990) analysed the large amount of data collected in previous experiments at Wallingford in terms of the Engelund coefficients. This data set contained measurements for a wide range of material sizes and gradations. The  $\alpha$  and  $\beta$  values were investigated for any dependence on grain size ( $D_{15}$ ). For material with a narrow grain size distribution laminar constant  $\alpha$  was found to increase with  $D_{15}$  in the way illustrated in Fig.(1). The turbulent constant  $\beta$  was found to decrease exponentially with  $D_{15}$ , as shown in Fig.(1). These results suggested that Engelund's expressions for  $a$  and  $b$  could be modified to provide a scaling law for the permeability. The coefficients  $a$  and  $b$  for the Forchheimer equation become.

$$a = \left[ \alpha_1 + \alpha_2 \left( \frac{g}{v^2} \right)^{\frac{2}{3}} D_{15}^2 \right] \frac{(1-n^3)}{n^2} \frac{v}{g D_{15}^2} \quad (6)$$

where  $n$  = porosity  $\alpha_1 = 1683.71$ ,  $\alpha_2 = 3.12 \times 10^{-3}$ ,  $v$  = kinematic viscosity of water  $\approx 1.14 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$ ,  $g$  = gravitational acceleration =  $9.81 \text{ ms}^{-2}$

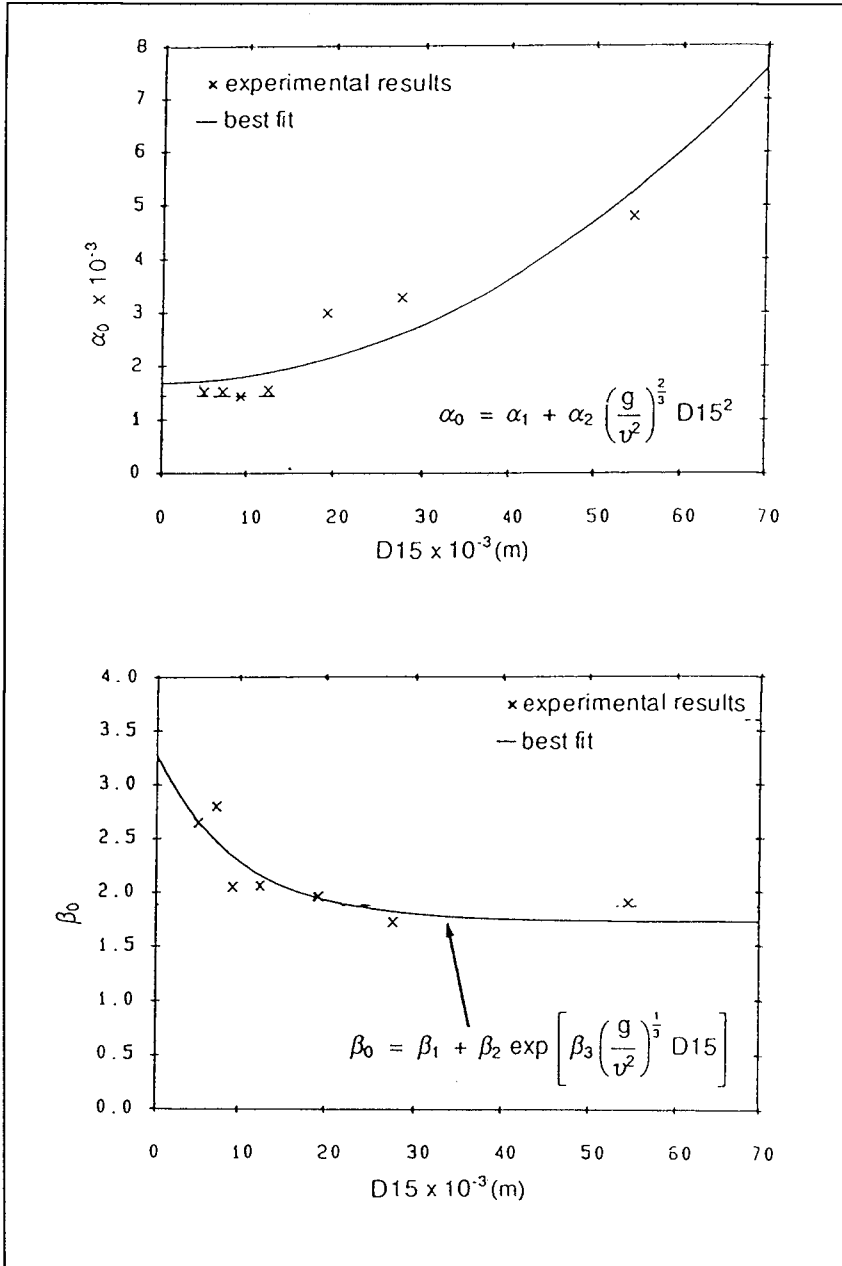

Figure 1 Shih's variation of  $\alpha$  and  $\beta$  with  $D_{15}$

$$b = \left\{ \beta_1 + \beta_2 \exp \left[ \beta_3 \left( \frac{g}{v^2} \right)^{\frac{1}{3}} D_{15} \right] \right\} \left\{ \frac{(1-\eta)}{n^3} \frac{1}{g D_{15}} \right\} \quad (7)$$

A similar analysis was carried out on the data from material with a wider size grading and a formula for an equivalent  $D_{15}$  is proposed for use in these formulae.

Following the analysis by Shih and inspection of data collected at Aalborg University, Burcharth & Christensen (1991) suggests that the Forchheimer equation does not accurately model the behaviour of the flow through porous media. He proposes that a plot of  $l/u$  against  $u$  does not have the linear form

**Figure 2** Flow regimes suggested by Burcharth

demand by the Forchheimer equation, but has the form shown in Fig.(2). The extreme portions of the graph represent laminar and turbulent flow regimes as indicated, while between these two extremes lies a transition region modeled by the Forchheimer equation.

Burcharth interprets the trends in  $\alpha$  and  $\beta$  as the result of differing flow regimes in the separate tests. The intercept and gradient of the line in Fig(2) is a measure of  $\alpha$  and  $\beta$  respectively. For tests conducted with small material the flow is describe by the Forchheimer equation and yields small values of  $\alpha$  and large values of  $\beta$ . Conversely of large material the flow regime is

turbulent and has correspondingly large values for  $\alpha$  and small values for  $\beta$ .

This would mean that the Forchheimer equation could not be used to extrapolate from small scale tests to prototype material. At this stage this hypothesis could not be confirmed as no single experiment had been conducted over sufficiently wide a range of Reynolds number to allow any deviation from the Forchheimer equation to be observed.

In addition to this interpretation there are further doubts about the validity of the scaling formulae proposed by Shih. The accuracy of the measurements of the  $\alpha$  and  $\beta$  coefficients are both functions of material size in just the form required to produce the trends reported by Shih.

## 5 THE PERMEAMETER EXPERIMENTS

To test Burcharth's hypothesis the permeameter at Wallingford was modified to approximately double its maximum flow rate. This would allow measurements to be made over a larger range of Reynolds number and thus increase the opportunity of finding deviations from the Forchheimer equation.

To test for the effects of shape five types of material were tested and were classified according to shape in the following manner:

- TABULAR: The maximum/minimum dimension was greater than two. Flat and elongate material was included. Selection was by eye.
- CUBIC: The maximum/minimum dimension was less than two and there was at least one pair of parallel faces. Selection was by eye.
- FRESH: The angular material left after the tabular rock had been removed.
- SEMI-ROUND: Fresh material was rounded by abrasion to achieve a 5 to 10% weight loss.
- ROUND: Fresh material was rounded by abrasion to achieve a 20 to 25% weight loss.

The source material was crushed Carboniferous limestone which had been sorted into the above classifications for a previous study on the effects of material shape on stability. The  $D_{50}$  of the material in each group  $\approx$  50mm. A full description of the material preparation is given by Bradbury et al. (1988).

The above material was tested in the large permeameter at Wallingford. This permeameter consists of a large cylinder of 0.6m diameter and 1m long, which is mounted with its axis vertical. The material is loaded into the permeameter and water is pumped into the bottom of the cylinder and allowed to flow freely out from the top. The pressure gradient is measured across the material by two pressure tappings 0.5m apart attached to a differential pressure cell. The corresponding flow rate is measured by a magnetic

flowmeter mounted in the entry pipe.

## 6 SHAPE ANALYSIS

The material used in the tests with the modified permeameter had previously been analysed by Latham, at Queen Mary College, University of London, and a full description of the technique is given in Latham et al. (1988).

A sample of each type of stone was placed on a light table and an image of its silhouette obtained with a video camera. The resulting image was then digitised and passed on to a computer. Both a Fourier transform and a fractal technique were used in the analysis of the results.

### 6.1 Fourier transform analysis

Once the digital form of the stone's silhouette has been obtained on the computer, it is a simple task to obtain the coordinates of the silhouette outline. From these coordinates the centre of the projected area or "centre of gravity" of the silhouette may be calculated and this is then used as a centre reference point. The outline may then be described in polar coordinates  $(r, \theta)$

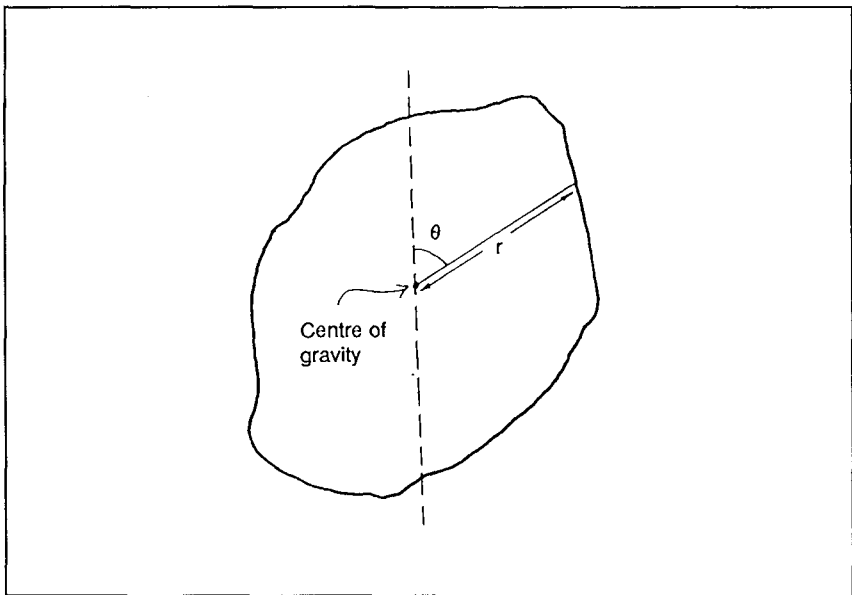

Figure 3 Coordinate system for shape analysis

using the centre of gravity as the origin (see Fig.(3)). A Fourier analysis was

carried out on the normalised radius vector of the outline. The outline was be described by a Fourier series in the following manner:

$$r(\theta) = C_0 + \sum_{n=1}^{\infty} C_n \cos(n\theta - A_n) \quad (8)$$

where  $C_n$  is the amplitude coefficient of the  $n^{\text{th}}$  harmonic,  $A_n$  is the phase angle of the  $n^{\text{th}}$  harmonic,  $n$  is the harmonic order,  $\theta$  is the polar angle measured from an arbitrary reference line.

The gross shape of the outline is described by the lower harmonics in the series, while the higher harmonics provide information on the degree of surface roughness.

The problem now remains of choosing suitable parameters from the resulting harmonic amplitude coefficients. It is useful to first define a coefficient  $Q$  which provides a flexible quantitative index which can be computed over all or a chosen range of harmonics and is defined as:

$$Q = (0.5 \sum C_n^2)^{0.5} \quad (9)$$

The following parameters are suggested by Latham & Poole (1987)

Symbol	Range of n	Name
$P_n$	1 to $\infty$	Fourier noncircularity
$P_C$	1 to 10	Fourier shape factor
$P_R$	11 to 20	Fourier asperity roughness factor

In their report Latham & Poole (1987) choose to give the results of the shape analysis in terms of  $P_C$  and  $P_R$ , and these results are presented in Table (1). Along with the mean values the 15, 50 and 85% exceedance values, are also given to provide an indication of the degree of spread within a sample.

## 6.2 FRACTAL SHAPE DESCRIPTION

A better measure of the convolution or roughness of a stones outline may be provided using the concepts of fractal geometry, described by Mandelbrot (1982). The concept is centred on the way the measured perimeter of the silhouette image changes as a function of the scale of the measuring instrument. In our case the perimeters of the silhouette were measured by stepping around the outline with a "hypothetical" pair of dividers set at a given step length. This process was then repeated many times with differing step

SHAPE	GROSS SHAPE Fourier Shape Contribution Factor $P_c$				ROUGHNESS Fourier Asperity Roughness $P_r$				SURFACE TEXTURE Fractal Coefficient $F_d$

Table 1 Shape analysis of rubble material

lengths so that the variation of measured perimeter with step length could be studied. A Mandelbrot-Richardson plot was then made of the log perimeter measured against the log step length. The gradient of the resulting plot is a measure of the roughness of the outline and is the negative of the fractal shape coefficient  $F$ . The resulting values of  $F$  are given in Table (1).

## 7 RESULTS

The data from each test was plotted as  $i/u$  against Reynolds number and a linear regression made to obtain values for  $b$  from which  $\beta$  was determined. It should be noted that for the size of material used in these tests the flow was always predominately turbulent so no attempt was made to measure the lamina coefficient  $a$  and  $\alpha$ .

Each data set was investigated for variations from the Forchheimer equation as proposed by Burcharth. No variation larger than the typical experimental error was observed for any of the data sets.

Figure 4  $\beta$  plotted against the Fourier shape contribution factor  $P_C$

The  $\beta$  values of each test have been plotted against each of the shape parameters described in Section 6, Fig(4,5 & 6). No trend can be seen for the Fourier shape contribution factor  $P_C$ . The Fourier asperity roughness and

Figure 5  $\beta$  plotted against the Fourier asperity roughness  $P_R$

the fractal coefficients both show  $\beta$  as a decreasing function. The Fourier asperity roughness and fractal coefficient are a measure of the surface roughness. It may be concluded that the nature of the surface of the test material is more important than the overall shape of the material in the determination of the turbulent coefficient  $b$ .

It should be stressed that the range of tested material was small (only five groups), so the form of  $\beta$  as a function of the  $F$  or  $P_R$ , can not be determined. Figs (4,5 & 6) show that this material forms only two distinct groups in terms of surface roughness. The equant, tabular and fresh rock all have very similar surface properties, which are essentially those of freshly crushed rock. The preparation of the round and semi-round material produces a smooth surface which behaves in a different way to turbulent flows.

The intention of these tests was to investigate the suitability of the shape analysis parameters, rather than to produce enough data to derive the form of  $\beta$  as a function of these parameters. It is hoped that these experiments will point the way for further tests, which will make use of these shape description techniques.

## 8 CONCLUSIONS

The Forchheimer equation has been used in the analysis of permeability data

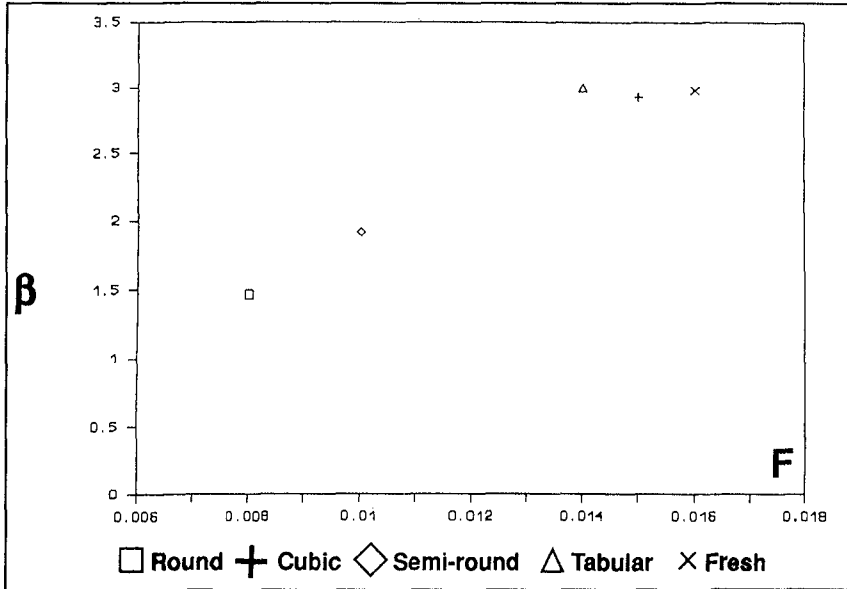

Figure 6  $\beta$  plotted against the fractal coefficient F

for many years and up to data there has been no significant evidence to suggest that it is not applicable over the whole range of possible flow rates. The data collected in these experiments supports this view, in that within the accuracy of the experiments no deviation from Equ.(2) could be found. The question still remains that the range of Reynolds numbers tested for a single sample might not be large enough to demonstrate a deviation from the Forchheimer equation. If this is the case then some caution must be used in the scaling up of laboratory tests to larger prototype material.

The material tested with the modified permeameter at Wallingford was made up of samples of narrow size grading of around 50mm, which had been hand graded with respect to shape. This material was analysed for shape by the use of a video imaging technique. The shape is described by three parameters, the gross shape of the material is provided by the Fourier shape contribution factor  $P_C$ , the surface roughness is described by the Fourier asperity roughness  $P_R$  and the fractal coefficient  $F$ . The value of  $\beta$  shows no distinguishable trend as a function of the Fourier shape contribution factor  $P_C$ , however  $\beta$  is a function of both the asperity roughness,  $P_R$  and the fractal  $F$ . These results indicate that the turbulent coefficient  $\beta$  is a function of the surface texture of the rubble material, rather than the overall gross shape of the material. The data set from these experiments was small and far more data is required over a wider range of material surface textures before the dependency of  $\beta$  can be determined.

## CHAPTER 132

### NEW METHODS TO EVALUATE WAVE RUN-UP HEIGHT AND WAVE OVERTOPPING RATE

Yoshimichi Yamamoto<sup>1</sup>  
Kiyoshi Horikawa<sup>2</sup>

#### Abstract

Recently, waterfront development and the mean sea level rise due to greenhouse effect have been noticed, and it has become important to develop a practical method to calculate wave run-up height or wave overtopping rate.

This paper presents new methods for calculating the wave run-up height on and the wave overtopping rate over a seawall located on a complicated bottom profile of sea coast. The proposed methods were tested both in the laboratory and in the field. The predicted results coincide well with the available data.

#### Introduction

Waterfront development has extended rapidly over recent years. Governmental agencies are also seriously concerned about the mean sea level rise due to greenhouse effect. The mean sea level is expected to be risen some 20cm to 110cm by the year of 2030. Under such circumstances, precise evaluation of the wave run-up height or of wave overtopping rate is of extreme importance for the future planning of coastal preservation.

Many conventional methods to calculate the wave run-up height and the wave overtopping rate exist, but the scope of applicability of these methods is limited (refer to Herbich, 1991). For example, Saville's nomograph (1957) for calculating the wave run-up height can not evaluate the difference of bottom profiles from the breaking point to the extent of maximum wave run-up. Goda's nomographs (1970a) for calculating the wave overtopping rate are graphs for the condition of vertical seawalls. Battjes' calculating method (1974) for the overtopping rates over sloped structures does not consider the influence

---

1 Graduate student, Saitama University, 255, Shimo-Okubo, Urawa, Saitama, 338, Japan.

2 President, Saitama University, ditto.

of bottom profiles. Thus this method is applicable only for non-breaking waves. Therefore it is important to develop methods that can be applied to a wide range of conditions such as complicated bottom profiles and arbitrary sloped seawalls.

Kobayashi et al.(1989) developed a numerical model for the calculation of the wave overtopping rate. In their study, shallow water long wave theory was used and a finite difference method was applied. However the effects of wave breaking on wave overtopping were not taken into account in the above model. Mizuguchi et al.(1988) considered the effects of wave breaking on wave run-up height by using a set of an energy equation including a term of energy dissipation by wave breaking and a time-averaged integral momentum equation. Although the wave run-up height can be obtained by using the above method, but the wave overtopping rate can not be obtained. These numerical models should be keenly promoted in order to develop suitable calculating methods.

On the other hand, it is also important to develop methods that can be easily applied to complicated coastal profiles on site using a personal computer. Therefore in this paper characteristics of wave run-up profile were investigated and new methods consisting of experimental equations were proposed.

### New Method for the Evaluation of the Wave Run-up Height

#### (1) For Breaking Waves

It is assumed that the influence of the complicated coastal profile on the wave run-up height can be evaluated by introducing a hypothetical single slope angle  $\alpha$  proposed by Nakamura et al.(1972) as follows:

$$\alpha = \tan^{-1} (R + h_b)^2 / 2A \quad (1)$$

where  $R$  is the wave run-up height,  $h_b$  is the breaking water depth and  $A$  is the shaded area from the depth at the breaking point to the extent of maximum wave run-up, as shown in Figure 1.

Figure 1. Hypothetical single slope angle (Nakamura et al.,1972).

By considering the balance between the potential energy of maximum wave run-up and the kinetic energy of waves on a shoreline, the wave run-up height can be expressed as follows:

$$R = (1 - k) U_s^2 / 2g \tag{2}$$

where,  $k$  is a coefficient of energy loss caused by sea-bed friction,  $U_s$  is the fluid velocity at the shoreline and  $g$  is the acceleration of gravity. According to Iwagaki et al.(1966),  $U_s$  can be expressed by Eq.(3).

$$U_s = C \sqrt{g \bar{\eta}_s} \cos \alpha \tag{3}$$

where,  $C$  is a coefficient dependent on the sea-bed topography in surf zone and  $\bar{\eta}_s$  is the wave set-up at the shoreline. Substitution of Eq.(3) into Eq.(2) gives

$$R = 0.5(1 - k) C^2 \bar{\eta}_s (\cos \alpha)^2 \tag{4}$$

If Eq.(4) is valid, the value of  $R / \bar{\eta}_s$  should be constant in case of the coasts with the same coefficients  $k, C$ . In the laboratory experiment against the same sea-bed, the wave set-up was measured at a shallow point near the shoreline by a servo-type waterlevel gauge. It was assumed that this measured value of the wave set-up corresponds to the value of  $\bar{\eta}_s$  and the relationship between the value of  $R / \bar{\eta}_s$  and the deep water wave steepness was investigated. Figure 2 shows the result of this investigation. From this figure, it is remarkable that Eq.(4) is applicable with the conditions of the experiment. Equation (4) indicates that the wave set-up is important for the evaluation of the wave run-up height for breaking waves.

Figure 2. Relation between  $R / \bar{\eta}_s$  and wave steepness.

Yamamoto (1988) obtained the following empirical equation:

$$\bar{\eta}_s = H_s / [2.4(\tan \alpha)^{0.3}] = 0.8(\tan \alpha)^{0.6} H_b \tag{5}$$

where  $H_s$  is the wave height at the shoreline and  $H_b$  is the breaking wave height. Sunamura (1983) obtained the following equation for  $H_b$ :

$$H_b = (\tan \alpha)^{0.2} (H_o / L_o)^{-1/4} H_o \tag{6}$$

where  $H_0$  and  $L_0$  are the wave height and the wavelength in deep water respectively. From Eqs.(4), (5) and (6), the following equation can be obtained:

$$R = 0.4(1-k)C^2 (\cos\alpha)^2 (\tan\alpha)^{0.8} (H_0/L_0)^{-1/4} H_0 \quad (7)$$

The coefficient  $(1-k)C^2$  is formulated by comparison of Eq.(7) with data of Nakamura et al.(1972) against several types of seawalls located on complicated bottom profiles as follows:

$$(1-k)C^2 = 3.125(\tan\alpha)^{-0.2} \quad [1/3 \geq \tan\alpha \geq 1/50] \quad (8)$$

Now, the wave run-up height  $R$  and the hypothetical slope  $\tan\alpha$  can be determined by using Eqs.(1), (7) and (8). Since the relationship between  $R$  and  $\tan\alpha$  is nonlinear, an iterative scheme is used.

First, the breaking water depth is evaluated by using the nomograph for non-overtopping by Goda (1970b). The reduction of the breaking water depth due to wave overtopping is ignored in order to simplify the treatment. The comparison of the breaking water depths and the breaking wave heights obtained from wave overtopping tests in this study with those for non-overtopping by Goda (1970b) is presented in Figure 3. This figure shows that the breaking water depth during wave overtopping is smaller than that for non-overtopping.

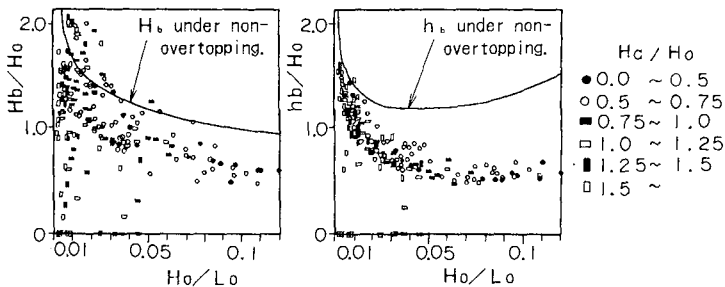

Figure 3. Breaking wave height and breaking water depth during wave overtopping.

Second, the wave run-up height is assumed and an approximate value of  $\tan\alpha$  is obtained by using Eq.(1).

Third, the wave run-up height is calculated by Eq.(7) with the evaluated  $\tan\alpha$ . The procedure is repeated until the difference between successive solutions of the wave run-up height  $R$  and  $\tan\alpha$  is less than some prescribed tolerance.

The wave run-up heights calculated by using Eqs.(1), (7) and (8) agree well with those obtained by using the nomograph presented by Nakamura et al.(1972) as shown in Figure 4. The comparison of calculated values with field data is shown in Figure 5.

Usually, the assumption that the influence of the seabed profile on the wave run-up height is small for non-breaking wave is acceptable. Thus the following equation of Sainflou (1928) was used to evaluate the wave run-up height.

$$R = (1.0 + \pi (H/L) \coth(2\pi h/L)) H_o \tag{9}$$

Figure 4. Comparison of R/Ho calculated by using Eq.(7) with R/Ho obtained by nomograph presented by Nakamura et al.

Figure 5. Comparison of R calculated by using Eq.(7) with field data.

New Method for the Evaluation of the Wave Overtopping Rate

(1) For Breaking Waves

The actual shape of the wave run-up profile is presented in Figure 6(a). Takada(1977) assumed that it could be approximated by the one presented in Figure 6(b) and studied the wave overtopping rate over one wave period  $T$ . He found that this value is proportional to the shaded area  $A$  in Figure 6(b). That is,

$$q \propto A \quad (10)$$

where  $q$  is the wave overtopping rate over one wave period ( $m^3/m/T$ ) and  $A$  is a hypothetical area above the seawall crown in a wave run-up profile shown in Figure 6(b) and obtained by the following equation.

$$A = (R - H_c) \times [(X_o/R) - \cot \alpha] (R - H_c) / 2 \quad (11)$$

where  $H_c$  is the freeboard above SWL and  $X_o$  is the horizontal length of the shape of the wave run-up profile.

(a) Actual shape

(b) Assumed shape

Figure 6. Actual shape and assumed shape of wave run-up profile.

From Eqs.(10) and (11), the overtopping rate  $q$  can be predicted by the following equation:

$$q = c [(X_o/R) - \cot \alpha] (R - H_c)^2 / 2 \quad (12)$$

where  $c$  is a overtopping coefficient which can be determined from experiment.

In Figure 6, the upper part of the actual shape of the wave run-up is thinner than that of the assumed shape, and the value of  $X_o$  in the actual shape is longer than that of the assumed shape. Thus if the

value of  $X_0$  of the actual shape is used, the resultant evaluation of the area  $A$  will be extremely exaggerated. Therefore the value of  $X_0$  of assumed shape is used. It is calculated by using the following equation obtained from geometrical relationship.

$$X_0/R = \cot[\alpha - \tan^{-1}(hm/R/\sin\alpha)] \quad (13)$$

where  $hm$  is the maximum thickness of the water tongue shown in Figure 6(b).

The expression for  $hm$  can be found by the following procedure: By using the long wave theory, the wave run-up profile on the uniform slope can be obtained as follows:

$$\eta = \frac{H_a}{2} J_0\left(-\frac{\omega}{2ig}\sigma\right) \sin\left(-\frac{\omega}{2ig}\lambda\right) - \frac{2gH_a^2}{\sigma^2} J_1^2\left(-\frac{\omega}{2ig}\sigma\right) \cos^2\left(-\frac{\omega}{2ig}\lambda\right) \quad (14)$$

where  $\eta$  is the water surface elevation above SWL,  $H_a$  is the wave height at the point where there is no energy loss by the breaking waves and the average water level  $\bar{\eta}$  nearly equals 0,  $\omega$  is the angular frequency ( $= 2\pi/T$ ),  $J_0$  and  $J_1$  are the Bessel functions of the zeroth and first order respectively,  $\sigma = 4\sqrt{g(iX + \eta)}$ ,  $\lambda = 2(u - g i t)$ ,  $i$  is the bottom slope ( $= \tan\alpha$ ),  $x$  is the spatial coordinate directed from shore towards offshore,  $u$  is the horizontal component of the water particle velocity and  $t$  is the time.

Next the simplified form of the energy equation proposed by Izumiya and Horikawa (1983) is solved in order to obtain the relationship between the wave height  $H_a$  and the breaking wave height  $H_b$ .

$$\frac{d\gamma}{dx} + \frac{5\gamma}{4x} - \frac{1}{400i} \frac{\gamma^2}{x} - \frac{9}{80i} \frac{\gamma^3}{x} \left(1 - \frac{0.072}{\gamma^2}\right)^{1/2} = 0 \quad (15)$$

Bottom friction term                      Breaking wave term

The coordinates used here is the same as that in Figure 6(a) and  $\gamma$  is the wave height - water depth ratio. By performing a Taylor expansion on the breaking wave term in Eq.(15) with respect to  $0.072/\gamma^2$  and omitting small terms at the position where the variable  $x$  is reasonably large, the remained term of the energy loss is the only that by the breaking waves. The integration of this simplified energy equation under the condition of  $\gamma = \gamma_b$  at the breaking point  $x = x_b$  results in Eq.(16).

$$\gamma = 1 / \left\{ \left( \frac{1}{\gamma_b^2} - \frac{9}{100i} \right) \left( \frac{x}{x_b} \right)^{5/2} + \frac{9}{100i} \right\}^{1/2} \quad (16)$$

Experimentally it can be assumed that the position where the average water level  $\bar{\eta}$  nearly equals 0 is expressed by  $x_a \approx 0.8x_b$ . Therefore  $H_a (\approx \gamma \times 0.8x_b i)$  is obtained by Eq.(17).

$$H_a = (0.8H_b/\gamma_b) / \left\{ 0.572 \left( \frac{1}{\gamma_b^2} - \frac{9}{100i} \right) + \frac{9}{100i} \right\}^{1/2} \quad (17)$$

If the maximum value of  $\eta$  at  $X=0$  is derived by the differential calculation of Eq.(14) and the wave set-up at the shoreline is considered by using Eq.(5), the following equation can be obtained as an approximation for  $hm$ .

$$\frac{hm}{H_b} = \frac{1}{2} \frac{H_a}{H_b} \cdot J_0 \left( \frac{4\pi H_b}{\sqrt{gTi}} \sqrt{\frac{hm}{H_b}} \right) + 0.8i^{0.6} \tag{18}$$

The results of the calculations by using Eq.(18) are shown as the dotted lines in Figure 7. The plotted data are the measured values of the experiment for non-overtopping. The length, width and height of the two-dimensional flume used were 18m, 40cm and 75cm respectively, while the slope of the seabed was 1/10. The front slopes of the sea-walls were 1:4, 1:2, upright. The wave height, period and water depth were variously changed.  $H_b$  was obtained by using Eq.(6). The values calculated by using Eq.(18) are larger than the measured values. It takes long time to calculate the Bessel function  $J_0$  in Eq.(18). Therefore the use of the approximate expression of the Bessel function and the substitution of realistic values for  $hm$  induce the following equation:

$$\frac{hm}{H_b} \approx 0.7 \left[ \frac{0.375}{\pi^{3/4}} \left( \frac{i}{\sqrt{0.8H_b/L_0}} \right)^{1/2} + 0.8i^{0.6} \right] \tag{19}$$

The results of the calculations by using Eq.(19) are shown as the solid lines in Figure 7.

Figure 7. Relation between the maximum thickness of the water tongue and the bottom slope.

Finally the overtopping coefficient  $c$  was investigated. The overtopping coefficient represents the percentage of the imaginary area of the wave run-up profile that passes over the sea wall crown and that actually reaches the inland side. It can be assumed that the overtopp-

ing coefficient increases with the increase of the lateral component of the water block movement of the wave run-up. Therefore this coefficient increases as the front slope angle of the seawall or the wave steepness becomes smaller. Because of this, the two parameters  $(\cos \theta + \cos \alpha) / 2$  and  $(L_o / H_b)^{1/3}$  were considered, and the relationship between the non-dimensional wave overtopping rate and these parameters was investigated. In the above expression,  $\theta$  is the front slope angle of the seawall. The experiment for overtopping was conducted by using the same flume and models that were used for the experiments of non-overtopping. The wave height, period and water depth were variously changed. The experimental results are shown in Figure 8 which indicates that the non-dimensional wave overtopping rate increases as the two parameters increase. By substituting experimental data into Eqs.(12), (13) and (19), Eq.(20) for the coefficient  $c$  can be obtained.

$$c = 0.1(L_o / H_b)^{1/3} (\cos \theta + \cos \alpha) / 2 \tag{20}$$

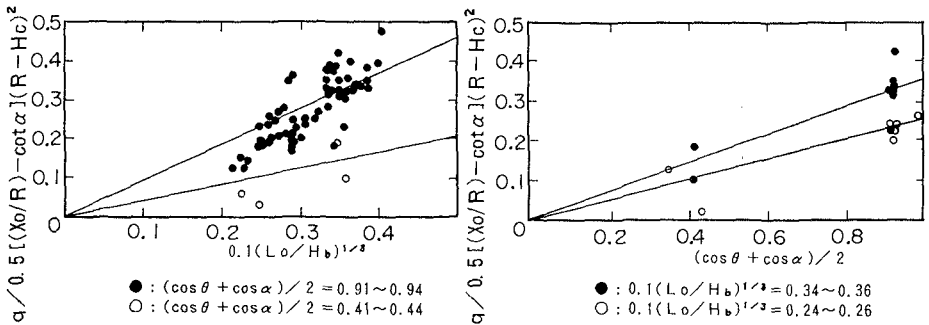

Figure 8. Relation between the wave overtopping rate and the wave overtopping coefficient.

Figure 9 depicts the comparison between the calculated values of  $q$  by Eqs.(12), (13), (19) and (20) and the experiment data. This figure suggests that there is a good fit between the calculated values of  $q$  and the measured ones. Figure 10 depicts the comparison of the values of  $q$  computed by using Eq.(12) with the ones computed by using the equation proposed by Kikkawa et al.(1967). Figure 11 is the same comparison between the values obtain by Eq.(12) and the experiment data for a compound bottom profile by Inoue et al.(1972). However the breaking water depths for non-overtopping were used for these calculations.

(2) For non-breaking waves

It can be assumed that the effect of the seabed profile on the wave overtopping rate is small for non-breaking waves. Therefore the following experimental equation by Takada(1977) was used.

$$q = 0.65 (R - H_c)^2 \tag{21}$$

where  $R$  is the wave run-up height determined by Eq.(9).

Figure 9. Comparison of  $q$  calculated by Eq.(12) with experimental data (regular waves).

Figure 10. Comparison of  $q$  calculated by Eq.(12) with  $q$  calculated by the Kikkawa et al.' equation (regular waves).

Figure 11. Comparison of  $q$  calculated by Eq.(12) with experimental data (regular waves).

(3) For irregular waves

The wave overtopping rate for irregular waves can be calculated by the following equation:

$$Q = \int_0^\infty \int_0^\infty q \cdot p \, dH \, dT \tag{22}$$

where,  $Q$  is the overtopping rate of irregular waves,  $p$  is the joint distribution function of wave heights and wave periods,  $q$  is the overtopping rate of the component waves and  $H$  and  $T$  are the wave height and the wave period of the component waves respectively. The term  $p$  proposed by Watanabe et al.(1984) can be expressed as follows:

$$\left. \begin{aligned} p &= p(\tau) p(\chi_f | \tau) / \chi_m(\tau), \\ p(\tau) &= \frac{\nu \sqrt{1 + \nu^2}}{1 + \sqrt{1 + \nu^2}} \frac{\nu^2}{[\nu^2 + (\tau - 1)^2]^{3/2}}, \\ \nu &= \sqrt{(m_0 m_2 / m_1^2) - 1}, \\ p(\chi_f | \tau) &= (32 / \pi^2) \chi_f^2 \exp[-4 \chi_f^2 / \pi], \\ \chi_f &= \chi / \chi_m(\tau), \\ \chi_m(\tau) &= \sqrt{S(f) f} / \int_0^\infty \sqrt{S(f) f} p(\tau) d\tau \end{aligned} \right\} \tag{23}$$

where  $\chi = H / \bar{H}$ ,  $\tau = T / \bar{T}$  (the overbar indicates an average value),  $f$  is the frequency,  $m_k$  is the  $k$ th order moment of the spectrum and  $S(f)$  is the Bretschneider-Mitsuyasu Spectrum.

The overtopping rate for breaking waves is calculated by using Eqs.(1), (7), (8), (12), (13), (19) and (20). That for non-breaking waves is

calculated by using Eqs.(9) and (21).

Figure 12 is comparison of the calculated values by this method with the prototype data. From this figure, it is remarkable that this method is applicable for the prototype conditions.

Figure 12. Comparison of  $Q$  calculated by Eq.(22) with field data. (irregular waves)

#### Application of The Present Method to Predict The Overtopping Rate in Case of The Mean Sea Level Rise Due to Greenhouse Effect

If the lapse-rate of air temperature is assumed to increase by greenhouse effect in future, there is a possibility that the intensity of typhoon becomes stronger. Manabe et al.(1990) predicted that the lapse-rate of air temperature is increased by this effect in the zone where many typhoons are generated. Therefore it is important to investigate the effect of the increment of the typhoon intensity on the wave overtopping rate in addition to the mean sea level rise.

Emanuel(1987) stated that 3° C increment in sea surface temperature leads to 30~40% increase in the maximum pressure drop of tropical cyclone and 15~20% increase in the maximum wind speed.

Now if these conditions are applied to a typhoon model (radius of the isopressure line 1000mb is 600km and central pressure 930mb), a remarkable increase in the wave overtopping rate were predicted by the present method and the results are shown in Figure 13. In this figure, type A is the case when there is a seawall of 10m height on the uniform sea bottom of 1/10 slope and type B is the case when there is the same seawall on the compound sea bottom of 1/10 and 1/100 slopes.

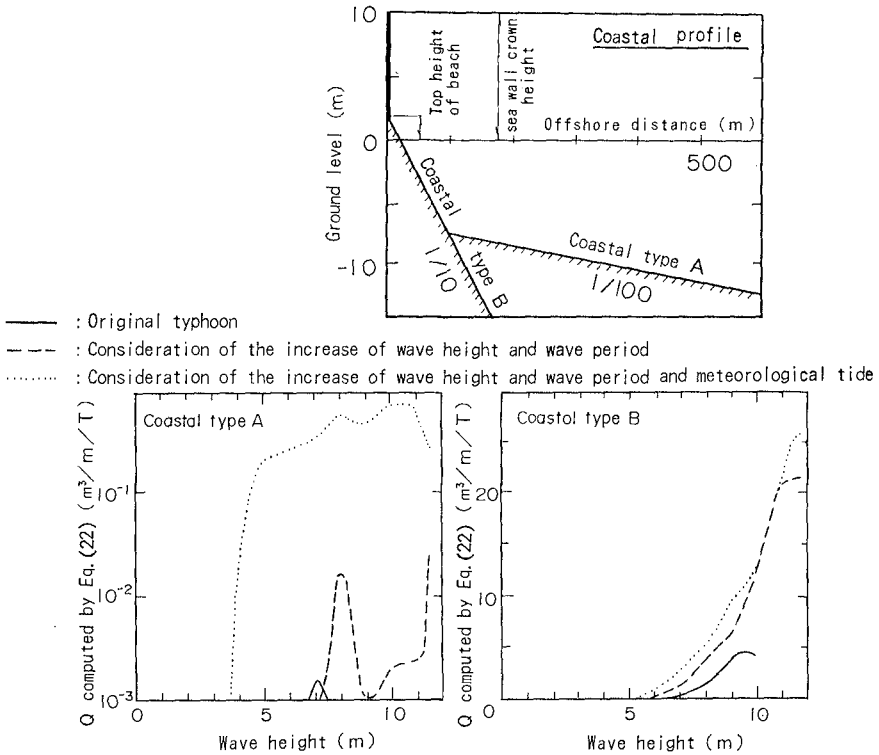

Figure 13. Increase in wave overtopping rate due to a typhoon.

Conclusions

- (1) The proposed methods have been checked with the laboratory data as well as the field data. The agreement between the calculated values and the available data is favourably good.
- (2) If the intensity of typhoon becomes stronger by the greenhouse effect, the rate of wave overtopping may increase remarkably by the small increment of the typhoon intensity.

In case the bottom slope of sea is mild, the heights of infra-gravity waves become large in the surf zone, and the wave overtopping rates by these waves cannot be ignored. This problem should be a subject of the future study.

## CHAPTER 133

### USE AND BEHAVIOR OF GABIONS IN COASTAL PROTECTION

Kees d'Angremond<sup>1</sup>, M.ASCE  
Egbert J.F. van den Berg<sup>2</sup>  
Jan H. de Jager<sup>3</sup>

#### Abstract

To limit erosion during severe storms, it is considered to apply a hard core in a dune, prior to beach nourishment. One of the potential structural alternatives is a gabion protection. The behavior of gabions was studied. It appeared that the rigidity is a factor that cannot be neglected in model investigations. Full scale tests have been carried out to establish the flexibility in prototype. A model material was developed to reproduce the flexibility on model scale.

#### Introduction

Erosion of sandy coasts is a well known phenomenon. It may be an ongoing process, caused by a gradient of the longshore transport, or it may be an alternating process, mostly caused by the cross section adapting itself to varying wave conditions. In many instances, the erosion will be noted first by a narrowing of the beach. Subsequently, the dunes along the beach will erode as well. In densely populated areas, or areas with a high recreational value, this process leads inevitably to loss of infrastructure and property and to a cry for remedial measures.

Over the years, landowners have tended to choose for the most direct way of protection through the construction of seawalls and revetments. The latter method is not always favored by the coastal engineers because of the risk of undermining of the foundation in case of ongoing erosion. A wide variety of technical solutions is available nowadays, ranging from the construction of (offshore) breakwaters and groins to extensive beach nourishment schemes. Especially the option of beach nourishment has the advantage that the recreational function of the beach is maintained in the best possible way. Landowners, however, keep their reservations with respect to this method as it is mostly not a permanent solution and needs to be repeated from time to time. Extreme weather conditions short before a planned replenishment may still cause erosion of the dune face, and may consequently lead to damage of property.

In the Netherlands, this type of damage causes little concern with the Central Government, as the function of the dune as sea defense is not jeopardized. Local authorities and landowners, however, would like to prevent too frequent occurrence of such damage. The cost of remedial measures must therefore be low. For this reason, it is frequently considered to construct a hard element inside the dune when the coast is being restored (Figure 1).

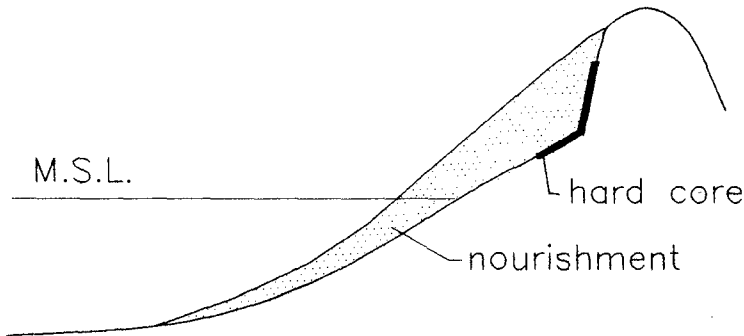

Figure 1. Hard core in dune.

In future storms this core may prevent erosion to make rapid progress. The core is not supposed, however, to survive extreme storms and to protect the hinterland from flooding under the most extreme conditions. Examples of such structures are available (or rather hidden under the sand) at various locations along the Dutch coast. Here again, however, the main risk is the undermining of the toe of such structures.

### Flexible Toe Protection

To prevent this erosion of the toe it is good engineering practice to provide an anti scour apron in front of the toe. The apron is constructed at the actual beach level, or slightly below, to prevent large quantities of excavation during construction. When the apron gets exposed, it should settle along with the erosion of the beach in front of it, and thus prevent the scour hole to reach the actual structure. It is evident that both, the apron and the structure must be flexible enough to follow the settlements, and that it should be heavy enough to resist the wave forces. Asphalt, fascine mattresses, geotextile covered with riprap are known materials for this kind of application. They all have their specific advantages and disadvantages. Recently, also the use of gabions has been suggested for this purpose in the Netherlands, as this may lead to considerable savings with respect to the cost of armor. Although there are examples of a satisfactory performance of gabions in other countries, not all reports were favorable. Therefore, it was considered useful to study the behavior of gabions once more. One of the most important questions was in how far the gabions would settle along with the deformation of the seabed directly in front. Model investigations into this effect are hampered till now by the impossibility to scale down the flexibility of the gabion mattresses. The flexibility of the gabions may influence at the same time the stability under wave attack.

### Flexibility of Gabions

To obtain insight into the flexibility of gabions, full scale tests have been performed on mattresses with varying fill rate. The dimensions of the mattresses were 4.00 m x 2.00 m x 0.5 m (L x W x t). A single test was carried out on a mattress of 0.3 m thick.

The gabions proper consisted of steel wire mesh, twisted in a hexagonal pattern as shown in Figure 2. The characteristic size D amounted to 8 cm. The steel wire had a diameter of 2.7 mm, and was coated with PVC, resulting in a gross diameter of 3.8 mm. The tensile strength of the wire material amounted to 380-500 N/mm<sup>2</sup>.

Figure 2. Wire mesh.

The gabions were filled with gravel with a density of  $2600 \text{ kg/m}^3$ , and dimensions between 80 and 120 mm. The bulk density was measured and amounted to  $1550 \text{ kg/m}^3$ , resulting in a porosity of about 40 %. The fill rate was determined by weighing the fill material and converting the weight into volume by using the measured value of the bulk density. The fill rate is defined as the ratio between the volume of the fill material and the nominal volume,  $L \times W \times t$ . The test conditions are summarized in Table 1.

Test no.	Thickness (mm)	Fill rate (%)
1	500	105
2	500	105
3	500	110
4	500	110
5	500	110
6	500	100
7	500	95
8	500	85
9	300	110

Table 1. Test Conditions

The stiffness was determined by lifting the mattresses in longitudinal direction, and measuring the curvature. Results of the tests have demonstrated the very high flexibility (or low stiffness). Originally, it was envisaged to derive a stiffness (EI) from the tests, and to relate the value of E to the fill rate of the gabions. The deformations, however, were so large that the normal theory of elastic bending could not be applied any more (Figure 3).

Figure 3. Deformation during lifting.

From the test results, it appeared that the gabions when lifted adapted with a reasonable accuracy to a circular shape. The diameter of the circles showed a direct relation to the fill rate (Figure 4).

Figure 4. Results stiffness test.

### Scaling

In order to prepare scale model tests with gabions in a dune base, one should analyze which effects need to be reproduced in the model, and which effects can be neglected for the time being. The main design aspects are:

- stability under wave attack
- erosion at the toe
- deformation of the toe
- sand tightness

When testing the stability under wave attack, one should ascertain the wave climate at the toe of the structure. This wave climate is fully determined by the water depth in front of the dune, and as such determined to a large extent by the (eroded) level of the foreshore. Unfortunately, erosion of the foreshore is not reproduced adequately under the scales that are usually applied for stability tests. The eroded level of the foreshore is therefore determined with the aid of the mathematical model DUROSTA, which in turn is based on large scale model experiments. Steetzel, 1990). For the actual stability tests, thus, a fixed bed model can be used with a calculated bottom profile. A similar procedure can be followed when stability is calculated on the basis of a Hudson-type formula. When selecting the scale for stability tests, proper attention shall be paid to the permeability in the model. To avoid complications in the transition between laminar and turbulent conditions inside the gabions, model material should preferably be larger than 1 cm diameter, which leads to model scales in the order of 1:10 to 1:20.

The erosion process at the toe of the structure is largely affected by the ratio between orbital velocities and the fall velocity of the sediment. This effect causes strict limits for model scales to be applied, as the grain size of the model material can not be reduced infinitely. Traditionally, this problem is solved by accepting distorted model scales. In case of a combination of morphological and stability problems, application of distorted models is not well possible, since distortion leads to different slopes in model and prototype. Proper reproduction of both phenomena in the same model necessitates model scales in the order of 1:5 to 1:10.

Deformation of the toe itself is a complicated process, which is initiated by erosion creeping forward under the edge of the structure. The extent of this process depends on the capability of the structure to follow the deformation without losing its coherence. It is evident that the flexibility of the structure should be similar in model and prototype. On the basis of the experiments described above, it is necessary that model gabions demonstrate a similar deformation when lifted. In general, model gabions tend to be far too rigid. Initially, two different model materials have been developed. One is consisting of model gabions made out of fabric, and filled with small size gravel. The flexibility is adjusted by manipulation of the fill rate. The other consists of a (fabric) base material of the proper flexibility, covered with artificial ballast. Before making a final choice, it was realized that another process influences the deformation, i.e. loss of base material through the voids of the structure. Although the idea of losing base material seems against the proper functioning of the structure, a closer look leads to a different judgement. By a controlled loss of material, it will be easier to achieve a condition where the toe structure will slowly follow the eroding bed, and eventually bring the erosion to a halt.

It is clear now that requirements for sand tightness must be defined in two different ways for the main body of the structure and for the toe. As sand tightness is ensured in prototype by the application of geotextile under the gabions, this can be done in model as well. The quality of the geotextile can be tested separately. The model scales are therefore hardly affected by considerations of absolute sand tightness. To reproduce the controlled loss of material from the deforming toe, it must be attempted to keep the ratio between base material and filter material constant. This leads to model scales in the order of 1:5 to 1:10, and to the selection of model gabions instead of a base with fixed ballast.

### Design

Before any model tests could be carried out, a preliminary design had to be made. It was decided to select a frequent problem area along the Dutch coast near Egmond as an example. The deep water design wave height was estimated to be around 8 m. Taking into account the erosion in front of the core and the storm surge level, wave heights up to about 2.5 m height could be expected just at the toe of the structure.

For reasons of hydraulic and soil mechanical stability, the main slope was designed under 1:3 between a level of M.S.L. + 2.5 m to M.S.L. + 8.0 m. This part of the slope should be sand tight and statically stable. Sand tightness is achieved by the application of geotextile under the gabions. To avoid local fluidization and micro loss of stability it is considered necessary to apply a layer of gravel in between gabion and geotextile. (Negative experiences reported elsewhere may be due to omission of such layer).

In front of this slope a toe is foreseen under a slope 1:10. As it is the purpose that this part of the structure will follow deformation of the sand bed, sand tightness is deliberately reduced here by leaving out both, geotextile and granular filter.

To initially assess the required thickness of the gabions, use was made of model experiments reported by Brown (1979). According to his studies the stability can be expressed in a Hudson-type stability formula:

$$H/\Delta t = C(1-n) (\cot(\alpha))^{1/3}$$

wherein

H	=	Wave Height in m
t	=	Thickness of gabion in m
C	=	Coefficient
n	=	Porosity
$\alpha$	=	Slope Angle
D	=	Relative Density

It must be noted, however, that derivation of stability on the basis of mechanical analysis would lead to the use of  $(1-n)^{1/3}$  instead of  $(1-n)$ . Fortunately, the variation in the porosity  $n$  is limited.

Figure 5. Design of dune core.

Pilarczyk et al(1987) have converted the Brown formula for irregular waves, leading to the expression:

$$H_g / \Delta t = 4 (1-n) (\cot(\alpha))^{1/3}$$

Here again,  $(1-n)$  is used instead of  $(1-n)^{1/3}$ .

Under the prevailing design conditions this leads to a value of 0.5 m for  $t$ , the thickness of the gabions. A schematic design of the cross section is given in Figure 5.

### Model Tests

Due to space limitations, it was not yet possible to carry out model tests on the structural design according to the preferred model scale 1:10. Instead, preliminary tests had to be performed on a linear scale 1:20. The prototype sand diameter of 0.24 mm was reproduced in model by a material with a grain size of 0.11 mm. Conditions in the flume could be reproduced in such a way that a scour hole of about 2.5 m deep developed right in front of the toe, well in line with the calculated scour depth. As can be noticed from Figures 6 and 7, the toe of the gabion structure was able to follow the erosion and thus to prevent undermining of the actual 1:3 slope.

Figure 6. Erosion at flexible toe.

### Further Research

The results of the investigations so far have demonstrated the possibility to design a satisfactory structure using gabions. The tests will have to be continued on a larger scale to further analyze problems of sand tightness and stability. These tests shall also make clear why in some cases gabion structures did not perform

Figure 7. View of scour test.

satisfactorily where they certainly did in other conditions. It is the present preliminary conclusion that failure in some cases was due to (micro) loss of stability due to the absence of a granular layer between gabions and geotextile.

## CHAPTER 134

### WAVE RUNUP AND OVERTOPPING ON COASTAL STRUCTURES

J.P. de Waal<sup>1)</sup> and J.W. van der Meer<sup>2)</sup>

#### Introduction

Delft Hydraulics has recently performed various applied research studies in physical scale models on wave runup and overtopping on various structures. Runup has extensively been measured on rock slopes. Runup and overtopping have been measured on smooth slopes, including the influence of berms, roughness on the slope, shallow water, short crested waves and oblique (long and short crested) waves. The paper gives an overall view of the final results, such as design formulas and design graphs.

#### Reference conditions

The slope of the structure which will be used as a reference for all kind of influences has a value between 1:1.5 and 1:8. The surface of the slope is smooth, for example concrete or asphalt. Wave conditions are according to common situations in nature. Only irregular waves with a spectrum like Pierson-Moskowitz or Jonswap are considered. The wave conditions are characterized by the significant wave height  $H_s$  of the incident waves at the toe of the structure and the peak period  $T_p$ . The significant wave height and the peak period are combined in the (dimensionless) wave steepness  $s_p$ :

$$s_p = H_s / \left( \frac{g}{2\pi} T_p^2 \right) \quad (1)$$

where:

$H_s$  = significant wave height, average of highest one-third (m)

$T_p$  = peak period (s)

$g$  = gravitational acceleration ( $m/s^2$ )

The wave conditions cover the range  $0.010 \leq s_p \leq 0.045$ . Under reference conditions the water depth  $h$  at the toe of the structure is at least  $3 H_s$ , which means that the wave height is assumed to be Rayleigh distributed.

Delft Hydraulics, P.O. Box 152, 8300 AD Emmeloord, The Netherlands

The runup on the slope under the irregular wave conditions is characterized by the 2% runup  $R_{u2\%}$ .  $R_{u2\%}$  is defined as the level with respect to SWL which is exceeded by two per cent of the number of incident waves.

Wave runup on plane smooth slopes

Runup is one of the aspects of the behaviour of waves on a slope and can be characterized by the breaker parameter (also called surf similarity parameter)  $\xi_p$ . This breaker parameter is defined as:

$$\xi_p = \frac{\tan\alpha}{\sqrt{s_p}} \tag{2}$$

where:  $\tan\alpha$  = slope (-)

The general formula for the 2%-runup  $R_{u2\%}$  is shown in Fig. 1 and has been described by Van der Meer and Stam (1992). It is given by:

$$R_{u2\%}/H_s = 1.5 \xi_{op} \text{ with a maximum of } 3.0 \tag{3}$$

It is usual to include some safety (about one standard deviation) which gives the following recommended design formula:

$$R_{u2\%}/H_s = 1.6 \xi_{op} \text{ with a maximum of } 3.2 \tag{4}$$

Figure 1 Runup in reference conditions

Eq. 3 and 4 are well known, except for the quantitative aspects of the influence of a berm, roughness, shallow water and oblique wave at-

tack. In order to take these influences into account the runup formula is adapted. (In this paper the influence factors are only introduced in Eq 3. For design purposes these factors should be used in a similar way in Eq. 4.) The adapted version of Eq. 3 is:

$$R_{u2\%}/H_s = 1.5 \gamma_r \gamma_h \gamma_\beta \xi_{p,eq} \quad \text{with a maximum of } 3.0 \gamma_r \gamma_h \gamma_\beta \quad (5)$$

where:

$\gamma_r$  = influence factor for roughness

$\gamma_h$  = influence factor for shallow water

$\gamma_\beta$  = influence factor for oblique wave attack

$\xi_{p,eq}$  = breaker parameter based on an equivalent slope

The influence factors  $\gamma_r$ ,  $\gamma_h$  and  $\gamma_\beta$  are defined as the ratio of runup on the specific slope to the runup in the reference situation with identical values of  $H_s$ ,  $T_p$  and  $\tan\alpha$  (TAW, 1974). The influence of a berm in the structure is taken into account by defining an equivalent slope which yields an equivalent breaker parameter  $\xi_{p,eq}$ . The influence factors will be described in the next sections.

#### Influence of a berm

A berm in the structure is characterized by the berm width  $B$  and the berm depth (with respect to SWL)  $d_B$ , see Fig. 2.

Figure 2 Berm parameters

About 120 tests have been performed on structures with a berm. The variation of the relevant parameters in the model investigation on the influence of a berm is given in Table 1.

$\tan\alpha$	(-)	1:3, 1:4
$s_p$	(-)	0.01, 0.02, 0.03, 0.04, 0.05
$H_s$	(m)	0.10 - 0.20
$B$	(m)	0.40, 0.60, 1.00
$d_B$	(m)	-0.08, 0.00, 0.08, 0.16

Table 1 Parameters in test programme for berms

In case of a berm in the structure an equivalent slope can be defined, which should be used to determine the equivalent breaker parameter  $\xi_{p,eq}$  in Eq. 5.

$$\xi_{p,eq} = \gamma_b \xi_p \tag{6}$$

where:  $\gamma_b$  = influence factor for a berm

The influence factor  $\gamma_b$  is defined as the ratio of the equivalent slope which takes account of the berm ( $\tan\alpha_{eq}$ ) to the average slope of the structure excluding the berm ( $\tan\alpha$ ). The combined influence of the berm width and berm depth is given by the following formula for  $\gamma_b$ :

$$\gamma_b = 1 - r_B(1 - r_{dB}) \quad \text{with} \quad 0.6 \leq \gamma_b \leq 1.0 \tag{7}$$

where:

$r_B$  = reduction of the average slope ( $\tan\alpha$ ) caused by the berm width B (a structure without berm yields  $r_B = 0$ )

$r_{dB}$  = reduction of the influence of a berm caused by the berm depth  $d_B$  (a berm at SWL yields  $r_{dB} = 0$ )

The average slope of a structure with a berm can be defined by drawing a straight line through the points on the slope excluding the berm at  $1 H_s$  above and  $1 H_s$  below SWL, see Fig. 3. The equivalent slope of a structure with a berm can be defined by drawing a straight line through the points on the slope including the berm at  $1 H_s$  above and  $1 H_s$  below the berm. The optimum value of  $1 H_s$  was a result of the analysis. This procedure results in the following formula for  $r_B$ :

$$r_B = \frac{B/H_s}{2 \cot\alpha + B/H_s} \tag{8}$$

Figure 3 Definition equivalent and average slope

A berm at SWL ( $d_B = 0$ ) is most effective in the reduction of the runup. In that case  $r_{dB} = 0$  and  $\gamma_b = 1 - r_B$ . For  $d_B \neq 0$  the influence of the berm will be less so that  $\gamma_b$  will be closer to 1. The influence of the berm on runup is negligible when the berm is about  $1.5 H_s$  above or below SWL. In that case  $r_{dB} = 1$  and  $\gamma_b = 1$ . This reduction of the influence of the berm caused by the berm depth can be expressed by the following formula for  $r_{dB}$ :

$$r_{dB} = \frac{1}{2} \left( \frac{d_B}{H_s} \right)^2 \quad \text{with } 0 \leq r_{dB} \leq 1 \quad (9)$$

The influence factor  $\gamma_b$  has a lower limit of 0.6. This implies that in a situation where  $\gamma_b = 0.6$  an increase of the berm width will not lead to a further reduction of the runup. For a berm at SWL an optimum berm width is given by the following formula, derived from Eq. (7) with  $\gamma_b = 0.6$  and  $r_{dB} = 0$ :

$$B = \frac{4}{3} H_s \cot \alpha \quad (10)$$

Fig. 4 gives in the upper graph the runup versus the breaker parameter  $\xi_p$ , based on the average slope, excluding the berm. The lower graph shows the results when Eq. 7 to 9 are used to determine the equivalent breaker parameter  $\xi_{p,eq}$ . The results show a good agreement with the formulas.

Figure 4 The influence of a berm on runup

Influence of roughness

The influence of roughness on runup is described in Table II.5.5 in TAW (1974) or the similar Table 7-2 in the Shore Protection Manual (CERC 1984). However, these tables have been based on regular waves. In this paper results of tests with irregular waves are discussed.

The influence of roughness has been investigated for various types of surface coverings in small scale as well as full scale tests. For impermeable structures the results of the investigations are summarized in Table 2 which gives recommended values for the influence factor  $\gamma_f$ . This table can be seen as an update of Table 7-2 in the Shore Protection Manual (CERC 1984). In total 20 tests have been performed.

Surface covering				Influence factor $\gamma_f$
Smooth, concrete, asphalt				1.00
Impermeable smooth block revetment				1.00
Grass (3 cm)				0.90 - 1.00
Ribs on smooth slope (l=9b)		l = length b = width h = height		0.60 - 0.70
h/b	b/H <sub>s</sub>	covering		
1.00	0.12-0.19	1/7.5		
Blocks on smooth slope (l=b)				0.70 - 0.75 0.75 - 0.85 0.85 - 0.95 0.85 - 0.95 0.75 - 0.85
h/b	b/H <sub>s</sub>	covering		
0.88	0.12-0.19	1/9		
0.88	0.12-0.24	1/25		
0.44	0.12-0.24	1/25		
0.88	0.12-0.18	1/25 (above SWL)		
0.18	0.55-1.10	1/4		
Rock				0.55 - 0.60 0.50 - 0.55
one layer		(H <sub>s</sub> /D = 1.5 - 3.0)		
two or more layers		(H <sub>s</sub> /D = 1.5 - 6.0)		

Table 2 Influence factor for roughness ( $1 < \xi_p < 4$ )

The parameters l, b and h in this table respectively stand for the length (parallel to the structure axis), the width along the slope (perpendicular to the structure axis) and the height of artificial roughness elements (blocks or ribs). The value for the covering stands for the relative area of the slope which is covered by the roughness elements. Finally the parameter D stands for the diameter of the rock. The recommended values of  $\gamma_f$  can be applied for  $1 < \xi_p < 4$ . For larger values of  $\xi_p$  (surging waves) the values of  $\gamma_f$  will slowly increase to 1.

The results for two or more layers of rock on a structure are only an average value. During his extensive test series on the stability of

rock slopes Van der Meer (1988) simultaneously measured wave runup. The results have been described by Van der Meer and Stam (1992). Preliminary results have also been published by CIRIA/CUR (1991). Two methods for the prediction of wave runup have been described by Van der Meer and Stam (1992). First, formulas were derived for various runup levels (2%, significant, etc.) as a function of wave height and surf similarity parameter. A second set of formulas gave the wave runup as a Weibull distribution.

Influence of shallow water

About 40 small scale tests have been performed on structures with a 1:100 foreshore in front and relatively shallow water at the toe. In addition the development of the wave conditions on the foreshore has also been investigated intensively in tests without a structure, in order to have accurate information about the incident waves in the situation with a structure. Table 3 gives global values of the relevant parameters in the investigations.

$\tan\alpha$	(-)	1:3, 1:4
$s_p$	(-)	0.01, 0.02, 0.03, 0.04, 0.05
$H_s$	(m)	0.10 - 0.20
$h$	(m)	0.18, 0.29, 0.33, 0.41, 0.60

Table 3 Parameters in test programme for shallow water

Figure 5 Wave height distribution in shallow water

In general the 2% runup  $R_{u2\%}$  is related to both the significant wave height  $H_s$  (which should be used to determine the breaker parameter) and the 2% wave height  $H_{2\%}$  which characterizes the higher waves. However,

in Eq. 5  $R_{u2x}$  is only related to  $H_s$ . This relation is therefore only valid for situations in which the wave height is Rayleigh distributed because then the ratio of  $H_{2x}$  to  $H_s$  is constant (equal to 1.4).

In situations with a shallow foreshore the higher waves will break before they reach the structure. Then the wave height at the toe of the structure is no longer Rayleigh distributed, see Fig. 5. In these situations the influence factor  $\gamma_e$  for shallow water can be described by the following simple formula:

$$\gamma_h = \frac{H_{2x}}{1.4H_s} \tag{11}$$

For a gentle foreshore slope of 1:100 the ratio of  $H_{2x}$  to  $H_s$  has been investigated which led to the influence factor  $\gamma_e$  (including the relative water depth) which is given in Fig. 6 and the following formulas:

$$\gamma_h = 1 - 0.03 \left(4 - \frac{h}{H_s}\right)^2 \quad \text{for } 1 \leq \frac{h}{H_s} \leq 4 \quad \text{and} \tag{12}$$

$$\gamma_h = 1 \quad \text{for } \frac{h}{H_s} \geq 4.0 \tag{13}$$

Figure 6 Influence factor for shallow water for a 1:100 foreshore

Influence of the angle of wave attack (for long and short crested waves)

Figure 7 Angle of wave attack

The definition of the angle of wave attack  $\beta$  is given in Fig. 7. The directional spreading parameter  $\sigma$  is defined as the standard deviation of the direction of wave propagation.

About 160 tests were performed in a multi-directional wave basin on wave runup and overtopping. The structure was 15 m long and was divided in 3 sections with different crest levels, see also Van der Meer (1989). Overtopping was measured at two sections and runup at the other. Smooth plane 1:2.5 and 1:4 slopes were tested and a 1:4 slope with a berm at SWL. The range of the main parameters is given in Table 4.

$\tan\alpha$	(-)	1:2.5, 1:4, 1:4 with berm
$s_p$	(-)	0.01, 0.02, 0.03, 0.04, 0.05
$H_s$	(m)	0.06, 0.12
$\beta$	( $^\circ$ )	0, 10, 20, 30, 40, 50, 60, 70, 80
$\sigma$	( $^\circ$ )	0, 12, 25, 32, 45

Table 4 Parameters in test programme for oblique waves

Short crested *perpendicular* wave attack gives similar results on both wave runup and overtopping as long crested perpendicular wave attack. The results are different when the wave attack on the structure is oblique ( $\beta > 0^\circ$ ), see Fig. 8.

The effect of oblique wave attack on runup on a 1:6 slope with regular waves has been studied by Tautenhain et al. (1982). Their results suggest that runup for normal wave attack ( $\beta = 0^\circ$ ), can be exceeded for small angles (say,  $\beta = 10-30^\circ$ ). Fig. 8 shows that the measured influence factor for these small angles is only higher than 1 for a few tests. The average trend shows no increase of the runup for small angles.

Figure 8 Measured influence factor for oblique wave attack

Long crested waves give an influence factor  $\gamma_\beta$  which is almost equal to 1 for  $\beta < 30^\circ$ , then decreases to 0.6 for  $\beta = 60^\circ$  and remains constant for  $\beta > 60^\circ$ . Short crested oblique waves, more similar to nature, give a different picture. The influence of the angle of wave attack on runup is much less than for long crested waves. This is due to the fact that even for large angles a number of waves arrive at smaller angles, giving a higher runup. For  $\beta$  increasing from  $0^\circ$  to  $90^\circ$  the runup influence factor decreases linearly from 1.0 to 0.8. The spreading of the multi-directional sea itself has no influence on the

results. As long as  $\sigma > 10^\circ$  the results are similar (and therefore different from long crested waves).

Wave overtopping is given per meter structure width. With oblique wave attack less wave energy will reach this meter structure width and therefore influence factors for oblique wave attack are smaller for overtopping than for runup. The recommended values for the influence factor  $\gamma_\beta$  are shown in Fig. 9 and are given in the following formulas ( $\beta$  in degrees):

Long crested waves (exceptional in nature)

Runup:

$$\gamma_\beta = \cos(\beta - 10^\circ); \quad (\gamma_\beta \geq 0.60 \text{ and } \gamma_\beta = 1.0 \text{ for } 0^\circ \leq \beta \leq 10^\circ) \quad (14)$$

Overtopping:

$$\gamma_\beta = \cos^2(\beta - 10^\circ); \quad (\gamma_\beta \geq 0.60 \text{ and } \gamma_\beta = 1.0 \text{ for } 0^\circ \leq \beta \leq 10^\circ) \quad (15)$$

Short crested waves (common in nature)

Runup:

$$\gamma_\beta = 1 - 0.0022 \beta \quad (16)$$

Overtopping:

$$\gamma_\beta = 1 - 0.0033 \beta \quad (17)$$

Figure 9 Recommended influence factors for oblique wave attack

Wave overtopping

The wave overtopping  $q$ , given as the mean overtopping discharge in  $m^3/s$  per  $m$  width, is strongly determined by the crest freeboard  $R_c$  which is defined as the crest level with respect to SWL. The relation between  $q$  and  $R_c$  given by TAW (1974) has been compared with the relations for several slopes given by Owen (1980). A generalized version has been derived from the exponential functions given by Owen (1980) and showed a good agreement with a large set of overtopping data, including the latest measurements. However, this relation turned out to be only valid for plunging (breaking) waves. For surging (non-breaking) waves another formula with different dimensionless parameters should be applied. In order to avoid this set of two different overtopping formulas a different approach has been followed which will be described here. The approach described above, according to Owen (1980) will be given elsewhere.

In the new approach the crest freeboard  $R_c$  is related to an expected runup level on a non-overtopped slope, say the  $R_{u2\%}$ . This "shortage in crest height" can then be described by:

$$\frac{R_{u2\%} - R_c}{H_s}$$

Eq. 5 can be used to determine  $R_{u2\%}$ , including all influences of berms, etc.

The most simple dimensionless form of the overtopping discharge is:

$$\frac{q}{\sqrt{gH_s^3}}$$

Figure 10 Overtopping formula and data

Fig. 10 shows the final results on overtopping and gives all available data, including data of Owen (1980, only plane slopes), Führböter et al (1989) and various tests at Delft Hydraulics. The horizontal axis gives the "shortage in crest height". For the zero value the crest height is equal to the 2% runup height. For negative values the crest height is even higher and overtopping will be very small. For a value of 1.5 the crest level is 1.5  $H_s$  lower than the 2% runup height and overtopping will obviously be very large. The vertical axis gives the logarithm of the mean dimensionless overtopping discharge.

Fig. 10 gives about 500 data points. The formula that describes more or less the average of the data is given by an exponential function:

$$\frac{q}{\sqrt{gH_s^3}} = 8.10^{-5} \exp \left[ 3.1 \frac{R_{u2\%} - R_c}{H_s} \right] \quad (18)$$

The reliability of Eq. 18 can be given by assuming that  $\log(q/\sqrt{gH_s^3})$  has a normal distribution with a variation coefficient (the ratio of the standard deviation to the mean value) of 0.11. Reliability bands can then be calculated for various practical values of mean overtopping discharges. The 90% confidence bands for two wave heights and four overtopping discharges are given in Table 5.

Mean discharge (l/s per m)	90% confidence band (l/s per m)	
	$H_s = 1$ m	$H_s = 2.5$ m
0.1	0.015 - 0.65	0.012 - 0.83
1.0	0.23 - 4.3	0.18 - 5.5
10.0	3.5 - 28.2	2.8 - 36.1

Table 5 90% confidence band for some overtopping discharges

Limitations of Eq. 18 are that for  $R_c/H_s < 1$  and also for cases (in nature) where  $q > 10$ -50 l/s/m and where an influence factor is applied, the reliability is small and in these cases Eq. 18 is not recommended.

### Conclusions

About 200 tests have been performed in a wave flume and about 160 in a wave basin for the investigation of the influence of a berm, roughness, shallow water and oblique (long and short crested) wave attack on wave runup and overtopping. The results of former investigations and investigations carried out by other institutes have been added to these data. Based on this large set of data design formulas for runup and overtopping are recommended which can be used under a very wide range of circumstances.

## CHAPTER 135

### NUMERICAL SIMULATION OF WAVE MOTION ON AND IN COASTAL STRUCTURES

J.W. van der Meer<sup>1)</sup>, H.A.H. Petit<sup>1)</sup>, P. van den Bosch<sup>1)</sup>, G. Klopman<sup>1)</sup>  
and R.D. Broekens<sup>2)</sup>

#### Abstract

A 2-dimensional program for simulation of wave motion on coastal structures is described. The program is based on the Volume Of Fluid method and is able to describe fully plunging waves on all kind of structures.

#### Introduction

Simulation of wave motion on coastal structures, such as dikes and breakwaters, has traditionally been done by using physical small scale models. Most phenomena in these models reproduce nature fairly well. But phenomena such as porous flow, wave impacts and viscous effects, can not be modelled correctly. Furthermore, measurement of flow fields in breaking waves on a slope is difficult and may be easier to calculate by a numerical model.

The numerical simulation of wave motion on coastal structures will be presented in this paper. Most literature on this subject describes the 1-dimensional "bore approach", i.e. breaking waves are not modelled correctly. Kobayashi and Wurjanto (1989) described such a model. Verification of that model by Van der Meer and Klein Breteler (1990) showed that wave runup and depth-averaged velocities were simulated fairly well and that wave rundown and wave pressures on a slope could not be predicted. A similar and improved model, including porous flow, is given by Van Gent (1992).

Other 2-dimensional models are based on potential flow theory, such as described by Klopman (1987). These kind of models can simulate an overturning wave tongue, but calculations stop before the wave tongue hits the water or a structure.

2) Rijkswaterstaat, P.O. Box 5044, 2600 GA Delft, The Netherlands

This paper will deal with a 2-dimensional description of the complete wave motion.

### The method

The 2-dimensional program SAVOF, developed by the National Aerospace Laboratory in The Netherlands, computes incompressible flow with a free surface in a closed container. The flow is described by the Navier-Stokes equations and the program is based on the program SOLAVOF, presented by Nichols and Hirt (1981). The programs use the volume of fluid (VOF) method which is, in contrast to surface tracking methods, capable to compute free surface flow when the fluid domain becomes multiply connected, i.e. when for example an overturning breaking wave hits the free surface. SAVOF has been modified and became the code as mentioned above. The new name for the code became SKYLLA.

The fluid is treated as incompressible and the resulting equation for the pressure is treated implicitly where in the original code artificial compressibility or limited compressibility was used in combination with an explicit solver. The results of a first calculation with the original SAVOF-program are shown in Fig. 1. The closed container was put on a slope of 1:4 and the calculation started with a "block" of water in the edge. Plots 5-10 show more or less a plunging breaker on a slope and the subsequent runup.

### Possible applications

Various applications can be considered when a numerical simulation of wave motion in and on coastal structures is possible.

- Wave motion on impermeable (smooth or rough) slopes, giving water velocities, accelerations, pressures and runup levels.
- Wave overtopping on impermeable low-crested structures, giving water velocities and overtopping discharges.
- Wave motion on a submerged impermeable structure, giving wave transmission.
- Wave motion on and in a porous rubble structure, giving the same parameters as for an impermeable structure, but also the porous flow, phreatic line and wave transmission.
- Wave motion on vertical structures as caissons, giving wave forces and overtopping.
- Simulation of wave-current interaction on sloping beaches including bars.

### Development of the research code SKYLLA

A feasibility study was performed (Broekens and Petit, 1991) on the modifications required or relevant for the application of SKYLLA on the simulation of wave motion on and in coastal structures. The main modifications were:

- prescription of incident waves and a weakly reflecting boundary condition
- description of an impermeable slope
- description of porous flow

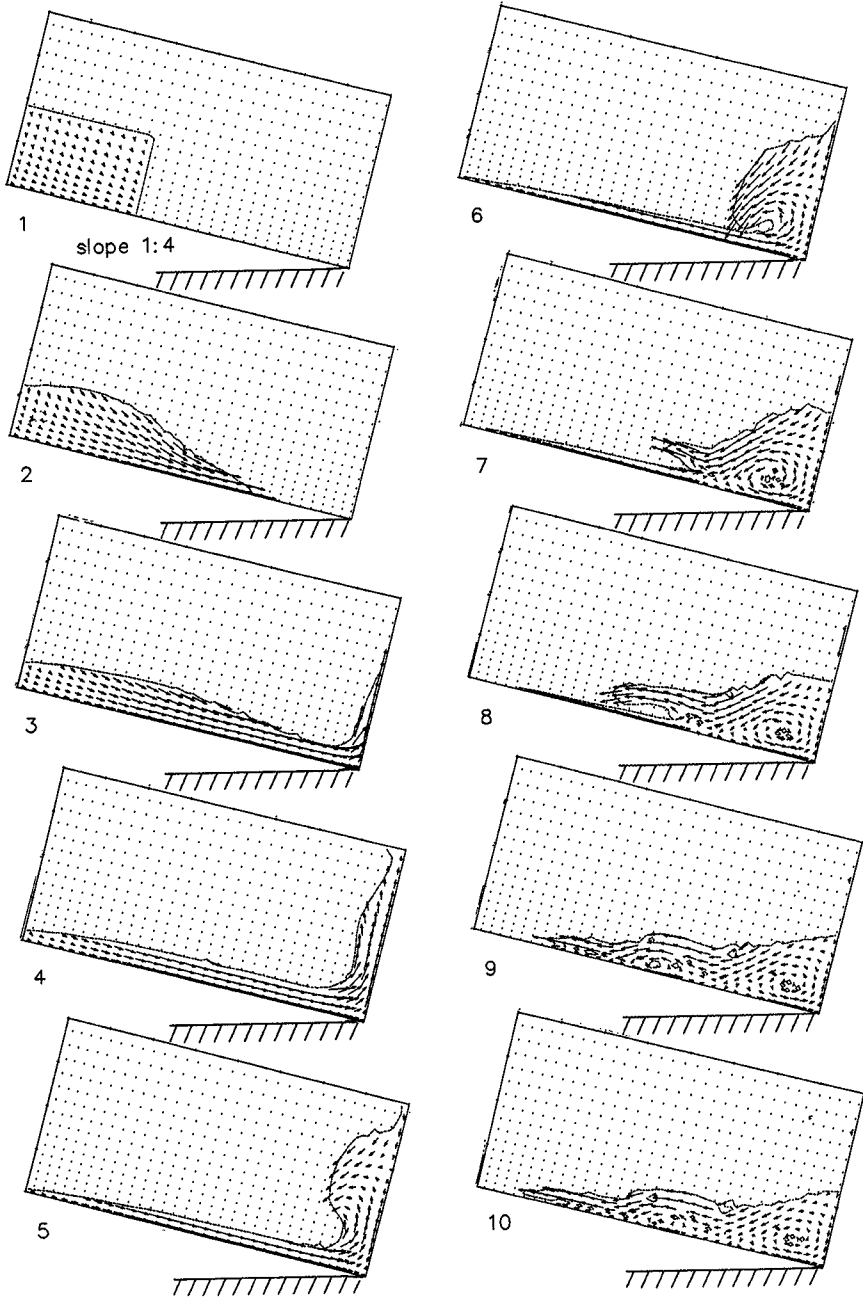

Figure 1 First calculations with SAVOF

The first two modifications will be summarized here and are more fully described in Petit and Van den Bosch (1992).

#### Weakly reflecting boundary condition

In order to give an idea of how a weakly reflecting boundary condition and an impermeable slope were implemented in the SKYLLA model first the pressure equation for the VOF method will be derived. The Navier-Stokes equations for the momentum in x and y direction respectively are:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = - \frac{\partial P}{\partial x} + \nu \nabla^2 u \quad (1)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = - \frac{\partial P}{\partial y} + \nu \nabla^2 v - g \quad (2)$$

where u and v are velocities in the x and y direction respectively and P denotes the reduced pressure  $P = p/\rho$ , with p = pressure and  $\rho$  = mass density of the fluid. Conservation of mass is, for constant  $\rho$ , expressed by:

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (3)$$

By discretizing the momentum equations in time the following equations are found:

$$\frac{u^{n+1} - u^n}{\Delta t} + u^n \frac{\partial u^n}{\partial x} + v^n \frac{\partial u^n}{\partial y} = - \frac{\partial P^{n+1}}{\partial x} + \nu \nabla^2 u^n \quad (4)$$

$$\frac{v^{n+1} - v^n}{\Delta t} + u^n \frac{\partial v^n}{\partial x} + v^n \frac{\partial v^n}{\partial y} = - \frac{\partial P^{n+1}}{\partial y} + \nu \nabla^2 v^n - g \quad (5)$$

Notice that the pressure is taken at the new time level n+1 while both the convection and the viscous terms are taken at the old time level n. Furthermore, the conservation of mass at the new time level n+1 is required:

$$\frac{\partial u^{n+1}}{\partial x} + \frac{\partial v^{n+1}}{\partial y} = 0 \quad (6)$$

From these equations the pressure Poisson equation can be derived by differentiating Eq. (4) to x, Eq. (5) to y and use Eq. (6) to eliminate the velocities at the time level n+1. The result is:

$$\begin{aligned} \nabla^2 P^{n+1} = & \frac{1}{\Delta t} \left( \frac{\partial u^n}{\partial x} + \frac{\partial v^n}{\partial y} \right) + \frac{\partial}{\partial x} \left( -u^n \frac{\partial u^n}{\partial x} - v^n \frac{\partial u^n}{\partial y} + \nu \nabla^2 u^n \right) \\ & + \frac{\partial}{\partial y} \left( -u^n \frac{\partial v^n}{\partial x} - v^n \frac{\partial v^n}{\partial y} + \nu \nabla^2 v^n - g \right) \end{aligned} \quad (7)$$

In space the VOF method uses a staggered grid like given in Fig. 2, where the velocities are given at the centre of the cell faces and the pressure is given at the cell centre. At the cell centre also the F value is given which indicates the fraction of the cell which is filled with fluid.

Figure 2 Staggered grid with velocities and pressures

By also discretizing in space the Navier-Stokes equations can be written (here, for simplicity, in the case of an equidistant grid in both x and y direction) as:

$$u_{ij}^{n+1} + \Delta t \frac{P_{i+1j}^{n+1} - P_{ij}^{n+1}}{\Delta x} = \tilde{u}_{ij} \quad (8)$$

$$\text{where } \tilde{u}_{ij} = u_{ij}^n + \Delta t \text{DISU}_{ij} \left( -u^n \frac{\partial u^n}{\partial x} - v^n \frac{\partial u^n}{\partial y} + \nu \nabla^2 u^n \right) \quad (9)$$

and  $\text{DISU}_{ij}$  stands for an operator that discretizes at the U velocity point.

$$v_{ij}^{n+1} + \Delta t \frac{P_{ij+1}^{n+1} - P_{ij}^{n+1}}{\Delta y} = \tilde{v}_{ij} \quad (10)$$

$$\text{where } \tilde{v}_{ij} = v_{ij}^n + \Delta t \text{DISV}_{ij} \left( -u^n \frac{\partial v^n}{\partial x} - v^n \frac{\partial v^n}{\partial y} + \nu \nabla^2 v^n - g \right) \quad (11)$$

Here  $\text{DISV}_{ij}$  is an operator that discretizes at the V velocity point.

The discretized version of Eq.(6) is given by:

$$(u_{ij}^{n+1} - u_{i-1j}^{n+1})\Delta y + (v_{ij}^{n+1} - v_{ij-1}^{n+1})\Delta x = 0 \tag{12}$$

By using this equation the velocities at time level n+1 can be eliminated and the discretized version of the pressure Poisson equation is found:

$$\frac{P_{i+1j}^{n+1} - 2P_{ij}^{n+1} + P_{i-1j}^{n+1}}{\Delta x^2} + \frac{P_{ij+1}^{n+1} - 2P_{ij}^{n+1} + P_{ij-1}^{n+1}}{\Delta y^2} = \frac{1}{\Delta t} \left( \frac{\tilde{u}_{ij} - \tilde{u}_{i-1j}}{\Delta x} + \frac{\tilde{v}_{ij} - \tilde{v}_{ij-1}}{\Delta y} \right) \tag{13}$$

The velocity arrows which are shown in Fig. 2 indicate all the velocities that are used in the discretization of the right hand side of Eq. (13). At an impermeable boundary, which coincides with a gridline, the velocity at the boundary at time-level n+1 can be left out in Eq. (12) and the velocities outside the flow domain, which are needed to calculate DISU or DISV at the boundary, can be chosen such that e.g. a free slip boundary condition is met. These velocities are called virtual velocities.

Once the pressure equation is solved Eq. (8) and (10) can be used to find the velocities at the new time level.

In Fig. 3 the situation at a left boundary is sketched. The velocities  $v_{0j}^n$  and  $v_{0j-1}^n$  are virtual velocities.

Figure 3 Left side boundary

In order to allow waves to enter and leave at the left boundary, the following equations were discretized:

$$\frac{\partial u}{\partial t} - c \frac{\partial u}{\partial x} = \frac{\partial u_{in}}{\partial t} - c \frac{\partial u_{in}}{\partial x} \quad (14)$$

$$\frac{\partial v}{\partial t} - c \frac{\partial v}{\partial x} = \frac{\partial v_{in}}{\partial t} - c \frac{\partial v_{in}}{\partial x} \quad (15)$$

$$\frac{\partial \eta}{\partial t} - c \frac{\partial \eta}{\partial x} = \frac{\partial \eta_{in}}{\partial t} - c \frac{\partial \eta_{in}}{\partial x} \quad (16)$$

The discretization of Eq.(14) was done upwind for the outgoing waves to yield an explicit expression for  $u_{0j}^{n+1}$ . Note that the right hand side of this equation involves the incoming wave and is supposed to be known. Eq. (15) was discretized implicitly using timelevels  $n$  and  $n-1$ , yielding an explicit expression for the virtual velocity  $v_{0j}^n$ . Equation (16) was also discretized upwind for the outgoing waves and explicitly in time where  $\eta$  in Eq. (16) can be related to the  $F$  values in the first two columns by:

$$\eta_i^n = \sum_{j=2}^{j_{s1}} F_{ij}^n \Delta y_j \quad \text{for } i = 1, 2 \quad (17)$$

where  $j_{s1}$  has the property:

$$F_{ij} = 1 \quad \text{for } j = 1(1)j_{s1} - 1$$

$$0 < F_{ij_{s1}} < 1$$

$$F_{ij} = 0 \quad \text{for } j > j_{s1}$$

Here it was implicitly assumed that near to the weakly reflecting boundary the surface is a single valued function of  $x$ .

#### Impermeable slope

Again, by setting virtual velocities, an impermeable free-slip slope could be included in SKYLLA, where the slope is allowed to intersect the grid arbitrarily. In Fig. 4 the four possible cell intersections of a climbing slope with pressure cells is shown. Cases where the slope intersects the cell at a corner can numerically be treated as one of the four cases. For each of the cases 2), 3) and 4) two virtual velocities were defined such that the velocity stencil given in Fig. 2 can be used at each cell which contains fluid. These virtual velocities are defined such that a free- or a no-slip boundary condition is satisfied at a given location point on the slope in the intersected cell.

Figure 4 Cells with an impermeable slope

The advantage of this approach over the pressure-velocity iteration technique (Viecelli, 1969), is that an elliptic solver (e.g. Conjugate Gradient Squared (CGS)) can be used to solve the pressure equation instead of the (Successive Over Relaxation (SOR) like) process of artificial compressibility needed for the pressure-velocity iteration technique. Since solving the pressure equation is by far the most time consuming process in the VOF solver, the use of versions of the CGS method that were specially built for vector computers meant a significant improvement of the performance of SKYLLA.

In order to achieve a more accurate free surface update after new velocities are determined the FLAIR method (Ashgriz and Poo, 1991) was adopted. Updating the fluid domain near the position where the free surface meets the slope proved to be rather difficult however.

#### Computational results

Various calculations have been done with SKYLLA on smooth impermeable structures in order to test the flexibility and the robustness of the program. Results of one calculation will be given here. No validation tests have been performed until now which means that the results are only output of a computer program and the correspondence with nature has not been verified.

The calculations showed that the grid size is of paramount importance to the results especially when breaking waves occur. The result is that in order to describe breaking waves on a slope small cells and time steps are required. This is not a drawback of the VOF-method as used in SKYLLA, but a direct result from the fact that a nonlinear highly instationary process is simulated.

Fig. 5 gives the cross-section of a dike with a berm. The upper and down slopes are 1:4 and the berm with a length of 5 m has a slope of 1:15 and is located just beneath the still water level. The water depth is 3.4 m at the toe of the structure. This cross-section was used for computation. The generated wave had a wave height of 1.2 m and a wave period of 4.5 s.

Figure 5 Cross-section used for computations with SKYLLA

In total 350 cells were used in the x-direction with a decreasing cell size from left to right from 0.101 m to 0.050 m. In the y-direction 69 cells were used with a refinement near the still water level (range: 0.041 m to 0.258 m). The basic time step was 0.025 s and the minimum time step needed was 0.0015 s (at 8.6 s, see Fig. 6). In total 17 s wave motion was simulated which required 5977 s of cpu time on a CONVEX C3820.

Figs. 6-9 show results of the calculations at 4 different time steps. Each Fig. has 3 subfigures. At the top the F function is shown where the black colour corresponds with cells that are completely filled with fluid ( $F = 1$ ) and white cells that are empty ( $F = 0$ ). The middle plot shows the velocity field in the wet domain. The lowest plot gives the tangential velocity at the free-slip slope as a function of the x-coordinate.

In Fig. 6, at  $t = 8.6$  s, the overturning wave tongue is about to fall on the backwash, thereby multiply connecting the region of the filled cells. Fig. 6c gives the location of the separation point. Fig. 7 gives the result 0.2 s later at  $t = 8.8$  s. The wave tongue has hit the water surface and a horizontal jet emerges from this process. The downstream velocity under the enclosed cylinder of "vacuum" increased. At about  $x = 18$  m the velocity has changed to a shoreward direction.

In reality the enclosed cylinder of air will change to large air-bubbles and escape rapidly upwards out of the fluid. Fig. 7 does not show this escape due to the fact that vacuum was modelled and not air. This is certainly a difference with nature.

Fig. 8 shows the results 2.3 s later when another wave arrives at the toe of the structure and steepens its slope, partly due to the back wash from the previous wave. Further on the slope the breaking goes on which is caused by the nearly horizontal berm and the up and back rushing water. Runup velocities are about 1 m/s. In Fig. 9 the wave starts to break again.

Figure 6 SKYLLA results at  $t = 8.6$  s

Figure 7 SKYLLA results at  $t = 8.8$  s

Figure 8 SKYLLA results at  $t = 11.1$  s

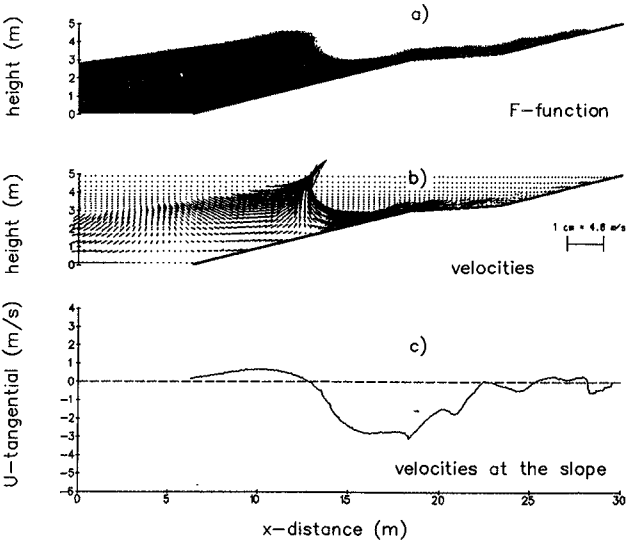

Figure 9 SKYLLA results at  $t = 12.0$  s

### Conclusions and recommendations

The results of the computations show that it is possible to simulate breaking waves on a slope. The next step, however, is to perform physical model tests in order to validate the accuracy of the results. The wave profiles at various time steps can then be compared and possibly the whole velocity field using a Partical Image Processing technique.

Attention has to be paid to the effect that vacuum "bubbles" do not escape from the water.

Calculations are still costly. By applying better solvers for solving the Poisson equation on a vector computer the SKYLLA-code has already become 4 times faster than the original code. With the expected increase in calculation speed of supercomputers in the (very) near future and the better solvers that are being developed it is expected that computation time will become less important.

The existing program can be developed further to cope with the possible applications which were mentioned earlier. Wave overtopping can be included and also a porous medium like a breakwater. Recent research on porous flow modelling (the same MAST research, see Acknowledgement) can easily be included, and suggestions to adjust the Navier-Stokes equations for a porous medium have been given in Broekens and Petit (1991). It seems well possible and even straight forward to add extra terms to the momentum equations and to include these in a VOF-method.

### Acknowledgements

The work has been performed under a project of the Commission of the European Communities, called MAST - G6 Coastal Structures, project 0032 and was further funded by the Dutch Public Works Department (Rijkswaterstaat) and Delft Hydraulics. Institutes and universities from Denmark, Greece, United Kingdom and The Netherlands were involved in the project.

The objective of the MAST-project was: the development of a physically based numerical formulation of the water motion on a smooth slope (runup, rundown, overtopping, water velocities, water pressures, wave breaking), and a formulation of the same water motion on, but also in a porous rubble structure (phreatic line, pressures and porous flow).

The authors are grateful to A. van der Ploeg who supplied us with a vectorizable preconditioner for the CGS method that was used to solve the pressure equation.

## CHAPTER 136

### IMPACT BREAKING WAVE PRESSURES ON VERTICAL WALLS

Masataro HATTORI<sup>1)</sup> and Atsusi ARAMI<sup>2)</sup>

#### ABSTRACT

Impact wave pressures acting on a vertical wall were discussed by simultaneous measurements of the pressure and wave shapes at impact.

Experiments confirmed the principal role of adiabatic processes of trapped air bubbles to the generation of impact pressures. The most severe impulsive pressure was observed when breaking waves hit the wall with trapping small air bubbles or a very thin lens-shaped air pocket. The larger the amount of the entrapped air, the lower the magnitude of the impact pressures. Due to the pulsation of the air pocket, damped pressure oscillations were observed immediately after the impact pressure.

A predictive model, taking account of the adiabatic compression processes of the trapped air pocket, predicts fairly well the maximum impact pressure and the frequency of the damped pressure oscillation, in the case when plunging breakers collide against the wall.

#### 1. INTRODUCTION

Impact pressures have been considered unlikely to be effective for sliding and overturning massive structures seawalls. Nevertheless, some studies (Weggel and Maxwell, 1970; Mogridge and Jamieson, 1980; Arami and Hattori, 1988) and recent field observations pointed out a clear evidence that such pressures can cause severe local damages to vertical wall type structures, and that the resulting damages would develop owing to successive attacks of breaking waves and cause sudden failures of the structures.

Since Bagnold (1939) proposed an air pocket model for the physics of the high impulsive wave pressure, many experimental studies have been performed to explicate the physics of wave-

---

1) Department of Civil Engineering, Chuo University, Tokyo

2) Ishikawajima-Harima Heavy Industries Co., Ltd., Tokyo

impact processes. However, published data from the various studies provide very wide and different views on the wave-impact physics. Therefore, more detailed and reliable examinations on this process are absolutely necessary to the development of physical models predicting for the impact pressure. The principal aims of this study are as follows;

1. To explicate the difference of the wave-impact processes under various colliding conditions of breaking waves onto the wall,
2. To examine aerodynamic contributions of the entrapped air to the generation of the impact pressure, and
3. To propose a predictive model, taking account of adiabatic compression processes of the air pocket entrapped between the structure and wave.

## 2. EXPERIMENTAL EQUIPMENT AND PROCEDURES

### 2.1 EXPERIMENTAL EQUIPMENT

General arrangement of the experimental equipment is shown in Fig. 1. Experiments were carried out in a glass-walled wave flume, 0.30 m wide, 0.55 m high, and 20 m long, in which a steel beach of 1/20 slope was installed. Regular waves were produced by a reflection-absorbing wave maker of flat type.

Fig. 1 General arrangement of the experimental equipment. (Units:m)

Vertical plane wall of a 35 mm thick plastic plate (0.30 m wide and 0.50 m high) was shored up with steel frames. The wall complex, having a natural frequency of 1.2 KHz in water, was mounted rigidly on a plastic mound with a foreshore slope of 1/10. Incident wave properties were detected by a capacitance-type wave gauge installed at the uniform water depth.

### 2.2 PRESSURE MEASUREMENTS

Impact pressures were measured by semi-conductor type transducers of 10mm in diameter. The pressure transducers have operational capacity of 100 gf/cm<sup>2</sup> and 200 gf/cm<sup>2</sup>, with 100% overload capability. Their natural frequency in water is 9.6 KHz and the frequency response range DC to 4.8 KHz.

Four pressure transducers were located vertically along the centerline of the wall at an interval of 2.0 cm. The maximum impact pressure is occurred most likely in the vicinity of the still

water level. Hence, two additional pressure transducers were set at 1.0 cm below and above the still water level and 5.0 cm apart from the centerline.

### 2.3 RECORDING THE IMPINGING BREAKING WAVE PROFILE

High-speed videos were simultaneously taken at 200 frames/s with the measurements of impact pressures. Photo. 1 is an example of the picture of wave shape at impact. Number of the last three digits in millisecond after the start of a test run. White arrows on the left hand side show the locations of the pressure transducers. Real-time pressure record from the pressure transducer ( $P_4$ ) at the still water level is monitored on the left hand side of the still. The synchronization between the pressure records and sequential stills was made by using the pressure monitor within an accuracy of 0.1ms.

Length measurements were made using a 1.0 cm square grid system, attached on the sidewall glass. The breaking wave height, the size and shape of trapped air pocket, the forward and upward velocities of wave surface at and in front of the wall were read from the pictures projected on a 29-inch video-screen.

### 2.4 EXPERIMENTAL PROCEDURES

In the repeated tests, impact pressures vary significantly owing to the instability of the wave breaking and the high reflection of the wall. We employed the two following procedures to ensure the repeatability of the experiments; (1) Every test run was made after the free surface disturbance due to the preceding test run was well subsided, and (2) The wave generator was controlled by a programmed analogue signal yielding a regular wave train.

Outputs of the impact pressures were recorded on digital recorders over six wave periods at a sampling frequency of 5 KHz for extensive processing by computer. Data analyses were made for four subsequent breaking waves preceded by some non-breaking waves.

Photo. 1 Example of the video picture.

### 3. EXPERIMENTAL RESULTS OF THE IMPACT PRESSURE CHARACTERISTICS

Since wave-impact processes depend closely on the wall location relative to the wave breaking position (Chen and Melville, 1988), it is reasonable to characterize them by the development of wave breaking at the wall, or the colliding conditions. In this study, we will examine into the essential characteristics of

Photo. 2 Sequence of the still pictures of the wave surface. (Flip-through condition)

WAVE PRESSURE RECORDS (No. 013-3)  
FOR THE FLIP-THROUGH IMPACT.

$H_i = 4.7 \text{ cm}, \quad T = 1.7 \text{ s}$

$H_b = 5.7 \text{ cm}, \quad \bar{\gamma} = 0$

$h_d = 2.5 \text{ cm}.$

$P_{\max} / \rho g H_b = 11.2$

Fig. 2 Wave pressure records (Flip-through condition)  
( $H_b=5.7\text{cm}, T=1.7\text{s}$ )

impact pressures for the four following conditions, somewhat similar to Oumeraci, Klammer, and Partenscky (1991):

- (1) " Flip-Through" condition with no air bubbles,
- (2) Collision of the vertically flat wave front with entrapping small air bubbles -- single peak pressure --,
- (3) Collision of plunging breakers with a thin air pocket -- damped pressure oscillations with high frequencies --, and
- (4) Collision of fully developed plunging breakers with a thick air pocket-- damped pressure oscillation with low frequencies --.

### 3.1 FLIP-THROUGH COLLISION WITH NO AIR BUBBLES.

Impact process due to the " flip-through" action (Cooker and Peregrine, 1991) is observed when incident waves break as upward deflected breaker near the wall. Photo 2, consisting of 8 still pictures, gives the wave shape changes during the collision on the wall. We notice from the sequential pictures that the wave shapes change a very similar process to the computation by Cooker and Peregrine (1991). The corresponding pressure records at various elevations are given in Fig. 2, in which 20 ms on the time axis refers to the time of the maximum peak pressure recorded at  $P_4$ , on the still water level. Thick arrows on the top of the pressure record at  $P_4$  represent the shooting instant of the pictures.

Although the resultant peak pressures are not so high in the magnitude ( $p_{\max, 4}/\rho g H_b = 11.2$ ), the pressure record at  $P_4$  shows that an impact is occurred without a clear hit of the wave front.

### 3.2 COLLISION OF VERTICALLY FLAT WAVE FRONT WITH SMALL AIR BUBBLES -- SINGLE PEAK IMPACT PRESSURE --.

Collision of breaking waves with vertical or slightly curled front brings about extremely high impact pressures ( $p_{\max, 4}/\rho g H_b = 109.6$ ), as seen in Photo. 3 and Fig. 3. However, even the highest impact at  $P_4$  is much lower than that due to a water hammer process.

The pictures about the instant of collision (Photo. 3 (e) and (f)) do not show apparently the air entrainment. But we can find out dark image indicating a group of small air bubbles trapped over the hitting region of wave crest (Photo. 3 (g) and (f)). The pressure records in this region (Fig. 3  $P_1 - P_3$ ) exhibit clear pressure fluctuations with very high frequencies of about 1,000 Hz during the impact. The peak pressures occur simultaneously at various elevations, but their magnitudes decrease remarkably with the distance from the hitting point of the wave crest.

If a small air pocket in a form of very thin lens is trapped in the vicinity of the impinging region of the wave crest, the pocket is collapsed into small air bubbles at impact. This also results in a single peak impact pressure. Occasionally we observed a fact that a fraction of the air bubbles was released upwards with wave splash. This results in noticeable reduction of the peak pressure and causes variability in the pressure magnitude. The experiments, however, confirm an important role of the trapped air bubbles to generation of the impact pressures.

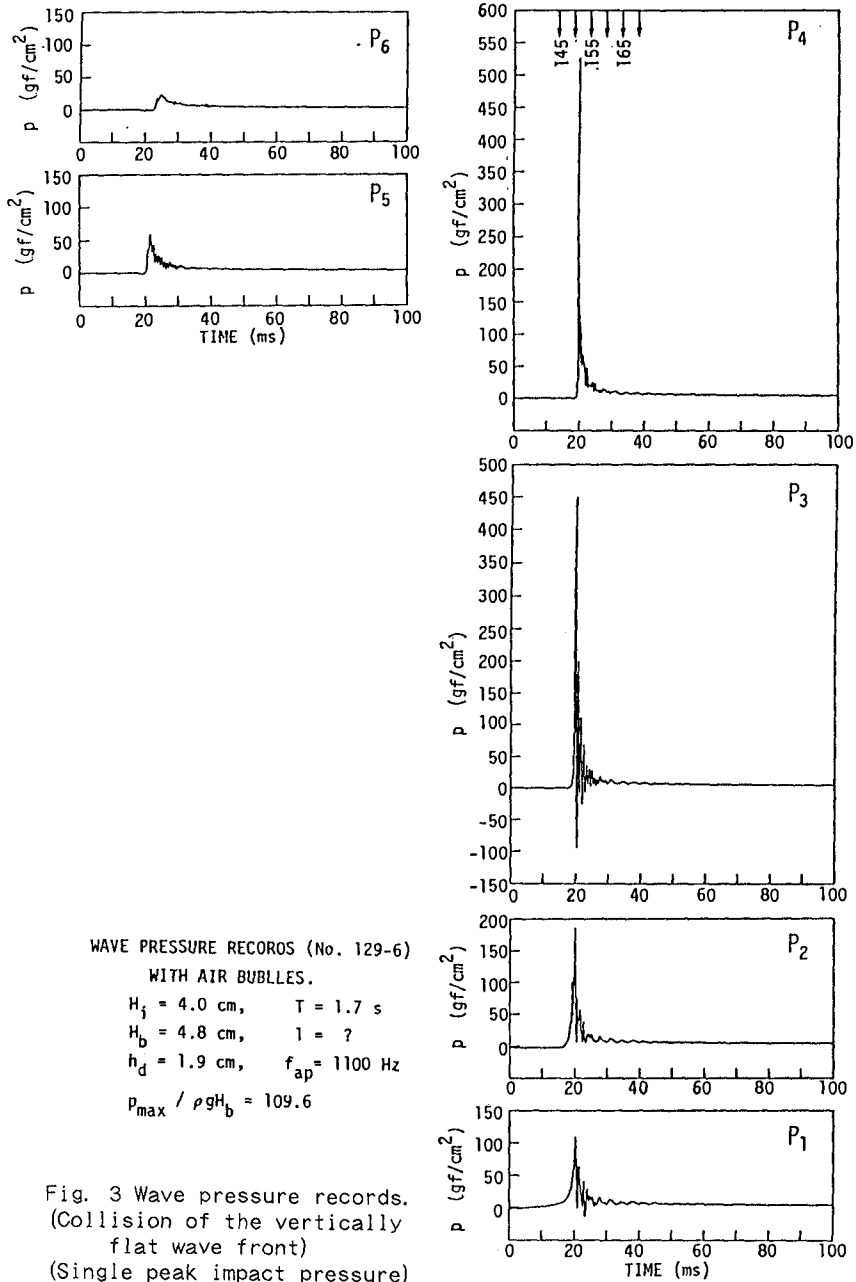

Photo. 3 Sequence of the still pictures of the wave surface.  
 (Collision of the vertically flat wave front)

### 3.3 COLLISION OF PLUNGING BREAKERS -- DAMPED PRESSURE OSCILLATIONS OF HIGH FREQUENCIES --

Photo. 4 gives the trapping process of a two dimensional air pocket between the wall and wave. The pressure records at various elevations in Fig. 4 show that the adiabatic action of the air pocket gives rise not only to relatively high impact pressures on the wall ( $p_{\max, 4} / \rho g H_b = 51.9$ ), but also to damped oscillations with a high frequencies of 250 Hz, immediately after a rapid pressure drop. The pressure records in the air pocket zone ( $P_1-P_3$ ) exhibit almost the same variations both in magnitude and in phase. This indicates repeated compression and expansion of the air pocket. Immediately after the collision, the air pocket transforms into a group of air bubbles, in which the bubbles rotate violently (Photo. 4 (f)), and this will likely play some role in the reduction of pressure oscillations (Cooker and Peregrine, 1991). We can not yet specify any dominant process of the energy dissipation due to the violent motion of the air bubbles.

From the simultaneous records of the pressure and wave, we found an evidence that damped pressure oscillations continue until the air bubbles start to escape through the wave surface.

### 3.4 COLLISION OF FULLY DEVELOPED PLUNGING BREAKERS -- DAMPED PRESSURE OSCILLATIONS OF LOW FREQUENCIES --

As plunging and curling of the breaking wave are developed, a large cylindrical air pocket will be trapped and confined between the wall and wave. As shown in Figs. 5 and 6, an increase of the air pocket thickness  $l$ , or the trapped air amount results in a decrease both in the peak pressure  $p_{\max}$  and in the frequency of damped pressure oscillation,  $f_{ap}$ . Both  $p_{\max}$  and  $f_{cap}$  are inversely proportional to  $l$ . However, the other principal characteristics of the impact pressure are almost the same as those for the plunging breaker collision.

Fig. 5 Relation between  $p_{\max}$  and  $l$ .

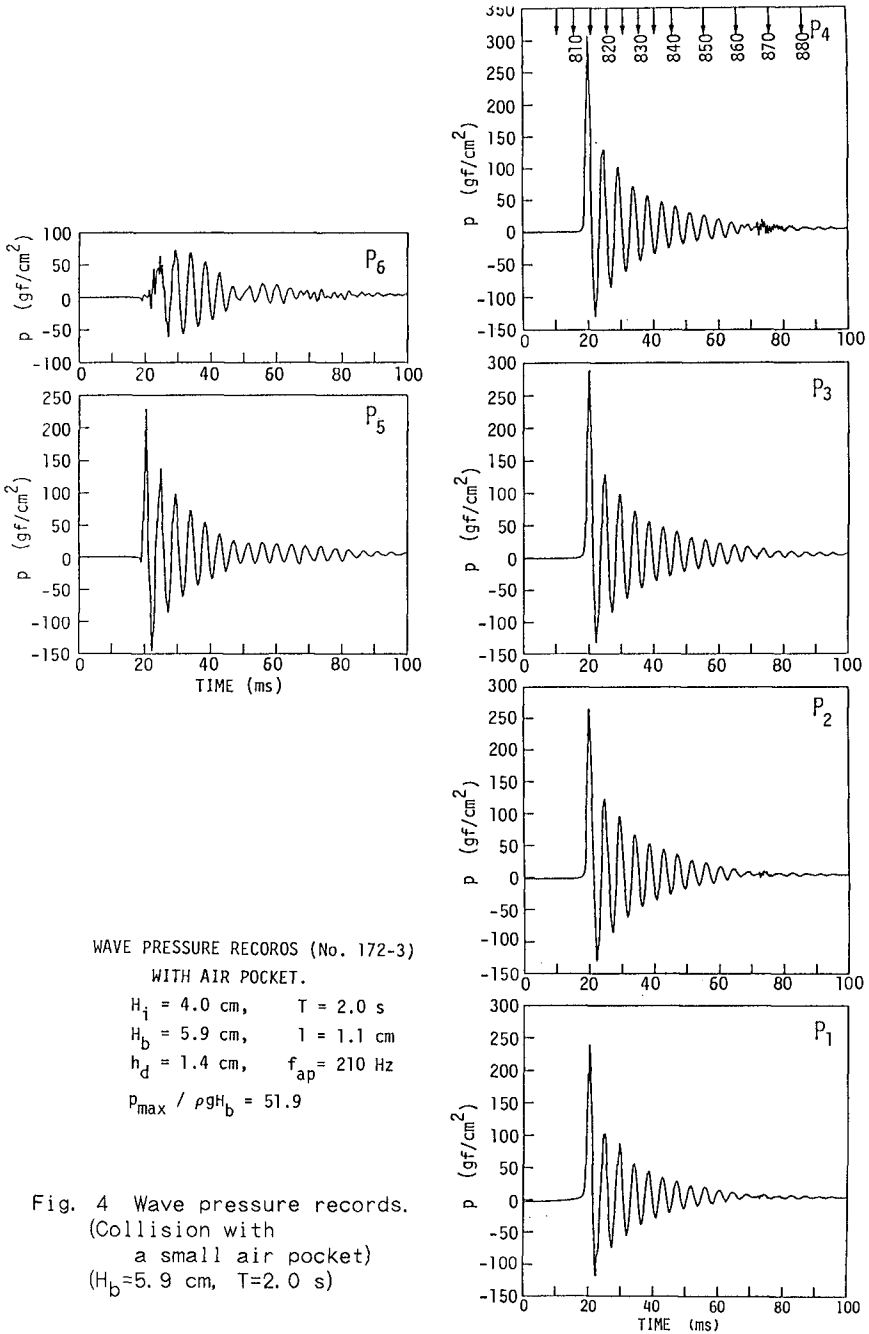

Photo. 4 Sequence of the still pictures of the wave surface.  
(Collision with entrapping a small air pocket)

Fig. 6 Relation between  $f_{ap}$  and  $l$ .

6. PREDICTIVE MODEL

Predictive model for the impact pressure is developed under the following assumptions:

- (1) The two dimensional air pocket can be substituted by a square pillar of width  $B$ , height  $d$ , and thickness  $l$ ,
- (2) The adiabatic process of the air pocket is represented by an equivalent spring system, as shown in Fig. 7, having apparent spring constant  $k$ , and
- (3) Radial oscillation and energy dissipation of the air pocket are ignored.

Fig. 7 Model of the air pocket.

The spring constant of the replaced air pocket can be written as  $k=(Ed/l)E_v$ , in which  $E_v(=1.4 p_{atm})$  is the bulk modulus of air and  $p_{atm}$  the atmospheric pressure. By introducing the virtual mass length  $K$  contributing the wave impact pressure (Bagnold, 1939), the maximum impact pressure  $p_{max}$  and the resonant frequency of the air pocket  $f_{ap}$  are obtained as

$$p_{max}=(\rho_w K E_v / l)^{1/2} u_b \tag{1}$$

and

$$f_{ap}=(E_v / \rho_w K l)^{1/2} \tag{2}$$

, in which  $\rho_w$  is the density of the water, and  $u_b$ : forward velocity of the breaking wave front. The virtual mass length can be evaluated by measurements of impact pressure  $p$ , the rising time  $\tau$ , and the forward velocity of wave front  $u_b$  (Bagnold, 1939):

$$K=\int_0^\tau p dt / \rho_w u_b \tag{3}$$

Figs. 8 and 9 show the agreements between the model and measurement,  $p_{max,M}/p_{max}$  and  $f_{ap,M}/p_{ap}$ , with respect to the air pocket thickness  $l$ , or the trapped air amount. Subscript M denotes the prediction. As seen in Fig. 8, due to the high variability in

measurement is not so good, especially when the air pocket is thin,  $l < 1$  cm. The agreement, however, becomes better with increasing the pocket thickness. From investigations of the measured data, we can specify the following main factors causing the high variability ; (1) The peak pressure region is much smaller than the diaphragm of pressure transducer, (2) The irregularity of the wave front changes the trapped air amount, and (3) The hitting location of wave crest tip is always shifted by high reflection of the wall. On the other hand, the model predicts reasonably well the frequency of the pressure oscillation, taking account of that the frequency should be lowered by boundary effects of the free surface, the bottom, and the wall (Topliss, Cooker, and Peregrine, 1992; Oumeraci and Partenscky, 1991).

Fig. 8 Comparison between the predicted and measured maximum pressures.

Fig. 9 Comparison between the predicted and measured frequencies of the damped pressure oscillation.

## 5. CONCLUDING REMARKS

Simultaneous measurements of the impact pressure and the wave shape change clarify that air bubbles and air pocket entrapped between the wall and the wave plays a predominant role to the occurrence of the high impact pressure. The wave-impact process is

occurrence of the high impact pressure. The wave-impact process is characterized by the development of the wave breaking at impact, because of that the entrapped air amount depends critically on the impinging front shape of breaking waves onto the wall. The larger air amount trapped gives the lower impact peak pressure and the longer period of damped pressure oscillations immediately after the impact. The damped oscillation continues until the compressed air in the pocket starts to escape through the free surface.

The model proposed describes the wave-impact process and predicts the maximum pressure and the frequency of damped pressure oscillations, when the air pocket of two dimensional form is trapped between the wall and the wave. High variability in the wave-impact process deteriorates validity of the model.

## CHAPTER 137

### NUMERICAL MODELLING OF THE STABILITY OF RUBBLE BASES

By

Wojciech Sulisz<sup>1</sup>

#### ABSTRACT

A numerical model is developed to predict the stability of rubble bases exposed to wave action. A boundary element method is applied to solve the problem of wave interaction with a caisson and its rubble base, and to calculate the velocity field. The predicted velocities are used to determine the destabilizing forces on individual stones. Theoretical results reveal two local minima in stability: in very shallow water and at intermediate depths. The rubble base stability increases with decreasing incident wave height, the rubble base height and the bench width. Preliminary results also show that the stability depends on the damping properties and that the stability increases with increasing permeability.

#### INTRODUCTION

A rubble base exposed to a wave action has to satisfy several requirements. The design of a rubble base requires an estimation of the weight of stones used to build the rubble base which is one of the most important design parameters. These stones have to provide stability of the rubble base during large waves.

There are several empirical formulae for the determination of the stability of a rubble base. The empirical formulae are mainly a result of some modifications of the classical Iribarren or Hudson equations. However, it is a well known fact that the empirical formulae have a number of limitations. Additionally, an analysis of various parameters involved in the stability based on laboratory experiments is very time-consuming and expensive. Moreover, some conclusions regarding the stability

---

<sup>1</sup>Chalmers University of Technology, Department of Hydraulics, 41296 Gothenburg, Sweden; on leave from IH PAS, Gdańsk.

based on laboratory experiments may be severely contaminated by scale effects. An alternative method for the analysis of the effect of various parameters on the stability is still a widely recognized need.

A numerical modelling of the stability of rubble mounds seems to be the alternative method. This method has been given more and more attention recently (McDougal and Sulisz 1990; Sulisz and McDougal 1991). The numerical modelling is employed in the present work by modelling theoretically the interaction of water waves with a caisson and its rubble base and then employing predicted flow fields in a stability model to determine the required stone size. A similar approach was applied to determine the stability of rubble mounds beneath caissons by Sulisz and McDougal (1991). However, they used a constant value of the damping coefficient, which may underestimate or overestimate damping properties of the rubble base.

**NUMERICAL MODEL**

The model for waves interacting with a caisson and its rubble foundation is based on the unsteady Forchheimer equation of motion in the pores of a coarse, granular medium (Sulisz 1983; Sulisz 1985). The wave flow in the porous domain  $\mathbf{R}$  and the adjacent wave field is governed by the following equations

$$\nabla^2\Phi = 0 \quad , \tag{1a}$$

$$S \frac{\partial\Phi}{\partial t} + \frac{1}{\rho} P + gz + f\omega\Phi = 0 \quad , \tag{1b}$$

where the damping coefficient  $f$ , is

$$f = \frac{1}{\omega} \frac{\int_{\mathbf{R}} d\mathbf{R} \int_t^{t+T} \epsilon^2 \left( \frac{vV^2}{K} + \frac{C_f \epsilon}{\sqrt{K}} |V| V^2 \right) dt}{\int_{\mathbf{R}} d\mathbf{R} \int_t^{t+T} \epsilon V^2 dt} \quad , \tag{1c}$$

and  $S$  is the inertial coefficient,  $\rho$  is the density of fluid,  $g$  is the acceleration due to gravity,  $v$  is the kinematic viscosity,  $\epsilon$  is the porosity,  $K$  is the intrinsic permeability,  $C_f$  is the turbulent damping coefficient,  $T$  is the wave period,  $P$  is the pressure,  $\Phi$  is the velocity potential, and the velocity vector  $V = V [\Phi_x, \Phi_z]$ .

The above model, Eqs. (1), has successfully been applied to describe the interaction of waves with a rubble-mound breakwater (Sulisz 1985), a composite

breakwater (Sulisz & McDougal 1988; Sulisz 1992b) and a rubble toe protection (Sulisz *et al.* 1989). The boundary element method has been used to determine  $\Phi$ . Various results from the theoretical model have been confirmed by experimental data.

Velocity fields determined by a solution of the problem of wave interaction with a composite breakwater (Sulisz 1992b) are used as the input data for a stability model. Forces acting on an individual stone are computed tangential and normal to the slope from the following Morison-type equations

$$F_s = \frac{1}{2} C_{Ds} \rho A_s V s |V \cdot s| + C_{Ms} \rho \nabla \frac{\partial V}{\partial t} s \pm \frac{1}{2} C_{Ls} \rho A_n (V \cdot n)^2, \quad (2a)$$

$$F_n = \frac{1}{2} C_{Dn} \rho A_n V n |V \cdot n| + C_{Mn} \rho \nabla \frac{\partial V}{\partial t} n \pm \frac{1}{2} C_{Ln} \rho A_s (V \cdot s)^2, \quad (2b)$$

where  $s$  and  $n$  are the tangential and normal unit vectors with respect to the slope, respectively;  $(C_{Ds}, C_{Dn})$ ,  $(C_{Ms}, C_{Mn})$ ,  $(C_{Ls}, C_{Ln})$  are the drag, inertia and lift force coefficients in the direction of  $s$  and  $n$ , respectively;  $A_s$  and  $A_n$  are the cross-sectional areas of the stone in the direction of  $s$  and  $n$ , respectively;  $\nabla$  is the volume of the stone.

The velocity vector in Eqs. (2) is calculated at various positions along the slope from a velocity potential corresponding to a fluid domain rather than rubble base domain. Due to uncertainties in determining the direction of the lift forces it is assumed that the lift forces maximize the instability.

Stability is based on the static equilibrium of the stone by examining lifting, sliding or rolling. An analysis shows that for a nearly spherical stone, the stability condition for rolling is the most critical. The detailed analysis of the static equilibrium of a sphere located on a layer of spheres in contact, shows that the critical condition for rolling is

$$W_B (\tan \beta - \tan \alpha) \cos \alpha < F_n \tan \beta - F_s \quad (3)$$

where  $W_B$  is the stone weight in water,  $\beta$  is the angle associated with location of spheres in relation to each other, and  $\alpha$  is the slope angle.

Several parameters like density, size, shape and placement scheme of the armor unit are involved in the stability model. Of course, the stability is also a function of the wave period, wave height, caisson shape, rubble base shape, porosity, permeability and turbulent damping properties of the rubble base. The model makes possible a detailed examination of the contribution of various parameters on the overall stability. Because calculations can be conducted on personal computers, the model may provide engineers with a useful tool for examining a variety of cases at a very low cost.

## RESULTS

The described model is first employed to calculate the flow field for a problem of interaction of water waves with a caisson founded on a rubble base (Fig. 1). The boundary element method is used to solve a boundary-value problem and to determine the velocity potential in the rubble base and in the vicinity of the caisson and its rubble base. The caisson of the width  $2b/h = 0.5$  is analyzed. The rubble base of the caisson is considered to be of trapezoidal cross-section and of various widths and heights, but of fixed slopes 1:2. Additionally, it is assumed that the inertial coefficient  $S = 1$ , porosity  $\epsilon = 0.4$ , and that the damping coefficient is known for each analyzed wave frequency ( $0.04 \leq kh \leq 4$ ). The calculations are conducted for a constant value of a dimensionless coefficient  $\hat{f}$  which is related to the damping coefficient  $f$  via the following relation

$$f = \hat{f} / (kh \tanh kh)^{0.5} \quad (4)$$

where  $k$  is the wave number and  $h$  is the water depth.

Fig. 1. Definition sketch

A presentation of the results based on Eq. (1b) may be confusing and their analysis difficult to follow if the damping coefficient  $f$  is kept constant over a wide range of wave frequencies, as is stressed by Sulisz (1992a). This is because the damping coefficient  $f$  is a function of the wave frequency even in a case where a pure Darcy motion law is applicable ( $C_f = 0$ ). Further analysis shows that the calculations based on a constant value of the damping coefficient usually underestimate rubble mound damping properties in shallow water or overestimate them for waves of intermediate lengths and in deep water. Of course the dimensionless coefficient  $\hat{f}$  is still a function of wave frequency which is evident from Eq. (1c) and Eq. (4). However, in a case of a pure Darcy flow the coefficient  $\hat{f}$  is directly related to a Darcy coefficient and the wave frequency is not involved in the relation. This implies that a presentation of the results versus a function of

wave frequency, based on a constant value of the dimensionless coefficient  $\hat{f}$ , properly reflects features of a case with the pure Darcy flow in a rubble mound. The presentations of the results versus a function of wave frequency for different values of  $\hat{f}$  also provide insight into a significance of the nonlinear damping term included in Eq. (1c) for an analyzed quantity.

A predicted flow field is used to calculate the required stone size of the rubble base. The calculations are conducted for the drag force coefficient  $C_{Ds} = C_{Dn} = 0.7$ , the inertia force coefficient  $C_{Ms} = C_{Mn} = 0.5$ , the lift force coefficient  $C_{Ls} = C_{Ln} = 0.5$ . These values of the force coefficients are chosen based on the results of some previous works on the stability problem. Of course the force coefficients are parameters of the stability model and they require further research based on experimental verifications.

The stability number,  $N_s$ , is used to present the output of the calculations conducted to estimate the required stone size of the rubble base. The stability number is defined as follows

$$N_s = \frac{(6/\pi)^{1/3} H_d}{(S_r - 1) D} \quad , \quad (5)$$

where  $S_r$  is the relative stone density,  $H_d$  is the incipient damage wave height, and  $D$  is the equivalent spherical stone diameter.

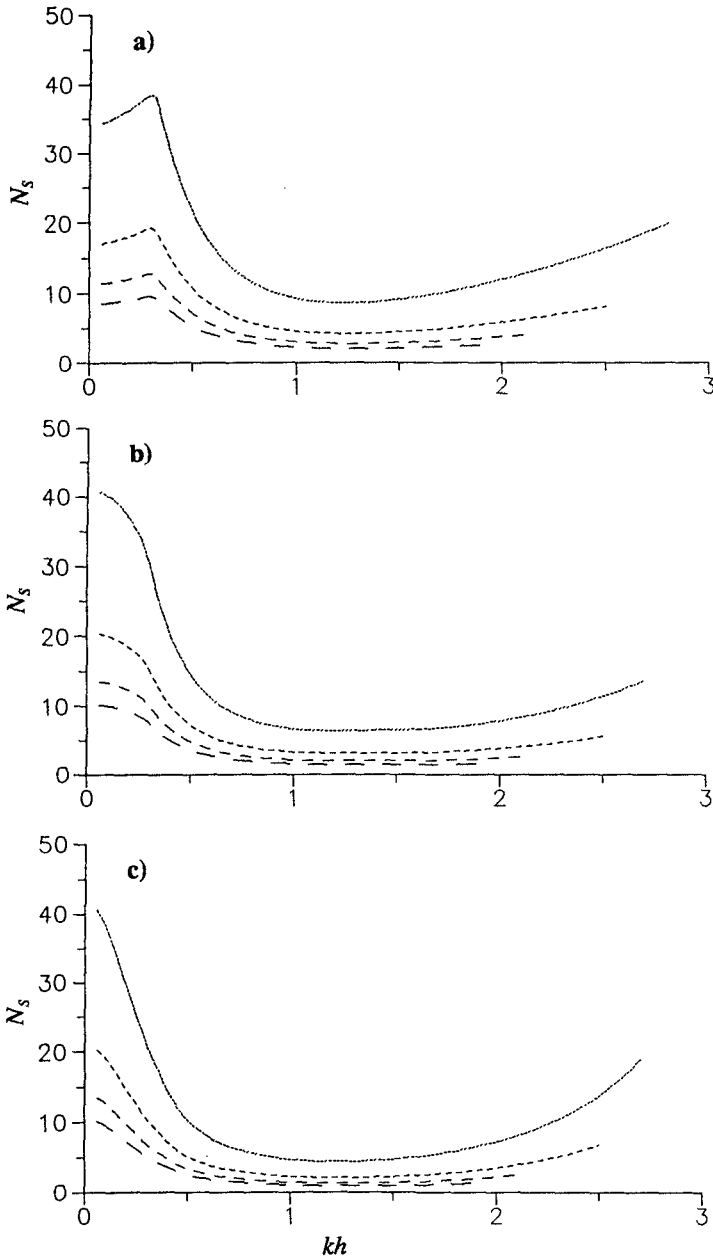

Fig. 2. Stability number versus  $kh$ ;  $d/h = 0.6$ ,  $c/h = 0.2$ ,  $H/h = 0.1$ ,  $\hat{f} = 1$ .

A typical dependency of the stability number on dimensionless wave number,  $kh$ , is presented in Fig. (2). In general, for relatively low rubble bases analyzed here, two local minima in stability may occur: a local minimum in very shallow water and a local minimum at intermediate depths. The local minimum in very shallow water is of interest only for rubble bases of small damping properties

**Fig. 3. Stability number versus  $kh$ ;  $d/h = 0.6$ ,  $\hat{f} = 1$ ,  $\cdots$   $H/h = 0.1$ ,  $- -$   $H/h = 0.2$ ,  $- \cdot - \cdot$   $H/h = 0.3$ ,  $- - -$   $H/h = 0.4$ ,  $- - -$   $H/h = 0.4$ , a)  $c/h = 0.2$ , b)  $c/h = 0.4$ , c)  $c/h = 0.6$ .**

where it may become a global minimum of the stability number. The local minimum in stability at intermediate depths is, in a majority of cases, our main interest, because this minimum is usually a global minimum of the stability number and requires further investigation. Of course in some cases, the plots of the stability number versus the dimensionless wave number may become more complex and additional minima may occur.

The results presented in Fig. (2) show that the incident wave length is essential to predict the stability number. An additional parameter involved in the stability that belongs to a group of parameters associated with wave excitation properties, is the incident wave height ( $H$ ). Figs. (3)-(4) show the stability number plotted versus dimensionless wave number for four ratios of the incident wave height to the water depth ( $H/h = 0.1, 0.2, 0.3, 0.4$ ). Some plots for the steepest waves are omitted because the corresponding parameters of the incident waves exceed the breaking limits for progressive waves. Breaking may still occur for some waves included in Figs. (3)-(4) due to large reflection from a composite breakwater.

The results in Figs. (3)-(4) are intuitive and the general conclusion follows that reported by Sulisz (1992a). The stability increases with decreasing incident wave heights. However, it is necessary to point out that the calculations are conducted for a constant value of the dimensionless coefficient  $\hat{f}$ . Thus the presented results correspond to a case of the pure Darcy flow in the rubble base. Although, a contribution from the nonlinear damping term in the motion equation that is included in Eq. (1c) is expected to be rather small due to large reflection, some changes in the presented results may occur if the incident wave height is additionally included in the calculations of velocities via Eq. (4) and Eq. (1c). The main changes are expected in shallow water where a contribution from the nonlinear damping term may be significant and where the stability model is sensitive to the rubble base damping properties.

The results presented in Figs. (3)-(4) also enable us to examine some parameters from a second group of parameters affecting the rubble base stability. This group is associated with the shape of the composite breakwater. The stability number is plotted versus dimensionless wave number for six rubble bases. An effect of the rubble base height and the bench width on the rubble base stability is investigated. The results show that deeper rubble bases are more stable. This conclusion is fairly well supported by experimental data (Brebner and Donnelly 1962). A somewhat surprising result refers to the effect of the bench width on the rubble base stability. The plots indicate an increase in stability with decreasing the bench width. This is observed for both analyzed rubble base heights.

The local minimum of the stability number in very shallow water was reported by Sulisz and McDougal (1991), who presented the stability number versus the dimensionless wave number based on a constant value of the damping coefficient. Since the damping coefficient is a function of wave frequency, the calculations based on a constant value of the damping coefficient usually, as is pointed out above, underestimate media damping properties in shallow water, or overestimate them at intermediate depths and in deep water. Further calculations conducted by applying the present approach with  $\hat{f} = \text{constant}$ , confirm an occurrence of the local

**Fig. 4.** Stability number versus  $kh$ ;  $d/h = 0.8$ ,  $\hat{f} = 1$ , ....  $H/h = 0.1$ , - -  $H/h = 0.2$ , - · -  $H/h = 0.3$ , —  $H/h = 0.4$ , a)  $c/h = 0.2$ , b)  $c/h = 0.4$ , c)  $c/h = 0.6$ .

minimum in very shallow water for rubble bases of small damping properties, however, this local minimum does not occur for rubble bases of significant damping properties as is shown in Fig. (5).

**Fig. 5. Stability number versus  $kh$ ;  $d/h = 0.6$ ,  $c/h = 0.2$ ,  $H/h = 0.1$ ,  $\dots \hat{f} = 1$ ,  $- - \hat{f} = 10$**

The results presented in Fig. (5) also show the importance of the rubble base damping properties for the stability of the rubble bases. Several conclusions may be drawn from the results presented in Fig. (5). A preliminary analysis indicates that if the damping property of the analyzed rubble base decreases, the minimum stability number increases. It has already been pointed out that in a case of a pure Darcy flow, the coefficient  $\hat{f}$  is directly related to the Darcy coefficient. The results in Fig. (5) indicate that for a pure Darcy flow in the analyzed rubble base, the stability of the rubble base increases with increasing its permeability. This conclusion is drawn on a base of the minimum stability number at intermediate depths which is our main interest. An opposite conclusion may be drawn in very shallow water. Additionally, the results indicate the importance of the nonlinear damping term included in the present approach in Eq. (1c) for the stability analysis. The analysis shows that this term is of relatively minor importance for the minimum stability number associated with intermediate depths, but may be of major importance in shallow water.

## CONCLUSIONS

A theoretical analysis of the stability of rubble bases is conducted, applying an approach based on numerical modelling. The flow in the rubble base of a caisson-type breakwater is described by a linearized Forchheimer equation of motion. The boundary element method is applied to solve the problem of wave interaction with

the caisson and its rubble base, and to calculate the velocity field. The predicted velocities are used in a Morison-type equation to determine the destabilizing forces on individual stones.

The stability is shown to depend on several parameters. There are three or even four groups of parameters involved in the stability analysis. The detailed analysis is conducted to investigate the parameters associated with incident wave properties and rubble base shapes. Preliminarily examined are some parameters associated with hydraulic properties of the rubble base.

The incident wave properties are shown to be essential to predict the stability number. Theoretical results reveal two local minima in stability: a local minimum in very shallow water and a local minimum at intermediate depths, but in some cases additional minima may occur. The local minimum at intermediate depths is usually becoming a global minimum. The stability, as intuitively expected, is also a function of the incident wave height and the stability increases with decreasing wave height. The rubble base shape belongs to the second group of parameters involved in the stability. The results show that the stability increases with decreasing rubble base height and the bench width. The preliminary results indicate the necessity of including damping properties in the stability analysis and show that for the analyzed rubble base the minimum stability number increases with increasing permeability.

## CHAPTER 138

### DEVELOPMENT OF THE VENICE MORPHOLOGICAL SYSTEM

P.SILVA(\*) and A.MOL(\*\*)

(\*)Technital S.p.A. (Verona, Italy)

(\*\*)Grabowsky & Poort (The Hague, Holland)

#### ABSTRACT

The paper discusses the morphological development of the Venice Lagoon since 1850 and, on the basis of analyses of the system, presents models to simulate large scale development of the lagoon and of various sub-basins.

The morphological development consists mainly in a continuous erosion of the salt-marshes and shallow areas, and the filling of canals. Also a general loss of sediment from the lagoon was observed. The main causes were identified in engineering structures like jetties, dredging of artificial canals and maintenance dredging.

These works resulted in a disequilibrium of the natural hydraulic system. In addition, loss of biological protection in shallow areas, due to pollution, has contributed.

Models were prepared on basis of time and partially averaged concentrations of sediment in shallow areas and canals. Averaging was carried on over a full year.

This approach facilitated the building of models of various complexity, which were found to be useful tools in the analysis of the effectiveness of remedial measures.

#### 1. HISTORICAL BACKGROUND

The lagoon of Venice is a salt water basin connected to the Adriatic Sea by three inlets (see fig. 1). Sediments range from silt in the inner areas to fine sands close to the inlets. The conditions in the present lagoon have been heavily influenced by man; since the Middle Ages significant human intervention has changed the brackish estuary into a saline lagoon which interacts only with the Adriatic Sea. This saline system was in relative equilibrium in the period 1600-1850.

Fig.1 - MAP OF 1970

Fig.2 - MAP OF 1810

Since 1850 engineering works including inlet control structures, dredging and land reclamation (fig. 2) and changes in the ecological system due to urban, agricultural and industrial discharge, have brought the system to a state of disequilibrium which, in the last 20 years, has accelerated changes in the lagoon.

Significant erosion is observed in the shallow area, while natural channels are silting up. Salt marshes are disappearing at an increasing rate (compare fig. 1 and 2). The ecological system is out of balance as indicated by excessive algal growth and the disappearance of many species.

The changes of the morphology also determine negative consequences on human activities, causing difficulties to navigation in natural channels and an heavier wave attack against the defences of villages and agricultural land (fig. 3).

Fig. 3 - EFFECTS OF MORPHOLOGICAL CHANGES

Erosion and sedimentation patterns for the lagoon are available from 1900 onwards and information on inlets and coastline since 1800. The morphological changes over these time periods correlate well with significant engineering works such as inlet control structures and dredging of navigation channels. Figure 4 presents the main findings on the basis of analyses of bathymetric maps.

Fig. 4 - MAIN PHENOMENA

## 2. ANALYSIS OF CAUSES

Section 1 described a significant change of the geometrical parameters of the lagoon, due to change in the morphological equilibrium. These changes have been caused by an imbalance of the total sediment budget of the lagoon (input-output, see fig. 5) and by an internal sediment redistribution (fig. 6). A detailed analysis, comprising all possible phenomena, followed by order of magnitude estimates, has resulted in the following most probable causes.

The first historical change to the sediment balance was caused by the diversion of rivers directly to the sea between 1500-1600 which reduced the sediment input by roughly 700,000 m<sup>3</sup>/year.

The main reason for this diversion was siltation of the lagoon. Since that period, the lagoon found a relative equilibrium, with only a slow reduction of the area of salt marshes (being former river deltas). From 1850 the jetty construction has reduced sediment input from the sea. Estimated reduction was 300,000 m<sup>3</sup>/year.

Particularly since 1970 there is evidence that the average sediment content of outflowing water has increased. The reasons are: the reduced resistance forces due to pollution (disappearance of biological protection) and the increase of active forces (shipping, fishing).

"Apparent" sediment loss was caused by subsidence of lagoon bottom due to water exploitation close to Marghera. This has been stopped since 1970.

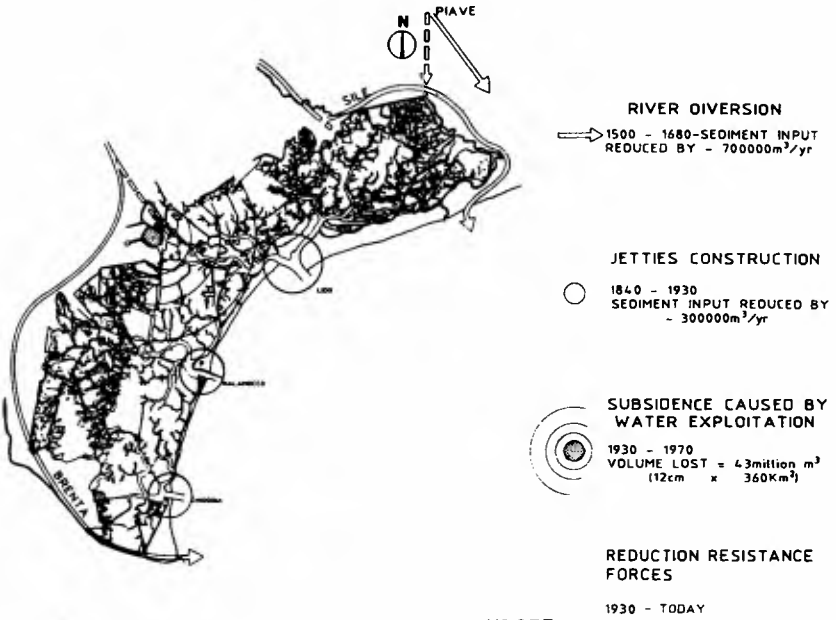

Fig.5-MAIN CAUSES : GLOBAL "VOLUMETRIC" BUDGET

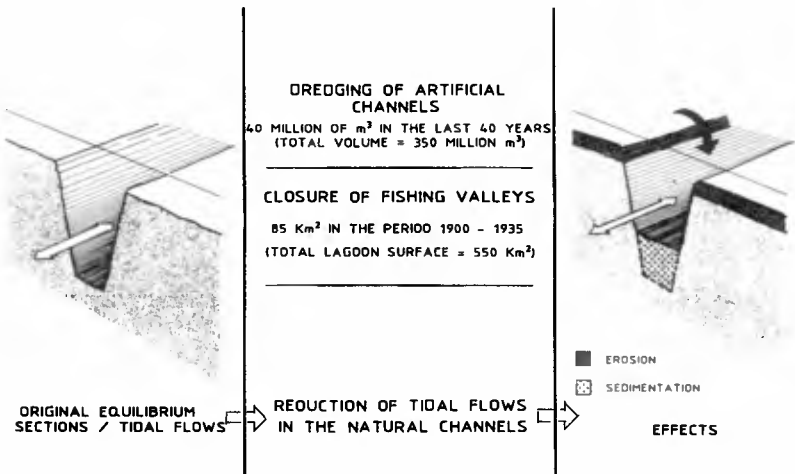

Fig. 6 - INTERNAL SEDIMENT REDISTRIBUTION

Another important element is the redistribution of sediment in the lagoon: erosion of shallow water areas and saltmarshes at the same time as sedimentation of natural and artificial channels have been found.

The main phenomena are:

- imbalance of hydraulic system due to dredging of artificial channels, increasing velocity in shallow areas and reducing velocity in natural channels;
- closure of fishing valleys reducing tidal volume, and then the velocities in the channels.

As a result the channels function today as sediment traps (see fig. 6).

### 3. STABILITY OF LAGOON CHANNELS

The lagoon channels have been remarkably stable since 1600 after the rivers were diverted. Comparison of maps available since 1910 show only slight changes due to natural causes. Meandering and geometrical profile characteristics (depth-width ratios) are noticeably similar. Total cross-section generally depends upon tidal volumes flowing through the cross-section, according to relations resembling similar laws for tidal inlets (see References (3) and (5)). An analysis was carried on following an approach developed by Marchi (Ref. (4)), who analytically developed a formulation equal to the Jarret relation for inlets.

This relation allows the introduction of the bottom characteristics using the Strickler coefficient. As the bottom characteristics of the various channels were measured, the relation between discharge and cross section was calculated. It was found that, since smaller channels had a smaller  $D_{50}$  of bottom sediment, on a logarithmic paper the new relation was within a similar band to the Jarret relation. Table 1 presents both relations, while figure 7 shows empirical plots of lagoon channels; the discharges were calculated using a finite elements hydraulic model.

In the Lido area (where no artificial dredging has been carried out) channels were found to follow the theoretical relation according to Marchi. The other lagoon channels, were found to have too large cross sections. This historical development however should a gradual decline towards the theoretical equilibrium, following the Marchi approach.

Hence, also for lagoon channels a general relation exist between tidal volume and cross section, or, as a general hypothesis one may say: lagoon tidal volume has a direct relation to volume of lagoon channels.

Table 1 - Discharge/section relations

#### 4. MEASUREMENTS AND ANALYSIS

In order to verify various hypotheses a measurement campaign was carried out. It was performed by Danish Hydraulic Institute and Ecomar on behalf of Consorzio Venezia Nuova. The main objectives were to assess:

- relation between wind, waves and meteorological component of water levels;
- relation between sediment concentration and waves/currents;
- effects of shipping upon sediment concentration.

Three fixed stations with sensors (to measure wind, velocity, waves) and sediment samples were installed in shallow areas and used for a period of one year. During the same period, a campaign was carried out by boat to establish the spatial variation of parameters, and to analyse the conditions in the channels.

The analysis of results lead to the following conclusions:

- wind-waves relation were similar to Brethschneider relations (fig. 8);
- sediment-wave/current relations (figures 9 and 10) could well be correlated using the Bijker formula, reducing in the lagoon the found concentration by a factor 5 to consider the conditions of not breaking waves and the silty to fine sand environment.

Note: The different symbols are referred to different areas of measurements.

Fig.9 - SUSPENDED SEDIMENT CONCENTRATION IN THE SHALLOWS MEASURED VS. CALCULATED DATA

Fig.10 - LITTORAL TRANSPORT IN FRONT OF THE INLETS: MEASURED VS. CALCULATED DATA

5. MODELLING OF SEDIMENT BUDGET

As morphological processes have a large time scale a schematisation was proposed averaging the tide and wind effects over a full year, following the approach of Di Silvio (Ref. (2)). Yearly averages were calculated of all parameters affecting the sediment budget model (see Table 2). Velocities were calculated on the basis of a finite element tidal model of the lagoon. The yearly averaged concentrations were calculated on the basis of the Bijker formula. It was found that in the canals the velocity was the driving force, and in the shallows the wave action. After the calculation of the wave statistics from wind statistics, and the subsequent calculation of the sediment concentration statistics on the basis of Bijker, it was found that an approximate linear relation existed between mean sediment concentration and the mean water depth.

For modelling purposes a rooted vegetation coefficient was added to model biological protection by seagrasses and benthic fauna.

A first schematization was prepared on basis of a three cell model for each of the three basins Chioggia, Lido and Malamocco (see fig. 11).

Computer simulations showed that the 3-cell model was a useful tool capable of simulating main events utilizing calibration of parameters which were considered realistic on the basis of measurements (figure 12).

	shallows $y = C_w \cdot C_v/d$
	$C_w$ = wave energy coefficient $C_v$ = rooted vegetation coefficient

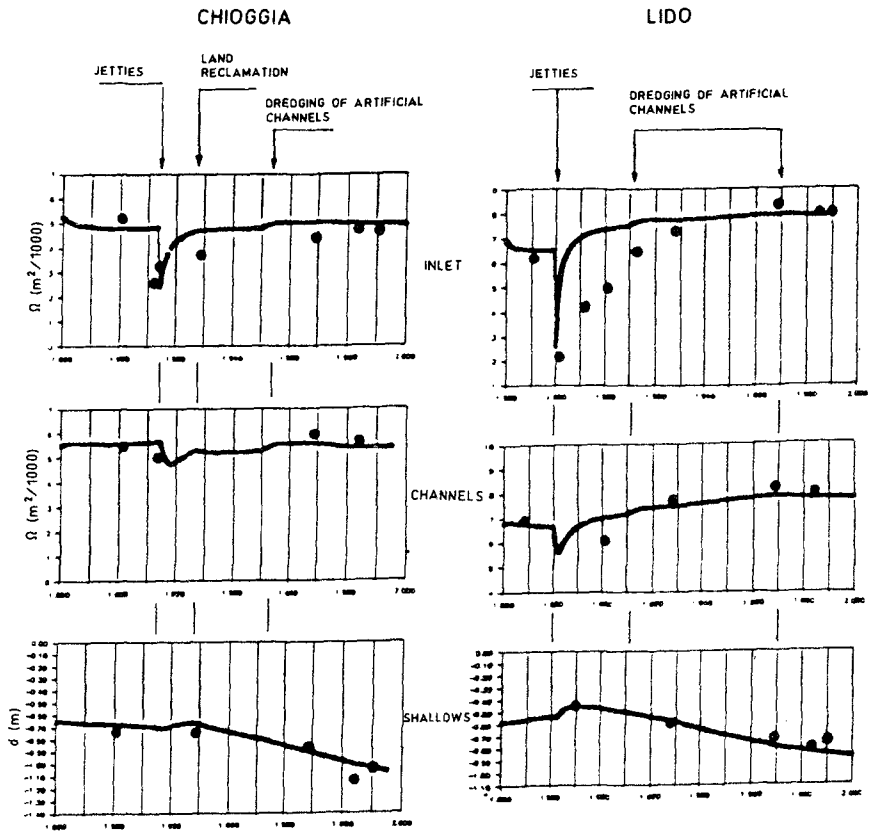

Fig.12 - 3 CELLS MODEL EXAMPLE OF RESULTS

In addition, a finite elements model was built dividing the lagoon into approximately 90 cells, to study the effects of the remedial measures, such as filling of artificial canals, nourishment of sediment, increase of biological protection, etc. Calibration of the model was carried out utilizing maps of 1970 and 1990. Parameters to be applied were within the range as measured during the field campaign, except for some complicated cells which were nodal points in the canal system around Venice.

Figure 13 presents the validation, demonstrating that the trend on virtually all cells is in agreement with reality. Figure 14 presents a forecast, without any measures, and with filling of artificial canals.

Fig.14 - MULTICELL BALANCE MODEL - PREDICTION

6. DISCUSSION

1. It is believed that the causes of the morphological disequilibrium in the lagoon have been identified. Nevertheless the effects of the huge algal growth in lagoon is not investigated in detail. The main occurrence is in the Lido basin, where it may have a stabilizing effect or even reduce depths due to deposits of organic material.
2. A major uncertainty is the effect of biological protection (benthic fauna, seagrass). The loss of this protection in large parts of the lagoon is undoubtedly due to pollution (biological, chemical) but also due to intensive illegal fishing. Although no figures are available, there are signs that large areas of the lagoon are frequently disturbed by heavy systems installed on fishing boats, destroying all biological protection and increasing mean sediment concentration.

3. The schematizations are all based upon granular material. However, in the lagoon stirring-up and deposit conditions will be different, and the models are not necessarily able to forecast adverse developments.
4. The models may oversimplify certain phenomena and are not able to include effects such as asymmetric tides. Nevertheless, calibration was easy and it is believed that the dominant phenomena are modelled.

## CHAPTER 139

### On the Chaotic Structure of Tide Elevation in the Lagoon of Venice

Giovanna Vittori <sup>1</sup>

#### Abstract

Sea level oscillations related to astronomical and meteorological tides in the Lagoon of Venice are analysed in order to find evidence of a possible chaotic nature of the phenomenon. On the basis of the analysis of the signal spectrum and by considering the values of the correlation dimension and of the largest Lyapunov coefficient of the attractor of the system, it is possible to infer that tidal oscillations inside the Lagoon of Venice are the result of deterministic dynamics, i.e. of a chaotic system characterized by few degrees of freedom. In the second part of the paper, taking advantage of the chaotic nature of the system, Farmer & Sidorowich's (1987) algorithm is used in order to make predictions of the time development of the system.

#### Introduction

The time development of dynamic variables of natural systems often shows random oscillations which sometimes are superimposed on a regular and predictable signal. Such behaviour can be the result either of a stochastic or deterministic non-linear process, highly influenced by initial conditions known in literature as "deterministic chaos". In the latter case, the time development of the system is somehow similar to that of a stochastic process even though from a mathematical point of view its dynamics are entirely deterministic.

From a practical point of view, the main difference between a stochastic process and a process showing deterministic dynamics is the different number of degrees of freedom necessary to describe the state of the system. In fact, when a system shows a chaotic behaviour, its dynamics can be described using a limited number of degrees of freedom. In other words, the time development of the system can be obtained by integrating a small number of ordinary differential

---

<sup>1</sup>Researcher, Istituto di Idraulica - Università di Genova - Via Montallegro, 1 - 16145 - Genova.

equations. This result is not applicable to the behaviour of stochastic systems which are characterized by an infinite number of degrees of freedom. The detailed description of such systems is extremely complex and stochastic or statistical methods are recommended for the study of the time development of the system.

Recent studies have shown the existence of deterministic chaos in the time development of climate variables such as wind velocity (Tsionis & Elsner (1989)), atmospheric pressure (Henderson & Wells (1988)), rainfall (Sharifi, Georgakakos & Rodriguez-Iturbe (1990)). Those studies have opened up new fields for the study of the predictability of natural events.

In this paper, the time oscillations of water elevation at Venice are considered, depurated from the contribution due to sea waves, to obtain information about "high waters" and in particular about their frequency and their predictability.

Tidal levels recorded at Punta della Salute and Diga Sud Lido between 1975 and 1984 and published by the "Consorzio Imprese Veneto-Emiliane" are considered. The study is based on recent measurements, however a preliminary investigation performed on data recorded at the beginning of the century has shown similar results.

Because extreme events are of more practical interest, the analysis is performed also for the signal envelope of maxima which is obtained starting from the knowledge of diurnal and semidiurnal tidal oscillations.

The procedure used in the rest of the paper is the following: first the time oscillations of the water level in the lagoon of Venice are analysed by studying both the hourly measurements and the 'envelope' of maxima recorded during one year for different years. The presence of a predictable periodic component and of an irregular component is shown. Indeed, the Fourier spectra of the signals relative to the hourly measurements show peaks related to the diurnal, semidiurnal and moon tide and a broad band part, which is characteristic of random and/or chaotic systems. Moreover, the intensity of the continuous part of the spectra turns out to be of the same order of magnitude as the peaks. Then the dynamic behaviour of the system is analyzed in the pseudo-phase space where the attractor is reconstructed by means of the time-delayed coordinate technique. The characteristics of the attractor are evaluated and in particular the correlation dimension, which gives indications of the degrees of freedom of the system, is computed along with the largest Lyapunov coefficient which is a measure of the sensitivity of the system on initial conditions. The results obtained give strong indications of the presence of chaotic dynamics. For this reason, an attempt to predict the time development of the system by using the deterministic algorithm by Farmer & Sidorowich (1987) is made. The success in predicting the future time development of the system on the basis of historical records by means of deterministic methods is a further indication of the presence of deterministic chaos.

### Signal and spectrum of tidal elevation

It is widely recognized that the understanding of the dynamics of currents and sea level oscillations is extremely important in most coastal regions and particularly in estuaries and lagoons. Typically, sea level oscillations related to the astronomical tide are the most significant even if sometimes meteorological factors such as wind, a non uniform distribution of atmospheric pressure and storms can induce sea level oscillations of the same order of magnitude as tidal oscillations.

Indeed, in Venice, "high" waters are often caused by the simultaneous presence of high tide and meteorological factors. While tidal oscillations, being the result of the periodic motion of celestial bodies, are deterministic and thus predictable, the effect of meteorological events is aperiodic and thus not easily predictable.

In fact, the astronomical tide is caused by spatio-temporal variation of the gravitational field due to the relative motion of the earth with respect to other celestial bodies. An analysis of the phenomenon taking into account all the possible influences is extremely complex. However, considering the order of magnitude of gravitational forces induced on the earth's surface by different celestial bodies, it can be inferred that in order to study sea level rise due to the astronomical tide it is sufficient to consider the relative motion of the earth, the moon and the sun. Usually tidal oscillations are decomposed into a number of sinusoidal time components, each with its own periodicity. Five basic periods are usually taken into account: 1 day due to the earth's rotation, 29.53 days due to the rotation of the moon around the earth, 365.24 days due to the rotation of the earth around the sun, 8.847 years due to the motion of the moon perigee and 18.616 years due to the rotation of the orbital plan of the moon.

Since in the present work we study sea level oscillations when meteorological factors prevail, the time scale of interest to us is of one week and thus periodicities of 365.24 days, 8.847 and 18.616 years can be ignored. In other words, we will assume that the sea level oscillates with periodicities of 1 and 29.53 days around a mean level slowly varying with moderate excursions during one year.

The periodic nature of the astronomic component of the tide is evident in figure 1 where the tidal levels ( $\eta$ ) recorded during the months of August and September 1981 are plotted. Similar results are obtained considering different years. During summer and spring, the influence of wind, storms and other meteorological events on sea level oscillations is usually negligible. On the other hand, aperiodic meteorological events become relevant in autumn and winter. In figure 2 the tidal curve relative to November and December 1981 is reported in order to show the aperiodic character of exceptional events. The aperiodic character of extreme events is still more evident by looking at figure 3 where the envelope of maxima is shown for the years 1980-1984.

The spectrum of the signal, shown in figure 4(a) for the year 1981, supports this argument showing two peaks related to the periodicities of 12 and 24 hours

Figure 1: Tidal levels recorded at Punta della Salute during August and September 1981.

Figure 2: Tidal levels recorded at Punta della Salute during November and December 1981.

Figure 3: Envelope of maxima for the years 1980, 1981, 1982, 1983 and 1984.

Figure 4: a) Spectra for the year 1981, b) Spectra of the 'envelope of maxima' for the years 1980, 1981, 1982, 1983 and 1984.

and a broad band part with the same order of magnitude.

The intensity of the broad band part varies when different years are considered: in fact, it is larger for years which have experienced more "high waters". However, considering different years, no relevant differences are found. The spectrum of the 'envelope' of maxima (see figure 4(b)) shows no peaks since the periodicities of 12 and 24 hours have been removed from the time sequence and the broad band part is larger and stronger with respect to that of the original signal.

So far, we have shown evidence of the non-periodic nature of sea level oscillations inside the lagoon of Venice; in the following we will investigate the nature of such oscillations. In fact, they could either be the result of a stochastic system, i.e. a dynamic system with a high number of degrees of freedom or the result of a chaotic system with few degrees of freedom.

### The Chaotic Character of Tidal Elevation

In order to study the aperiodic character of tidal oscillations, it is necessary to perform a quantitative study of the attractor of the system. As suggested by Takens (1981) the trajectory of the system is reconstructed into a "pseudo-phase" space by using the time sequence of the values attained by one physical variable characteristic of the phenomenon. More specifically the  $N$ -dimensional vectors  $\vec{s}$ , describing the trajectory of the system in the pseudo-phase space, are obtained on the basis of the measurements  $f(t)$  of the tidal level performed at the stations of Punta della Salute and Diga Sud Lido:

$$\vec{s}(t) = [s_1, s_2, \dots, s_N] = [f(t), f(t - \tau), \dots, f(t - (N - 1)\tau)] \quad (1)$$

where  $f$  is the water level as a function of time and  $\tau$  is an arbitrary time delay.

Takens (1981) showed that an attractor topologically equivalent to that of the original system, is obtained independently of the value of  $\tau$  if  $N$  is sufficiently large. However, for computational reasons, it is necessary to accurately choose these parameters in order to have an accurate estimate of the characteristics of the attractor. In fact, if  $\tau$  is too small, the attractor collapses along the line  $s_1 = s_2 = s_3 = \dots$  and the computation of the characteristics of the attractor becomes inaccurate.

In literature, it is suggested that the value of  $\tau$  as the time delay relative to the first zero of the autocorrelation function be chosen. According to Battiston & Zambella this procedure gives a value of  $\tau$  equal to 20 hours. However, in the following we have used values of  $\tau$  equal to 50, 100 and 200 hours because these values have led to a better estimate of the Lyapunov exponent and of the correlation dimension. As far as the value of  $N$  is concerned, we have computed the characteristics of the attractor for increasing dimensions of the pseudo-phase space until non relevant differences were observed between  $N$  and  $N + 1$ .

It is well-known that a chaotic attractor possesses a geometric structure called fractal attractor which has a finite and generally non integer dimension. To establish the nature of the aperiodic oscillations of the tidal wave, it is necessary first to evaluate the dimension of the attractor. In order to obtain a quantitative estimate of the possible fractal structure of the attractor, we computed the correlation dimension as defined by Grassberger & Procaccia (1983). As suggested by Takens (1981), the trajectory of the system into the pseudo-phase space is represented by a set of  $M$  points  $\vec{s}_i$  defined by (1) and their relative distance is computed using the Euclidean distance. Then the correlation function is defined as the limit for  $M$  tending to infinity of the number of pairs with a relative distance  $d_{ij}$  less than  $r$  divided by  $M^2$ .

$$C(r) = \lim_{M \rightarrow \infty} \frac{1}{M^2} \{\text{Number of pairs } (\vec{s}_i, \vec{s}_j) \text{ such that } d_{ij} < r\} \quad (2)$$

Grassberger & Procaccia (1983) showed that for many attractors the correlation function for  $r$  tending to zero behaves like a power law, i.e.

$$\lim_{r \rightarrow 0} C(r) = ar^d \quad (3)$$

The correlation dimension is then defined as the exponent  $d$  of the power law, which can be expressed as:

$$d = \lim_{r \rightarrow 0} \frac{\log_{10} C(r)}{\log_{10} r} \quad (4)$$

In figure 5, the correlation function relative to the signal of tidal elevation is plotted for the years 1980 and 1982 and for a few dimensions  $N$  of the embedding ( $r_{max}$  denotes the maximum linear extent of the attractor). It is possible to observe that in both cases, by increasing  $N$ , the slope of the correlation function

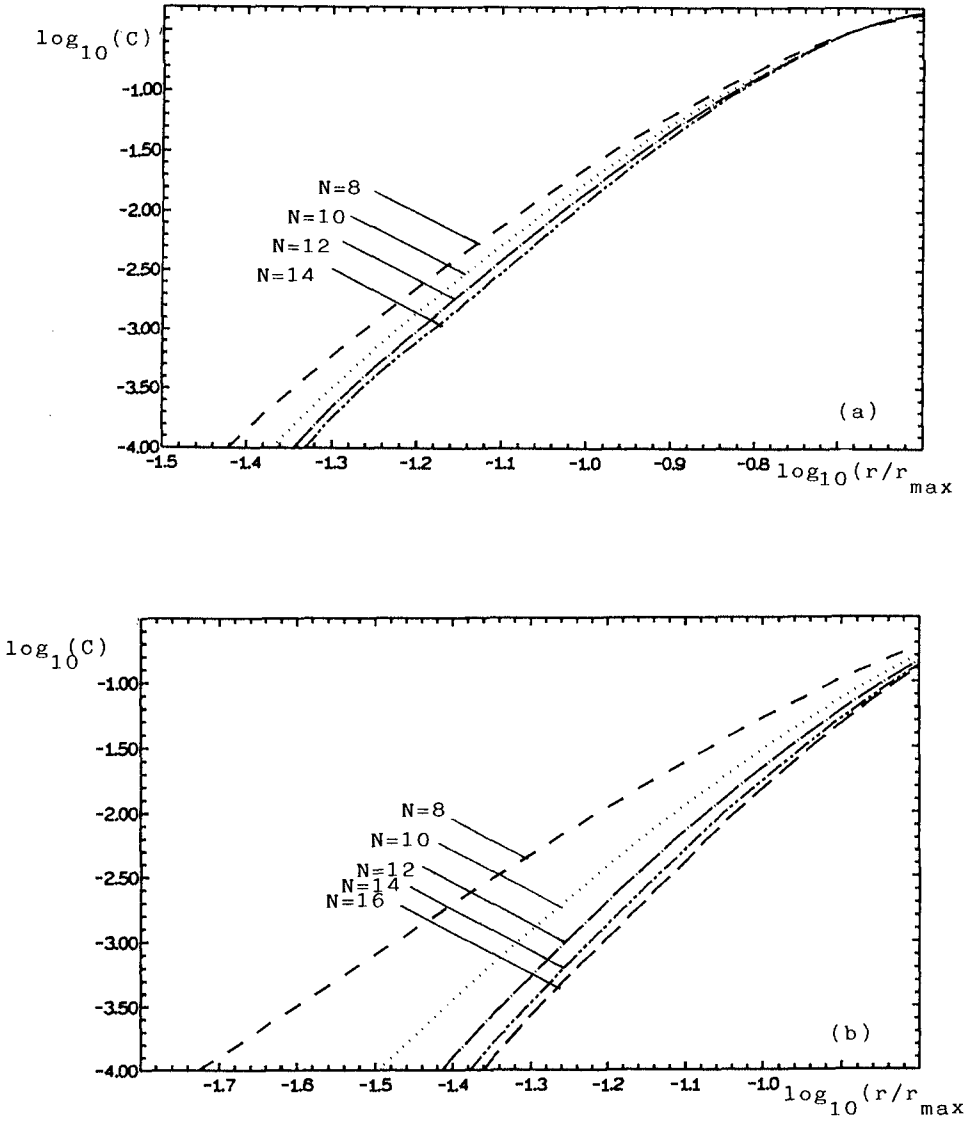

Figure 5: Correlation function for the years a) 1980  $\tau = 200$ ; b) 1982  $\tau = 200$ .

Figure 6: Slope of the correlation function for the years a) 1980  $\tau = 200$ ; b) 1982  $\tau = 200$ .

Figure 7: Correlation function for the 'envelope of maxima' relative to the years 1980, 1981, 1982, 1983 and 1984  $\tau = 40$ .

reaches a limiting value for small but finite values of  $r$  where the limit defined by (4) can be evaluated and in the meantime boundary effects can be ignored. The value of the correlation dimension can best be estimated by looking at figure 6 where the function  $S(r)$ , corresponding to the slope of the correlation function, is plotted as a function of  $\log_{10}(r/r_{max})$  for the same years as in figure 5.

It can be seen that for sufficiently large values of  $N$  and for small values of  $\log_{10}(r/r_{max})$ ,  $S$  attains a constant non integer value close to 6. This value can be regarded as an approximation of the correlation dimension  $d$ .

A smaller value of the correlation dimension is obtained considering the attractor relative to the envelope of maxima. In figure 7, where the slope of the correlation function relative to the envelope of maxima is plotted for different values of  $N$  it can easily be seen that for small  $r/r_{max}$  the correlation dimension tends to a constant non integer value close to 2. The fact that the correlation dimension of the envelope of maxima is lower than that of the original signal is reasonable since by extracting the envelope of maxima a number of degrees of freedom related to the astronomic tide have been removed. As we shall see in the following, the lower dimension of the envelope of maxima turns out to be an advantage when making predictions of the temporal development of the system.

From the results shown so far, it is possible to conclude that sea level oscillations inside the lagoon of Venice are the result of a chaotic dynamic system since the number of degrees of freedom of the attractor is limited. Hence, in principle, it would be possible to predict the time development of tidal elevation

by integrating a limited number of ordinary differential equations.

The following step is to determine the time interval within which a trajectory of the system can be predicted with a given uncertainty starting from an initial state known with an assigned error. It is well-known that chaotic attractors show an exponential divergence of the trajectories in the phase space. After some time, two states initially close to each other develop into two states far apart. Thus, the prediction of the time development of a given state, known with a given uncertainty, can be obtained only for a time interval which depends on the rate of divergence of the trajectories in the phase space. This rate of divergence is expressed by the largest Lyapunov coefficient.

Lyapunov coefficients can be defined by considering the time development of a hypersphere lying on the attractor reconstructed into the pseudo-phase space. Due to the chaotic nature of the system, the hypersphere will develop into an ellipsoid. The  $i$ -th Lyapunov coefficient is defined in terms of the length of the  $i$ -th principal axis of the ellipsoid ( $p_i$ ) by means of the following relationship:

$$\lambda_i = \lim_{(t_1 - t_0) \rightarrow \infty} \frac{1}{t_1 - t_0} \log_2 \frac{p_i(t_1)}{p_i(t_0)} \quad (5)$$

where the values of  $\lambda_i$  are ordered in ascending order and  $t_1 - t_0$  is the time interval during which the computation is performed.

Thus, the Lyapunov coefficients are related to the average expansion or contraction of the hypersphere in the different directions of the phase space. Axes which expand on average originate positive values of  $\lambda_i$  while axes which on average contract give rise to negative values.

In the present paper the procedure suggested by Wolf et al (1985) to compute the largest Lyapunov coefficient is employed.

In table 1 the values obtained for the largest Lyapunov exponent ( $\lambda_1$ ) are reported for the years ranging between 1980 and 1984.

TABLE 1

year	1980	1981	1982	1983	1984
$\lambda_1$ (hours <sup>-1</sup> )	0.025	0.024	0.026	0.023	0.026

Similar values are obtained by taking into account the 'envelope of maxima'.

The values obtained for  $\lambda_1$  would lead to the conclusion that sea level oscillations inside the Lagoon of Venice could be predicted for long periods, at least from a theoretical point of view. However, it should be considered that the use of a finite number of experimental data does not allow the desired infinitesimal length scales of the attractor to be tested. These scales are also inaccessible due to the presence of noise on finite length scales. Therefore, also taking into account that the chaos-producing structure of the attractor might be of small spatial extent, the estimate of the largest Lyapunov exponent of the system and thus of the timescale on which the system dynamics becomes unpredictable may be

affected by a significant error. This fact can cause an underestimate of the largest Lyapunov coefficient.

### The Predictions

Even though the characteristics of its attractor could not be quantified accurately due to the knowledge of a finite number of data, from the results previously described it is possible to infer that the system has a chaotic nature. Therefore, the prediction of the time development of the system can be attempted by using algorithms which take advantage of the deterministic nature of the system.

Even though the extreme sensitivity of the time development of the system on initial conditions poses some limits to the possibility of predicting its future time development, it is possible to make accurate predictions for small times and, at least in principle, to give an estimate of the error affecting the predictions.

In the present paper use has been made of the method proposed by Farmer and Sidorowich (1987). As a first step, a time sequence of data is used to represent a state on the attractor in the pseudo-phase space by means of (1). Secondly, a functional relationship between the current state  $\vec{s}(t)$  and the future state  $\vec{s}(t+\Delta t)$  is assumed to exist:

$$\vec{s}(t + \Delta t) = f_{\Delta t}(\vec{s}(t)) \quad (6)$$

Due to the chaotic nature of the system, the function  $f_{\Delta t}$  is certainly non-linear. To obtain an approximation to  $f_{\Delta t}$ , Farmer & Sidorowich (1987) suggest using the knowledge of the time development of a number of points on the attractor which are near to  $\vec{s}(t_0)$ , i.e. to the state whose time development we want to predict. Let us consider the  $P + 1$  points of the attractor ( $\vec{s}(t_j)$ ,  $j = 1, 2, \dots, P + 1$ ) which are the nearest to  $\vec{s}(t_0)$ . A local approximation of  $f_{\Delta t}$  is obtained on the basis of the values  $\vec{s}(t_j + \Delta t)$  attained by the  $P + 1$  points. The easiest procedure would be a zero order approximation where  $P = 0$ . In this case  $\vec{s}(t_1 + \Delta t)$  could be assumed to be the approximation of  $f_{\Delta t}$ . A better approximation is obviously obtained assuming  $P + 1$  larger than  $N$  and determining, by means of the least square method, the coefficients of the linear relationship  $a * \vec{s}(t_j) + \vec{b}$  which best approximate  $\vec{s}(t_j + \Delta t)$ .

After the values of the matrix  $a$  and  $\vec{b}$  have been obtained, the prediction can easily be performed:

$$\vec{s}(t_0 + \Delta t) = a * \vec{s}(t_0) + \vec{b}.$$

The results obtained are presented in figures 8 and 9 where predicted and measured levels are plotted as a function of time both for tidal levels and for the envelope of maxima. The measurements of tidal elevations during the years 1980, 1981, 1982 and 1983 have been used to reconstruct the attractor and the

Figure 8: Predictions (—) and measurements (- - -) of tidal elevations at Punta della Salute in the last months of 1984. a)  $\Delta t = 2$  hours; b)  $\Delta t = 24$  hours.

prediction of tidal levels has been made for the last three months of 1984 when there were some exceptional events.

In figure 8 the observed (- - -) and the predicted (—) tidal levels are shown for November 1984 when three events of high water were observed. In figure 8(a) the prediction 2 hours into the future is shown while in figure 8(b) the prediction 24 hours into the future is presented. In figure 9(a) and (b) the predictions of the envelope of maxima are shown for 12 and 24 hours into the future respectively.

It is possible to see that the predictions relative to the envelope of maxima are more accurate than those of the original signal; this fact can be explained on the basis of the lower correlation dimension of the signal envelope of maxima with respect to that of the signal of tidal elevations.

As expected, by increasing  $\Delta t$  the predictions are less accurate both for the

Figure 9: Predictions (—) and envelope of maxima (- - -) at Punta della Salute in the last months of 1984. a)  $\Delta t = 12$  hours; b)  $\Delta t = 24$  hours.

original signal and for the envelope of maxima.

However, the prediction could be improved by considering larger data set to reconstruct the attractor and by using a higher order approximation to obtain the local predictor  $f_{\Delta t}$ . In order to evaluate the performance of the proposed model it is necessary to take into account that, as reported by different authors (Battiston & Zambella (1981), Cecconi et al (1992)), the error of the statistical methods for predictions for a time in the future less than 15 hours ranges between 10 to 15 cm.

### Acknowledgements

Many thanks are due to Prof. Tomasin of "Istituto per la Dinamica delle Grandi Masse" of C.N.R. who kindly provided some of the data used in the paper.

## CHAPTER 140

### THE ITALIAN WAVES MEASUREMENT NETWORK

M. DE BONI<sup>1</sup>, Manager; L. CAVALERI<sup>2</sup>, Researcher;

A. RUSCONI<sup>3</sup>, Manager

#### 1. INTRODUCTION

The Rete Ondametrica Nazionale (RON) - the Italian Wave Measurement Network - is a system for recording directional wave motions along the Italian coasts, operational since 1st July 1989. The network includes eight wavec directional wave Datawell buoys and the corresponding land-based receiving stations.

Following an international tender, the Ministry of Public Works appointed TEI SpA for the design and management for the network and for data processing. Following the reorganization of the National Technical Services, the responsibility for the network and its activities has been transferred to the Italian Hydrographic and Tidal Service ("Servizio Idrografico e Mareografico, (SIM)"- under the aegis of the "Presidenza del Consiglio dei Ministri" (President of the Ministries Council), a special parliamentary body.

After three years of continuous operations (1989-1992), it is now possible to make a preliminary general account of the venture, analysing in particular the following aspects:

- Reliability of the technical solutions and efficiency of the network management system;
- Scientific and technological applications of statistical data;
- Use of the data in wind-waves numerical modelling for the Mediterranean Sea;
- Prospectives of development and follows-up.

<sup>3</sup> Presidenza del Consiglio dei Ministri Servizio Idrografico e Mareografico Nazionale Direzione Centrale, via Nomentana, 2 - 00198 Roma, Italy

2. TECHNICAL DESCRIPTION

The Italian Wave Measurement Network (henceforth referred to as RON) includes eight stations, whose position is shown in Fig. 1.

The choice of the locations has been done with the aim of:

- a) monitoring the sea conditions in areas of intense wave activity;
- b) optimizing the distribution of wave measurement around Italy, given the already existing instruments (see Fig. 1).

Preliminary activity started in early 1989 and the network became operational on 1st July, 1989. In this section we give a compact description of the measuring instruments, of the network and of the data processing.

MEASURING INSTRUMENTS

Each station (see Fig. 2) includes a Wavec buoy, manufactured by Datawell, and a receiving station. The buoy has been amply described in the literature and we give here only a very compact description of it (see e-g, Manual of direc receiver, Manual of wavec buoy from Datawell B.V. Haarlem).

The buoy, moored using a flexible system that allows maximum freedom of movements, is of the surface following type.

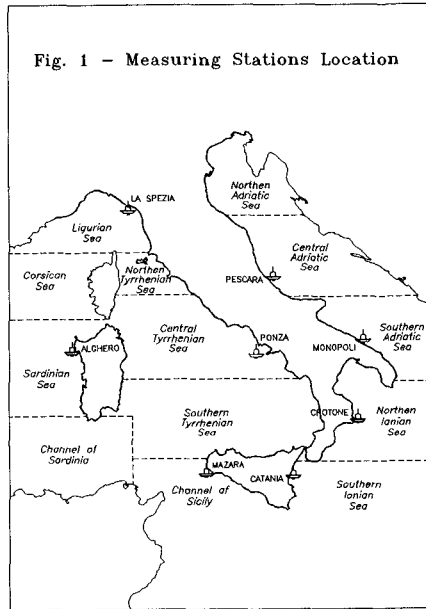

Fig. 1 - Measuring Stations Location

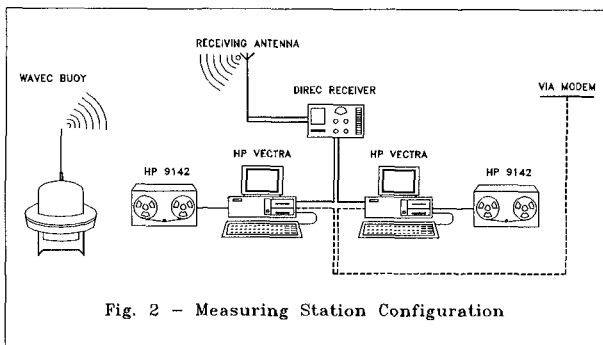

Fig. 2 - Measuring Station Configuration

Vertical acceleration, pitch and roll of the buoy, and relative components of the earth magnetic field are measured and used to deduce the heave and slopes (in North and South direction) of the local sea surface.

Each parameter is sampled at 128 Hz frequency and the data are continuously transmitted by radio to the receiving station located on the main land.

Each buoy is located far enough from the main land to allow full representativeness of open sea conditions.

The mooring depth varies from 80 to 100 m. The buoys are powered by self-contained batteries, with an autonomy of 10 months.

The system for the acquisition and processing of data, of which the Direc receiver is an integral part, is made up of two AT compatible HP Vectra ES 12 Personal Computers.

The PCs are connected by means of serial ports to the MAIN and UAX gates of the Direc; the second serial port is connected to a telephone modem used for tele-servicing and real-time remote control. Through the MAIN computer, it is possible to program the Direc receiver for the functions of sampling time, time, type of data output from the AUX port (monitor, real-time, CQ), and the  $H_s$  above which the system must sample continuously. This PC is also used to store the processed data, and the directional spectra are displayed every 30 minutes, as well as a set of data on the functioning characteristics of the buoy such as tilt, platform offset, compass offset, battery voltage, and water temperature, and a report on the quality of the signals received in the previous half-hour.

As already noted, the AUX PC is used only for the acquisition of data (monitor, real or CQ) sent from the AUX port of the Direc receiver. To minimize the risk of loss of data due to hardware failures in the two computers, each day the data recorded on the hard disk are downloaded to the streaming tape as a sequential file, and then at the end of the month both the physical copy on the hard disk and the daily recordings on tape for each computer are saved.

A detailed description of the network organization and all the technicalities involved is given by Rusconi et al (1990, 1992).

#### DATA PROCESSING

The combined analysis of heave, pitch and roll of the sea surface at a given location, pioneered by Longuet-Higgins et al (1962), provides estimates of:

- a) the one-dimensional wave frequency spectrum  $E(f)$ , and related quantity as significant wave heights  $H_s$ , mean and peak period  $T_m$  and  $T_p$  respectively;

b) directional distribution of energy at each frequency represented by mean direction  $\theta(f)$ , second mean direction  $\theta_2(f)$ , skewness and kurtosis, and the deduced mean spectral direction  $\theta_m$ .

## MANAGEMENT

The degree of reliability of the technical solutions adopted and the efficiency of the Network Management System set is demonstrated by the percentage of valid data which, for each recording station, is supplied every three months to the SIM (Table 1).

	S 89	A 89	W 90	S 90	S 90	A 90	W 91	S 91	E 91	A 91	W 92	TOT
La Spezia	91,30	99,70	86,00	96,40	96,70	93,30	97,10	95,40	94,20	95,40	91,10	94,24
Alghero	94,80	98,90	96,70	95,90	98,50	94,60	97,10	86,70	99,70	93,60	98,80	95,92
Pescara	95,60	100,00	99,90	93,30	89,80	85,20	93,50	96,10	96,70	93,30	99,90	94,85
Monopoli	99,00	96,10	89,90	99,00	98,90	96,30	96,30	99,90	96,00	86,00	97,50	95,90
Ponza	95,90	94,00	86,20	97,50	98,60	90,80	85,10	99,30	98,80	98,80	90,40	94,13
Crotone	96,20	99,70	96,50	85,00	96,70	95,00	99,90	92,00	96,60	92,50	95,50	95,05
Catania	89,80	86,40	85,40	89,80	97,80	96,10	95,70	98,40	94,80	91,20	92,90	92,57
Mazara d.V.	93,30	99,50	86,80	94,60	95,00	85,20	88,80	93,50	88,30	99,60	95,50	92,74
Totale	94,49	96,79	90,93	93,94	96,50	92,06	94,19	95,16	95,64	93,80	95,18	94,42

The following considerations can be made:

- the global reliability of 94,4% is considerably above the minimum limit of 85% required by the SIM;
- this degree of reliability, following a preliminary phase, has been maintained at a level more or less constant thanks to the Management System and to the use of the Argos satellite. This service started in 1990, and it is used for remote control of the position of the buoys;
- no substantial variations of reliability have been noted with the seasons (2% lower than the mean value), which confirms that the technological choice was correct and that reliability depends only to a limited extent on weather conditions;
- loss of data is basically the result of fishing activities: it is a random event more frequent in certain southern areas.

Two activities of considerable technological importance have been implemented to guarantee these reliability levels:

- connection of all the buoys to the Argos satellite in order to check the positioning of the measuring system;
- a star-shaped telecommunications connection via modem between the peripheral recording stations and the central interrogation system.

A permanent Assistance Service has been organized for the RON network to fully exploit these technological supports. It has the twin tasks of an immediate intervention and both a preventive and ordinary maintenance.

## PREVENTIVE AND ORDINARY MAINTENANCE

These activities comprise:

- Downloading to streaming tape and monthly checking of data.
- processing and checking of the quality of the data received (the task of TEI Data Processing Centre), which issues a monthly bulletin, for use by the Assistance Service, on the quality of functioning of the sensors and the percentage of valid data. These activities provide a concise statistical picture of the functioning of the equipment and make it possible to establish in advance the ordinary and special maintenance interventions required.
- Maintenance support activities, for each peripheral site corresponding to a wave gauge station, carried out by two local operators: one for the sea parte, providing immediate nautical intervention in the event of equipment breakdowns; the other for the land part, having the task of carrying out preventive maintenance and the monthly downloading of data.
- Monthly checks on the state of the wave gauge equipment, the relative photographic documentation, underwater inspections to check the moorings, and the preparation of a service report to be delivered to the Data Processing Centre.
- Monthly checks of the equipment on land, with an evaluation of the degree of wear of components such as processors, aerials, cables, ecc.
- Calibration of the wave meters taken out of service for maintenance, using the "Ferris Wheel" system and preparation of the relative certificates.

These preventive activities make it possible to guarantee replacements with a maximum delay of 48 hours for the breakdown of any component on land, and a similar facility within 48-72 hours of notification for incidents involving a wave gauge buoy at sea, using personnel and tenders available on site.

## ALARMS MANAGEMENT

This activity consists of:

- Checking of daily reports supplied via modem by the Argos service, concerning the correct positioning of each buoy.  
If a buoy is found a drift out of its area of action (which is calculated on the basis of the length of the mooring cable), its movement is continuously tracked and repeated via telex or modem to the centre, where the specialist control team will forward the required instructions to the people on site in order to rapidly recover the buoy and to ensure that it is immediately repositioned or replaced.  
This system, based on equipment for the transmission of signals to the Argos satellite, is installed on the wave gauge buoy. It has produced

excellent results and it is certainly one of the reasons that has guaranteed the high percentages for recorded data.

- Daily activation of the automatic interrogation procedure of the peripheral stations, making it possible to check at any moment the functioning of the individual stations/components and to transfer concise wave data.

#### 4. RESULTS

The availability of large quantities of data allows some basic analysis of the wave conditions around Italy, both for basic physical problems as for engineering applications.

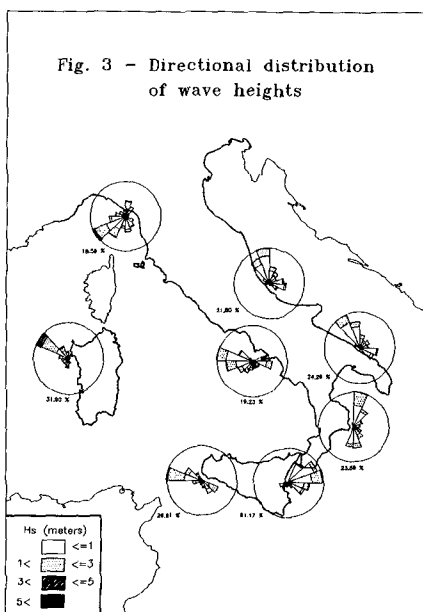

##### A) Wave climate

From the statistical point of view, a number of specific analyses are usually carried out for each station concerning:

- the statistical distribution of  $H_s$ ;
- the combined distributions ( $H_s, T_m$ ), ( $H_s, \theta_m$ );
- the seasonal variability of the above distributions.

Fig. 3 shows, in synoptic form, the directional distribution of the wave height, evaluated on all the data so far collected.

Fig. 4 shows the distribution functions  $p(H_s)$  relative to all the data recorded for the various stations.

The figure highlights the various energy levels corresponding to the different sites, and also the existence of different slopes for the various curves. These distributions cannot be considered conclusive because three years of data are by far a too short period for the deduced statistics to be significant. Besides, the data show a clear yearly variability that depends on the general meteorological pattern of the period. Hence the above statistics should be considered with much care. Because the data collection is continuing, updated statistics will be published as soon as available.

#### B) Extreme waves analysis

A further consideration more concerned with engineering is the selection of the extreme events recorded in the three year period under consideration. Table 2 shows, for the various stations, the maximum values of  $H_s$ ,  $T_p$ ,  $T_z$  and the corresponding mean direction evaluated during the most violent storms at each station.

Undoubtedly the area most exposed to wave motion is the west coast of Sardinia: for this station, in correspondance with the storm of 20th December 1991, a significant wave height of 8.92 m has been recorded.

STATION	$H_s$ (m)	$T_p$ (s)	$T_M$ (s)	MeanDir( $^{\circ}$ N)
La Spezia	6.60	11.10	8.00	60
Alghero	8.92	12.50	9.50	135
Pescara	5.10	9.10	6.00	170
Monopoli	4.40	9.10	7.00	233
Ponza	5.70	12.50	5.40	94
Crotone	5.60	11.10	8.10	302
Catania	5.20	11.10	8.10	275
Mazara	5.50	12.50	8.30	105

## 5. APPLICATION TO NUMERICAL MODELLING

One of the most interesting applications for the data collected by the wave gauge network is the validation of numerical models for the calculation of wave motion.

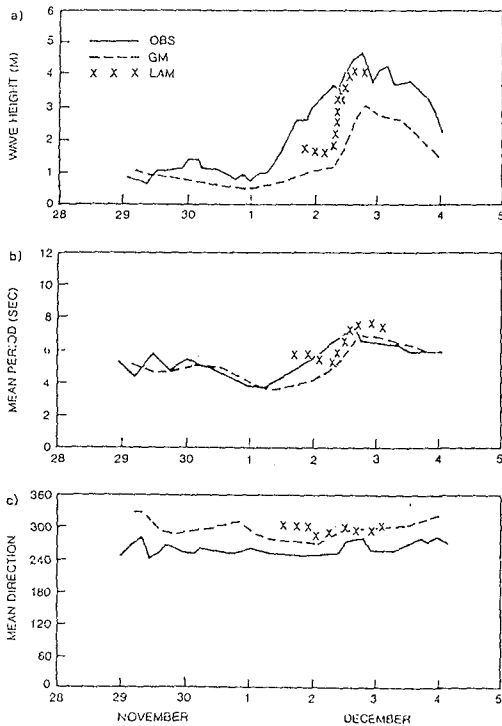

Models at various levels of complexity have been repeatedly applied in the Mediterranean Sea, and the results improve as the approach becomes more sophisticated. Presently one of the most advanced model is WAM, the product of the coordinated work of a large group of specialists in the field (WAMDI Group, 1988). This model has been repeatedly applied in the Mediterranean basin (Cavaleri et al., 1991).

The main result has been to assess the difficulty of correctly representing the field of surface wind in the basin, and consequently the wave field associated with it. An error of 20% in wind speed leads to an error of the significant wave height  $H_s$  of 30-40%, and consequently to an error of 70-100% for the energy of the wave motion, which is the variable of most practical interest in engineering applications. Errors of this level are unacceptable!! We must recognize, however, that different meteorological models, with different solutions, give wind fields that can differ well over 20%. It is also very difficult to thoroughly test a wind model, as the complicated orography of the basin, particularly along the Italian coasts, can affect the local wind field in a drastic way and the stations of interest are located on the coast.

This makes any comparison between a detailed item of measured data (typically wind speed and direction) and the results of a meteorological model of limited significance, when the latter cannot take orographical details into account.

The solution, although neither complete nor definitive, may come from an analysis of the results of the wave field. The conditions of wave motion in a given location represent an effect, integrated in time and space, of the wind field on the entire basin. The recorded wave conditions provide therefore a validation of the combined meteorological and wave models.

Because the performance of a wave model is not affected by the geometry of the surrounding orography, particularly in areas like the Mediterranean Sea, recorded wave data, combined with the models results, can provide useful indications

[Fig. 5 Comparison between recorded and computed wave heights by using the ECMWF (GM) and LAM models]

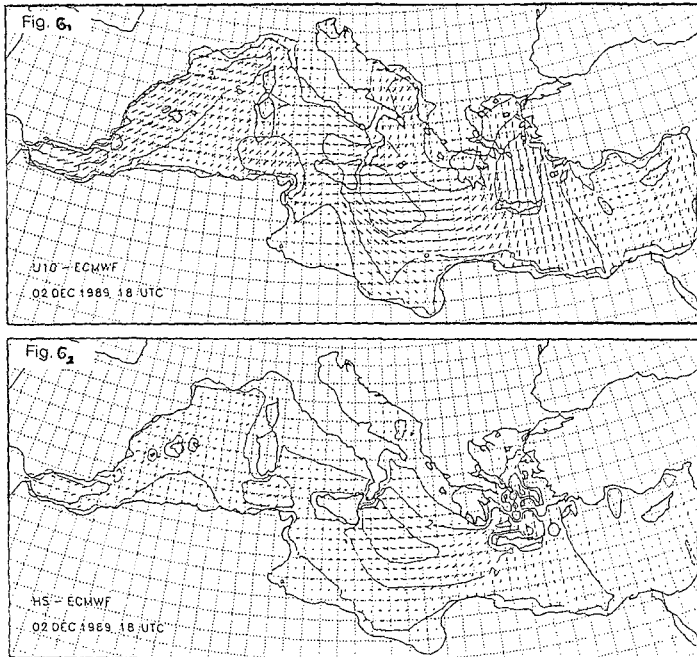

on the accuracy of the input wind fields.

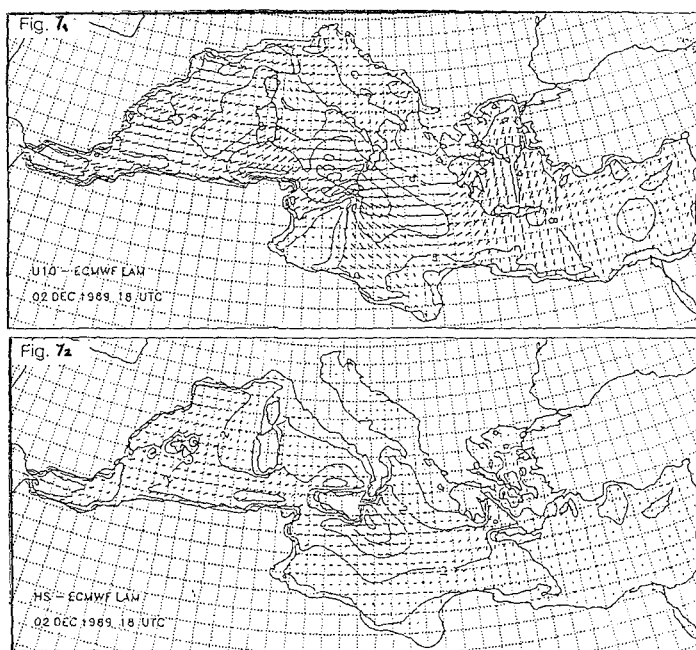

The Mediterranean Sea is characterized, as well as by large-scale events, also by events of a smaller scale, and yet extremely violent. An example is provided by the storm that hit the Malta area on 2nd December 1989 during the meeting between Presidents Bush and Gorbachov. A detailed study of this event has been made by Dell'Osso et al. (1992). The storm was characterized by the development of a deep pressure on the Ionian Sea, characterized by very strong winds with an extremely high spatial gradient. Results of the computation of the wave field by the WAM model have been compared with the experimental data recorded at Catania (Fig. 5). While the direction of the field is correct, there is a considerable underestimate of the wave height, a strong suggestion that the wind has been underestimated.

This led to repeating the meteorological simulation with a finer mesh (40 km, compared with the 125 km resolution of the global model of the ECMWF).

The results, in terms of wind and wave fields, are shown in Fig. 6). There is a strong increase and concentration of the wind in the area of Capo Passero, with a consequent increase of the wave height in the Catania area. Fig. 7 shows the obvious consequent improvement in the wave model results.

[Fig. 6 Windfield (6<sub>1</sub>) computed by ECMWF model and associated waves field (6<sub>2</sub>)

[Fig. 7 Windfield (7a) computed by ECMWF model and associated high resolution waves field (7b) computed by LAM model]

In general, the results of the modelling exercise indicate that a resolution of 125 km, such as that in the operative model of ECMWF until the end of September 1991, is not sufficient to provide the necessary accuracy of the wind field. A 70 km resolution, as that corresponding to the new model of ECMWF (T213), seems the minimum required for a sufficient reliability of the wave model results.

## 6. PRESENT SITUATION AND FUTURE DEVELOPMENTS

In view of the high reliability of the RON System, the Hydrographic and Tidal Service has decided to proceed with the monitoring activities for three more years, appointing once more TEI for the management of the project.

To improve the system the following additional activities have been added:

- connection in real-time of the existing eight stations with the central station at TEI in Milan;
- transfer of the data to a workstation located at the Rome Centre of the Hydrographic and Tidal Service;

- display of the recorded data, in real-time, using the RAI (Italian Broadcasting Corporation) Televideo Service.

Future expected activities include:

- the extension of the present network to four more stations;
- the distribution of the wave data collected and analysed in real time to the GTS - This will allow the assimilation of the wave data in the present Mediterranean Sea wave forecasting system (Cavaleri and Bertotti, 1992) with a consequent improvement of the wave forecast in the basin.

# CHAPTER 141

## EVALUATION OF DESIGN WAVES ALONG THE COAST AND AT THE INLETS OF THE VENICE LAGOON

Paolo De Girolamo(\*), Giancarlo Passacantando(\*\*)  
David Hurdle(\*\*\*) and Alberto Noli(\*)

### Abstract

The prevention of flooding inside the Venice lagoon requires a system to disconnect the North Adriatic sea and the lagoon hydraulically in order to control water level. This paper describe the method followed to define design wave conditions to support the design of the new storm surge barriers. The derivation of design waves was not straightforward because of the presence of an extended continental platform and irregular geografic boundaries.

### 1.Introduction

The prevention of flooding inside the Venice lagoon (Fig.2) requires a system to disconnect the North Adriatic sea and the lagoon hydraulically to control water level. One of the most feasible ways to achieve this is to use a system of moveable storm surge barriers (Varisco 1992).

Definition of the wave and water level conditions is required for the associated design activities. This paper describes the work carried out in order to define the design waves for normal and extreme conditions. The emphasis is on the statistical methodology to derive the extreme conditions and on the appropriate modelling approach for the simulation of the wave behaviour close to the inlets. A number of numerical models were evaluated to select the appropriate one for the preliminarily and design phases. The derivation of the conditions at the outside boundary of these models is discussed by Hurdle et al.(1993). This paper also discusses the special characteristics of the North Adriatic sea (in particular the extended continental shelf) and the predominant wind conditions. For the purposes of this paper, it is sufficient to know that three wind types are important for the design conditions: the Scirocco wind (from the South East), the Levante wind (from the East) and the Bora wind (a cold wind from East North East).

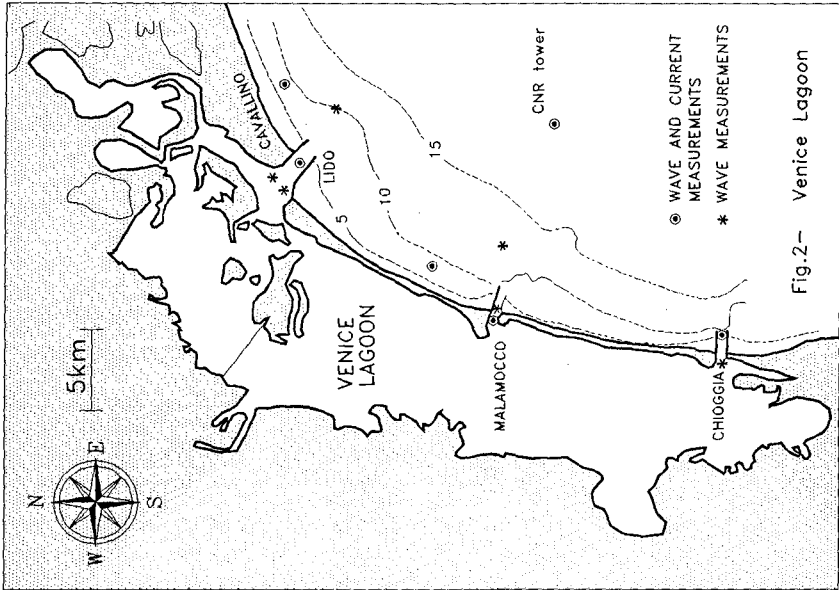

Fig.2- Venice Lagoon

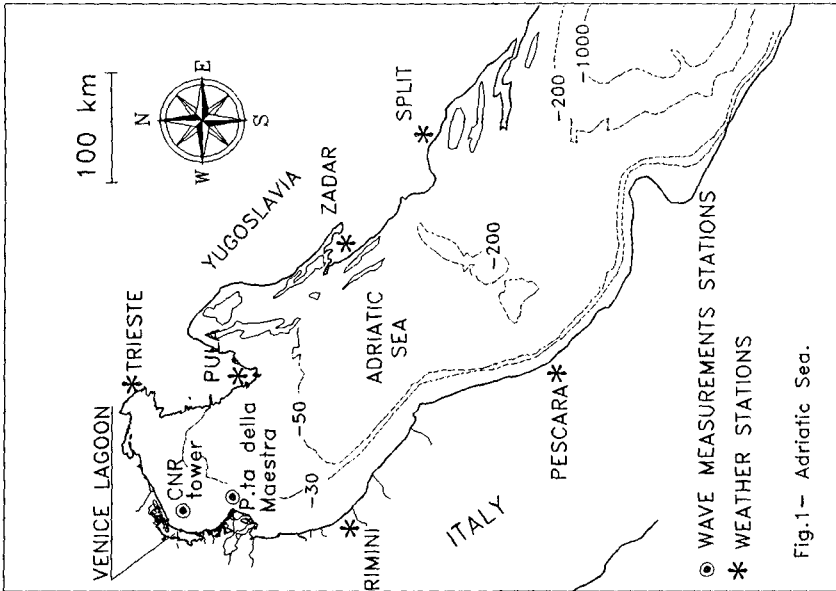

Fig.1- Adriatic Sea.

Even in the preliminary phase, the design of the moveable storm surge barriers required a careful evaluation of the extreme wave conditions in front of the barriers. In fact, initial studies using simple numerical models indicated that a moveable storm surge barrier would not be feasible without the construction of offshore detached breakwaters to reduce the wave penetration. Such structures would have affected the delicate morphological balance of the surrounding coasts. However, the application of a more sophisticated wave model showed that the offshore breakwaters are not necessary; an important result giving both environmental and economical advantages.

## 2. Methodology to derive extreme design conditions.

Extreme wave conditions are required for the following purposes:

- design of the moveable storm surge barrier (extreme wave conditions, high water levels only, inside inlets);
- design of the associated fixed structures (extreme wave conditions, all water levels, inside inlets).

In principle there are two fundamental ways to obtain extreme wave and water level conditions. These are illustrated in Fig. 3.

In the first method, illustrated by the clockwise route in Fig.3, the input data is the history of meteorological conditions in the area. These are then statistically extrapolated to get a nominal extreme storm (meteorological condition). Wave and flow models are then applied (modelling phase) to predict the extreme wave and water level conditions at the locations of interest. This method has the following drawbacks:

- It is very difficult to define "extreme meteorological conditions". This can be done in a schematised way by obtaining the extreme wind speed in a number of direction classes and assuming stationary and uniform wind conditions.

- It is unlikely that it will be sufficient to model only one condition, since it is not known which combination of extreme conditions gives the most severe results (e.g. if the meteorological conditions are defined by the extreme wind speed in each direction sector, runs will have to be made for several direction sectors);

- The final results depend on the performance of the models used to predict the extreme wave and water level conditions. The models used must therefore be validated for some real cases.

In the second method, (anti-clockwise route in Fig. 3), the basic data is the same set of meteorological conditions. A series of the most severe events is selected and models are used to hindcast the required parameters at the site of interest. These parameters may then be converted to a damage factor of some kind (e.g. significant wave height) which can be statistically extrapolated to obtain the extreme damage. Alternatively, an analysis can be carried out to obtain the joint extreme statistics of the required parameters. This method has the following drawbacks:

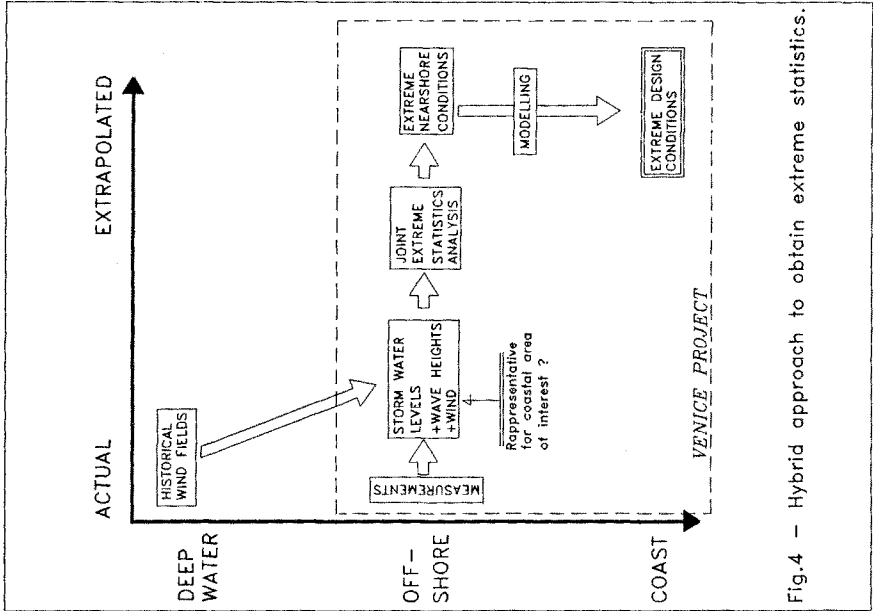

Fig.4 - Hybrid approach to obtain extreme statistics.

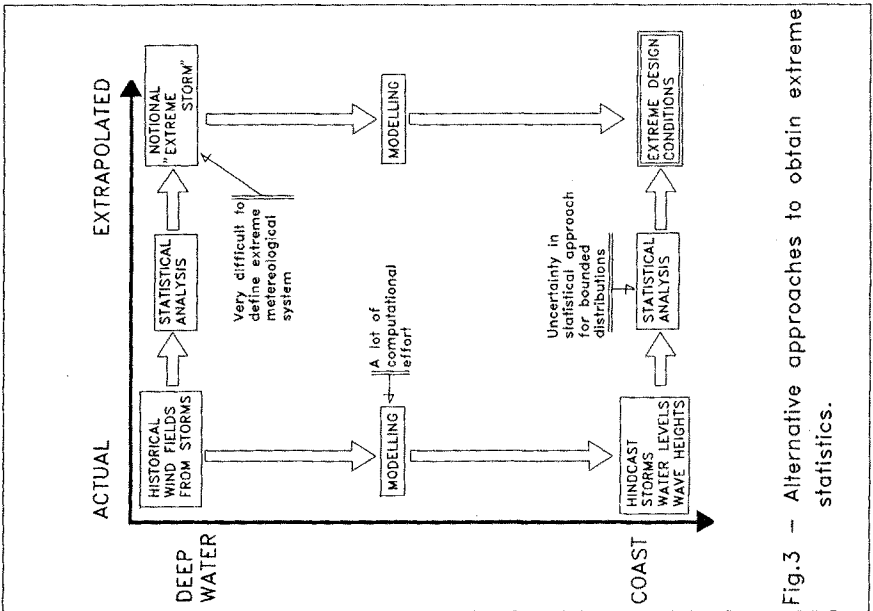

Fig.3 - Alternative approaches to obtain extreme statistics.

- It is difficult to make a restricted and correct selection of the most severe events. For example, if water level and wave height are the parameters of interest, the conditions which give the highest wave height may be very different from those which cause the highest water levels.

- The distribution of parameters at the site of interest is often bounded (e.g. wave height in shallow water). The prediction of the extreme values of such distributions is difficult and often sensitive to errors.

A practical solution to these problems is to use a hybrid approach between the two methods with or without the additional use of measurements of relevant parameters at an intermediate station. Such an approach is illustrated in Fig. 4. In this approach the physical processes are separated into two phases, between which the statistical extrapolation is carried out. The phases are:

- A wave generation phase in which depth limitation plays a minor role but in which the wind field is treated as non-stationary and non-uniform in any modelling. Any modelling is large scale and does not have to include accurate representation of the coastal area. Modelling of water levels and currents in this phase is also on a large scale and applies non-uniform non-stationary wind fields.

- A wave propagation phase in which refraction, shoaling and dissipation by bottom friction and by breaking play an important role. However, the area being modelled is sufficiently small to be able to consider wind fields and incident wave conditions to be stationary.

Real storms are modelled in the first phase, thus avoiding any problems of characterising the non-stationary and non-uniform wind fields. Sometimes, this modelling phase can be omitted when a sufficient period of measured values is available. Otherwise, measurements may be used to calibrate the models. The results of the first phase (wave height, period and direction, water levels and wind speeds and direction) are then statistically analysed to get design values which can be applied as stationary boundary conditions for the modelling of the second phase. The application of this method poses some questions about which combinations of extreme values give the most onerous design conditions at each site of interest. In practice the most onerous design scenario is likely to depend on what is being designed (e.g. breakwater, storm surge barrier, refuge harbour) and where it is located. There is therefore no single combination of the design boundary conditions which can be considered to give the design scenario for all purposes.

In the Venice project three design scenarios were considered according to the wind direction in the Venice gulf (Bora, Levante or Scirocco). Each of them has been characterized only by one wave condition according to the wind direction. For each of these scenarios the design wind and wave conditions were taken to be fully dependent. This restricted the number of design scenarios which had to be considered to three (Bora, Levante, Scirocco). The relationship between the extreme water levels and the extreme wave conditions was derived on the basis of a joint probability analysis carried out only for Scirocco/Levante storms. For Bora storms lower

levels were considered. Of course, some sensitivity studies were carried out to examine the effect of changes in the boundary conditions for the modelling of the second phase.

The activities carried out to derive the extreme wave conditions at the barriers are shown by Fig. 5. The boundary conditions at the outer boundary of the models of the wave behaviour in the inlets for each scenario (significant wave height  $H_B$ , peak period  $T_p$ , diectional spreading, and water level  $h_w$ ) were derived from measurements and wave modelling in the offshore area is described by Hurdle et al. (1993).

### 3. Selection of the wave mathematical models.

There is no mathematical model capable of simulating all the relevant physical phenomena over the entire generation and propagation area. Therefore the governing processes were itemized and the area in which they act determined. The area was then divided into sub-area and numerical models selected for each sub-area to model the relevant phenomena to give the degree of accuracy required for each design phase. Relevant physical phenomena and the area on which they act are shown in Table 1.

Although the Table provides a valuable insight into the relevant phenomena, it should be noted that it is generally not possible to account for the phenomena in isolation because of the way they interact. The selected sub-areas are an offshore (OUT) and coastal area (CST) and the three lagoon inlets and the channels leading to them (INL) as it is shown by Fig. 6. In the offshore and coastal area, the wave propagation is dominated by depth refraction, shoaling and external energy effects. In the inshore areas the wave propagation is dominated by refraction, shoaling and diffraction. For extreme waves, wave breaking is also of some importance in these areas.

Apart from the wave dissipation processes, the most interesting non-linear wave aspects are those which give rise to the generation of free long waves from the short wave field. These long waves will not have a significant effect on the short wave propagation but may be of interest in themselves. For example, they may have an onerous effect on the efficiency of the storm surge barriers or may excite long waves resonances in the inlets. Such non-linear effects could play a role throughout the area between the CNR tower and the coast.

In all areas, a correct representation of the directional spectrum of the wave field is of importance because of the role that this plays in the wave propagation. A correct transfer of information about the directional spectrum on the boundaries between the areas is also very important.

The criteria applied for the selection of the model for the offshore and coastal area were that the directional spectrum should be properly represented and that refraction, shoaling and external energy effects should be modelled. The wave model applied will be called "spectral wave refraction model" (SRM) (see Hurdle et al. 1993).

In the inner area, different models were applied at different design phases. All the applied models accounted for refraction, shoaling and reflection effects while diffraction was accounted for

either approximately or exactly. The models were a refraction-diffraction ray model (RDR), a mild-slope model (MSM) and a Boussinesq model (BM). Table 1 shows also the capability of reproducing the physical phenomena for each numerical model. All of the models are depth integrated and the only non linear model is the Boussinesq model.

Some elucidation of the comments in the table about the limitation of physical models is now given. In general, the porosity and roughness of structures are difficult to reproduce at small scales and surface tension effects, which do not play a role at full scale, become increasingly important for waves of small height and length. This results in reduced energy transmission and increased reflection by porous structures at model scale. Further it is difficult to distinguish long wave resonances which results from the wave basin from those occurring in reality.

#### 4. Wave penetration into the inlets.

The three inlets which connect the North Adriatic sea to the lagoon (Lido, Malamocco and Chioggia, Fig. 2) are protected by breakwaters of length between 1.5 + 2 km. The bottom topography of the inlets is characterised by the presence of navigational channels maintained by the effect of the tidal current and periodic dredging works. As an example Fig. 7 shows the bottom topography of Malamocco inlet. The new storm surge barriers have been located inside the inlets at 1.5 + 2 km far from the breakwater heads so that they are sheltered from wave activity by the breakwaters.

As mentioned in the introduction, a careful evaluation of the extreme wave conditions at the barriers was required even in preliminary design phase. This is because the feasibility of a solution using floating barriers is very sensitive to the wave conditions due to the loads acting on their foundations and decrease in their efficiency for high incident wave conditions and wave overtopping.

As it is shown in Tab.1, almost all of the wave propagation phenomena become relevant close to and inside the inlets. When the waves approach the navigational channel the concave shape of the bottom causes refraction of waves out of the channel and the concentration of wave energy on the shallow areas bounding the channel. This spreading effect (sometimes known as channel refraction), due to the bottom refraction, is balanced by bottom diffraction which tends to increase the wave energy inside the channel. The concentration of wave energy over the shallows is limited by wave breaking. The tidal current, which increases inside the inlets, influence the wave propagation through a refraction effect. The combined action of waves and current interferes with the floating flap gates during the closing operations of the inlets. During surge events the barriers are subjected to both short and long wave actions. Long waves are associated with wave groups and surf-beat along the beaches located outside the inlets and can excite natural modes of oscillation of the floating flap gates.

Due to the complexity of the physical phenomena involved, a preliminary study was carried out in order to analyse the importance of each phenomenon for the wave penetration of the inlets and the capability of the numerical models to reproduce them.

A first analysis was carried out in order to understand the effects and the importance of frequency and directional spreading of the energy spectrum and of non-linear interactions among wave components. With this purpose a Boussinesq model was applied to the Malamocco inlet for three different wave conditions:

Case 1: long crested monochromatic waves;

Case 2: long crested irregular waves;

Case 3: short crested irregular waves.

All of the mentioned cases were run with the same significant wave height  $H_g$  and peak period  $T_p$ . The results obtained showed that the wave penetration inside the inlet increases considerably with the inclusion of energy directional spreading (Case 3). The effect of frequency spreading (Case 2) does not give important differences with respect to monochromatic waves (Case 1).

It is to be noticed that at the time of the work the available Boussinesq models did not include the effect of wave breaking which is still a research subject. Due to the importance of wave breaking for extreme wave conditions inside and around the inlets, it was decided to study whether linear models, for which the inclusion of wave breaking has proved to be successful (De Girolamo et al. 1988), could be applied. A mild-slope model (MSM) was then applied with the inclusion of directional spreading and compared to the Boussinesq model. The results showed that a proper reproduction of directional spreading was enough to guarantee a correct wave field inside the inlets and that the effect of non-linear interference between wave components was of secondary importance for the purposes of the study.

The reproduction of directional spreading in the MSM was obtained by using the superposition principle for a number of wave direction components. Due to the fact that wave breaking introduces a non-linear condition in the model, this was run using an iterative approach. Fig. 8 shows some results obtained for a point located at the site of the storm surge barriers inside the Malamocco inlet. The continuous line shows the obtained amplification coefficients for different offshore directions of incoming unidirectional waves. The spreading effect (channel refraction) due to the concave bathymetry of the inlet increases as the waves approach the navigation channel with a direction close to the inlet axis. This effect causes a strong reduction of wave height at the barriers. The effect of including directional spreading is clearly shown in the Figure by the square points and is stronger for the waves coming along the channel axis for which the wave height can increase by up to three times.

Some applications for the Chioggia inlet including wave breaking using the Batjjes and Janssen (1978) formulation are presented in De Girolamo et al. (1988). Fig. 9 shows an example of the verification of the computation of the wave penetration of the Malamocco inlet during ebb and flood tidal conditions. In this case the model was run simulating current refraction effects (Kostense et al. 1988).

Fig.8 - Influence of directional spreading on wave penetration of the Malamocco inlet (MSM model).

Fig.9 - Comparison between wave measurements and numerical simulations obtained with the mild-slope model (MSM).

The preliminary design required the study and the comparison of a number of different layouts for each inlet. For this reason it was important to distinguish a simple numerical model which could be used, as an alternative to the MSM, as a practical tool for such a work.

A very efficient and simple tool was found in a refraction-diffraction ray model (RDR see Tab.1 - Southgate 1985). The model simulates the diffraction effects around obstacles using an analytical approach but neglects bottom diffraction. Further it can be easily run with directional spreading. Even if the model cannot be used in some situations for a correct quantitative analysis (De Girolamo et al. 1989) it can give insight into the wave paths and can be used to compare different layouts. The most important limitation of the model is the neglect of bottom diffraction which in presence of an undersea channel plays an important role in containing the energy spread due to the refraction effects.

Summing up the numerical work was split into two phases using the more suitable model for each of them.

In the first phase the existing situation (before the construction of the new structures) was analysed and various alternative layouts were studied. The simple RDR model was used in order to carry out the large number of required simulations.

For the second phase the more complex models (MSM and BM) were used in order to study the selected layouts for each inlet. The large extent of the inlet areas required up to 150.000 computational grid points for the MSM model. The most important result obtained with the MSM was to show that the construction of new offshore detached breakwaters was not necessary.

For the final design of the structures, physical models in wave basin, reproducing the real topography of the inlets, have been used. The work, which is still being carried out, requires a scale ratio ranging from 1:60 to 1:80 in order to minimize the limitations mentioned at Paragraph 6 for physical models. The maximum modelled area is 11.000 m<sup>2</sup>. The models will be used in order to reproduce the effective hydrodynamics of the area including the interference by waves and tidal currents with the floating flap gates, already tested in a three dimensional basin (Varisco 1992) using a constant water depth. The translation waves caused by the closure of the floating flap gates during surge events will also be investigated. Due to the large extent of the modelled area, directional wave spectra will be not reproduced. Consequently the results obtained using uni-directional waves will be analysed and interpreted with the support of the results for short crested waves obtained using numerical models.

##### 5. Concluding remarks.

The definition of design waves for the Venice project was not straightforward. Diverse models (numerical and physical) have been used to derive the design waves. Simple models were valuable in the feasibility phase and sophisticated models in later phases.

Because of the diverse limitations of both physical and numerical models it was necessary to distinguish three distinct areas where different physical phenomena are dominant: the outer area, the coastal area and the area in and around the inlets.

In the inlet areas directional spreading has an important influence on the wave penetration of the inlets while frequency spreading is less important.

The ebb tidal current, with the barriers open, increases the wave height for normal conditions while the height of extreme waves is limited by wave breaking.

Refraction of uni-directional waves propagating parallel to the access channels leading to the inlets gives a strong reduction in the wave height. The effect of bottom diffraction and directional spreading reduce this effect. The mentioned effects and wave dissipation by breaking limit energy concentration inside the inlets which can take place for other incoming wave directions.

In spite of the very large width of the inlet entrances (ranging from 460 m to 900 m) the significant wave height,  $H_g$ , in front of the barriers does not exceed 3+3.7 m for the 1000 year return period. The three dimensional wave basin simulations showed a satisfactory behaviour of the floating flap gates under these wave conditions.

#### Acknowledgements.

The studies presented in this paper were carried out for Consorzio Venezia Nuova under the coordination of Technital. Consorzio Venezia Nuova is concessionary for the studies and works related to the Venice protection project on behalf of the competent Italian state authority Magistrato alle Acque.

The numerical studies were carried out by Danish Hydraulic Institute, Delft Hydraulics, HR Wallingford and TEI; the physical models by Protecno and field measurements by Ecomar.

The authors are grateful to CNR and ENEL for the supply of wave data measured in the Venice gulf.

#### 1. INTRODUCTION

Long-term coastal processes [9, 10] usually consist in slight net morphological changes that result from large positive and negative oscillations occurring to a much shorter time-scale. As soon as one is not interested in these short-term variations, one may perform a preliminary time averaging of the basic waterflow and sediment transport equations in order to obtain a much simpler and manageable model for long-term simulations [6].

Long-term mathematical models, in fact, not only require much less computer time, but can run without knowing the detailed time - history of all the boundary conditions (which on the contrary is absolutely needed by short-term mathematical models).

Averaging of non-linear equations, on the other hand, produce residual terms that either may be neglected or should be expressed, in some convenient way, as a function of the averaged quantities. The procedure, indeed, is analogous to the averaging of the Navier-Stokes equations in order to eliminate turbulence pulsations, where the Reynolds stresses should be conveniently expressed in terms of averaged velocity.

In the case of long-term morphological models of tidal lagoons, semi-empirical expressions of the residual terms can be found. The relative calibration coefficients may be then identified by comparison with field data and/or with a limited number of simulations carried out on short-term models.

In some previous papers, long-term morphological models of a tidal lagoon have been developed with different space-resolution (zero-dimensional [4] and two-dimensional [5] approach) by considering only one equivalent (uniform) sediment grainsize. The zero-dimensional procedure, in particular, has been applied to the Lagoon of Venice [8].

In the present paper the two-dimensional model is re-considered and extended to the case of particles with different grainsize, ranging from sand to silt.

#### 2. TWO DIMENSIONAL LONG-TERM MODEL

The  $n$  two-dimensional balance equations for the sediments belonging to the  $i$ -th grainsize class ( $i = 1, 2, \dots, n$ ) are written as:

$$\frac{\partial T_{x_i}}{\partial x} + \frac{\partial T_{y_i}}{\partial y} = E_i \quad (1)$$

where  $T_{x_i}$  and  $T_{y_i}$  are the long-term sediment transport (averaged over a long period of time) in the direction  $x$  and  $y$  respectively and  $E_i$  is the long-term rate of removal from the lagoonal surface.

The following expression for the "net" sediment transport are obtained by integrating the suspended transport equations over a long period of time:

$$T_{x_i} = h \left( C_i U - D_x \frac{\partial C_i}{\partial x} \right) \quad (2)$$

$$T_{y_i} = h \left( C_i V - D_y \frac{\partial C_i}{\partial y} \right) \quad (3)$$

where  $h$  is the average water depth and  $C_i$  the average sediment concentration of the  $i$ -th class over the water column. The components of the residual currents,  $U$  and  $V$ , are mainly due to the inland water input but also to the (eulerian) net circulation produced by the asymmetry of tidal flow. Even with a symmetrical tidal flow, however, a large amount of net transport is due to the intertidal dispersion produced by the irregular morphology of the lagoon; dispersion coefficients  $D_x$  and  $D_y$  result in fact being quite large (hundreds of  $m^2/s$ ), as recently confirmed by experiments in the lagoon of Venice [7]. The quantities  $U$ ,  $V$ ,  $D_x$  and  $D_y$  may be provided by a tidal model.

The long-term evolution of the water depth,  $h$ , is given by adding up the bottom erosion rate  $\Sigma E_i$  (removal of all the grainsize classes), the eustatism rate  $\alpha_c$  (rise of mean sea level) and the subsidence rate  $\alpha_s$  (settlement of ground surface):

$$\frac{dh}{dt} = \Sigma E_i + \alpha_c + \alpha_s \quad (4)$$

A first-order reaction equation is assumed for the bottom erosion rate:

$$E_i = w_i (\beta_i C_{ji} - C_i) \quad (5)$$

where  $C_{ji}$  is the equilibrium concentration of the  $i$ -th grainsize class,  $\beta_i$  is the percentage of the same class present in the bottom and  $w_i$  a parameter that, for fine particles, coincides with the fall velocity of the particle with a diameter  $d_i$ . Eq. (5) shows that the equilibrium concentration of the  $i$ -th class in a certain place is the average sediment concentration over the water column which would yield neither erosion or deposition, should the bottom be composed by that grainsize ( $\beta_i = 1$ ). Equilibrium concentration  $C_{ji}$  depends on the grainsize diameter  $d_i$ , on the local hydrodynamics (waves and currents) and on the local depth, as it will be discussed in the subsequent section.

The mathematical model should also include the balance equation of the  $i$ -th class in the bottom:

$$\frac{d(\beta_i \delta)}{dt} = - E_i + \beta_i^* \Sigma E_i \quad (6)$$

where  $\delta$  is the thickness of the "mixing layer" (i.e. the amplitude of the bottom variation during the annual cycle) and

$\beta_1^*$  is the grainsize percentage in the mixing layer (if  $E_1 < 0$ ) or below it (if  $E_1 > 0$ ).

The numerical integration of eqs. (1) to (6) provide the evolution of water depth, sediment transport and grainsize composition all over the lagoon, provided that initial and boundary conditions are duly prescribed.

### 3. EQUILIBRIUM CONCENTRATION

The expressions of the equilibrium concentration,  $C_{ij}$ , constitute the crucial link coupling hydrodynamics, sediment transport and morphology of a lagoon. These expressions are obtained by integrating over a long period of time (say, one year) any transport formula of sediments by currents and waves. By assuming a plausible statistical distribution for wave climate and tidal flow and by treating residual terms with necessary simplifications, one comes to a formulation of this type:

$$C_{ij} = C_{ji}(W, Q, d_i, h) \quad (7)$$

which is in principle different for channels ( $C_{ij} \equiv C_{ci}$ ), shoals ( $C_{ij} \equiv C_{si}$ ), and tidal flats ( $C_{ij} \equiv C_{fi}$ ), where  $w$  and  $Q$ , respectively, are quantities related to the local wave climate and tidal flow; coefficients in eq. 7 are to be determined via calibration against morphological and sedimentological data.

An approximate form of eq. (7) is a simple monomial expression; however, if one considers a threshold-value for the waves and currents capable of picking-up the sediment from the bottom (incipient motion), one comes to more complicated expressions that can explain various interesting features of the lagoon's morphology and sedimentology.

### 4. CONCLUSIONS.

Grainsize distribution in estuaries and tidal lagoons is generally far from being uniform. In the Lagoon of Venice, for

example, a systematic survey [1, 2, 3] shows that sediments tend to be sandy near the inlet sand to decrease towards the periphery, especially in the northern-eastern part, where silt and clay definitely prevail (Fig. 1). Another distinction, although less clear, exists between a channel and the adjacent shoals where sediments are generally finer.

In a lagoon with negligible sediment input by rivers and moderate eustatism and soil subsidence, this typical pattern is essentially due to the "threshold effect" of the pick-up function by currents and waves. Indeed, as the net transport through the lagoon should be practically zero, the average concentration of each grainsize class in the water column should be almost the same all over the lagoon. Consequently, shoals that are less subject to wave action result to have a smaller depth and a finer bottom composition; in this way all the particles here are put in suspension less frequently but with a higher concentration with respect to the particles in more exposed shoals.

In general, however, grainsize distribution is also controlled by the sediment net fluxes towards the sea (by river input) or towards the periphery (by eustatism and soil subsidence), as well as by any long-term evolutionary process. The relative importance of the various mechanisms in the transport of non-uniform grainsize particles in estuaries and tidal lagoons can be assessed and discussed by the mathematical model described above.

## CHAPTER 143

### Mixing processes in a shallow lagoon

J. IMBERGER\* and G. DI SILVIO\*\*

\*Centre of Water Research, University of Western Australia

\*\*Istituto di Idraulica, Università di Padova, Italy

#### Introduction

Lagoons are enclosed water basins at the boundary between the land and the ocean; they usually have one or a number of streams entering around the perimeter and are open to the ocean at one or a number of entrances. Lagoons are shallow and the motion of water within them is governed by a delicate balance between tidal forces, wind stresses, bottom friction and density induced pressure forces. In general, ocean water enters a lagoon via deeper channels whereas the river inputs enter through alluvial fans. The freshwater, being lighter, overflows the lagoon waters whereas the entering ocean water, being heavier, underflows. This leads to a strong vertical stratification in the main channels and a general horizontal stratification in the shallows. Much work has been done on estimating the net horizontal mixing in large water bodies and, in general, it is assumed that the water column is fully turbulent and the horizontal scales of motion range from the size of the lagoon to millimetres and vertical scales from the depth to millimetres. Under such conditions it is assumed that there is a cascade of energy similar to normal turbulent shear flow (Tennekes and Lumley, 1972). For water bodies which have dimensions in the tens of kilometres, it is found both by fitting the results from numerical models (Di Silvio and Fiorillo, 1981) and from large scale field comparisons (Dronkers *et al.* 1981) that a horizontal diffusion coefficient of the order of 50 to 500 m<sup>2</sup> s<sup>-1</sup> is applicable.

This logic, however, ignores two major recent findings. First, in shallow waters, Wolanski *et al.* (1984) have found that the bottom friction is usually sufficient to overcome the horizontal inertial forces so that the *effective* Reynolds number of the flow can be as low as 30 or 40. Numerous cases have now been documented where the wake behind islands, flows over undulating topography or past headlands. All appear to shed eddy structures which are reminiscent of slow viscous flow rather than of an inertial turbulent regime. Second, with recent remote sensing techniques and fast fine-scale sampling (Luketina and Imberger, 1987) it has been revealed that lagoons and coastal waters are partitioned by a complicated network of fronts. These fronts form a mosaic of lenticular structures which move under the influence of the tide, the wind field and baroclinic forces. The role of the fronts is to enhance mixing at small scales through shear flow dispersion, but they appear to inhibit the natural cascade of energy from the larger scales through the intermediate scales to the smaller scales of the horizontal eddy structures. Thus both bottom friction and the presence of fronts prevents an energy cascade and the development of a full turbulent velocity spectrum. It therefore remains to be explained why the net horizontal eddy diffusion coefficients in shallow lagoons are comparable to the open ocean values summarised by Okubo (1974).

#### Field Campaign

Two field campaigns (respectively commencing 11th June 1990 and 2nd March 1991) were carried out in the Lagoon of Venice, involving detailed fine-scale temperature and conductivity measurement surveys. The aim of these experiments was to assess the role and influence of the buoyancy introduced around the perimeter, by freshwater inputs, on the dispersion in the lagoonal waters. A portable fine-scale profiler was used both in a vertical profiling mode and in horizontal tow mode. The fine-scale profiler was equipped with SeaBird conductivity and temperature sensors and a Digiquarts pressure transducer (Fozdar *et al.* 1985). The resolution of these sensors was 10<sup>-4</sup> Sm<sup>-1</sup>, 10<sup>-3</sup> °C, and 10<sup>-3</sup> m respectively. In addition to these fine-scale measurements, in the winter experiment some temperature and conductivity microstructure was also gathered in order to estimate the turbulent kinetic energy dissipation (Imberger and Ivey, 1991). During both experiments velocity estimates were obtained using bucket drogues, drogued to different depths.

During the summer experiment, most of the data collection was in the area influenced by the Dese River (Figure 1). By comparison, the winter experiment concentrated on the Venice Lagoon as a whole in order to obtain a broader overview (Imberger, 1991).

The investigations showed the following major features:

- (a) The tidal flow in the canal system is a mixture of barotropic and baroclinic flows; the degree of baroclinicity being dependent on the phase of the tide and on the salinity difference within the canals and was strongest in the areas which had direct freshwater input. However, the measurements show that sufficient salinity differences existed almost everywhere for baroclinicity to be important.
- (b) The water masses on the shoals appeared to be formed in an orderly explicable way. As the water rose in the channels and reached a point where the water breached the shoals, the salinity of the inflowing water was completely determined by the surface salinity at the point of breach in the tidal channel. A shoal may thus be envisaged as a region of land with a perimeter where water of increasing salinities is ejected on the rising tide. It appeared that these injections formed well-defined lenticular structures which were separated by stable fronts, leading to a patchwork of water masses over the shoal at high tide which retained their identity throughout the tidal cycle but which were moved by the tidal motion and the surface wind stresses. These lenticular structures, observed throughout the whole lagoon, originate from buoyant jets at the river mouths and move over the shoals and along the channels with little tendency to decay. The shallowness of the water of the shoals led to a pseudo potential flow.

### Large Scale Flushing

In Figure 1 we show a typical set of salinity isohalines contoured over the whole Venice Lagoon. The data shown is depth averaged salinity and clearly shows that there was a major freshwater inflow into the Venice Lagoon in the northern and southern regions, but that the lagoon as a whole had a horizontal gradient of salinity from the perimeter to the three entrances. A bulk estimate of the horizontal diffusion coefficient may be obtained by equating the flushing time  $V_f/Q_f$  to an average horizontal mixing time  $L^2/\epsilon_x$ , where  $Q_f$  is the total freshwater input into the lagoon,  $V_f$  is the total volume of freshwater in the lagoon,  $L$  is a typical horizontal length scale of the lagoon and  $\epsilon_x$  is an average horizontal diffusion coefficient. There are numerous other ways of estimating an average diffusion coefficient and we have calculated the estimate  $\epsilon_x$  by a number of different techniques. Using the data collected in the campaign, the various methods gave a typical flushing time of approximately three tidal cycles and a horizontal diffusion coefficient ranging from 100 to 400  $m^2 s^{-1}$ . These values were compared against more detailed estimates obtained in two canals by fitting a horizontal advection diffusion model to the documented inter-tidal gradient of salinity. This techniques yielded estimates in the same range.

In summary, therefore, the fine-scale measurements in the Venice Lagoon yielded global dispersion coefficients averaged over many days (averaged over tidal and wind motions) of the same magnitude as found in open deep water.

### Lenticular Structures

The mechanisms by which freshwater entered a particular shoal was investigated in considerable detail during the winter experiment. In Figure 2, we show a typical salinity plot at the commencement of the falling tide and it is clearly seen that the freshwater outflow produced a plume of fresher water extending a distance of 2 or 3 km from the mouth and being swept alongshore by the prevailing tidal current. A similar exercise was conducted in the central part of the lagoon (Figure 3) which shows that even in the middle of the lagoon, far removed from the direct influences of the fresh river inputs, lenticular structures with horizontal length scales of the order of 1 to 2 km could be clearly identified. As seen from Figure 3, the salinity differences associated with the lenticular structures, even in the central part of the lagoon, are comparable to those found at the perimeter near the entrance inflowing river plumes (Figure 2). Lastly a series of drogues released in this latter study area showed that even over a period of three to four hours, drogues placed in close proximity remained together. Thus, the horizontal dispersion was always minimal until some drogues pass from channel to shoal or viceversa. Only at this point did the drogues in the shoal lag behind those in the channel. The same is true for lenticular structures that are moved around the lagoon by the tidal motion and the wind induced stresses. These lenticular structures thus only mix across fronts and by vertical entrainment over channels. No evidence was found of large scale eddy type structures.

### Conclusions

These and other findings lead to the conclusion that mixing in the lagoon operates at different scales:

(i) Large structures, with scales determined by the morphology and of under  $10^4 - 10^3 m$  are responsible for the global

horizontal dispersion; they control the flushing of the lagoon as well as the distribution and the shape changes of the lenticular structures, but not the mixing.

(ii) Intermediate and small scale turbulence of the order of 10 metres and less control the mixing over the depth and the weak horizontal dispersion during the tidal cycle. This is responsible for the slow annihilation of the lenticular structures.

## CHAPTER 144

### WATER FLOW MODELLING OF THE VENICE LAGOON

Enrico Marchi <sup>(1)</sup>  
Attilio Adami <sup>(2)</sup>  
Alfredo Caielli <sup>(3)</sup>  
Giovanni Cecconi <sup>(4)</sup>

#### Abstract

The paper describes the relevant set of analogical, mathematical and physical models used to simulate the hydrodynamics phenomena of the Venice lagoon. The various models are divided in two classes, depending on the scale: the great scale models, to examine the problems interesting the entire lagoon, and the little scale models for the problems localized near the inlets, where the barrages will be built to control the lagoon water level.

#### 1 - Foreword

In 1984 the Italian Government commissioned the "Consorzio Venezia Nuova" to undertake what had been called the "Venice Project"; this project comprised a number of works necessary for the safeguarding of the city of Venice and its lagoon. Amongst these, by far the most expensive and technically difficult task was the project for the deployment of flapgates across the three lagoon entrances for the control of high tides within the lagoon.

It was evident straight from the start of works that such a large and complex project would have to be supported by a series of model tests in order to investigate the various project hypotheses.

It was also evident that one model only would not have been enough, and that due to the many different problems studied, the project would have to avail itself of investigative means that were in keeping with the different aspects to research.

For the purpose of the research, the project-related phenomena were classified in two categories: the large scale phenomena, which concern the general behaviour of the

lagoon, and the small scale phenomena, which concern the phenomena in the immediate vicinity of the flapgates.

When the New Venice Consortium became operational in 1987 the following models of the Venice lagoon already existed, so they were also adopted for the new activities: the general physical model of the lagoon, the specific physical model of the Lido entrance and the unidimensional mathematical model of the entire lagoon itself.

Alongside these models a new set of models were prepared, a description of which follows hereafter.

## 2-1 Large Scale Models

### 2,A - General Model of the Lagoon

The model (refer to Fig. 1) reproduces the entire lagoon to a planimetric scale of 1:250 and an altimetric scale of 1:20. The area occupied by the model is approximately 12,000 sq.m. Its distortion ratio of 12.5, which is typical for maritime models — in this case with a morphology consisting of canals and shoals — creates problems with regard to the roughness of the walls, which generally appear too smooth. The model is equipped with a tide generator for each of the three entrances; the three generators operate automatically and are controlled by a computer.

Due to the size of the model and the encumbrance of test handling, typical of physical models, the general model was not widely used in the engineering work concerning the lagoon entrance flapgates; thus it was often replaced by the mathematical models discussed hereafter. Nonetheless, it is the best means of investigating the phenomena that take place in the innermost parts of the lagoon where continuous contouring is a fundamental characteristic. Refer to [1] for a more detailed description of the possible uses of the model.

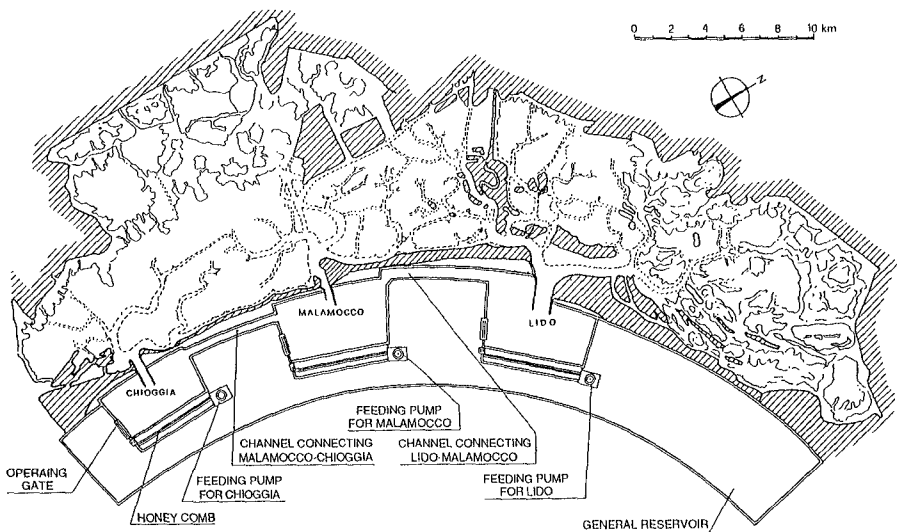

Fig. 1 - General plants of the model of the entire lagoon of Venice.

## 2,B - Mathematical Models

From a historical point of view the first mathematical model of the lagoon that was ever made is the one that mapped the lagoon with its network of interconnected canals alongside which are the shallow areas whose main function is that of providing storage capacity. This lay-out features the great advantage of simplicity and a reduced number of unknown quantities (unlike other lay-outs); but it requires an in-depth knowledge of the actual phenomena to be able to trace an illustrative network of canals and therefore work out the shallow water basin on both sides of each canal. Today this 1D model is still employed in a recent version (i.e. the fourth generation) whose network is shown in Fig. 2.

More recently, a 2D model has been developed using the finite element technique whose mesh is shown in Fig. 3, and another 2D finite difference model whose mesh is shown in Fig. 4, which also shows a stretch of sea opposite the entrances. This model blocks out the lagoon with a mesh having a 300 m pitch, and has the advantage of being able to zoom in on areas of limited surface area by reducing the spatial grid to 50 m.

Table 1 compares the characteristics of the three adopted models.

At present, in the engineering work, all three models are used depending on their different characteristics and on the phenomenon that is to be investigated. In fact, the finite difference model has proved to be the best in representing lagoon hydrodynamics in the areas closer to the entrances by depicting both the adjoining stretch of sea and the somewhat flat bathymetry of the area (with very wide canals and deeper shoals). The finite element models have instead proved to be very versatile in reproducing phenomena in the intermediate area of the lagoon where canals and shoals are clearly

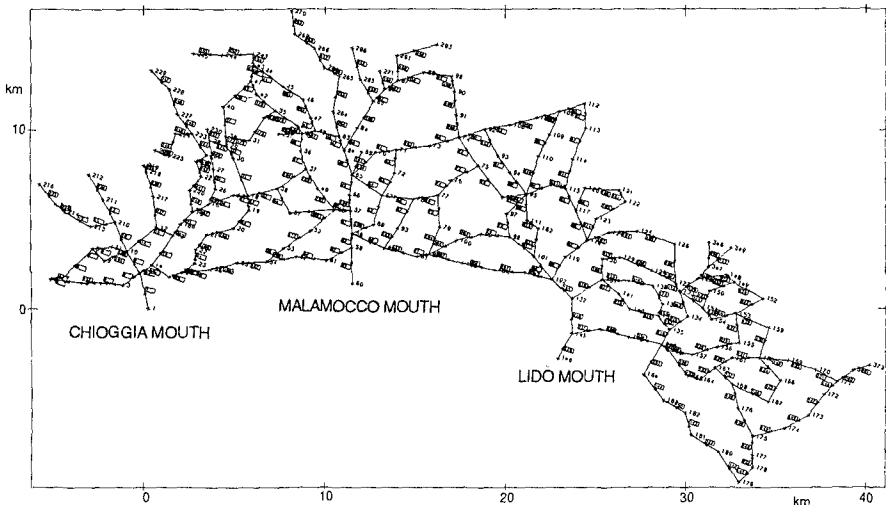

Fig. 2 - The channel net of the 1 D, mathematical model.

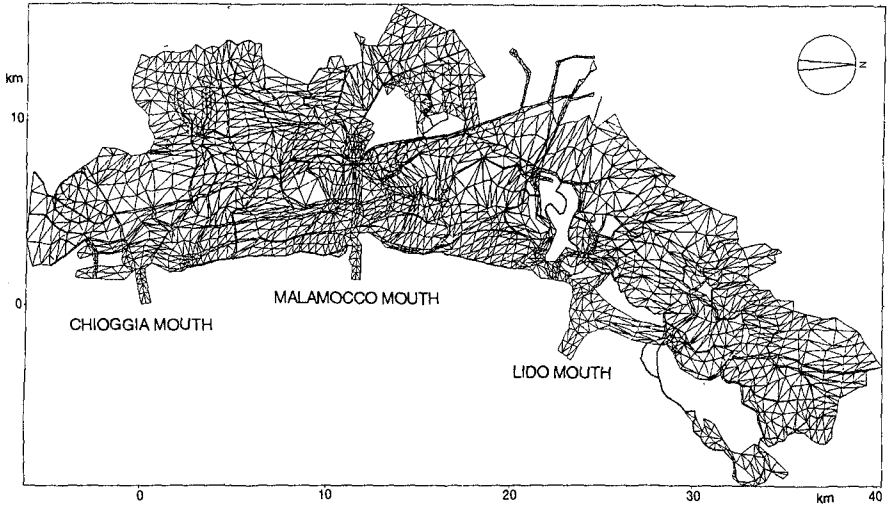

Fig. 3 - The mesh of the 2 D, finite elements mathematical model.

Table 1

	1 dimension	2 dimension Finite elements	2 dimensions Finite difference
Type of mesh and number of elements	323 multiconnected branches	2580 vertices and 4528 triangular elements	Square grid with 13,851 vertices
Dimension of elements	1000 - 2000 m	Distance between two vertices 100 - 1000 m	Squares 300 x 300 m
Average number of elements for km <sup>2</sup> of lagoon	0.9	7	11
Roughness coefficient	Chezy C=50m <sup>1/2</sup> /s	Strickler k=30,25,20 m <sup>1/3</sup> /s in channel and shallows	Strickler k=28 m <sup>1/3</sup> /s
Time step	600 s	300 s	90 s
Resolution method	Implicit with iterations	Two level time scheme, semi-implicit	Algorithm of alternate direction, implicit
Time to simulate 24 h of tide with a VAX 8600	6 minutes	60 minutes	75 minutes

distinguishable. Finally, the unidimensional model is still considered the best for the reproduction of phenomena in the innermost area of the lagoon where the tidal flow takes place nearly exclusively along the narrow submerged canals — a phenomenon that is hardly reproducible in the other lay-outs. A factor in favour of the unidimensional model is the calculation time which is nearly one order of magnitude less than that required for the other two models.

More detailed information about these models and the algorithms used can be found in [4].

### 3 - Small Scale Models

This name has been attributed to those models detailing the port entrances; they have allowed the study of localised phenomena that take place in the vicinity of the new barrage structures. The models that were used are described below.

#### 3,A - Aerodynamic Models

These types of models are not widely used in current techniques; but in this case they were found to be a very effective means of research. Obviously, in aerodynamic

models the water flow is replaced by an air flow and the flow must take place in a confined field. For this reason the free surface of the water is replaced by a solid plate which acts as a covering lid for the model. The result is a double approximation of a top contour of the flow with a horizontal plain and a zero speed. At any rate, in this case the differences in level between the sea and the inside of an entrance are maximum 20/30 cm over a depth that may vary from 8 to 15 metres; this means a percentage level variation of less than 10%; consequently, the above mentioned approximations appear acceptable, especially if one researches data not in the absolute sense but merely as a parametric value, i.e. to highlight what happens in the presence or absence of a certain modification to the flow contours. A critical appraisal about these types of models can be found in [2].

The scales used in the models have been 1:3000 in planimetry and 1:1000 in altimetry; the models reproduced (refer to Fig. 5) the inlet, the initial tract of the lagoon canals that stem from the entrance, and a sufficient stretch of open sea. A further simplification was introduced in these models; this consisted in the fact that, unlike the real case, the flow was permanent. Given the extent of complexity to correctly reproduce the periodical variations of current, a decision was taken to represent in the model a certain configuration of the flow, usually the one at peak flow rate, and to maintain it steady throughout the time needed to take the measurements. The model boundary conditions, i.e. the flow rate at the entrance and in the adjacent canals, were provided by the mathematical models.

It is understood that by reproducing a stationary flow the model does not reproduce the forces linked to temporal accelerations, but this is acceptable if one bears in mind that under maximum speed conditions these forces are practically null.

The information elicited from these models concerned the course of the water levels by drawing up an analogy between Euler's number of the model and Froude's number of the real flow, velocity distribution, paying special regard to the areas of current separations and to wakes. The great advantage of these models is the rapid and economical reproduction and study of the inlet flapgates layout, immediately indicating their major defects.

Fig. 5 - The general scheme of the aerodynamical model of the Malamocco mouth.

### 3,B - The Mathematical Models of the Mouths

These derive from the finite difference bidimensional model of the lagoon, already mentioned previously, where it was possible to perform close-ups reducing the mesh size to only 50 m. For the "mouths" (refer to Fig. 6) a rotation of the mesh was performed which was different for each entrance, so that one direction of the two axes would coincide with that of the breakwaters that project into each entrance — this was done to reproduce the contours of tidal flow in the best possible way.

Of course the boundary conditions were provided by the general mathematical model of the lagoon; thus flood and ebb tides were correctly represented.

Fig. 6 - A typical flow field of the 2 D mathematical model of the Lido mouth with a 50 m space grid.

### 3,C - Detailed Physical Models

As already stated, the first detailed model of Lido mouth had been constructed far back in 1972 for a number of studies that were then being conducted on the hydrodynamics of that entrance. The model was made to a scale of 1:60, undistorted. This model, like the aerodynamic ones previously mentioned, is not equipped with a tide generator, so it was used for permanent tide flow by reproducing a certain tide flow condition and keeping it steady throughout the whole test.

Thanks to the experience gained with that model, the New Venice Consortium built similar models on the same scale for the other two lagoon mouths, Chioggia and Malamocco. The three models have a fixed bottom, but the facility to reproduce a movable bottom in limited areas is featured, and this is where the flapgates will be deployed. These models can accommodate a wave generator as wide as 20 m which enables hydrodynamic studies to be combined together with those about the penetration of wave motion from the sea into the entrances. Fig. 7 shows a planimetry of the Chioggia mouth model, in which one may notice the large area of sea reproduced; this allows the simulation of heavy seas heading from the principal sectors of the prevailing winds. The other two models are absolutely similar.

Fig. 7 -The map of the particular model of Chioggia mouth in scale 1:60.

The three models have been constructed at the Experimental Centre of Voltabarozzo in Padua, adjoining the shed that houses the physical model of the entire lagoon. The shed also houses the aerodynamic models, so that all the physical models in question have been concentrated in the same location for practical purposes. Fig. 8 shows an aerial photograph of the centre at Voltabarozzo which illustrates the various locations of the models.

Fig. 8 - Aerial view of the Voltabarozzo Center with the models of the three mouths.

#### 4 - Use of the Models

In the research work about the inlet flapgates, Project REA (environmental recovery) [3] the following procedure was adopted:-

- Literally starting off at the drawing board, the engineers designed all the planimetric configurations of the flapgates that were deemed feasible: eventually six possible lay-outs were produced for Lido mouth, seven for Chioggia mouth and as many as twelve different lay-outs for Malamocco mouth.

- All of these feasible solutions were reproduced and studied on the aerodynamic models, out of which were rejected those that caused an excessive current contraction, which meant speeds unacceptable for navigation and large areas of separation and vorticity.

- The solutions that passed the first test were studied on the mathematical models of the entrances in order to have more detailed information about the distribution of speeds, with special emphasis laid upon its transversal components which are the most hazardous for navigation.

- The information elicited from these models also allowed the correct reproduction of these lay-outs on the general mathematical models so that the large scale effects following their construction could be assessed.

- Finally, the solution that was judged to be the best for each mouth is currently undergoing study on the detailed physical models to allow a more in-depth study and to proceed with optimisation of the configuration of the flapgates.

## 5 - Conclusions

To proceed with the design of the "mouth" flapgates for the control of the high tides in the Venetian lagoon, the New Venice Consortium has constructed a set of physical, analogic and mathematical models for the reproduction of lagoon hydrodynamics, discriminating between models for large scale phenomena and models for small scale phenomena.

For the study of large scale phenomena three mathematical models of the entire lagoon, having different characteristics, were used; for the small scale phenomena, i.e. for those localised in the lagoon entrances, an extra small scale aerodynamic model, a mathematical model and an undistorted physical model were used.

These models are used in sequence with different retroactions, in the sense that the mathematical models of the lagoon create the boundary conditions of the aerodynamic models and undistorted physical models; these produce information that allows to improve the performance of detailed mathematical models of the inlets and of the general mathematical models of the lagoon. To sum up, the end result has been a complex hybrid system of models that together enact maximum verisimilitude of incoming results.

## CHAPTER 145

### HYDRAULIC AND MATHEMATICAL MODELLING OF HISTORICAL AND MODERN SEAWALLS FOR THE DEFENCE OF VENICE LAGOON

Leopoldo Franco<sup>1</sup> and Giuseppe R. Tomasicchio<sup>2</sup>

#### Abstract

This paper gives an overview of the development of design and construction of coastal defence works in Venice. In fact shore protection is one of the tasks of the present large project for the safeguard of Venice lagoon. A brief description is given of the most interesting steps of the new design supported by extensive field measurements and interactive model testing. An introductory review of the old historical structures for the defence of the lidos (in part still existing) is also given to underline the important links with the past experience and the unusual constraints of the present designs.

#### Introduction

The lagoon of Venice is connected to the Adriatic Sea by three tidal inlets (the port entrances of Lido, Malamocco and Chioggia) which divide a system of barrier islands and sand beaches (Fig.1). These thin strips of land, named "lidi", extend for some 40 km and have long since been representing vital natural barriers to defend the physical integrity of the lagoon and even the military safety of Venice. Therefore, the protection of the littorals has always been a fundamental issue for Venetian Authorities and has been dealt with by a special Water Committee (Magistrato alle Acque) managed since 1501 by elected hydraulic experts. Despite their efforts, progressive shore erosion has been taking place after the diversion of the river mouths to avoid the lagoon siltation and after construction of the inlet jetties to ease navigation.

### Historical evolution of sea defence works in Venice

Interesting information on historical sea defences in Venice can be found in a nice book by Grillo (1989). Written reports of local shore protection works date back as early as 537 a.C., when wicker faggots were used to hold the earth dykes reinforcing the sandy dunes formed from river supply, wind and wave action.

Strict environmental regulations were issued since the 13th century to preserve the littoral defences, such as prohibiting the transit of cattle upon the dykes, the removal of sand or vegetation and the export of materials useful for shore protection. These were mainly timber and rock, often combined in a sort of cribwork.

The typical seawall in the 17th century was made by rows of longitudinal fences of timber piles half embedded along the dyke outer slope and at the toe which contained a few layers of stones (as shown in fig.2 in the drawing of 1692 by M.Alberti in comparison with the Dutch standards). The timber piles however had only few years lifetime and excessive maintenance work was needed.

Therefore the Authorities, around 1700, sought for innovative designs: various technical solutions were experimented at the own risk of consultants and contractors (who might get paid only after the proved effectiveness of the work!). Coastal protection works included either seawalls and revetments (made with riprap, gabions, smooth marble blocks linked with mortar and steel, flexible steel strips, regularly placed stepped limestone blocks and various elements to increase the slope roughness) or groynes (made with timber and steel piles, often filled with rock).

Finally around 1740 a durable monolithic seawall structure was proposed by the mathematician B. Zandrini which worked successfully until today (Fig.3): the so called "murazzi" are composed by a smooth white flagstone revetment supported at toe and crest by massive walls. The innovative technology was in fact represented by the effective block bonding with "pozzolana" mortar (a lavatic powder hardening in water, shipped from Naples). The "murazzi" have been maintained and repaired in the last 250 years: the existing structure was reinforced in the middle of past century with a toe rock revetment and recently even with diaphragms and anchor piles (Fig. 4).

Rock groynes have also been built along the beaches of Lido, Cavallino and Pellestrina even in front of the "murazzi". The construction of the inlet jetties (Malamocco 1856, Lido 1887 and Chioggia 1914) and the dredging of navigation channels changed the sediment transport conditions along the littoral. Sand has been trapped by the long end jetties with accretion taking place in the lee areas (especially against the jetties at north Lido and south Chioggia), whereas strong erosion kept occurring in central Lido and Pellestrina beaches. Shoreline retreat has been enhanced in the last 40 years due to sea level rise (mainly because of subsidence) and to the reduction of river sediment supply, partly lost offshore during ebb tidal flows.

Fig.3 The original "murazzi" seawall at Caroman in a drawing by B.Zendrini (1743) (Grillo,1989)

Fig.4 The present reinforced murazzi seawall at Caroman

The disappearance of the emerged beach and the erosion of the submerged seabed profile (with deposition occurring at depths below -8 m), results in larger waves reaching the seawall with increased overtopping and reduced stability of the rock protection. In fact a large breaching took place during the severe storm of 4 November 1966, when an extreme water level of nearly +2.0 m M.S.L. was recorded.

Therefore, within the present large project for the safeguard of Venice, new sea defence works have been designed in order to preserve not only the valuable coastal strips, but also the existing monumental old defence works themselves, without any negative aesthetical impact.

#### New design of coastal defence works with model studies

An accurate design process has been undertaken by TECHNITAL on behalf of the CONSORZIO VENEZIA NUOVA. The main design efforts have been devoted to the most vulnerable Pellestrina littoral and included detailed field investigations on the coastal morphology and dynamics and a large set of advanced physical and mathematical model studies for the design optimization.

At the basic design stage an extensive series of small scale (1:30) model tests was carried out in the 42.5 m long random wave flume at the hydraulic laboratory of the Magistrato alle Acque in Voltabarozzo (Padua). The tests were conducted and reported by PROTECNO (1990) with the assistance of DHI (Denmark) for the weakest "murazzi" sections at Pellestrina (first phase) and Caroman (second phase).

The following measurements were made in each test of 6 hours duration (prototype) with five Jonswap wave spectra (up to  $H_s=4.5$  m and  $T_p=11.0$  s) and four water levels (0,+1.0,+1.5,+2.0 m MSL) : wave heights and reflection coefficient, wave overtopping discharge, rock armour stability (by counting the coloured displaced stones), forces on the old vertical wall (by a strain gauge), pressures inside the rubble mound (by two transducers), toe scour of the mobile seabed (Fig.5). The beach profile, with a slope of 1:100, was modelled to a depth of -8 m MSL.

Initial testing of the existing structure showed unacceptable overtopping rates and damage of the 2-5 t rock armour under the design conditions (sea level +2.0 m).

For the "murazzi" at Caroman (the area at the southern border of Pellestrina strip) four alternative defense schemes with submerged berms with variable width and elevation were tested. The design choice was to extend the rubble mound toe underwater to avoid any visual impact, whereas a beach nourishment was not regarded as a cost-effective option due to the particular convex coastline planshape. The model tests showed that a satisfactory reduction of wave forces on the old vertical wall, overtopping discharge, and armour damage was obtained with a berm crest at -0.5 m to m.s.l. extending offshore for 30 m, whilst no further benefits related to the forces on the wall were found by increasing the berm width to 40 m. The scheme shown in fig. 6 (together with the local existing section) was then adopted for

Fig. 5 Model set-up of existing "murazzi" at Pellestrina

Fig. 6 Model test sections for the Caroman murazzi

the final protection design at Caroman. The stability of the submerged rock berm was also checked by profiling along two longitudinal axes after each test.

For the "murazzi" at Pellestrina several alternative reinforced structures have been tested, following the "environmental requirement" that crest elevations could not be increased. The remedial works mainly consisted in larger and heavier rock revetments (even including proper underlayers) and beach nourishment. The results showed a significant decrease of the overtopping discharge and of the cumulated damage of the main armour (always reduced below 2%). The most effective solution turned up to be a combination of a larger rubble seawall and a beach nourishment protected by submerged rock barriers.

The final design of the protection scheme for Pellestrina was recently optimized with the support of an interactive system of both 2-D and 3-D mathematical and hydraulic mobile-bed models performed by HR, Wallingford (1992). The main conclusions of the study allowed an inshore displacement of the submerged rock sill and a larger spacing of the rock groynes, partly submerged, which confine the artificial beach with just a 2-3% yearly volume loss of sand (provided a borrow fill material with D<sub>50</sub> in excess of 0.1 mm). The final and optimized design schemes are shown in fig. 7.

At present detailed geophysical surveys and vibrocore sampling are being undertaken to verify the exploitation of ancient sand deposits in depths of 17-22 m off the Malamocco inlet, to be dredged and pumped ashore. It may be interesting to remark that even this "modern" scheme of artificial beach nourishment was among the shore protection solutions proposed three centuries ago, when primitive dredgers were in use to excavate the channels of Venice lagoon!

#### Comparison of model results with formulae of static stability

The above studies demonstrate the great efficiency of a combined use of physical and mathematical models to verify the complex sea-structure interactions in the coastal zone. Generally the laboratory tests can be used to study small scale processes and to calibrate the numerical model tests, which in turn can be quickly repeated to investigate the influence of many parameters and extend the analysis to a larger temporal-spatial scale. Model tests can also be useful to calibrate practical empirical design formulae which can then be easily applied for a greater number of hydraulic and geometric conditions.

It was then believed useful to make a comparison between the results obtained from the application of some well known formulae of armour stability against the observed damage of the existing murazzi rock revetment. The count of the displaced stones at the end of each test enables to determine the numerical value of the damage parameter  $S = A_e/D_{n50}^2$ , where  $A_e$  is the erosion area in a cross section,  $D_{n50}$  is the nominal diameter of the stones. The damage parameter  $S$  is physically the number of cubic stones with a side of  $D_{n50}$  eroded within a  $D_{n50}$  wide strip of the structure.

Fig. 7 New defence of Pellestrina littoral: basic design plan and final optimized design

The parameter S can be related to the actual number of displaced stones ( $N_d$ ):

$$S = N_d * D_{n50} / [B * (1-n_v)] \quad \text{where:}$$

B = length of modelled seawall;

$n_v$  = porosity of the mound.

S = 2 signifies start of damage, S = 8 means that the underlayer is visible (slope 1:2).

Two well known equations for static stability have been considered: the one proposed by Van der Meer (1988) for plunging waves :

$$H_s / \Delta D_{n50} * \sqrt{\bar{\epsilon}_m} = 6.2 P^{0.18} (s/\sqrt{N})^{0.2} \quad (1)$$

and the Hudson formula given in SPM (1984) and modified by Van der Meer (1988):

$$H_s / \Delta D_{n50} = 0.70 (K_D \cot \alpha)^{1/3} s^{0.15} \quad (2)$$

$N = 2500-4000$  is the number of waves in the various test series.

$P = 0.4$  is the assumed value of the permeability factor

$T_m = T_p/1.25$  is the assumed average wave period in each test.

Eq. (1) and (2) were obtained for not overtopped structures. The test conditions and some results are given in tabs.1, 2 for the two slopes and in figs. 8, 9. The high rate of wave overtopping on the "murazzi" influences the observed damage. The results may also be affected by the depth limited wave conditions at the seawall. This analysis enables to verify the reliability of the two proposed formulae for static stability when predicting the rock armour damage of the existing "murazzi" seawalls. Van der Meer's formula was used to predict the cumulated damage for all the considered water level conditions and the results show a good agreement with the observed damage up to a water level of +1.5 m MSL, with a slight expected overestimation (see Fig.8 for the 1:2 slope). The application of the modified Hudson formula (with  $K_D = 2$  for breaking waves) does not describe the cumulated damage and produces unreliable results for both slopes of the "murazzi". A stability factor  $K_D=5$  should be used in this case to match the experimental results.

For all the tests with water levels up to +1.5 m MSL a good correlation was found between the measured overtopping discharge and the difference of the computed ( $S_{vdM,cum}$ ) and the observed ( $S_{obs}$ ) damage as shown in fig. 9. Only for the highest water level, near to the seawall crest (+2.0 m), the data is more dispersed. In the figure data from both Pellestrina and Caroman test series is plotted.

This analysis confirms the correlation between the stability of the front armour and the overtopping rate of a low-crest coastal structure. It also shows that the Van der Meer formulae can give acceptable conservative results even for low seawalls in shallow waters.

### Final remarks

The development of an effective system of coastal defence works plays an important role within the present large project for the safeguard of Venice lagoon. Careful studies have been carried out to optimize a modern design in harmony with the past experience, in order to ensure the required level of structural stability and environmental protection. The chosen solutions, a confined beach nourishment at Pellestrina and submerged berm at Caroman, are compatible with the conservation of the historical "murazzi" seawall and the former one also with the increasing touristic use of the beach. Since the sediment available for beach nourishment is very fine, the design of the longitudinal and transversal structures for the sand containment required extensive simulations with advanced interactive mathematical and physical models. Results from model tests have also been used to check the efficiency of two popular formulae for armour static stability in depth-limited wave conditions. The equations by Van der Meer seem to give reasonable conservative predictions in the case of the low crest "murazzi" seawall and the difference between the computed and observed damage is in fact fairly correlated with the overtopping discharge.

### Acknowledgements

The authors wish to thank Mr P. Silva and Mr. F. Galante of TECHNITAL, Verona, design engineers of Venice coastal defences, and Mr A. Venuti of PROTECNO, Padua, model engineer, for the kind supply of useful information. The model studies have been conducted for the Consorzio Venezia Nuova, concessionary for the studies and works related to the Venice project on behalf of Magistrato alle Acque.

## CHAPTER 146

### OBSERVATIONS OF GRANULAR-FLUID MIXTURE UNDER AN OSCILLATORY SHEET FLOW

by

Toshiyuki Asano<sup>1</sup>

#### 1. Introduction

Sediment transport due to wave action has been classified into three modes; bed load over a practically flat bed under small tractive force, suspended load over a rippled bed under moderate shear stress, and sheet flow under high shear stress where ripples are washed out. Studies of the sheet flow have recently received much attention because a large amount of sand is transported under this mode. However, sheet flow is a grain-fluid mixture flow of high concentration, thus the mechanism is more complex than that of the other two modes. In the sheet flow region where several layers of grains are mobilized, grain to grain collision performs a main role in the momentum exchange. The relationship between the applied stress and the bulk deformation is not a Newtonian, and depends on the grain concentration and the rate of deformation.

Hanes - Bowen(1985) have proposed a granular - fluid model to describe intense bed - load transport in an uni-directional flow. In their model, the flow is divided into two regions; grain collision dominated granular fluid region, and fluid stress dominated fluid shear region. They have derived a relation mathematically between the grain transport rate and applied shear stress.

Shibata - Mei(1986) have proposed another granular - fluid model in so-called macro viscous region where the shear rate is low and granular friction is as important as granular collision. Mathematical expressions to describe velocity profiles and granular discharge have been deduced.

These studies provide physical insight into the mechanism of sheet flow, however, the results are not able to be applied directly because the oscillatory sheet flow is a dynamic process under an unsteady flow.

---

<sup>1</sup>Dept. of Ocean Civil Engineering, Kagoshima University, Korimoto 1-21-40, Kagoshima, 890, Japan

The author (1990) has proposed a two-phase model for oscillatory sheet flow based on the conservation of mass and momentum for fluid and sediment. The model provides the quantitative description on the sheet flow properties, however, reliable experimental data are essentially required to examine the validity of the model. Since the mechanism of time varying grain densely mixed flow is highly complicated, clear experimental understandings have not sufficiently been obtained.

Even for macroscopic properties, there is much difference among reported results. For example, Horikawa et al.(1982) reported that their data on sediment transport rate agree well with Madsen - Grant formula in which the sediment transport rate is proportional to the 3rd power of the Shields number. Meanwhile, Sawamoto-Yamashita(1986) reported to the 1.5 power relationship between the sediment transport rate and Shields number.

In the present paper, detailed measurements on the intrusion depth of the sheet flow, sediment transport velocity and concentration etc. are carried out in order to obtain basic data which are useful to investigate the flow mechanism of oscillatory sheet flow.

## 2. Experimental Apparatus

An oscillatory flume capable of generating oscillatory sheet flows was constructed. The flume illustrated in Fig.1 is 8.0m long for horizontal section and 2.5m high for vertical section. The total length of the water column when the flume is filled is 10.2m including the joint section. The natural frequency of the oscillation calculated by the total length is 4.53sec. The horizontal section was made of clear acrylic which allows direct visual observation, and has a 15cm × 15cm square cross-section. The bottom of the central section is depressed to form a bed material container which is 1.8m long and 5.0cm deep. The oscillatory flows were generated via a piston driven by an electric servo motor and a drive shaft.

For the convenience of video frame tracing analysis, large and light plastic particles, 4.17mm in diameter and 1.24 in specific gravity, were used. Some parts of the particles were painted in various colors, and the water in the flume was also dyed in order to obtain clear pictures. Motion of the particles under oscillatory flows was taken with a high speed video camera at an exposure speed of 1/1000 sec, and also taken with a 35mm motor-driven camera as an auxiliary.

During one experimental run, special attention is paid to maintain the upper surface of the particle assembly flat and uniform in the flow direction. Keeping it uniform over a long time was found to be difficult because a large amount of particles is moved under sheet flow condition. Consequently, an oscillatory flow was generated just for 2 periods for each run, the data from the second half to the fourth half period in which uniformity of the flow had been assured was used for the analysis.

Table 1 shows the experimental conditions. The Shields number,  $\Psi$  in the table was tentatively calculated by assuming a friction factor  $f=0.01$ , since the movable bed friction under oscillatory flows is not sufficiently understood yet.

Figure 1: Oscillatory Flume

### 3. Experimental results

#### (a) particle motion

Picture-1 shows the behavior of the particles every 0.5sec. The period of this run(Case-C1) is 4.64sec, so that these six pictures cover over a little more than half a period. The indicator attached beneath the bottom shows the water surface level in the right vertical flume section.

The indicator in Picture (a) shows that the water level in the right vertical section rises to the maximum. In this phase, the flow velocity becomes zero, and the pressure gradient is the maximum. The particles have already started to move due to the pressure gradient. In the phase (b), the thickness of the sheet flow grows larger and moving velocity also increases. The particles move in saltation mode in the flow region  $z > 0$ , and move in sheet flow mode in the region  $z < 0$ , where a datum level ( $z=0$ ) is taken as an upper surface of the particle assembly under still water condition. Although the flow velocity increases toward phase (c) and takes the maximum between phases (c) and (d), the particle velocity starts to decrease in the sheet flow layer  $z < 0$ , meanwhile the particles maintain large velocity in the saltation layer  $z > 0$ .

Picture-1 Sheet Flow and Saltation Motion under an Oscillatory Flow (CASE-C1)

Picture-1 Sheet Flow and Saltation Motion under an Oscillatory Flow (CASE-C1) (Continued)

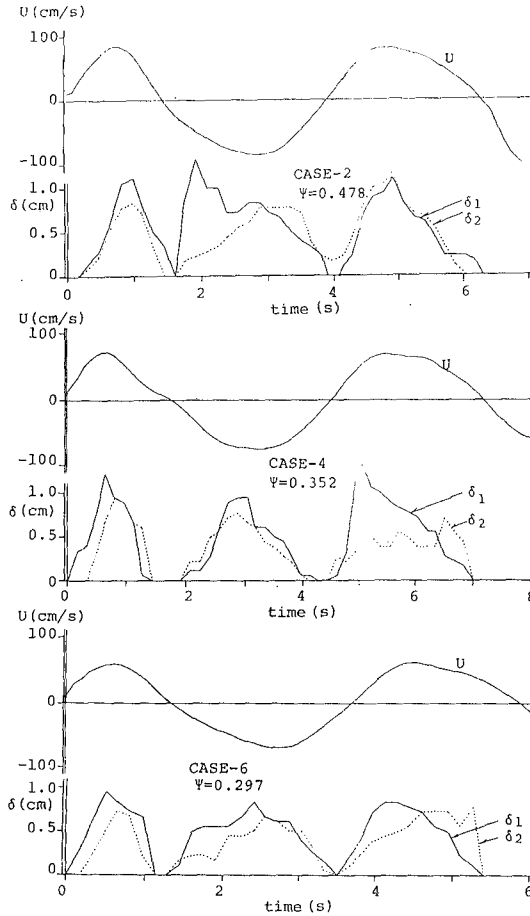

Figure 2: Temporal variations of thickness of sheet flow layer  $\delta_1$  and saltation layer  $\delta_2$

In the phase (e), particles in the sheet flow layer turn the direction to the right due to the pressure gradient although the mean stream velocity still moves from right to left. Some particles near  $z=0$  are found to rotate because the flow direction may change there. In the phase (f), the thickness of the sheet flow layer starts to increase again.

In brief, the particle motion shows remarkable phase precedence from mean stream flow due to pressure gradient in the sheet flow layer, but relatively small phase precedence in the saltation layer.

Figure 3:  $\hat{\delta}_1, \hat{\delta}_2$  vs Shields number  $\Psi$

(b) Thicknesses of Sheet flow layer and Saltation layer

A sheet flow layer thickness  $\delta_1$  is determined by an intrusion depth of moving particles below the datum level ( $z=0$ ), and the saltation layer thickness  $\delta_2$  is defined by the maximum jumping height upward from  $z=0$ . Fig. 2 shows the phase variation of  $\delta_1$  and  $\delta_2$ .

Fig. 3 shows the measured maximum thicknesses during half an oscillatory period  $\hat{\delta}_1$ , and  $\hat{\delta}_2$  in relation to the Shields number  $\Psi$  for CASE- 1 ~ 6. The sheet flow layer thickness  $\hat{\delta}_1$  increases almost linearly with the Shields number, and shows good agreement with the relation which the author proposed (1990). The relation that  $\hat{\delta}_1$  is proportional to the applied shear stress has been confirmed by Hanes and Bowen (1985) and Wilson (1984), although their data were obtained in uni-directional flows.

Meanwhile, the maximum saltation layer thickness  $\hat{\delta}_2$  increases gradually with the Shields number. The rate of increase is, however, small compared to results of stationary saltation for uni-directional flows (for example; Tsuchiya 1969). The reason why the difference arises is explained as follows: The momentum of a successively saltating particle increases with the number of times of saltation, however, the number is restricted under an oscillatory flow because the change of flow direction forces a saltating particle stop every half a period. Moreover, under sheet flow condition, the bed itself, on which a saltating particle collides and rebounds, moves as a sheet flow layer, so that a colliding particle does not receive enough momentum at the collision.

The thickness of the sheet flow layer might be governed by the dynamic Coulomb yield criterion which states the proportion between a shear stress

and a normal stress acting on a plane. The normal stress which consists of static pressure of the particle lattice, dispersive pressure due to particle collision and pore-fluid turbulence stress, balances not instantaneously but time-averagingly with the immersed weight of grains above. Applying the criterion at the boundary between mobile and immobile layers yields the following relation.

$$\tau_{-\delta_1} = \int_{-\delta_1}^0 \rho g(s-1)c \, dz \tan \phi_r \tag{1}$$

in which,  $\phi_r$  is the critical dynamic angle of internal friction. For the simplicity, the profile of sediment concentration  $c$  is herein assumed to be uniform throughout a sheet flow layer. After some algebra of Eq.(1), the thickness of the sheet flow layer is given as a function of the Shields number  $\Psi = u_*^2/\{g(s-1)D\}$  as follows.

$$\frac{\delta_1}{D} = \frac{\Psi}{\bar{c} \tan \phi_r} \tag{2}$$

In an oscillatory sheet flow, the angle of internal friction may be varied between an initial yield angle and an dynamic yield angle reflecting the flow unsteadiness. Tentatively adopting  $\phi_r = 26.5^\circ$  constant over a period, and  $\bar{c} = 0.40$  provides,

$$\frac{\delta_1}{D} = 5.0\Psi \tag{3}$$

This coefficient 5.0 is found to be the same order as the value 8.5 obtained in the experiment in Fig. 3.

(c) Sediment Transport Velocity

The profiles of the horizontal particle velocity when the velocity becomes the maximum are shown into a non-dimensional form in Fig. 4. The figure shows that the velocity profile is upward convex, and approximately expressed by 1.5 power of  $z/\hat{\delta}_1$ .

To visualize the velocity profile, additional experiments are performed in which white and red painted granulars are placed separately before generating an oscillatory flow. Picture-2 shows the results. The boundary is found to be upward convex, which coincides with the property of velocity profile illustrated in Fig. 4.

Fig. 5 shows the phase variations of the sediment transport velocity and mean stream velocity.

(d) Particle concentration

Instantaneous particle concentration was measured by counting the particles adjacent to the side wall within vertically divided grids. Fig. 6 shows the profiles of particle concentrations at the phase when mean stream velocity

 $t^* = 0.00s$  $t^* = 0.25s$  $t^* = 0.50s$  $t^* = 0.75s$  $t^* = 1.00s$ 

Picture-2 Particle Movements in a Sheet Flow Layer  
(CASE-B5,  $T=4.60\text{sec}$ ,  $\hat{U} = 91.3\text{cm/sec}$ ,  $\Psi = 0.425$ )

Figure 4: Profiles of Sediment Transport Velocity

Figure 5: Phase Variations of Sediment Transport Velocity

becomes the maximum. The profiles are approximately expressed by upward convex curves in the sheet flow layer and by exponentially decay curves in the saltation layer. The curves in Fig. 6 show calculated concentrations using Eqs.(9) and (10) described later.

Figure 6: Profiles of Sediment Concentration at phase  $\pi/2$

Figure 7: Phase Variation of Sediment Concentration Profile

The phase variations of the profiles are illustrated in Fig. 7.

Fig. 8 shows that the phase variation of the concentration at the boundary between the sheet flow layer and saltation layer;  $z=0.5\text{cm}$ . The reason why  $z=0.5\text{cm}$  is adopted here as the boundary is that the dilatancy of the particle assembly raises the boundary by around one particle diameter. This large dilatancy results from relatively large spheres used in the experiments as the bed material. If ordinary sea bed sand is used, the dilatancy effect would not arise so noticeably. Estimated concentration according to Englund-Fredsoe(1976) formula is also drawn in the figure, which is originally proposed for an uni-directional flow.

#### 4. Sediment Transport Rate

In this section, the relation between sediment transport rate  $Q$  and the Shields parameter  $\Psi$  is considered by synthesizing the above results.

The non-dimensional sediment transport rate during a half cycle is calculated as follows.

Figure 8: Phase Variation of Sediment Concentration at  $z=0.5\text{cm}$

$$Q = \frac{q}{w_0 D} = \frac{\hat{U}}{\pi w_0} \int_0^\pi \int_{-\delta_1(t)/D}^{\hat{\delta}_2/D} c(z, \theta) \frac{u_s(z, \theta)}{U} dz^* d\theta \quad (4)$$

where,  $w_0$  is the fall velocity of a particle,  $z^*$  is  $z/D$ ,  $\hat{U}$  is the amplitude of mean stream fluid velocity expressed as a function of  $\Psi$  as follows.

$$\hat{U} = \sqrt{2(s-1)gD\Psi/f} \quad (5)$$

First, based on the results in Fig. 3, the thicknesses of the sheet flow layer  $\delta_1(t)$  and saltation layer  $\hat{\delta}_2$  are assumed to be given by,

$$\delta_1(t)/D = 8.5[\Psi(t) - \Psi_{cr}] = 8.5[\Psi \sin^2 \sigma t - \Psi_{cr}] \quad (6)$$

$$\hat{\delta}_2/D = 1.25 \quad (7)$$

According to the results in Fig. 4, the sediment transport velocity  $u_s$  is given by,

$$\frac{u_s(t)}{U} = 0.41 \left( \frac{z}{\delta_1(t)} + 1 \right)^{1.5} \sin \sigma t \quad (8)$$

Concerning the particle concentration, the following profiles are assumed.

$$c = c_{max} - \{c_{max} - c_B(t)\} \exp(\alpha_1 z^*) \quad z^* < 0 \quad (9)$$

$$c = c_B(t) \exp\{-\alpha_2 z^*\} \quad z^* > 0 \quad (10)$$

in which,  $z^* = z/D$ ,  $\alpha_1 = D/\delta_1(t)$ ,  $\alpha_2 = D/\hat{\delta}_2$ , and  $c_{max}$  is the maximum concentration (here, 0.65 is used). The time dependent concentration  $c_B(t)$  at the datum level is given by Engelund - Fredsøe formula. The calculation of Eq.(4) is carried out using the present experimental condition;  $s=1.24$ ,  $D=4.17\text{mm}$ . The friction factor is given by constant 0.01.

Figure 9: Calculated Non-dimensional Sediment Transport Rate

The calculated sediment transport rate  $Q$  shown in Fig. 9 is found to be proportional to the  $3/2$  power of the Shields number if  $\Psi$  is greater than around 0.8, and the power approaches to 2 with decrease of  $\Psi$ . This result is explained as follows. The sheet flow layer thickness  $\delta_1(t)$  which occupies most of the integral range is found to be proportional to  $\Psi$ , and  $u_s/U$  does not show clear dependence on  $\Psi$ , so that  $u_s \sim U \sim \Psi^{1/2}$ . Consequently, the sediment transport rate  $Q$  is approximately proportional to the Shields number  $\Psi$  raised to the  $3/2$  power. According to Engelund-Fredsoe formula  $C_B$  also varies with  $\Psi$ , however, the dependence on  $\Psi$  is little if  $\Psi$  is greater than around 0.8.

## 5. Conclusions

- (1) The particle motion is characterized by two modes; saltation mode above the datum level and sheet flow mode below that. The phase precedence of the particle motion against mean stream motion is becoming noticeable with entering downward in the sheet flow layer.
- (2) The maximum thickness of the sheet flow layer is found to increase linearly with the Shields number, which is assured by simple kinematic model. Meanwhile, the maximum thickness of the saltation layer increases gradually with the Shields number.
- (3) The profiles of the horizontal particle velocity at the phase of the maximum mean flow velocity are expressed by upward convex curves expressed

by 1.5 power of  $z/\hat{\delta}_1$ .

(4) The particle concentration is approximately described by a simple profile proposed here, where the concentration at datum level is given by Engelund-Fredsøe formula.

(5) Summarizing the above results, a semi-empirical relation between sediment transport rate  $Q$  and the Shield number  $\Psi$  is proposed. The sediment transport rate is found to be proportional to  $\Psi$  raised to the 1.5 power for large tractive force  $\Psi > 0.8$ .

### ACKNOWLEDGEMENT

The author wishes to express his appreciation to Mr. Kazuo Nakamura, technician of Dept. of Ocean Civil Engrg., Kagoshima Univ. for designing and fabricating the electronic driving unit of oscillatory flow. The author also expresses his thanks to Mr. Yasuhiro Nakano and Mr. Toshimitsu Takazawa, former students; and to Mr. Kenji Tamai, graduate student of Ocean Civil Engrg., Kagoshima Univ. for their help in performing experiments and data analyses.

This research is partly sponsored by the Grant-in Aid for Scientific Research of the Japanese Ministry of Science, Culture and Education.

## CHAPTER 147

### FINE-SCALE MEASUREMENT OF SEDIMENT SUSPENSION BY BREAKING WAVES AT SUPERTANK

Stephen F. Barkaszi, Jr.<sup>1</sup> and William R. Dally<sup>2</sup>; M. ASCE

#### ABSTRACT

During the SUPERTANK data collection project, a mobile, vertical array of five Optical Backscatterance Sensors was used to measure sand suspension in the outer surf zone. Test conditions included both regular and random waves, and two different wave energy levels. Examination of the data reveals significant cross-shore variation in both the structure of the time-dependent concentration, as well as mean suspended load.

#### INTRODUCTION

A primary element of sediment transport in the nearshore is the process of sand entrainment by breaking waves and the resulting suspended load that is available to be carried by currents. Field measurements of Hanes (1988) outside the surf zone and Beach (1989) inside the surf zone indicate that sand suspension often occurs on a wave-by-wave basis; i.e., important phase information may be lost when transport is calculated based upon the long-term mean concentration. Most field measurement efforts have been limited to documenting the mean suspended load and its distribution with depth; however, temporal and spatial detail of the initiation, movement, and settling of sand clouds has not been examined.

The SUPERTANK Data Collection Project (Kraus, Smith, and Sollitt, 1992) provided the opportunity to make high-resolution measurements of sediment suspension by breaking waves in a controlled laboratory setting at large scale. Hydrodynamic data, consisting of fluid velocity and free surface displacement, were also collected. The experiments were designed to study the behavior of sand suspension under breaking waves, measured at high spatial and temporal resolution, with the aim of developing and verifying quantitative models for sand

---

<sup>1</sup>Graduate Student, <sup>2</sup>Associate Professor, O/OE/EVS Dept, Florida Institute of Technology, 150 W University Blvd, Melbourne, FL 32901

transport. The two data sets selected are an initial investigation of the substantial amount of concentration measurements obtained near the break point during the SUPERTANK project.

**EQUIPMENT**

Tests were conducted at the large wave channel operated at the O.H. Hinsdale Wave Research Laboratory, Oregon State University. A 76-m long beach of well sorted quartz sand was placed in the channel at the beginning of the SUPERTANK project. Figure 1 is a plot of the fall speed distribution for the sand used during the SUPERTANK project. Data obtained in the settling tube analysis also provided grain size distributions from the fall speed of the sand grains.

Figure 1 Fall speed distribution of the sand used during the SUPERTANK project.

The median grain diameter determined from the fall speed distribution was 0.25 mm. Result of these analyses are similar to those obtained by other SUPERTANK participants using mechanical sieve analysis.

Suspended sediment concentration was determined using five Optical Backscatterance Sensors (OBS), whereas free-surface displacement was obtained with a capacitance wave gage. The vertical and cross-shore components of the fluid motion were measured with four electromagnetic current meters (EMCM). A 8mm-format video camera was used to visually record the waves as they passed by the instruments. From this, qualitative, macro-characteristics of each passing wave could be determined.

The OBS were mounted to an aluminum sailboat mast, with the sensor beam axis oriented parallel to the wave crests. The array could be

adjusted vertically using a pulley and winch system, to accommodate changes in bed elevation. The wave gage was mounted to a second sailboat mast and could also be moved vertically, to compensate for changes in the water level under different test conditions.

The EMCs were mounted on an aluminum strut, with the instruments evenly spaced in the vertical, and oriented so that the vertical and cross shore components of the fluid velocity would be detected.

The three arrays were mounted on the shoreward side of a self-propelled carriage, which spanned the walls of the wave channel. The cross-shore position of the sensors could be changed with relative ease by moving the carriage.

## PROCEDURE

SUPERTANK was a collection of tests dedicated to cross-shore processes in a large wave channel. Each of the major tests were broken into runs which were short periods of continuous wave activity. The mobile OBS array was utilized in a total of 179 runs during the SUPERTANK project. The data presented in this paper are from four runs out of the test series labeled ST 20, second out of a total of twenty tests. Two of the runs were with regular waves, and two were with random waves. In all runs, the breakers were of the plunging type.

Data collection began approximately 45 sec before the start of a run so that still-water offsets for the OBS array could be determined. The video camera was manually started at the beginning of the run and did not require further adjustment. While a run was underway, the sensors could be monitored by viewing graphical displays.

In the two regular wave runs, the carriage was moved across the region of incipient breaking, pausing at five locations which ranged from 6 m seaward of the break point to just shoreward of the plunge point. Data were collected for approximately five minutes at each position. The entire procedure was repeated for a second 40-minute run with different wave conditions.

OBS must be calibrated for the sand at the project site due to variations in optical properties. Calibration was accomplished by immersing each sensor into a tank containing a sand/water mixture. The mixture was stirred continually to ensure a constant mean concentration in the region of the sensor.

Fig. 2 presents the calibration curves for the five OBS. It can be seen that the OBS were linear, therefore the sensor output can be converted to engineering units by applying the appropriate gain and offset.

The measurements records were found to contain occasional spikes which are attributed to electronic noise and not actual fluctuations in sediment concentration. All of the SUPERTANK OBS data were filtered

Figure 2 Calibration curves for OBS used during SUPERTANK.

by a program which removes outlying points, replacing the value with one interpolated between the preceding and succeeding points.

**REGULAR WAVES: TIME SERIES**

The following time series plots pertain to the sensor closest to the bed under regular waves. In most cases the sensor at the bottom of the array detected the greatest concentrations and most clearly displayed the event-based structure that is of interest.

Regular Wave Run #1

Fig. 3 presents the OBS time series for a sensor approximately 8 cm from the bed, with a cross-shore position 6 m seaward of breaking. Offshore conditions for this run were a wave height of 0.6 m and period of 3 s. At this location the waves were just beginning to strongly shoal, and the OBS record showed only a small amount of suspension near the bed.

Figure 3 OBS time series 7.8 cm from the bed

Fig. 4 presents data from a position 4 m seaward from the break point, and is an example of concentration fluctuation that is directly correlated to the 3 sec oscillatory motion. The sensors indicate regular changes from a low background concentration to relatively high concentration within one wave period.

Figure 4 OBS time series 7.5 cm from the bed

Moving to a position 2 m from the breakpoint, the background concentration increased from 1 g/l to 2-3 g/l as seen in Fig. 5. The events at this position are regular, but are not as sharply peaked as those found 4 m from the breakpoint. The complete time series for this run contains a noticeable long period oscillation, part of which can be seen in this 100-sec segment, and may be caused by seiche in the channel.

Figure 5 OBS time series 6.8 cm from the bed

At the break point (Fig. 6), the background concentration increased to nearly 5 g/l, and some peak concentrations lie above 10 g/l. The oscillatory structure is absent and peak concentrations are no longer strongly linked to the wave period.

Figure 6 OBS time series 6.8 cm from the bed

In Fig. 7, which corresponds to a location 2 m shoreward of the break point and just shoreward of the plunge point, the most noticeable feature in the OBS record is that the background concentration has dropped to about 2 g/l. However, the peak concentrations remain relatively high. This time series shows no indication of wave-correlated structure, with the peaks in sediment concentration not following a distinguishable pattern.

Figure 7 OBS time series 6.8 cm from the bed

These records indicate the temporal and spatial structure of the boundary between the relatively clear water outside the surf zone, and the cloud of sediment entrained and maintained by the intense turbulence levels induced by breaking. As the boundary advected back-and-forth in the oscillatory flow, it was visually observed to drift offshore several meters from its origin near the breaking point. A sharp gradient in suspended sediment concentration defined the boundary between the cloud and the surrounding water.

Figure 8 OBS time series 7.5 cm from the bed

### Regular Wave Run #2

In this second run, the offshore wave height was increased to 0.8 m, whereas the wave period remained at 3 sec. The position of the break point shifted approximately 4 m offshore from the previous run. Fig. 8, corresponding to a position 2 m seaward of this break point, shows that the magnitude of the sediment concentration in this time series oscillated regularly, much like in the previous run (Fig. 5); however, the background concentration was notably less with the larger wave conditions.

As seen in Fig. 9, by moving only half a meter closer to the breakpoint the peak concentrations increased, indicating deeper penetration into the sediment cloud as the boundary advected past the sensor. Suspension peaks were regular but not all of the same magnitude.

Figure 9 OBS time series 8.4 cm from the bed

At the break point (Fig. 10), there was a notable increase in the amount of sediment in suspension. Peak concentrations ranged from 15 to 20 g/l, and the background concentration was about 5 g/l, which are significantly greater than was observed at the break point in the first run.

Figure 10 OBS time series 8.4 cm from the bed

Fig. 11 displays data that were collected 0.8 m inside the point of incipient breaking, which was still seaward of the plunge point. In this region, the highest peak concentrations of suspended sediment and greatest suspended load were found. No regular structure is apparent in the time series, and only in a few instances can 3-sec period events be observed.

Figure 11 OBS time series 8.4 cm from the bed

4.3 m shoreward of the break point (Fig. 12), the background concentration drops to approximately 3 g/l and the peaks are reduced to the 5 to 10 g/l range. Fluctuations in sediment concentration appear to be considerably more random after the plunge point. The shoreward boundary of the sediment cloud is not as well defined as the seaward boundary, indicating more efficient cross-shore mixing in the broken wave region as would be expected.

Figure 12 OBS time series 7.5 cm from the bed

**REGULAR WAVES: MEAN CONCENTRATION PROFILES**

Fig. 13 and Fig. 14 present mean concentration for all five OBS in the vertical array, for the two regular wave conditions discussed above. Mean concentration was calculated from the entire record that was collected at each station. Sensor elevations ranged from 7 to 34 cm above the bed.

Regular Wave Run 1

Fig. 13 displays the mean concentration profiles at the five cross-shore positions identified in Fig. 3 through Fig. 7. The profiles are labeled 1 through 5, with Profile 1 being the most seaward and Profile 5 being the most shoreward.

Figure 13

The first curve is for the cross-shore position 6-m seaward of the break point, where there was little suspended material as indicated by the low mean concentrations and the absence of vertical structure. The second curve, which is 2-m closer to the break point, shows an exponential decrease in concentration with distance from the bed. Profile 3 is 2 m seaward of the break point, where the curve is similar in shape to the previous, but with an increase in the amount of suspended material.

Profile 4, which was taken at the position where the wave crest began to curl over the front face, the concentration nearly doubled from the previous location. Here the profile is no longer smooth, but has a noticeable kink. After breaking (Profile 5) there is a distinct inversion in the mean sediment concentration profile.

### Regular Wave Run 2

Fig. 14 displays the mean concentration profiles at the five cross-shore positions identified in Figs. 8-12. The mean concentration profiles are numbered 1 through 5 as in Fig. 13.

Figure 14

Seaward of the break point, the mean concentration profiles again show an exponential shape similar to those in Fig. 13. Profile 2 shows that the amount of suspended material was nearly twice of that in Profile 1, even though these locations were only 0.5 m apart. At the break point (Profile 3), the vertical structure loses its exponential character, as in Profile 4 of the previous run.

The highest mean concentrations measured at any cross-shore position are found in Profile 4, which was located between incipient breaking and the plunge point. Here the profile has an irregular shape, but concentration still decreases with distance from the bed. Even though this profile was taken less than 1 m landward of the previous position, mean concentrations doubled. Profile 5, which is shoreward of the plunge point, the concentration profile was inverted, but not to the degree observed in the first regular wave case.

### RANDOM WAVES: TIME SERIES

Most of the tests during the SUPERTANK project dealt with random waves. Unfortunately, there were no runs with random wave conditions during which the OBS array was shifted to different positions in the surf zone. However, for comparison of random and regular waves, two random wave runs were identified that had similar energy levels and

breaking conditions as the two regular wave runs. All four runs were conducted in immediate succession, so that the bottom profile underwent only slight change.

### Random Wave Run 1

The design wave conditions were 0.6-m significant height and 3-sec peak period. For the entire 40 min run, the OBS array was positioned about 5.4 m seaward of breaking, 0.6 m shoreward of the first position for the regular wave case.

Figure 15 OBS time series 7.6 cm from the bed

Fig. 15 presents a 100-sec segment of the 40 min run. Concentrations measured at this position under random waves were comparable to those measured in the first regular wave case (Fig. 3). Background concentration was low and the suspension events were sparse during both runs.

### Random Wave Run 2

The offshore conditions for the second random wave case were 0.8-m significant wave height and 3-sec peak period. The OBS array was positioned about 2.1 m seaward of breaking, nearly the same as the first position for the 0.8-m regular wave case.

Figure 16 OBS time series 7.5 cm from the bed

In Fig. 16 it can be seen that with random waves the sediment suspension events are intermittently spaced and the peak concentrations are less uniform than those in the regular wave run (Fig. 8). There are also sections where little suspension occurs; however, no new structure (i.e. structure that was not encountered at some location in the regular wave run) is evident. Visual observations confirmed that smaller waves produced a sediment cloud of smaller dimensions and lower concentration.

### RANDOM WAVES: MEAN CONCENTRATION PROFILES

Average concentrations for each of the sensors in the OBS array were calculated and the mean concentration profiles were generated for the random wave cases. Since data were available at only one cross-shore position for the two random wave tests, the random wave profiles are plotted together with a concentration profile from a comparable position during the regular wave runs.

Figure 17 Mean Concentration Profiles

Fig. 17 shows the mean concentration profiles for the two types of waves at positions nominally 6 m seaward of breaking. The position of the array in the regular wave case was 0.6 m seaward of the random wave case. The shape of the curves and magnitude of the concentration are nearly identical.

Fig. 18 shows sediment concentration profiles under comparable regular and random wave conditions, but from a location nominally 2 m seaward of breaking. They display very similar exponential decay in concentration with distance from the bed. The mean suspended load for the random wave case is slightly lower than in the regular wave case. The consistent amount of energy available on a wave-by-wave basis for regular wave conditions may generate this higher background concentration.

Figure 18 Mean concentration profiles

## CONCLUSIONS

The temporal behavior of suspended sand concentration, as well as the mean suspended load, changes dramatically as one moves through the outer edge of the surf zone. Suspension just outside the breaking region is characterized by a relatively well-defined boundary between clear water and sediment in suspension. The position of this boundary oscillates with the motion of the waves and drifts offshore with the mean cross-shore current, resulting in a concentration that varies regularly with the wave period. Mean concentration profiles in this region display the classical exponential shape.

The highest concentrations of suspended sediment are found in the region of initial breaking, where the sand cloud originates. Here much of the oscillatory structure in the time series is lost, with peaks in concentration occurring randomly, even for regular waves. Mean concentration adopts a profile that decays roughly linearly with distance from the bed. Just shoreward of the region of initial breaking the profile of mean concentration inverts.

For random waves, suspension is more irregular and intermittent, as should be expected. However, the mean concentration profiles are similar in both magnitude and shape as for regular waves.

## ACKNOWLEDGEMENTS

Appreciation is given to Dr. Nicholas C. Kraus for encouragement and discussions. This work was partially funded by the Dredging Research Program of the US Army Corps of Engineers' Coastal Engineering Research Center.

## CHAPTER 148

### STATISTICALLY SIGNIFICANT BEACH PROFILE CHANGE WITH AND WITHOUT THE PRESENCE OF SEAWALLS.

David R. Basco<sup>1</sup>, Douglas A. Bellomo<sup>2</sup>, and Cheryl Pollock<sup>3</sup>

#### Abstract

The interaction of beaches and seawalls is a highly controversial subject today. Many of the arguments both "for" and "against" the construction of seawalls have been speculative. Few are based on actual field or laboratory measurements. This paper is part of a continuing study at one location, which intends to shed some light on this controversy using statistical analysis of real field data.

#### 1. Introduction

Sandbridge, Virginia (USA) is the site for an ongoing investigation of seawall and beach interaction. The study area lies on the east coast of the United States. Sandbridge is located south of the Chesapeake Bay and north of the Virginia-North Carolina border, as depicted in Figure 1. The beach is used by local property owners, residents, and tourists as a recreational area.

The long term shoreline recession rate (Everts et al., 1983) has been shown to vary at Sandbridge from 1.1 m/yr at the north end, to 2.9 m/yr at the south end. For this reason, many beach front private property owners have acted to protect their investments by constructing timber, steel or concrete seawalls (bulkheads). The protection of septic tanks, concrete slabs, and other property at ground level are a few reasons for their construction. The majority of homes in the area are on piles above the one percent chance storm surge event.

A few wall sections were constructed as early as 1978; however, most were erected in the mid to late 1980's. Fifteen sections of wall presently exist totaling 4816 m, roughly 60 percent of the 7.7 km study length (See Figure 1, insert). In general these sections lie about 46 m seaward of our baseline, Sandfiddler Road. Some sections, particularly those south of profile 162, are located within the daily tidal range. During storm events, the beach berm, seaward of the walls, is submerged at all locations. This allows waves to break at or near the walls.

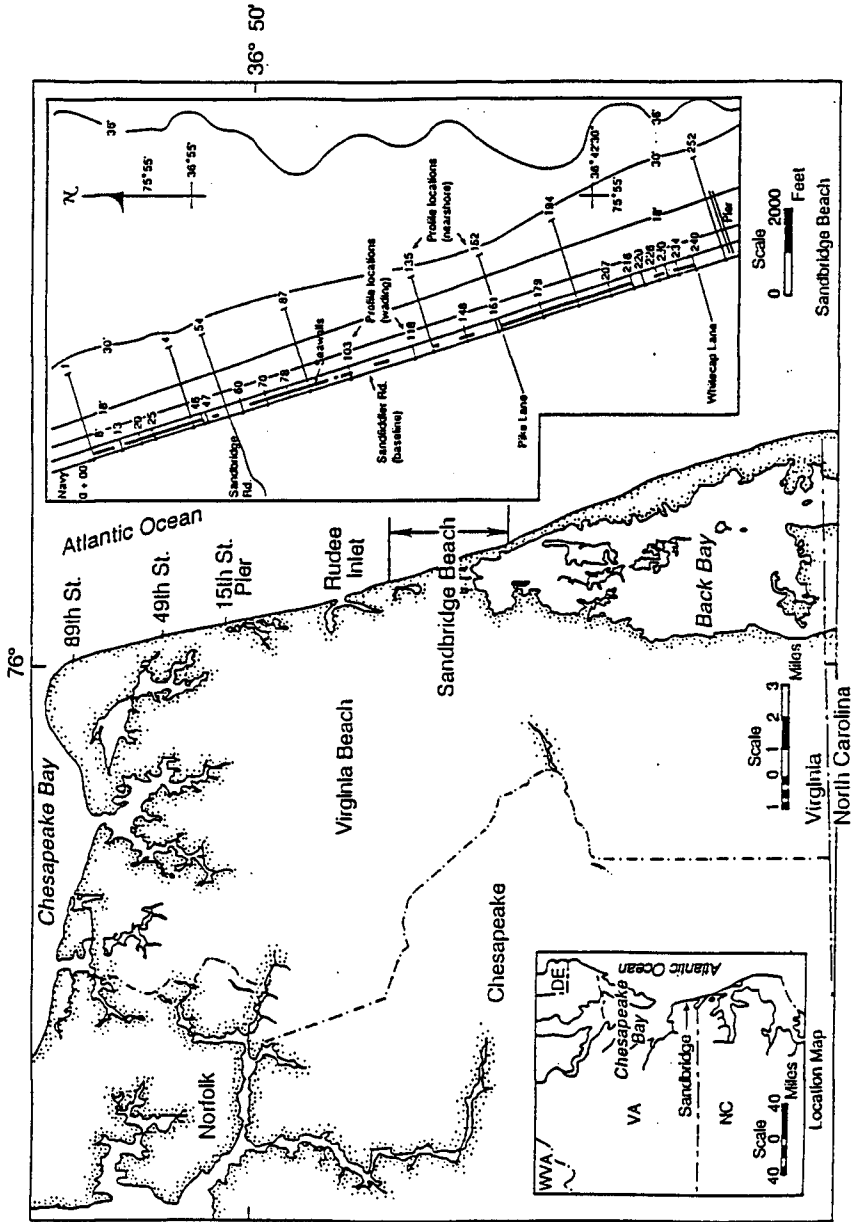

Figure 1 Location Map

The effects seawalls have on beaches, and their overall performance as a shoreline protection strategy, is the subject of much controversy today. The Journal of Coastal Research's 1988 Special Issue Number 4 entitled, "The Effects of Seawalls on the Beach", was specifically devoted to this topic (Kraus and Pilkey, 1988 Editors). Of the eight articles in this issue, none contained a rigorous statistical analysis of beach profile "change".

Profile data has been collected at Sandbridge since 1980, and continues to be collected today. Using this data, long term trends can be observed. These trends can then be used to determine statistical differences in walled and non-walled profiles. This statistically based information will help determine if the seawalls are responsible for altering the existing "natural " variations in beach profile data.

## 2. Field Efforts and Data Base

In August of 1990 Old Dominion University (ODU) began collecting monthly profile data at 28 locations along Sandbridge Beach. The project, sponsored by the Corps of Engineers' Coastal Engineering Research Center (CERC), has been extended through 1995. Of the 28 profile locations, 12 contain walls, 10 are across dunes, and 6 are located near wall ends, as shown in Figure 1. Profiles are taken out to low tide wading depths (-0.6 m), extending seaward about 122 m from the baseline.

The City of Virginia Beach began survey work in 1980 with profiles at roughly 305 m intervals. Most profiles extend only out to wading depths, however, some nearshore profiles (ie. to depths of -8 meters) have been taken. The time between City surveys varies over the past 12 years.

Other agencies, for instance the Corps of Engineers and the Virginia Institute of Marine Science, have also sponsored survey work at Sandbridge.

Compiling all the data from all the sources, 78 profile locations have been established. Today over 1600 separate profile lines have been taken at these 78 locations. At some locations 80 separate surveys have been taken, and by 1995 many will have over 100 surveys, spanning a 15 year period. Each profile has been archived to a common vertical and horizontal datum in CERC's Interactive Survey Reduction Program (ISRP). Using this data, statistical statements can now be made regarding the "differences" in beach profile response at walled and non-walled locations.

## 3. Quantification of Profile Change, Five Parameters

To quantify profile "change" we have adopted five parameters as depicted in Figure 2.

### 3.1 Profile Section Volumes

There are three section volume parameters, namely: landward volume ( $V_L$ ), seaward volume ( $V_S$ ), and total volume ( $V_T$ ), each carrying units of  $m^3/m$ . The

Figure 2 Definition Sketch

area between the profile and the MLW line is calculated using the trapezoidal rule. To obtain a volume, this area is then multiplied by a unit length parallel to the beach. The different volumes (landward, seaward, and total) are calculated using different right and left hand boundaries. Landward volume is bounded on the left by the survey baseline. For a walled profile, the right hand boundary for landward volume is the wall itself. However, for a dune/beach profile, an imaginary partition is used as the landward right hand boundary. This imaginary partition is located at the same distance from the baseline as the nearby seawalls. Seaward volume is bounded on the left by the imaginary partition or seawall, and on the right by the intersection of the profile and the MLW line. The total volume is simply the sum of the landward and seaward volumes. Figure 2 graphically depicts these definitions.

### 3.2 Berm Elevation

The berm elevation ( $E_b$ ) is measured in meters above the vertical datum. It is simply defined as the elevation of the profile at the seawall or imaginary partition, as shown in Figure 2.

### 3.3 Shoreline Position

The shoreline position ( $P$ ) is also shown in Figure 2. It is defined as the distance from the baseline, to where the profile intersects the MHW line. The MHW vertical datum has been chosen here to be consistent with map and aerial photograph data.

In Figure 3, the heavy solid line represents the shoreline position at Old Dominion University's 28 profile locations in August 1990. The heavy dotted line represents the shoreline position two years later in August 1992. The shoreline change, over that two year period, is indicated by the light solid line. Profile locations are depicted as short vertical lines at the bottom of Figure 3, and the

horizontal lines represent the walled sections. Notice how close the shoreline is to the baseline ( $P=0$ ) for profile numbers greater than 162. It is easily seen, that the long term receding shoreline poses an immediate threat to home and property owners.

#### 4. Methods of Data Analysis

##### 4.1 Jack Knife (JK) Technique

The Jack Knife (JK) technique (Dolan et al., 1991) has been used to determine a linear relationship between a given profile parameter and time. The first step in this method is to linearly regress all of the data points for one parameter versus time. This produces one slope and one intercept. Then by linear regression of all the points except the first, another slope and intercept can be calculated. Regressing all points except the second gives a third slope and intercept, ect. Given  $X$  surveys at one location, a "family" of  $X+1$  slopes and intercepts can be generated using this method. From this "family" of slopes, the average slope, as well as the standard deviation associated with that average slope, can be computed. Two methods of data analysis have been employed using the Jack Knife technique.

Figure 3 Shoreline Position

Figure 4a Profile 0

Figure 4b Profile 25

4.2 Compare Nearby Locations (CNL) Method

In this method, four profile pairs were selected at various locations along the beach. Each pair consists of a dune/beach profile and a seawall profile. Seawall profiles 25, 74, 194 and 205 were paired with dune/beach profiles 0, 60, 161, and 220, respectively. The variation in the long term shoreline recession rate along the study length, coupled with the availability of data dating far enough back in time, played a role in the selection of these pairs.

Figures 4a and 4b are envelope plots for profiles 0 and 25, respectively. Each profile line represents the beach cross section at a particular time. From each of these lines the five parameters  $V_L$ ,  $V_s$ ,  $V_T$ ,  $E_B$ , and  $P$  can be calculated. Each parameter can then be plotted versus time. Figure 5 shows each of the three section volumes versus time for the dune/beach profile 0. Figure 6 is the same type of plot for the walled section, profile 25, 760 m south of profile 0.

In Figures 5 and 6, the data has been divided into three groups: those points prior to October 1988 (dotted), those after October 1988 (dashed), and all the points inclusive (solid). The data has been divided at October 1988 simply because this is when the nearby wall at profile 25 was constructed. The JK technique was then employed on all three data groups for each profile. Statistics for the other two parameters,  $E_B$  and  $P$ , were calculated in a similar fashion. In Figures 7 and 8, the x's represent parameter values for profile 25, and the o's represent parameter values for profile 0. The light lines are the JK lines through profile 25 data, and the darker lines are those through profile 0 data. These types of calculations were made for all four profile pairs selected (0/25, 60/74, 161/194, 205/220).

At this point, the null hypothesis test was used to determine if any statistical

Figure 5 Section Volumes Profile 0 (dune/beach)

Figure 6 Section Volumes Profile 25 (seawall)

Figure 7 Berm Elevations Profile 0 and 25

Figure 8 Shoreline Positions Profile 0 and 25

differences existed between the dune/beach and seawall line slopes generated by the JK technique. This was done for all 3 groups (prior to wall construction, after wall construction, and all data inclusive) and all four pairs. A five percent signifi-

cance level or 95 percent confidence was used for the null hypothesis. Since large degrees of freedom existed (ie. more than 29 slopes generated), a standard normal curve was used (Scheaffer and McClave,1990). The results found using this technique are discussed in Section 5 and summarized in Table I.

#### 4.3 Weighted Average (WA) Method

The second of the two data analysis techniques used is the Weighted Average (WA) method. Carefully distinguishing between walled and non-walled sections, each of the five parameters were integrated along the beach. The integrated values were then divided by a representative length, resulting in a weighted average parameter value. For example,  $V_L$  was calculated at various walled locations along the beach. These values were then used to integrate  $V_L$  along each of the fifteen walled sections. At this point an estimate of the total volume of sand in cubic meters, behind the walls was known. The weighted average  $V_L$  for the seawall sections was then calculated by dividing this total cubic volume by the entire wall length. Similar computations were made to calculate the total volume of sand behind an imaginary partition for the dunes.

To carry out this technique, data was collected monthly at 28 specific profile locations for a two year period. As mentioned earlier, Figure 3 shows the location of the 28 profiles (vertical lines), and walled sections (horizontal lines). Of the entire study length, roughly 4600 meters (60 percent) is walled and 3100 meters (40 percent) is duned. Note that not all walled sections nor duned sections have profiles running through them. These sections, however, make up only 14 percent of the study length. For this small percentage, parameter estimates were obtained using nearby profile data.

Calculating the seawall and dune/beach weighted average volumes for each of the monthly surveys, and plotting them versus time, results in Figure 9. Again we have  $V_L$ ,  $V_s$ , and  $V_T$  versus time as in the CNL method. The time span, however, is only 2 years in this case. In Figure 9, an "x" represents the weighted average parameter value for the seawall sections, and an "o" represents the weighted average parameter value for the dune/beach sections. The dashed and solid lines represent the Jack Knife line through the seawall and dune/beach data, respectively. Figure 10 shows the weighted average berm elevation ( $E_B$ ) versus time, and Figure 11 the weighted average shoreline position (P) versus time.

Again the null hypothesis test was used to determine if any statistical differences could be found in the slopes generated by the JK technique. The results are discussed in section 5, and are summarized in Table II.

#### 4.4 Littoral Drift Effects

One of the major concerns with this type of analysis is the independence between the two populations (seawall and dune/beach slope "families"). Two truly independent populations must exist; otherwise, it is impossible to make any valid statistical statements using the null hypothesis technique. If the sediment transport was strictly in the onshore-offshore direction, there would be no problem in

Figure 9 Section Volumes WA method

Figure 10 Berm Elevations WA method

Figure 11 Shoreline Positions WA method

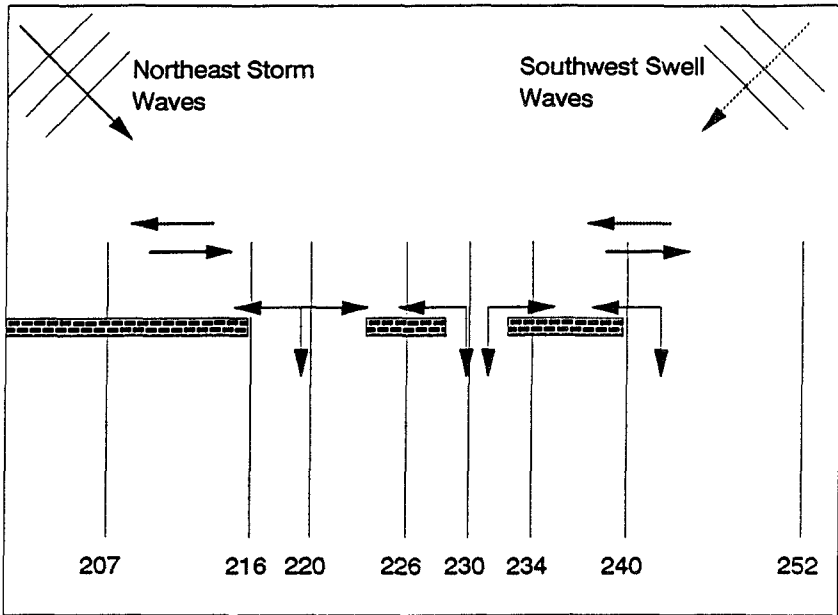

Figure 12 Littoral Drift Effects

making the independence assumption. However, this is not the case since longshore transport does exist.

In Figure 12 we depict to scale the seawall and profile locations at the southern end of the study area. Also shown are the directions for the northeast storm waves and the southwest swell waves. These produce a longshore sediment transport in the southerly (solid arrow) and northerly (dotted arrow) directions, respectively. Sand is moved from walled areas to dune/beach areas and vice-versa during the time periods corresponding to the reversals in wave direction. This is also shown schematically in Figure 12.

For the *long-term* trends analysis discussed herein, both the CNL and WA methods have tacitly assumed that the lateral transport processes **balance each other out over long periods of time**. In other words, sand moves locally from in front of walls to adjacent dune/beach areas, and in the reverse direction in approximately balanced quantities, **over the long term**. This assumption will be investigated as part of the overall project in the future, when the focus will be on end-of-wall effects on adjacent beaches, and storm induced changes over short time intervals.

## 5. Results

### 5.1 Compare Nearby Locations (CNL) Method

The five parameters  $V_L$ ,  $V_s$ ,  $V_T$ ,  $E_B$ , and  $P$  were tested on all four profile pairs. Each profile pair consisted of six JK lines, three for the dune/beach, and three for the seawall. Recall that these three lines were generated by dividing the data at the date when the local wall in the particular area was constructed. One line used data points before wall construction, the second used points after wall construction, and the third JK line used all the data points.

The results using the null hypothesis test on the slopes generated from the JK technique are found in Table I. The first column in the table states the hypothesis being tested. Columns two, three, four, and five represent profile pairs 0/25, 60/74, 161/194, 205/220, respectively. An "x" in a column means that the pair agreed with the hypothesis (i.e., both seawall and dune/beach regression slopes came from the same population). If no "x" exists, the hypothesis was found to be false. Column six is the number of profile pairs out of four in agreement with the hypothesis.

The trends are clearest for Group 1 (i.e., all the data is regressed). Seawalls retain sand behind them, therefore, the higher volume loss rate for the dune/beach sections behind the imaginary partition is to be expected. This also contributes to the higher loss rate for the total volume,  $V_T$  of a dune/beach section. The volume loss rate **seaward** of the partition was shown to be **higher** for the seawall in three of the four profile pairs. Berm elevation and shoreline position comparisons were inconclusive, since two pairs exhibited one trend and two, another.

The results for Groups 1 and 2 (i.e., before and after wall construction) are

Hypothesis	Profile Pair				Number in agreement
	0 25	60 74	161 194	205 220

VI	-5.34	0.359	+0.58	0.203	Dune weighted average VI loss rate is higher.
Vs	-2.86	0.406	-3.24	0.449	Seawall weighted average Vs loss rate is higher.
Eb	-0.17	0.014	-0.22	0.024	Seawall weighted average Eb loss rate is higher.
P	-1.40	0.174	-1.30	0.266	Weighted average P loss rates are same.

Table II Results WA method

less conclusive. We are investigating other profile pairs to expand the number used in the CNL method.

5.2 Weighted Average (WA) Method

All five parameters were tested over the 2 year period from August 1990 to August 1992. Two JK lines were calculated for each of the 5 parameters. One line was calculated using the dune/beach WA method values and the other used seawall WA method values. The results using the null hypothesis test on the slopes generated from the JK technique are found in Table II. Column one shows the profile change parameter being tested. Column two shows the average slope calculated using dune/beach WA method values, and the JK technique. Column three represents the standard deviation associated with the average slope in column two. Columns four and five are similar to two and three, only they were calculated using seawall WA method values. Column six states the result of the null hypothesis test.

The integrated, weighted average results for total and landward volume loss rates, again show that seawalls hold more sand in the profile. These are the same results a for the CNL method. Also, the volume loss rate seaward of the partition

(or wall) was higher for the seawalls. The averaged seaward volume loss rate was  $-2.86 \text{ m}^3/\text{m}$  (per year) for all the dune areas compared to  $-3.24 \text{ m}^3/\text{m}$  (per year) for all the seawalled sections. The standard deviations of all the slopes determined by the JK technique were similar (0.406 versus 0.499) for this estimate. The WA method also shows that the berm elevation loss rate is higher for the seawalls than for the dune/beach sections.

Despite these results for weighted average seaward volumes and berm elevation at the partition (seawall), statistical evidence does not permit a similar conclusion to be drawn regarding the shoreline position change rate over the two year study period.

## 6. Conclusions

The seawalls were installed at Sandbridge as an effort to protect the land and other property behind them from the encroaching sea. This study has shown, that at seawalled sections, the landward loss of sediment was much lower, and the seaward loss was slightly higher. Because of the volume held behind the walls, total loss of sediment was lower. It was also shown that the berm lowering rate, is slightly larger at seawalled sections in comparison to dune/beach sections. However, no strong statistical evidence was found to support the claim that seawalls have caused higher shoreline recession rates at Sandbridge. These results include the assumption that the lateral transport rates are in balance over long time periods.

These results are based upon 12 years of data for the CNL method and 2 years for the WA method. They are reflective of one 7.7 km stretch of East Coast shoreline in the United States. At the end of the study in 1995, we should have significantly more data for the WA method to make stronger conclusions. These results are applicable to the Sandbridge site with the complicated number of short seawall segments. The extrapolation of these results to other locations should be used with caution. Future efforts to sort out the end-of-wall and short term storm effects will aid in determining the validity of the "lateral transport balance" assumption. This will also help to determine if these results can be generalized and applied to other locations.

## CHAPTER 149

# PREDICTION OF TURBIDITY CURRENTS WITH BOUSSINESQ VISCOSITY AND SECOND-MOMENT CLOSURE MODELS.

Bård Brørs<sup>1</sup> and Karl J. Eidsvik<sup>1</sup>

### ABSTRACT

Sediment auto-suspension criteria (specifying the limit between eroding, self-accelerating flow and depositing, decelerating flow depending on the slope angle and particle settling velocity) differ by two orders of magnitude for different models in use. Experiments suggest that the results from ordinary density currents are applicable to turbidity currents. In the present study, models based upon well-known turbulence closures are applied in order to obtain a realistic description of turbidity currents:

A two-equation ( $k-\varepsilon$ ) model predicts phase plane behaviour in accordance with results from theoretical work reported in the literature, and with limits for auto-suspension within the range of conventional estimates. However, by its design, this model and simpler gradient diffusion models are unable to produce turbulent diffusion of sediments up through the level of the velocity maximum.

A model with second-moment Reynolds stress turbulence closure is applied. This model proves to overcome the problem of vanishing turbulent diffusivity in the velocity maximum and give plausible results for vertical distribution of flow parameters in turbidity currents.

### INTRODUCTION

Turbidity currents belong to the class of flows called gravity currents. A turbidity current is forced by the down-slope component of the gravitational acceleration acting on the soaring sediment grains, which in turn are kept in suspension by the turbulence generated by the current itself. Turbidity currents on the sea-bottom are known to have travelled hundreds of kilometers at speeds of more than 25 m/s and to have left turbidites (sediment deposits) of over 100 km<sup>3</sup>. The present study considers the portion of the flow well behind the advancing front, where horizontal gradients of flow variables may be ignored. Figure 1 shows a sketch

---

<sup>1</sup>Norwegian Hydrotechnical Laboratory, N-7034 Trondheim, Norway.

of the situation with suggested mean velocity and mean concentration profiles. As long as the slope is sufficiently steep and sediments are available, the flow increases its height, velocity and amount of sediments in suspension. For this

Figure 1: Turbidity current sketch.

shallow near-to-uniform flow, the thin shear layer approximation can be made, the equations for the mean velocity  $U$  and mean sediment concentration  $C$  may be written

$$\frac{\partial \rho U}{\partial t} = \frac{\partial \tau}{\partial z} + (\rho_s - \rho_f) C g \sin \beta, \tag{1}$$

$$\frac{\partial C}{\partial t} = -\frac{\partial}{\partial z} (\overline{cw} - w_T \cos \beta C). \tag{2}$$

Here,  $\rho_s$  and  $\rho_f$  are the solid and fluid densities and  $w_T$  is the particle settling velocity (positive downwards) and  $g$  is the gravitational acceleration.

Sediment auto-suspension criteria differ by two orders of magnitude for different models in use (Seymour, 1986). It is a limited supply of data for model verification, but experiments suggest that results from ordinary density currents are applicable to turbidity currents (Simpson, 1982). In the present study, several models based upon well-known turbulence closures are applied in order to obtain a realistic description of turbidity currents.

## MODELS

The equations for  $U$  and  $C$  given above contain two additional unknowns, the turbulent shear stress  $\tau$  and the turbulent sediment flux  $\overline{cw}$ . The shear stress may be expressed as  $\tau = -\rho \overline{uw} + 2(\rho_s - \rho_f)(w_T \cos \beta)^2 C + \rho_s w_T \cos \beta C U$ , and turbulence closures are needed for the normal-the-slope fluxes of turbulent momentum  $\overline{uw}$  and sediment concentration  $\overline{cw}$ .

### Boussinesq viscosity model

In Boussinesq viscosity models, the turbulent fluxes are expressed in terms of the mean flow gradients and some specified diffusivity. The results to be reported here are obtained with the use of the well known ( $k$ - $\epsilon$ ) model. Dynamic equations are solved for the turbulent kinetic energy  $k$  and the rate of dissipation  $\epsilon$  of turbulent kinetic energy:

$$\frac{\partial k}{\partial t} = \frac{\partial}{\partial z} \left( \frac{\nu_T}{\sigma_k} \frac{\partial k}{\partial z} \right) + P + G - \epsilon, \quad (3)$$

$$\frac{\partial \epsilon}{\partial t} = \frac{\partial}{\partial z} \left( \frac{\nu_T}{\sigma_\epsilon} \frac{\partial \epsilon}{\partial z} \right) + \frac{\epsilon}{k} (C_{\epsilon 1} P + C_{\epsilon 3} G - C_{\epsilon 2} \epsilon). \quad (4)$$

The fluxes are expressed in terms of  $k$ ,  $\epsilon$  and the mean flow gradients as

$$-\overline{uw} = \nu_T \frac{\partial U}{\partial z}, \quad -\overline{cw} = \frac{\nu_T}{\sigma_c} \frac{\partial C}{\partial z}. \quad (5)$$

The diffusivity  $\nu_T$  (often termed the eddy viscosity) is expressed as  $\nu_T = C_\mu k^2/\epsilon$ . The coefficients of the model are  $(C_\mu, C_{\epsilon 1}, C_{\epsilon 2}, C_{\epsilon 3}, \sigma_c, \sigma_k, \sigma_\epsilon) = (0.09, 1.44, 1.92, 0, 1.0, 1.0, 1.22)$ . Further details of this model is given in (Eidsvik and Brørs, 1989) and (Brørs, 1991).

### Reynolds stress model

In Reynolds stress models, dynamic equations are solved for  $\overline{uw}$  and  $\overline{cw}$ , and there is no need for an eddy viscosity. However, several additional unknowns emerge in the Reynolds averaging process. It is the Reynolds normal stresses  $\overline{u^2}$ ,  $\overline{v^2}$ ,  $\overline{w^2}$ , the concentration flux  $\overline{cw}$  and the variance of the concentration fluctuations,  $\overline{c^2}$ . With the  $\epsilon$  equation, this adds up to an eight equation model:

$$\begin{aligned} \frac{\partial \overline{u^2}}{\partial t} &= \frac{\partial}{\partial z} \left( C_s \overline{w^2} \frac{k}{\epsilon} \frac{\partial \overline{u^2}}{\partial z} \right) - \frac{\epsilon}{k} \left( C_1 (\overline{u^2} - \frac{2}{3} k) - C'_1 f \overline{w^2} \right) \\ &\quad - \left( 2 - \frac{4}{3} C_2 + \frac{2}{3} C_2 C'_2 f \right) \overline{uw} \frac{\partial U}{\partial z} + \left( 2 - \frac{4}{3} C_3 + \frac{2}{3} C_3 C'_3 f \right) \overline{cw} g' \sin \beta \\ &\quad - \left( \frac{2}{3} C_3 - \frac{4}{3} C_3 C'_3 f \right) \overline{cw} g' \cos \beta - \frac{2}{3} \epsilon, \end{aligned} \quad (6)$$

$$\begin{aligned} \frac{\partial \overline{v^2}}{\partial t} &= \frac{\partial}{\partial z} \left( C_s \overline{w^2} \frac{k}{\epsilon} \frac{\partial \overline{v^2}}{\partial z} \right) - \frac{\epsilon}{k} \left( C_1 (\overline{v^2} - \frac{2}{3} k) - C'_1 f \overline{w^2} \right) \\ &\quad - \left( \frac{2}{3} C_2 + \frac{2}{3} C_2 C'_2 f \right) \overline{uw} \frac{\partial U}{\partial z} + \left( \frac{2}{3} C_3 + \frac{2}{3} C_3 C'_3 f \right) \overline{cw} g' \sin \beta \\ &\quad - \left( \frac{2}{3} C_3 - \frac{4}{3} C_3 C'_3 f \right) \overline{cw} g' \cos \beta - \frac{2}{3} \epsilon, \end{aligned} \quad (7)$$

$$\begin{aligned} \frac{\partial \overline{w^2}}{\partial t} &= \frac{\partial}{\partial z} \left( C_s \overline{w^2} \frac{k}{\varepsilon} \frac{\partial \overline{w^2}}{\partial z} \right) - \frac{\varepsilon}{k} \left( C_1 (\overline{w^2} - \frac{2}{3} k) + 2 C_1' f \overline{w^2} \right) \\ &\quad - \left( \frac{2}{3} C_2 - \frac{4}{3} C_2 C_2' f \right) \overline{w w} \frac{\partial U}{\partial z} + \left( \frac{2}{3} C_3 - \frac{4}{3} C_3 C_3' f \right) \overline{c u} g' \sin \beta \\ &\quad - \left( 2 - \frac{4}{3} C_3 + \frac{8}{3} C_3 C_3' f \right) \overline{c w} g' \cos \beta - \frac{2}{3} \varepsilon, \end{aligned} \tag{8}$$

$$\begin{aligned} \frac{\partial \overline{w w}}{\partial t} &= \frac{\partial}{\partial z} \left( C_s \overline{w^2} \frac{k}{\varepsilon} \frac{\partial \overline{w w}}{\partial z} \right) - \frac{\varepsilon}{k} \left( C_1 + \frac{3}{2} C_1' f \right) \overline{w w} \\ &\quad - \left( 1 - C_2 + \frac{3}{2} C_2 C_2' f \right) \overline{w^2} \frac{\partial U}{\partial z} + \left( 1 - C_3 + \frac{3}{2} C_3 C_3' f \right) \overline{c w} g' \sin \beta \\ &\quad - \left( 1 - C_3 + \frac{3}{2} C_3 C_3' f \right) \overline{c u} g' \cos \beta, \end{aligned} \tag{9}$$

The closed equations for the scalar fluxes and half the variance of the scalar fluctuations are:

$$\begin{aligned} \frac{\partial \overline{c u}}{\partial t} &= \frac{\partial}{\partial z} \left( C_{cs} \overline{w^2} \frac{k}{\varepsilon} \frac{\partial \overline{c u}}{\partial z} \right) - \overline{w w} \frac{\partial C}{\partial z} - \frac{\varepsilon}{k} C_{c1} \overline{c u} - (1 - C_{c2}) \overline{c w} \frac{\partial U}{\partial z} \\ &\quad + (1 - C_{c3}) \overline{c^2} g' \sin \beta, \end{aligned} \tag{10}$$

$$\begin{aligned} \frac{\partial \overline{c w}}{\partial t} &= \frac{\partial}{\partial z} \left( C_{cs} \overline{w^2} \frac{k}{\varepsilon} \frac{\partial \overline{c w}}{\partial z} \right) - \overline{w^2} \frac{\partial C}{\partial z} - \frac{\varepsilon}{k} (C_{c1} + C_{c1}' f) \overline{c w} \\ &\quad - (1 - C_{c3} + C_{c3} C_{c3}' f) \overline{c^2} g' \cos \beta, \end{aligned} \tag{11}$$

$$\frac{\partial \frac{1}{2} \overline{c^2}}{\partial t} = \frac{\partial}{\partial z} \left( C_c \overline{w^2} \frac{k}{\varepsilon} \frac{\partial \frac{1}{2} \overline{c^2}}{\partial z} \right) - \overline{c w} \frac{\partial C}{\partial z} - \varepsilon_c. \tag{12}$$

The model equation for turbulence energy dissipation is

$$\frac{\partial \varepsilon}{\partial t} = \frac{\partial}{\partial z} \left( C_\varepsilon \overline{w^2} \frac{k}{\varepsilon} \frac{\partial \varepsilon}{\partial z} \right) + \frac{\varepsilon}{k} (C_{\varepsilon 1} P - C_{\varepsilon 2} \varepsilon + C_{\varepsilon 3} \max(0, G)). \tag{13}$$

The dissipation of scalar variance is approximated from an assumed constant ratio  $R$  between the scalar and dynamic turbulent time scales:

$$\varepsilon_c = \frac{1}{2R} \frac{\varepsilon}{k} \overline{c^2}. \tag{14}$$

In the equations,  $P$  and  $G$  denote the generation rate of turbulent kinetic energy by the mean velocity gradient and by gravitational effects:

$$P = -\overline{w w} \frac{\partial U}{\partial z}, \tag{15}$$

$$G = \overline{cu} g' \sin \beta - \overline{cw} g' \cos \beta. \quad (16)$$

The function  $f$  is a damping function for the wall echo effect on the pressure strain correlations. It is normalized to a value of one near the wall and is expressed by the turbulent length scale  $\ell$ :

$$f \propto \left(\frac{\ell}{z}\right), \quad \ell \equiv \frac{k^{\frac{3}{2}}}{\varepsilon}. \quad (17)$$

The present model is equivalent to the one presented by Gibson and Launder (1977) and the same set of coefficients is used. Further details are given in Brørs (1991) and Brørs and Eidsvik (1992). The model takes into account the proximity or "echo" effect of the bottom on the turbulent stresses. All coefficients with primes in equations (6) to (13) indicate terms with this purpose.

## RESULTS

The two-equation ( $k$ - $\varepsilon$ ) model predicts phase plane behaviour in accordance with results from theoretical work reported in the literature, and with limits for auto-suspension within the range of conventional estimates (Eidsvik and Brørs, 1989). However, by its design, this model and simpler gradient diffusion models are unable to produce turbulent diffusion of sediments through the level of the velocity maximum. This feature is considered to be important for the development of turbidity currents, and should be reproduced by a proper model. Modifications of the ( $k$ - $\varepsilon$ ) model with algebraic stress models and algebraic length-scale expressions are made but do not solve this problem. Use of second-moment Reynolds stress turbulence closure (Brørs, 1991, Brørs and Eidsvik, 1992) proves to overcome the problem of vanishing turbulent diffusivity in the velocity maximum, and plausible results for vertical distribution of flow parameters in turbidity currents are obtained. Predictions with the full, eight-equation Reynolds stress model mentioned here compare favourably with available data for this type of flow.

Figure 2 (a) and (b) shows predicted normal-to-the-slope profiles for a turbidity current on a  $\beta = 0.05$  radians slope. The flow has been allowed to develop for  $t = 320$  seconds, from a 0.3 m high stationary cloud. The sediment grain diameter is 50  $\mu\text{m}$  and the settling velocity is 0.15 cm/s. The initial concentration is  $C = 0.3$ . At the time shown, the flow has reached a height of about 7 m. The ( $k$ - $\varepsilon$ ) and Reynolds stress models are seen to produce nominally nearly identical velocities, although the former predicts a very pointed velocity maximum. The Reynolds stress model predicts a fuller  $C$  profile.

The turbulent kinetic energy  $k$  and eddy viscosity  $\nu_T$  are shown in Figure 2 (c) and (d). For the Reynolds stress model, an eddy viscosity is back-calculated from the prediction using the expression  $\nu_T = C_\mu \overline{w^2} k / \varepsilon$ , with  $C_\mu$  being a constant equal to 0.263 and  $\overline{w^2}$  the variance of the velocity fluctuations normal to the slope. The dashed line shows the  $\nu_T$  profile for the ( $k$ - $\varepsilon$ ) model. The eddy viscosity is seen to be zero at the level ( $z \sim 0.2$  m) of the mean velocity maximum. Here, the turbulence energy production  $P = \nu_T (\partial U / \partial z)^2$  in (3) is zero. The velocity

minimum inhibits the transport of sediments to the outer part of the flow, and a strong density gradient is created at this level. The steep density gradient causes a large negative value for the bouyancy production term  $G = g'(\nu_T/\sigma_c)(\partial C/\partial z)$ . This reduces  $k$  further, it eventually approaches zero, and so does  $\nu_T$ .

In zero-equation models it is usual to omit the problem by using a so-called "linear bridge", that is by exchanging the portion around the minimum of the  $\nu_T$  profile with a straight line connecting the maxima on either side. An approach like this has been applied on the present ( $k$ - $\epsilon$ ) model, both to  $\nu_T$  and to  $k$ . The dashed-dotted lines in Figure 2 show predicted profiles when the dip in the  $k$  profile is replaced with a value 0.15 times the near-bottom  $k$  maximum value. Although the  $k$  bridge is seen to give  $U$  and  $C$  profile shapes similar to those produced by the full Reynolds stress model, it causes a large (about 50% for the velocity) nominal increase in the values. This could possibly be corrected by changing the model coefficients, although this has not been attempted.

Figure 3 shows a prediction of one of the laboratory saline gravity currents of Ellison and Turner (1959). The profiles are normalized, and  $z_{1/2}$  is the level in the outer layer where the velocity is reduced to one half the profile maximum  $U_m$ . The Reynolds stress model is seen to be superior to the ( $k$ - $\epsilon$ ) model in representing this experiment.

Figure 2: Predicted profiles for self-accelerating turbidity current. Full line; Reynolds stress model, dashed line;  $(k-\epsilon)$  model, dashed-dotted line;  $(k-\epsilon)$  model with bridge across the  $k$  profile dip.

Figure 3: Predicted mean flow profiles for saline gravity current. Symbols represent laboratory experiments by Ellison and Turner (1959). Line types as in Figure 2. The slope is  $\beta = 0.24$  radians.

## CHAPTER 150

### CROSS-SHORE TRANSPORT MODELLING IN TERMS OF SEDIMENT CONCENTRATIONS AND VELOCITIES

Zhiwen Chen<sup>1</sup>

#### ABSTRACT

The fluctuations of sediment concentration and velocity during a wave period may play an important role in cross-shore sediment transport. In this study, the contribution of the fluctuations was estimated by measuring time-varying sediment concentration and velocity under laboratory conditions. The results showed that the contribution can only be neglected if the mean flow is relatively strong compared to the wave orbital motion.

#### 1. INTRODUCTION

The phenomenon of cross-shore transport has been widely investigated for a long time. The solution of many real life problems relies on a proper description of the cross-shore transport mechanism [e.g., beach and dune erosion during storm surges; beach profile response to global sea level rise]. Many beach evolution models start by calculating the cross-shore transport distribution along a beach profile.

The cross-shore transport rate through a vertical plane with unit width can be

---

<sup>1</sup> Assistant researcher, Dept. of Civil Engineering, Delft University of Technology, Stevinweg 1, 2600 GA, Delft, The Netherlands.

expressed in principle by:

$$q = \int_0^{h+\eta} \overline{u(z,t) * c(z,t)} dz \quad (1)$$

Where:

- $q$  : cross-shore transport rate, [kg/ms]  
 $u(z,t)$  : instantaneous cross-shore velocity at level  $z$ , [m/s]  
 $c(z,t)$  : instantaneous sediment concentration at level  $z$ , [kg/m<sup>3</sup>]  
 $h$  : water depth, [m]  
 $\eta$  : maximum water surface elevation, [m]  
 $z$  : elevation above the bed level, [ $z = 0$  at the bottom], [m]  
 $t$  : time, [s]  
 overline : time-average

Eq.(1) offers a proper description of cross-shore transport. However, the direct use of Eq.(1) has been proved very difficult because of our entirely insufficient knowledge of the parameters  $u(z,t)$  and  $c(z,t)$ . This holds especially inside the surf zone, the most active part of a beach profile. For this reason, coastal engineers in the past have often used more or less integral approaches to calculate cross-shore transport [e.g., Swart (1974) and Dean (1982)].

Recent models for cross-shore transport have attempted to consider a greater degree of detail in the internal mechanism of cross-shore transport [i.e., velocity multiplied by concentration]. For example, those of Bowen (1980) and Bailard (1981) estimated cross-shore transport on the basis of velocity fluctuations alone, indicating that some function of velocity fluctuations is used as a model for concentration variations; those of Stive and Battjes (1984) and Steetzel (1990) calculated cross-shore transport from the product of time-averaged velocities  $\overline{u}(z)$ , and time-averaged concentrations  $\overline{c}(z)$ , by assuming that sediment transport due to the fluctuations of concentration and velocity is negligible. In the latter case,  $\overline{u(z,t) * c(z,t)}$  can be approximated by  $\overline{u}(z) * \overline{c}(z)$ . The aim of this paper is to study some fundamental aspects of cross-shore transport modelling in terms of sediment concentrations and velocities, with an emphasis on:

- The temporal behaviour of sediment concentration under waves and a current on an intra-wave scale.

- The relative importance of the fluctuations of sediment concentration and velocity in cross-shore transport.

A description of the experiments is given in Chapter 2. The experimental results are presented in Chapter 3. Conclusions of this study are given in Chapter 4.

## 2. EXPERIMENTAL SET-UP

The experiments for this study were performed in a small-scale wave flume in the Hydromechanics Laboratory of the Civil Engineering Department of the Delft University of Technology. Regular waves were generated in the flume. A current, directed against the wave propagation, was superimposed on the waves in order to 'simulate' a return flow as caused by wave breaking under field conditions. Measurements of local time-varying sediment concentration and velocity were obtained using an optical concentration meter (OPCON) and an electro-magnetic flow meter (EMS) at a number of elevations above the bottom. The experiments were conducted first over a fixed bed and then over a sandy bed. Five tests were carried out, three under waves and a current and two under waves only.

In the fixed bed tests, artificial triangular ripples were used over the horizontal flume bottom. The ripple height was 20 mm and the ripple length was 80 mm. The measuring cross-section was located in the middle of the flume. During the tests, sediment was fed constantly upstream of the measuring cross-section. The increase in the volume of sediment downstream of the measuring cross-section was measured during a test to check whether a 'steady' sediment transport condition was achieved. A 'steady' condition was required because it took a rather long time to perform the velocity and concentration measurements at many elevations over the water depth. It was found that the transport rate kept approximately constant.

In the sandy bed tests, the middle part of the flume was filled with sand. No sand feeding was applied. The bed level change during a test was measured. Consequently, the net sediment transport rate through the measuring cross-section was computed.

The main characteristics of the tests are listed in Table 1.

test	condition	$H$	$T$	$h$	$\bar{u}$	$\eta$	$\lambda$	$D_{50}$
A	w+c, fixed bed	0.065	1.76	0.25	-0.08	0.02	0.08	0.18
B	w+c, fixed bed	0.065	1.76	0.25	-0.08	0.02	0.16	0.20
C	w, fixed bed	0.065	1.76	0.25	0	0.02	0.08	0.20
D	w+c, sandy bed	0.065	1.76	0.25	-0.08	0.01	0.07	0.20
E	w, sandy bed	0.065	1.76	0.25	0	0.01	0.07	0.20

**Table 1** Characteristics of the tests

Where:

w+c : under waves with a current

w : under waves only

$H$  : wave height, [m]

$T$  : wave period, [s]

$h$  : water depth, [m]

$\eta$  : ripple height, [m]

$\lambda$  : ripple length, [m]

$\bar{u}$  : depth-averaged current velocity, [m/s]

$D_{50}$  : diameter, 50% by weight is finer, [mm]

### 3. RESULTS

#### 3.1 THEORETICAL CONSIDERATIONS

If a periodic water motion is assumed, the velocity and concentration at height  $z$  above the bed in a wave period can be described as:

$$u(t) = \bar{u} + u_1 \cos(\omega t - \alpha_1) + u_2 \cos(2\omega t - \alpha_2) + \dots \quad (2)$$

$$c(t) = \bar{c} + c_1 \cos(\omega t - \beta_1) + c_2 \cos(2\omega t - \beta_2) + \dots \quad (3)$$

Where:

$u_n, c_n$  : amplitudes of the harmonic components  
 $\alpha_n, \beta_n$  : phase angles of the harmonic components  
 $\omega$  : wave frequency, [s<sup>-1</sup>]

The sediment transport at height  $z$  is then given by:

$$\overline{u(t) * c(t)} = \bar{u} * \bar{c} + \frac{1}{2} u_1 c_1 \cos(\beta_1 - \alpha_1) + \frac{1}{2} u_2 c_2 \cos(\beta_2 - \alpha_2) + \dots \quad (4)$$

The total cross-shore transport can be found by integrating Eq.(4) over the water depth. As shown in Eq.(4), the transport rate can be decomposed into a number of components. The  $\bar{u} * \bar{c}$  term represents the contribution due to the mean flow. The sum of the other terms on the right hand side of Eq.(4) represents the contribution due to the fluctuations.

Under wave action, large  $u_1$  and  $c_2$  components can be expected. Due to wave asymmetry, the  $u_2$  component usually has a large magnitude. Till it can be proved that the  $c_1$  component is very small or that  $\beta_1 - \alpha_1$  is in the order of 90° [similar remarks can be made to the third and higher terms in the right hand side of Eq.(4)], one has to be very careful in neglecting the contribution due to the fluctuations.

## 3.2 TEST RESULTS

Some preliminary results were described by Chen and Van de Graaff (1991). A more extensive description is given below.

### Temporal Behaviour of Sediment Concentration

The measured time-varying sediment concentration and velocity data were first used to study the temporal behaviour of sediment concentration in a wave period. The test results showed that the concentration at a point varies strongly in time

at the wave cycle scale. The concentration fluctuations do not repeat in time from one wave period to another. This means that the concentration fluctuations consist of a periodic component and a random component. [However, the random components are of little importance to the net sediment transport, as will be further discussed below].

An example of the periodic fluctuations of sediment concentration, measured over the ripple crest in Test A, is given in Fig.1,

**Fig.1** Velocity and concentration in a wave period [measured over ripple crest, Test A]

As shown, near the bed, three concentration peaks can be found in a wave period. Two are related to the vertical ejections of the high concentration clouds departing from the ripple crest when the flow reverses. The other one is due to the wave orbital motion which carries the high concentration at the flow reversal horizontally from a ripple crest to the neighboring one. In the upper column of the water depth, the concentration fluctuations become insignificant.

The test results under other conditions showed that the time-variations of sediment concentration in a wave period depend very much on the local bed geometry and local flow conditions. A mathematical description is very difficult. This implies that the cross-shore transport modelling based on the separate

descriptions of velocity and concentration as a function of time cannot be accomplished at this stage. In the following discussion, only the product of velocity and concentration [i.e., sediment transport rate] will be considered. Emphasis will be placed on the relative roles played by different forcing agents in sediment transport, especially the mean flow versus the fluctuations.

## Sediment Transport Due to Mean Flow and Fluctuations

**Role of the random components:** The measured time-varying sediment concentration and velocity data were decomposed into period components and random components. It was found from the results that the random components, though relatively large compared to the periodic fluctuations, do not contribute much to the sediment transport.

**Role of the higher harmonic components:** With the periodic fluctuating components, harmonic components were calculated with Eq.(2) and Eq.(3). Consequently, the transport due to each harmonic component was calculated with Eq.(4). The calculation results showed that the harmonic components with a frequency higher than  $2\omega$  together with the random components contribute less than 5% of the total transport.

**Role of the first and second harmonic components:** The transport contributions due to these components, as indicated in Eq.(4), depend on the amplitudes of the harmonic components the phase differences. The test results showed that the  $c_1$  and  $c_2$  components at a level are not small compared to the  $\bar{c}$  component at the level. Since  $u_1$  and  $u_2$  are larger than  $\bar{u}$ , the magnitude of  $\frac{1}{2}u_1c_1$  and  $\frac{1}{2}u_2c_2$  is not negligible compared to with  $\bar{u}\bar{c}$  [see Fig.2]. This implies that the phase differences may play an important role in the resulting sediment transport.

It was found that significant phase lags occur between the concentration and velocity fluctuations. The distributions of the phase lag over the water depth exhibit, in some cases, fairly distinct trends. The magnitude of  $\beta_1 - \alpha_1$  decreases with height above the bottom. Under waves with a relatively strong current, the  $\beta_1 - \alpha_1$  values are approximately  $90^\circ$  close to the bottom, suggesting that the transport due to the  $u_1$  component close to the bottom is small. Under waves alone, the  $\beta_1 - \alpha_1$  values close to the bottom increase [order of magnitude over

100°], resulting in an increase in the transport due to the  $u_1$  component, see Fig.3.

Taking both the contributions of the  $u_1$  and  $u_2$  components into account, the sediment transport due to the fluctuations was determined. The test results showed that the transport due to the fluctuations relative to that due to the mean flow may vary over the water depth, both in magnitude and direction. In general, both transports at a level are in the same order. Under the specific wave conditions for this study, the transport due to the fluctuations and due to the mean are in the same direction close to the bottom and in opposite direction in the upper column of the water depth. Therefore, in some cases, the depth-integrated transport due to the fluctuations may be negligible compared to the transport due to the mean flow, even though both transports may be well-matched in magnitude at a specific level above the bed.

**Role of the mean flow:** It appeared from the test results that an increase in the magnitude of the current velocity may alter the relative contributions due to the fluctuations and due to the mean flow [see also Fig.4 and Fig.5, a negative value means that the transport is opposite to the direction of the mean flow]. If the mean flow is relatively weak, both contributions are of the same order of magnitude. If the mean flow becomes strong, the transport by the mean flow may play a dominant role, in that case, the transport due to the fluctuations may be neglected.

#### 4. CONCLUSIONS

The test results indicate that, in general, the contribution due to the fluctuations of velocity and concentration should be considered in cross-shore transport calculations. However, under some specific conditions - for example, in a surf zone where the mean flow may be strong due to wave breaking - the contribution of the fluctuations may be neglected as a first order of approximation.

## CHAPTER 151

### EVOLUTION OF A BEACH WITH AND WITHOUT A SUBMERGED BREAKWATER: EXPERIMENTAL INVESTIGATION

G. Chiaia, L. Damiani, A. Petrillo\*

#### Abstract

In the present report experimental results about the efficiency of a submerged structure are presented. The experiment, carried out with random waves, covered about 2500 hours until equilibrium profile was reached. The most significant results are the good behaviour of the tested breakwater as a sand holding structure and its slowing effect produced on the shoreline backing, whereas the final position of the shoreline was nearly the same with and without breakwater.

#### 1. INTRODUCTION

In coastal areas where tide excursions are limited, submerged breakwaters can be used to protect the beaches from the strong eroding wave action. This choice mostly depends on the better water exchange between the inner and outer zones of the submerged breakwater, which reduces the waterlogging area. Moreover it doesn't disfigure the seascape and allows to better enjoying the beach for all touristic activities, unlike emerged structures. Submerged breakwaters are also used to protect beach nourishment works. Many Italian researchers are involved in the study of this kind of structures (Aminti et al., 1983; Lamberti et al., 1981; Lamberti et al., 1984). This paper presents an experimental investigation about the cross-shore evolution of an unprotected beach subjected to random waves, as compared to the evolution of the same beach, protected by a submerged breakwater.

Trials showed significant results about the long-term evolution of a beach under the action of different wave attacks, and about the behaviour of each attack.

## 2. EXPERIMENTAL SET-UP

Tests were performed in the wave channel of the Hydraulics and Hydraulic Constructions Institute of Bari Polytechnic. The channel is about 45 m long, 1 m wide and 1.2 m high (fig. 1). It was longitudinally divided into two equal parts by a thin glass wall, in order to simulate an unprotected beach on the first half of the channel and a protected beach with a submerged breakwater on the other half. Eighty gauging cross-sections, numbered from the shoreline to the wave generator paddle are located along the channel. The wave maker consists of a flat paddle which receives a rotatory-translational motion through a kinematic mechanism, able to reproduce any kind of waves.

Figure 1. Experimental channel.

A beach of the Middle Adriatic coast was reproduced in the channel, in Froude Number similitude with undistorted 1:10 scale. The channel bottom is covered with a sandy layer of a pretty uniform size with  $d_{50} = 0.15 \text{ mm}$ , and fall velocity  $w = 0.018 \text{ ms}^{-1}$ . The mean water level in the channel was kept constant during the tests and the depth near the paddle was equal to 0.80 m.

Five wave attacks were chosen to simulate the sea wave conditions; they were characterized by JONSWAP energy density spectra with  $\gamma = 3.3$  and  $w = 0.07$  for  $f < f_p$  and  $w = 0.09$  for  $f > f_p$ . The wave attack characteristics, near the paddle, and their duration are reported in Table 1.

In the trials the attacks were grouped in a six-storm cycle with sequence 1-2-3-1-4-5 to simulate different energy sea conditions. The duration of the two attacks number 1 of the cycle was assumed equal to half the time reported in Table 1. The experiment covered 17 cycles over about 2400 hours, when the equilibrium profile was reached in both sides of the channel.

<i>ATTACK</i>	$m_o$ [ $m * 10^{-4}$ ]	$f_p$ [ $s^{-1}$ ]	$t$ [ $h$ ]
1	3.0	0.63	88.0
2	15.5	0.47	12.5
3	6.0	0.47	32.2
4	30.5	0.38	5.5
5	15.0	0.38	11.2

Table 1. Wave attack characteristics and their duration.

Figure 2. Tested submerged breakwater.

On the left side of the channel the submerged breakwater was located between sections 36 and 41; this position, with the characteristics of the selected wave attacks, is just outside the breaking zone and only the highest waves of attack n. 4 break offshore the structure. The breakwater face slope is about 1/1.5 and the submergency ( $h/d$ ) is 0.17 (fig. 2).

The first results of the here presented trials were already discussed in previous papers (Lamberti et al., 1985; Chiaia et al., 1990).

### 3. PROFILE EVOLUTION IN THE LONG PERIOD

The starting profile (fig. 3) in the experiment was far from equilibrium so as to simulate an artificial filling action.

Figure 3. Comparison between protected and unprotected beach profiles.

Basically three constant slope zones may be observed: the first from section 70 to section 40 with  $1.8^\circ$  slope, the second between sections 40 and 13 with  $1.08^\circ$  slope and the third from section 13 to the shoreline with  $2.33^\circ$  slope. The zone close to the shoreline was concave with a maximum slope of about  $5^\circ$ . The initial profile, shown in figure 3, was obtained after the action of a low energy level wave attack, in order to simulate a sand compaction closer to reality.

Figure 4. Unprotected beach evolution.

Figure 5. Protected beach evolution.

The global evolution both in the protected and unprotected beach are reported in figures 4 and 5 in which the backing of shoreline and the formation and migration of bars are clearly shown in both configurations.

The efficiency of the tested submerged breakwater was firstly studied by comparing the profiles observed both on the unprotected and protected beach at the end of each wave attack. The beach profiles obtained at the end of some cycles are shown in next figures.

The behaviour of the two beach profiles starts becoming substantially different at the end of the first storm cycle (fig. 6). A notable offshore transport is observed in the unprotected beach resulting in a sharp backing of the shoreline and the formation of a bar.

Figure 6. Comparison between protected and unprotected beach profiles.

Sand transport is far less marked in the protected beach, although its characteristics are the same as in the unprotected one (shoreline backing and offshore transport). However, the action of the submerged breakwater in reducing the offshore transport is noticeable since the beginning.

Such a behaviour is clearly shown in fig. 7, in which the profiles at the end of the 4th cycle are reported.

Figure 7. Comparison between protected and unprotected beach profiles.

The surf-zone in the protected beach is, on the average, less deep if compared to the unprotected one and a deposit area forms just at the back of the breakwater which increases until equilibrium conditions are reached. This behaviour confirms the efficiency of the breakwater in reducing the offshore transport.

Figures 6 and 7 show an erosive trough at the toe of the structure which tends to become deeper and to stabilize when the equilibrium profile is reached. Most of the eroded material is deposited offshore forming a bar (sketched in figs. 6 and 7), and a part of it is found out, as indicated later on, in the surf-zone. This does confirm that, despite its selectivity, the breakwater allows onshore transport, under given conditions (Aminti, 1986).

For the unprotected beach, figures 6 and 7 show the formation of two bars; the offshore bar moves in deepwater direction till it reaches a stable position, thus defining the surf-zone width. As the surf-zone width becomes stable, the shoreline reaches a condition close to equilibrium, at about the 7th cycle, as shown in figure 4.

After the 7th cycle of attacks, in the protected beach a sharp deepening of the erosion trough is noticed (fig. 8), as observed in the previous cycles together with the formation of a well-defined bar which causes the breaking of the highest waves and thus a further erosion of the trough until equilibrium is reached.

Figure 8. Comparison between protected and unprotected beach profiles.

Starting erosion at the offshore toe of the structure can be mostly related to the back currents coming from the onshore zone. Indeed at the beginning of the experiments only few waves broke before reaching the structure. Therefore, wave breaking cannot be the major active mechanism in the trough formation.

Into the surf-zone of the protected beach a substantial flattening of the profile is observed, with a sharp backing of the shoreline tending to the same position as in the unprotected beach.

In the subsequent cycles (fig. 9) the re-alignment of the shoreline between the unprotected and protected beach, as well as the deepening of the erosion trough and the bar formation in the protected beach are more pronounced until a substantial equilibrium condition is reached.

Figure 9. Comparison between protected and unprotected beach profiles.

It was observed that the equilibrium profile of the unprotected beach in the onshore zone before the bars, may be interpreted by Dean's equilibrium profile (Dean, 1977):

$$h = a x^b \tag{1}$$

where  $h$  is the bottom depth in the section considered,  $x$  is the distance from this section to the shoreline and  $a$  is a parameter which, as shown experimentally, mainly depends on the sand beach particle-size (Moore, 1982). Assuming a constant energy dissipation per unit volume in the whole surf-zone, Dean obtained the law (1) theoretically with  $b = 2/3$ . In a beach with a particle-size characterized by  $d_{50} = 0.15\text{mm}$ , the same researcher (Kriebel et al., 1986) found an equilibrium profile which is well interpolated by the law  $h = 0.075 x^{2/3}$ .

Based on many laboratory and field experimental data, relating to beaches of different sand particle-size, Vellinga (1986) found that the law  $h = 0.35 w^{0.44} x^{0.78}$ , where  $w$  is the fall velocity, does well interpolate the onshore equilibrium profile for a wide range of particle-sizes. On the other hand, the same author disproves the constant dissipation assumption made by Dean, stating that coefficient  $b$  can have different values, especially when the sea state is variable and the profile is bar-shaped. Indeed, in the presence of bars, the onshore profile follows the experimental law (1) only in the proximity of the shoreline whereas, approaching the bar, depths tend to be first constant and then to decrease.

Our trials showed that till section 20 the profile is well interpolated by the law  $h = 0.125 x^{0.44}$  which is quite different from the one found by the previous authors on a beach with the same sand mean particle-size.

In figure 10 the unprotected beach profiles, observed in the last storm cycle, and the above indicated interpolation laws are reported; it may be observed that the equilibrium profile shows a greater erosion in the onshore area, near the shoreline.

Figure 10. Profiles measured after each wave attack of the last cycle and theoretical and interpolation laws for equilibrium profile.

The behaviour observed in our experimental results is in accordance with those found by other authors (Swart, 1974; Larson 1988), who tested bar-shaped beach profiles. In accordance with Vellinga, it may be stated that this behaviour, which deserves further attention, is to be attributed to the change in the dissipation mechanism in the surf-zone in the presence of a bar on the profile.

In order to evaluate the efficiency of the submerged breakwater under study, for all beach zones, some global parameters of the profile were introduced which enable assessing structure effects on emerged and submerged beaches.

#### 4. ANALYSIS OF BREAKWATER EFFICIENCY

##### 4.1 Shoreline Zone

The parameters selected to describe this area are the swash-zone slope and the shoreline position, both determined after each wave attack. As to the slope, the mean value observed in the first cycle of attacks (about  $8.5^\circ$ ) kept stable with some fluctuations ( $5^\circ \div 14^\circ$ ), due to the different action of single wave attacks; at the end of the trials, however, slope fluctuations in the swash-zone are reduced.

Figure 11. Evolution of swash-zones slope.

Figure 11 shows that, regardless of the type of beach profile considered, the beach slope in the swash-zone is basically affected by the characteristics of the wave attack it is subject to; it is indeed poorly influenced by transformations of waves in their transfer from offshore to the shoreline, although in the case of unprotected beach, slope values are generally a little higher and fluctuations are lower.

Experiments did confirm that the beach slope is inversely proportional to the wave attack energy, and its variations are very rapid; in fact, the slope observed after each storm is reached few minutes after the action of the attack.

The shoreline, at the end of trials, tends to reach more or less the same position both in the presence and in the absence of the breakwater (Fig. 12). Therefore, when the breakwater is used to reduce erosion of the emerged beach, it has no effectiveness in the long period, whereas it proves to be useful in slowing down its backing.

Figure 12. Evolution of shorelines position.

In fact, while in the unprotected beach equilibrium is achieved after about 600 hours, the protected beach needs a double time. The analysis of the action of each wave attack on the shoreline shows that attack 1 is reconstructive, attacks n. 2 and n. 4 are destructive whereas attacks n. 3 and n. 5 are characterized by an intermediate behaviour. These results were observed in both sides of the channel.

#### 4.2 Surf-Zone

Sand transport from the surf-zone to the outer zone of the breakwater was evaluated using the  $B_0$  parameter, i. e. the water volume contained between the breakwater and the first section of the channel, complementary to the sand volume.

Figure 13. Evolution of water volume contained in the first 40 sections of the channel.

Moreover, under equilibrium condition,  $B_0$  is decreasing in the protected beach, whereas in the unprotected beach, despite some fluctuations,  $B_0$  is constant.

This means that, in the unprotected beach, once the two bars have formed, sand displacements are moderate, because of the action of wave attacks which compensate each other within the cycle.

On the other hand, for the protected beach, although an equilibrium condition is reached in the emerged beach (see Sp and tg  $\beta$ ), a further evolution of the profile is observed in the onshore area. Indeed, due to the sand accumulation at the back of the breakwater, return currents cause an off-shore transport which goes on slowly even when the profile is substantially under equilibrium.

Figure 14. Evolution of integrals of the moments of depths respect to channel central section.

The behaviour of parameter  $A_1$  (integral of the moments of depths observed in each section with respect to the channel central section 40) (fig. 14) shows offshore sand displacement and does confirm the above interpretation of its evolution. Really it can be observed that also in the unprotected beach,  $A_1$  goes on decreasing until the end of tests, denoting a sand displacement inside the

The temporal evolution of  $B_0$ , evaluated assuming a negative depth, is reported in figure 13.

For the unprotected beach,  $B_0$  decreases sharply thus indicating an intensive sand flux offshore, whereas in the presence of the breakwater, sand transport is slower and less marked. The breakwater is clearly shown to be an effective holding structure.

During the trials it was observed that the breakwater under study acts as a filter also to the nourishment action of summer waves, but it allows some onshore transport by the highest waves which suspend the material offshore the breakwater, particularly at the start of experiment.

surf-zone.

An interesting indication is provided by parameter  $B_1$  (integral of moments of depths in the first 40 sections of the channel with respect to section 20). Fig. 15 shows that, for the unprotected beach it first decreases sharply and then it shows a fluctuating evolution (caused by the onshore bar displacements), whereas for the protected beach it decreases and, under equilibrium, tends to a constant value.

Figure 15. Evolution of integral of the moments of the first 40 section depths with respect to section 20.

This is due to the presence of a well formed deposit area, close to the breakwater, and to the achievement of a stable and flat configuration of the beach profile in the surf-zone.

### 4.3 Offshore Zone

By offshore zone we mean here the zone outside the breakwater which is not necessarily the outer zone of breaking waves; in fact, as previously indicated, under equilibrium conditions, both protected and unprotected beach profiles show a bar around section 53 which causes the breaking of the highest waves, thus dividing the surf-zone from the offshore zone.

Figure 16. Evolution of offshore bar location in unprotected beach.

The profile of the zone under consideration is indeed characterized by the presence of the bar and by an erosion trough at the toe of the breakwater.

The first difference observed between the protected and unprotected beach concerns the bar position.

Figures 4 and 5 show that, for the unprotected beach, the offshore bar does form initially around section 40 and then migrates offshore and gives a stable length to the surf-zone; on the other hand, the bar on the protected beach does start forming initially in a position close to the final one, without any notable displacement.

Figure 17. Evolution of offshore bar depth in unprotected beach.

Figure 18. Evolution of bar depth in protected beach.

Fig. 19 shows a good correlation between the pit deepening and the depth reduction on the bar.

This shows that one of the active mechanisms for the trough formation is the presence of the vortex (site of dissipation) produced by the breaking occurring on the bar. This mechanism is the same acting on the unprotected beach.

Figure 19. Evolution of depth of eroding trough at the offshore toe of the structure.

Figure 16 shows the offshore bar displacement on the unprotected beach along its evolution, whereas figure 17 reports the depth on the bar, taken as the difference between the initial and actual depth. The end position of the bar is comparable in both sides of the channel, while depth is higher in the case of the protected beach (Fig. 18).

This is due to the fact that the bar in the unprotected beach is formed with all the material eroded in the surf zone, while in the protected beach sand mostly comes from the trough.

Another parameter used to describe the offshore region is, as already mentioned, the erosion trough at the toe of the breakwater, whose genesis needs further studies.

In addition to the previously described mechanism, a contribution to the trough formation in the initial stage of trials is given by return currents as above mentioned.

However, it should be noted that, regardless of the causes which produce

erosion at the toe of the breakwater, the pit depth reaches a maximum equilibrium value so that, to prevent any failure in the foundation, either the bearing surface should go below that depth, or the breakwater should be displaced offshore.

## 5. CONCLUSIONS

Laboratory experimental results enabled assessing the efficiency of the tested submerged breakwater relating to the cross-shore transport action. Breakwater proved to be an excellent holding tool for the sand contained in the surf-zone, although it does not seem selective at all to offshore transport.

On the other hand, the protective action from erosion in the swash-zone is not equally effective; the presence of the breakwater did not reduce the backing of the shoreline which reached almost the same position both in protected and unprotected beach profiles. Nevertheless, it should be pointed out that the breakwater caused a notable slowing down of the wave eroding action on the emerged beach, in fact the time taken for equilibrium to be reached in the protected beach is double as compared to the unprotected one.

In the outer zone of breakwater, the configuration is similar both in the protected and unprotected beach (bar-trough conformation). Some interesting considerations can be drawn from the results relating to the erosion trough. Indeed, although the study on pit formation needs further research, it has been observed that it reaches a constant depth at equilibrium. Such a result can be helpfully used for design, in that the bearing surface of the structure should go below that level to prevent any subsidence which could jeopardize the breakwater stability.

Experimental results need being further processed so as to provide indications on the action of each wave attack and to understand the hydraulic behaviour of the breakwater through the study of the reflection, transmission and dissipation coefficients and the wave set-up in protected and unprotected beach profiles.

## CHAPTER 152

# Equilibrium Beach Profiles with Random Seas

Christopher G. Creed<sup>1</sup>, Robert A. Dalrymple\*  
David L. Kriebel<sup>2</sup>, James M. Kaihatu\*

### Abstract

Three quantitative equilibrium beach profiles models are presented for random wave fields. Two models follow the work of Larson where improvements to the spilling breaker assumption are made with spectral estimations of wave breaking. The third model is established by imposing a no-net sediment transport condition on Bailard's (1982) cross-shore sediment transport formulation. Modelling the flow field as in Roelvink and Stive (1989), an equilibrium solution is achieved which includes a longshore bar.

### Introduction

It has been observed that the beach profile shape is a function of the characteristics of the incident wave field. Dean (1977) examined a number of U.S. East and Gulf Coast beach profiles and found that the majority of the profiles could be described by the following simple equation:

$$h = Ax^m \quad (1)$$

where  $h(x)$  is the water depth and  $x$  is the offshore distance perpendicular to the shoreline. The value of  $m$  which best fit all of the data was 0.667, though  $m$  ranged between 0.1 and 1.4. Dean developed a theoretical justification for a value of  $m$  of  $2/3$ , based on the concept that the rate of energy dissipation per unit volume of fluid,  $\mathcal{D}_*$ , would be constant across the equilibrium beach profile.

$$\frac{d\mathcal{F}}{dx} = -\epsilon_b = -h\mathcal{D}_* \quad (2)$$

---

<sup>1</sup>Center for Applied Coastal Research, Department of Civil Engineering, University of Delaware, Newark, DE 19716

<sup>2</sup>Naval Systems Engineering Department, United States Naval Academy, Annapolis, MD 21402

where  $\mathcal{F}$  is the energy flux, defined as the energy per unit area times the group velocity of the waves,  $C_g (= \sqrt{gh}$  in shallow water), and  $\epsilon_b$  is the dissipation per unit surface area:

$$\mathcal{F} = \frac{1}{8} \rho g H^2 \sqrt{gh} \quad (3)$$

Assuming a spilling breaker ( $H = \kappa h$ , where  $\kappa \sim O(1)$ ), and substituting into Eqn. (2) results in an equation for  $h$ :

$$h(x) = Ax^{2/3} \quad (4)$$

This model, with its concave upwards shape, has proved to be useful in a number of coastal applications (Dean, 1991).

In this paper, several models for equilibrium profiles will be developed using different representations of the wave field. The first, developed by Larson (1988) for monochromatic waves, is extended to a random wave field. The second and third models are based on random breaking models by Thornton and Guza (1983), which were developed from field data taken from California beaches.

**Larson's (1988) Model**—Larson (1988) and Larson and Kraus (1989) replaced Dean's spilling breaker assumption with the breaking model of Dally *et al.* (1985):

$$\frac{d\mathcal{F}}{dx} = -\frac{K}{h} (\mathcal{F} - \mathcal{F}_s) \quad (5)$$

where  $\mathcal{F} = EC_g$ .  $K$  is an empirical constant equal to 0.17, and  $\mathcal{F}_s$  is the stable energy flux the wave field is trying to obtain.  $\mathcal{F}$  is based on a stable breaking wave height,  $H_s = \gamma h$ , where  $\gamma$  is a constant empirically determined to be 0.4. Equating this energy flux relationship to Dean's constant energy dissipation per unit volume yields the following equation for  $H$ :

$$H = \sqrt{\frac{8h^2 D_*}{\rho g \sqrt{gh} K} + \gamma^2 h^2} \quad (6)$$

which provides the wave height across the surf zone as a function of the profile depth,  $h$ . Substituting this into the energy flux equation, (2), leads to

$$2\frac{h}{K} + \frac{5}{24} \rho g^{3/2} \left( \frac{\gamma^2 h^{3/2}}{D_*} \right) = x \quad (7)$$

This equation, which relates the equilibrium water depth to the distance offshore, is best solved for the distance  $x$  in terms of  $h$ . Note the inclusion of a linear term which removes the infinite slope at the shoreline that occurs in Dean's model.

**Application of Random Wave Breaking**—To apply random waves to Larson's model, we first determine the breaker line location via the breaking depth,  $h_*$ .

At this depth, we assume that the breaking index is the correct predictor of breaking wave height.

$$H_b = \kappa h_* = \sqrt{\frac{8h_*^2 D_*}{\rho g \sqrt{g h_*} K} + \gamma^2 h_*^2} \quad (8)$$

from Eqn. 6. Solving for  $h_*$ , we have

$$h_* = \left( \frac{8D_*}{\rho g^{3/2} K (\kappa^2 - \gamma^2)} \right)^2 = \left( \frac{D_*}{\beta} \right)^2, \quad (9)$$

which defines the parameter,  $\beta$  for later use. Rearranging,

$$D_* = \frac{K}{8} \rho g \sqrt{g h_*} (\kappa^2 - \gamma^2) \quad (10)$$

which indicates that the magnitude of the constant energy dissipation/unit volume is dependent on the incident wave height (through  $h_*$ ).

From these expressions we can determine the width of an equilibrium surf zone. Denoting  $W_*$  as this width, we have, from Eqn. 7,

$$W_* = 2 \frac{h_*}{K} + \frac{5}{24} \rho g^{3/2} \left( \frac{\gamma^2 h_*^{3/2}}{D_*} \right) = 2 \frac{h_*}{K} \left[ 1 + \frac{5}{6} \left( \frac{\gamma^2}{\kappa^2 - \gamma^2} \right) \right] \quad (11)$$

By putting in the values of  $\kappa$  and  $\gamma$ , we have  $W_* = 15.0 h_* = 19.3 H_b$  for the equilibrium profile width.

The Larson model shows that the wave height distribution across the surf zone and the beach profile depends on  $\mathcal{D}_*$ , the volumetric dissipation, which in Eqn. 10 is shown to be related to the incident wave height (through the breaking depth). This development was for a single wave train; now we extend it to the case for an random wave field.

Given that the wave height probability distribution is a Rayleigh distribution and that the variables,  $H$ ,  $h_*$  and  $D_*$  are related, the probability density function for  $H$  can be related to those for  $h_*$  and  $D_*$  through a transformation, e.g.,

$$P(h_*) = P(H_*)|_{H_*=\kappa h_*} \frac{dH_*}{dh_*} = \frac{2\kappa^2 h_*}{H_{\text{rms}}^2} e^{-\left(\frac{\kappa^2 h_*^2}{H_{\text{rms}}^2}\right)} \quad (12)$$

Using (9), the probability distribution for  $D_*$  is found by

$$P(D_*) = P(h_*)|_{h_*=D_*^2/\beta^2} \frac{dh_*}{dD_*} = \frac{4\kappa^2 D_*^3}{\beta^4 H_{\text{rms}}^2} e^{-\left(\frac{\kappa^2 D_*^4}{\beta^4 H_{\text{rms}}^2}\right)} \quad (13)$$

with  $\beta$  defined by (9). To find the expected value of  $D_*$ , we integrate:

$$\bar{D}_* = \int_0^\infty D_* P(D_*) dD_* = \sqrt{\frac{\beta^2 H_{\text{rms}}}{\kappa}} \Gamma\left(\frac{5}{4}\right) = \frac{\kappa}{8} \rho g (\kappa^2 - \gamma^2) \sqrt{g h_*} \quad (14)$$

The last expression is similar to (10), except that *expected* values for  $h_*$  are used to find  $\bar{D}_*$ .

**Random Wave Dissipation Models**—A number of random wave breaking models have been developed. For example, Battjes and Janssen (1978) utilized the conservation of energy flux within the surf zone with dissipation determined from a random model of the breaking wave field (based on truncating the Rayleigh probability density function at the local breaking wave height) and a turbulent bore energy dissipation term to predict root-mean-square (or  $H_{rms}$ ) wave heights in the surf zone. This model was modified by Thornton and Guza (1983), who developed two empirical distributions of breaking wave heights within the surf zone: one with a simplified energy dissipation and another with a more accurate dissipation term. Substituting their breaking wave distribution into a bore dissipation model, they determined the expected dissipation of energy within the surf zone. Wave heights predicted from their models agreed with both field and laboratory data very well.

The energy flux wave model for normal wave incidence is given by Eqn. (2). The forms for dissipation term,  $\epsilon_b$ , from Thornton and Guza (1983) are

$$\text{Simple: } \epsilon_b = \frac{3\sqrt{\pi}}{16} \rho g \frac{B^3 \bar{f}}{\gamma^4 h^5} H_{rms}^7 \quad (15)$$

$$\text{Complete: } \epsilon_b = \frac{3\sqrt{\pi}}{16} \rho g \frac{B^3 \bar{f}}{\gamma^2 h^3} H_{rms}^5 \left[ 1 - \frac{1}{(1 + (H_{rms}/\gamma h)^2)^{5/2}} \right] \quad (16)$$

where  $B$  is an empirical constant smaller than unity,  $\bar{f}$  = frequency of the incident wave train, and  $\gamma = 0.42$ , the breaking index based on the assumption that  $H = 0.42 h$  for the inner surf zone.

**Simple EBP Model**—The first step in the simple random EBP model is to use righthand side of the energy equation (2) with the dissipation term (Eqn. 15):  $\epsilon_b = h\mathcal{D}_*$ . This yields a representation for  $H_{rms}$  after some rearranging:

$$H_{rms} = \left( \frac{\gamma^2 \mathcal{D}_*}{A} \right)^{1/7} h^{6/7} \text{ where } A = \frac{3\sqrt{\pi} \rho g B^3 \bar{f}}{16\gamma^2} \quad (17)$$

The equation for  $H_{rms}$  indicates that for equilibrium beaches under random waves the statistical wave height should vary nearly linearly with the water depth.

Substituting this relationship for  $H_{rms}$  into the left hand side of the energy flux relationship (Eqn. 2) allows the calculation of the water depth across the profile, after using the shallow water limit of  $C_g = \sqrt{gh}$ :

$$\frac{\rho g^{3/2}}{8} \left( \frac{\gamma^2 \mathcal{D}_*}{A} \right)^{2/7} \frac{d(h^{12/7} \sqrt{h})}{dx} = h\mathcal{D}_* \quad (18)$$

Simplifying and integrating with respect to the distance offshore,  $x$ , with the initial condition,  $h(x) = 0$ , at  $x = 0$ ,

$$h(x) = \beta x^{14/17} \text{ where } \beta = \left( \frac{136\mathcal{D}_*}{31\rho g^{3/2}} \left\{ \frac{A}{\gamma^2\mathcal{D}_*} \right\}^{2/7} \right)^{14/17} \quad (19)$$

Thus we have arrived at a simple model for the description of the equilibrium beach profile and the associated wave height distribution in closed form for a random sea state.

**Complete EBP Model**—The more inclusive model involves the complete expression for the energy dissipation term within the surf zone, given in Eqn. 16. Equating the dissipation terms, we have

$$h\mathcal{D}_* = \frac{AH_{\text{rms}}^5}{h^3} \left[ 1 - \frac{1}{(1 + (H_{\text{rms}}/\gamma h)^2)^{5/2}} \right] \quad (20)$$

This equation can not be readily solved for  $H_{\text{rms}}$ ; however, it is straightforward to use numerical techniques such as the Newton-Raphson method to obtain solutions. Note that the wave height will depend on parameters such as  $\mathcal{D}_*$  and  $h$ , but not explicitly on the distance offshore.

To find the profile, the energy flux expression (Eqn. 2) is used. It can be rearranged into:

$$\frac{1}{8}\rho g\sqrt{gh}H_{\text{rms}} \left( 2\frac{dH_{\text{rms}}}{dx} + \frac{H_{\text{rms}}}{2h}\frac{dh}{dx} \right) = h\mathcal{D}_* \quad (21)$$

Since  $H_{\text{rms}}$  does not depend explicitly on  $x$ , we use

$$\frac{dH_{\text{rms}}}{dx} = \frac{dH_{\text{rms}}}{dh} \frac{dh}{dx}$$

where the derivative of  $H_{\text{rms}}$  with respect to  $h$  is found from Eqn. 20. We therefore can rewrite the last equation as

$$\frac{dh}{dx} = \frac{8h\mathcal{D}_*}{\rho g\sqrt{gh}H \left( 2\frac{dH_{\text{rms}}}{dh} + \frac{H_{\text{rms}}}{2h} \right)} \quad (22)$$

This equation is integrated numerically to determine the variation of the depth across the equilibrium profile and, given the depth, the wave height is found from Eqn. 20.

**Results**—Figure 1 shows a comparison of the simple and complete equilibrium profile models to data obtained under the National Sediment Transport Study at Torrey Pines Beach, CA (reference). The values of  $B$  and  $\mathcal{D}_*$  are adjusted to

Figure 1: Equilibrium beach profile solutions for *simple* (dashed) and *complete* (dotted) dissipation models compared to wave and profile data. (Torrey Pines CA., November 18, 1978)

achieve the best fit to the wave height and profile data, respectively. As can be seen, both profile models adequately represent the data. The complete model is not a significant improvement over the simple model, suggesting that the analytical model is perhaps sufficient for describing a monotonic equilibrium beach profile under a random wave field.

## Generalized Equilibrium Beach Profile Model

The generalized equilibrium beach profile model (GEBP) is founded on the work of Bowen (1980) which is based on the concept of local time-averaged net sediment transport across the nearshore region. More specifically, the GEBP follows the work of Bailard (1981), who, like Bowen, used Stokes' second order wave theory and Longuet-Higgins' (1953) streaming velocities to model the wave-induced nearshore flow and the mean longshore current, respectively. However, both theories have shortcomings in the nearshore area. Stokes' wave theory is only valid for relatively deep water, and thus inapplicable for most nearshore wave conditions. Longuet-Higgins' streaming velocity solution assumes mean flows in the direction of wave propagation only, which is clearly not the case in the surf zone with undertow present. Thus it is the objective of this work to determine the effects of more accurate representations of the nearshore wave

and current climate to the equilibrium solution of Bailard's sediment transport expression. To do this, the method of Roelvink and Stive (1989), denoted as R&S, is adopted by modelling the asymmetric velocities with a Stream Function representation of the unbroken wave field and the mean current with an undertow model that establishes an offshore directed mean flow inside the surf zone. Here, for simplicity, the turbulent flow induced by wave breaking, which is modelled by R&S to improve the location of the maximum intensity of the undertow, is neglected. Further, only short wave contributions to the total odd moments will be considered and thus group-induced long-wave flows will be excluded.

The GEBP is developed assuming wave energy, mean water surface level and bottom depth are coupled through the energy, momentum and bottom slope equations, respectively. Variations in wave energy across the nearshore region for a random wave field are modelled following the work of Battjes and Stive (1985). The change in energy flux due to random wave breaking is equated to the time-averaged rate of energy dissipation per unit area,  $D$ , as

$$\frac{\partial EC_g}{\partial x} + D = 0, \quad (23)$$

The mean water surface elevation is modelled according to the momentum balance

$$\frac{\partial S_{xx}}{\partial x} + \rho gh \frac{\partial \bar{\eta}}{\partial x} = 0 \quad \text{where } h = d + \bar{\eta}. \quad (24)$$

The bottom slope equation is not as well established. Here we use the total load cross-shore sediment transport equation of Bailard (1982) to describe the interaction of near-bottom water velocities with the sediment in the nearshore region. The time-averaged form of the expression is

$$\langle \vec{i}_x \rangle = c_f \rho \left[ \frac{\varepsilon_b}{\tan \phi} \left[ \langle \vec{u} |\vec{u}|^2 \rangle - \frac{\tan \beta}{\tan \phi} \langle |\vec{u}|^3 \rangle \right] + \frac{\varepsilon_s}{w} \left[ \langle \vec{u} |\vec{u}|^3 \rangle - \frac{\varepsilon_s}{w} \tan \beta \langle |\vec{u}|^5 \rangle \right] \right] \quad (25)$$

where  $\tan \beta = -dd/dx$  is the bottom slope,  $\langle \vec{u} |\vec{u}|^2 \rangle$ ,  $\langle \vec{u} |\vec{u}|^3 \rangle$ ,  $\langle |\vec{u}|^3 \rangle$ ,  $\langle |\vec{u}|^5 \rangle$  are the total velocity moments in the cross-shore direction and the instantaneous, total cross-shore velocity vector is  $\vec{u}_i = (\tilde{u} + \bar{u})\hat{i}$ , where  $\tilde{u}$  is the time-varying velocity component,  $\bar{u}$  is the steady current component, and  $\hat{i}$  is the onshore unit vector.

The equilibrium condition and thus the bottom slope equation is found by applying the time-averaged no-net sediment transport condition ( $\langle \vec{i}_x \rangle = 0$ ) of Bowen (1980) to the sediment transport relationship where the bottom slope is expressed as

$$\tan \beta = \left[ \frac{\varepsilon_b}{\tan \phi} \langle \vec{u} |\vec{u}|^2 \rangle + \frac{\varepsilon_s}{w} \langle \vec{u} |\vec{u}|^3 \rangle \right] \left[ \frac{\varepsilon_b}{\tan^2 \phi} \langle |\vec{u}|^3 \rangle + \left( \frac{\varepsilon_s}{w} \right)^2 \langle |\vec{u}|^5 \rangle \right]^{-1} \quad (26)$$

This form of the bottom slope equation is most general because the total velocity moment terms are expressed in terms of the total bottom velocity,  $u$ . Following R&S, the total velocity moments are expanded and approximated in terms of the steady current,  $\bar{u}$  and a time varying current,  $\tilde{u}$ , where  $\tilde{u} \gg \bar{u}$ . This produces representations of the total velocity moments as combinations of the steady current, and central odd, ( $\langle \tilde{u} |\tilde{u}|^2 \rangle$  and  $\langle \tilde{u} |\tilde{u}|^3 \rangle$ ) and even ( $\langle |\tilde{u}|^3 \rangle$  and  $\langle |\tilde{u}|^5 \rangle$ ) moments as

$$\langle \bar{u} |\bar{u}|^2 \rangle = \langle \tilde{u} |\tilde{u}|^2 \rangle + 3\bar{u} \langle |\tilde{u}|^2 \rangle; \quad \langle \bar{u} |\bar{u}|^3 \rangle = \langle \tilde{u} |\tilde{u}|^3 \rangle + 4\bar{u} \langle |\tilde{u}|^3 \rangle \quad (27)$$

$$\langle |\bar{u}|^3 \rangle = \langle |\tilde{u}|^3 \rangle; \quad \langle |\bar{u}|^5 \rangle = \langle |\tilde{u}|^5 \rangle \quad (28)$$

Only the first terms of the total even moments are retained, assuming that wave asymmetry does not strongly contribute to these terms.

Approximating the odd moments with Stokes second order theory, the even moments with linear theory and the mean current with Longuet-Higgins' streaming velocity solution recovers Bailard's results. Building on these results, the following models for the wave and current fields will be applied to determine the effects of more accurate models to an equilibrium beach profile solution.

**Steady Current Component - Undertow Solution**— Across the nearshore region the mean cross-shore flow is known to move onshore outside the surf zone (where wave breaking is not prevalent) and offshore inside the surf zone. This dominant mean cross-shore flow inside the surf zone is the undertow. To model this transition in mean flow from onshore to offshore we follow Stive and de Vriend (1987), who model the mean flow across the nearshore area as a linear combination of the flow from the unbroken and broken fractions of the wave field across the surf zone. For the unbroken wave field, the Longuet-Higgins streaming velocity solution is applied. For the broken wave field, a three layer approach is adopted. This result provides a continuous solution for the mean current across the nearshore region different than that of a monochromatic breaking wave.

It is of interest to note that a change in the direction of the mean bottom velocity has been hypothesized (Dyhr-Nielsen and Sorensen 1970) to contribute to longshore bar formation. In support of this hypothesis, Dally (1987) observed that the dominant mechanism in the establishment of the longshore bar is the breaking induced mean return flow where, as wave breaking begins, the mean current changes from onshore to offshore. In light of this, the model of Stive and de Vriend seems to be a suitable mean flow model to establish one component of the probable flow conditions required to form a longshore bar in a beach profile.

**Central Odd and Even Velocity Moments**—From the expansion of the total time-averaged flow moments, the terms  $\langle \tilde{u} |\tilde{u}|^2 \rangle$  and  $\langle \tilde{u} |\tilde{u}|^3 \rangle$  are found to contribute to the representation of the total odd moments. As a first approximation,

the group-induced long wave flows are assumed to be negligible and thus we represent the time-averaged central, odd moments with only the short wave flows under nonlinear wave forms as

$$\langle \tilde{u} |\tilde{u}|^2 \rangle = (1 - Q_b) \langle u_s |u_s|^2 \rangle; \quad \langle \tilde{u} |\tilde{u}|^3 \rangle = (1 - Q_b) \langle u_s |u_s|^3 \rangle \quad (29)$$

where  $u_s$  is the bottom-velocity obtained from 6<sup>th</sup> order Stream Function theory. The contributions to the odd moments from the unbroken waves are represented by considering the fraction of waves breaking,  $Q_b$ . These expressions represent the unbroken short wave contributions to the central odd velocity moments. The input monochromatic wave height needed by Stream Function theory is approximated with the  $H_{rms}$  wave height from the breaking model.

The results of Guza and Thornton (1985) are adopted to model the even moments. The even moments  $\langle |\tilde{u}|^n \rangle$  are nonzero for symmetric wave forms and thus do not require the high order nonlinear wave solutions to produce contributions to the mean flows in the surf zone. For the case of a random wave field, Guza and Thornton suggest as a first approximation representing the wave field using a Gaussian description of the wave heights in the surf zone of a linear random sea.

**Model Summary**—The governing equations for the GEBP are the energy, momentum and bottom slope equations. These first order ordinary differential equations are solved numerically as a coupled initial value problem where initial wave height and water depth are given outside the surf zone.

**Results**—The input wave conditions are the deep water incident root-mean-squared wave height,  $H_{rms0}$ , the peak wave period,  $T_p$ . The mean water surface displacement,  $\bar{\eta}$ , is taken to be zero far offshore from the surf zone. The selection of the input depth,  $d$ , is arbitrary as long as wave breaking has not been initiated. Given the deep water incident wave conditions, the effective  $H_{rms}$  wave height,  $H_{rmsc}$ , is determined at the starting depth by linear shoaling theory.

As an example of the use of the GEBP, the 1981 average wave and profile data from the U.S. Army Corps of Engineers Field Research Facility (Miller *et al.* 1981) are used. The  $H_{rms}$  wave height is 1.02 m, the peak wave frequency,  $T_p$  is 10.0 sec and the starting depth is 20 m. The sediment fall velocity is assumed to be 0.04 cm/s and constant across the nearshore region. Bailard's (1981) bedload and suspended load sediment transport efficiency factors of  $\epsilon_b = 0.025$  and  $\epsilon_s = 0.01$ , respectively, are used. The internal angle of friction sand,  $\tan \phi$ , is taken as 0.63, the fluid density,  $\rho$ , is 1000 kg/m<sup>3</sup> and the gravitational acceleration,  $g$ , is 9.81 m/s<sup>2</sup>.

Figure 2a shows the results for the  $H_{rms}$  wave height across the equilibrium beach profile, where  $x$  is positive onshore. As the waves shoal, the  $H_{rms}$  wave height first increases up to a point where the percent of waves breaking is such that energy dissipation is more dominant than wave shoaling. At this point the

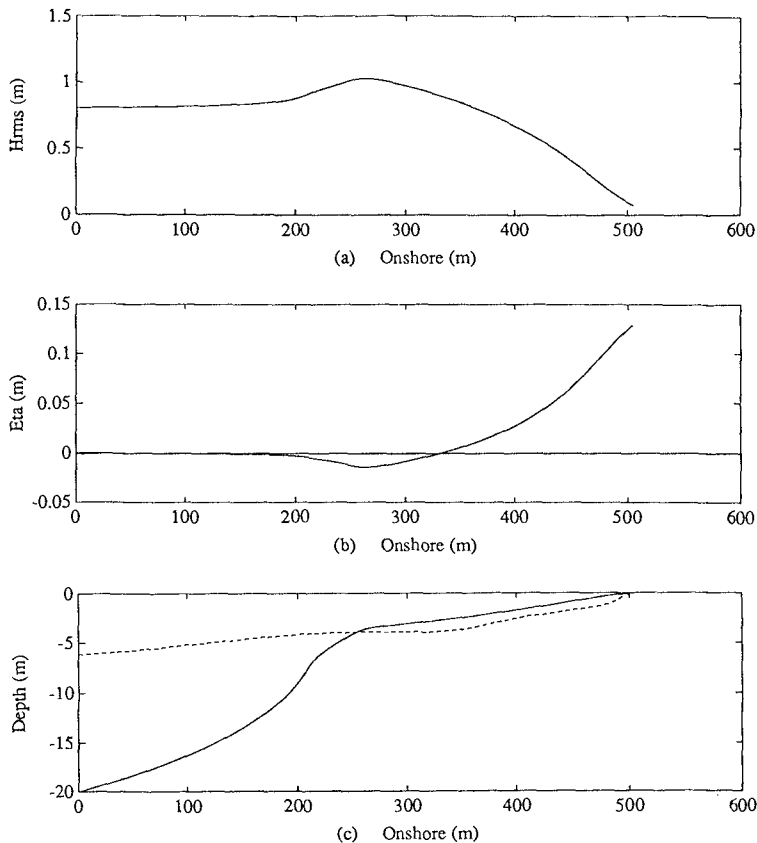

Figure 2: GEBP Solutions; (a)  $H_{rms}$ , (b)  $\bar{\eta}$ , (c)  $d$  (solid) and Mean Profile FRF (1981) (dashed)

$H_{rms}$  wave height will decrease until a stable water depth is reached for all waves or until all energy is dissipated from the waves at the shoreline.

Figure 2b shows the solution for the mean water surface,  $\bar{\eta}$ , across the equilibrium solution. It can be seen that set-down is most pronounced as the waves shoal to their maximum height and set-up increases as wave breaking intensifies.

Figure 2c shows the equilibrium beach profile as a function of onshore distance. The point of interest is the change in slope in the equilibrium solution between  $x = 200$  m and  $x = 250$  m where the slope changes from a steep offshore slope before breaking to a milder foreshore slope after breaking has initiated. This is the result of a change in the direction from onshore to offshore of the steady current,  $\bar{u}$ , as wave breaking dissipation increases with the decrease in depth. In figure 3, the resulting mean flow across the surf zone changes direction at approximately  $x = 200$  m. As seen in Eqn. 26, a change in the steady

Figure 3: Steady Current,  $\bar{u}$ , Across an Equilibrium Beach Profile.

current,  $\bar{u}$ , is directly related to the bottom slope equation through the total odd velocity moments, and a decrease in magnitude or change in sign of  $\bar{u}$  results in a decrease in bottom slope. In other words, the bottom slope is influenced by a balance of forces between the flow field and gravity. In the offshore region, the flow forcing is entirely in the onshore direction where the mean wave-induced current and asymmetric flows are onshore. The combination of onshore flows works against the effects of gravity and produces a steep bottom slope. This result is equivalent to the findings of Bowen (1980) and Bailard (1981). As wave breaking begins and the mean return flow is established, the onshore flow forcing is reduced as the result of the offshore directed mean current opposing the asymmetric onshore flows and the slope becomes milder. The resulting change in slope due to the change in direction of the steady current is considered to be a longshore bar based on the findings of Dyhr-Neilsen and Sorensen and Dally. The steep slope of the depth solution outside the surf zone is attributed to the inclusion of Longuet-Higgins' streaming velocities for the mean flow in the unbroken wave field. As expected, these slopes are on the same order of magnitude as those found by Bailard.

Figure 4a shows the total odd moments across the equilibrium profile. In the equilibrium state, the magnitude of the total odd moments,  $\langle u|u|^2 \rangle$  and  $\langle u|u|^3 \rangle$  in Eqn. 26, is forced by the relative magnitude of the central moments and the steady current. As seen in figure 4a, the total odd moments are predominately positive across the entire surf zone. This is a result of the net balance of the flow forcing in the onshore direction. The balance is established through the

Figure 4: Total Moments Across an Equilibrium Beach Profile (a) Odd:  $\langle u|u|^2$  (solid),  $\langle u|u|^3$  (dashed), (b) Even:  $\langle |u|^3$  (solid),  $\langle |u|^5$  (dashed).

combinations of the central odd and even moments and the steady current where net onshore flows are required to balance the system and maintain a negative sloping bottom, reducing the depth from offshore to onshore.

Figure 5 shows the central odd moments, which are the result of the asymmetric onshore flow of the nonlinear wave form in the nearshore region to maintain positive values across the entire surf zone. The relative magnitudes of these terms in the GEBP model are governed by the balancing of the equilibrium solution between the suspended load and bedload.

For this case, the positive values for the total odd moments across the surf zone exhibit different characteristics as those measured and modelled by R&S. R&S present negative values for the total odd moments across the surf zone. A source of difference possibly lies in the equilibrium or average wave field representation in this example as opposed to the erosive sea state used by R&S. A comprehensive study of the model's response to variations in wave climate and sediment characteristics was conducted by Creed (1992).

## Conclusions

Several approaches to modelling equilibrium beach profiles assuming a random sea state have been addressed. The simple and complete models advance the models of Dean and Larson, but still only offer a monotonic representation

Figure 5: Central Odd Moments Across an Equilibrium Beach Profile:  $\langle \tilde{u}|\tilde{u}|^2 \rangle$  (solid),  $\langle \tilde{u}|\tilde{u}|^3 \rangle$  (dashed).

of the beach profile.

The GEBP can produce non-monotonic equilibrium solutions of a beach profile when a time-averaged no-net sediment transport condition is applied. The formation of a bar in the equilibrium beach profile is attributed to a change in the direction of the near-bottom mean current from onshore to offshore as wave breaking establishes a mean return flow inside the surf zone. The model does not produce realistic bottom slopes outside the surf zone, but inside the surf zone, where the sediment transport characteristics are better quantified, the equilibrium shape of the beach compares favorably with time-averaged field data.

<sup>3</sup>J. Hardisty and <sup>4</sup>A. Cramp.

#### ABSTRACT

The British Beach And Nearshore Dynamics (B-BAND) programme is a three year collaborative research project aimed at improving understanding of surf zone sediment transport processes. Field studies were carried out on dissipative, intermediate and reflective beaches during both neap and spring tides (tidal range up to 9m), and during storm wave ( $H_b > 3\text{m}$ ) conditions.

The field research system comprises up to 7 pressure transducers (PT's), 11 electromagnetic current meters (EMCM's) and 12 optical backscatter sensors (OBS's). The focal point of the instrument array was a 1600m<sup>2</sup> box which was instrumented at each corner and designed to allow the calculation of alongshore and cross-shore suspended sediment fluxes through the box.

The largest sediment transport rates (up to 0.6 kgm<sup>-2</sup>s<sup>-1</sup>) occurred in the inner surf zone of the dissipative beach during storm conditions and showed strong offshore-directed sand transport at infragravity frequencies. The extent to which infragravity oscillations developed was seen to vary inversely with the degree of beach reflectivity, and directly with the incident breaker height. Sediment transport patterns often exhibited strong tidal asymmetry, attributed to the effects of beach dewatering and to a lag between hydrodynamics and bedform alteration.

## INTRODUCTION

Many large multi-institutional field studies examining nearshore processes, using dense arrays of fast response sensors, have taken place over the last decade. These include; the Nearshore Sediment Transport Study (NSTS) on the west coast of the USA (Seymour, 1989), the Natural Environmental Research Council (NERC) project in Japan (Horikawa, 1987), the Canadian Coastal Sediment Transport Study (C<sup>2</sup>S<sup>2</sup>, Willis, 1987), and the DUCK experiments (eg. DUCK82, Mason *et al.*, 1984 and SUPERDUCK86, Martens and Thornton, 1987) carried out on the east coast of the USA.

These studies have substantially improved the understanding of surf zone hydrodynamics. However, progress in understanding the sediment response has been disappointing (Battjes, 1988). This is partially due to the fact that many of the field experiments have taken place on microtidal and mesotidal beaches with complex profiles and bedforms. Also our knowledge of the bedload phase is limited, because devices capable of obtaining high frequency bedload measurements on natural beaches are still under development (Hardisty, 1991).

The British Beach And Nearshore Dynamics (B-BAND) programme (1990-93) (Russell *et al.*, 1991) is a UK-based multi-institutional project. Its aim is to improve knowledge of surf zone sediment dynamics and shoreline evolution through the application of dense arrays of fast response sensors and detailed measurements of the associated shoreline change. Data was collected from high energy macrotidal beaches, which typically have a broad tidal and intertidal sand flat of shallow linear slope almost completely devoid of bedforms. A complementary low energy UK field study (Bedform And Suspension EXperiments, BASEX, cf. Osborne and Vincent, this volume) is examining small-scale suspension processes over rippled beds seaward of the surf zone, using acoustic suspension profiling techniques.

This contribution provides an overview of the environments sampled during the B-BAND experiment, the techniques used and some of the results obtained.

## FIELD STUDIES

The field research system comprised up to 7 pressure transducers (measuring depth and surface waves), 11 electromagnetic current meters (measuring bi-directional horizontal near-bed currents) and 12 optical backscatter sensors (measuring suspended sediment concentrations, SSC's). The focal point of the array was a 1600m<sup>2</sup> box which was instrumented at each corner (Figure 1). These corner stations typically consisted of 3 EMCM's at heights of 0.10, 0.25, and 0.63m above the bed, 3 OBS's at heights of 0.04, 0.10, and 0.25m above the bed, and a single PT. This arrangement was designed to allow the calculation of both the alongshore and cross-shore suspended sediment fluxes through the box, whilst standard beach

profiling techniques in conjunction with a dense array of depth of disturbance rods provided estimates of net erosion and accretion within the box over a tidal cycle. Additionally, a cross-shore array of 5 PT's permitted measurements of wave shoaling characteristics across the profile. Self Generated Noise (SGN) and Ultrasonic Current Meter (UCM) sensors were also deployed to estimate bedload sediment transport and 3 dimensional current flow close to the bed, respectively.

The sensors were secured by burying their mountings below the sand surface, and the 200m cables were buried back up to the logging equipment in the mobile laboratory at the head of the beach. The large tidal range on these macrotidal beaches allowed a profile of measurements to be obtained through and beyond the surf zone over a tidal cycle. Care was taken to ensure that the instrument mountings were buried in excess of 10cm below the sediment-water interface so as to prevent self-suspension by the rigs themselves. Depth of disturbance measurements indicated that maximum disturbance depths were less than 10cm over a tidal cycle. The OBS's were mounted to a slender (3mm diameter) stem which protruded out of the sediment-water interface from the subsurface mountings. No signs of scour were observed around these stems.

Signals were low-pass filtered (cut-off frequency = 1Hz) and digitised at a rate of 2Hz on a personal computer. Each data run was 17.07 minutes in duration giving 2048 data points per channel. Data were recorded continuously from just after low water on the flooding tide to just before low water on the ebbing tide. Beach profile and depth of disturbance measurements were obtained during each low water period.

Figure 1: Generalised B-BAND field set-up.

Field investigations were carried out at three macrotidal beach sites: Llangennith, South Wales; Spurn Head, North East England and Teignmouth, South West England (Figure 2). Following Wright and Short's (1984) morphodynamic classification of beaches, these sites will hereafter be referred to as the dissipative, intermediate and reflective beaches respectively.

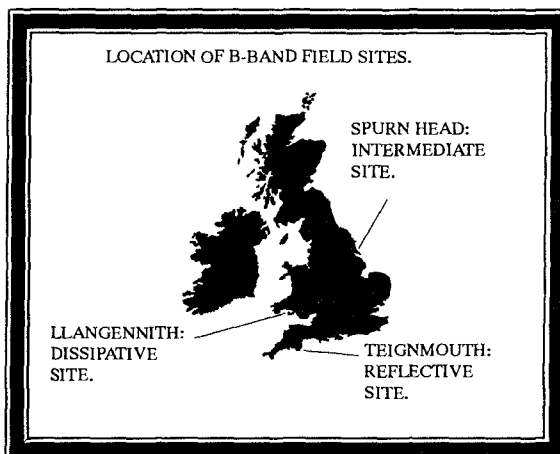

Figure 2: B-BAND field sites.

The dissipative beach is a 10km long, high energy beach with a shallow concave beach profile (gradient = 0.014-0.020) consisting of fine to medium grained quartz sands ( $D_{50} = 0.21\text{mm}$ ). The wave climate on this exposed west facing beach is a mixture of high energy Atlantic swell approaching from the WSW, and locally generated wind waves driven by the prevailing W and SW winds. The low beach gradient, high energy waves and large (up to 9m) tidal range combine to produce both broad surf (up to 350m wide) and intertidal (up to 500m wide) zones.

The intermediate beach site is located near the end of a 5km long spit and faces into the North Sea. The prevailing wave climate is milder than that of the dissipative beach, but the coast is exposed to occasional violent storm waves which approach obliquely from the north-east and can produce plunging breakers with heights in excess of 3m. The beach profile consists of a steep high tide beach (gradient = 0.0975) comprised of fine to medium gravels and a shallow sloping (gradient = 0.023) low tide terrace consisting of a lens of well sorted, medium quartz sands ( $D_{50} = 0.35\text{mm}$ ) overlying boulder clays. Strong (up to 1m/s) rectilinear tidal currents (tidal range = 3 to 6m) run parallel to the coast flowing in a south-westerly direction on the flood and north-easterly direction during the ebb. These currents exert a significant dynamical effect even within the surf zone.

The reflective beach site faces south-east into the English Channel and is consequently sheltered from swell waves generated in the Atlantic Ocean. The local wave climate is dominated by infrequent periods of wind-driven waves from the east. The beach profile is headed at its shoreward extent by a vertical sea wall. The upper profile adjacent to the sea wall is convex and the lower profile seawards of the neap low tide level is slightly concave. The beach is comprised of medium

Figure 3: Wave height variation during the B-BAND experiments.

quartz sand ( $D_{50} = 0.24\text{mm}$ ). Due to the steep beach profile (gradient = 0.067 to 0.142) the intertidal zone at the reflective beach is comparatively narrow (<70m) in spite of the large (up to 6m) tidal range in this area.

A wide range in incident wave conditions were experienced during each field deployment (Figure 3). Measurements were obtained during both calm conditions and

through two storm events ( $H_{1/3} = 2$  to  $3\text{m}$ ) at the dissipative beach. The start of the intermediate beach experiment was marked by the largest storm in 3 years ( $H_{1/3} > 3\text{m}$ ) which breached the sand spit leaving it isolated from the mainland at high water. Wave energy levels were much lower during the reflective beach experiment. However, two periods of high wave energy for the locality did occur during the experiment (tides 3-4 and 11-12) when significant wave heights were between 0.5 and 1m.

## RESULTS

The following discussion of the time series data is subdivided into hydrodynamics, sediment suspension, sediment transport and beach response. Further divisions are made where appropriate into oscillatory and steady components.

### Hydrodynamics. a) Oscillatory flows:

The typical cross-shore pattern for the distribution of hydrodynamic variance observed on all the beaches sampled irrespective of the degree of profile reflectivity is shown in Figure 4. This example, recorded at the intermediate beach, shows the variation of the cross-shore current velocity spectrum with offshore distance. The energy distribution with offshore distance of all the principal components (incident, incident harmonics and infragravity components) of the spectrum appears to conform to current theory (cf. Ursell, 1952; Wright *et al.*, 1982). The shorewards decay of incident wave energy and its associated harmonics within the surf zone is accompanied by a simultaneous increase in energy within the infragravity band.

Although this basic pattern for the distribution of hydrodynamic variance is

Figure 4: (above) Variation in the cross-shore current spectrum with offshore distance, (intermediate beach).

Figure 5: A comparison of cross-shore current spectra from the intermediate and dissipative beaches.

Figure 6: Infragravity response to incident wave forcing. (results from the inner surf zone of the dissipative beach).

common to all the beaches occupied, the relative importance of the principal components of the spectrum varies depending on the reflectivity of the environment. Two cross-shore current velocity spectra from the intermediate and dissipative beaches recorded in equivalent water depths ( $h = 0.8\text{m}$ ) during comparable incident wave conditions ( $H_{1/3} = 2.5\text{m}$ ) are presented in Figure 5. Hydrodynamic spectra recorded at the dissipative beach are strongly dominated by oscillations at infragravity frequencies, whilst at the more reflective environment, incident wave motion dominates the spectrum.

Results obtained in this experiment have supported the findings of other researchers (cf. Holman, 1981) who have demonstrated that, for a given beach, the shoreline infragravity energy levels are linearly related to incident wave height. This proportionate response of the infragravity band with increased incident wave forcing is demonstrated in Figure 6 (and in Huntley *et al.*, 1992). However, observations on beaches of varying reflectivity indicate that levels of long wave energy are not simply a function of the incident wave climate and that beach slope is an important factor which must be considered when predicting infragravity energy within the nearshore zone.

#### b) Mean Flows: Longshore currents.

The typical patterns for the variation in longshore current velocity with offshore distance through and beyond the surf zone at the intermediate and reflective sites are illustrated in Figures 7a and b. These figures show the effect of both the temporal variation in the tidal component and the spatial variation in the wave driven flow. The wave driven longshore flow in both cases is negative (to the south), enhancing tidal flows on the flood tide and opposing tidal flows during the ebb. The variation in the magnitude of the wave driven component conforms qualitatively to the theoretical profile of Longuet-Higgins (1970) which predicts low velocities within the inner/outer surf zone and a mid-surf maximum.

Observations indicated that the net longshore current was the resultant of wave and tidally driven components. The relative importance of these components varied with tidal state, cross-shore location and beach reflectivity.

Figure 7a, b: Variations in the mean longshore current with run number (depth) for a) the intermediate beach and b) the reflective beach.

The tidal component was found to be particularly important in coastal regions where dominant tidal flows run parallel to the coast at the intermediate and reflective beach sites. At the dissipative beach, mean longshore flows were found to be weak due to both the low angle of wave attack and the prevalent direction of tidal flow which is perpendicular to the shoreline.

### Mean Flows: Cross-shore currents.

Comparative plots for the cross-shore component of flow are shown in Figure 8a and b. The pattern of flow is very repeatable both temporally within a given environment and at different sites. Within the surf zone, a strong (0.2m/s) near-bed offshore flow (undertow) is evident. On the intermediate beach there is also a weak (0.05m/s) near-bed onshore flow seawards of the surf zone. These results suggest a convergence in the steady near-bed cross-shore flow towards the break point. Similar results have been obtained by other workers, (eg. Bailard, 1987).

Figure 8a, b: Variation in mean cross-shore current velocity with run number (depth) at a) the intermediate beach and b) the reflective beach.

A second feature of the mean cross-shore flow field commonly observed within the surf zone is an onshore near-surface flow. This is particularly noticeable in the readings obtained from the upper current meters just prior to them coming out of the water. In some cases there is evidence for a vertical flow reversal (see for example runs 2, 3 and 28, Figure 8b) with onshore flow close to the surface and offshore flow at depth. Similar results have been presented by Wright *et al.* (1982) and Bailard (1987).

### Sediment Suspension.

Typical SSC and cross-shore velocity time series measured at the intermediate and dissipative beach are shown in Figures 9a and b respectively. These data were collected in similar water depths ( $h = 0.4-0.45\text{m}$ ) within the inner surf zone during similar (incident) wave conditions. The suspension characteristics shown in Figure 9a are typical of those observed on both the intermediate and reflective beaches, with suspension events generally occurring on each wave cycle at incident

Figure 9a, b: Typical cross-shore current and SSC time series measured in the inner surf zone on a) the intermediate beach and b) the dissipative beach.

wave frequencies and the associated harmonics, with some secondary modulation at infragravity wave frequencies. Conversely, on the dissipative beach, suspension events are long lived (30 to 60s), dense (30 to 50g/l) and closely correlated with prolonged offshore flows at infragravity frequencies.

Several of the B-BAND data sets show a profound tidal asymmetry in both the steady and oscillatory sediment suspension components. Examples of this phenomenon recorded at the intermediate beach during two different tides are shown in Figures 10a to d. These plots illustrate tidal asymmetry in the suspension data at different heights in the water column (top, middle and bottom OBS sensors), and at different spatial locations on the beach (eg rigs A3 and A2) in both the mean (Figures 10a and c) and oscillatory components (Figures 10b and d). The main reasons for the observed tidal asymmetry are thought to be de-watering of the beach during the ebb and a time-lag in bed-form response to changing hydrodynamic conditions (Davidson *et al.*, in press).

## SEDIMENT TRANSPORT.

### 1) Cross-shore

Co-spectral techniques were extensively employed to examine the magnitude and direction of fluctuating sediment fluxes with frequency at different locations.

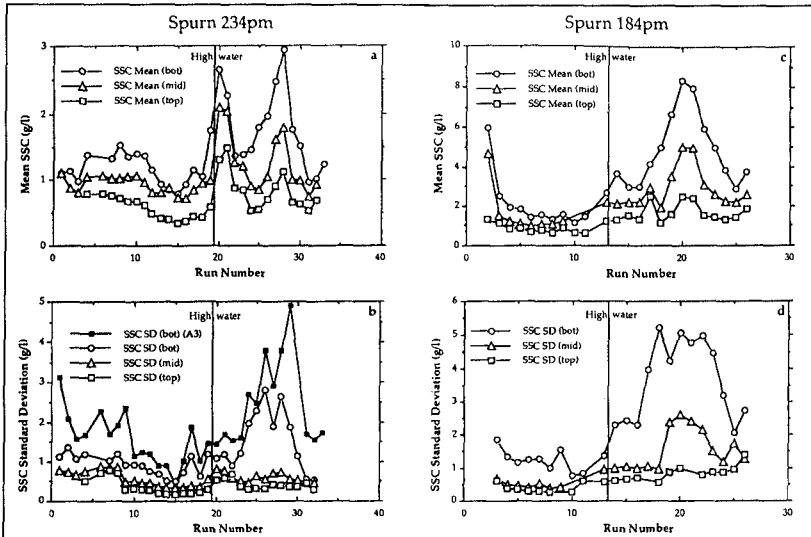

Figure 10a, b, c, d: Variation in steady and oscillatory SSC with run number (offshore distance) and height above the bed (intermediate beach).

These results have supported earlier research carried out on beaches of low tidal range. For example, weak onshore transport at incident wave frequency was found seaward of the surf zone (eg. Huntley and Hanes, 1987, and Figure 11). Conversely, within the surf zone, offshore sediment fluxes at infragravity frequencies were much greater in magnitude than the corresponding onshore transport at incident wave frequencies (eg. Russell, 1990, Figure 12 from the dissipative beach, and Figure 13 from the intermediate beach).

However, other processes can alter this basic pattern. For example, the co-spectrum in Figure 14 illustrates strong offshore transport at incident wave frequencies over a rippled bed seawards of the surf zone at the intermediate site. This reverse transport at

Fig. 11

Fig. 12

Figures 11 and 12: Cross-shore current, SSC co-spectra.

incident wave frequencies over rippled beds has been noted by other workers (cf. Dingler and Inman, 1976).

2) Longshore.

In the longshore direction, the oscillatory transport contributions were negligible since the fluctuating component of longshore velocity and SSC were uncorrelated. The steady (both wave-driven and tidally modulated) flows dominated the longshore transport of sediment.

BEACH RESPONSE.

The sequence of beach profiles collected during the dissipative beach deployment are illustrated in Figure 15. This data has been re-plotted in Figure 16 as a 2-dimensional plan to illustrate the change in beach level between consecutive profiles, so that areas of erosion and accretion can be readily observed. The classic pattern of offshore transport from a berm to an offshore bar is observed during the storm wave conditions at the start of the experiment (profile numbers 1-4), followed by a subsequent return of sand from the bar to the berm during small swell wave conditions later in the deployment (profile numbers 8-11).

Figure 13 and 14: Cross-shore current, SSC co-spectra. (13) Inner surf zone. (14) Over ripples (14).

Figure 15: Beach profile evolution (Llangennith).

Figure 16: Beach changes during the dissipative beach experiment.

Depth of disturbance (DOD) measurements gave detailed bed level changes inside the box averaged over a tidal cycle. A typical result is illustrated in Figure 17. However, no reliable quantitative comparisons could be made between the measured bed level changes in the box and sediment fluxes measured at fixed heights by the sensors. This is because of the inability of the suspension (OBS) and velocity (EMCM) sensors to measure sediment suspension either within the swash zone or within the bottom boundary layer. Hence, the calculation of accurate time- and depth-integrated sediment fluxes over a tidal cycle was not possible. The accurate measurement of the total load sediment transport rates in the surf zone awaits further development of instruments which are capable of obtaining reliable fast response concentration and velocity profiles which extend well into the bottom boundary layer, and are also capable of measuring within the swash zone.

Figure 17: Bed level changes within the box.

## CONCLUSIONS.

Results obtained using dense arrays of PT's, EMCM's and OBS's are invaluable for furthering our understanding of hydrodynamic and sediment transport processes on natural beaches. Results of particular interest so far include:

- i) The tidal asymmetry, affecting sediment transport processes on macrotidal beaches.
- ii) The relative importance of steady flows, long waves (surf beat) and incident waves to the total sediment transport rates in the surf, breaker and offshore zones and on beaches with differing slopes.
- iii) The relationship between infragravity response and incident wave forcing. The magnitude of infragravity perturbations are inversely related to beach reflectivity and directly related to incident breaker height.
- iv) The magnitude and phase relationships between cross-shore flows and sediment suspension with height above the bed.
- v) Assessing the reliability of fast response sensors in the prediction of the divergence of sediment across a given area.

Work is continuing on analysing the vast (325 Mbyte) B-BAND data set, with particular emphasis on the influence of mean flows, reflection from coastal structures, infragravity sediment transport and beach response.

## ACKNOWLEDGEMENTS

The B-BAND experiment is being funded by the Natural Environment Research Council (NERC) (UK) research grant GR3/7128. The post doctoral research associates, Mark Davidson and Paul Russell would like to thank the Welsh Office and the NERC respectively for supporting their work on this project. The authors would also like to extend their thanks to Gareth Lloyd and Steven Jacques for assistance with drafting the figures.

## CHAPTER 154

### LONGSHORE BAR GENERATION MECHANISMS

Robert G. Dean<sup>1</sup>, Rajesh Srinivas<sup>1</sup>, and Trimbak M. Parchure<sup>2</sup>

#### ABSTRACT

A laboratory study was conducted to investigate mechanisms of bar formation with particular focus on infragravity wave and break point mechanisms. With one exception, all tests commenced with a planar beach composed of fine sand. Infragravity (IG) waves, the result of a biharmonic primary wave spectrum, were generated and documented. For various frequency differences of the components of the primary spectrum and thus the frequencies of the IG wave, the changes in nodal/antinodal positions were compared with the changes in positions of the bar formed during the experiment. It was found that the bar position experienced relatively small movements whereas the nodal/antinodal positions changed substantially as expected with the difference frequency of the primary waves. The approximately constant bar position was interpreted as due to the relatively constant primary wave height characteristics. The effects of the wave spectrum and wave height distribution on bar formation were investigated. The shape of the wave height probability distribution function was found to exert a noticeable control on the degree of bar relief, with those distributions characterized by a substantial concentration near the maximum wave height causing the more prominent bars. This is interpreted in terms of a transport influence function which, if held stationary, would result in a narrow prominent bar. The distributions with a small concentration near the maximum wave height resulted in a less prominent bar. A conceptual model is proposed which incorporates the transport distribution function and which results in bar characteristics which depend on the initial conditions.

## INTRODUCTION

Several mechanisms have been proposed for the formation of offshore bars, which can be described as rather low, generally shore-parallel positive features which rise a substantial fraction of the water depth above the sea floor. Bars occur singly or as a series of such features. In many locations of the world, they are correlated with seasons or episodic events of higher wave activity. In other locations, bars are perennial.

Four mechanisms for the formation of bars are reviewed briefly below: (1) Break point, (2) Standing waves formed by reflection from shore back out to sea, (3) Standing edge waves, and (4) Overtake of harmonic waves.

### Break Point Mechanism

The break point mechanism ascribes bar formation to the convergence of sediment transport due to either or a combination of sand transport seaward and/or landward towards the final bar position. The primary effect is seaward transport by the breaking process due to the vortex formed as the breaking wave transfers a torque to the water column which causes a local seaward bottom velocity. This seaward flow may be considered as undertow compensating for the landward mass transport. However, this undertow is locally reinforced by the aforementioned breaking induced torque. Bars frequently occur in wave tanks under the action of monochromatic waves. Such bars are referred to as "break point" bars in recognition of their causative mechanism.

### Standing Waves Formed by Reflection from Shore Back Out to Sea

A wave propagating toward the shoreline will reflect to some degree from the shoreline forming partial nodes and antinodes. The degree of reflection increases with longer wave periods and steeper beach slopes. The shore parallel nodes and/or antinodes are attractive as an explanation for the bar formation (Sallenger and Howd, 1989). Some proponents of this mechanism suggest that formation can occur under either the nodes or antinodes (Carter et al. 1973). A narrow spectrum will cause the formation of long waves, generally termed as "infragravity" waves with frequency characteristics determined by the spectral width. These long waves reflect efficiently from the beach. It is well-known that bar-like features form in wave tanks under standing wave envelopes.

### Edge Waves

The explanation for this mechanism is somewhat similar to that described in the preceding paragraph. The only difference is that edge waves are trapped by reflection thereby maintaining the energy within the nearshore trapping region

whereas for the preceding mechanism, the waves are "leaky" with the reflected energy propagating offshore.

### Overtake of Harmonic Waves

The basis for this explanation is the alternate reinforcement and cancellation of waves of periods corresponding to the first harmonic of the dominant fundamental wave (e.g., Buhr Hansen and Svendsen, 1974). Two waves of this frequency are required: one bound to the fundamental by nonlinear mechanisms and a second free wave propagating at its own speed. Since the propagational speeds of these two waves are different, they will interfere, alternatively reinforcing and canceling at positions which, for a uniform water depth, are periodically spaced along the direction of wave propagation. Contrary to most field observations in which the bar spacing decreases with decreasing water depth, the overtake mechanism predicts an increasing bar spacing with decreasing water depth.

### EXPERIMENTAL FACILITIES

The experiments described in this study were conducted in the facility shown in Figure 1 which consists of a wave tank with programmable wavemaker. The tank is approximately 37 m long, 2 m wide and 1.3 m deep. A long partition extends from near the wavemaker to the distal end of the tank forming two channels each of 0.9 m width. A beach of initial slope 1:19 was formed of fine sand ( $D_{50\%} \approx 0.21$  mm) in one side of the partitioned tank. The wavemaker is driven by hydraulic actuators at two levels, each of which can be controlled independently.

Figure 1. Schematic and Cross-Section of Wave Tank Facility.

## INVESTIGATION CHARACTERISTICS AND RESULTS

The experiments have attempted to address the question of bar formation mechanisms as well as the spectral characteristics that will result in the presence of a bar. All tests were conducted for at least 4.5 hours and the profiles appeared to be near equilibrium. Two study components were carried out and are described below.

### Correlation of Bar Characteristics And Infragravity Waves

This study component is essentially an extension of that conducted by W. R. Dally (1987) in which the incident wave system was biharmonic, i.e. composed of two discrete components, thus resulting in a pronounced infragravity wave component. Reflection of the infragravity component from the wavemaker, an artificiality due to the wave tank, increased its amplitude; the locations of the nodes and antinodes were fixed by the long wave period and the beach profile. The infragravity wave characteristics were measured by a manometer and stilling well apparatus that damped the primary waves. An example of the primary and long wave systems and their associated spectra is presented in Figure 2. The associated wave height probability distribution function and initial and final beach profiles are presented in Figure 3. The method of relating the bar and nodal/antinodal positions to test this hypothesis differed from that of Dally. A total of four experiments of this type was carried out: the analysis and results will be described later.

In addition to documenting the long wave envelope structures generated in the laboratory, they were calculated considering the long wave to be free and represented by the following equation

$$\sigma^2 \eta + g \frac{\partial}{\partial x} \left( h \frac{\partial \eta}{\partial x} \right) = 0$$

which was formulated and solved in finite difference form and found to compare favorably with the analytical solution for a planar beach

$$\eta = J_0 \left( 2\sqrt{\kappa x} \right)$$

where

$$\kappa = \frac{\sigma^2}{g m}$$

and  $J_0$  is the zeroth order Bessel function of the first kind,  $\sigma$  is the long wave angular frequency,  $g$  is gravity and  $m$  is the profile slope. The agreement was found to be good. Figure 4 presents an example of calculated and measured long wave envelopes for Case 3.

Figure 2. Case 1. Biharmonic Waves. Primary Wave Frequencies = 0.47 and 0.53 Hz.

Figure 3. Wave Height Probability Distribution and Initial and Final Profiles for Case 1.

Figure 4. Comparison of Measured (Dashed) and Computed (Solid) Long Wave Envelopes for Case 3.

Table 1 summarizes the positions of the bar and nearest measured IG wave node and antinode. Plotted in Figure 5 is the relationship between the measured changes in bar and measured IG wave nodal/antinodal positions. The changes are relative to the next lower difference frequency (Table 1). If the bar were formed by the infragravity wave system, it is expected that a change in the IG nodal/antinodal position from one frequency to another would correspond to exactly the same change in bar position. Stated differently, the points in Figure 5 should fall along a straight line inclined at  $45^\circ$ , whereas although the positions of the nodes and antinodes changed as expected with IG frequency, the bar location experienced little change. Based on these results, the hypothesis that the bar is caused by the position of envelope of the IG wave is rejected. The nearly unchanging position of the bar position with nearly constant wave height supports the break point hypothesis of bar formation.

#### Effect of Wave Spectra and Wave Height Probability Characteristics on Bar Formation

A series of experiments was conducted to attempt to identify the effects of different incident wave spectral characteristics on bar formation. Table 2 summarizes the characteristics of these tests. Both continuous and discrete spectral shapes were tested. Figures 2 and 3 have presented an example for Case 1 showing primary and long wave records, the associated probability distributions and resulting profiles. Similar results for Case 5 are presented in Figures 6 and 7. Figure 8 documents the wave height probability distribution and initial and final profiles for Case 7 and the profiles for Case 8.

Table 1

Characteristics of Experiments with Biharmonic Primary Waves

Case	Primary Frequencies (Hz)	Difference Frequencies (Hz)	Nodal Position (m)	Antinodal Position (m)	Bar Position (m)
1	0.47, 0.53	0.06	14.3	15.3	14.8
2	0.46, 0.54	0.08	13.5	15.0	14.9
3	0.45, 0.55	0.10	12.5	15.0	14.8
4	0.44, 0.56	0.12	11.6	13.1	14.5

b) Initial (Solid) and Final (Dashed) Profiles. Case 7.

c) Initial (Solid) and Final (Dashed) Profiles. Case 8.

Figure 8. Wave Height Characteristics (Case 7) and Profiles (Cases 7 and 8).

Table 2  
Test Characteristics for Various Spectral Characteristics

Case	Initial Profile	Spectral Character.	Mean Freq. (Hz)	Final Bar Position (m)	Maximum Wave Height (m)
5	Planar	Multifreq.	0.5	15.0	0.16
6	Barred	Multifreq.	0.5	15.0	0.16
7	Planar	Continuous	0.5	14.3	0.11
8	Planar	Monochrom.	0.5	13.9	0.11

The effects of the wave height probability density (WHPD) function are evident by comparing Figures 3, 7 and 8. The WHPD functions for Cases 1 and 5 have either primary or secondary peaks near the maximum wave height, whereas for Case 7, the most probable wave heights occur at a height of approximately one-half the maximum height. For Case 8 (monochromatic), the peak is at the maximum wave height. The final profiles for all cases with primary or secondary peaks near the maximum wave heights have pronounced bars whereas the final profile for the WHPD function with no peak near the maximum wave height is relatively subtle and diffuse (Figures 8a and 8b). Also, it was noticed during the experiments that the rate of evolution towards a fully developed bar was more rapid for those WHPD functions with a primary peak near the maximum wave height.

#### SUGGESTED MECHANISM FOR BAR FORMATION

Based on the results of this and previous studies, the following model is proposed for bar formation. The break point mechanism is responsible for the type of bars investigated here in the laboratory. Moreover, they also apply to bars that we have investigated in the field (Dolan and Dean 1985).

In order for bars to form, the fall velocity parameter  $H_0/(wT)$  ( $H_0$  = deep-water wave height,  $w$  = sediment fall velocity and  $T$  = wave period) must be greater than approximately 3 (Kriebel et al. 1986). Multiple bars require a sufficiently mild slope such that wave reformation and multiple breaking occurs. For conditions that are marginally favorable for bar formation, the probability distribution of breaking wave heights can result in non-formation if the WHPD function does not have a peak near the maximum wave height. Bars tend to be self maintaining by trapping waves to break on the bars. Conditions that are marginally favorable for bar formation can form a prominent bar if a bar feature is initially present.

The mechanism for bar formation can be considered in terms of a transport influence function,  $f(x')$  where  $x'$  is the local coordinate fixed to the time-varying breaking point and the function  $f(x')$  is scaled according to the breaking wave height or wave energy dissipation per unit water volume. Seaward of the breaking point the transport is landward, and landward of the breaking point the transport is directed seaward. When intense breaking wave conditions extend across a wide breaking zone, the net bar generating transport mechanisms are diminished relative to a stable breaking wave position. To reach equilibrium, there must be a negative feedback on the influence function. The failure to date to adequately define this feedback mechanism appears to be one of the major impediments in our attempts to quantify the full mechanisms for bar formation and equilibration.

### SUMMARY AND CONCLUSIONS

A series of wave tank experiments has been conducted to investigate mechanisms of bar formation. Conditions encompassed monochromatic waves and a variety of wave spectra, including cases specifically planned to generate and document the characteristics of the infragravity waves known to accompany a narrow spectrum of primary waves. The conclusions reached from this investigation are presented in the following paragraphs.

The tests conducted with two primary waves which produced a long standing wave were analyzed and the changes in bar position and changes in long wave nodal/antinodal positions compared. It was found that while the long wave nodal/antinodal positions changed as expected with the long wave period, the bar position experienced relatively small displacements. It is concluded that the bar position is governed by the breaking position rather than the long wave envelope structure.

Tests were conducted with a range of spectral shapes and a corresponding range of wave height probability density functions. It was found that for the tests conducted with a density function characterized by a primary or secondary peak near the maximum wave height, intense breaking occurred over a smaller range of positions and the bar was more accentuated and concentrated in position. For conditions with a maximum density near the mid-range of wave heights, breaking occurred over a correspondingly broader range of positions and the bar was somewhat more subdued and less concentrated. These results are interpreted as the result of the dynamic equilibrium in which, as the bar breaks at a particular location, it induces bar formation transport mechanisms; however, due to the aforementioned variation in breaking wave position, the breakpoint transport pattern is not positionally stable for a sufficient duration to cause the bar to form to the degree that would occur under a constant breaking position. On the basis of these findings, a conceptual model for bar formation is proposed, which has as a significant element, a transport influence function with characteristics near the breakpoint that tend to result in bar formation. Depending on the wave height

distribution function and the initial beach profile characteristics, the break point ranges across the active profile and thus results in a dynamic equilibrium.

It is hoped that the results presented herein will stimulate further research on bar formation which will either support the mechanisms presented here or will lead to a more thorough understanding and robust models of bar formation and maintenance.

### ACKNOWLEDGEMENT

The support of the Florida Department of Natural Resources for the work described in this paper is gratefully acknowledged.

## CHAPTER 155

# SHEET FLOW UNDER NONLINEAR WAVES AND CURRENTS

Mohammad Dibajnia <sup>1</sup> and Akira Watanabe <sup>2</sup>

### Abstract

Experiments were conducted on initiation and transport rate of sheet flow under asymmetric oscillations. Values of net sand transport rates under asymmetric oscillations and superimposed currents were also measured. In this paper, based on physical interpretations, a new parameter representing the observed transport mechanism is derived. Using this parameter a general transport formula is then presented and applied to estimating the net transport rate and its direction; fairly good agreement with the experimental results is observed. It is shown that the newly introduced parameter together with the sediment Reynolds number can fairly well express the inception of sheet flow.

### 1. Introduction

This paper is concerned with intense sand transport under high oscillatory shear stress conditions when ripples have been washed out and the bed is flat; the so-called sheet flow transport. As the orbital velocity of fluid over a rippled bed is increased, the oscillatory ripples lose their height and finally will all disappear. Sediment motion then occurs as a sheet of sand within a few centimeters of the bottom, moving with the intense orbital motions. A nearly flat bed with a high sediment transport rate is a condition that can be expected over much of the surf zone during storms (see for example Dingle and Inman, 1976). Therefore,

detail knowledge of sheet flow transport is of decisive importance in a successful modeling of beach topography change.

There have previously been several experimental studies of sheet flow transport from different points of view. Among them Manohar (1955), Chan *et al.* (1972), Komar and Miller (1975), Kaneko (1981), and Horikawa *et al.* (1982) have considered the inception of sheet flow, while Horikawa *et al.* (1982), Sawamoto and Yamashita (1986), and Ahilan and Sleath (1987) have been concerned with the rate of sediment transport. These studies, however, have all considered the sheet flow under purely sinusoidal oscillatory motions. Hence, only transport rates over half a cycle have been obtained, because in a sinusoidal oscillation the net transport over a complete cycle is zero. In reality, however, waves are nonlinear and asymmetry of the near-bottom velocity during the two half cycles of the orbital motion or steady currents superimposed on the waves can produce significant net transport.

The objectives of the present study were to investigate the initiation of sheet flow under asymmetric oscillations, to measure the net sheet sand transport rate under asymmetric oscillations and superimposed steady currents, and, to establish a transport rate formula to be used in modeling of beach topography change.

## 2. Experiments

The present experiments were carried out in a loop-shape oscillatory/steady flow water tunnel at the University of Tokyo. The tunnel is driven by a piston to generate oscillations of any given arbitrary shape and by a pump to superimpose a steady current on the oscillation. It has a horizontal test section of rectangular cross section with glass side walls and removable acrylic ceilings. The test section is of 2.0 m length, 0.22 m height, and 0.24 m width. For the present experiments the width of the test section was reduced to 0.12 m in order to provide large values of velocity. Sand traps made of honeycombs were installed at both ends of the test section in order to trap the sand which would otherwise move out of the test section. Toyo-ura sand with median grain size of 0.2 mm and mean fall velocity,  $W$ , of 2.3 cm/s was used. The depth of the bed of sediment was approximately 7 cm with a length of 1.6 m.

Five oscillation periods ranging from 1 s to 4 s and four nonlinearity indices  $u_{max}/\hat{u} = 0.5, 0.6, 0.7, 0.8$  (see Fig. 1) were selected. Longer oscillation periods could not be used because of the limited length of the test section. Time histories of the water particle displacement were simulated on the base of the first-order cnoidal wave theory which is valid in relatively shallow water. A laser-Doppler velocimeter was used to measure the water particle velocities through the side wall of the tunnel. Velocity profiles corresponding to each case were measured over a fixed bed and were then repeated over the sandy bed.

At first, conditions for disappearance of ripples and inception of sheet flow were investigated and net transport rates due to pure oscillatory motions were

Figure 1: A typical velocity profile.

measured. Then four steady flow velocities ( $U \simeq -20, -10, 10, 20$  cm/s) were superimposed on each of the oscillations and resulting net transport rates were measured.

To investigate the initiation of sheet flow, the normal test procedure was for the tunnel to be set in motion with the required frequency and nonlinearity index, while the bed was flat. At the beginning the amplitude of the oscillation was small in order to let the ripples appear and form. Then the amplitude was gradually increased until the ripples disappear and the bed became flat again. For the measurement of net transport rate the procedure was as follows. First a thin plate was carefully placed at the middle of the test section, to separate its two sides completely, and the sand was weighted and placed in each side in such a way to make a uniform flat bed. Then the plate was removed and the tunnel was set in the required motion for as long as 100 cycles of oscillations provided that the bed remained nearly flat. The test time duration was shorter if the bed started to distort. Finally the thin plate was again placed at the middle of test section and the sand from each side was removed and weighted to give the net transport rate.

### 3. Initiation of Sheet Flow

A total of 18 cases covering periods of 1 to 4 s and nonlinearity indices  $u_{\max}/\hat{u} = 0.5$  to 0.8 were tried. There was no steady current. In order to classify the data by using the conventional parameters, a knowledge of near-bottom orbital velocity amplitude and period is required. Unlike a sinusoidal velocity profile, appropriate definitions for the above mentioned quantities are less clear for an asymmetric velocity profile and they could be different according to the phenomenon under investigation.

Analysis of the current data shows that the maximum velocity for the incep-

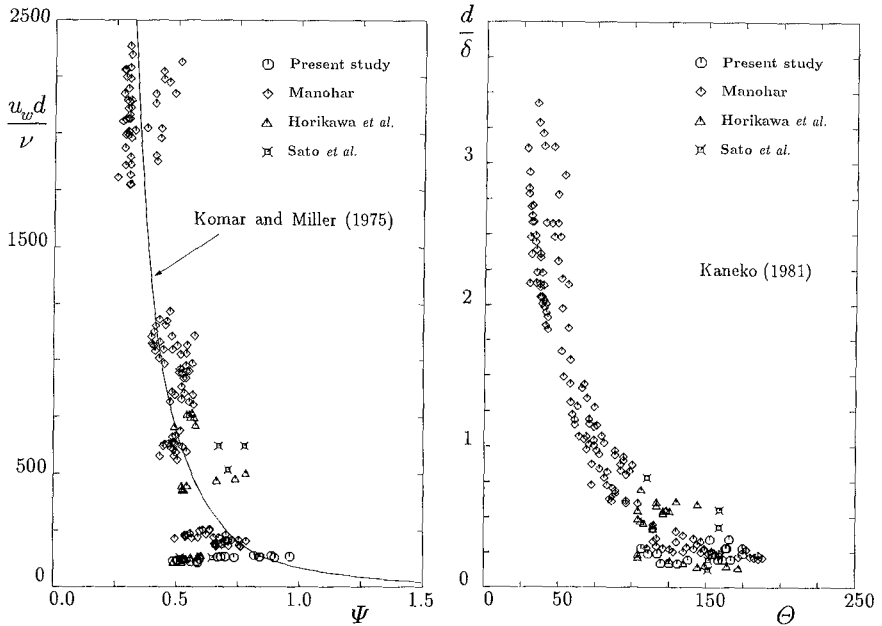

Figure 2: Behavior of two of the available criteria for inception of sheet flow.

tion of sheet flow changes with both the wave period and nonlinearity but the effect of nonlinearity is much more significant; namely, for a given wave period, a more asymmetric velocity profile requires a higher maximum velocity to wash out the ripples and initiate the sheet flow transport. It is concluded that as far as the disappearance of ripples and inception of sheet flow is concerned, it is the energy contained in the near-bottom velocity profile which is the important factor in defining the near-bottom orbital velocity amplitude,  $u_w$ . That is why for a more asymmetric profile, with a slender crest and a wide but small trough, a higher maximum velocity is required. Hence,  $u_w$  is defined as

$$u_w^2 = 2u_{rms}^2 = \frac{2}{T} \int_0^T u^2 dt \tag{1}$$

in which  $u_{rms}$  is the root mean square value of  $u$  and the other definitions are given in Fig. 1. In case of a sinusoidal velocity profile  $u_w$  obtained by (1) is equal to the velocity amplitude. Hence,  $u_w$  defined by (1) is an equivalent sinusoidal velocity amplitude for the asymmetric velocity profile.

Manohar (1955) has reported data on disappearance of ripples for a wide range of sediments and under different flow conditions. His data are reanalyzed and used together with the data of Horikawa *et al.* (1982), Sato *et al.* (1987), and the present data. Several different parameters and their combinations are examined. It is found that the two parameters used by Kaneko (1981),

Figure 3: Sheet flow inception criterion of this study.

$$\Theta = \frac{u_w^2}{sgd} \quad \text{and} \quad \frac{d}{\delta} ,$$

give a more continuous and clear trend, shown in Fig. 2, than the other existing criteria including that of Komar and Miller (1975). Here  $d$  is the grain size,  $\delta = \sqrt{2\nu T/\pi}$  the Stokes layer thickness,  $\nu$  the fluid kinematic viscosity,  $g$  the acceleration of gravity, and  $s = (\rho_s - \rho)/\rho$  with  $\rho_s$  and  $\rho$  being the densities of sand and fluid, respectively. One can say that under an intense fluid motion it is the strong turbulence structure near the bottom which destroy the ripples rather than a shear mechanism. Therefore,  $\Theta$  which represents the flow energy or intensity is more appropriate than the relative bottom shear stress,  $\Psi$ , used by Komar and Miller.

In the next section a new parameter,  $\omega$ , is introduced which may be further changed to

$$\Lambda = \frac{u_w^2}{sgWT} \cdot \left(\frac{\delta}{d}\right)^2 . \tag{2}$$

The following relation is then found to give a good inception criterion (Fig. 3).

$$\frac{Wd}{\nu} = 42.5 \left(\frac{1}{\Lambda} - 0.05\right)^{0.69} \tag{3}$$

It should be pointed out again that the present data are for the initiation of sheet flow over a rippled bed. In case of an initially flat bed, however, sheet flow could occur in lower flow velocities. This is because that over a rippled bed an excess amount of energy, comparing with a flat bed, is required to level the bed.

#### 4. Net Transport Rate

More than 100 experiments were carried out and the net transport rates were measured. According to Ahilan and Sleath (1987), the sheet sand transport rate over a half cycle of a sinusoidal oscillation can be well estimated as a function of the Shields stress,  $\Psi$ , by the formula of Shibayama and Horikawa (1980),

$$\phi = 19.0 \Psi^3, \quad (4)$$

which is same as the formula of Madsen and Grant (1976) with a different value of the coefficient. In this relation  $\phi = (1 - \lambda)q/Wd$  is the nondimensional transport rate,  $q$  the volume of transported sand per unit time, and  $\lambda$  the porosity of sand. Madsen and Grant suggested that under an asymmetric oscillation the overall net sediment transport rate,  $\Phi = (1 - \lambda)Q/Wd$ , could be calculated by integrating their formula with respect to time, half cycle by half cycle and taking the difference between the rates during successive half cycles. Denoting this by  $\Phi_{cal.}$ , one may write

$$\Phi_{cal.} = \frac{19.0}{T} (T_c \Psi_c^3 - T_t \Psi_t^3) \quad (5)$$

in which

$$\Psi_c = \frac{1}{2} f_c \frac{u_c^2}{sgd}, \quad \Psi_t = \frac{1}{2} f_t \frac{u_t^2}{sgd}$$

and

$$u_c^2 = \frac{2}{T_c} \int_0^{T_c} u^2 dt, \quad u_t^2 = \frac{2}{T_t} \int_{T_c}^T u^2 dt \quad (6)$$

where  $u_c$  and  $u_t$  are equivalent sinusoidal velocity amplitudes for the positive and negative portions of the velocity profile, respectively, and  $f_c$  and  $f_t$  are their corresponding friction factors. Figure 4 shows the comparison between calculated and measured net transport rates,  $\Phi_{cal.}$  and  $\Phi_{meas.}$ , for all the cases. It is seen that except for few cases the disagreement is generally high and this method fails to predict not only the magnitude of the net transport rate but also its direction. It is clear that such a procedure could be correct only if the sand transports during the two half cycles are completely independent of each other. Then, under such a condition and for a velocity profile similar to the one shown in Fig. 1 (*i.e.*  $|u_{max}| \gg |u_{min}|$  and  $T_c \leq T_t$ ), the net transport rate should usually be in the direction of positive velocity. However, during the present experiments it

Figure 4: Comparison between  $\Phi_{meas.}$  and  $\Phi_{cal.}$ .

was noticed that especially for highly asymmetric profiles (*i.e.*  $u_{max}/\hat{u} = 0.8$ ) the sand which had been entrained during the positive half cycle, was brought back into the negative direction by the successive negative half cycle; and this mechanism in some cases was strong enough to make the net transport to be in the negative direction. In fact, it was observed that sheet flow is the motion of a condense suspended sand layer which is confined to the region near the bottom and its thickness depends on the magnitude of velocity. Once there was a positive velocity large enough to raise up sand particles to such a level that they could not reach the bottom before the negative velocity occurred, then these particles tended to be carried to the negative direction.

In order to evaluate this mechanism we assume, as a first approximation, that the fluid and sediment should move together with the same velocity, and that the flow kinetic energy is transferred to the required potential energy to raise up sand particles through the strong but confined eddies which exist inside the sand sheet layer. Hence, the kinetic energy,  $E_k$ , of a sand particle with volume  $V$  moving with its ambient fluid, averaged over the time under the positive velocity,  $T_c$ , may be estimated as

$$E_k = \frac{1}{2} \rho V u_c^2 \quad (7)$$

The potential energy,  $E_p$ , required to raise that particle as high as one unit of length is

$$E_p = (\rho_s - \rho) V g \quad (8)$$

Therefore, the distance that a sand particle travels upward, or in other words, the thickness of sand sheet layer,  $\Delta_s$ , can be obtained as

$$\Delta_s = \frac{E_k}{E_p} = \frac{1}{2} \frac{u_c^2}{s g} \quad (9)$$

According to this expression the thickness of sheet layer is proportional to the square of velocity and independent of the grain size. Now let's consider a sand particle which is entrained. It will fall into the bottom by its free fall velocity,  $W$ . The time required for this particle to reach the bed,  $T_{\text{fall}}$ , will be

$$T_{\text{fall}} = \frac{\Delta_s}{W} = \frac{1}{2} \frac{u_c^2}{s g W} \quad (10)$$

Suppose a case in which  $T_{\text{fall}}$  is longer than  $T_c$ . Then what will happen is that before the sand particle reaches the bottom, the negative velocity will occur and will carry it into the negative direction. This means that the ratio of  $T_{\text{fall}}/T_c$  can be an appropriate indication for the phenomenon of our interest. Thus, we define  $\omega_c$  as

$$\omega_c = \frac{1}{2} \frac{u_c^2}{s g W T_c} \quad (11)$$

to represent the intensity of the above suspension mechanism. In Fig. 5 the measured net transport rates,  $\Phi_{\text{meas.}}$ , under pure oscillatory motion are plotted against their corresponding values of  $\omega_c$ . It is seen that  $\Phi_{\text{meas.}}$  increases with increasing  $\omega_c$  until it reaches a maximum at around  $\omega_c = 1$  and, due to the already-mentioned suspension mechanism, starts to decrease thereafter. For values of  $\omega_c$  greater than about 2.5, the mechanism is so strong that makes the net transport to be in the negative direction. From this figure we can see that  $\omega_c$  is an appropriate tool not only for the prediction of transport direction but also for estimating the magnitude of net transport rate. In fact  $\omega_c$  is a time ratio which in turn is an indication of the intensity of suspension, and/or an indication of the sand concentration.

Up to now we have only considered the positive portion of a velocity profile. However the same suspension mechanism could happen during the negative half cycle. Therefore we introduce  $\omega_t$  as

$$\omega_t = \frac{1}{2} \frac{u_t^2}{s g W T_t} \quad (12)$$

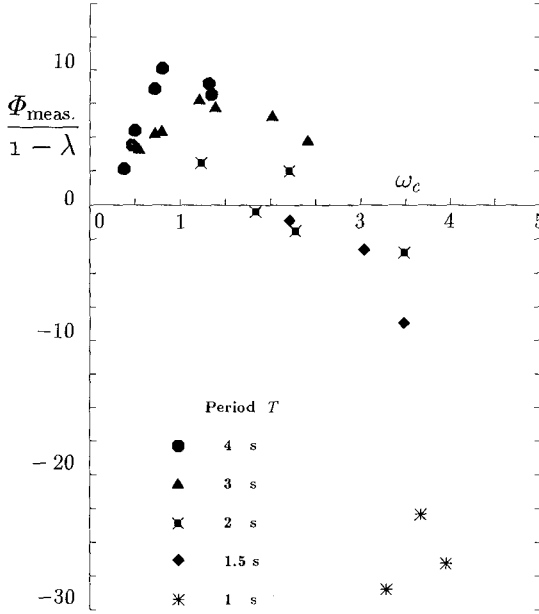

Figure 5: Relation between the measured net transport rates and the parameter  $\omega_c$ .

Now, the net transport rate should be obtained as the difference between the rates during the two half cycles including the effect of suspension during one half cycle on its successive half cycle. It was already described that part of the sand entrained during the positive half cycle of velocity profile may remain in suspension and be carried by the velocity of the successive negative half cycle into the negative direction, and vice versa. Hence, for example, the negative velocity has two groups of sand to carry; one is the sand which is entrained by the negative velocity itself, and the other one is the sand remaining in suspension from the previous positive half cycle. Having this in mind, we define a parameter,  $\Gamma$ , to represent the net transport rate, as

$$\Gamma = \frac{u_c T_c (\Omega_c^3 + \Omega_t'^3) - u_t T_t (\Omega_t^3 + \Omega_c'^3)}{(u_c + u_t) T} \quad (13)$$

In this relation  $\Omega_c'$  represents the amount of suspended sand remaining from the positive half cycle, to be carried by the negative velocity. Similarly  $\Omega_t'$  stands for the amount of sand still in suspension from the negative half cycle which will be transported to the positive direction. On the other hand,  $\Omega_c$  represents that amount of sand which is entrained and carried only by the positive velocity;

and  $\Omega_t$  indicates the amount of sand which is entrained, transported, and settled during the negative half cycle.

It was already discussed that if the values of  $\omega$  ( $\omega_c$  and  $\omega_t$ ) are less than unity there will be no exchange of suspended sand between the two half cycles; both  $\Omega'_c$  and  $\Omega'_t$  will then be equal to zero. It was also mentioned that  $\omega_c$  (or  $\omega_t$ ) is a parameter with two meanings; namely, it represents the time ratio  $T_{fall}/T_c$  (or  $T_{fall}/T_t$ ) and also it indicates the intensity of sand concentration. Now suppose a case in which  $\omega$  ( $\omega_c$  or  $\omega_t$ ) is greater than one. Consider  $\omega$  as representing the sand concentration. It should be divided into two parts; one part corresponding to the sand transported and settled during the current half cycle,  $\omega_m$ , and the second part,  $\omega'$ , corresponding to the sand which will be delivered to the successive half cycle. This time consider  $\omega$  as the time ratio. If this ratio is greater than one the suspension mechanism will be effective. The larger a value of  $\omega$  the more suspended sand to be delivered to the next half cycle. Hence, we may assume that  $\omega'$ , as a first approximation, is equal to the amount that  $\omega$  surpasses unity; namely,

$$\left\{ \begin{array}{l} \text{if } \omega \leq 1 \\ \text{if } \omega > 1 \end{array} \right\} \left\{ \begin{array}{l} \omega_m = \omega \\ \omega' = 0 \\ \omega_m = 1 \\ \omega' = \omega - 1 \end{array} \right. \quad (14)$$

Based on the above interpretation, the following relations are used to estimate values of  $\Omega_c$ ,  $\Omega'_c$ ,  $\Omega_t$ , and  $\Omega'_t$ :

$$\left\{ \begin{array}{l} \text{if } \omega_c \leq 1 \\ \text{if } \omega_c > 1 \\ \text{if } \omega_t \leq 1 \\ \text{if } \omega_t > 1 \end{array} \right\} \left\{ \begin{array}{l} \Omega_c = \omega_c \cdot \frac{WT_c}{d} \\ \Omega'_c = 0 \\ \Omega_c = \frac{WT_c}{d} \\ \Omega'_c = (\omega_c - 1) \cdot \frac{WT_c}{d} \\ \Omega_t = \omega_t \cdot \frac{WT_t}{d} \\ \Omega'_t = 0 \\ \Omega_t = \frac{WT_t}{d} \\ \Omega'_t = (\omega_t - 1) \cdot \frac{WT_t}{d} \end{array} \right. \quad (15)$$

Figure 6: Relation between  $|\Phi_{\text{meas.}}|$  and  $|\Gamma|$ .

Figure 6 shows values of  $|\Gamma|$  plotted versus  $|\Phi_{\text{meas.}}|$  for the present sheet flow data and for the previous data on suspended load above ripples. Fairly good relation is observed for the present data. The solid line which is fitted for the present data reads

$$|\Phi_s| = 0.001 |\Gamma|^{0.55} . \quad (16)$$

Values of  $\Phi_s$  based on this relation are compared with the measured values in Fig. 7;  $\Phi_s$  taking the same sign as  $\Gamma$ . It is seen that both the magnitude and direction of net transport rate under sheet flow condition are very well predicted.

The generality of  $\Gamma$  defined by (13) also permits its application to estimating the net transport rate over ripples. It is well known that suspended load is the predominant transport mode over sand ripples. Although the suspension mechanism above a rippled bed is different from that of sheet flow, but one may expect that the present concepts generally hold, though in a different scale, for suspended transport over ripples. It should be noticed that in the presence

Figure 7: Comparison between  $\Phi_{\text{meas.}}$  and  $\Phi_s$ .

of ripples usually most of the sand suspended during one half cycle is carried by the velocity of the coming successive half cycle. This means that over the ripples values of  $\Omega'$  should be much larger than their corresponding values of  $\Omega$ . Hence, in relations (14), we may change the critical value of  $\omega$  from unity to a value of the order of 0.001 corresponding to bedload condition. This is tried for the experimental data of Sato (1987), Watanabe and Isobe (1990), and Sunamura (1982) and the results are shown in Fig. 7. It should be mentioned that measured velocity profiles for the data of Sato and those of Sunamura were not available; they are calculated by using the Stream Function Method from the reported flow conditions. Also for the data of Watanabe and Isobe, only the maximum and minimum values of velocity and values of  $T_c$  and  $T_t$  were available. Sunamura's data have been obtained in a wave flume, while those of Sato, and Watanabe and Isobe are from the same flow tank as that of the present experiments. Considering these points we can see the reasonable performance of  $\Gamma$  in estimating the transport rate above ripples.

It is instructive to note that the third power of  $\Omega$  which corresponds to the sixth power of velocity is used in relation (13), and then nearly the square root of  $\Gamma$  is taken in (16). This shows the correlation of transport rate with nearly the third power of velocity. However, using a power of 1.5 instead of 3 for  $\Omega$  in (13) gives a slightly weaker correlation than what is seen in Fig. 6.

In a real field, there is a transition region between the rippled bottom of

suspended load and the flat bed of sheet flow. Over this region, the ripple height decreases and the net transport rate changes its direction from the offshoreward suspended load to the shoreward sheet flow. The critical value of  $\omega$ , should then be gradually changed from 0.001 to unity over this transition region. Further study on the critical value of  $\omega$  for suspended load is also required.

## 5. Conclusions

Experiments were conducted on the initiation of sheet flow under asymmetric oscillations, and on the net sand transport rate under asymmetric oscillations and superimposed currents. Concerning the inception of sheet flow it is found that for a velocity profile with an arbitrary shape, it is the energy contained in that velocity profile which is the important factor in defining the near-bottom orbital velocity amplitude. Among the available criteria, it is found that the parameters used by Kaneko (1981) give a more continuous and clear trend than those by the others. A new parameter is also introduced which together with the sediment Reynolds number can fairly well express the inception of sheet flow with a better performance than that of Kaneko.

The validity of the method of Madsen and Grant (1976) in predicting the net transport rate and its direction under sheet flow condition is examined. It is found that except for few cases this method fails to predict not only the magnitude of the net transport rate but also its direction. Their procedure could be correct only if the sand transports during successive half cycles of oscillations are completely independent of each other. In the present study it is found that once there is a positive velocity large enough to raise up sand particles to such a level that they can not reach the bottom before the negative velocity occurs, then these particles tend to be carried to the negative direction. Based on physical interpretations a new parameter representing this phenomenon is derived. Using this parameter a general transport formula is presented in which the above-mentioned mechanism is taken into account. It is shown that both the magnitude and direction of net transport rate under sheet flow condition are very well predicted by the new formula, and that the formula is potentially applicable to estimating the net transport rate of suspended load above ripples.

It should be mentioned that in the present formulation, the steady current velocity is added to the oscillatory velocity profile and the resulting velocity profile is then used and analyzed. This is different from those methods who consider the transports due to waves and currents separately. It is seen that the present method is successful and more realistic, while its application to the horizontal plane problems is also straightforward. Another point is that the Shields parameter is not used in this study for estimating the transport rate. This is because of the uncertainty still involved in estimating values of friction factor under intense flow conditions. Once the shear stress at the bottom could be accurately determined, then it should be used in the formulations.

## CHAPTER 156

### Assessment of Coastal Processes for the Design and the Construction of the Zeepipe Landfall in Zeebrugge

ir. A. EIDE, Senior Geotechnical Engineer - STATOIL (Norway)  
ir. B. MALHERBE, Project Manager - HAECON N.V. (Belgium)  
ir. M. MERCANTI, Senior Pipeline Engineer - SNAMPROGETTI (Italy)  
ir. E. LAHOUSSE, QA Manager - HAECON N.V. (Belgium)

#### ABSTRACT

Early 1991, Statoil started with the installation of a 40 inch diameter gas pipeline between the Sleipner and later Troll field in the Norwegian sector of the North Sea and the harbour of Zeebrugge on the Belgian coast.

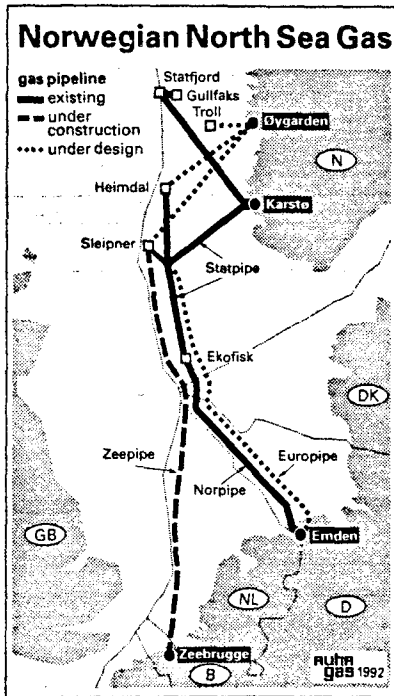

The connection between the offshore and the onshore pipeline was performed in August 1991, in the landfall area of Zeebrugge. The design and the construction of the landfall in the nearshore area required an extensive survey and engineering program taking the environmental parameters and the coastal processes into account.

#### 1. INTRODUCTION

The Zeepipe Gas Pipeline Project for the delivery of natural gas extracted from the Sleipner field was approved by the Norwegian Parliament in December 1986. Den Norske Stats Oljeselskap A.S. (Statoil, Stavanger - Norway) is the operator on behalf of the Zeepipe owners and is responsible for the planning, the construction and the operation of the Zeepipe system.

Zeepipe is the largest offshore pipelaying project undertaken up till 1991. Approximately 810 km of 40", 38 km of 30" and 230 km of 20" pipelines will go through the Norwegian, Danish, German, Dutch and Belgian sectors of the North Sea.

Zeepipe is a pipeline system for the transport of gas from the Norwegian Sleipner field to Zeebrugge on the Belgian Coast.

**Figure 1** : Description of Zeepipe system

In the North Sea (figure 1) the Zeepipe system will also be connected to the existing Statpipe- and Norpipe systems (Stolberg - 1992).

Via the terminal in Zeebrugge Zeepipe will be connected to the European gas distribution system. The gas will be distributed to purchasers from Germany, France, Belgium, the Netherlands and Spain.

The landfall of Zeepipe was planned to be in the Zeebrugge Harbour with the Landfall Valve Station (LVS) on the LNG-peninsula of Zeebrugge.

The design of the landfall had to take all nearshore coastal processes, geotechnical and sedimentological characteristics of the area into account to allow proper pipelaying and pipeline operation.

## 2. THE ZEEBRUGGE LANDFALL AREA

### 2.1. General site description and morphology

The landfall area on the Belgian Coast is located on the eastside of the Zeebrugge Harbour southeastern dam (rubblemound breakwater). The offshore area in which Zeepipe is installed is a part of the Southern Bight of the North Sea.

The area (figure 2) under concern for Zeepipe and the landfall is part of the fore-delta of the Western Scheldt estuary. Strong hydrodynamic, morphological and sedimentological conditions are characterizing this region of the North Sea where relative "young" quaternary deposits occur on the seabed.

Some kilometers north of the Zeebrugge harbour, two important shipping lanes are draining most of the in- and outgoing traffic to and from the Western Scheldt estuary, i.e. the Scheur and the Wielingen.

**Figure 2 :**  
Nearshore and shore approach  
area for the landfall of  
Zeepipe in Zeebrugge.

**Figure 3 :**  
Differential map (1990-  
1986) of the shore  
approach and beach area  
processed with DTM.

In order to assess the environmental conditions related to the bottom lithology and the soil conditions during the engineering, detailed pre-laying surveys have been executed.

## 2.2. Bathymetric survey

In order to provide recent and detailed data on the seabed topography, bathymetric surveys have been carried out in a corridor, centered along the Zeepipe axis (corridor width : 1000 m).

The bathymetric survey has been executed using the Atlas Fansweep 200 kHz swathe echosounder (sweep angle : 126°) simultaneously with a dual-beam Atlas Deso 20 echosounder (detection of loose mud deposits).

The swathe echosounder Fansweep, used for the first time on operational basis, delivered very detailed bathymetric maps with on average 1 depth value/m<sup>2</sup> (Vessel used : "M.S Pegasus" from Geoconsult A.S). Tide-reduction was achieved by using the official tide-gauges and 1 extra shorebased and 1 extra offshore selfrecording tide gauge.

Bathymetric survey data were processed using advanced DTM-processing (Digital Terrain Model) on HP-9000 CAD-computer to produce the combined survey maps.

Parallel to these bathymetric surveys, all available existing hydrographic data from 1980 to 1990 and in a 5 km wide corridor along Zeepipe were collected (data-base Haecon N.V.) and processed as differential maps to determine natural and man-made recent morphological changes of the seabed (e.g. fig. 3)

### 2.3. Geophysical survey :

Because of the known soil heterogeneity and the local presence of outcropping tertiary geologic layers, shallow seismic survey has been conducted in the surveyed Zeepipe corridor in order to pilot the geotechnical/geologic soil investigation.

A shallow seismic survey was carried out by using alternatively a 50 J EG & G Minisparker and a Thompson Pipeliner (3,5 + 7 kHz) in order to optimize penetration.

The significant seismic reflectors are associated with important layers for the design, i.e. :

- a. the erosion surface of the tertiary layers marking the transition from tertiary to recent quaternary deposits (often associated with gravel) ;
- b. overconsolidated tertiary clay layers

In combination with the shallow seismic tracks, side-scan sonar surveys were executed (apparatus : Klein 531T (100 kHz) + EG & G260 (100 kHz)) in order to identify :

- a. possible obstacles (wrecks, cables, ...) ; 4 significant obstacles were detected ;
- b. morphologic bottom features such as ripples, sand-waves, ... reflecting residual bed-load transport directions ; ripple and sand-wave fields crossing Zeepipe at Bol van Heist Sandbank could clearly be identified.

All geophysical data were digitally transferred to the HP-9000 CAD and Intergraph 6040 workstation for combined map production.

### 2.4. Geotechnical/geologic surveys

Different geotechnical/geologic surveys with corings and piezocone penetration testings (PCPT) were executed along the Zeepipe route in the offshore and onshore part to ascertain/verify geophysical survey and to get

geotechnical information for the design of the pipelaying and landfall works.

Vessels mobilised for the soil investigation include the self-elevating platform "Tijl II" (HSS) and the "M.S. Bucentaur" (Farmand Survey).

Coring was executed by continuous sampling of the soil layers (figure 4). Piezocone penetration testing was done to investigate soil cone resistance, sleeve friction and pore-water pressure ; geotechnical parameters such as friction angle, relative density and undrained shear strength could be deduced.

Figure 4 : Example of geotechnical/geologic soil investigation results.  
Coring + PCPT in the landfall area.

All geotechnical data were digitally transferred to the HP-9000 CAD and Intergraph 6040 system for the production of the combined survey maps.

In selected boreholes wireline loggings (density and resistivity logs) were done in order to assess porosity and density of the soil layers. These parameters are important for the assessment of soil compaction degree and liquefaction potential.

### 2.5. Geochemical analysis

During the geotechnical survey, soil samples were frozen and stored in a freezing installation. According to the Convention of Oslo, chemical characteristics of the samples were analysed in order to assess a possible contamination and/or contaminant remobilization during trenching/dredging. Heavy metal and organic compound contents were found to be below base quality reference material contents.

### 2.6. Hydrometeorological conditions

Vertical tides are important in this part of the North Sea. Tides in Zeebrugge range from 3,00 m (Neap Tide) to 5,00 m (Spring Tide).

The tidal currents (SW : ebb ; NE : flood) in relation to the vertical tide are the strongest and highest in the shallow parts of the North Sea such as the Belgian nearshore area. Offshore current roses are either elliptical or circular and nearshore ones are usually bidirectional. This means that offshore water is constantly flowing while nearshore water circulation is similar to that in an estuary.

Storm surges may be particularly dramatic in this part of the North Sea because of wind set-up combined with the relative high tidal ranges. Dominant wind directions are SW with NW for storm conditions. NW, N and NE-winds together with atmospheric depressions are able to cause considerable wind set-ups (up to 2,00 m in extreme conditions).

Wave action is intense in the Southern Bight due to shallow water depths, refraction, reflection and diffraction. Registered wave characteristics show typically short period and steep waves.

## 3. COASTAL PROCESSES

### 3.1. Tidal gulleys

The morphological evolution in the nearshore and landfall area is influenced by the tidal mechanisms in the North Sea, by the discharge of the Scheldt river and also, locally, by the Zeebrugge harbour. Long term seabed variations are due to the continuous development of the ebb - and flood gully system.

Ebb - and flood gulleys are closed in the direction of the residual sediment transport, are typically approx. 4

to 10 km long, approx 1 to 4 km wide and have depths of 0,50 m to 3,50 m w.r.t. original seabed ; they interact closely and form a hydrodynamic and physical equilibrium. Flood gulleys are shallow and more frequent close to shore. Ebb gulleys are deeper and located more offshore.

### 3.2. Sand banks and sand waves

The Zealand banks located in front of the Belgian coast seem to be stable sand bodies. During storms, some of the megaripples and sand waves on top of the banks are crest-cutted but soon afterwards they are built-up again. Sand wave height is approximately 1,5 m to 2,5 m and the wave length ranges between 100 and 200 meters.

### 3.3. Turbidity maximum area (TMA) and sediment transport

The nearshore area is characterized by a much varying bottom lithology with essentially the presence of muddy tidal flats (C. De Meyer, B. Malherbe 1986). Intensive field measurements have been executed in this part of the North Sea since several years. Such measurements allowed to establish a general residual sediment transport pattern. Figure 5 shows the variation of tidal elevation, tidal currents and suspension concentration. They revealed the existence of an encounter zone of residual sediment transports in front of the Belgian Coast which results in a marine Turbidity Maximum Area (T.M.A.).

Figure 5 : Simultaneous recordings of tidal elevation, tidal currents and suspension concentration close to the Landfall Area.

The T.M.A. is characterized by a loose mud deposit layer (thickness : 0,50 - 1,00 m) trapped within the T.M.A. The volume of this loose mud is significant and may amount to several millions of tons dry material. The T.M.A. centre of gravity is further moving in function of the residual flow and sediment transport.

#### 3.4. Beach stability

The sandy beach on the landfall area could be subjected to morphological changes due to wave response; these morphological changes are unavoidable modifications in the beach equilibrium profile.

Before the extension works of the Zeebrugge harbour started (1977), the seabottom level was almost equal to MSL -7,00. Afterwards, a progressive accretion / sedimentation has taken place which is due to human activities (disposal of dredged material) and to natural sand accumulation (trapping of longshore transport by eastern dam of Zeebrugge).

#### 4. LANDFALL OF ZEEPIPE : DESIGN ASPECTS

##### 4.1. Design criteria for the landfall

The different criteria used for the design of the Zeepipe Landfall are related to the following parameters :

- a. geotechnical stability of the pipeline
- b. foundation of future marina dams which have to cross the Zeepipe route
- c. depth of the marina access channel and basin
- d. technical requirements for trenching, dredging and pulling equipment
- e. tidal gulley development
- f. allowable stresses in the pipeline
- g. pipelaying/welding requirements
- h. beach erosion
- i. risk analysis of the pipe in relation to navigation
- j. authority requirements

The geotechnical stability is related to the liquefaction potential and the differential settlements.

Liquefaction is likely to occur if no artificial backfill of the trench is done. Natural backfill with sand is very progressive and repeated liquefying effects by short wave action may consequently cause progressive pipeline uplift during trench filling. Natural backfill with loose mud deposits ( $\rho_{sat} = 1,05 - 1,15$ ) will generate more

consolidated mud deposits ( $\rho_{\text{sat}} = 1,40 - 1,50$ ) after ca. 1 or 2 months ; this may as well cause progressive pipeline uplift.

The different marina master plans in this area foresee the building of a sanddune (visual barrier) and a marina dam which will be built as a rubble-mound breakwater with a foundation of soil-replaced sand.

The sanddune (height : ca. 30 m) is likely to cause the most important settlements (up to 0,20 m). Due to the heterogeneity of the quaternary seabed soil layers (mud, sand, peat) differential settlements are to be expected.

The foundation of the marina breakwater dam will need an excavation of the natural quaternary soil layers with poor bearing capacity. Cutter suction excavation works have to be avoided in the close vicinity of Zeepipe. Because there is a limit to the trenching depth of Zeepipe an adapted foundation solution has to be found for this part of the marina breakwater.

The marina access-channel and basin (design depth is greater than TOP : top of pipe) will have to be designed in accordance with the Zeepipe "as-laid" profile.

The equipment for the trenching, dredging and pipe-pulling have given water depth requirements, i.e. ca. MSL - 9,00 m (Castoro II pulling barge ; Vlaanderen XIX CSD). Therefore, the minimal trench depth is fixed to MSL - 9,00 m.

As can be seen on figure 3 a typical flood tidal gully has been developing close to the Zeepipe route since the end of the Zeebrugge Harbour Works. Such tidal gully developments are followed carefully by interpreting differential bathymetric maps.

Regarding the soil-pipeline interaction it can be stated that the pipeline profile will influence the stresses in the pipeline itself. The stresses may be induced by temperature loads, internal pressure settlements (soil deformation), seismic waves, etc ... Thorough stress calculations have been executed, taking the particular soil conditions in this area into account.

To execute the dry tie-in (in a dry cofferdam) of the spool and the landfall-string by welding a maximum working depth within the cofferdam of - 7,25 m MSL was required. This means that the tie-in part of the landfall has been designed at that level.

Beach erosion phenomena may affect the submarine beach up to a depth of ca. - 6,50 m MSL. Beach erosion and equilibrium slope calculations was done to evaluate beach

response to the design storm conditions (water level + wave height with e.g. R.P. of 50 years). Recent beach evolution can also be assessed from differential mapping.

Damaging risks during operation and within life-time (50 years) had to be assessed in order to design the appropriate cover and/or protection. Therefore a risk-analysis was executed taking all external factors such as navigation, maintenance dredging, ship's collision, etc ... into account.

This risk analysis has a major relevance for the crossing of the Scheur and Wielingen navigation channels.

Authority requirements refer essentially to the soil conditions after pipeline-installation and the stability of the existing harbour infrastructure. Furthermore an environmental impact assessment (EIA) had to be done in relation to the planned dredging, trenching and dumping works (LDC/OSCON-convention).

#### 4.2. Landfall design alternatives

The arrival point of the offshore pipeline was fixed, i.e. the Landfall Valve Station on the LNG-peninsula of the Zeebrugge Harbour.

Three major landfall alternatives were identified :

1. by directional drilling and subsequent pipe-pulling from sea to land ;
2. by micro-tunnelling with a pushed tunnel from shore to sea ;
3. with a conventional sheet-piled cofferdam for the shore approach in combination with a cross-breakwater solution.

The original landfall-concepts, by directional drilling or micro-tunneling, were abandoned due to the particular soil conditions and the close vicinity of the rocky rubble-mound breakwater.

The alternative concept basically consists of a conventional landfall, with a sheet-piled cofferdam into which the pipeline, is pulled ashore. The pipeline is tied into a spool piece that goes through and above the breakwater and which connects Zeepipe to the Landfall Valve Station.

#### 4.3. Trenching/dredging of the pipeline

In order to fulfill the design-criteria the pipeline had to be trenched over a wide stretch of the nearshore and shore-approach area.

In the Scheur shipping channel the trench was designed taking into account the risk-analysis, the soil conditions with quaternary sands and tertiary overconsolidated clays and silts, the authority requirements and the plans for deepening the channel. On figure 6 the designed crossing of the Scheur is illustrated. The trenching works were designed to be executed by seagoing cutter suction dredgers. (N. Pille, F. Warnier, B. Lahousse - 1988).

Figure 6 : Design of the crossing of the Scheur shipping lane by Zeepipe.

In the "Wielingen" Shipping Lane the designed pipelaying/trench is less deep than in the Scheur. Therefore a combination of predredging (trailing suction hopper dredgers) and post-trenching (jetting sledge with jet-barge) has been foreseen.

Between the "Wielingen" and the shore a 1750 m shore-approach trench up to - 9 m MSL (bottom width : 50 m) has been designed (initially box-cut and subsequently 1/7 slopes). The shore approach trench connects to the sheet-piled cofferdam (figure 7).

Because of the dry tie-in of the pipeline into a spool piece and the need for extra work space, a temporary artificial island was built along the eastern breakwater. Excavation works were executed within the cofferdam for :

- a. connection between offshore trench and tie-in area ;
- b. soil replacement works (with gravel) because of the presence of muddy soil layers (Cone resistance  $Q_{ct} < 1$  MPa) likely to cause (differential) settlements.

Figure 7 : Shore approach trench in sheet piled cofferdam and artificial landfall island.

Figure 8 : Pipeline profile in the landfall area

In this way the pipeline would be in a safe operational condition from a stress point of view, i.e. below 70 % of the specified minimum yield strength.

#### 4.4. Backfill of the pipeline trench

To avoid damaging risks of the pipeline due to navigation hazards (trailing anchors, sunken ships, etc ...) and/or maintenance dredging, a continuous gravel cover (gravel diameter : 0,11 m) of the pipeline was designed in the Scheur crossing area.

The design of the backfill of the shore approach trench in the transition zone between pre-trenching and post-trenching does fulfill the criteria, related to, a.o. :

- pipeline stability against liquefaction and flotation
- authority requirements

The backfill was designed by a series of separated gravel berms alternating with sand berms (figure 9) in order to optimize the backfill costs.

The gravel solution was retained because :

- a. it offers a better solution against liquefaction (to ensure vertical stability) ;
- b. it reduces execution problems if the trench is filled with loose mud deposit.

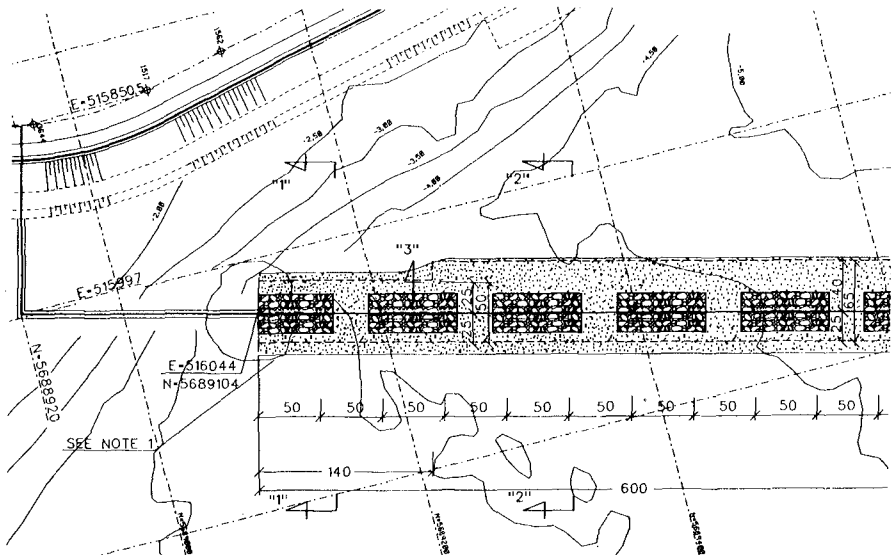

Figure 9 : Scheme of backfill of the shore-approach trench.

The backfill operations were designed to be executed by split hoppers and side-dumping vessels.

#### 4.5. Crossing of the breakwater

For the crossing of the breakwater the upper layers of the rubble-mound structure had to be carefully dismantled, taking into account the as-built drawing and the foundation of the dam (soil replacement, willow-matras, berm). In the berm and breakwater crossing a sandasphalt core in which the spool piece is bedded has been designed (thickness of sandasphalt under and above pipe ca. 1 m).

#### 5. ZEEPIPE LANDFALL CONSTRUCTION

In order to execute the pulling ashore operation in controlled environmental conditions, a sheetpiled cofferdam has been constructed first.

The landward end of the cofferdam has been driven in a temporary artificial island. The purpose of this temporary island was to provide a protection against sea conditions during the opening of the breakwater and the installation of the spoolpiece across the breakwater.

A trench has been excavated within the cofferdam, into which the pipeline has been pulled ashore from a flat bottom laybarge by winches placed on the beach.

The island has than be used as a work platform in front of the trench.

After the pipeline was pulled ashore, the cofferdam has been plugged with clay and dewatered allowing the tie in operation to be done in dry conditions.

The seaward end of the cofferdam has been filled with seagravel and sand.

Finally the pipeline has been tied-into a spoolpiece that has been laid across the breakwater previously.

## CHAPTER 157

# A Field Experiment on a Nourished Beach

A.J. Fernández\*  
G. Gómez Pina \*  
G. Cuenca\*  
J.L. Ramírez\*

### Abstract

The performance of a beach nourishment at "Playa de Castilla" (Huelva, Spain) is evaluated by means of accurate beach profile surveys, visual breaking wave information, buoy-measured wave data and sediment samples. The shoreline recession at the nourished beach due to "profile equilibration" and "spreading out" losses is discussed. The modified equilibrium profile curve proposed by Larson (1991) is shown to accurately describe the profiles with a grain size varying across-shore. The "spreading out" losses measured at "Playa de Castilla" are found to be less than predicted by spreading out formulations. The utilization of borrowed material substantially coarser than the native material is suggested as an explanation.

## 1 INTRODUCTION

Fernández et al. (1990) presented a case study of a sand bypass project at "Playa de Castilla" (Huelva, Spain) and the corresponding monitoring project, that was going to be undertaken. The Beach Nourishment Monitoring Project at the "Playa de Castilla" was begun over two years ago. The project is being

---

\*Dirección General de Costas. M.O.P.T, Madrid (Spain)

carried out to evaluate the performance of a beach fill and to establish effective strategies of coastal management and represents one of the most comprehensive monitoring projects that has been undertaken in Spain. This paper summarizes and discusses the data set for wave climate, beach profiles and sediment samples.

## 2 STUDY SITE & MONITORING PROGRAM

Playa de Castilla, Fig. 1, is a sandy beach located on the South-West coast of Spain between the Guadiana and Gualdalquivir rivers. The beach extends over  $25\text{km}$  between Mazagón and Matalascañas, and has experienced a long-term trend of erosion. The shoreline at Playa de Castilla has been receding at a rate of  $1.5\text{m/year}$  during the last 30 years (Fernández et al., 1990). The main causes of this shoreline recession are the net litoral drift from West to East, that has been evaluated in  $390.000\text{m}^3/\text{year}$  (CEDEX, 1979), and the civil works in the nearby rivers that have reduced the volume of sand carried to the coastline.

In 1989, an artificial nourishment of the beach was carried out. The fill project was conducted by the Ministry of Public Works of Spain and consisted of a sand bypass from the updrift side of the Tinto-Odiel Estuary to Playa de Castilla. The volume of sand moved was  $1.690.000\text{m}^3$ . The sand was dredged by a trailing suction hopper dredger and transported  $2\text{km}$  down drift. The total volume of sand was placed in the updrift extreme of "Playa de Castilla", forming a protruding area about  $2\text{km}$  long and  $115\text{m}$  wide, Fig. 1. The borrowed sand was coarser than the native sand being  $D_{50} = 0.63\text{mm}$  and  $D_{50} = 0.3\text{mm}$  for the borrowed and native sand respectively.

A monitoring program was established to evaluate the performance of the nourishment. The field program includes wave measurements, beach profiles and sand samples (Fig. 2).

The wave climate measurements cover daily visual observations of wave direction in shallow water, surf zone width, wave period and wave height within the surf zone (two measurements per day). In addition, waves are recorded by a buoy gauge located in intermediate depths ( $18\text{m}$ ).

Beach profile data are acquired bimonthly from 42 shore-normal profiles located between Mazagón and Matalascañas. Alongshore spacing of the profiles is approximately  $500\text{m}$ . Each profile is surveyed from the beach dune up to a depth of about  $10\text{m}$ .

Sediment samples are collected from each beach profile during each bi-

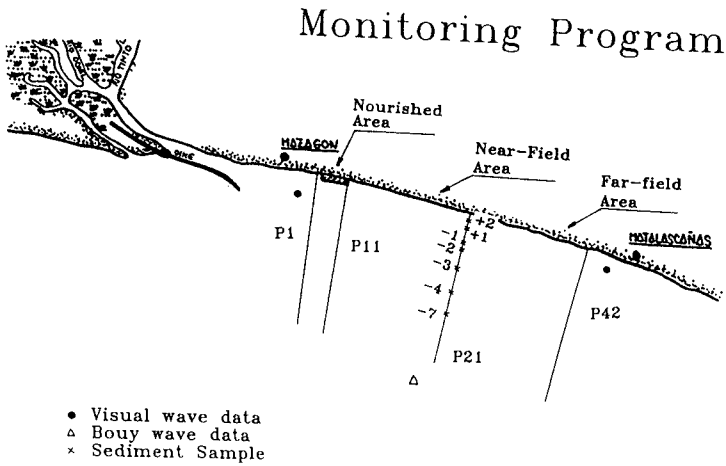

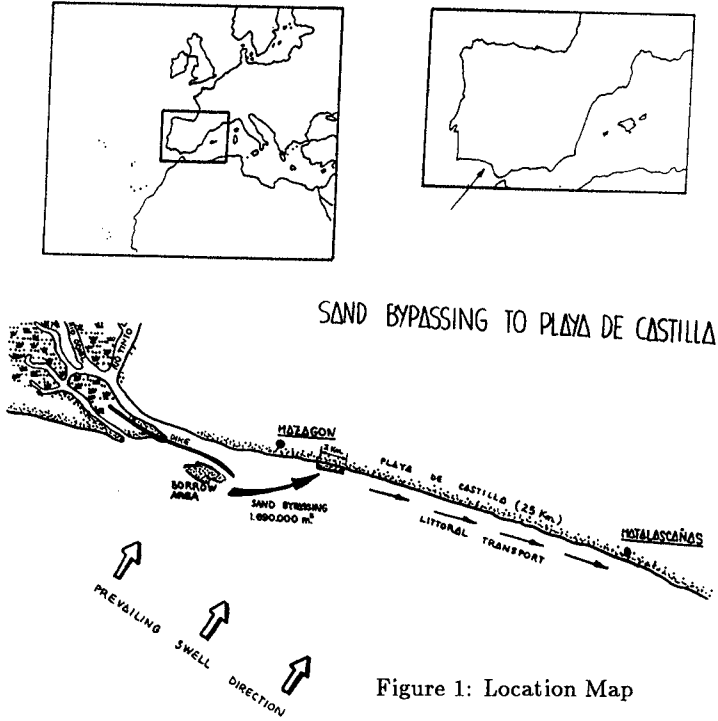

Table 1: Measured Wave Parameters

Variable	Max.	Mean	Min.
$H_s$	3.80 m	0.65 m	-
$H_{max}$	5.90 m	1.00 m	-
$T_z$	9.40 s	4.10 s	2.40 s
$T_s$	15.60 s	5.00 s	2.80 s

monthly survey from the dune to offshore. Samples are collected at the following locations: swash zone, surf zone (-1 m, -2 m), and offshore (-3 m, -4 m, -7 m). Each sample is processed in the laboratory for grain size parameters.

## 3 RESULTS

### 3.1 Wave Climate

Since waves are the primary agent for nearshore changes at Playa Castilla, several wave parameters are collected. Daily, visual observations are taken at Mazagón and at Matalascañas 25km downdrift. Morning and afternoon measurements of the following parameters are recorded: wave direction, breaking width, wave period and breaking wave height.

Average breaking wave height is of the order of 0.4m. Wave heights during the strongest storms are on the order of 2.0m. Most of these storms are locally generated with wave periods in the range of 6 – 8sec. The breaking zone width varies between 5m and 200m with 10m as an average value. The predominant approach direction is from the SW/SSW sector, with more than 60the data corresponds to calm periods.

In order to obtain a more complete description of the wave climate, a permanent station for wave height recording was installed. The station was located in intermediate depths, (18 m) between Mazagón and Matalascañas. The buoy gauge consists of a Data Well Buoy model Waverider 6000, a recording unit and a power source. The data are recorded on cassettes and is computer analyzed to yield significant wave heights and periods. Table I presents the range of values for the different wave parameters.

where  $H_s$  is the significant wave height,  $H_{max}$  is the maximum wave height,  $T_z$  is the upcrossing period and  $T_s$  is the significant period.

### 3.2 Beach Profiles

The beach profile data are acquired bimonthly from 42 shore normal profiles across the nourished beach (profiles 2-6) and adjacent beaches (profile 1 is updrift and profiles 7-12 are downdrift). The transect spacing was designed to monitor the whole beach (nourished and unnourished) and to resolve the long term "spreading out" losses of the nourishment though it might not be adequate to resolve the spacing of rhythmic topography, which can be closely spaced. In the first survey, the alongshore spacing in the nourished beach was 250 meters. These additional profiles were included to determine information about the profile readjustment that occurs from the linear project profile until finally arriving at the natural equilibrium profile.

### 3.3 Unnourished Section, Far Field

The Eastermost profiles are (far apart) from the nourishment and give information from the natural changes of the beach profiles. The storm season profiles (Sep./90 and Jun./91, Fig. 3) show a dissipative profile with a steep beach face, a marked break point bar and a very mild offshore slope beyond the 3 m contour. The bar can be observed in almost all the campaigns with minor changes in its offshore position and seasonal changes in its elevation. During calm periods (Feb./91 and Feb./92), the bar trough is filled and the bar becomes a step which separates the steeper beach face and the milder offshore profile.

The dune erosion process is clearly shown in the measured profiles. During storm conditions, the landward part of the profile retreats and the dune is eroded. The dune material is transported to the offshore part of the profile, beyond the bar (Sep./90 and Jun./91). This excess of sediment in the offshore profile is lost during calm periods (Feb./91 and Feb./92) but the foreshore does not recover the pre-storm position and, consequently, the erosion process is completed.

### 3.4 Unnourished Section, Near Field

The morphology of the profiles which are adjacent to the nourished beach are qualitatively quite similar to those at the far field, with a steep beach face, a marked bar during the storm season and a mild offshore slope beyond the 3 m contour (Fig. 4). However, the magnitude of the bar is not generally as important as in the far field. During calm periods, the bar becomes a step as in the far field. It can be observed from Figure 5, that the foreshore part of

Figure 3: Beach Profile. Far Field

Figure 4: Beach Profile. Near Field

Figure 5: Beach Profile. Nourished Area

the profile benefited from the project, at the beginning, (Sep./90 to Jun./91), with a net accumulation of sediment, mainly above low tide level. However, the offshore part of the profile, retreated afterwards during the period (Feb./91 to Feb./92). This part of the profile, beyond the bar, shows the seasonality above mentioned with a significant accretion during storm conditions and a gradual lowering of the offshore beach during calm periods.

### 3.5 Nourished Section

In the nourished beach there is no bar but a permanent step or a transition between the very steep beach face and the more gently sloping offshore profile (Fig. 5). The offshore changes of the profiles are as important as those encountered at the near field and far field profiles. The foreshore part of most of the profiles displays a loss of material. Nearly all of this loss is located in the swash zone of the intertidal beach.

### 3.6 Sediments

Sediment samples are collected from each beach profile each bimonthly survey. The samples are acquired by hand-operated grab samplers, and represent approximately the upper 10 cm of sediment at each location. The samples are analyzed in the laboratory and grain sizes are computed by sieving according to the ASTM standards. Samples are taken for each profile at the swash zone, surf zone (-1 m, -2 m) and offshore (-3 m, -4 m, - 7 m).

### 3.7 Swash Zone

The grain size at the swash zone (Fig. 6) is the most stable in time of all the locations, with minor changes at the unnourished beach and more important fluctuations at the nourished part. The temporal variations of the mean size exhibit a similar variability in the alongshore direction, being coarser or finer at all the profiles depending on the survey. Spatially, the nourished beach represents a discontinuity in the distribution of grain size.

The unnourished backbeach is characterized by a very uniform grain size in the alongshore direction with an average  $D_{50} = 0.32mm$ , while the nourished beach shows a less uniform alongshore distribution with an average  $D_{50} = 0.51mm$ . There is, however, a slight tendency for decreasing grain size variability both temporally and spatially in the nourished beach throughout the campaigns.

### 3.8 Surf Zone

Grain size temporal variability is much more important in the surf zone than in the backbeach (Fig. 7). The average  $D_{50}$  in the surf zone is  $0.25\text{mm}$  with a range of values from  $0.4\text{mm}$  to  $0.2\text{mm}$ . As in the backbeach, there is a clear trend in the grain size to be coarser or finer in all the profiles depending on the campaign. Unlike the landward location, there is almost no discontinuity in the alongshore direction due to the nourished beach. The nourished beach was coarser during the first campaign but afterwards achieved a grain size similar to the rest of the beach.

### 3.9 Offshore Zone

The offshore part of the beach shows different characteristics depending on the depth. At the  $3\text{m}$  and  $4\text{m}$  contour, the beach shows a fine sand, with slight temporal and spatial variations (Fig. 8). The average  $D_{50}$  is  $0.14\text{mm}$  with values in the range of  $0.2\text{mm}$  and  $0.12\text{mm}$ . No discontinuity is found at the nourished beach. At the  $7\text{m}$  contour, the mean grain size shows great temporal and spatial variation. Samples range from fine sand,  $D_{50} = 0.12\text{mm}$  to coarse sand  $D_{50} = 0.9\text{mm}$ . Most of the coarse samples are obtained at fixed locations throughout the program.

## 4 DISCUSSION

In addition to the seasonal changes that may occur in a natural beach, it is well known that the nourished beaches suffer modifications both in the cross-shore and alongshore directions, due to the profile equilibration and the "spreading out" losses. The performance of a beach nourishment project may be evaluated by the magnitude of these changes compared to the initial configuration of the designed beach fill.

### 4.1 Profile Equilibration

Beach fills are constructed using a broad range of designs, but generally the material is placed using profiles which are steeper than the natural profile for the size of sediment that is used in the beach nourishment project. Thus, the profile will tend to equilibrate to its natural shape. Profile equilibration occurs gradually, depending on the specific project characteristics (sand volume, average grain diameter...) and the wave and water level conditions, and usually

Figure 6: Grain Size. Swash Zone

Figure 7: Grain Size. Surf Zone

Figure 8 : Grain Size. Offshore Zone (-4)

last for a few years, Dean and Grant (1989). In considering the last profile equilibration, these are the most important questions to be answered: What will be the final equilibrium profile and when will this equilibrium profile be achieved?

Equilibrium beach profiles have been found by Bruun (1954) and Dean (1977) to be reasonably well represented by:

$$h(y) = Ay^{\frac{2}{3}} \quad (4.1)$$

in which  $h$  is the depth at a distance,  $y$  seaward of the shoreline and  $A$  is a scale parameter primarily dependent on sediment size (assumed to be constant along the profile), Moore (1982). If the grain size varies markedly along the profile, as (it occurs) at Playa Castilla, significant deviations may be encountered. Different approaches have been made to take into account the cross-shore distribution of sediment grain sizes.

Larson (1991) modified the equilibrium profile equation to better represent the grain size variation along the profile as:

$$h = A[y + (\frac{D_0}{D_\infty} - 1)(1 - e^{-\lambda y})]^{2/3} \quad (4.2)$$

where  $D_0$  and  $D_\infty$  are the equilibrium energy dissipation for the material at the shoreline and in the offshore respectively ( $D_0 \geq D_\infty$ ) and  $\lambda$  is an empirical coefficient. Eqs. (4.1) and (4.2) are assumed to represent the equilibrium profile up to a "closure depth",  $h_*$ . Usually, Hallermeier (1981), littoral zone limit ( $H_* = 2.28H_{s0.137} - 68.5(H_{s0.137}^2/gT_s^2)$ ) or Birkemeier (1985), ( $H_* = 1.75H_{s0.137} - 57.9(H_{s0.137}^2/gT_s^2)$ ) are adopted.

From the buoy data, the values of the closure depth are found to be 7.74 m and 7.87 m for Hallermeier and Birkemeier formulations, respectively.

Figure 9 displays a comparison between the measured beach profile at Playa Castilla and the least-squared fit of eq. (4.2) and eq.(4.1) for a beach profile located at the nourished beach (Figure 9a) and a beach profile located at the unnourished beach (Figure 9b). As seen from the figures, the agreement between the measured and calculated profile improves considerably if eq. (4.2) is used in comparison to eq.(4.1). The improvement is even more evident at the nourished beach, where there is a strong variation of the sediment size in the cross-shore direction.

From the 378 profiles analyzed, it was found that the best fit, when applying the classical  $2/3 - power$  curve, eq.(4.1), was obtained using a value of the A-

parameter that corresponds roughly with the grain size located at the surf-zone, in accordance with Moore's curve. It is remarkable that the offshore part of the profile beyond the bar (or step), where the sediment size is almost constant, can be well-represented by a simple  $2/3$ -power curve (see Figures 9a and 9b). The modified equilibrium equation provides an improved description of the profiles with decreasing grain size with distance offshore, however, at present, the parameters involved in the equation must be estimated by a best-fit procedure. Additional work is being carried out to establish the dependence of the parameters on the grain and wave characteristics.

From the analysis of the temporal evolution of the constructed profile to the natural equilibrium profile (not shown), it can be concluded, that the equilibrium profile was well achieved in less than one year, as suggested by Kamphuis and Moir (1977).

## 4.2 "Spreading out" Losses

The placement of a beach nourishment project usually results in a planform that interacts with the waves to result in a spreading out of the sediment, with the consequent loss of material from the region in which it was placed. In addition to the erosion due to the anomalous plan form of the nourishment project, there is usually a background erosion which was present prior to the placement of the beach nourishment project (and which made it necessary) that is superposed to the spreading out. The superposition of these two components yields the shoreline recession at the nourished beach.

The equations available to represent the planform evolution are a sediment transport equation and a sand continuity equation.

Using Komar's and Inman (1970) sediment transport equation and combining it with the sand conservation equation, an equation governing the evolution of a beach system can be obtained, Dean and Grant (1989),

$$\frac{\partial y}{\partial t} = G \frac{\partial^2 y}{\partial x^2} \quad (4.3)$$

in which the parameter  $G$  can be interpreted as the alongshore diffusivity, and primarily depends on the wave height and on the sediment transport coefficient,  $K$ , which depends on the sediment size. The wave direction is relatively unimportant on a long uninterrupted shoreline as "Playa de Castilla", Dean and Grant (1989).

The solution of equation (3) can be obtained once an initial condition is established. Using equation (3) with the designed beach nourishment project

Figure 9a: Measured Profile vs Calculated Profile. Far Field

Figure 9b: Measured Profile vs Calculated Profile. Nourished Area

Figure 10: Shoreline Evolution

characteristics at Playa Castilla (borrowed sand diameter  $D_{50} = 0.63$  and background erosion  $1.5m/year$ ), about 20 % of the material should have been spread out in two years; however, except for the initial profile equilibration, no significant loss has been measured at the nourished beach. Furthermore, if we compute the losses with the actual grain size measured during the campaigns and take into account the cross-shore distribution of grain size as in Moutzouris (1988), more than 40 % should have been transported down drift.

It seems that the utilization of a material substantially coarser than the native sand has armor the beach in the nourishment area thereby resulting in less transport from the nourished area. The similarity of the changes of the offshore part of the profiles at the nourished beach and the unnourished beach, and the alongshore uniformity of grain size in the submerged part of the profiles indicate that the natural littoral drift is being re-established and that the nourishment area has been passed, as if it were a jetty.

In Figure 10, the shoreline evolution during the period Feb-91/Feb-92 for the contour lines +2 and -4 is presented. It can be observed from figure 10 that: the shoreline in the unnourished section has retreated with the similar rate of erosion in the far-field and in the near-field. The shoreline in the nourished area shows a tilting motion with recession in the updrift area and accretion in the downdrift area.

## 5 SUMMARY

The "Playa de Castilla" beach nourishment monitoring data set has been presented. The data include beach profiles surveys, wave measurements and sand samples. Availability of accurate levellings and soundings, sea conditions information and sediment distribution has provided the opportunity to evaluate the performance of the beach fill at "Playa de Castilla". The performance has been described in terms of beach "profile equilibrium" and "spreading out" losses. It has been shown that the equilibrium profile was achieved in less than one year, as suggested by Kamphuis and Moir (1977). The classical  $2/3 - power$  curve proposed by Bruun (1954) and Dean (1977) to represent the equilibrium beach profile has been found to be inadequate to describe the strong grain size varying across-shore beach profiles existing at "Playa de Castilla". The modified  $2/3 - power$  curve proposed by Larson (1991) has been shown to accurately represent the profiles with the cross-shore distribution of sediment size of "Playa de Castilla". The "spreading out" losses evaluated by profile measurements were less than those determined by spreading out formulations. It has been suggested that the utilization of a substantially coarser material for the beach fill has armor the beach in the nourished area, resulting in a

decreased transport from the nourished area.

## ACKNOWLEDGEMENTS

## CHAPTER 158

### Thirty Year Erosion Projections in Florida: Project Overview and Status

Emmett R. Foster<sup>1</sup>

#### Abstract

A project to analyze historic shoreline erosion and to predict future erosion in Florida is discussed in this paper. Information is given concerning the data base and the methods of analysis. Some examples are provided illustrating the use of various analysis tools. The utility of numerical modeling as a newly developed analysis tool is discussed in particular. Some of the general results of the study are noted, as well as conclusions and opinions concerning the effectiveness of the program.

#### Introduction

Since 1985, the Florida Department of Natural Resources (DNR), Division of Beaches and Shores, has been required to consider thirty year erosion projections in the regulation of coastal construction. Certain types of major structures are prohibited seaward of the thirty year projection of the "seasonal high water line" (SHWL). This elevation contour is defined by rule to be a function of the mean high water (MHW) elevation and the mean tide range at a site. In many areas of the state the SHWL corresponds well with the vegetation line or the base of the dune escarpment. The SHWL is assumed to move in close correspondence with the MHW line in the longer term.

-----  
<sup>1</sup>Professional Engineer, Florida Department of Natural Resources, Division of Beaches and Shores, 3900 Commonwealth Blvd., Tallahassee, FL 32399-6515.

There are approximately 1250 km (780 miles) of sandy beaches in Florida for which thirty year erosion projections must eventually be made. Due to staffing limitations, first priority is given to analyzing and making erosion projections for areas where there are frequent applications for construction permits. The second priority is completion and updating of the historic data base. The third priority is to perform regional analyses.

The author works for the Division as a coastal engineer assigned to build and maintain the historic shoreline data base, and to analyze the data. In effect, the author acts as a consultant in recommending to the engineering staff and management which erosion rates to apply as thirty year erosion projections. Any of the staff engineers may elect to perform their own analyses. The author's recommendations in a case are subject to acceptance or not, per the judgment of the staff engineers and managers. This allows for useful scientific debate. The party making the final thirty year erosion determination in a case is responsible for its' defense. The following is a description of the DNR historic shoreline data base, and the author's analysis methods and opinions.

#### Data Base

In order to have a reasonable chance of predicting the future, it is helpful to have a reasonably good understanding of the past. Therefore the author's methods of analysis are based on obtaining a high quality, reliable data base, and a working understanding of the coastal processes controlling long term shoreline changes in Florida.

In the initial data acquisition phase, all the U.S. Government historic coastal topographic survey maps of Florida from the 1850's to the 1980's were precision digitized by skilled personnel on state-of-the-art equipment. This was done for the Department at Florida State University, primarily by Dr. S. Demirpolat. The results include an atlas of historic mean high water (MHW) change maps, which are computer-generated map overlays on a common coordinate system. Paper copies on standard scales of 1:24000 and 1:2400 are available. Digital copies which can be used with several computer assisted design (CAD) or geographic information system (GIS) software packages are now becoming available. An example historic shoreline change map is shown as Figure 1.

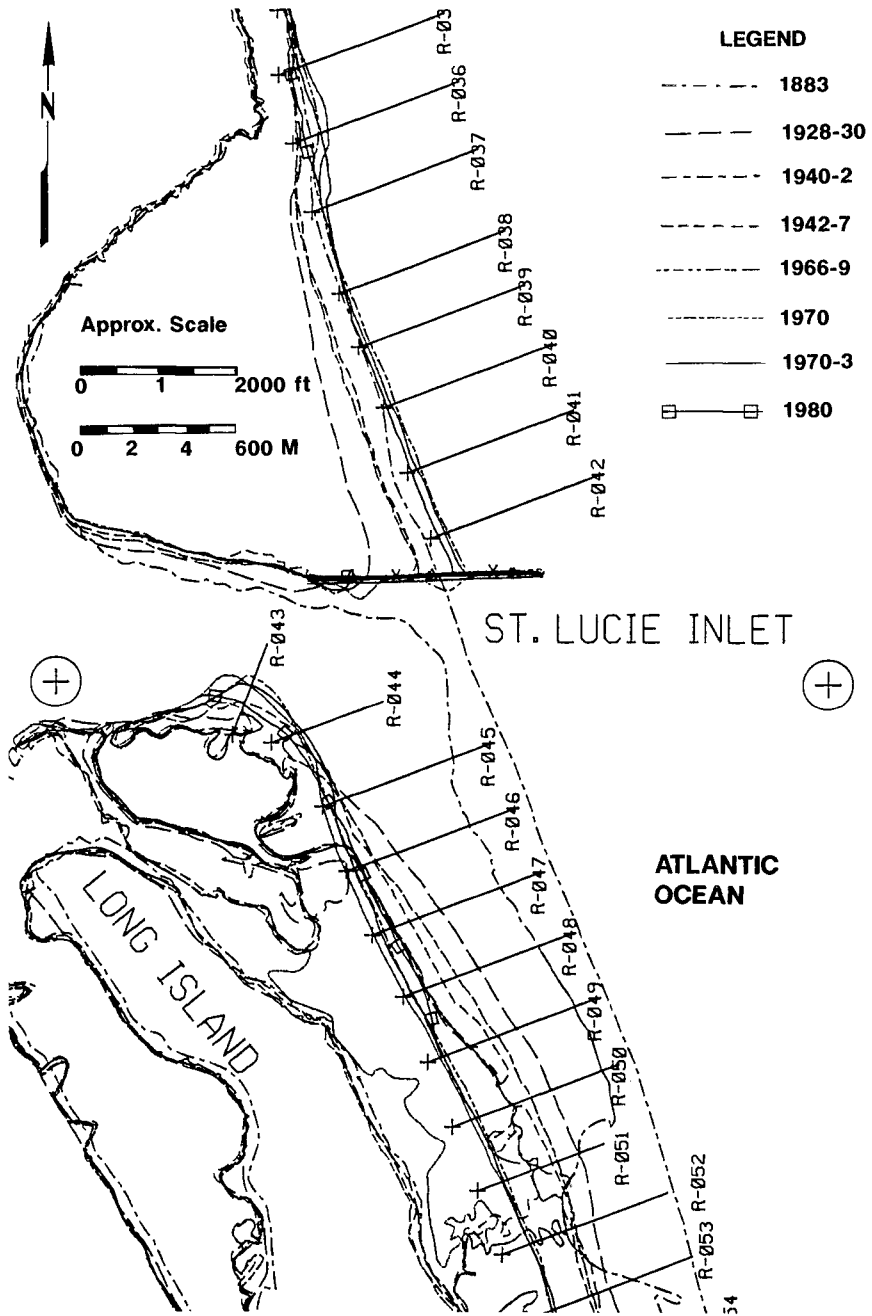

Figure 1. Example, Historic Map

The maps provide the basis for files of tabulated MHW locations referenced to fixed DNR survey points ("R" monuments) at approximate 300 m (1000 ft) intervals along the Florida coast. Beach profiles from these points have been surveyed semi-periodically since the early 1970's. The MHW data from the field surveys is systematically being added to the historic data tables. As new surveys are taken, the data base is continually updated. Strict data quality control is necessary, although this requires a large investment of time and effort. In the past when similar projects have proven unreliable, it was usually because of poor data quality control. The data base is supplemented with sets of controlled and uncontrolled aerial photographs, bathymetric maps, bathymetric profiles, full beach profiles, and access to university and Division libraries.

The accuracy of the historic map data is estimated to be +/- 10-15 meters, or better. The field derived data is +/- 3 meters, and usually better. Not all data are equal. The process of comparing the historic shorelines with physical reality during the analysis helps to determine data of questionable reliability.

### Analysis

A methodology has been developed and tested over several years which works well in analyzing this data set. A useful graphic tool is the distance versus time plot. To illustrate, an example of an enlarged portion of a shoreline change map is shown as Figure 2a. The distances from reference point "R-1" to the various historic shoreline locations, along a fixed, approximately shore-normal direction, are plotted versus time in Figure 2b. A downward sloping line indicates erosion. An upward sloping line indicates accretion. The greater the slope, the more rapid the rate of change. The advantage of the distance versus time plot is simply to give a perspective on the rate of change, which is not readily discernable from the plan view maps. Plots for several adjacent reference points, as shown on the left side of Figure 3, may be combined onto one graph, as shown on the right side of Figure 3. The advantage of the single graph with multiple plots is simply to show that the plots, when viewed in sequence, are related in a pattern.

An example of a non-linear erosion pattern in the historic data is shown in Figures 4a and 4b. The example is the downdrift (south) side of St. Lucie Inlet, in southeast Florida. In a graph such as Figure

Figure 2a. Example, Enlarged Map Area

Figure 2b. Example, Distance vs. Time Plot

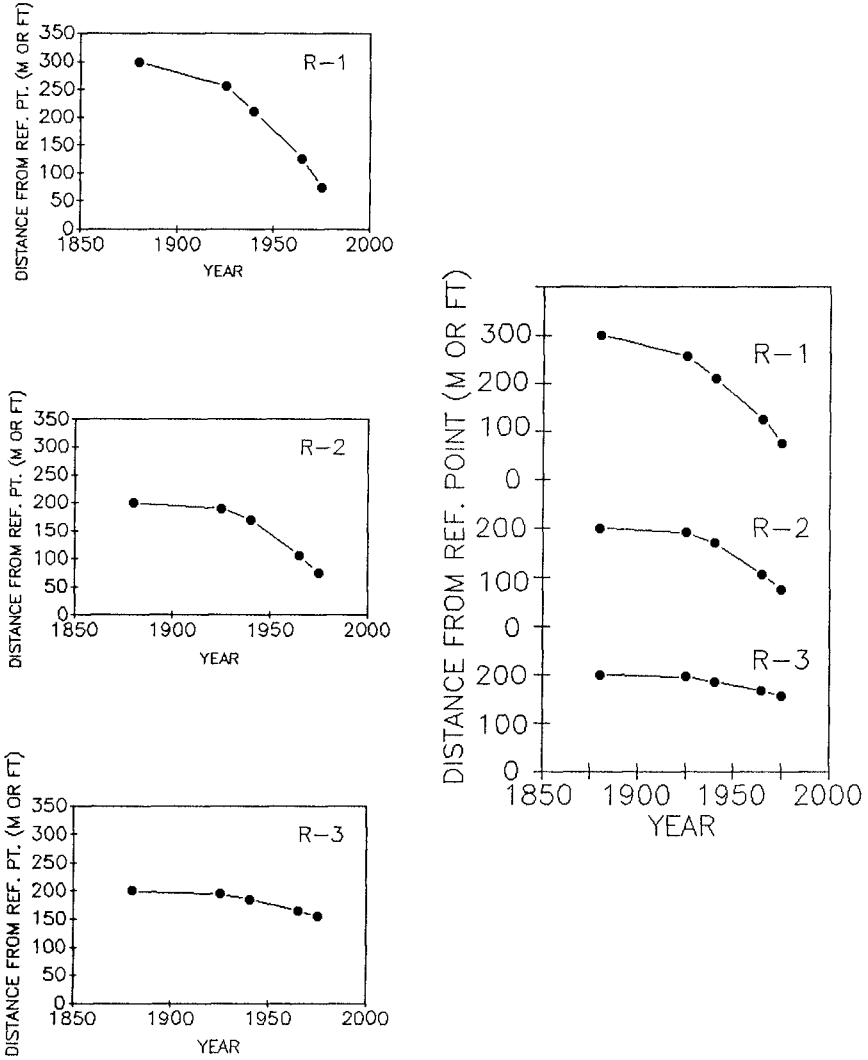

Figure 3. Combining Distance vs. Time Plots

Figure 4a. Plan View, Historic

Figure 4b. Time Plot, Historic

4a, the historic shoreline locations at the reference points can be plotted in a connect-the-dot manner, in any coordinate system. The vertical and horizontal scales can be used to exaggerate the longshore features as desired. The time history of shoreline change along a sequence of selected reference points is given in Figure 4b. Note that the erosion pattern was interrupted by renourishment projects in the early 1970's.

The erosion pattern is easily recognized by comparison to a modeled idealized case, shown in Figures 5a and 5b. A one-line, two-season, longshore numerical (finite difference) model was used to illustrate what theoretical erosion pattern to expect downdrift from a jettied inlet. Note the essential similarity of the non-linear erosion curves in Figure 5b to those of Figure 4b, exclusive of the renourishment period.

Once the erosion pattern is recognized, the task is to resolve the pattern into time segments during which the rate of shoreline change is approximately linear. Three rate calculation methods are then applied to each approximately linear time segment to achieve a consensus estimate, thereby avoiding the potential bias of any individual rate calculation method. Rate estimates are generally averaged alongshore with a floating six or seven point averaging technique, unless there is reason not to do so. Longshore averages are usually rounded upward to the nearest  $-0.15$  m/yr ( $-0.5$  ft/yr) as a conservative practice. The data base and analysis methods are described in greater detail by Foster and Savage (1989a).

A case study where the same numerical model as previously mentioned was calibrated with the entire record of historic data is described by Foster (1991a). The location of the case study area and some of the results of that work are shown in Figures 6a and 6b, respectively. Note that the historic data and the model data match reasonably well. There are two physical equations on which the model is based: a version of the longshore transport equation and an equation for volumetric continuity. The primary factors causing shoreline erosion in this case were indicated by the very limited range of parameters in the model which resulted in a match with the historic data. In addition, the model indicated that the erosion process is non-linear and far from completed, both observations that were not necessarily intuitive.

It must be noted that it is not at this time usually practicable to do calibrated modeling for most

Figure 5a. Plan View, Model

Figure 5b. Time Plot, Model

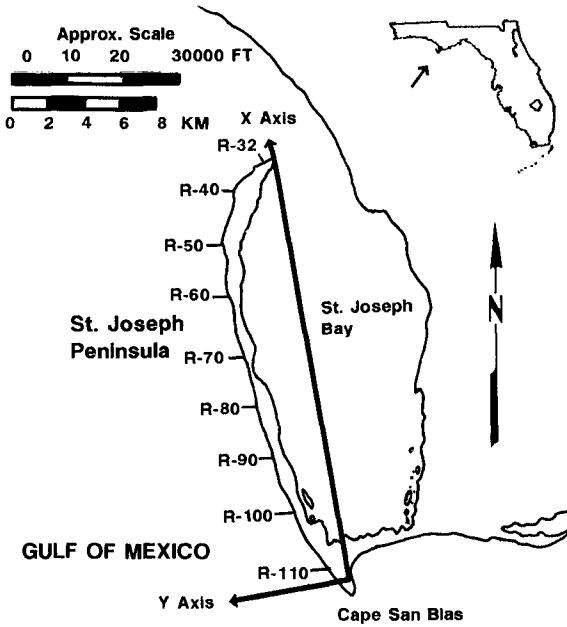

Figure 6a. Location Map

Figure 6b. Comparing Historic Data with Model Results

of the state due to applicability and workload constraints. However, it is becoming increasingly useful to perform general case modeling to help understand and explain to others some of the less obvious erosion patterns. Also, not all areas require an involved analysis for practical results. In some basically stable areas, where inlets are relatively far away, it may not be necessary to know immediately what is occurring as a process throughout the entire region. In such cases, it is usually only necessary to recognize if the historic data are within the range of beach width changes normally observed at the site, and if there is no obvious sand deficit problem. As a conservative practice, a minimum estimate of  $-0.3$  m/yr ( $-1$  ft/yr) is usually forecast for all historically stable areas and even for areas with accretionary trends (exclusive of uncontrolled inlet areas). The use of the minimum estimate allows for some uncertainty about future conditions in general, and about our ability to accurately measure very low levels of shoreline change.

Generally the method of forecasting has been to assume that the most recent major trend will continue linearly forward for the next thirty years. If the case warrants calibrated modeling, such may be used to help project the erosion trend forward for thirty years. However, the use of modeling is a new technique. Typically, the expected rate of change even in a non-linear system is not so rapid as to preclude use of the actual measured data to make projection rates, if the time period for the rate calculation is properly selected.

It is advisable to test the analysis methods and results versus on-site observations and new surveys after several years. If such observations are not consistent with expectations, a review is in order. In our program, preliminary analyses were performed for several regional areas in 1986-89 which are expected to be tested in upcoming years with new regional survey data. Site surveys submitted with permit applications are also used on a daily basis to test previous erosion projections. Another simple test is to ask whether or not the analysis method would have successfully predicted the erosion of the last decade or so, if only data prior to that time were available. If not, the analysis method or the level of understanding about the coastal process is lacking.

The question of the potential effect of sea level rise requires some comment. The historic data necessarily includes the effects of all causes of shoreline change over the last 100+ years, including any

sea level rise and any land subsidence or emergence. Land movement is not believed to have been significant in Florida over the last 100+ year record. The effect of sea level rise appears to be entirely obscured in the data by accuracy limitations, the effects of storms and littoral barriers, and the longshore movement of sand. For the time being, erosion projections will continue to be based on the historic record of change and the observed longshore processes.

## Results

Descriptions of the general findings for some regional areas have been published in various conference proceedings (Foster 1989b, 1991b). However, most of the results exist as in-house reports, pending verification and time to prepare items for publishing.

The historic shoreline maps and data reveal that Florida's sandy beaches have changed in systematic, progressive patterns over the historic record. The shoreline changes appear to be occurring in patterns dictated by the longshore sediment transport equation. The primary factors appear to be the local sand supply situation, the prevailing wave climate, and local geographic features such as rock and peat exposures, nearshore reefs, and man-made littoral barriers. In some areas, the coast is dominated for many kilometers by nearshore rock/reef. It is necessary to account for these features if a thorough understanding of the historic record is to be obtained.

There is certainly randomness in the short term due to seasonal changes, storms, and yearly climatic variations, but these tend to average out over a longer time period. Major storms such as hurricanes also inject an element of randomness by occasionally altering the local conditions, particularly at inlets. In the situation of an uncontrolled inlet, although we may have some understanding of what is occurring, it is not generally a very predictable process.

## Problems

There are several problems which eventually need to be better resolved. At the current staffing level it will necessarily take many years of persistent, careful work to update the data base and to complete the analysis of the state.

One technical issue involves the analysis of areas with existing coastal armoring, including seawalls, revetments, and groinfields. Some of these areas have been armored for most of the historic record, and the condition of the structures varies tremendously. Another technical issue involves setting a thirty year erosion limit in the vicinity of uncontrolled inlets, where large beach width changes are frequent and random. Yet another technical problem involves predicting erosion in the several large areas of the state which have been controlled by repeated beach renourishments over several decades. There is usually insufficient monitoring data for these areas, as well as the complications of varying fill placement volumes, locations, and sand quality. Better monitoring and the use of modeling should help in this situation.

In most areas there is a lack of information regarding nearshore and subsurface geologic features such as rock, peat, and reef formations. The effects on the MHW of dune/bluff recession and overtopping caused by storms are not fully understood at this time. There is also insufficient information to prepare a reliable volumetric budget for many areas.

Beyond the technical issues, there is the human problem of dealing with preconceived, simplistic assumptions about erosion. The data and physics indicate that shorelines are very often not changing at a constant rate, contrary to popular belief and the desire for convenience.

#### Conclusions and Recommendations

A high quality, reliable, updated historical shoreline data base, necessarily including ground truth data, is a worthwhile investment. The data should be related to observed coastal processes in order to reach a basic understanding of cause and effect. The analysis methods and results should include projections of future changes, regardless of whether there is a legal need, and these should be tested over time. In Florida, the shoreline changes are very often non-linear, i.e. not occurring at a constant rate. However, the patterns of shoreline change appear to be very consistent with the physics of the longshore sand transport equation. Longshore models are useful and will probably become necessary in the analysis of many cases.

In the opinion of the author, it is now possible for an analyst to develop a basic understanding of longshore coastal processes for most areas of Florida

based on reliable data and physics, rather than subjective judgments. Many problems remain, but a reasonably good start has been made.

## CHAPTER 159

### Grain-sorting over ripples induced by sea waves

Enrico Foti<sup>1</sup>, Paolo Blondeaux<sup>2</sup>

#### Abstract

A predictive theory for the formation of ripples under sea waves is presented for a sandy bottom characterized by a large grain-size distribution. The theory is based on a linear stability analysis. The conditions for the amplification or decay of bottom perturbations are determined and the experimentally observed sorting effect due to the presence of the bedforms is modelled. A comparison between the experimental data available in literature and the present results is attempted.

#### Introduction

In the past, the dynamics of sediment in nearshore regions was extensively studied in terms of a uniform material. However, coastal sediment typically has a wide range of grain sizes and the presence of mixtures has a large influence on coastal morphodynamics. Indeed, the grain sorting process which is typical of the transport of mixtures may inhibit or enhance sediment transport in areas characterized by low shear stress. For this reason, the last decade saw a major change in thinking, and important problems involving mixtures were at least formulated correctly and a fair number of them were solved as well, at least for sediment in transport in rivers, (Parker, 1991).

In accordance with this viewpoint, a predictive theory is presented in the present paper for ripple formation under sea waves in the case of a cohesionless bottom made up of a mixture. Following Blondeaux (1990), the theory is based on a linear stability analysis of a flat bottom subject to a viscous oscillatory flow. The aim of the work is twofold: first, to determine the conditions for the decay or the amplification of a bottom perturbation and second to study the grain-sorting

process which leads the coarser fraction to accumulate along the crests of the perturbation while the finer fraction tends to move towards the troughs (Mei, 1989).

The procedure used in the rest of the paper is the following: in the next section, the problem is formulated by focusing our attention on the equation forcing the sediment mass balance and the relationship between sediment transport rate and fluid flow. Indeed, the above equations need particular care when written for a mixture. As discussed more deeply in the following, the continuity equation is written introducing: i) an active layer, scaled on the largest grain sizes and characterized by a vertical uniform size density (Hirano, 1971), which corresponds to the reservoir of material directly available for transport, ii) a bottom layer underneath the active layer, the sediment of which can be entrained by the flow only because of bottom erosion. In the bottom layer, the size density may have a vertical structure. The sediment transport rate is evaluated by means of a formula valid for a uniform sediment times the size density evaluated in the active layer. The sheltering effects exerted by the large grains on small ones are taken into account by introducing a "hiding" factor in the sediment transport rate formula (Parker, 1991).

In §3 an approximate analytical solution for the bed evolution is obtained taking into account that the time scale of the bed time development is much longer than the period of fluid oscillations, i.e. the period of sea waves. Finally in §4 the quantitative results are presented along with a qualitative comparison with the experimental data available in literature.

### Formulation of the problem

As pointed out in the introduction, a significant feature of coastal areas is the wide range of sediment sizes found there. Let us then consider an initially cohesionless sea bottom formed by a sand mixture uniformly distributed in space. To deal with the statistics of the mixture, the logarithmic sedimentological scale  $\phi$  is used, defined by

$$d^*/l^* = 2^{-\phi} \quad (1)$$

where the grain size  $d^*$  is made dimensionless by means of a characteristic length scale of the problem  $l^*$  which will be defined in the following. Hence, the characteristics of the sand mixture are specified in terms of the size distribution  $p_f(\phi)$  or the size density  $p(\phi)$ . The function  $p_f(\phi)$  is defined such that fraction  $p_f(\phi)$  of a sample is finer than size  $\phi$  while  $p(\phi)$  is its derivative, i.e.  $p(\phi) = dp_f(\phi)/d\phi$ .

There are other statistical parameters that summarize the characteristics of the mixture: the geometric mean size  $d_m^*$  and the geometric standard deviation  $\sigma_g$  given by

$$d_m^*/l^* = 2^{-\phi_m} \quad \sigma_g = 2^\sigma \quad (2)$$

where

$$\phi_m = \int_{-\infty}^{+\infty} \phi p(\phi) d\phi \quad \sigma^2 = \int_{-\infty}^{+\infty} (\phi - \phi_m)^2 p(\phi) d\phi \quad (3)$$

A Cartesian orthogonal coordinate system  $(x^*, y^*, z^*)$  is then defined with the  $x^*$  and  $z^*$  axis lying on the sea bottom and the  $y^*$  axis directed upward. Because of the presence of a two-dimensional surface gravity wave, let us assume that the fluid close to the bottom but outside the viscous boundary layer oscillates in time with velocity

$$(u^*, v^*, w^*) = \left(-\frac{1}{2}U_0^* e^{i\omega^* t^*} + c.c., 0, 0\right) \quad (4)$$

where  $t^*$  is time,  $\omega^* = 2\pi/T^*$  the angular frequency of the sea wave,  $U_0^*$  the amplitude of the irrotational velocity oscillations evaluated close to the bottom, c.c. denotes the complex conjugate of a complex number and  $(u^*, v^*, w^*)$  are the velocity components according to the Cartesian coordinate system  $(x^*, y^*, z^*)$ . If the bottom is flat and all the grain sizes in the sand mixture are much smaller than the characteristic thickness of the bottom boundary layer  $\delta^*$ , the fluid motion is described by the well known Stokes' solution and the sediment moves to and fro. The thickness  $\delta^*$ , which can be defined as  $\sqrt{2\nu/\omega^*}$  ( $\nu$  being the kinematic viscosity of sea water), can then be assumed as the length scale of the problem, i.e.  $l^* = \delta^*$ .

The study of the time development of a two-dimensional bottom perturbation in the form

$$y^* = \eta^*(x^*, t^*) = \epsilon^* C_1(t) e^{i\alpha^* x^*} + c.c. \quad (5)$$

is posed by the vorticity equation, the flow and sediment continuity equations plus a relationship between sediment flow rate  $q^*$  and flow properties, along with boundary conditions which force the matching of the flow with the irrotational motion outside the bottom boundary layer and the no-slip condition at  $y^* = \eta^*$ . Because of the presence of the sand mixture, the sediment continuity equation needs to be discussed in detail. Assuming all grains to have the same density, the statement of mass balance for each grain size can be reduced to a similar one for volume balance

$$-\frac{\partial(q^* p_s)}{\partial x^*} = (1-n) \frac{\partial}{\partial t^*} \int_{-\infty}^{\eta^*} p dy^* \quad (6)$$

where it is assumed that the volume transport of bedload per unit time per unit width of grain in the size range  $(\phi, \phi + d\phi)$  is provided by the relationship describing the sediment transport rate for a uniform material ( $q^*(\phi)$ ) times the

size density  $p_s(\phi)$  at the surface. As discussed in Parker (1991), to simplify the problem it is assumed that near the surface there is an active layer characterized by a thickness  $L_a^*$  which corresponds to the reservoir of material directly available for transport and where the grains are well mixed. It follows that the size density  $p_s$  within it has no vertical structure even though it can have a streamwise and time structure. Below the active layer lies the substratum material with size density  $p_b$ . This may vary arbitrarily in  $x^*$  and  $y^*$  but cannot change directly in time because it is not directly subject to movement. Material can be exchanged between the substratum and the active layer through the intermediary of bed aggradation or erosion as outlined below.

By applying Leibnitz's rule, the following result is obtained from (6)

$$-\frac{\partial(p_s q^*)}{\partial x^*} = (1 - n) \left\{ p_i \frac{\partial \eta^*}{\partial t^*} + \frac{\partial}{\partial t^*} (L_a^* p_s) \right\} \tag{7}$$

The value of  $p_i$  can be specified in the case of a degrading bed as  $p_b$ , since substratum is incorporated into the surface layer as the bed elevation drops. In the case of an aggrading bed  $p_i$  can be assumed equal to  $p_s$  since the surface material is transferred directly to the substratum.

$$p_i = \begin{cases} p_s & \text{if } \partial(\eta^* - L_a^*)/\partial t > 0 \\ p_b & \text{if } \partial(\eta^* - L_a^*)/\partial t < 0 \end{cases} \tag{8}$$

Finally, it should be pointed out that  $L_a^*$  can be assumed to scale with some large size, e.g.  $d_{90}^*$ .

Let us then define the following dimensionless variables

$$(x, y) = (x^*, y^*)/\delta^* \quad t = t^*\omega^* \quad \epsilon = \epsilon^*/\delta^* \quad \alpha = \alpha^*\delta^* \quad L_a = L_a^*/\delta^*$$

$$\eta = \eta^*/\delta^* \quad \psi = \psi^*/U_0^*\delta^* \quad q = \frac{q^*}{[(\rho_s - \rho)gd_{m0}^*]^3/2}$$

where  $g$  is the gravity,  $\psi^*$  is the stream function such that  $u^* = \partial\psi^*/\partial y^*$ ,  $v^* = -\partial\psi^*/\partial x^*$  and  $d_{m0}^*$  the mean size of the initial uniform mixture characterized by a size density  $p_o(\phi)$ .

The governing differential problem then reads:

$$\frac{2}{R_\delta} \frac{\partial}{\partial t} (\nabla^2 \psi) + \frac{\partial \psi}{\partial y} \frac{\partial}{\partial x} (\nabla^2 \psi) - \frac{\partial \psi}{\partial x} \frac{\partial}{\partial y} (\nabla^2 \psi) = \frac{1}{R_\delta} (\nabla^4 \psi) \tag{9}$$

$$\frac{\partial \psi}{\partial y} \rightarrow -\frac{1}{2} e^{it} + c.c. \quad \frac{\partial \psi}{\partial x} \rightarrow 0 \quad \text{for } y \rightarrow \infty \tag{10}$$

$$\frac{\partial \psi}{\partial y} = 0 \quad \frac{\partial \psi}{\partial x} = 0 \quad \text{for } y = \eta \tag{11}$$

where the flow Reynolds number  $R_\delta$  is defined as follows:

$$R_\delta = \frac{U_o^* \delta^*}{\nu}$$

As pointed out previously, in order to close the above formulation, we need a relationship between sediment flow rate  $q^*$  and flow properties. Presently, a modified version of the Grass-Ayoub (1982) formula is used. The differences consist in the introduction of the effect of gravity related to the bed elevation and in the introduction of the "hiding" factor  $(\frac{d^*}{d_{mo}^*})^r$ . This formula, even though simple and possibly rough, appears to contain the main physical ingredients controlling the process of transport:

$$q = a \left( \frac{2}{R_{do}} \right)^b \left( \frac{d^*}{d_{mo}^*} \right)^{-0.03-b} \cdot \left| \left( \frac{d^*}{d_{mo}^*} \right)^r v_t - \frac{\beta R_{do}}{2F_{do}^2} \frac{\partial \eta}{\partial x} \right|^{b-1} \cdot \left( \left( \frac{d^*}{d_{mo}^*} \right)^r v_t - \frac{\beta R_{do}}{2F_{do}^2} \frac{\partial \eta}{\partial x} \right) \quad (12)$$

where  $a = 1.23$ ;  $b = 4.28$ ;  $\beta = 0.15$  and  $v_t$  is the fluid velocity evaluated at  $y^* = d^*/2$  parallel to the bed profile. It can be seen that values of  $r$  close to one as discussed by Parker (1991) correspond to the condition for equal-mobility.

The particle Reynolds number  $R_{do}$  and the particle Froude number  $F_{do}$  are defined in terms of the geometric mean size  $d_{mo}^*$  to the initial grain size distribution:

$$R_{do} = \frac{U_o^* d_{mo}^*}{\nu}; \quad F_{do} = \frac{U_o^*}{[(s-1)g d_{mo}^*]^{1/2}}; \quad s = \frac{\rho_s}{\rho};$$

Since the bottom waviness is assumed to be of a small amplitude the quantity  $\epsilon$  can be assumed much smaller than one and the solution to the problem can be expanded in power series of  $\epsilon$  in the form:

$$\psi = \psi_0(y, t) + \epsilon C_1(t) \phi_1(y, t) e^{i\alpha x} + c.c. + 0(\epsilon^2) \quad (13)$$

$$q = q_0(\phi, t) + \epsilon C_1(t) q_1(\phi, t) e^{i\alpha x} + c.c. + 0(\epsilon^2) \quad (14)$$

$$p = p_0(\phi) + \epsilon C_1(t) p_1(\phi, t) e^{i\alpha x} + c.c. + 0(\epsilon^2) \quad (15)$$

By substituting (13)  $\div$  (15) into (9)  $\div$  (12) and equating similar powers of  $\epsilon$ , at order one a problem is found which can easily be solved. As pointed out previously, the flow is described by the well-known Stokes' solution and the sediment moves to and fro. Because the moving material is still considered as belonging to the bottom, the size density  $p_0$  does not change with time. Moreover,  $p_0$  does not depend on  $x$  because of the supposed uniformity of the problem.

At order  $\epsilon$  the problem reads:

$$\begin{aligned} \frac{2}{R_\delta} \frac{\partial}{\partial t} \left( \frac{\partial^2 \phi_1}{\partial y^2} - \alpha^2 \phi_1 \right) + i\alpha \left[ \frac{\partial \psi_0}{\partial y} \left( \frac{\partial^2 \phi_1}{\partial y^2} - \alpha^2 \phi_1 \right) - \frac{\partial^3 \psi_0}{\partial y^3} \phi_1 \right] = \\ = \frac{1}{R_\delta} \left[ \frac{\partial^4 \phi_1}{\partial y^4} - 2\alpha^2 \frac{\partial^2 \phi_1}{\partial y^2} + \alpha^4 \phi_1 \right], \end{aligned} \tag{16}$$

$$\frac{\partial \phi_1}{\partial y} \rightarrow 0, \quad \phi_1 \rightarrow 0, \quad y \rightarrow \infty \tag{17}$$

$$\frac{\partial \phi_1}{\partial y} = -\frac{\partial^2 \psi_0}{\partial y^2}, \quad \phi_1 = 0, \quad y = 0 \tag{18}$$

$$-\frac{2F_{d0}}{R_{d0}}(1-n) \frac{dC_1(t)}{dt} = i\alpha q_1(t) C_1(t), \tag{19}$$

$$\begin{aligned} q_1 = ab \left( \frac{2}{R_{d0}} \right)^b \left( \frac{d^*}{d_{m0}^*} \right)^{-0.03-b} \left| \frac{\partial \psi_0}{\partial y} \left( \frac{d^*}{d_{m0}^*} \right)^r \right|^{b-1} \cdot \\ \cdot \left\{ \left[ \frac{\partial \psi_1}{\partial y} + C(t) e^{i\alpha x} \frac{\partial^2 \psi_0}{\partial y^2} \right]_{y=\frac{d}{2}} \left( \frac{d^*}{d_{m0}^*} \right)^r - \frac{i\alpha \beta R_{d0}}{2F_{d0}^2} C(t) e^{i\alpha x} \left( \frac{d^*}{d_{m0}^*} \right)^2 \right\} \end{aligned} \tag{20}$$

It should be pointed out that at order  $\epsilon$ , the term proportional to the time derivative of  $C_1(t)$  in the vorticity equation has been ignored. From a physical point of view, this corresponds to ignoring the influence of the variation of bottom elevation on fluid motion. From a mathematical point of view, this assumption is justified by the small value usually attained by the dimensionless parameter

$$Q = 0.615((s-1)/s) F_{d0}^{-1.45} (R_{d0}/R_\delta)^{4.28} / (1-n) \sim \frac{dC_1(t)}{dt} / C_1(t). \tag{21}$$

Solution

Because of the assumption  $dC_1/dt \ll C_1(t)$ , flow development has been decoupled from the sediment motion. Equations (16) ÷ (20) and boundary conditions (17) ÷ (18) can then be solved with the same procedure used in Blondeaux (1990) to which the reader should refer for details. Once the stream function is known, the bottom time development can be obtained from the sediment continuity equation and the sediment flow rate formula, which at order  $\epsilon$  provides

$$\begin{aligned} (L_0 p_1 + p_0) \frac{dC_1}{dt} = -L_0 C_1 \frac{\partial p_1}{\partial t} - \\ - \frac{i\alpha R_{d0}}{2F_{d0}(1-n)} [q_0 p_1 + p_0 q_1] C_1 \end{aligned} \tag{22}$$

By integrating (22) over the whole range of  $\phi$  and forcing that

$$\int_{-\infty}^{+\infty} p_0(\phi) d\phi = 1 \quad \int_{-\infty}^{+\infty} p_1(\phi, t) d\phi = 0 \quad (23)$$

an equation for  $C_1(t)$  is obtained which allows the time development of the ripple amplitude to be determined once the function  $p_1(\phi, t)$  is known,

$$\frac{dC_1}{dt} = -\frac{i\alpha R_{d0}}{2F_{d0}(1-n)} \left[ \int_{-\infty}^{+\infty} (q_0 p_1 + p_0 q_1) d\phi \right] C_1 \quad (24)$$

The perturbation of the grain size distribution  $p_1(\phi, t)$ , can be obtained by substituting (22) for (24):

$$\begin{aligned} \frac{\partial p_1}{\partial t} = & -\frac{i\alpha R_{d0}}{2F_{d0}(1-n)L_0} \{ [q_0 p_1 + p_0 q_1] - \\ & - (L_0 p_1 + p_0) \int_{-\infty}^{+\infty} (q_0 p_1 + p_0 q_1) d\phi \} \end{aligned} \quad (25)$$

The solution to the problem posed by equations (24) and (25) cannot be found in closed form. However, an asymptotic solution can be determined by taking advantage of the small values usually attained by the quantity  $Q$ . Indeed, it turns out that:

$$\frac{dC_1}{dt} = -i\alpha Q \left[ \int_{-\infty}^{+\infty} (\tilde{q}_0 p_1 + p_0 \tilde{q}_1) d\phi \right] C_1 \quad (26)$$

$$\frac{\partial p_1}{\partial t} = -\frac{i\alpha Q}{L_0} \left[ \tilde{q}_0 p_1 + p_0 \tilde{q}_1 - (L_0 p_1 + p_0) \int_{-\infty}^{+\infty} (\tilde{q}_0 p_1 + p_0 \tilde{q}_1) d\phi \right] \quad (27)$$

where the quantities  $\tilde{q}_0, \tilde{q}_1$  (defined below) along with  $p_0, p_1, L_0$  are expected to be quantities of order one:

$$(\tilde{q}_0, \tilde{q}_1) = \frac{R_{d0}}{2F_{d0}(1-n)Q} (q_0, q_1) \quad (28)$$

The functions  $C_1(t)$  and  $\phi_1(\phi, t)$  can then be expanded in power series of  $Q$ :

$$C_1(t) = C_{10} + QC_{11}(t) + 0(Q^2); \quad (29)$$

$$p_1(\phi, t) = p_{10}(\phi) + Qp_{11}(\phi, t) + 0(Q^2) \quad (30)$$

The functions  $C_{10}$  and  $p_{10}$  turn out to be time independent. The constant  $C_{10}$  can be fixed equal to one without loss of generality while the function  $p_{10}$  depends on the initial conditions. By substituting (29) and (30) for (26) and (27) it can be seen that

$$\frac{dC_{11}}{dt} = -i\alpha \left[ \int_{-\infty}^{+\infty} \tilde{q}_0 p_{10} + p_0 \tilde{q}_1 d\phi \right] = f(t) \quad (31)$$

$$\frac{\partial p_{11}}{\partial t} = -\frac{i\alpha}{L_0} \{ \tilde{q}_0 p_{10} + p_0 \tilde{q}_1 - (L_0 p_{10} + p_0) \int_{-\infty}^{+\infty} (\tilde{q}_0 p_{10} + p_0 \tilde{q}_1) d\phi \} \quad (32)$$

The right hand side of (31) is a periodic complex function of time denoted  $f(t)$ . The growth or decay of the perturbation amplitude, i.e. ripple formation, is thus controlled by the sign of the real part of the time average of  $f(t)$ . The time average of the imaginary part is related to ripple migration and turns out to vanish because of the symmetry of the problem. The oscillating parts of  $f(t)$  with vanishing time average describe the time variation of the perturbation profile during a wave cycle. More precisely the real part describes oscillations of the amplitude of the bottom perturbation while the imaginary part controls the small longitudinal oscillations of the ripple profile around its average position. The value of the time average of the real part of  $f(t)$  is negative or positive depending on the values attained by the flow and sediment parameters  $\alpha$ ,  $R_\delta$ ,  $R_{do}$ ,  $F_{do}$ ,  $p_o$ .

### Discussion of the results

As in Blondeaux (1990), two contributions to  $\bar{f} = \frac{1}{2\pi} \int_0^{2\pi} f(t) dt$  can be identified. The former is associated with the steady component of the fluid velocity and is usually destabilizing since the steady drift close to the bed tends to carry sediments from the troughs towards the crests of the perturbation, thus causing its growth. The latter contribution is due to the component of the gravity along the bed profile which has a stabilizing effect. In fact, gravity opposes the tendency of the flow to carry sediments from the troughs towards the crests of the perturbation, thus causing the decay of the latter. Assuming that  $p_o(\phi)$  is a normal distribution, so that the standard deviation  $\sigma_o$  identifies the grain size distribution once  $R_{do}$  is fixed, the behaviour of the perturbation is controlled by a balance between the two effects described above which depends on the values of  $\alpha$ ,  $R_\delta$ ,  $R_{do}$ ,  $F_{do}$  and  $\sigma_o$ .

In figure 1 the value of  $\bar{f}$  is plotted versus the wave number of the disturbance  $\alpha$  for fixed values of  $R_\delta$ ,  $R_{do}$  and  $\sigma_o$  and for different values of  $F_{do}$ . It appears that a critical value  $F_{dc}$  of  $F_{do}$  exists such that: for  $F_{do}$  less than  $F_{dc}$  the bottom perturbations characterized by any value of the wave number  $\alpha$  decay; for  $F_{do}$  larger than  $F_{dc}$  disturbances characterized by values of  $\alpha$  falling within a restricted range experience an average amplification during a cycle.

The qualitative behaviour of the results does not change when different values of  $\sigma_o$  are considered. However, in figure 2 it can be seen that the critical value

of  $F_{do}$  increases when increasing values of  $\sigma_o$  are considered: a bottom made up of a mixture is more stable than one composed of well sorted material. Similar results are obtained for different values of  $R_{do}$ .

In figure 3 the critical wave number of the bottom perturbation  $\alpha_c$  is plotted versus  $R_\delta$  for fixed values of  $R_{do}$  and  $\sigma_o$ .

A comparison between the present theoretical findings and experimental data by Blondeaux et al. (1988) is shown in figure 4 where the ratio between the amplitude of fluid displacement  $a^*$  and the critical ripple wavelength  $l^*$  is plotted versus  $R_\delta$ . The theoretical predictions are shown considering sediments characterized by a specific weight  $\rho_s/\rho = 2.65$ ;  $R_{do} = 10$ ;  $\sigma_o = 0.05$ . The experimental data refer to a well sorted silt characterized by a mean diameter equal to 0.124 millimeters, a standard deviation equal to 0.02 millimeters and a specific weight equal to  $2.65t/m^3$ . The experimental conditions are such that  $R_\delta$  ranges between 20 and 85 and the Reynolds number of the sediments falls within the range (5,15). The agreement seems satisfactory even though the lack of experimental data in literature concerning mixtures characterized by large values of the standard deviation  $\sigma_o^*$  does not make a good test for the present theory possible.

The tendency of the process to pile up larger sediments towards the crests is described by means of the integration of equation (32). Also in this case the right hand side of (32) turns out to be a periodic function and the process is thus controlled by the time average of  $\frac{\partial p_{11}}{\partial t}$ . If initial perturbations are absent in the grain size distribution, i.e.  $p_{10}(\phi) = 0$ , the time average of  $\frac{\partial p_{11}}{\partial t}$  shows that smaller grains are shifted towards the troughs and larger grains towards the crests, as experimentally observed (Mei, 1989). Indeed, figure 5 shows that the time average of  $p_{11}$  is real and positive for small values of  $\phi$  and negative for large values of  $\phi$ . It is worthwhile pointing out that values of  $r$  close to one have been used in obtaining the results shown in figure 5. These values of  $r$  are suggested by experimental measurements by Parker (1990) and correspond to equal mobility of all grains, i.e. the bias toward fine material in the bedload relation is almost counteracted by the mean of the hiding function  $(\frac{d^*}{d_{m\phi}})^1$ .

Figure 6 where the time average of  $p_{11}$  is plotted for the same values of the parameters as in figure 5 but for  $r = 0$  shows that the hiding effects exerted by large grains on small ones is essential in describing the sorting process. In fact, when hiding effects are ignored, small grains tend to pile up near the crests and large grains towards the troughs.

The authors would like to thank Professor Parker for his interesting discussions on various issues arising from the work.

This work is part of E.F.'s Ph.D thesis.

## CHAPTER 160

### Oscillatory Bedload Transport Studies by Imaging of Tracers

E.L. Gallagher<sup>1</sup> and R.J. Seymour, M. ASCE<sup>2</sup>

#### Abstract

Full scale laboratory flows producing vigorous bed load transport are conducted at varying periods but constant maximum velocities. The time-varying sediment transport in the first half cycle is measured using video imaging of dyed natural sand. The acceleration of the fluid (proportional to the frequency of the oscillation in these experiments) is found to significantly affect the velocity of the sediment response (bedload transport), and the phase and the absolute magnitude of fluid velocity associated with the initiation of sediment motion.

#### Introduction

Bedload has long been recognized as an important element in surfzone sediment transport because, over a great portion of the nearshore, and excepting those areas of greatest near bottom fluid energy, bedload is recognized as the only means for moving sediment. Observing and quantifying bedload is inherently more difficult than for suspended sediment because the density of the carpet flow precludes the conventional acoustical and optical scattering measurements that have been developed for the relatively sparse suspensions above the bed. Further, the assumption that the suspended material moves at the velocity of the adjacent fluid cannot be made for bedload, requiring that both the fluid and the sediment velocities be measured independently to understand the response of the sediment to fluid forcing.

As a result of these difficulties, few observations are available of bedload under oscillatory flows under either field or laboratory conditions and little is known about the character of these important flows. Recognizing this, we began a program of full scale laboratory investigations in an oscillatory tunnel employing traps several years ago (King et al., 1984, King, 1991). More recently, the present authors developed an improved technique for observing bedload remotely in this same tunnel without the problems associated with integrating sediment response over time that is inherent with traps. This method is described in general in the following section and in detail in Gallagher et al. (1991).

---

<sup>1</sup> Graduate Student, <sup>2</sup> Head, Ocean Engineering Research Group, Scripps Institution of Oceanography, University of California San Diego, La Jolla, CA 92093-0222.

As first suggested by King (1991), our work strongly indicated that accelerations played an important role in bedload transport, affecting significantly the magnitude of the sediment velocity with a fixed fluid velocity amplitude, as well as affecting the phase of the response and the initiation of the sediment motion. Given that present predictive models for bedload transport depend only upon the magnitude of the velocity and ignore its time rate of change (see King and Seymour, 1989 for a review of models), we felt that these findings were significant and should be brought to the attention of other researchers concerned with quantifying bedload transport. It should be noted that Hallermeier (1982) discussed the dependence of bedload transport and concluded that fluid accelerations played a "direct role" in sand transport and suggested laboratory work to clarify the effects. The present paper describes our initial work and suggests that these results are of sufficient importance to justify further research in this area, particularly utilizing other means (such as acoustical bedload sensors) to verify and to further quantify these effects.

### Measurement Techniques

The oscillatory flow tunnel (OFT) at the Scripps hydraulic laboratory is a flat U-tube with a long rectangular center section and cylindrical risers on either end (see Figures 1 and 2). It is driven by a hydraulic cylinder powering a ram in one of the risers. The test section is 39.4 cm wide, 40 cm high, and 600 cm in length. The maximum water particle excursion in the test section is 214 cm. There is no free surface and the water is forced in solid body motion of arbitrary waveform by computer control. Additional details are contained in King et al. (1984) and King (1991). As described in Gallagher et al. (1991) and Gallagher and Seymour (1991), a smooth bed of natural sand is prepared in which there is a section of the same sand dyed a contrasting color. The general arrangement is shown in Figure 3. In these experiments, a half cycle of sinusoidal water motion was then commanded with a maximum free stream velocity of 80 cm/s. Holding this maximum velocity constant, the period of the oscillatory motion was varied in each experiment over a range from 3 to 6 seconds. That is, the maximum acceleration varied by a factor of two while the maximum velocity remained constant.

As the fluid accelerates from rest, it reaches a condition at which the sand in the bed begins to move and during the deceleration portion of the half cycle, the sand eventually all comes to rest. The motion is detected in these experiments by video imaging. A video camera with a wide angle lens is mounted just above the transparent top of the OFT and images are recorded at approximately 30 hz. These video records are recorded on super VHS format and can be output as steady single frames from a high quality medical-imaging-type tape player. In the color image, the dyed sand is readily recognizable from the natural sand. Therefore, each image shows the accumulated motion in a single direction, to that time, of the dyed sand, since the flow does not reverse. The single frame images are readily stored in a PC computer using a standard commercial framegrabber board and its related software.

The sediment does not move as a monolithic block. Rather, there is a large dispersion in the response that increases with time and distance downflow, in spite of the well sorted character of the sand (median and mean diameter = 1.1 mm, sorting factor = 0.29, skewness = 0.02, kurtosis = 0.66).. This response dispersion is shown conceptually in Figure 4. Because a particle-by-particle tracking strategy seemed too cumbersome, the method used in Gallagher et al., 1991 was employed. Simply stated, the image in the computer is converted to grey scale and the numbers

Figure 1. General view of the oscillatory flow tunnel in the SIO hydraulic laboratory.

Figure 4. Schematic view of upper surface of the bed following the experiment. Water and sediment motions have been from left to right.

representing the intensity (darkness) of each pixel in the image are averaged over a column extending across the tunnel, orthogonal to the flow. This average color intensity is then a measure of the amount of dyed sand in the upper layer or two that has moved into that column of pixels. In general, this number should increase with time until the sediment motion stops and then remain steady. In practice, that is what is observed. The dyed sand section has sufficient length, relative to the sediment motion, that no undyed sand is imported into the image.

Figure 5 shows a representative plot of these intensities along the flow axis from a single image. Some low level noise of the type shown here is always present, but the data also always show a clear underlying curve representing the distribution of distances travelled by the dyed sand grains. A smooth curve is passed through the data using a high order polynomial fit and this smooth curve then represents the results of a single image from an experiment. To define a representative distance traveled for each of these distributions (images), the intersection of the smooth curve with an arbitrary intensity level was chosen (see dashed line on Figure 5.)

Prior work (King, 1991) had shown that the free stream velocity could be accurately determined from a linear position transducer on the ram and this position was recorded on a PC during the experiment. The computer periodically actuated a light visible in the video image in approximately one out of each 15 images, which allowed time synchronization within about 0.015 seconds. In this manner, the free stream velocity could be obtained by differentiating the ram position and the position of the representative dyed sand intensity contour could be time correlated with it. The sediment velocity and acceleration were obtained by successive differentiation of the positions obtained from the images.

## Results

Experiments were conducted at periods of 3,4,5 and 6 second periods, all with amplitudes resulting in a maximum velocity of 80 cm/s. The response of the sediment is shown in Figure 6. Note that time has been nondimensionalized by the period so that a single curve represents the fluid velocity in each case. It can be clearly seen that the higher accelerations (lower periods) result in an initiation of motion at a later phase than for the lower accelerations. The phases are plotted as angles against peak accelerations in Figure 7. The results are shown in dimensional form in Table I and it is clear that the absolute initiation velocities are higher when the rate of change of fluid velocity is higher, which might be considered counter-intuitive.

The resulting sediment velocities are shown in Figure 8. Smooth curves have been fitted to the calculated velocity values. Note that the maximum sediment velocity increases monotonically with the maximum fluid acceleration and it occurs at a later phase. The shortest period oscillation (3 seconds) results in a maximum sand velocity of almost 60 cm/s - about 75% of the maximum free stream fluid velocity.

Figure 5. A non-dimensional plot of the intensities of the image (higher intensity signifies greater fraction of dyed versus natural sand) against distance down the flume. The origin of the abscissa is the initial boundary between the dyed and the natural sand.

Figure 6. Sediment movement and fluid velocity plotted against nondimensionalized time (fraction of oscillatory period). The periods of the water motions are plotted adjacent to the sediment responses. The effects of acceleration can be clearly recognized.

Exp No.	Period (sec)	Phase (deg)	Velocity (cm/s)	Acceleration (cm/s <sup>2</sup> )
6	3	46.8	58.3	114.7
9	4	41.4	52.9	94.3
12	5	34	44.7	83.3
15	6	31	41.2	71.8

Figure 7. The phase of the initiation of motion (in degrees) plotted against the magnitude of the peak acceleration for each run.

Figure 8. The velocity of the fluid and the resulting velocities of the sediment at various periods of oscillatory flow are plotted against nondimensional time.

### Discussion and Conclusions

These experiments were begun from rest after long stilling periods such that laminar flow conditions existed at least at the initiation of fluid flow. Because the flow was stopped as it decreased to zero (no flow reversal) there was little or no opportunity to develop a boundary layer typical of continuing oscillatory flows - in which the bottom stress is theoretically expected to lead the free stream by  $\pi/4$ . Therefore, there was unlikely to be any substantial phase differences between the free stream and the nearbed flows. In fact, careful observation of suspended particle velocities in King (1991) indicate no discernible phase shift right down to the bed in the half cycle flows.

The significance of this is that any phase shifts between sand and the fluid observed would be a function only of the response of the sediment to the bottom stress. We observed substantial velocity phase leads for the sediment in the longer period experiments, but these reduced to near zero for the shortest period. In fact, in all of the experiments the sediment came to rest either before the maximum free stream velocity had been reached or before it had dropped to 75% of its maximum value. This very surprising result would indicate a response mechanism that is highly sensitive to acceleration - as the positively directed acceleration approaches zero, the bedload ceases, even though the free stream velocity is at or near its maximum value. Sleath (1978) observed a phase lead of the sediment of roughly  $\pi/8$  in continuously oscillating flows and discounted inertial effects because the acceleration leads the velocity by  $\pi/2$ . However, the present evidence - which removes any effects of phase shifts in the boundary layer - seems to indicate that acceleration is indeed a first order factor in bedload transport.

Because the experiments do not replicate the turbulence and the fully developed boundary layer under waves, we do not believe that the absolute numbers measured here for sediment response are useful values. However, we believe we have succeeded in isolating a very important and largely overlooked factor in the forcing of bedload that must be accounted for in realistic predictive models.

## CHAPTER 161

### WAVE-INDUCED POREWATER PRESSURE AND SEABED STABILITY

A. Hattori<sup>1</sup>, T. Sakai<sup>2</sup>, M. ASCE and K. Hatanaka<sup>3</sup>

#### ABSTRACT

The boundary layer approximation solution by Mei and Foda(1981) is applied to and its applicability is confirmed for the porewater pressure variation in a seabed under a breaking wave in a surf zone. Then the approximate solution is modified to take into account effects of the wave-induced bottom shear which is not negligible in the surf zone. This modified solution is applied to estimate the terms in the right hand side of the momentum equations for the solid skeleton under the breaking wave. The instability proposed by Madsen(1974) is discussed based on the estimated results. It is suggested that the instability just after the wave crest passing is more likely to occur than the instability just before the crest passing. Just after the crest passing, the horizontal gradient of the porewater pressure is large, while the vertical effective stress is small.

#### INTRODUCTION

There are two kinds of the porewater pressure response to waves. One is the cyclic excess porewater pressure variation. Another is the mean excess porewater pressure buildup. Earthquake induces the mean excess porewater pressure buildup. Here the cyclic porewater pressure variation is treated.

Under the wave trough, the porewater pressure does not decrease so much as the bottom wave pressure(Fig.1). The porewater pressure bears more load than the vertical effective stress on the solid skeleton

3 Engineer, Construction Div., West Japan Railway Co., Kita-Ku, Osaka, 530, Japan.

bears. In some cases the vertical effective stress becomes zero near the bed surface. Here we call this "momentary liquefaction".

**Fig.1 Momentary liquefaction of seabed due to waves**  
(Zen et al., 1987)

The depth of this momentary liquefaction can be calculated by using a theory of the transient porewater pressure variation due to waves. Fig.2(Sakai et al., 1992) shows the result by using the boundary layer approximation solution of Mei and Foda(1981). This approximate solution is applicable to a wide range of the wave and soil conditions. The uncoupled analysis proposed by Finn et al.(1983) is applicable only to soft and coarse sand case.

In this figure there are many parameters.  $k$  is the permeability coefficient.  $G$  is the shear modulus of the solid skeleton.  $\beta$  is the effective bulk modulus of the porewater. It is related to the degree of saturation of porewater  $S$ .  $H$  is the wave height.  $z_L$  is the depth of the momentary liquefaction.

$\rho_w$  is the density of the water.  $g$  is the gravity.  $T$  is the wave period.  $h$  is the water depth.  $\gamma'$  is the submerged unit weight of the solid skeleton.  $n$  and  $\nu$  are the porosity and Poisson's ratio of the solid skeleton.

When the bed material becomes fine, the value of  $k$ , so that, the value of the ordinate  $kG/\rho_w g^2 T h$  becomes small. Also, when the porewater becomes soft with increasing amount of gas, the value of  $\beta$

becomes small, so that , the value of the abscissa  $G/\beta$  becomes large. Therefore the finer the bed material and larger the amount of gas in the porewater, the deeper the depth of the momentary liquefaction.

In this analysis, however, the sinusoidal waves were assumed. In surf zone, the wave profile is not sinusoidal but asymmetric. The bottom wave pressure has also an asymmetric time profile.

**Fig.2 Momentary liquefaction depth in surf zone (Sakai et al., 1992)**

### **APPLICABILITY OF BOUNDARY LAYER SOLUTION FOR ASYMMETRIC WAVES**

Here the applicability of the boundary layer approximation solution for asymmetric waves in surf zone is examined.

Zen et al.(1989) measured the porewater pressures under waves in a surf zone at a Japanese Pacific Ocean coast. The measurement was done at the head of an observation pier of the Port and Harbour Res. Inst. of Japanese Ministry of Transport. The water depth  $h$  was about 4m(Fig.3). The 50% sand grain size was 0.16mm.

**Fig.3 Measuring apparatus of porewater pressures (Zen et al., 1989)**

Fig. 4 is one of the records(Fig.19(b) in their paper). The second figure shows the bottom wave pressure. The lowest figure shows the water level variation. The three figures from the third to fifth show the porewater pressures at three levels near the bed surface. The wave No.7 was selected as a typical surf zone wave. The wave period  $T$

was 14.7sec, and the wave height  $H$  was 1.9m.

**Fig.4 Example of record of bottom wave pressure and porewater pressures(Zen et al., 1989)**

In the boundary layer approximation solution, when the bottom wave pressure  $p_b$  is given by the small amplitude wave theory as

$$p_b = p_0 \cos(\lambda x - \omega t) = \frac{1}{2} \frac{\rho_w g H}{\cosh(\lambda h)} \cos(\lambda x - \omega t), \quad (1)$$

the porewater pressure variation  $p'$  is given by Eq.(2).

$$p' = p_0 \frac{1}{1+m} \exp\left(\frac{-2\pi z}{L}\right) \cos(\lambda x - \omega t) + p_0 \frac{m}{1+m} \exp\left(\frac{-z}{\sqrt{2}\delta}\right) \cos\left(\lambda x - \omega t + \frac{z}{\sqrt{2}\delta}\right). \quad (2)$$

Eq.(2) includes two parameters  $m$  and  $\delta$ .  $m$  is a non-dimensional parameter proportional to a ratio of  $G$  and  $\beta$ (Eq.(3)).  $\delta$  is the thickness of the boundary layer(Eq.(4)).

$$m = \frac{n}{(1 - 2\nu)} \frac{G}{\beta}, \quad (3)$$

$$\delta = \left( \frac{KG}{\omega} \right)^{\frac{1}{2}} \left( n \frac{G}{\beta} + \frac{1 - 2\nu}{2(1 - \nu)} \right)^{-\frac{1}{2}}. \quad (4)$$

The other parameters are as follows :  $p_0$  is the amplitude of bottom wave pressure,  $\lambda$  ( $= 2\pi/L$ ) is the wave number,  $L$  is the wave length,  $x$  is the horizontal distance in the wave propagation direction,  $\omega$  ( $= 2\pi/T$ ) is the wave angular frequency,  $t$  is the time,  $g$  is the gravity,  $z$  is the depth beneath the seabed surface, and  $K = k/\rho_w g$ .

This solution is linear. The time profile of the bottom wave pressure of the selected wave No.7 was decomposed into its Fourier series components. The porewater pressure variation  $p'$  was calculated for each component by using Eq.(2). The typical values in the sandy bed in the surf zone were used for the parameters ( $n = \nu = 0.33$ ,  $G = 1.0 \times 10^8 \text{N/m}^2$ , and  $k = 2.8 \times 10^{-4} \text{m/sec.}$ ). The porewater pressure variation of wave No.7 was obtained by summing up those of all components.

Fig.5 is a comparison between the calculated and measured results. The comparison was done for the maximum value of the porewater pressure. Four kinds of value were applied to the effective bulk modulus of porewater  $\beta$ . The measured values at lower two levels agree well with the calculated curve of  $\beta = 3 \times 10^7 \text{N/m}^2$ . The measured value at the highest level rather agrees with the calculated curve of  $\beta = 6 \times 10^6 \text{N/m}^2$ . The porewater pressure at the highest level has a different trend from that of other two levels. Nevertheless the boundary layer approximation solution roughly explains the measured porewater pressure even under the asymmetric wave in the surf zone.

#### MODIFIED SOLUTION INCLUDING EFFECTS OF WAVE-INDUCED BOTTOM SHEAR

In surf zone, usually the wave-induced bottom friction is not negligible. The solution by Mei and Foda(1981) neglects this effect. Here a modified solution including the effects of the wave-induced bottom shear is derived.

**Fig.5 Comparison of calculated porewater pressure(-) with measured porewater pressure(x)**

The time profile of the wave-induced bottom shear is not sinusoidal even for sinusoidal waves, because the bottom shear is proportional to the square of the bottom velocity. But here for simplicity, the time profile of wave-induced bottom shear is assumed sinusoidal.

The following boundary conditions are applied:

$$\tau_{xz} = -b \exp\{i(\lambda x - \omega t)\}, \quad \tau_{zz} = -p_0 \exp\{i(\lambda x - \omega t)\}, \quad (5)$$

in which  $\tau_{xz}$  and  $\tau_{zz}$  are the shear stress and vertical total stress on the bed surface,  $b$  is the amplitude of the wave induced bottom shear stress,  $i$  is the imaginary unit. The first equation is added to the condition in Mei and Foda(1981).

The porewater pressure variation  $p'$ , the vertical effective stress variation  $\sigma_{zz}$  and the shear stress  $\sigma_{zx}$  are given as follows :

$$p' = p_0 \frac{1}{1+m} \exp\left(-\frac{2\pi}{L} z\right) \cos \theta + p_0 \frac{m}{1+m} \exp\left(\frac{-z}{\sqrt{2}\delta}\right) \cos\left(\theta + \frac{z}{\sqrt{2}\delta}\right) + b \frac{1}{1+m} \left\{ \exp\left(-\frac{2\pi}{L} z\right) \sin \theta - \exp\left(\frac{-z}{\sqrt{2}\delta}\right) \sin\left(\theta + \frac{z}{\sqrt{2}\delta}\right) \right\}, \quad (6)$$

$$\begin{aligned} \sigma'_{zz} = & p_0 \left( \frac{m}{1+m} + \frac{2\pi}{L} z \right) \exp\left(-\frac{2\pi}{L} z\right) \cos \theta \\ & - p_0 \frac{m}{1+m} \exp\left(\frac{-z}{\sqrt{2}\delta}\right) \cos\left(\theta + \frac{z}{\sqrt{2}\delta}\right) \\ & - b \left( \frac{1}{1+m} - \frac{2\pi}{L} z \right) \exp\left(-\frac{2\pi}{L} z\right) \sin \theta \\ & + b \frac{1}{1+m} \exp\left(\frac{-z}{\sqrt{2}\delta}\right) \sin\left(\theta + \frac{z}{\sqrt{2}\delta}\right), \end{aligned} \quad (7)$$

$$\sigma'_{zx} = p_0 \frac{2\pi}{L} z \exp\left(-\frac{2\pi}{L} z\right) \sin \theta + b \left( 1 - \frac{2\pi}{L} z \right) \exp\left(-\frac{2\pi}{L} z\right). \quad (8)$$

Here  $\theta = \lambda x - \omega t$ . The terms which do not include  $b$  are the solution of Mei and Foda itself.

### SEABED INSTABILITY UNDER BREAKING WAVES

Madsen(1974) proposed a criterion on the stability of sand bed under breaking waves.

$$-\frac{\partial p'}{\partial x} \geq (\rho_t - \rho_w) g \tan \phi, \quad (9)$$

$$-\frac{\partial p'}{\partial z} \geq (\rho_t - \rho_w) g. \quad (10)$$

Eq.(9) is for the horizontal direction, and Eq.(10) is for the vertical direction. Here  $\rho_t$  is the density of the saturated bed material, and  $\phi$  is the angle of internal friction of bed material.

He mentioned in his paper as follows : Under a steep front face of breaking wave, the horizontal gradient of the porewater pressure is larger than the vertical gradient. The angle of internal friction is smaller than 45 degree. The horizontal condition(Eq.(9)) is satisfied before the vertical condition(Eq.(10)) is satisfied.

**Fig.6** is one of the figures of Tsuruya and Korezumi's paper(Fig.7, 1990). This figure shows a part of the record of the measurement of the sediment concentration near the bed( $b$ ) and the porewater pressure( $p_m$  in (e)) near the bed surface and others in an actual surf zone. The figure (d) shows the calculated vertical effective stress( = static stress +  $p_b - p'$  ). The black part indicates 0 effective stress occurrence. They suggested a relation between the high sediment concentration and the momentary liquefaction of the seabed.

The horizontal and vertical gradients of the porewater pressure are included in the right hand side of the horizontal and vertical momentum equations for the solid skeleton,

$$\rho_s \frac{\partial v_{sx}}{\partial t} = \frac{1}{1-n} \left( \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{zx}}{\partial z} \right) - \frac{\partial p}{\partial x} + \frac{1}{1-n} \frac{n^2}{K} (v_{wx} - v_{sx}), \quad (11)$$

$$\rho_s \frac{\partial v_{sz}}{\partial t} = \frac{1}{1-n} \left( \frac{\partial \sigma_{xz}}{\partial x} + \frac{\partial \sigma_{zz}}{\partial z} \right) - \frac{\partial p}{\partial z} - \rho_s g + \frac{1}{1-n} \frac{n^2}{K} (v_{wz} - v_{sz}). \quad (12)$$

In these equations,  $\rho_s$  is the density of the solid skeleton,  $v_{sx}$ ,  $v_{sz}$ ,  $v_{wx}$  and  $v_{wz}$  are the horizontal and vertical velocities of the solid skeleton and the porewater respectively.  $p$  is the sum of the static pressure and its variation  $p'$ .

To examine Madsen's suggestion, the value of each term in the right hand side of two momentum equations is calculated for the asymmetric wave measured by Zen et al., wave No.7, by using the new solution including the effects of the wave-induced bottom shear, Eq.s (6), (7) and (8).

To emphasize the effects, the wave period is shortened to 7.0sec, and the wave height is multiplied by 1.5. The amplitude of the bottom shear  $b$  is taken to be 1/10 of that of the bottom wave pressure  $p_0$ . The values of the parameters are as follows :  $h = 4.0\text{m}$ ,  $\rho_t = 1,910\text{kg/m}^3$ ,  $n = \nu = 0.33$ ,  $G = 1.0 \times 10^8 \text{N/m}^2$ ,  $\beta = 1.0 \times 10^7 \text{N/m}^2$  and  $k = 2.8 \times 10^{-4} \text{m/sec}$ . The value of  $\beta$  is determined based on the fact that it is  $10^6 \text{N/m}^2$  for the degree of saturation of 99%.

**Fig.7** shows the result at the level of 10cm below the bed surface. The bottom wave pressure is also shown in the top figure. The middle figure shows the phase variation of each term in the right hand side of the horizontal momentum equation for the solid skeleton. The horizontal gradient of the horizontal effective stress  $\partial \sigma_{xx} / \partial x$  and the vertical gradient of the shear stress  $\partial \sigma_{zx} / \partial z$  are as large as the horizontal gradient of the porewater pressure  $\partial p / \partial x$ . The horizontal

Fig.6 Sediment concentration (b) and vertical effective stress in seabed (d) (Tsuruya and Korezumi, 1990)

**Fig.7 Phase variation of terms in right hand sides of momentum equations of solid skeleton(10cm below bed surface)**

drag force due to the relative velocity of the porewater and solid skeleton  $1/(1-n) \cdot n^2/K \cdot (v_{wx} - v_{sx})$  is negligible.  $-\partial p/\partial x$  becomes maximum at a phase of front of crest ( $t = 1.2\text{sec}$ ), and reaches the critical value of the horizontal momentary failure given by Eq.(9).

The bottom figure shows the phase variation of each terms of the vertical momentum equation for the solid skeleton. The value of term is one order larger than that of terms of the horizontal momentum equation. The vertical gradient of the vertical effective stress  $\partial\sigma_{zz}/\partial z$  and the vertical drag force  $1/(1-n) \cdot n^2/K \cdot (v_{wz} - v_{sz})$  are as large as the vertical gradient of porewater pressure  $\partial p/\partial z$ .  $-\partial p/\partial z$  becomes maximum at a phase of the back of the crest ( $t = 2.6\text{sec}$ ), and is larger than the critical value of the vertical momentary failure given by Eq.(10). It is found also that at this phase the vertical effective stress becomes zero.

From this result we can say as follows : Under a wave having a very steep front face, a momentary failure of the seabed may occur just before the crest passes. Then a momentary liquefaction occurs near the bed surface just after the crest passes. At the same phase, the absolute value of the horizontal porewater pressure gradient becomes large again as seen in the middle figure. The momentary failure of the seabed is therefore more likely to occur just after the crest passing than just before the crest passing.

## CONCLUSIONS

- (1) The boundary layer approximation solution for the wave-induced transient porewater pressure variation in seabed by Mei and Foda(1981) is applicable to an asymmetric wave in a surf zone.
- (2) This solution was modified so as to take into account effects of the wave-induced bottom shear which is not negligible in the surf zone.
- (3) Under a steep breaking wave the momentary failure of the seabed proposed by Madsen(1974) is more likely to occur just after the wave crest passes than just before the crest passes.

## ACKNOWLEDGMENTS

# CHAPTER 162

## INTERCOMPARISON OF COASTAL PROFILE MODELS

Ida Brøker Hedegaard<sup>1</sup>, J.A. Roelvink<sup>2</sup>, Howard Southgate<sup>3</sup>  
Philippe Pechon<sup>4</sup>, John Nicholson<sup>5</sup>, Luc Hamm<sup>6</sup>

### Abstract

The present paper briefly presents 6 different models for short term coastal profile modelling for direct incoming waves. The models have been tested against measured profile evolutions from a large wave flume. Features such as wave height distribution, cross shore current profiles and sediment transport are compared and discussed.

### Introduction

The described models are all established with the same structure of modules for hydrodynamics, sediment transport and bed level evolution but with different degrees of determinism/empiricism and refinement. The basic structure of the modules and a definition sketch for the coastal profile models are presented in Fig. 1.

Fig. 1. Basic Structure of the Morphological Models and Definition Sketch.

### Description of the Models

LITCROSS, Danish Hydraulic Institute.

The variation of the wave heights across the profile is determined from the criteria that the wave has either constant energy flux or wave heights decreases in accordance with an empirical relation first suggested by Andersen and Fredsøe (1983):

$$\frac{H}{D} = 0.5 + 0.3 \exp(-0.11 \frac{\Delta x}{D_B})$$

where  $\Delta x$  is the distance from breaking point and  $D_B$  is the depth at the breaking point. The areas of the surface roller of the breaking waves are assumed to correspond to hydraulic jumps apart from a zone just inside the breaker point where the area is assumed to vary according to measurements by Buhr Hansen (1991). Random waves are treated as individual waves with no interaction.

Hydrodynamic modelling. The vertical distributions of currents and turbulence are assumed to be determined by the local depth, wave conditions and sediment properties. The basis for the model is the combined wave current boundary layer model of Fredsøe (1984). In breaking waves a major contribution to the turbulence comes from the loss of energy in waves and surface rollers. This contribution is calculated by the vertical transport equation for turbulent energy, Deigaard et al. (1986). The vertical distribution of the wave period averaged velocities is derived from the distributions of shear stresses and wave period averaged eddy viscosity. The shear stresses include the contributions from breaking waves, Deigaard and Fredsøe (1989), from streaming, determined as outlined by Longuet Higgins (1953), from the increased density due to suspended sediment in case of sloping bed and from a setup of the water surface which is determined such that the total flux including the wave drift and the water carried in the surface rollers equals zero, Svendsen (1984).

The net sediment transport is calculated as bed and suspended load. The instantaneous bed load and nearbed boundary condition for the vertical distribution of suspended sediment are determined as functions of the instantaneous shear stress, Engelund and Fredsøe (1976). The time varying vertical distribution of suspended concentrations is calculated by the vertical diffusion equation, Deigaard et al. (1986). The total wave period averaged net transport is found from

$$q_s = \frac{1}{T} \int_{\text{period}} \int_{\text{depth}} c \cdot u \, dz \, dt + \int_{\text{depth}} u_1 \cdot \bar{c} \, dz$$

where  $u_1$  is Lagrangian drift. The last term is included to compensate the omission of convective terms in the solution of the concentration field.

The bed level evolutions are determined by the continuity equation for the sediment. The numerical solution is explicit. A modified Lax-Wendroff scheme has been applied to reduce the numerical diffusion and to obtain a stable solution. LITCROSS is described in more detail in Brøker Hedegaard, Deigaard and Fredsøe (1991).

### UNIBEST, Delft Hydraulics.

UNIBEST-TC stands for UNiform BEach Sediment Transport, Time-dependent Cross-shore. It is a direct descendant of the models OSTRAN (Stive and Battjes, 1984) and COSTRAN (Stive, 1986). In Roelvink and Stive (1989), the model has been tested against wave flume measurements and improved on some points. The model aims at predicting long-term development of the profile of beaches that are approximately uniform in along-shore direction, and which are subjected to obliquely incident wave fields, varying water levels and tidal currents. The morphodynamic behaviour due to cross-shore transport only is considered, however, effects of longshore currents on cross-shore transport are accounted for.

For the present study, cross-shore effects only are considered, and the formulations as given in Roelvink and Stive (1989) are used. Mechanisms included here are:

- Wave shoaling and breaking and associated set-up according to Battjes and Janssen (1978);
- Cross-shore current description according to de Vriend and Stive (1987);
- Transition zone effects on the return flow according to Roelvink and Stive (1989); Short wave velocity moments based on Rienecker and Fenton's (1981) Fourier approximation of the stream function method;
- Long wave effects according to the same paper;
- Sediment transport according to Bailard (1981);
- A Fully implicit scheme for the bed evolution.

For the case of regular waves, the wave decay model is adapted simply by setting the fraction of breaking waves to 1 after the wave height exceeds a given fraction of the water depth.

### NPM, Hydraulic Research.

NPM (Nearshore Profile Model) is a model for waves, longshore and cross-shore current and sediment transport on uniform beaches for obliquely or direct incoming waves. A brief summary of the physical processes represented in the NPM is given below.

- Wave transformation by refraction (by depth variations and currents), shoaling, Doppler shifting, bottom friction and wave breaking. For random waves, a Battjes and Janssen (1978) framework is used for determining the distribution of wave height and the fraction of time that waves are breaking at any point.
- Wave setup determined from the gradient of wave radiation stress.
- Driving forces for longshore wave-induced currents, determined directly from the spatial rate of wave energy dissipation.
- Longshore currents from pressure-driven tidal forces and wave-induced forces, and the interaction between the two types of current.
- Cross-shore undertow velocities using a three-layer model of the vertical distribution of cross-shore currents (de Vriend and Stive, 1987).
- Transition zone effects (the transition zone is the distance between where a wave starts to break and where turbulence becomes fully developed).

- Cross-shore and longshore sediment transport rates using an 'energetics' approach (Bailard, 1981; Stive, 1986).
- Seabed level changes due to cross-shore sediment transport using a Lax-Wendroff scheme.

Tests (Southgate, 1991) have shown that the model results are particularly sensitive to the transition zone length and to the height above the seabed at which the undertow velocity is taken for input to the sediment transport calculations. Recent improvements to the NPM therefore include:

- A reanalysis of transition zone data (O'Shea et. al., 1991) to give a more accurate formula for the transition zone length.
- The use of a concentration-weighted average undertow velocity in the sediment transport calculations.

NPM is described in detail in Southgate and Nairn (1993) and Nairn and Southgate (1993).

WATAN 3, University of Liverpool.

The model WATAN3 consists of a wave sub-model and a sediment sub-model. The wave sub-model (Watanabe and Dibajnia, 1988) comprises a set of two equations which are equivalent to a time-dependent version of the mild-slope equation and contain an additional term to allow for energy dissipation in the surf zone. The latter term represents the rate at which energy is dissipated by breaking and is set to zero wherever the broken waves have reformed inside the surf zone, as well as outside the surf zone. An empirical criterion (Watanabe et al, 1984) is used to determine the point of breaking, and setup and setdown are computed by solving the momentum balance equation.

The sediment sub-model (Ohnaka and Watanabe, 1990) is based on the sediment transport rate due to wave action:

$$Q = (A_W (\tau_B - \tau_C) + A_{WB} \tau_T) F_D \hat{u}_B / (\rho g)$$

where  $Q$  is the sediment transport rate,  $A_W$  and  $A_{WB}$  are coefficients,  $\tau_B$  is the maximum nearbed shear stress due to wave action,  $\tau_C$  is the threshold of movement shear stress.  $\tau_T$  is the shear stress generated by breaker turbulence,  $F_D$  is a dimensionless directional function and  $\hat{u}_B$  is the maximum nearbed orbital velocity. Having derived the transport rates throughout the computational domain, the former are then modified to allow for bed slope effects, so that:

$$Q_M = Q - \epsilon |Q| \tan \beta$$

where  $Q_M$  is the modified transport rate,  $\epsilon$  is a coefficient and  $\tan \beta$  is the local bed slope. Finally, the bed level changes are computed using the sediment mass conservation equation.

An additional feature of the present version of the sediment sub-model is the inclusion of a breaker transition length, within which turbulence generated by the post-breaking surface roller is distributed throughout the water column. A re-analysis of work

carried out by Nairn et al (1990) yielded the following expression for the transition length (O'Shea et al, 1991):

$$L_T = L_B (0.56 \xi^{-1.47}) \tan \beta$$

where  $L_T$  is the transition length,  $L_B$  is the wave length at breaking and  $\xi$  is the Iribarren No. The effects of the transition length are incorporated into the sub-model by switching off the breaker turbulence contribution to the transport rate within the transition length.

SEDITEL, Laboratoire National d'Hydraulique.

SEDITEL computes the wave refraction and shoaling, wave height decay in the surf zone, time-averaged three-dimensional currents (2DV currents here) induced by breaking waves, sediment transport rates, bed evolution.

The wave refraction is derived from the classical Snell's law. The wave height is deduced from the equation of the flux of energy where the dissipation is supposed to be similar to the one of a hydraulic jump in the surf zone. In order to have a good estimation of the wave characteristics in shallow water, non-linear effects are considered in the calculation of the flux of energy, see P echon (1987).

The time-averaged currents induced by breaking waves are computed with the three-dimensional model TELEMAC-3D outlined in Lepeintre et al. (1991). In order to establish the equations the instantaneous velocity is separated into three contributions: an unknown mean current, a purely periodic current corresponding to the wave motion, and turbulent fluctuations. In the time-averaged equations some closures are required to express the velocity correlations (see details in P echon, 1992). They are given by previous works of Svendsen (1984), De Vriend and Stive (1987), Deigaard and Freds e (1989).

The sand transport is computed using Bailard's formula, Bailard (1981), but the suspended load efficiency factor is increased in the surf zone to take the breaking effect into account. The proposed expression is:

$$e'_s = \left( 1 + a \frac{|u_b|}{\sqrt{gD}} \right) e_s ;$$

- $e_s$  : efficiency factor, non breaking
- $e'_s$  : efficiency factor, breaking
- $a$  : constant
- $u_b$  : mean velocity at the bottom

The bed evolution is computed by solving the continuity equation for the sediment. To reproduce the process of avalanching of dune in the application presented here, the measured amount of sediment is distributed between the crest of the bar and the shoreline before each hydrodynamic computation. Moreover a maximum stability slope of 15/100 is specified out of the breaking zone.

The wave and current patterns are updated when the bottom evolution becomes significant. However, in order to reduce the number of iterations, an additional treatment is performed during the computation of the bottom evolution: considering the bed evolution

at the breaking point, its location is moved along the coastal profile and the wave and current characteristics are moved the same way.

#### REPLA, SOGREAH.

REPLA is a wave-averaged, finite amplitude, current-depth shoaling and refraction model to simulate regular or random wave propagation from deepwater to the shoreline.

The formulation is detailed in Fornerino et al (1992). A set of four equations is to be solved with an iterative procedure because of the influence of the wave height on the wave celerity.

Stokes third order theory is used for small Ursell numbers. For large Ursell numbers a cnoidal second order theory is used. The model can, however, also be run with Stokes first order waves.

The wave breaking criteria derived by Weggel (1972) is used. In presence of an adverse current, this expression is modified following Sakai et al.(1988). The bore model is used to express the energy dissipation. In order to simulate wave reformation after breaking on a bar, the dissipation rate is put to zero when the wave height is less than half the local maximum wave height.

For random waves, two methods are implemented. The parametric approach of Battjes and Janssen (1978) and the individual wave method Mase and Iwagaki (1982); Mizuguchi (1982) in which each class is propagated independently with the regular wave model.

#### Results from the various Models

The models have been tested against experimental results obtained from the large wave flume in Hannover in 1986 and 1987, Dette and Uliczka (1986) and Dette and Oelerich (1991). The experiment from 1986 was carried out with regular waves. The 1987 experiment was run with irregular waves and included a comprehensive measuring program focusing on waves.

#### Regular Wave Case

The experiment with regular waves constitutes a severe test of the models due to the fact that all waves are breaking nearly at the same position. This first test gives the opportunity to tune the possible model parameters in the various models. Results in the form of calculated and measured profiles from this first test are presented in Fig. 2.

The calculated profile evolution is the integrated result of the modelling of several physical mechanisms. The interpretation of the differences between the modelled evolutions can therefore only be pointed out after comparison of each individual element in the various models. These comparisons are carried out for a similar case, but now the initial profile is a plane beach with an initial slope of 1:20. Below, the initial wave heights, current fields and sediment transport along this plane beach are considered.

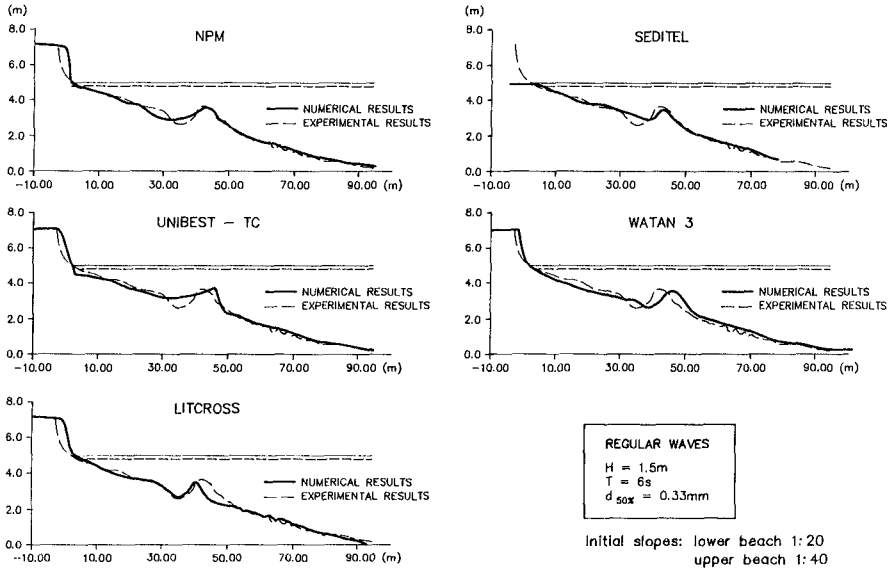

Fig. 2. Comparison of Measured and Calculated Coastal Profiles after 4.3 hours of Exposure.

The figures 3, 4, and 5 show wave heights across the plane profile, vertical distribution of horizontal wave averaged velocities, for Seditel also the vertical velocity component just shoreward of the breaker point and the vertical flow pattern, and the initial cross shore sediment transport. Already the comparison of wave heights show large spreading across the surf zone. This spreading is reflected in deviations in the assumed cross section area of the surface rollers. The differences in the vertical distribution of horizontal velocities exist due to differences in the formulation of the vertical distribution of shear stresses, eddy viscosities and the area of surface rollers.

The above comparisons illustrates differences in the models, but suffer unfortunately from lack of measured data. The calculated initial transport rates highlight the fact that the bar forms at a 'critical' position, seen from a model view point where the onshore transport under the non breaking waves turn into offshore transport inside the surf zone.

Further, although discrepancies exist between the distribution of horizontal velocities calculated by the one DV models and the 2 DV model, Seditel, the 2 DV results indicate that the order of magnitude of vertical velocities shoreward of the breaker point are comparable with the settling velocity of sand. Therefore, in a narrow zone inside the breaker point, the sediment transport models which take into account only velocities parallel to the bottom might underestimate the amount of suspended sediment.

Fig. 3. Wave heights as calculated by 6 different models.

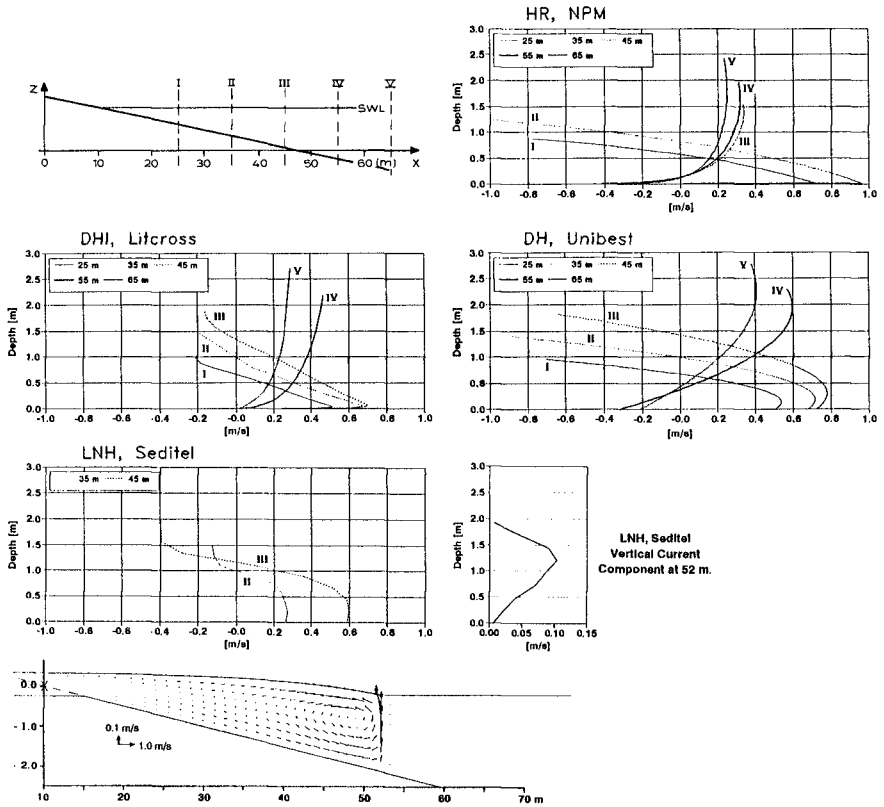

Fig. 4. Velocity components and the 2 DV current field as calculated by Seditel.

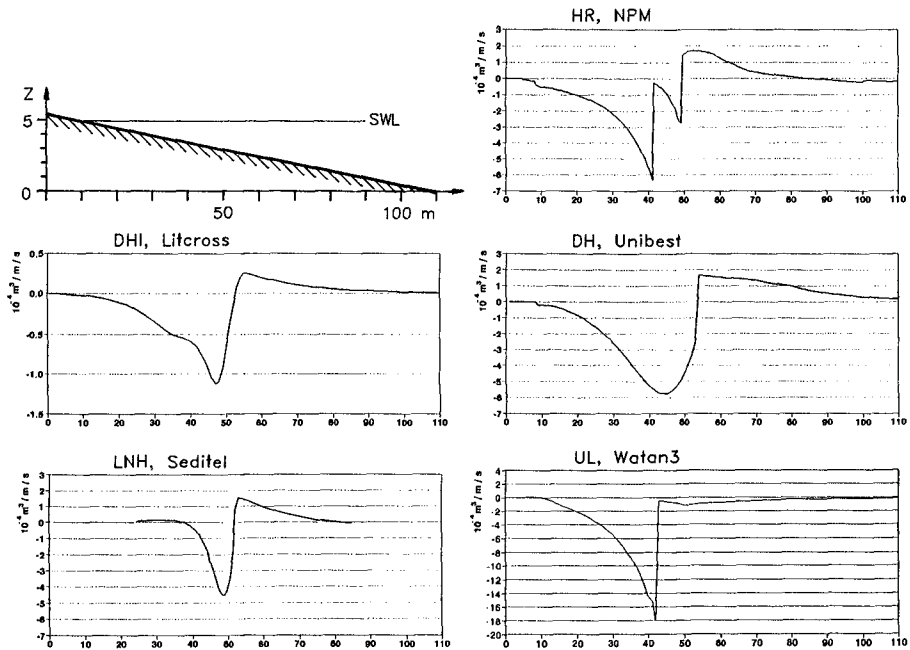

Fig. 5. Cross shore sediment transport calculated by NPM, Unibest, LITCROSS, Seditel and Watan 3.

It appears that the cross shore transport models when applied in a morphological calculation sequence in combination with more or less smoothing, either on the calculated transport or on the bed levels between updates, are able to reproduce to a certain extent the evolution of a breaker bar. In the case of regular waves it seems clear that the mechanisms just shoreward of the breaker point are essential for the bar evolution.

For irregular waves these complex mechanisms are expected to be less important for the profile evolution. In the following the models are compared with measurements in the case of irregular waves.

#### Irregular Waves Case

This test was carried out with irregular waves, Jonswap spectrum, with  $H_s = 1.5\text{m}$  and  $T_p = 6\text{ s}$  at 5 m depth in front of the wavemaker. The profile was built out of natural well sorted sand with a mean diameter of 0.22 mm. The test was subdivided into 45 runs of 780 s each. The wavemaker was stopped after each run. The wave generation was first order with no long waves reflection compensation. The observed bathymetry, the wave heights ( $H_{\text{RMS}}$ ), the sediment transport derived from successive observations of the bed evolution and the wave energy spectrum as measured at three positions are presented in Fig. 6.

In this case a pronounced bar is not formed but the relatively steep profile is flattened out. The wave heights in the surfzone decrease concurrently with the flattening of the profile, i.e. the energy is dissipated further and further offshore. These tendencies are reflected in the cross-shore transport rates which are largest at the beginning of the test. From the spectral analysis of wave energy it appears that the spectra become double-peaked while the waves approach the beach, i.e. in the nearshore area low frequency waves become more important, see figure 6. From analysis of correlations between bound long waves and the observed low frequency waves it seems clear that the major part of the low frequency energy come from reflections in the flume.

In figures 7 and 8 measured and simulated variations of the wave heights across the profile for the observed bathymetries in runs 2, 14 and 32 are compared. These results are produced by REPLA applying both the parametric approach and the individual wave method with both linear and non linear wave theory. With the first approach it appears that when  $\gamma$  is adjusted corresponding to the highest wave heights, the heights inside the surf zone are underestimated for runs 2 and 14. The individual wave method is seen also to underestimate the near shore wave heights. It might be necessary to include mechanisms as the extra variations of the water level and flow due to the long waves and the opposing undertow in the wave modules.

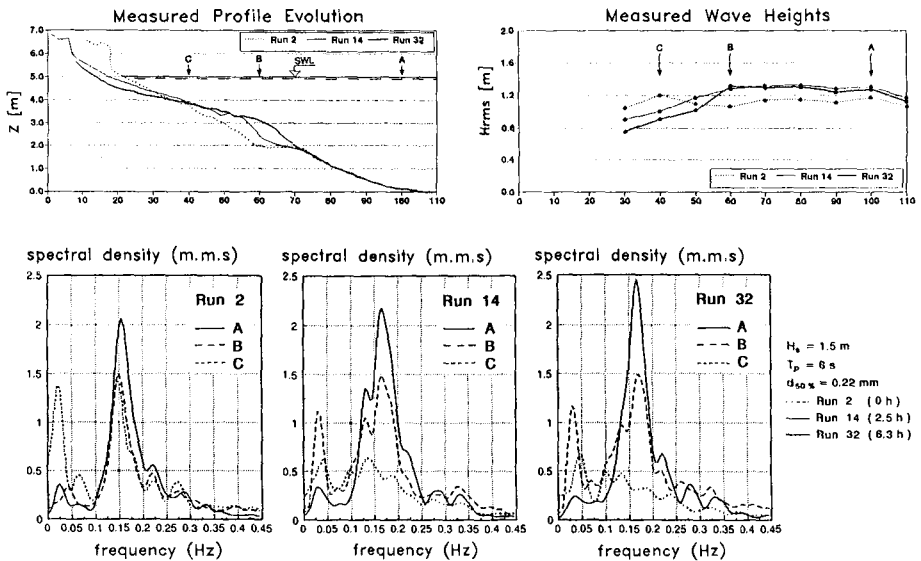

Fig. 6. Observed bathymetries, measured  $H_{RMS}$ , and wave energy spectrum at 3 positions.

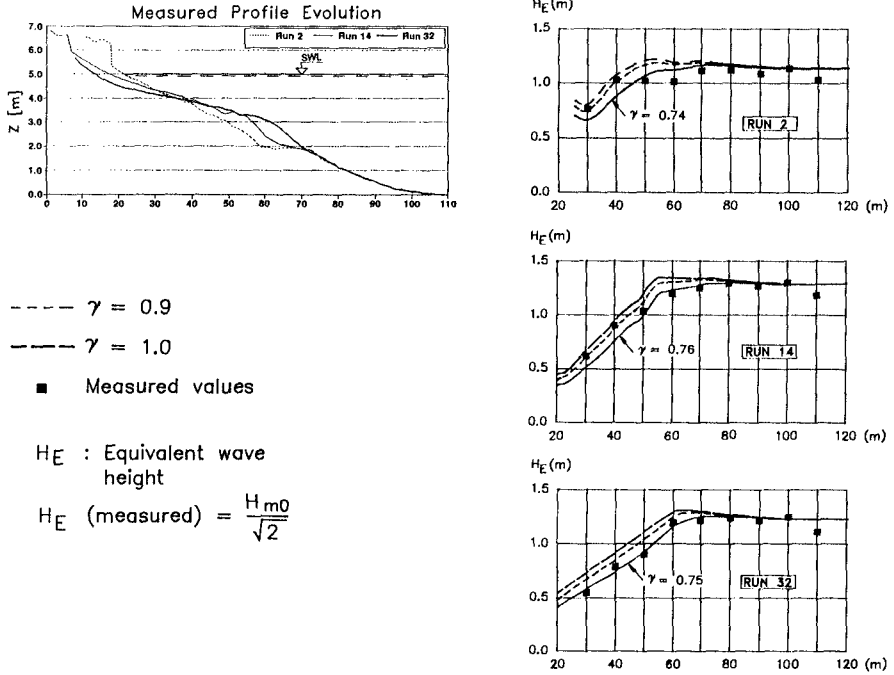

Fig. 7. Measured and calculated equivalent wave heights. Calculations by REPLA applying Battjes and Janssen's parametric approach.

Fig. 8. Measured and calculated  $H_{RMS}$ ,  $H_S$  and  $H_{1/10}$ . Calculations by REPLA applying the individual wave approach with linear and non linear wave theories.

Figure 9 shows the measured and calculated cross-shore transport. It is seen that the models are very sensitive to even small humps in the bed and that the observed relatively

large initial offshore transport is not very well reproduced. The Watan 3 model has been run with 5 wave components only which obviously gives a very scattered transport pattern.

Figure 10 shows results of morphological modelling of the coastal profile. The modelled evolutions obviously suffer from the underestimation of the initial offshore transport and the lack of description of the erosion in the steep dune front.

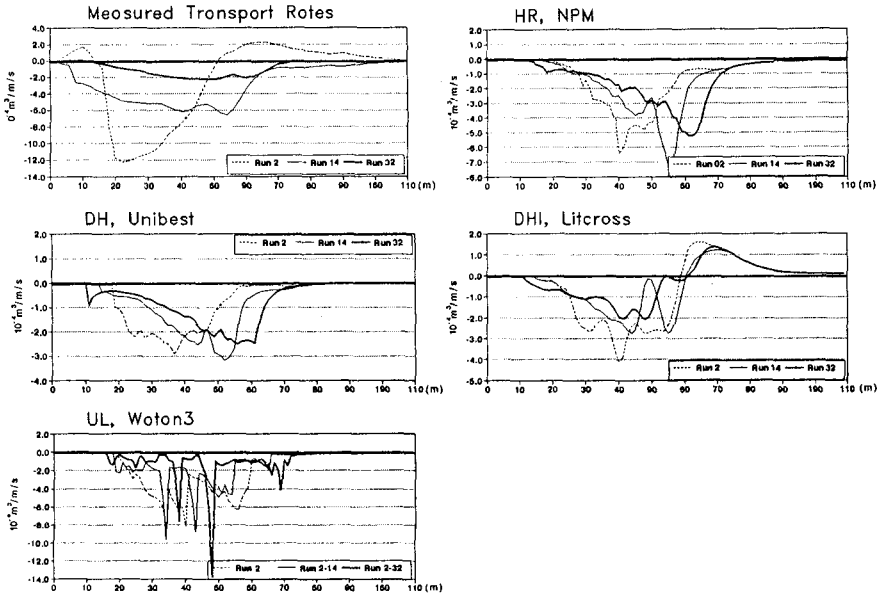

Fig. 9. Measured and calculated cross-shore transport rates. These calculations are carried out with the observed bathymetries.

Fig. 10. Measured profile evolution. Simulated evolution. HR, NPM and DHI, LITCROSS from 'initial' to Run 32. UL, WATAN 3 from Run 2 to Run 32.

### Concluding remarks

Large differences exist between the coastal profile models presented above. However, based on the experience gained through the comparisons with experimental data the following general comments are given:

- The models generally underestimate the offshore transport on relatively steep profiles. One reason seems to be related to poor wave description in cases where reflections and long waves, free and bound, exist.
- The swash zone processes and dune erosion are not described in the models. In combination with the above mentioned underestimation of transport on steep slopes the exchange of material from the dune to the bar is too slow in the case of a steep, initial profile.
- The vertical velocities close to the breaker point seem to reach a significant order of magnitude and might influence the bar formation, at least in the case of a closed flume. Generally, the velocity field in the area just before and after the (average) break point is still understood rather poorly.

It is noted that with the outlined concept of a coastal profile model the pronounced breaker bar in regular waves and the flattening of a steep profile in irregular waves can be modelled. In nature the coastal profiles are formed by 3D phenomena. It seems that the understanding of cross-shore processes has now reached a stage where it is relevant to extend the models into 3D to be able to judge where the 'weakest point' appears and where most effort in the future should be spent.

### Acknowledgements

This work has been undertaken as part of the MAST G6 Coastal Morphodynamic Research Programme. It was funded partly by the Commission of European Communities, Directorate General for Science, Research and Development under MAST Contract No. 0035-C and partly by national fundings, among these The Danish Technical Research Council (STVF), Service technique Central des Ports Maritimes et des Voies Navigables (Compiègne, France), The Netherlands 'Coastal Genesis Programme' (Kustgenese).

The authors would like to thank Dr. Dette and Dr. Oelerich, Hannover University, for the delivery of processed data from the experiments in the large wave flume.

## CHAPTER 163

### OSCILLATORY FLOW BEHAVIOR IN THE VICINITY OF RIPPLE MODELS

Kiyoshi Horikawa<sup>1</sup> F. ASCE  
Suguru Mizutani<sup>2</sup>

#### ABSTRACT

In the previous paper, a fixed ripple model with a sharp crest was used to investigate the characteristics of oscillatory flow in the vicinity of wavy boundary. The above ripple model is useful to proof the adaptability of the analytical treatment presented by Longuet-Higgins (1981) and to extend our knowledge on the present subject. However the stated model is too simple to represent the real shape of sand ripples appeared on the sea bottom. From such a view point, in the present study another fixed ripple model with a round crest was selected. This model has the shape almost similar to the previous one except in the vicinity of the crest.

A two-dimensional LDV was used to measure the flow velocity at preset grid points. By using these velocity data the vorticity at each grid point was calculated and the equivorticity lines were drawn for the sharp crest ripple as well as the round crest ripple at various phases of oscillatory flow. Then the circulation outside the vortex was evaluated. Based on the available data the temporal variation of the circulation was discussed quantitatively. Finally criteria of vortex formation were introduced and the physical meaning of these criteria was discussed.

## INTRODUCTION

This paper is a continued work to the previous paper on the characteristics of oscillatory flow over a ripple model (Horikawa and Ikeda, 1990). In the foregoing paper were presented the extensive results of laboratory investigations carried out by using an oscillatory flume in which a fixed ripple model with a sharp crest was installed.

Figure 1 shows the shape and size of the stated model which were determined on the basis of the treatment presented by Longuet-Higgins (1981). This ripple model seems to be quite useful to analyze the flow phenomena in the vicinity of a wavy boundary. However the shape with such a sharp crest as this model may be unrealistic as a model of sand ripples appeared on the sea bottom. In order to investigate the actual flow phenomena in the vicinity of sand ripples generated by wave action, a more realistic model was selected.

According to Sleath (1984), the shape of two-dimensional vortex ripples for fine sand can be well expressed by the following equations :

$$\begin{aligned} y &= (Hr/2) \cos kr\xi \\ \xi &= x + (Hr/2) \sin kr\xi \end{aligned} \quad (1)$$

where  $(x,y)$  are the Cartesian coordinates,  $\xi$  is the curvilinear coordinate following the wavy boundary with its origin at  $x=0$  and  $y=Hr/2$ ,  $Hr$  and  $Lr$  are the ripple height and the ripple length respectively, and  $kr=2\pi/Lr$  is the ripple wave number as shown in Figure 2.

In order to keep the continuity and consistency in the series of research work, the ripple length was fixed at 30cm as that of the sharp crest ripple model. The ripple height of the new model was selected to be 4cm instead of 5cm in the previous model to make the height-length ratio 0.133 which is nearly equal to that of natural sand ripples. The shape of the new ripple model thus determined is shown in Figure 3. Figure 4 indicates the difference of both models. That is to say, the overall features of both models are practically similar each other except in the limited region of ripple crests.

EXPERIMENTAL PROCEDURES

Experimental Conditions

Table 1 gives the experimental conditions adopted so far at the Hydraulic Laboratory, Saitama University by using the fixed ripple model with a sharp crest (Figure 1) as well as that with a round crest (Figure 3) installed inside an oscillatory flow flume with 13m in length and 0.3m x 0.3m in cross-section. Among these, four particular cases namely Cases A, B, C and D in Table 1 will be selected in discussing the characteristic differences of organized vortices formed behind the two kind ripple crests. Particularly in Cases A and B the oscillatory flow conditions are the same, but the shapes of the ripple crest are different each other.

Table 1 Experimental conditions.

Profile	T (s)	3	4	6		9
Sharp 	$d_o$ (cm)	20.0	—	20.0	40.0	40.0
	$U_{max}$ (cm/s)	20.9	—	10.5	20.9	13.9
		(Case C)				(Case A)
Round 	$d_o$ (cm)	—	44.0	—		40.0
	$U_{max}$ (cm/s)	—	34.6	—		13.9
		(Case D)				(Case B)

$d_o$  :orbital total amplitude of fluid just outside the boundary layer at the bed  
 $U_{max}$ :amplitude of free stream horizontal velocity component

Experimental Apparatus and Flow Data Analysis

A 2-D LDV was used to measure horizontal and vertical components of flow velocity at each preset grid point at various phases of oscillatory flow. By using the obtained records various physical quantities such as the temporally averaged fluid velocity, stationary (or residual) velocity, kinematic Reynolds stress, and kinematic eddy viscosity, were calculated and the resulted data were plotted in figures to illustrate the temporal and spatial variations of flow characteristics. The detailed descriptions of the experimental apparatus and data processing were given in the previous paper (Horikawa and Ikeda, 1990).

The main topic in this paper, however, is to investigate the characteristic behavior of an organized vortex formed behind a ripple crest. The discussion on

fine structures of oscillatory flow in the vicinity of ripple crest either with the sharp crest or with the round crest will be made in the forthcoming paper which is now in preparation.

### BEHAVIOR OF AN ORGANIZED VORTEX

#### Overall Pattern of Vorticity

Evaluation of vorticity at each grid point was made by using the temporally averaged velocity components at four grid points surrounding the prescribed point. As a typical example, spatial distribution patterns of vorticity for Cases A and B at the same phase of the oscillatory flow are shown in Figures 5(a) and (b) respectively. The irregularity of distribution patterns is thought to be strongly influenced by the grid spacing of measuring points.

Comparing these two diagrams in Figure 5, it is easily realized that the vorticity formed behind the

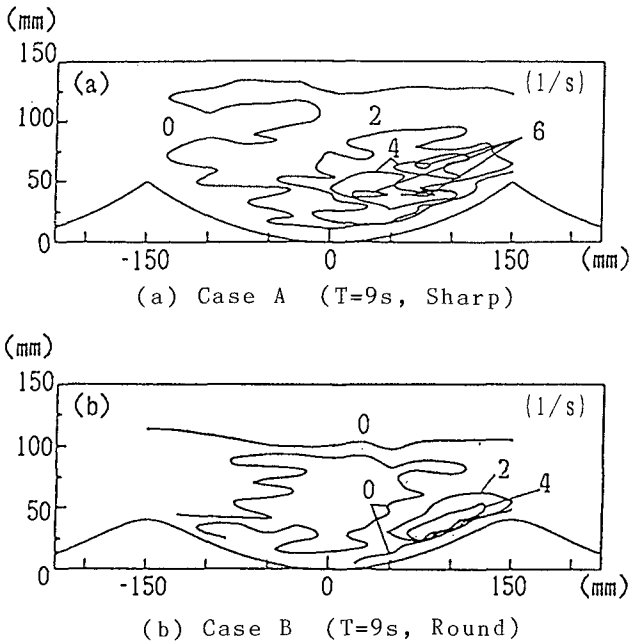

Fig.5 Spatial distribution of vorticity at the phase of  $\omega t = 0$ .  
 [(a) Sharp crest ripple (b) Round crest ripple]

sharp crest (Case A) is stronger than that behind the round crest (Case B) as it is expected. In order to draw more clear pictures, the following treatments were made. The space area enclosed by the equivorticity curve with the prescribed value was calculated at each phase. The obtained values were plotted as indicated in Figures 6(a) and (b) for Cases A and B respectively. From these diagrams the following fact can be easily observed. Here the phases  $-\pi/2$  and  $\pi/2$  correspond to the phases at the maximum free stream velocity.

In case of the sharp crest ripple (Case A) the flow streamline along the ripple bed separates definitely at the crest. The vortex thus formed grows up with the increase of free stream velocity and then diffuses rather rapidly. Finally the overall vorticity decays due to reverse of the free stream direction.

On the other hand, in case of the round crest ripple (Case B) the size of vortex seems to be fairly small in general compared with the previous one. The streamline along the ripple bed separates hardly at the early stage of oscillatory flow phase, but does at a certain phase stage. The vortex area increases up to a certain phase and then decreases gradually.

In both cases, the developing, diffusing and decaying processes of vorticity can be observed clearly in Figures 6 (a) and (b). Even though the magnitude and spacial scale of vortex depend strongly upon the shape of ripple crest and free flow conditions, the processes stated above appears similarly in any case.

In order to investigate the growth and decay of overall vortex strength, the integrated vorticity with respect to the area for Cases A, B, C and D were calculated and the obtained values were plotted in Figure 7. The above integrated vorticity corresponds to the circulation outside the vortex,  $\Gamma$ . From Figure 7 the following can be pointed out :

- (1) In case of the sharp crest ripple (Cases A and C), the flow separation initiates immediately after changing the flow direction. Then the circulation increases very rapidly and reaches its maximum,  $\Gamma_{\max}$ , at the phase of  $-(\pi/4)$ , a little after the maximum velocity of free stream. After that the

Fig.6 Temporal variation of the area occupied by the vortex with the prescribed vorticity. [Case A : Sharp crest ripple Case B : Round crest ripple]

Fig.7 Temporal variation of circulation outside the vortex generated behind a ripple crest.

Fig.8 Temporal variation of nondimensional circulation.

circulation decreases gradually to zero at the phase of  $\pi$ .

- (2) In case of the round crest ripple (Cases B and D), the flow separation appears at the phase of  $-(\pi/2)$ . The circulation increases rather rapidly and reaches its maximum at the phase of  $-(\pi/8)$ . Then the circulation decreases gradually to zero.

In order to determine the general form of the temporal variation of the circulation for both the sharp crest ripple and the round ripple crest, the term  $\Gamma/\Gamma_{max}$  is illustrated in Figure 8, where  $\Gamma_{max}$  is the maximum value of  $\Gamma$  for each case. These curves suggest us that the temporal variation of the circulation can be expressed by an appropriate curve for each ripple model. To accomplish the above treatment, the absolute value of  $\Gamma_{max}$  should be determined.

Available data of the maximum value of circulation were summarized in Table 2. The first four data were reported by Ikeda et al. (1988) who used the sharp crest ripple with  $H_r/L_r=0.167$ . The second four data were given by Sawamoto et al. (1980) who used the round crest ripple with  $H_r/L_r=0.100$  installed in an oscillatory air flume. The last four data are those of Cases A, B, C and D in the present investigation, where the values of  $H_r/L_r$  are 0.167 for Cases A and C and 0.133 for Cases B and D.

 Horikawa et al. Round → H. R.

Two nondimensional terms,  $\Gamma_{max}/(TU_{max}^2)$  and  $U_{max}Hr/\nu$ , were correlated each other in Figure 9, where the effect of ripple model characteristics on the circulation was clearly distinguished. The scattering of data points is fairly large probably due to the fact that the applied evaluation methods for circulation are largely different each other. Therefore tentatively evaluated values are suggested by dotted lines in Figure 9. The ranges of the Reynolds number  $Re=U_{max}Hr/\nu$  and the Keulegan-Carpenter number  $KC=TU_{max}/Hr$  are limited in each group of data (see Table 2). It is needless to say that additional data in a wide range of  $Re$  and  $KC$  are required to make more clear evaluation of the maximum circulation value under the various conditions.

Adaptability of the Present Data

In the previous investigations, the relationship among the grain size, the driving force of fluids, and the resulted sand ripple size was ignored. In order to keep the consistency of laboratory investigations the

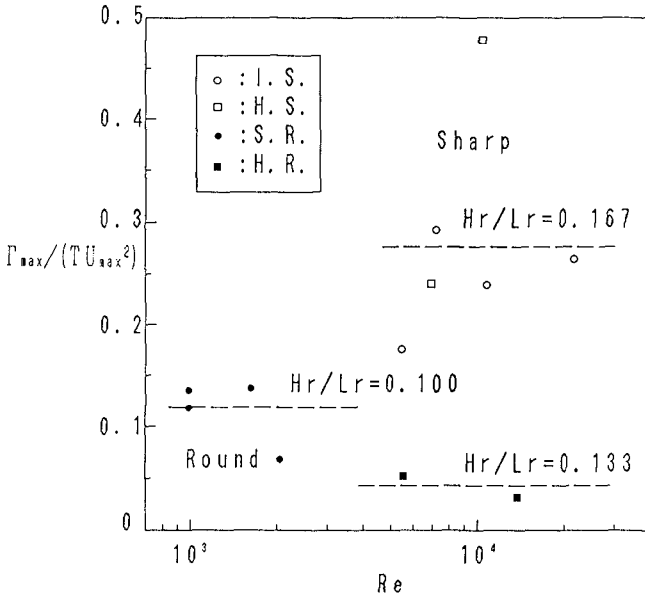

Fig.9 Tentative evaluation of maximum circulation.

oscillatory flow conditions were determined by using two types of empirical diagrams presented by Mogridge and Kamphuis (1972) and Sato (1987) respectively under the conditions of  $H_r=4\text{cm}$ ,  $L_r=30\text{cm}$ , and  $D=0.4\text{mm}$ . Here  $D$  is the grain size of sand. The flow conditions thus obtained are  $T=4\text{s}$  and  $U_{\text{max}}=30\text{cm/s}$  which correspond to the condition of Case D in the present experiments.

Figure 10 gives the cumulative grain size of sand particles adopted to the following experiment. The medium grain size of  $D_{50}=0.43\text{mm}$  is nearly equal to the expected value of  $0.4\text{mm}$ . Figure 11 shows the comparison between the profile of fixed ripple model with the round crest and the measured profile of the sand ripple generated in the oscillatory flow flume. The agreement seems to be extremely good.

Fig.10 Cumulative grain size curve of sand particles used for the laboratory experiment.

— : Fixed Model  
 ○ : Ripple Measured

Fig.11 Comparison of measured sand ripple profile with the fixed ripple model.

Criteria of Organized Vortex Formation

Again the fixed model of ripple with the round crest was installed in the oscillatory flume and the maximum horizontal size of organized vortices was measured visually by using a scale under the numerous combinations of period and amplitude of the piston stroke. The measured data were plotted on a diagram with the abscissa of Reynolds number,  $Re$ , and the ordinate of Keulegan-Carpenter number,  $KC$ , as shown in Figure 12. Different symbols were used to indicate roughly the vortex size.

Fig.12 Criterion Curves I, II and III for vortex formation (fixed ripple model with the round crest).

In this figure three different curves denoted by I, II and III were drawn as criteria of vortex formation. The physical meaning of these three curves will be discussed in the following :

- (1) Curve I shows that the Reynolds number should exceed a certain number to generate the organized vortex. The possible minimum value of the Reynolds number might be 400.
- (2) Curve II corresponds to the following condition. It is well known that the Strouhal number of the vortex

shedding induced to a circular cylinder in a steady flow depends upon the Reynolds number. The KC number in the present investigation corresponds to the reciprocal of Strouhal number. Therefore it seems to be natural that the critical KC number for vortex formation depends upon the Reynolds number.

- (3) Sleath (1984) introduced the following relationship for any given sediment to determine the wavelength  $L_r$  of the rolling grain ripples

$$\beta L_r = \alpha = \text{constant} \quad (2)$$

where  $\beta = \sqrt{\omega/2\nu}$ ,  $\omega = 2\pi/T$ , and  $\nu$  is the kinematic viscosity of fluid. Transformation of Equation (2) yields

$$KC = \frac{\pi}{\alpha^2 (H_r/L_r)^2} Re \quad (3)$$

In the present case  $H_r/L_r=0.133$ , hence the KC number is proportional to the Reynolds number. Based on the above discussion, Curve III may be closely related to the criterion of rolling grain ripple formation.

The experimental conditions of the Sawamoto et al. cases, and Cases B and D in the present investigations fall within the region of vortex formation as demonstrated in Figure 12.

### CONCLUSIONS

In this paper the characteristics of the organized vortex formed behind a ripple crest in an oscillatory flow were investigated in detail. Two ripple models were adopted for the present study ; the first is the ripple model with a sharp crest and the second is that with a round crest. The main conclusions are as follows :

- 1) The vorticity of the organized vortex induced by the sharp crest ripple is naturally stronger than that by the round crest ripple.
- 2) The circulation outside the vortex region was evaluated for each phase of oscillatory flow. The nondimensionalized circulation has temporally a specified form for each type of ripple profile. In

order to determine clearly the variational form with the phase of oscillatory flow, additional data are needed.

- 3) Vortex formation due to the round crest ripple was clearly observed in a certain region in the domain of the Reynolds number versus the Keulegan-Carpenter number. The physical meaning of the three criteria was described.

## CHAPTER 164

# Berm Formation and Berm Erosion

Kazumasa KATOH<sup>1</sup> and Shin-ichi YANAGISHIMA<sup>2</sup>

### Abstract

To investigate the mechanism of beach erosion in a storm, a daily survey of beach profile and the measurement of infragravity waves near the shoreline have been carried out in a field during two and half years. Analyses of these data reveal that the infragravity waves and the level rising of water table play a important role in the berm erosion in a storm. The infragravity waves run up beyond the berm crest to the backshore. The swashed water permeates into the beach, which contributes to a high water table. The permeated water rises to the surface of foreshore, where the beach is eroded by the backwash of infragravity waves.

### 1. Introduction

In a storm, a beach erodes rapidly within one or two days due to the sand transport from the beach to the offshore. Formerly, wind waves had been considered to be a main external forces of beach erosion in a storm. The wind waves, however, lose their energy when they propagate into the surf zone. Breakers in the surf zone are saturated, that is, the wave height at any point is limited by the local water depth. The larger waves in a storm break further offshore making the surf zone wider but leaving the wave height in the inner surf zone same. Therefore it is basically difficult to attribute the abrupt beach erosion in a storm to the offshore wind waves.

In contrast to the wind waves, the infragravity waves of about 30 seconds to several minutes in a period well develop in a storm (Guza and Thornton, 1982), and do not break in the surf zone, being the largest at the shoreline

---

<sup>1</sup>Chief of the Littoral Drift Laboratory, Port and Harbour Res. Inst., 3-1-1, Nagase, Yokosuka, Kanagawa, JAPAN

<sup>2</sup>Member of the Littoral Drift Laboratory

( eg., Bowen and Huntley, 1984; Holman, 1984). Based on the field data, Katoh and Yanagishima (1990) showed that the berm, or the beach, abruptly erodes in a storm due to not the wind waves but the infragravity waves. Then, in the consideration of the mechanism of beach profile change, it should be very important to take into account the infragravity waves as the external force.

In this study, paying attention to the changes of berm on the shore and the infragravity waves near the shoreline, a field observation has been carried out every day during two and half years. Evidences of berm erosion and berm formation have been abstracted from the data obtained, being 58 cases and 219 cases respectively. By analyzing these data, the differences of physical condition between the berm formation and berm erosion will be examined, by which the mechanism of berm erosion will be discussed.

## 2. Field Observation at Hazaki Oceanographical Research Facility (HORF)

The site of field observation is a entirely natural sandy beach, being exposed to the full wave energy of the Pacific Ocean, and is classified as micro-tidal beach with the tide range of about 1.4 meters ( see Figure 1). On this beach, Port and Harbour Research Institute, Ministry of Transport, constructed the Hazaki Oceanographical Research Facility ( HORF, see Photo.1) in 1986 for carrying out the field observation in the surf zone even under sever sea conditions. The research pier is 427 meters long and supported by concrete-filled steel piles in a single line, at 15 meters interval.

The mean profile during about one year is shown in Figure 2. The foreshore slope is mild, about 1/50 in average, while the mean bottom slope in the surf zone is a little milder, 1/60. The mean diameter of sediments on the

Figure 1 Site of field observation.

Photo. 1 Hazaki Oceanographical Research Facility.

beach is usually 0.18 mm, which changes occasionally in the narrow range between 0.16 mm and 0.20 mm due to the accumulation and the erosion.

On this beach, the field observations on the berm erosion/formation and the infragravity waves had been carried out for about two and half years from August 1987 to January 1990. The observations conducted in conjunction with this study are as follows;

- (a) survey of the beach profile,
- (b) observation of the infragravity waves near the shoreline,
- (c) wave observation in the offshore,
- (d) observation of the water table under the beach.

The observation methods related to the items from (a) to (c) and the primary analyses of them have been described by Katoh and Yanagishima (1990). To measure the water table, two pipes of 12.5 centimeters in diameter were sunk into

Figure 2 Mean profile of study site.

Figure 3 Arrangement of instruments.

the beach at the horizontal reference point of -65m and -115m as shown in Figure 3, and water level meters were installed inside the pipes. The measurement were done during 20 minutes of every hour for about two years from February 1988 to January 1990 including a interruption of about 6 months due to sensor troubles.

3. Level of sand accumulation in the storm

Based on the beach profile data, the evidences of berm erosion have been abstracted. Those are 58 cases in total. Table 1 is the largest ten values of offshore significant wave height in the berm erosions. Two typical examples in the storms have already been reported and discussed by Katoh and Yanagishima (1990) with the data of wind waves and infragravity waves.

19 Nov. '88	4.02	9.7

Figure 4 shows one of them during the days when the typhoon No.8713 passed near the observation site. The berm had been formed by the 12th of September, but it had eroded within the short term of two days from the 12th to the 14th

Figure 4 Berm erosion during typhoon No.8713.

of September. One more notice must be given in Figure 4. There was a interesting paradox that the sand deposited on the higher elevation when the berm eroded, as Bascom(1954) had already pointed out. This kind of sand accumulation existed in 48 cases out of 58 evidences of berm erosion.

Katoh and Yanagishima (1990) presented that the critical level of sand accumulation can be predicted by the following equation, which had been empirically obtained with the limited field data,

$$D_L = (\bar{\eta})_0 + 0.96(H_L)_0 + 0.31 \quad (\text{m}). \quad (1)$$

where  $D_L$  is the critical level of sand accumulation in a storm,  $(\bar{\eta})_0$  is the mean sea level at the shoreline,  $(H_L)_0$  is the height of infragravity waves at the shoreline. The third constant term is considered to represent the run-up effect of incident wind waves, because it is independent of the condition of offshore wind waves (Guza and Thornton, 1982).

In Figure 5, the relation between measured values of  $D_L$  and values estimated by Eq.(1) with the data of the mean water level and the height of infragravity waves are plotted for 48 cases of the berm erosion. Since the data are plotted close to the solid line, the validity of Eq.(1) is reconfirmed here.

Figure 5 Reconfirmation of Eq.(1).

#### 4. Evidences of the Berm Formation and level of berm crest

Based on the beach profile data, the evidences of successive berm formation for more than several days have been abstracted. Those are 219 cases. Figure 6 shows the typical example of berm formation during the period from the 5th to 15th of August, 1987. The height of offshore wind waves was usually about 1.0 meter with the exception of the short period from the 6th to the 7th when it was 1.8 meters in maximum. The height of infragravity waves at the shoreline was usually smaller than 0.3 meter.

The process of berm formation is characterized as follows;

- (a) The berm was formed with the horizontal berm crest.
- (b) The foreshore slope became gradually steeper.

Figure 6 Example of berm formation.

(c) The berm formation was accompanied with a slight erosion at the base of berm.

The features (a) and (b) are recognized in almost all remaining cases. The slight erosions at the base of berm are recognized in 109 cases out of 219 cases. Including the other case that the profile of the base of berm was almost the same as that in the day before, 153 cases are counted in total.

In Figure 7, the relation of the berm crest level,  $A_L$ , which is the upper limit level of sand accumulation in the berm formation, and the value estimated by Eq.(1) is plotted with a symbol of triangle. In this figure, the

Figure 7 Relation between the berm crest level and the value estimated by Eq.(1).

critical levels of sand accumulation,  $D_L$ , are also plotted with a symbol of circle. As almost all of the data agree well with the straight line, the berm crest level in the process of berm formation can be expressed by the same equation as Eq.(1), that is,

$$A_L = (\bar{\eta})_0 + 0.96(H_L)_0 + 0.31 \quad (m). \quad (2)$$

Although the berm erosion and the formation are the phenomena which are contrary to each other, it has been shown that the critical level of sand accumulation in the berm erosion and the berm crest level in the berm formation can be expressed by the single equation.

**5. Difference of Conditions between the Berm Erosion and the Berm Formation**

Now, the consideration on the correspondence between two kind levels of sand accumulation,  $D_L$  and  $A_L$ , and the wave run-up level,  $R_{MAX}$ , makes us assume

$$R_{MAX} = (\bar{\eta})_0 + 0.96(H_L)_0 + 0.31, \quad (3)$$

with the proviso that this assumption changes the physical meaning of  $R_{MAX}$  from what is called the run-up level of waves to the upper limit level where the waves may make the significant profile change.

The total value of the second term in the right side of Eq.(3) have been calculated for each event of berm erosion and berm formation, respectively. The total value of the third term which is considered to correspond to the run-up height of incident wind waves have been also calculated for each event. Figure 8 shows the rates of resultant values, by normalizing with the total value of the third term in each event. It may be said that the berm eroded when the run-up height of infragravity waves was relatively large, and the berm was formed when the run-up height of incident wind waves was relatively large.

Next, Figure 9 shows the relation between the wave run-up level,  $R_{MAX}$ , and the berm crest level in the previous day, which is denoted by  $(A_L)_{FORMER}$ . A linear quadratic discriminant analysis has been done to

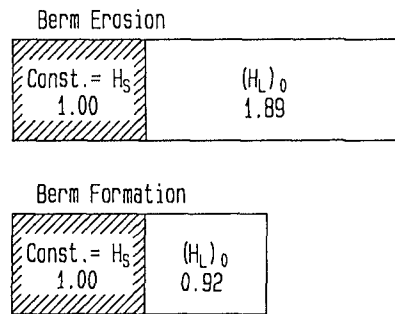

Figure 8 Comparison of run-up heights between the incident wind waves and the infragravity waves in each event.

Figure 9 Relation between  $(A_L)_{\text{FORMER}}$  and  $R_{\text{MAX}}$ .

classify these data into two groups. The boundary between two groups is drawn with a straight solid line in Figure 9. The occurrence distribution of data in each group is shown in the upper right corner of Figure 9. From this result, we have

$$R_{\text{MAX}} > 0.54(A_L)_{\text{FORMER}} + 1.11 \quad (\text{m}), \quad (4)$$

as the condition for the berm erosion. In short, the occurrence that the waves run up beyond the existing berm crest to the higher level is a prerequisite for the berm erosion.

Moreover, in Figure 10, the critical level of berm erosion ( see Figure 4 ) and the level of slight erosion in the berm formation (see Figure 6 ) are plotted against the wave run-up levels,  $R_{\text{MAX}}$ . The critical level of berm erosion is 0.39 meter lower than  $R_{\text{MAX}}$ , while the level of slight erosion is about 0.9 meter lower than  $R_{\text{MAX}}$  with some scattering of data. In short, the critical level of berm erosion is relatively higher than the level of slight erosion.

After all, three conditions are known for the berm erosion. When the berm eroded, (a) the height of infragravity waves at the shoreline was large, (b) the waves run up beyond the berm crest to the higher level, and (c) the critical level of erosion was relatively high.

Figure 10 Relation between the erosion level and the wave run-up level.

#### 6. Relation between the Critical Level of Berm Erosion and the Level of Ground Water Table

It has been said for a long time that the position of the water table under the beach has an important bearing on deposition and erosion of the foreshore and backshore. For example, Grant (1948) explained the importance of the wetness or dryness of beach in the changes of beach profile. When the water table under the beach is very high and contiguous with the surface of most of the foreshore, the backwash of the waves is accelerated by addition of water rising to the surface throughout the saturated foreshore. This saturated area is called the effluent zone. The increased volume of backwash by ground water escaping to the surface of the foreshore also dilates the sand and propels the finer grains into the turbulent flow. These enhance the erosion of the foreshore.

The causes of high water table, which have been pointed out up to these days, are;

- (a) The water due to the heavy rain storm in the hinterland flows to the backshore ( Grant, 1948 ),
- (b) As the water table under the beach lags 1 to 3 hours behind the tide, the water table is relatively higher than the tide during the ebb tide ( Emery and Foster, 1948; Duncan, 1964 ),
- (c) Hot springs flow out at some beach in Japan ( Sato et al., 1982 ).

All of these, however, are not the causes which take part

Photo. 2 Maximum wave run-down ( taken from the rooftop of HORF ).

in the berm erosion in a storm. Now, we can add one more cause of high water table which is directly related to the beach erosion in the storm; that is to say, there is a possibility that the water run-up beyond the berm crest penetrates into the beach, which makes the water table high.

In the field observation, it was recognized that the large scale wave run-up beyond the berm crest occurred with a period of 1 to 2 minutes in the storm. Photo. 2 was taken from the rooftop of the laboratory in HORF under the situation of maximum wave run-down. In this picture, the existing berm crest of running in the longshore direction is inspected to be exposed to the air. In the left side, or the land side, the beach was covered with the water which stayed on the backshore for a good while. On the backshore, the authors recognized that air bubbles came out from the ground through the surface of beach, which was due to the replacement with the water penetrated into the ground. As a result, it is not difficult to infer the situation that the level of water table under the beach became higher, and the penetrated water flowed out through the surface of foreshore.

Then, the seepage level, which is the upper limit of the effluent zone, has been determined by the numerical simulation of the finite element method which was developed by Bathe and Khoshgoftaar (1979) for analysis of steady unconfined seepage conditions in two-dimensional case.

The area of simulation is from the reference point of -

115m ( see Figure 3 ) to the offshore in the cross-shore direction, and from the beach surface to the level of -20 meters in the downward direction. The beach profile is approximated by a straight line. In calculation, distorted rectangular elements are made by dividing the area of simulation with the interval of 0.5 meter in the vertical direction, and with the interval of 5 meters, being nearly parallel to the beach slope, in the cross-shore direction. The level of water table measured at the reference point of -115m, which has been confirmed to be usually stable independent of the tide or wave run-up on the beach, is used as the boundary condition at the land side. For the boundary condition at the shoreline, the sum of the mean sea level at the shoreline and the run-up height of incident wind waves, that is  $(\bar{\eta})_0 + 0.31$  (m), is utilized. A reason why the run-up of incident waves is taken into consideration is owing to the fact that the incident waves run up repeatedly with the short period of about 8 seconds, which keeps the beach wet. A coefficient of permeability in the beach is employed as  $1.14 \times 10^{-2}$  cm/s, based on the result of permeability test conducted by Zen et al. (1989) with the sand sampled from the study site.

At first, in order to verify the applicability of simulation model, the water tables have been calculated for the calm wave conditions of 74 cases, in which the significant wave heights and the periods in the offshore were less than 1 meter and 8 seconds, respectively. Figure 11 shows the comparison of the observed levels of water

Figure 11 Comparison of observed level of water table with the calculated one.

table,  $(G_w)_{\text{HRS}}$ , at the reference point of  $-65\text{m}$  with the calculated ones,  $(G_w)_{\text{CAL}}$ , at the corresponding point. The calculated water tables agree approximately with the observed ones.

Next, the free surfaces of water table have been calculated for the berm erosions in the storms. The calculated levels of water table at the reference point of  $-65\text{m}$ , however, were lower than measured ones. The difference between them increases with the run-up height of infragravity waves. Therefore, in the calculation of water table in the storm, it is necessary to take into account one more condition that the water on the horizontal portion of the berm penetrates into the beach.

In order to simulate the penetration of water into the beach, the steady discharge of penetration through the beach face has been assumed. The distribution of discharge along the beach surface is set as a triangle, being zero at the wave run-up level,  $R_{\text{MAX}}$ . The value of discharge has been determined by trial and error so as to coincide the calculated water table at the reference point of  $-65\text{m}$  with the measured one in the field. The resultant value of discharge is in a range of  $0.2$  to  $0.5 \text{ m}^3/\text{h}$  per unit longshore length, which has a tendency to increase with the height of infragravity waves.

In this convenient manner, the water table under the

Figure 12 Relation between the critical level of berm erosion and the seepage level of ground water.

beach is calculated for each case of the berm erosion. After that, the seepage level is determined at the intersection of the water table and the foreshore profile, which is denoted by  $(G_w)_0$ . In Figure 12, the seepage levels are plotted against the critical levels of berm erosion in the storms. The plotted data agree approximately with the straight line; that is to say, the critical level of berm erosion corresponds roughly to the seepage level of water.

Based on this result, we can make another consideration. In the process of berm formation, the run-up level is low and the water goes down immediately along the foreshore slope without staying, which is enhanced by the increase of foreshore slope. As a result, the level of slight erosion in the berm formation is relatively lower in comparison with the run-up level ( see Figure 10 ).

## 7. Conclusions

The main conclusions reached in this study are as follows;

- (1) Both the critical level of sand accumulation in the berm erosion and the berm crest level in the berm formation can be expressed by Eq.(3), which contains the effect of run-up of infragravity waves on the beach.
- (2) As the infragravity waves run up beyond the berm crest in the storm, the sea water stays for a good while on the horizontal area of the berm, which accelerates the saturation of water into the beach. As a result, the water table becomes higher, and the water flow out through the surface of foreshore. The seepage level of water corresponds to the critical level of berm erosion.

## Acknowledgement

The authors should like to express our grateful thanks to Dr. Masaki Kobayashi, the Director of the Soil Division of the Port and Harbour Research Institute, for helpful suggestions for using the computer program of seepage flow which has been developed by him.

## CHAPTER 165

### COUPLING OF A QUASI-3D MODEL FOR THE TRANSPORT WITH A QUASI-3D MODEL FOR THE WAVE INDUCED FLOW

Irene Katopodi<sup>1</sup>, Nikos Kitou<sup>1</sup> and Huib J. de Vriend<sup>2</sup>

#### ABSTRACT

In this paper the coupling of a quasi-3D model for the suspended sediment transport with a quasi-3d model for the wave driven flow is presented. The quasi-3d model for the transport is based on an asymptotic solution of the wave-averaged convection-diffusion equation while the quasi-3D wave driven current model is based on a profile function technique. The resulting model is a low cost but detailed alternative to a full 3D model. An application is presented concerning cross-shore transport. Preliminary conclusions are drawn.

#### 1. INTRODUCTION

The prediction of suspended sediment transport and subsequently of bed evolution in coastal areas is of vital importance for the operation and maintenance of engineering works. Numerical models are expected to play an increasingly significant role as a design and decision tool of the coastal engineer.

A variety of models have been presented in the literature with various degrees of sophistication as far as the constituent models are concerned. The present model involves two basic submodels of the same degree of sophistication: Both wave induced currents and suspended sediment transport are computed using quasi-3D techniques that exhibit the low computational cost of the 2DH models while at the same time provide information about the vertical structure of the flow and the suspended sediment concentration.

Moreover, in cross-shore flows local equilibrium is

---

2 Delft Hydraulics, P.O. Box 152, 8300 AD, Emmeloord, the Netherlands.

assumed for the suspended sediment and as a result suspended sediment transport formulae are widely used for the calculation of the bed-level changes. Herein, in a cross-shore case the full convection-diffusion equation has been used.

## 2. THE QUASI-3D MODEL FOR THE SUSPENDED SEDIMENT TRANSPORT (LOG VELOCITY PROFILE)

The present work is an extension of the suspended sediment transport model presented by Katopodi and Ribberink (1990, 1992). A short description of the model follows:

The model is based on an asymptotic solution of the wave-averaged 3D convection-diffusion equation. The asymptotic solution was developed by Galappatti and Vreugdenhil (1985) for unidirectional flow under certain scale considerations. In the quasi-3D model for currents and waves the wave influence is included through a suitable modification of the vertical mixing coefficient and through the near-bed boundary condition (van Rijn, 1986). Two bed boundary conditions are used: Either the sediment concentration ("concentration" b.c.) or its vertical gradient at the near-bed reference level ("gradient" b.c) is assumed to adapt immediately to equilibrium conditions and are given as functions of local hydraulic and sediment parameters (for expressions see van Rijn, 1986).

Under the assumption that the velocity is described by  $u(x, \zeta, t) = \bar{u}(x, t) p(\zeta)$  and  $v(x, \zeta, t) = \bar{v}(x, t) p(\zeta)$  (one logarithmic component only) and the use of the "concentration" bed boundary condition the depth averaged equation reads:

$$\begin{aligned} \bar{c}_e = \bar{c} + \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s} \frac{\partial \bar{c}}{\partial t} + \frac{\gamma_{22}}{\gamma_{11}} \frac{h \bar{u}}{w_s} \frac{\partial \bar{c}}{\partial x} + \frac{\gamma_{22}}{\gamma_{11}} \frac{h \bar{v}}{w_s} \frac{\partial \bar{c}}{\partial y} - \\ - \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s} \frac{\partial}{\partial x} \left( \epsilon_x \frac{\partial \bar{c}}{\partial x} \right) - \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s} \frac{\partial}{\partial y} \left( \epsilon_y \frac{\partial \bar{c}}{\partial y} \right) \end{aligned} \quad (1)$$

where  $\bar{c}$  and  $\bar{c}_e$  are the depth averaged concentration and equilibrium concentration,  $\bar{u}$  and  $\bar{v}$  depth averaged velocities,  $h$  the water depth, the sediment fall velocity is  $w_s$  and  $\gamma_{ij}$  coefficients that depend only on the explicit knowledge of the vertical mixing coefficient, the fall velocity and the normalized velocity profile  $p(\zeta)$  and can be computed in advance. After equation (1) has been solved for  $c$ , the vertical concentration profile can be constructed in terms of already known profile functions (see Katopodi and Ribberink, 1992).

Equation (1) can be written as:

$$\bar{c}_e = \bar{c} + T_A \frac{\partial \bar{c}}{\partial t} + L_x \frac{\partial \bar{c}}{\partial x} + L_y \frac{\partial \bar{c}}{\partial y} - T_A \left( \frac{\partial}{\partial x} (\epsilon_x \frac{\partial \bar{c}}{\partial x}) + \frac{\partial}{\partial y} (\epsilon_y \frac{\partial \bar{c}}{\partial y}) \right) \quad (2)$$

with

$$T_A = \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s}, \quad L_x = \frac{\gamma_{22}}{\gamma_{11}} \frac{\bar{u}h}{w_s}, \quad L_y = \frac{\gamma_{22}}{\gamma_{11}} \frac{\bar{v}h}{w_s} \quad (3)$$

Equation (2) describes the adjustment of the depth-averaged concentration to its equilibrium value. The parameters  $T_A$ ,  $L_x$  and  $L_y$  represent the characteristic scales in time and space of this adjustment process (adaptation time, adaptation lengths). If the "gradient" bed boundary condition is used, only the expressions for the adaptation time and length change in equation (3), (see Katopodi and Ribberink, 1992).

### 3. THE QUASI-3D MODEL FOR THE WAVE INDUCED FLOW

In (1) the velocity profile was assumed logarithmic which is not realistic in the wave driven nearshore circulation. Instead, the quasi-3D model for nearshore currents presented by de Vriend and Stive (1987) as modified by de Vriend and Ribberink (1988) is employed in this work (DVS in the following). This model is based in a profile function technique combined with a 2DH current formulation. The current is divided into a primary component and a number of secondary components due to the vertical nonuniformities of the various driving forces. The velocity is given as a similarity series:

$$u(x, \zeta, t) = \sum_{i=1}^n \bar{u}_i(x, t) p_i(\zeta) \quad (4a)$$

$$v(x, \zeta, t) = \sum_{i=1}^n \bar{v}_i(x, t) p_i(\zeta) \quad (4b)$$

where  $\bar{u}_1$ ,  $\bar{v}_1$  are depth averaged primary current,  $\bar{u}_i$ ,  $\bar{v}_i$  depth invariant parameters representing secondary current intensity,  $\zeta = z/h$  and  $p_i(\zeta)$  profile functions with:

$$\int_0^1 p_1(\zeta) d\zeta = 1 \quad \text{and} \quad \int_0^1 p_i(\zeta) d\zeta = 0 \quad \text{for } i > 1 \quad (5)$$

Equations (5) imply that the depth averaged flow is entirely determined by the primary current. The model consists of a depth-averaged wave-driven current module

(see application, chapter 5) and the velocity profile extraction part.

In the DVS model complete description of the undertow and the boundary layer streaming is included. The model though is written in a general way so that secondary flows other than those due to waves (like Coriolis induced or wind induced flows) can easily be included.

The wave induced secondary velocity is consisting of a number of components due to various driving forces:

$$\begin{aligned}
 u_s(\zeta) &= u_2(\zeta) + u_3(\zeta) + u_4(\zeta) + u_5(\zeta) \\
 &= \bar{u}_2 p_2(\zeta) + \bar{u}_3 p_3(\zeta) + \bar{u}_3 p_3(\zeta) + \bar{u}_4 p_4(\zeta) \quad (6)
 \end{aligned}$$

where

- $u_2(\zeta)$  secondary current due to the surface shear stress
- $u_3(\zeta)$  secondary current due to secondary bottom shear stress
- $u_4(\zeta)$  near-bottom drift due to spatial variation of the orbital velocity
- $u_5(\zeta)$  near-bottom drift due to the boundary layer.

For expressions for the secondary velocities the reader is referred to Ribberink and de Vriend (1989). In fig.1 the velocity and its components are shown at the cross section of the flume  $x=30$  m (cf.example). Near the bottom the effect of the boundary layer is clear.

Fig.1 Current velocity and its components (x=30m)

#### 4. COUPLING OF THE TWO QUASI-3D MODELS

In (1) the velocity was consisting of only one component (similarity was assumed). If the velocity is given as a similarity series, eq.(4), then equation (1) becomes:

$$\begin{aligned}
 \bar{c}_e = & \bar{c} + \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s} \frac{\partial \bar{c}}{\partial t} + \\
 & + \left( \sum_{i=1}^n \bar{u}_i \frac{\gamma_{22,i}}{\gamma_{11}} \right) \frac{h}{w_s} \frac{\partial \bar{c}}{\partial x} + \left( \sum_{i=1}^n \bar{v}_i \frac{\gamma_{22,i}}{\gamma_{11}} \right) \frac{h}{w_s} \frac{\partial \bar{c}}{\partial y} \\
 & + \left( \beta \frac{\gamma_{23}}{\gamma_{11}} + \frac{\gamma_{24}}{\gamma_{11}} \right) \frac{1}{1+\beta} \frac{\partial z_s}{\partial t} \frac{1}{w_s} \bar{c} \\
 & + \sum_{i=1}^n \left( \frac{\partial}{\partial x} (\bar{u}_i h) \frac{\gamma_{25,i}}{\gamma_{11}} \right) \frac{1}{w_s} \bar{c} \\
 & + \sum_{i=1}^n \left( \frac{\partial}{\partial y} (\bar{v}_i h) \frac{\gamma_{25,i}}{\gamma_{11}} \right) \frac{1}{w_s} \bar{c} \\
 & - \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s} \left( \frac{\partial}{\partial x} \left( \epsilon_x \frac{\partial \bar{c}}{\partial x} \right) + \frac{\partial}{\partial y} \left( \epsilon_y \frac{\partial \bar{c}}{\partial y} \right) \right) \quad (7)
 \end{aligned}$$

where  $\beta$  is the reference level normalized by the depth.

New terms have been added to the RHS of eq.(7), compared to eq.(1): The third and fourth term are now sums of similar terms due to the separate velocity components. The fifth term arises from the vertical transformation. The sixth and seventh terms are due to the vertical velocities that are computed via the continuity equation.

The above equation can be written in a more convenient form, similar to equation (2):

$$\begin{aligned}
 \bar{c}_e = & (1 + V_T + V_x + V_y) \bar{c} + T_A \frac{\partial \bar{c}}{\partial t} + L_x \frac{\partial \bar{c}}{\partial x} + L_y \frac{\partial \bar{c}}{\partial y} \\
 & - T_A \left( \frac{\partial}{\partial x} \left( \epsilon_x \frac{\partial \bar{c}}{\partial x} \right) + \frac{\partial}{\partial y} \left( \epsilon_y \frac{\partial \bar{c}}{\partial y} \right) \right) \quad (8)
 \end{aligned}$$

with

$$T_A = \frac{\gamma_{21}}{\gamma_{11}} \frac{h}{w_s}$$

$$\begin{aligned}
 L_x &= \left( \sum_{i=1}^n \bar{u}_i \frac{\gamma_{22,i}}{\gamma_{11}} \right) \frac{h}{w_s} & L_y &= \left( \sum_{i=1}^n \bar{v}_i \frac{\gamma_{22,i}}{\gamma_{11}} \right) \frac{h}{w_s} \\
 v_T &= \left( \beta \frac{\gamma_{23}}{\gamma_{11}} + \frac{\gamma_{24}}{\gamma_{11}} \right) \frac{1}{1+\beta} \frac{\partial z_s}{\partial t} \frac{1}{w_s} \\
 v_x &= \sum_{i=1}^n \left( \frac{\partial}{\partial x} (\bar{u}_i h) \frac{\gamma_{25,i}}{\gamma_{11}} \right) \frac{1}{w_s} \\
 v_y &= \sum_{i=1}^n \left( \frac{\partial}{\partial y} (\bar{v}_i h) \frac{\gamma_{25,i}}{\gamma_{11}} \right) \frac{1}{w_s} \tag{9}
 \end{aligned}$$

After (7), or (8), is solved for the depth-averaged concentration, the concentration profile can be constructed in terms of already known profile functions.

If "gradient" bed boundary condition is used only the expressions in (9) are different.

Although the number of coefficients to be computed in equation (7), or (8), has now increased significantly compared to (1), or (2), the time required for their computation keeps the model at operational level.

## 5. APPLICATION

The model described in the previous section was applied for a cross-shore case with field and wave data taken from the experiment conducted in the Hannover Big Wave Flume (Dette and Uliczka, 1986) in order to study the beach profile evolution due to the wave action at prototype scale. This experiment was used for intercomparison of profile models under the MAST-G6 Morphodynamics programme (Hedegaard et al, 1992). The waves were monochromatic ( $H=1.5\text{m}$   $T=6\text{s}$ ) and the wave propagation direction normal to the shore (bed configuration fig.2a).

In the present computation no wave-current interaction was included, the wave field was stationary and the steady-state current was computed. The steps followed are described below:

1. The wave heights (fig.2a) were computed with the use of the energy equation. Dissipation due to breaking was calculated using the bore analogy (see description of UNIBEST in Hedegaard et al, 1992).

2. For depth-averaged current the 1D continuity and momentum equations were solved:

$$\frac{\partial(\bar{u}h)}{\partial x} + \frac{\partial}{\partial x} \left( \frac{M_x}{\rho} \right) = 0 \quad \text{continuity} \tag{10}$$

with

$$M_x = \frac{E}{c} \left( 1 + \frac{7h}{L} Q_b \right) \quad (11)$$

where  $\bar{u}$  is the depth-averaged current velocity,  $M_x$  the wave mass flux,  $E$  the wave energy,  $c$  the wave celerity,  $L$  the wave length,  $h$  the water depth,  $Q_b$  fraction of breaking waves set equal to 1 for breaking waves and to 0 for non-breaking waves and  $\rho$  the water density. The second factor in the parenthesis is the roller contribution.

$$0 = -g \frac{\partial z_s}{\partial x} + \frac{1}{\rho h} \frac{D}{c} - \frac{\tau_{b,p}}{\rho h} \quad \text{momentum} \quad (12)$$

where  $z_s$  is the free surface,  $D$  the total wave energy dissipation (due to breaking and due to bed friction),  $\tau_{b,p}$  primary bed shear stress given by de Vriend and Stive (1987) as function of the depth mean velocity, the eddy viscosity and the bottom roughness amplification factor. In fig.2b and fig.2c the bed configuration and set-up and the depth averaged (primary) velocity are shown along the flume.

3. The secondary velocities were calculated according to Ribberink and de Vriend (1989), and the velocity profiles were constructed (fig.3a). In fig.3b velocity profiles are also shown in more detail (note the vertical axis where the position of the cross-section along the flume is depicted).

4. The adaptation time  $T_\lambda$  and length  $L_x$  (fig.4a and 4b) as well as the factor due to vertical velocities  $V_x$  and the depth-averaged value of  $\bar{c}_e$  (fig.5a) were computed by a separate module before the calculation of  $\bar{c}$ . The term  $V_\tau$  is zero because the steady state is examined.

5. Equation (8), was solved with upstream (shore) condition imposed equilibrium concentration and downstream (offshore) condition zero second derivative of the concentration. For "gradient" bed boundary condition the expressions (9) are different. The value of the horizontal eddy viscosity (fig.4c) was given by:

$$\epsilon_x = M h \left( \frac{D}{\rho} \right)^{1/3} \quad (13)$$

where  $M$  is a coefficient of the order of one. The depth averaged concentration for the two bed boundary conditions is shown in fig.(5a).

6. The concentration profiles (fig.5b and 5c) were then constructed in terms of the depth averaged concentration and profile functions computed before.

7. Finally, the suspended sediment transport rate was

calculated using the following equation:

$$S_x = h \int_0^1 u c \, d\zeta - h \int_0^1 \epsilon_x \frac{\partial c}{\partial x} \, d\zeta \quad (14)$$

In fig.6 the suspended sediment transport rate computed from equation (14) is plotted for "concentration" and for "gradient" boundary condition. In the same plot the suspended sediment transport rate under equilibrium conditions is also shown.

The results of the example are discussed in the following:

Considerable difference exists between the equilibrium concentration and the concentration computed from the convection-diffusion equation. This is shown in fig. (5a) as far as depth-averaged quantities are concerned for both boundary conditions. The difference is more important in cross section at  $x=40m$  where the equilibrium concentration is bigger and at cross section at  $x=50 m$  where the opposite happens. The peak of the concentration is more onshore for equilibrium conditions. In figures 5b, 5c (concentration profiles) the difference between the concentrations computed with the use of the two bed boundary conditions should be noticed, especially in the cross-section at 40m. The gradient bed boundary condition results in somewhat smoother concentration (result of the bigger adaptation length (see fig.4a). No definite conclusion on which boundary condition is appropriate can be drawn until comparison with measurements is made.

In fig.6 we can see that the non-equilibrium transport presents a discontinuity in cross-section at  $x=40m$ . This is due to the wave formulation we have chosen. In the computation of the wave mass-flux the roller term is added suddenly as soon as the waves start breaking and this causes a discontinuity in the depth averaged velocity. This discontinuity can be removed with an alternative formulation of the roller contribution to the wave mass flux. Inclusion of random waves will make even smoother the quantities involved. The discontinuity occurs in the first term of the RHS of (14) where the concentration is multiplied by the velocity.

Nevertheless, the horizontal gradients of the non-equilibrium transport are smaller than those of the equilibrium one and it is expected that the bar that will be formed will have more damped shape than the one computed if suspended sediment transport is assumed to be in equilibrium (as is implied in transport formulae).

In Katopodi and Ribberink (1990,1992) it was argued that when the space (time) computational grid size is smaller than the adaptation length (time) then the adaptation process (to equilibrium) should be described with the use of a non-equilibrium transport model

Fig.6 Suspended sediment transport rates

(convection-diffusion equation). Following the above reasoning, the importance of the non-equilibrium effects could be foreseen (before the solution of the convection diffusion equation) by comparison of the adaptation length (fig.4b) with the required computational space grid. In the experiment of Dette and Uliczka (1986) the bar has a width of about 10 m and a grid of about 0.5 m is required to describe it. The grid size is much smaller than the adaptation length in the biggest part of the flume, especially in the surf zone, and this indicates that non equilibrium effects should be taken into account in the transport computation. Of course, their impact on the bed-level changes should be shown quantitatively

## 6. CONCLUSIONS

A model for the suspended sediment transport is presented for wave induced flows. The current velocities are given as a (similarity) series of vertical profiles. The suspended sediment transport is computed with the use of a quasi-3d model of the convection diffusion equation. The effect of the vertical velocity that is computed via the continuity equation is included.

Although the number of coefficients to be computed before the solution of eq. (7) is much larger than when the velocity was consisting of a unique profile, the time required for their computation is very small compared to that of the actual solution of the equation.

Both current and transport modules require gradual changes in hydraulic conditions and are particularly

suitable for large computational areas.

This work is a first attempt to develop a sediment transport model and the effort has been put mostly at the technical part (formulation of the coupling). The Lagrangian and the wave asymmetry transport have not yet been included despite their importance. After the inclusion of the Lagrangian drift correction (as an additional profile), the wave asymmetry transport as well as bed load transport and bed slope effects, we will be able to reach more definite conclusions about the real magnitude and importance of the different phenomena on the sediment transport in the coastal zone.

## CHAPTER 166

### FIELD OBSERVATION ON SAND RIPPLES UNDER ROUGH SEA STATE

Yoshiaki Kawata<sup>1</sup> M. ASCE, Toru Shirai<sup>1</sup> and Yoshito Tsuchiya<sup>2</sup> M. ASCE

#### Abstract

The process of sediment sorting under rough sea state was made clear in the cross-shore direction. Field observation reveals that ripples can be formed under high shear stress in which the Shields number is more than two. The plane bed condition is observed at narrow area of wave breaking. Strong undertow distorts the shape of ripples. The criterion of bed configuration given by Kaneko (1981) is in good agreement with the field data which were rearranged with significant wave characteristics. The criterion of Komar and Miller (1975) is also applicable with mean wave ones.

#### Introduction

In order to develop 3D model of beach processes, it is necessary to get accurate information about sea bottom topography changes, i.e., sediment structure and small scale undulations. The former is the effect of sediment mixture on transport phenomena. In the nearshore environment, sediment sorting is much developed in comparison with that in rivers, but the assumption of uniform sediment in the longshore and cross-shore directions is too rough to predict accurate beach changes. Bottom roughness mainly depends on the formation of wave-formed ripples.

In the field, some observations were conducted at offshore or continental shelf (Forbes et al. 1987, Boyd et al. 1988) and at shallow water environment under moderate wave conditions (Dingler et al. 1976). So far, the measurements were done with the Shields number of less than one. In our observation, simultaneous measurements were also made about waves, currents and sedimentary structures along the T-shaped Observation Pier (TOP) in the surf zone.

### Observations

The field experiments were conducted in December 5 and 6, 1989. The bottom topography was measured with the comb in which 60 fine stings (each sting is 23cm long and 3cm spacing each other) with grease spread on the sting surface can stick the fine sediment in the bed and trace out of the unevenness of sea bottom of 1.8m long in the cross-shore direction. The compass and VTR were also equipped on the instrument to record the overall bottom surface conditions and confirm their accurate direction. The grease can catch the fine sediment after sticking into the bed. The total weight of the equipment is about 100kg.

At the same position, bottom sediment sampling was done with the Smith-Mackintire sampler with which surface layer sediment in around 10cm deep was picked up. The standard sieve analysis was applied to the sampled sediment. Sediment-size distributions and their moments were calculated.

Fig.1 shows the measuring points and cross-shore changes of mean sediment diameter before and after storms. The maximum significant wave height was 3.34m and its period was 8.64s and the Shields number estimated by small amplitude wave theory was 4.64. The beach profile in the figure was measured in December 5. The formation of shoal was remarkable and in accompany with acceleration of beach erosion due to construction of west breakwater at Naoetsu harbor the beach changed to a wave energy reflected beach. Table 1 shows characteristics of waves, sediment and bottom topography.

### Characteristics of sediment

Fig. 2(a) and (b) show the sediment-size distributions with  $\phi$ -scale on a normal probability paper. As already shown in Fig. 1, it was detected that the mean sediment diameter became smaller in the offshore direction and at the end of the TOP the diameter was one tenth of those at the shoreline. Before and after storms, the mean sediment diameter at St. 3 became small and at on and offshore points in the cross-shore direction the sediment changed to rough. This fact shows that relative fine portion of sediment was carried to St. 3 under storm waves. In comparison with Fig. 2(a) and (b), the sediment at St. 3 remarkably became fine after storm. Shirai (1990) has examined annual changes of sediment-size in the cross-shore direction from 1973 to 1979 on the Ogata coast. He pointed out that sediment sorting in a same mother group did not appeared in the field, but eight mother groups of sediment with different mean diameter mixed each other and the four finer sediment groups move in the offshore direction in every storm, even if in summer swell wave conditions. The changes of sediment characteristics in a short-term as shown in Fig. 2 can be regarded as fluctuation of the long-term changes which links to the beach erosion of the Ogata coast.

### Characteristics of bottom topography and its classification

The estimation of bottom roughness depend on the formation of ripples which controls wave transformation and nearshore current system. The field data of bottom roughness were collected with the Shields number of more than four. In our data in Table 1, only three cases include the measurement of height and length of ripples, but in other cases sea bottom conditions were only checked with VTR. With the data, the characteristics of bottom topography could be discussed.

#### (1) Characteristics of bottom topography

Fig. 3(a), (b) and (c) show the bottom topography measured in December 6. The final points of wave breaking were around St. 7, so that it was impossible to measure the bottom topography with the equipment due to rough sediment and washing motion of breaking water. At St. 1, we observed twice. The dominant wave direction was NW, that is parallel to the cross-shore axis of the TOP. VTR recorded as following: St. 1; completely plane bed, Sts. 2 and 3; transition area from ripple bed to plane one. Sts. 4 to 6; irregular (three dimensional) ripples. They were called as irregular ripples or cross ripples (Clifton, 1976). The steep slope crest of ripples were recorded at the vicinity of shoreline. This is due to rapid sorting of sediment by breaking waves, and relatively rough sediment at trough of ripples could not be detected by the measuring stings. After the storms the ripple shape could be clearly measured in December 6, so that the scale was listed in Table 1.

(a) Sts. 1 and 3

(b) Sts. 4 and 5

(c) Sts. 1 and 6

Fig. 3 bottom topography measured

Fig. 4 shows the relationship between  $d_o/D$  and  $\lambda/\sqrt{D}$ , in which  $d_o$ ; trajectory diameter of water particle motion on the bed,  $D$ ; sediment diameter and  $\lambda$ ; ripple length. This relationship was firstly proposed by Clifton (1976). The former ratio shows the effect of acceleration (Abou-Seida, 1964) and the latter ratio was proposed by Bagnold (1946). The data in the figure were collected in the field by Inman (1957) and Dingler et al.(1976). Three open circles shows our data which were calculated with significant wave characteristics. From this figure, it was found that two of them correspond to suborbital ripples whose length is in inverse proportion to  $d_o$  and correlates to  $D$ . Another (the data measured at St. 2 in December 6) exhibits longer length of ripples than usual data. Then, the steepness of ripples was shown in Fig. 5 in which  $u_m$ ; amplitude of water particle velocity on the bed,  $\sigma$  and  $\rho$ ; densities of sediment and water respectively. The semi-empirical curve in the figure was proposed by Dingler et al.(1976). The data measured at St. 2 was plotted far from other data set.

The reason of this discrepancy can be recognized as following: At close to St. 2, we had measured flow velocity at the two points of 1.5m and 2.5m from the bottom with ultra-sonic type current meter. On the Ogata coast, easterly swell waves come after storms and strong undertow at the velocity of 0.5 to 1m/s is generated (Tsuchiya et al., 1989). The wave climate in December 6, 1989 was similar to that at the time when the observation of nearshore currents were carried out. Therefore, the undertow may contribute to the distortion and stretching of the ripple profile.

Fig. 4 Relationship between acceleration of wave motion and ripple length (Clifton, 1976)

Fig. 5 Relationship between steepness of ripples and dimensionless water particle velocity

## (2) Classification of ripple formation

Fig. 6 shows the classification diagram of wave-ripples formation proposed by Kaneko (1981) in which  $\delta (= \sqrt{2\nu/\omega})$ ; laminar boundary layer thickness,  $\omega$ ; wave frequency and open and black circles show ripple and plane bed conditions respectively. Dimensionless parameters were calculated with small amplitude wave theory using significant wave height and its period. The criterion curves were given by Kaneko (1981). The numbers in the figure show the different kind of ripples such as (1): irregular ripples, (2): two dimensional ripples with steep crest and (3): those with round crest. From this figure it was revealed that the boundary between ripple bed and plane bed can be given by the Kaneko's curve. Moreover, as already shown in Fig. 3, the ripples in a shallow water on the Ogata coast are very irregular so that they belong to ripples in area(1). Therefore, Kaneko's criterion is good for prediction of ripple formation. The arrangement with mean wave height and its period was inadequate.

Fig. 7 shows the relationship between sediment-fluid number  $D_{v*}$  and the Shields number  $\tau_*$ . In the figure, circles with cross bar correspond to significant waves and  $D_{v*} = \{(\sigma/\rho)g/\nu^2\}^{1/3}D$ . The empirical curves in the figure show the boundary between plane bed (black circle) and ripple bed (open circle) and were reduced by Tsuchiya et al.(1987) who used the data of Komar et al.(1975) and Nielsen (1979). The curves slightly changes with the parameter of  $d_o/D$  and in the

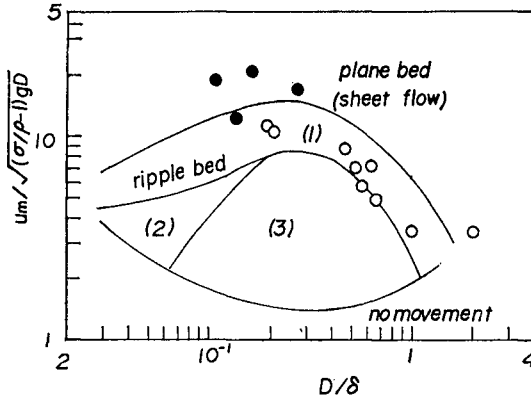

Fig 6 Classification diagram of ripple formation (Kaneko, 1981)

Fig. 7 Classification diagram with sediment-fluid number

Fig. 8 Classification diagram with wave acceleration

case of calculation with mean wave height and its period, two bed forms can be well divided by the curves.

Fig. 8 shows the criterion of ripple bed and plane bed given by Sato et al.(1987). When we arrange the field data with significant wave characteristics, the criterion can be expressed as,

$$\tau_* = 7.8(d_o/D)^{-1/3} \quad (1)$$

it was found that the curve can not well divide the both bed conditions. The estimation of the Shields number is very difficult in the breaker zone, but Tsuchiya et al.(1987) and Kawata (1989) pointed out that the ratio  $d_o/D$  is not effective to classify such bed conditions.

### Conclusions

The sediment sorting process and classification of ripple formation were analyzed with the field data under storm wave conditions. The major results of this study to date are as following:

1) On the Ogata coast, beach sediment belongs not to single mother group but to eight mother ones. The finer four groups continuously move in the offshore

direction in every storm, therefore beach erosion has been brought in accompany with sediment sorting process.

2) Kaneko's criterion is good for prediction of ripple formation. Relationship between sediment-fluid number and the Shields number is also good to estimate small-scale bottom topography.

## CHAPTER 167

About Conditions for the Wave Ripple Existence

Ruben D. Kos'yan<sup>1</sup>, Alexander D. Kochergin<sup>2</sup>

### Abstract

For the prognostication of sediment flow during storm period an investigator has to know if there are any microforms at the bottom in a certain place and under certain wave conditions, and what are their characteristics.

On the basis of field and laboratory data we tried to determine the most universal range of conditions for the wave ripple existence.

In the nearshore zone the gradients of near-bottom velocities and shear stress values depend both on wave motion influence upon the erodible bottom and on the bottom form influence upon this motion. To estimate the dependence of hydrodynamical flow structure on the bottom microrelief it is very important to realize in

---

1. Director of the Southern Branch of the P.P.Shirshov Institute of Oceanology, Russian Academy of Sciences. Okeanologiya 353470 Gelendzhik-7 Krasnodar region, Russia.
2. Engineer of the Southern Branch of the P.P.Shirshov Institute of Oceanology, Russian Academy of Sciences. Okeanologiya 353470 Gelendzhik-7 Krasnodar region, Russia

what conditions microforms, usually called ripples, originate, exist and disappear.

The object of this work is to get quantitative estimation of ripple existence on a certain area of the underwater shore slope under the known parameters of surface waves.

It is generally accepted that ripples are formed when near-bottom velocities of water flow slightly exceed those required to set sediment in motion. M. Manohar (1955) estimates the ratio of these velocities as 1, 2 and other authors as 1, 1 (Carstens et al., 1969).

To evaluate the critical velocities for different phases of motion, the relations of the following type are often used:

$$u = K \sqrt{gd} \quad (1)$$

where  $\bar{d}$  is the mean diameter of bed-sediment particles,  $g$  is gravitational acceleration and  $K$  is a constant with some dependence on  $\bar{d}$ . There is a great variety of similar formulae. Beugner (1980) alone gives a selection of 50 equations of this type.

All the criteria for the existence of wave induced ripples differ from similar formulae for progressive flow only in that the maximum value of nearfloor orbital velocity was taken into account rather than the near-floor current velocity. However, some authors (Dingler, 1979; Komar, Miller, 1975; Vongvisessomjai, 1984 and others) indicate that to describe the behaviour of bed particles properly, specific features of the hydrodynamic regimes of various flow types should be considered, the influence of wave period ( $\bar{T}$ ) first of all.

Oscillating water masses affect the erodible floor most visibly when the nearfloor velocity ( $u$ ) becomes maximal. The shorter the surface wave period, the longer the duration of the action of  $u$  during a storm. Moreover, the thickness of the nearfloor boundary layer of

the wave flow is proportional to the square root of the wave period. Thus, waves with shorter periods create favourable conditions for the initiation of sediment motion.

Among the criteria for the initiation of the ripples formation accounting for  $T$  influence, the most common is the empirical equation of P.Komar and M.Miller (1975). It links sediment mobility parameter  $F$  with a ratio of nearbottom orbital diameter  $d_o$  to the sediment particle diameter  $\bar{d}$

$$F_b = b \sqrt{d_o / \bar{d}} \quad (2)$$

where  $F = \frac{\rho u_m}{(\rho_s - \rho) g d}$ ;  $d_o = u_m T / \pi$ ;  $\rho_s$  and  $\rho$  are densities of solid particles and liquid, respectively. To calculate the beginning of ripple formation, the authors propose using a value of the dimensionless coefficient  $b = 0.11$ ; a value of  $b = 0.21$  is used to estimate the initiation of movement of developed ripples.

In some other papers the conditions for the ripple formation are given by the sediment mobility parameter  $F$ :

$$F_b = 3 \quad (\text{Brebner, 1980}) \quad (3)$$

$$F_b = 0.89 (d_o / \bar{d})^{1/3} \quad (\text{Vongvisessomjai, 1984}) \quad (4)$$

$$F_b = 0.033 (d_o / \bar{d})^{2/3} \quad (\text{Kos'yan, 1988}) \quad (5)$$

$$F_b = 0.04 (d_o / \bar{d})^{2/3} \left( \frac{g \bar{d}^3 (\rho_s - \rho)}{\nu^2 \rho} \right) \quad (\text{Dingler, 1979}) \quad (6)$$

where  $\nu$  is a kinematic viscosity coefficient.

The upper limit of ripple existence is controlled by the upper smooth phase of sediment movement when bedforms are obliterated and suspended sediment transport becomes very intensive. According to laboratory tests of Carstens Carstens and others (Carstens et al., 1969), ripples are disappearing when

$$d_o / \bar{d} = 34000 \quad (7)$$

while S.Kennedy and M.Falcon (1965) on the basis of analysis of D.Inman in-situ measurements data (Inman, 1957) got the value:

$$d_o / \bar{d} = 16000 \quad (8)$$

J.Dingler defined the upper limit of ripple existence by mobility factor as:

$$F_c = 240 \tag{9}$$

Having analysed the effect of wave period,

S.Vongvisessomjai (1984) obtained:

$$F_c = 12.7(d_o/\bar{d})^{1/3} \tag{10}$$

In the Kos'yan's paper it was obtained:

$$F_c = 0.54(d_o/\bar{d})^{2/3} \tag{11}$$

The equations (2) - (11) describe the peculiarities of ripple formation more completely than the equation (1) does. But in some cases such limitations may be wrong, as at constant  $U_m$  and  $T$  values, the nature of the bed sediment motion can vary considerably due to artificial damping or increasing of nearbottom turbulence of floor roughness.

The value of the bed tangential stress ( $\tau$ ) takes turbulence and floor roughness into account so it seems logical to use this parameter to characterize the specific interaction between moving water masses and sediment.

The conditions for ripple existence can be determined, for example, by Shield's parameter value ( $\Psi$ ). This parameter expresses the relationship between maximum nearbottom shearing force and the force resisting the wave movement:

$$\Psi = \frac{\tau \bar{d}^2}{(\rho_s - \rho) g \bar{d}^3} = \frac{0.5 f_\tau \rho U_m^2}{(\rho_s - \rho) g \bar{d}} = 0.5 f_\tau F \tag{12}$$

where  $f_\tau$  is a wave friction factor.

According to Nielsen, Shield's parameter, describing the existence of wave ripples varies:

$$\text{from } \Psi_b = 0.04 \quad \text{to} \quad \Psi_c = 1.0 \tag{13}$$

There are another expressions using Shield's parameter for the determination of the upper limit of ripple existence in wave flow:

$$\Psi_c = 4.4 (U_m \bar{d} / \nu)^{-1/3} \quad (\text{Komar, Miller, 1975}) \tag{14}$$

$$\Psi_c = 0.5 - 0.6 \quad (\text{Horikawa et al., 1982}) \tag{15}$$

To verify the criteria for conditions of wave ripple existence and to deduce our own one we used our own laboratory tests and field observations results and those available from literature.

Variation ranges of laboratory test characteristics (Antsyferov et al., 1977; Keremetchiev, private report; Manohar, 1955; Miller, Komar, 1980b; Nielsen, 1979) is given in table 1.

Variation ranges of field observation parameters (Inman, 1957; Kos'yan, 1988; Miller, Komar, 1980a; Nielsen, 1984; Tanner, 1971) are summarized in table 2.

In all the tests the fact of ripple existence under certain parameters of surface waves and of solid particles and liquid characteristics was noted. For all this, the ripple characteristics and forms were not taken into account. In Manohar's experiments (Manohar, 1955) some measurements were made in the moments of ripple disappearance.

V. Tanner (1974) carried out sea works under low waves, when the maximal nearbottom velocities were wittingly less than the shifting ones. In this case only passive ripples were observed, therefore sea data obtained by V. Tanner were not used in this paper. Only his observations in lakes were used. The selection of experimental data obtained by M. Miller and P. Komar (1980a) was made according to their recommendations.

Amplitudes of nearbottom orbital velocities during ripple observations were calculated using the Airy wave theory, when analyzing the data of sea investigations the values of significant (calculated from the height of mean from one third of the largest waves of a group) orbital velocities were taken into account. According to existing estimates (Kos'yan, 1985; Miller, Komar, 1980a; Nielsen, 1981) parameters of these particular waves determine the nature of sediment movement, when waves are irregular. Using these parameters one may

compare the results of field works with laboratory tests data, obtained under monochromatical waves.

Equations (1) - (15) limiting the area of wave ripple existence were verified by experimental data. The results of some verifications were published earlier in the works of Kos'yan, 1978; Kos'yan, Pykhov, 1991. Figures 1 - 3 show the typical examples of such verified comparisons of measured and calculated values.

On the basis of accomplished comparisons we can make some conclusions:

1. Various boundary conditions of ripple existence differ greatly from each other, which might result, possibly, from the fact that each author, while deducing his own equation, used a relatively small number of data on ripple observation.

2. The results of verifications show that such criteria as equations (2), (4), (6), (8), (10), (14), (15) are not fulfilled as a great number of test points lie beyond the limits of ripple existence.

3. Almost all of the observation results remain in the range of equations (1), (3), (7), (9), (13). But overwhelming majority of test points lie far from the curves described by these equations. Therefore these criteria may be used only for a rough evaluation of the conditions for ripple formation and flattening.

4. All experimental points, corresponding to the conditions for ripple existence on any coordinate systems occupy the surface contoured on the every side, while the given criteria contour it partially only on one side.

Combining criteria of all authors which give satisfactory results when being compared with field observation data, one can get a range of conditions for ripple existence. In this case this range will be described by the systems of equations which roughly contours the

field of points from every side (Kos'yan, Pykhov, 1991).

Let's try to express conditions for ripple existence by the single equation which contours the entire observation field as close as possible.

Universal conditions for bottom form existence accounting for the influence of both the wave period and roughness of bottom may be obtained in the coordinate system of  $\Psi$ ,  $d_0/\bar{d}$ . Best of all the whole field of experimental points is contoured by the ellipsis equation with the following parameters:

$$\frac{(-5.80 + 0.88 \ln d_0/\bar{d} + 0.47 \ln G)^2}{8.41} + \frac{(5 - 0.47 \ln d_0/\bar{d} + 0.88 \ln G)^2}{1.69} = 1 \quad (16)$$

This expression may be simplified and reduced to typical square equation.

In fig. 4 one can see a comparison of experimental data with those calculated by the formula (16). Here the curve (16) contours the absolute majority of test points ( $\sim 98,8\%$ ) very closely from every side. Besides the curve (16) shows a good agreement with results obtained by Manohar for ripple flattening.

Should new results of ripple observations appears, some correction of eqn. (16) parameters determining the dimensions of the ellipsis and its incline to coordinate axes will become possible. But we believe that such a correction will be insignificant.

## CHAPTER 168

### SUPERTANK LABORATORY DATA COLLECTION PROJECT

Nicholas C. Kraus<sup>1</sup>, Jane McKee Smith<sup>2</sup>, Charles K. Sollitt<sup>3</sup>

**ABSTRACT:** In the summer of 1991, a multi-institutional cooperative laboratory data collection project called SUPERTANK was conducted to investigate cross-shore hydrodynamic and sediment transport processes using the large wave channel located at Oregon State University, Corvallis, Oregon. The channel is 104 m long, 3.7 m wide, and 4.6 m deep, into which a 76-m long sandy beach was emplaced. SUPERTANK is believed to be the most densely and comprehensively instrumented nearshore processes data collection project performed in the laboratory or the field. At the peak of data collection, the channel was instrumented with 16 resistance wave gages, 10 capacitance wave gages, 18 two-component electromagnetic current meters, 34 optical backscatter sensors (OBS), 10 pore-pressure gages, 3 acoustic sediment concentration profilers, 1 acoustic-Doppler current profiler, 1 four-ring acoustic benthic stress gage, 1 laser Doppler velocimeter, 5 video cameras, and 2 underwater video cameras. Broad- and narrow-band random waves and monochromatic waves were run with zero-moment wave heights in the range of 0.2 to 1.0 m and with peak spectral periods in the range of 3 to 10 sec. The wave generator absorbed waves at the peak spectral frequency that were reflected from the beach and structures such as dunes and seawalls. Twenty major data collection runs were made, most defined as starting from a new beach profile, and approximately 350 profile surveys were taken to record beach response during the 129 hr of wave action. This paper gives an overview of the SUPERTANK project and presents example results.

#### INTRODUCTION

The design of beaches to protect against storm erosion, flooding, and wave attack requires quantitative prediction of cross-shore hydrodynamics, sediment transport, and beach profile change. Large wave tanks (LWT) capable of producing waves and beach profile change without scale effects provide an inexpensive means, as compared with field data collection, to obtain data for developing mathematical models of cross-shore processes and to investigate fundamental hydrodynamic and sediment-transport processes under controlled conditions.

---

(1) Senior Scientist, and (2) Research Hydraulic Engineer, USAE Waterways Experiment Station, Coastal Engineering Research Center, 3909 Halls Ferry Road, Vicksburg, MS, 39180-6199, USA; (3) Professor and Director, O. H. Hinsdale Wave Research Laboratory, Department of Civil Engineering, Oregon State University, Corvallis, OR, 97331-2302, USA

A limited number of LWT experiments on beach change have been performed (e.g., Kajima et al. 1982, Vellinga 1986, Dette and Uliczka 1987) since the pioneering study of Saville (1956) and related U.S. Army Corps of Engineers tests (Kraus and Larson 1988), but none has taken advantage of the full range of modern instrumentation to capture the breadth of processes acting across the profile.

In support of numerical model development activities for predicting storm-induced beach erosion (Larson and Kraus 1989), in May 1987 the Coastal Engineering Research Center (CERC) at the U.S. Army Engineer Waterways Experiment Station began planning of a LWT data collection project that was called SUPERTANK. As planning progressed, it was realized that the offshore region would provide an ideal environment for hydrodynamics (waves and currents) and sediment transport measurements by researchers concerned with movement of dredged sediment placed seaward of the surf zone. Thus, one unique characteristic of SUPERTANK was utilization of the entire length of the beach in the LWT channel, extending from near the wave generator through the surf zone to the limit of runup.

This paper presents an overview of the SUPERTANK Laboratory Data Collection Project. Project planning and the major test series are described, and example results are given from the hydrodynamics and beach profile measurements.

## PROJECT PLANNING

SUPERTANK was conducted as a multi-institutional effort similar to cooperative field data collection projects first performed in the 1970s, for example, the Nearshore Sediment Transport Study (NSTS) in the United States (Seymour and Duane 1978), the Nearshore Environment Research Center (NERC) project in Japan (Horikawa and Hattori 1987), and U.S. Army Corps of Engineers-sponsored projects such as DUCK85 (Mason, Birkemeier, and Howd 1987) and SUPERDUCK (Birkemeier et al. 1989). Cooperative efforts that pool expertise, instrumentation, and a wide range of research interests have led to advances unattainable by a single or small group of investigators. The advantages of cooperative research were readily carried over to the LWT environment of SUPERTANK.

Pre-project planning was led by a 6-person steering committee formed of CERC and non-CERC members initially divided in the three basic subject areas of (1) hydrodynamics, (2) sediment transport, and (3) beach profile change, including beach and structure interaction. During the course of periodic planning meetings, steering committee members and principal investigators formed into three operational groups as (1) total-channel hydrodynamics and sediment transport, (2) foreshore and beach profile change, including swash zone hydrodynamics, and (3) instrument tests and measurements made offshore that centered around acoustic instruments and a laser-Doppler velocimeter.

Participants joining CERC at SUPERTANK came from the Florida Institute of Technology, Naval Postgraduate School, North Carolina State University, Ohio State University, Oregon State University, QUEST Integrated, Inc., RD Flow, Inc., Seatech, Inc., U.S. Naval Academy, University of California at Santa Cruz, University of Delaware, University of Florida, and University of Washington. Observers came from the Danish Hydraulics Institute (Denmark), Delft Hydraulics Laboratory (The Netherlands), and one investigator from Nihon University (Japan) actively participated. U.S. Army Corps of Engineers field office personnel and undergraduate and graduate students from various institutions around the U.S. assisted SUPERTANK investigators in data collection.

## PROCEDURE

### Planning

SUPERTANK was conducted using the LWT located at the O.H. Hinsdale Wave Research Laboratory (WRL), Oregon State University. This LWT has the largest wave channel in the United States in which a sandy beach can be emplaced. SUPERTANK subsequently ran for the 8-week period from July 29 to September 19, 1991. With the first and last weeks dedicated to mobilization and demobilization, data were collected over the six weeks from August 5 through September 13. Two 1-week tests of instruments were conducted six months and 1 month before the start of SUPERTANK. These valuable shakedown exercises were one reason that full-scale data collection proceeded without major problems and virtually no instrument down time.

The daily work schedule was 12 hours of wave action and associated activities from Monday through Thursday and 8 hours on Friday, starting from a daily meeting of principal investigators at 7 am. Plans for the day were reviewed and optimized at the morning meetings and in the evenings, for which data taken that day, particularly the beach profile change data, were inspected. Evenings and weekends were spent in major mechanical operations of beach profile reconstruction, emplacement and removal of dunes and seawalls, and inspection and moving of instruments, for which the tank was drained. For example, changes in wave conditions from higher to lower waves required shoreward translation of large numbers of instruments to optimize measurement coverage in the vicinity of the breaker zone and in the surf zone.

Previous LWT projects (and most small-scale laboratory experiments) on beach profile change typically initiated all tests from the same uniform slope in a test series, which required substantial sand transfer and profile regrading with heavy equipment. In the case of SUPERTANK, where a large number of researchers were on site and an even larger number of instruments were mounted in the tank, extensive regrading of the profile, with the associated delays, was not economically feasible or compatible with investigators' schedules. Execution of the pre-planned test series was modified and redirected as necessary through observation of the data (almost all data sets could be inspected during collection or shortly thereafter) and discussion by investigators participating in the particular test.

### Channel, Equipment, and Operating Procedures

The channel of the LWT at the WRL is 104 m long, 3.7 m wide, and 4.6 m deep, into which a 76-m-long beach was constructed for the SUPERTANK project. Fig. 1 shows the interior of the WRL enclosure, and Fig. 2 is a view of the LWT during an instrument change. The beach was composed of approximately 600 cu m of uniform-size quartz sand of 0.22-mm median diameter. The direct, digital controlled servo-hydraulic wave generator was equipped to absorb waves at the peak spectral frequency that were reflected from the beach and structures, such as dunes and seawalls. Broad- and narrow-band random waves and monochromatic waves were run with zero-moment wave heights in the range of 0.2 to 1.0 m and with peak spectral periods in the range of 3 to 10 sec. Waves were run in "bursts" of typically 10, 20, 40, and 70-min duration to enable profile surveys to be made in calm conditions, to adjust instruments and measure elevation changes at the Optical Backscatter (OBS) sensors, and to suppress tank seiching.

Fig. 1. Wide-area view of LWT channel and control room during SUPERTANK

SUPERTANK is believed to be the most densely and comprehensively instrumented nearshore processes data collection project conducted in the laboratory or field. At the peak of data collection activities, the LWT channel was instrumented with 16 resistance wave gages, 10 capacitance wave gages, 18 two-component electromagnetic current meters, 34 OBS sensors, 10 pore-pressure gages, 3 acoustic sediment concentration profilers, 1 acoustic-Doppler current profiler, 1 four-ring acoustic benthic stress gage, 1 laser-Doppler velocimeter, 5 video cameras, and 2 underwater video cameras. The resistance wave gages, capacitance wave gages, and electromagnetic current meters formed the core of SUPERTANK data collection and were maintained throughout the project. Synchronous sampling by separate data acquisitions systems was accomplished by digital input of WWV time code to all computer clocks.

### CORE MEASUREMENTS

Core measurements constitute data collection fundamental to all investigators. The core measurements consist of wave and current data collection and beach profile surveys. CERC investigators were responsible for these measurements.

### Hydrodynamics

Wave transformation was measured with 16 resistance wave gages mounted on the west channel wall (right side of LWT in Fig. 2), spaced 3.7 m apart. The array of resistance gages extended from near the wave generator to a water depth of approximately 0.5 m. An array of 10 capacitance wave gages extended from the most shoreward resistance gage to the maximum runup limit. These gages were also mounted from the west channel wall, but they were mobile with spacing that varied from 0.6 to 1.8 m. In addition to measuring wave

Fig. 2. Close-up view of LWT with SUPERTANK instrumentation

transformation, the capacitance gages also measured runup and the elevation of the sand surface at gages that were intermittently submerged (Fig. 3). Fourteen Marsh-McBirney electromagnetic current meters were mounted on the east channel wall together with arrays of OBS (Fig. 4). The current meters were deployed in vertical arrays of 1 to 4 sensors with vertical spacing of approximately 0.3 m, designed to quantify the undertow profile. Each array was configured to share a timing pulse (close-proximity option) to reduce electronic interference. The meters were deployed in depths of 0.3 to 1.8 m, with selection of sensor position based on the wave conditions, water level, and bottom profile. An additional 4 electromagnetic current meters, 5 OBS, and 1 capacitance wave gage were deployed on a roving carriage (Fig. 5). The current meters were arranged in a vertical array (0.3-m spacing) off an adjustable wing extending beneath the carriage. The carriage was positioned prior to each test to locate the wave gage, current meters, and OBS sensors in the incipient breaking zone, adjacent to a wall-mounted current meter array (for finer vertical resolution), or some other point of interest. Three video cameras, mounted on a scaffold overlooking the surf zone, recorded a continuous image of surf-zone wave transformation, swash, and runup. Ten pressure gages were buried in the sand beach to measure pore pressure.

Portions of the hydrodynamic data were analyzed (spectra and time series) during or immediately after the tests for quality control and planning of subsequent tests. The instrumentation performed extremely well during the project. Instrument noise and cross-talk problems were identified and eliminated prior to the main project in shakedown tests. The wave gages were calibrated once a week during the project by raising and lowering the water level. Wave gage offsets were recorded at the beginning of each test. The current meters were calibrated before and after the project.

Fig. 3. Capacitance bed surface and water surface gages on the foreshore

Fig. 4. Vertical arrays of current meters and optical backscatter sensors

Fig. 5. Roving instrument carriage fully configured at SUPERTANK

The SUPERTANK wave conditions were designed to balance the need for repetition of wave conditions to move the beach profile toward equilibrium and development of a variety of conditions for hydrodynamics studies. The TMA spectral shape, applicable to finite water depths (Bouws et al. 1985), was used to design all random-wave tests, with spectral width parameter  $\gamma$  between 1 (broad-banded) and 100 (narrow-banded). Other parameters that controlled the hydrodynamics, such as water level, bottom profile shape, and shoreward boundary (seawall, dune, and terrace), also varied between tests, changing the nearshore hydrodynamics for the same imposed offshore wave conditions. Low-frequency wave energy (frequencies lying below that of the incident band) did not increase with increasing run length as might be expected due to build-up of channel seiching.

A three-day series of tests conducted during the third week was dedicated to hydrodynamics. These tests included time-varying wave conditions, varying spectral width, and bimodal spectra. The hydrodynamic data will be used to develop and verify advanced hydrodynamic models (vertical current structure, wave breaking, transformation of bimodal spectra, wave setup, and nonlinear wave transformation), as well as support modeling of beach profile change and sediment transport.

### **Beach Profile Change**

Approximately 350 full-length surveys were performed to record the response of the beach profile to wave action and to changes in shoreward boundary conditions, such as emplacement of a seawall. Surveys were made with an auto-tracking infra-red geodimeter, which targeted a prism attached to a survey rod mounted on a carriage that was pushed along the channel by two persons. The survey rod, which could move freely in a sleeve with guide

rollers, made contact with the bed via a pair of wide-tread wheels. Typically, 15 minutes were required to set up equipment and survey the profile with a nominal spacing of 0.3 m, but with much finer resolution over features such as dunes, steps, and bars which had large across-shore gradients in elevation. At the start and end of a major test, the profile was surveyed along the center line of the channel and on lines located 0.9 m from each of the channel walls to assess uniformity of the profile across the channel width. Three-line surveys also were occasionally made when cross-tank flow was observed or suspected. In between wave bursts, surveys were made only along the center line.

Observation of the profile rod wheels indicated a nominal penetration depth of a few millimeters, depending on sediment compaction; this depth would tend to cancel in quantitative comparison of differences between profile surveys. Survey measurements were recorded to the nearest 3 mm in horizontal distance and elevation. Performance of the profiling system was evaluated by conducting 10 consecutive profile surveys in which the four survey crew members rotated in and out of the operation. The 10 unedited profile surveys and the standard deviation in profile elevation are plotted in Fig. 6. The standard deviation is typically less than 0.5 cm. The large deviation in one area offshore was caused by rod operator error in one survey and is easily detected in the data file and corrected.

Fig. 6. Plots and standard deviation of ten consecutive beach profile surveys

Although not strictly part of the core measurements, OBS and fluorescent sand tracer measurements were supported by CERC and conducted by Drs. Reginald Beach and Paul Komar of Oregon State University. The fluorescent sand tracer experiments required sampling by SCUBA-equipped divers, and divers also measured and adjusted, as necessary, the bed-referenced elevations of OBS and other sensors at the end of each wave burst. The tracer experiments measured dispersion of sand in the offshore, as a comparison to transport

rates obtained with the OBS, and recorded macro-scale movement and layering of sand in regions of rapid morphologic change, such as in areas of bar formation and dune erosion.

### Test Series

The 20 major data collection tests performed are listed in Table 1. Wave conditions designed to produce erosion or accretion were selected through use of predictive criteria described by Kraus, Larson, and Kriebel (1991). Several tests had objectives separate from monitoring evolution of the beach profile, such as dedicated hydrodynamic, suspended sediment, and instrument tests that examined local fluid and sediment transport conditions. Representative wave conditions are listed in Table 1. For tests involving random waves, the wave height is the significant (zero-moment) height, and the period is the peak spectral period. Sixty-six different wave conditions were run for a total of 129 hr of wave excitation; 70 percent of the wave conditions involved random waves.

Test Number	Description	Date	Representative Significant Wave	
			Height m	Period sec
ST_10	Erosion toward equilibrium, random waves	8/05 – 8/09	0.8	3.0
ST_20	Acoustic profiler tests (random; monochromatic)	8/11 – 8/13	0.2-0.8	8.0-3.0
ST_30	Accretion toward equilibrium, random waves	8/14 – 8/16	0.4	8.0
ST_40	Dedicated hydrodynamics	8/19 – 8/21	0.2-0.8	8.0-3.0
ST_50	Dune erosion, Test 1 of 2	8/22 – 8/22	0.5-0.8	6.0-3.0

## EXAMPLE RESULTS

In this section we present example results from Test ST\_10 (Table 1), the first and longest test (21 hr of wave action) of SUPERTANK. This test was conducted to observe beach response to erosive random waves together with the associated hydrodynamics and sediment transport. Selected results illustrate beach profile response to random and monochromatic waves, and wave transformation and vertical structure of the mean cross-shore current.

### Profile Change

The beach was configured as a planar foreshore joining to the subaqueous portion formed in a concave shape as  $h = Ax^{2/3}$ , where  $h$  is still-water depth and  $x$  is horizontal distance from the shoreline. Several wave conditions were imposed, starting from an 8-sec, 0.8-m zero-moment wave for the first 400 min of wave action ( $\gamma = 20$  for first 270 min, followed by runs with  $\gamma = 3.3$  or 20), 70 min of monochromatic 3-sec, 0.8-m waves, and 80 min of 3-sec, 0.8-m waves, after which the period was increased to 4.5 sec and water level lowered by 0.15 m to move the bar and to increase runup for promoting change in the foreshore.

Fig. 7 shows beach profile evolution in ST\_10 starting from the initial profile for selected times of 60, 290, 470, and 820 min of wave action. For clarity, the profile was truncated seaward of the bar at a depth of 3 m. After 60 min, the foreshore had already eroded and a break-point bar had formed. By 290 min, the foreshore had eroded considerably, and a gradually sloping terrace formed that led to a trough followed by a substantial bar; this beach configuration did not change appreciably under another 110 min of similar wave action. However, 70 min of monochromatic waves produced a sharply defined and asymmetric larger bar. After that, the longer period (4.5-sec, 8-m) random waves produced a berm while maintaining the terrace that joined with a subdued trough followed by a small bar and more round and symmetric larger bar located farther offshore.

### Hydrodynamics

Beach profile change is driven by such hydrodynamic processes as decay of breaking wave height, vertical profile of the cross-shore current, setup, and long-period swash energy. Figs. 8 and 9 respectively summarize selected hydrodynamic measurements of erosional random waves in the first 20 min and after 550 min of wave action in Test ST\_10 (20-min and 40-min averages, respectively). The decay of the maximum wave height  $H_{\max}$  and statistical significant (average of highest one-third waves) wave height  $H_s$  from the resistance wave gages are shown in the upper half of the figures. The direction and magnitude of the mean cross-shore current measured at various locations is represented with arrows. Wave breaking on the initial profile occurs primarily at the most shoreward resistance gage and further shoreward. The cross-shore current seaward of the surf zone is directed offshore and is weak. After 550 min of wave action, Fig. 9, the wave height envelope shows steep decay over the prominent bar, and the current structure has strong offshore flows in the surf zone and particularly over the bar, with weaker offshore-directed flow seaward of the bar. The bottom half of the figures show the proportioning of wave energy, plotted as wave height, between incident (high pass) and low frequencies. The energy was segregated by using a low-pass filter with a cutoff at half the peak frequency. In both Figs. 8 and 9, the high-pass or incident-band wave height decreases through breaking, whereas the low-pass wave height tends to increase.

Fig. 7. Selected profile surveys for Test ST\_10

Wave transformation across shore includes not only linear shoaling and wave breaking, but also nonlinear energy transfer to frequencies higher and lower than the peak frequency. Figs. 10 and 11 are measured wave spectra at three cross-shore locations (most seaward gage, a gage in the active surf zone, and the most shoreward gage) for a narrow-band ( $\gamma = 20.0$ ) and a broad-band ( $\gamma = 3.3$ ) incident spectrum, respectively. The narrower spectrum displays clear first and second harmonics of the peak frequency at the shallower measurement locations. The broader spectrum possesses a small peak at the first harmonic and small general increase in energy at higher frequencies. Both cases show an order of magnitude increase in low-frequency energy at shallower depths, similar to what is observed in the field.

## SUMMARY AND FUTURE ACTIVITIES

SUPERTANK succeeded as a cooperative multi-institutional data collection project in which investigators shared resources and expertise toward achieving common goals. Advancements in engineering tools, such as improvement of numerical models of beach change and wave transformation through the surf zone, as well as improved understanding of basic sediment transport and bottom boundary layer processes, are already emerging from the project.

Although data collection has been completed, reduction and analysis of the enormous (multi-gigabyte) data set is still in progress. Significant effort has been dedicated to organize and clean the data sets so that they may be accessed by all researchers, including those who did not participate in SUPERTANK. The first year after SUPERTANK has been devoted to reduction of all major data sets -- converting quantities to engineering units and cleaning and organizing the data. The following two years will include data exchange among SUPERTANK investigators and data analysis. In September, 1994, three years after SUPERTANK was performed, the data will be made available to the public.

## ACKNOWLEDGEMENTS

SUPERTANK succeeded through the efforts of numerous individuals who assisted over several years in planning, instrument testing, mobilization, execution of the project, and subsequent demobilization. The tireless efforts and professionalism of the investigators will be forever engraved in the huge, high-quality data set they created for coastal engineering. Drs. William R. Dally, David L. Kriebel, and William G. McDougal were SUPERTANK Steering Committee members together with the authors. We thank Mr. Jesse Pfeiffer, Headquarters, U.S. Army Corps of Engineers, for assisting in the difficult contracting process, and Messrs. Terry Dibble, William Hollings, and David Standley of the Wave Research Laboratory and Mr. William Grogg of the Coastal Engineering Research Center for electronic, mechanical, and computer support. Permission was granted by the Chief of Engineers to publish this information.

## CHAPTER 169

# A FIELD EXPERIMENT ON THE FORMATION OF BEACH CUSPS

Michio Sato\*    Keiji Kuroki†    Tomoaki Shinohara‡

### Abstract

This paper describes an attempt at investigating the actual time scale needed to form beach cusps, and the issue whether beach cusps are accretionary features or erosional ones. Data was collected through a field experiment. The experiment was conducted by tracking the process of beach cusp formation on a beach face, which had been flattened in advance by erasing previously formed beach cusps with a bulldozer. New beach cusps gradually developed with every high tide and attained a similar size to the previous ones after three tides.

### INTRODUCTION

Beach cusps have been concerns of many researchers. Main interests seem to have been directed to the aspects on the basic origin and what control their rhythmic spacing. However, in spite of numerous contributions on the subject, contradictory observational results and views in many aspects of beach cusp formation have prevented us from grasping beach cusps in their totality.

It seemed to us that to accumulate measured field data on cusp formation, especially the one which relates the cusp origin to wave conditions, was indispensable. In conducting field measurement, care must be taken to the point whether the waves being measured are the ones which are actually building the cusps or not, as has been pointed out by Johnson (1919). In other words, we should know about the actual time scale needed to form beach cusps.

Smaller cusps are known to be built and eliminated in a relatively short time; in one tide cycle at most (e.g. Longuet-Higgins and Parkin (1962); Komar (1973)). However, the time seemed too short for the formation of beach cusps with spacings of 15 to 20m which the authors sometimes saw. Then, a field experiment was planned to investigate this point.

The purpose of this paper is to describe the attempt at investigating the actual time scale needed to form beach cusps, and the issue whether beach cusps are depositional features or erosional ones.

## FIELD EXPERIMENT

**LOCATION OF STUDY** The experiment was carried out from 18 to 21 December, 1980 at Motte Beach, Kagoshima Prefecture, Japan (Figure 1). The beach is a part of sandy beach which extends 8.2km north-north west from the foot of Mt. Kaimon-dake and is exposed to the action of waves from the East China Sea.

Figure 2 shows the cross sectional profile of the center of study area. The beach face had steep slope of over 1/10 and a terrace of 20m wide followed. Beach material was well sorted sand with the median diameter of 0.7mm and the sorting coefficient, introduced by Trask, of 1.29 on average.

**PRELIMINARY SURVEY** The spacing of the beach cusps previously formed was measured over the 500m beach area and was 15.2m on average. The variation of the measured cusp spacing and cusp height along the beach are shown in figure 3. The cusp spacing ranged between 7m to 26m and the histogram is shown as well in the figure.

Though the spacing is widely distributed, the variation of it along the shore seems to have a definite tendency that the spacing increased with the alongshore distance from 100m to 400m, then, decreased abruptly due to the appearance of a small cusp in the middle of pairs of cusps and their growth to the size which determines the spacing. The similar variation seemed to repeat along the beach.

Therefore, our impression was that the broad distribution of cusp spacings in the histogram did not mean the lack of regularity in the spacing of cusps but it was due to the alongshore variation in the cusp spacing controlled by a certain mechanism. Nishi and Sato (1991) pointed out that one unit of the spacing variation corresponded to the spacing of a giant cusp based on the photographs taken from the top of Mt. Kaimon-dake for six years period.

The variation of the height seemed to increase slightly with the increase of cusp spacing.

The experimental site was the center of the measured area.

**FIELD CONDITIONS DURING THE EXPERIMENT** During the experiment, tides were semidiurnal with maximum range of 2.7m, and waves of about 0.5m in significant wave height with periods of 6.5-8.5sec acted on the beach continually (Figure 4). The maximum breaking wave height was about 1m. The change of wave height during the experiment was small though the period changed in the range from 6.5sec to 8.5sec. Wave incidence was almost

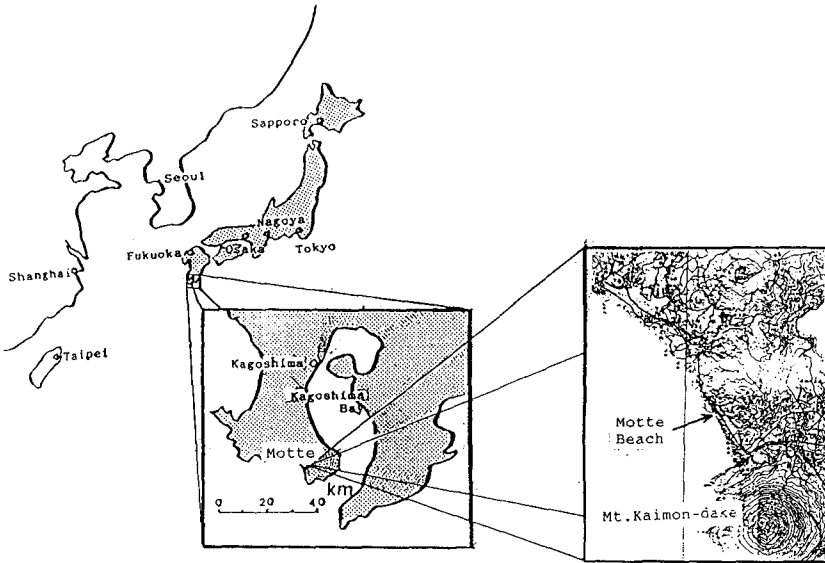

Figure 1: Location of study area

Figure 5: Contour maps of original cusp and topography just after the bulldozing

normal to the beach. North wind of 4 to 7m/sec blew on December 19 and 20, but it almost ceased on the following day.

**ORIGINAL CUSP** Prior to the experiment, the area of both the beach cusp field and the foreshore zone, in a 60m alongshore section, was surveyed at the grid points. The alongshore increment was 4m and the on-offshore one was 1.5m. Elevation of each grid point was accurately measured using a precision level. Figure 5-(a) shows the survey of original beach cusps. Contours were drawn every 0.1m. Cross sectional profile along a line AB parallel to the shoreline is shown in figure 10. We can recognize 3 cusps in this area.

**EXPERIMENTAL METHOD** On the following day, the alongshore area of over 100m including the surveyed part was flattened by a bulldozer during

low tide(Figure 6). Figure 5-(b) is the contour map just after being flattened. Three cusps in figure 5-(a) were completely erased.

After that 168 iron rods, 2m in length, were driven into the beach face at intervals of 4m parallel to the shoreline, and at 2m intervals perpendicular to the shoreline. This made a grid system of 52m  $\times$  22m shown in figure 7.

Repeated levelings of the beach face were carried out every low tide by measuring the amount of the rod exposed. And, in the day time, the subsidence of the iron rods was checked with a level.

Waves were measured with 12 capacitance type wave gauges during every high tide. Eight of the wave gauges were arranged parallel to the shoreline, and the rest were arranged perpendicular to it. The arrangements are shown in figure 7 and figure 2.

In order to track sediment movement, tracer technique was applied by using dyed sand with fluorescent color as the tracer. Two 30 liter buckets of dried sand were dyed red and green, respectively. At 5:30pm December 20, 1980, they were placed on the beachface; red sand at grid point(4,4) and green sand at(9,9) in figure 7. Sampling of about 300 gram of beach materials was done at the grid points at 1:00pm and 10:30pm December 21, 1980. All samples were dried and examined for fluorescent coated particles using ultra-violet lamp. The centroids of the distribution maps of dyed sands were tracked by

$$x = \frac{\sum_{i=1}^n m_i x_i \Delta x \Delta y}{\sum_{i=1}^n m_i \Delta x \Delta y}, \quad y = \frac{\sum_{i=1}^n m_i y_i \Delta x \Delta y}{\sum_{i=1}^n m_i \Delta x \Delta y}$$

where  $(x, y)$  is the position of the centroid,  $\Delta x$  and  $\Delta y$  denote the grid intervals,  $(x_i, y_i)$  is the distance between the origin(i.e. the place where the tracer was deposited initially) and  $i$ -th grid point, and  $m_i$  is the number of fluorescent coated sand particles found per 1,000cm<sup>2</sup>.

## RESULTS

The development of beach cusps after bulldozing can be seen in a series of contour maps(Figures 8). Contours were drawn every 0.1m as well as in figure 5. Figures 9-(a,b,c) show the difference in height between the beach profile just after bulldozing and those after each high tide. Shading in the figures mean eroded part.

In Figure 8-(a), the contour map drawn based on the survey after one high tide from the bulldozing, we can not recognize any cusps. After two high tides, three cusps with a similar spacing to the original ones appeared on almost the same position(figure 8-(b)). And after three high tides they finally attained a similar size to the original cusp formation(figure 8-(c)).

Figures 10-(a,b) are the cross sectional profile along a line A-B parallel to the shoreline of the flattened beach face just after bulldozing and in the course of the development, respectively.

Figure 6: Bulldozing

9 •

Figure 7: Grid system and arrangement of wave gauges

Figure 8: Development of cusps(contour maps)

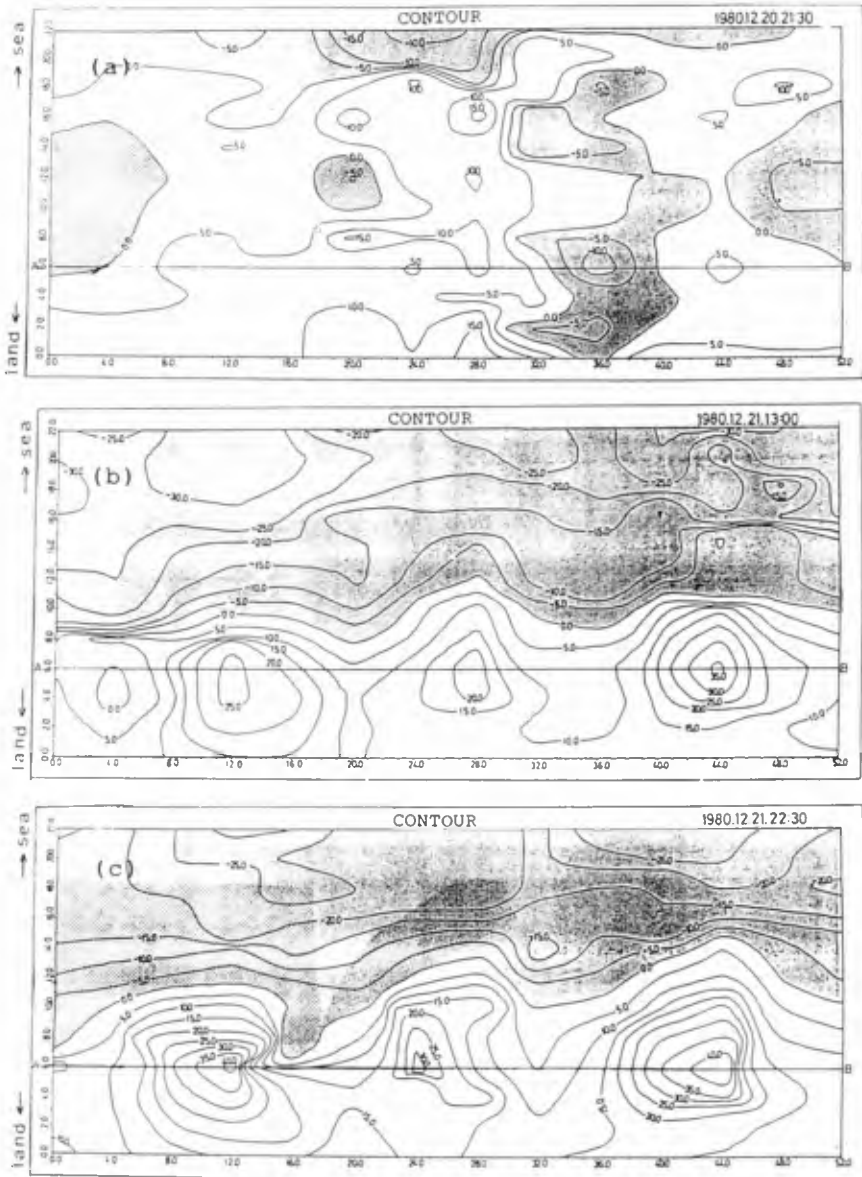

Figure 9: Development of cusps(topographical changes from the flattend contour map)

Figure 10: Cross sectional change along the line parallel to the shoreline

It can be seen from these figures that new beach cusps gradually developed. This gradual development was in contrast to the observation of smaller cusp formation (e.g. Longuet-Higgins and Parkin (1962); Komar (1973)). Figures 9-(b) and (c) indicate that sand carried landward from the lower foreshore zone accumulated even in the bay position of the newly formed beach cusps. This is backed up by the trace of dyed sand shown by arrows in figure 8-(c). Thus, beach cusps are purely accretionary features with the horns experiencing more deposition than the bays.

Samples of beach materials were analysed with sieves. Median grain size and sorting coefficient of each sample were obtained. The median diameters ranged from 0.5mm to 1.1mm and the average was 0.7mm as shown in figure 11. In this figure,  $\Delta h$  is the difference in height between the profile just after being flattened and the one after three high tides. Negative  $\Delta h$  corresponds to the lower foreshore part, and larger positive  $\Delta h$  means cusp horns. This figure shows that the sediments of lower foreshore were coarser than cusp area, it also

Figure 11: Sediment grain size

shows the median diameters of sediments of cusp horns were slightly larger than the ones of bays.

As to the sorting coefficients, they ranged from 1.14 to 1.8 and the average was 1.29. In lower foreshore area, the sorting coefficients showed larger values; but they were smaller and in cusp and bay field compared to the lower foreshore.

These results add support to the description by King (1972), Williams (1973) and Komar (1973).

Lastly, it may be worth to note about the variation of the density of beach materials in cusp field. When we were pulling out the iron rods from the beach, we found that the rods in cusp area were easily pulled out, but those in bay area were hard to be pulled out and some of them needed two or three persons to be removed. No one realized the difference when we drove the rods into the beach. This seemed to mean that the sediments in bay area became

dense and the ones in cusp area became loose as the cusps developed. The difference of the density of sediments between bay area and cusp area causes the difference of permeability. The difference of permeability has been pointed out by many authors. And the reason has been considered to be the difference in composition of beach materials(Longuet-Higgins and Parkin(1962)). However,even if there is not definite difference in composition of beach materials between cusps and bays,the difference of density,which is due to the difference of compaction,seems to be a reason of the difference in permeability.

## CONCLUSION

A field experiment was conducted by tracking the process of beach cusp formation on a beach face, which had been flattened in advance by erasing previously formed beach cusps with a bulldozer. New beach cusps gradually developed with every high tide and attained a similar size to the previous ones after three tides.

Sand carried landward from the lower foreshore zone accumulated even in the bay position of the newly formed beach cusps. This is backed up by the trace of dyed sand.Thus,beach cusps are purely accretionary features with the horns experiencing more deposition than the bays.

The sediments of lower foreshore were coarser than cusp area,and the median diameters of sediments of cusp horns were slightly larger than the ones of bays.

The sorting coefficients ranged from 1.14 to 1.8 and the average was 1.29. In lower foreshore area,the sorting coefficients showed larger values;but they were smaller in cusp and bay field compared to the lower foreshore.

## CHAPTER 170

### DYNAMICS OF LONGSHORE BARS

Magnus Larson<sup>1</sup> and Nicholas C. Kraus<sup>2</sup>

**ABSTRACT:** This paper presents empirical predictive expressions describing the cross-shore movement of linear nearshore bars, based on intensive analysis of survey data from Duck, North Carolina. The analysis centers on 300 beach profile surveys taken at approximately 2-week intervals for the continuous period from 1981 to 1989, together with accurate measurements of the wave conditions. The geometry and dynamics of bars derived from the surveys are related to wave characteristics, and criteria previously developed by the authors to predict beach erosion and accretion are found to be applicable to bar movement if a multiplicative empirical coefficient in each criterion is modified. The results indicate that onshore movement of bars is more probable than previously estimated. The implication is that linear bars formed of dredged material are more likely to move onshore to nourish the surf zone and beach than previously thought.

#### INTRODUCTION

The beach is a dynamic system that resists inundation and erosion by storage of material on the foreshore and dune complex and by storage of sand in the offshore in longshore bars. Bars also reduce erosive energy entering the surf zone by breaking the higher incident waves. Sediment moves between the shore face and bars according to the wave and water level conditions, grain size of the beach material, and other factors. During storms, characterized by higher waves and water levels, sediment moves from the beach face and, possibly, dunes to form bars, whereas under lower waves bars tend to lose volume and move onshore to resupply the surf zone and beach. Sediment also moves alongshore in a direction mainly controlled by the angle of the incident waves. In the present study, only cross-shore sediment transport processes are considered.

---

1) Assistant Professor, Department of Water Resources Engineering, Institute of Technology, University of Lund, Box 118, S-221 00 Lund, Sweden.

2) Senior Scientist, U.S. Army Engineer Waterways Experiment Station, Coastal Engineering Research Center, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199.

In recognition of the positive effects of bars for promoting beach growth and protecting beaches, nourishment projects have been performed to construct bars or "nearshore berms" from dredged material with the intent of the placed bars to either serve as a wave break and/or to supply or "feed" the beach with material (McLellan 1990, McLellan and Kraus 1991). Engineering motivation for the present study is the need for quantitative criteria for predicting the movement of material placed to serve as an active or feeder berm. In order to derive such criteria, extensive analysis of field data on the characteristics and movement of natural sand bars was carried out, as described further in Larson and Kraus (1992).

In this study, the dynamics of longshore bars were determined from field data and related to the prevailing waves. Depth to bar crest, maximum bar height, bar volume, location of bar center of mass, and time dependencies of these quantities, as well as speed of bar movement, were calculated for a large number of profile surveys made on fixed lines at Duck, North Carolina, at the Field Research Facility (FRF) operated by the Coastal Engineering Research Center (CERC), U.S. Army Engineer Waterways Experiment Station.

The analysis procedures adopted rely on two assumptions; first, the profile change admitted to this study must be dominated by cross-shore transport, meaning that longshore homogeneity exists, and, second, short-period incident waves are the direct and dominant sediment-transport driving mechanism. Engineering studies have long recognized the appearance of three-dimensional patterns in beach morphology in the surf zone (Homma and Sonu 1962). Intensive high-resolution beach profile surveys (Howd and Birkemeier 1987) and inference of morphology through long-term remote sensing (Lippman and Holman 1990) at the FRF indicate that bars tend to become linear (two-dimensional) during storms and rhythmic (three-dimensional) 5 to 16 days following the peaks of storms. Care was taken in the present study to identify potential occurrences of three-dimensionality, mainly through comparison of shapes of the profiles at different survey lines and through censoring of the data by imposing threshold values to consider only larger change. Although incident waves may be one contributing mechanism to the mean flow, other forcing mechanisms such as the tide and wind-generated currents also enter in the total mean flow. Thus, during times of mild wave conditions in particular, correlations between bar movement and incident waves, such as sought in the present study, may be weak and should be viewed with caution.

## DATA EMPLOYED

Beach profile data collected at the FRF were analyzed to provide information on the spatial and temporal properties of natural longshore bars located in the nearshore (depth less than 15 m). The beach profile was surveyed at a nominal 2-week interval along four shore-normal lines from 1981 to 1989, where each survey extended from a base line behind the dune out to a water depth of about 9 m. All depths in this paper are referenced to the National Geodetic Vertical Datum (NGVD), which lies 6.7 cm below mean sea level at the FRF. The locations of the four profile lines, numbered 58, 62, 188, and 190, are given in Howd and Birkemeier (1987). Typically, between 20 to 50 distance-elevation pairs were recorded in each survey, and the total number of surveys during the studied period varied between 250 and 300, depending on the profile line. The surveys were usually carried out to a water depth exceeding the depth of profile closure (Birkemeier 1985). The profiles were surveyed using the Coastal Research Amphibious Buggy (CRAB), which has an accuracy in elevation on the order of 5 cm.

The wave data used in this study were taken by a waverider buoy located in 18-m water depth seaward of the FRF research pier. Wave height was obtained as energy-based significant wave height calculated as four times the standard deviation for a 20-min water level record. The wave period was determined as the period corresponding to the peak in the energy spectrum. Wave height and period were typically recorded every 6 hr but more frequently during the end of the 9-year observation period, for which hourly values are available. The influence of water level was not included in this study, because its period of variation was significantly shorter than the time elapsed between surveys, and the variation in most cases was almost symmetrical about the mean value.

## BASIC PROPERTIES OF PROFILE CHANGE

### Profile Shape

The average profile was computed for each line from all surveys for the period 1981 to 1989. Because individual survey points were taken at varying distances from the baseline, (linear) interpolation was employed between measured points to derive the average profile. Also, maximum and minimum depths recorded at any point were determined across shore together with the standard deviation of elevation. These quantities indicate the profile variability during the measurement period and the areas along the profile where the most active sand transport occurred. Fig. 1 displays the average profile and the aforementioned quantities for Line 62, for which the largest number of surveys exists (in total 300).

Fig. 1. Average profile and profile variability for Line 62

Average profiles of the four survey lines were similar, having a steep foreshore joining a gently sloping profile at a small distance seaward of the shoreline. Because longshore bars are usually present at the FRF, the average profiles are influenced by these features, and the computed average profiles have two regions where the beach gradient is not monotonically

decreasing, related to the inner and outer bars commonly observed at the FRF. The inner bar in shallower water closer to shore is almost constantly exposed to breaking waves, whereas waves break at distances from the shoreline out to about 400 m (depth between 4 and 5 m) for all survey lines, representing the region of most active sand transport.

The average profile was compared to theoretical equilibrium profile shapes. The modified equilibrium profile equation employed in this study is (Larson 1991),

$$h = A \left[ x - x_s + \frac{1}{\lambda} \left( \frac{D_o}{D_\infty} - 1 \right) \left( 1 - e^{-\lambda[x - x_s]} \right) \right]^{2/3} \quad (1)$$

where  $h$  is depth,  $A$  is a shape parameter,  $x$  is distance from the baseline,  $x_s$  is the location of the shoreline from the baseline,  $D_o$  and  $D_\infty$  are, respectively, the equilibrium wave energy dissipation per unit water volume in the inshore and offshore, and  $\lambda$  is a characteristic (decay) length at which  $D_o$  approaches  $D_\infty$ . The term containing the factor  $1/\lambda$  augments the original equilibrium profile equation  $h = A(x - x_s)^{2/3}$  derived by Dean (1977) and describes a trend of decreasing grain size with distance offshore. The equilibrium profile equation of Dean was least-square fitted to the average profile, determining the optimum value of the shape parameter as  $0.09 \text{ m}^{1/3}$ , with root-mean square error in deviation in depth of  $\Delta h_{\text{rms}} = 0.20 \text{ m}$ . The corresponding median grain size is  $0.20 \text{ mm}$  according to an empirical curve given by Moore (1982).

In the offshore, agreement between the Dean equilibrium profile and average profiles is satisfactory (Fig. 2); however, close to the shoreline the original equilibrium profile equation provided a poor fit, because the average profile is considerably steeper in this region. The larger beach gradient at the shoreline owes to the coarser grain size found near the shoreline. The typical median grain size on the foreshore at the FRF is  $1.0 \text{ mm}$ , whereas the grain size in the offshore region of the profile approaches  $0.1 \text{ mm}$  (Howd and Birkemeier 1987). The trial and error best-fit of eq. 1 used the previous shape parameter and  $D_o/D_\infty = 3.3$  and  $\lambda = 0.039 \text{ m}^{-1}$ , with  $\Delta h_{\text{rms}} = 0.15 \text{ m}$ . The modified equilibrium profile equation well accounted for fining of sediment across the profile and achieved a better overall description of the average or equilibrium shape of the profile.

### Definition of bars

In order to describe and quantify bar formation and movement, a consistent definition of a bar feature is needed. Previous investigations involving laboratory profiles have defined bars with reference to the initial profile (Larson and Kraus 1989). Areas along the subaqueous part of the profile where material accumulates with respect to the initial profile were defined as bars. Crossings between a specific profile and the initial profile defined the beginning and the end of the bar. However, in the field, such a definition is not operational due to the absence of an unambiguous "initial profile," and thus a different method must be employed. In the present study, several methods were tested for defining bars, and, after evaluation, the modified equilibrium profile equation was found to give the most reliable reference profile for definition of a bar and was employed in the following analysis. As an example of how bars were defined, Fig. 3 illustrates a surveyed profile at Line 62 together with the modified equilibrium profile least-square fitted to the 9-year average profile.

Fig. 2. Average profile at Line 62, equilibrium, and modified equilibrium profiles

Fig. 3. Definition of longshore bar extent using the modified equilibrium profile equation (hatched areas represent bars)

### Volumetric Profile Change and Contour Movement

To determine and characterize the long-term beach evolution at the FRF, the time-variation in subaerial sand volume above selected elevation contours was calculated. Over the 9-year interval encompassed by the data set, the subaerial portion of the beach at the FRF displayed a slight trend of accretion, especially at Line 62, indicated primarily by a long-term increase in the sand volume above NGVD. Strong seasonal variations, including those attributed to large storms, were superimposed on this trend, with the subaerial sand volume mainly lying below the average value during the first half of the measurement period, and above it during the second half. Fig. 4 displays the variation in the volume of sand above NGVD as a function of time for Line 62. Time is given in consecutive days starting at 810101, and the sand volume is referenced to the average volume,  $104 \text{ m}^3/\text{m}$ , above NGVD from a point located 66 m seaward of the FRF baseline. The 66-m location was the minimal distance seaward common to all profile surveys.

Analysis of volumetric profile change and contour movement showed that the FRF beach accreted somewhat above NGVD for the measurement period, but no long-term change in the subaqueous portion of the beach was detected. Survey lines located north of the FRF research pier (Lines 58 and 62) experienced slightly more accretion than those south of the pier (Lines 188 and 190). The increase in subaerial sand volume is probably due to sand transport by wind. A stable subaqueous beach profile indicates no long-term differential in the longshore sand transport or no significant loss of material to the offshore. Thus, the profile data from the FRF provides a good basis for analysis of natural longshore bar properties because the data set is, on the average, not strongly influenced by a longshore bias. However, short-term longshore variations could still influence profile evolution, and identification of possible times of longshore nonuniformity required tedious visual inspection of the plotted profile surveys.

### BAR PROPERTIES

Because the four profile survey lines displayed similar long-term behavior, analysis of bar properties was focussed on survey Line 62. The largest number of surveys (300) was available for Line 62, and this line was judged to exhibit the most representative bar response. Each profile survey was visually examined for bar features, and shoreward and seaward boundaries of the bar were determined from the crossings between a profile and the modified equilibrium profile. The following properties were calculated for every identified bar from each profile survey:  $V_b$  = bar volume,  $l_b$  = bar length,  $h_c$  = minimum bar depth,  $z_m$  = maximum bar height,  $x_{cg}$  = location of bar center of mass, and  $\Delta x_{cg}/\Delta t$  = speed of bar movement, where  $t$  = time. Fig. 5 schematically illustrates these bar properties for a typical profile survey from the FRF data set (inner bar shown).

#### Inner Bar

Short-term variability in bar properties was considerably greater for the inner bar because it was frequently located in the breaker zone, experiencing significant sand transport and influence of beach change on a shorter time scale than the outer bar. A distinct inner bar was identified in 200 of 300 surveys, and statistical quantities were computed for bar properties (Table 1). Disappearance of the inner bar was primarily due to welding to shore or to offshore movement until the inner bar became or merged with the outer bar. Thus,

minimum and maximum values in Table 1 depend on determination of when the inner bar welded on to the shore or joined with the outer bar as it moved offshore, respectively.

Fig. 4. Temporal variation in subaerial sand volume above NGVD at Line 62

Fig. 5. Definition sketch of bar properties calculated for each survey

Property	Mean	Minimum	Maximum	$Q_{25}^*$	$Q_{75}^*$
Depth to crest, m	1.6	0.6	2.5	1.3	1.9
Bar height, m	0.9	0.2	1.4	0.7	1.0
Bar volume, m <sup>3</sup> /m	42	6	98	27	55
Bar length, m	95	35	280	65	100
Bar mass center, m	215	150	330	195	230

\*  $Q_{25}$  and  $Q_{75}$  denote limits for which 25 % and 75 % of the values are below, respectively.

The average depth to bar crest was 1.6 m, implying a mean breaking wave height of about 2 m, as estimated from an empirical expression given by Larson and Kraus (1989). Bars in large wave tank (LWT) experiments with monochromatic waves (Larson and Kraus 1989) display marked similarities with the inner bar, although bars in the field tend to be smoother due to shifting of forcing under random waves and varying water level. Thus, inner bar volume is similar to that found in LWT experiments, whereas maximum bar height is considerably lower in the field. Fig. 6 illustrates volume of the inner bar with time, in which time periods when no bar existed have been left blank. Change in bar volume was used to derive a time scale for the inner bar by the fractal box-counting method (Larson and Kraus 1992). A break point occurs in the box-counting curve for a box size of about 60 days, which is interpreted as the typical duration between events that move the inner bar offshore.

### Outer Bar

A distinct outer bar was identified for 221 profile surveys, and statistical quantities were computed for the bar properties (Table 2). During extended periods of low waves, the outer bar moved slightly onshore simultaneously with flattening, to finally disappear. The outer bar disappeared as an identifiable morphological feature by flattening before it moved a significant distance onshore. In comparison with the geometric properties of the inner bar, variability of the outer bar is significantly smaller. This is because once the outer bar has formed, it is only exposed to wave breaking and large sand transport during severe storms, and transport induced by non-breaking waves produces less rapid change in bar properties.

Property	Mean	Minimum	Maximum	$Q_{25}^*$	$Q_{75}^*$
Depth to crest, m	3.8	1.3	5.1	3.4	4.1
Bar height, m	0.4	0	1.4	0.27	0.6
Bar volume, m <sup>3</sup> /m	45	0	120	20	67
Bar length, m	170	25	280	150	200
Bar mass center, m	410	200	520	390	440

\*  $Q_{25}$  and  $Q_{75}$  denote limits for which 25 % and 75 % of the values are below, respectively.

Fig. 6. Volume of inner bar as a function of time

Fig. 7. Volume of outer bar as a function of time

The average depth to bar crest of the outer bar was 3.8 m, which indicates the presence of individual breaking waves with heights on the order of 4 to 5 m associated with modifications of the outer bar. Volume of the outer bar is shown in Fig. 7 as a function of time, displaying regular, long-term variations, where the bar grows rapidly to maximum size after which it decreases in volume at a lower rate until it flattens completely. Comparison of Figs. 6 and 7 illustrates the different time scales in responses of the inner and outer bar to wave forcing in the nearshore. Box-counting analysis of change in outer bar volume produced a break point in the box-counting curve corresponding to 120 days. Thus, the inner bar moves offshore at least every second month, whereas about four months at most separate wave events that move the outer bar seaward.

### Bar Speed

The speed of bar movement was determined for the inner and outer bar as the distance  $\Delta x_{cg}$  the bar center of mass moved between two consecutive surveys divided by the time  $\Delta t$  between the surveys. However, because bar movement may be rapid, particularly during storms (Sallenger, Holman, and Birkemeier 1985, Sunamura and Maruyama 1987, Larson and Kraus 1989), values obtained underestimate bar speed through the assumption that the movement is constant during the time between surveys. A storm with a typical time scale of days that moves a bar offshore would produce rapid bar movement not apparent in the calculation if surveying is done with a longer time interval. If the bar is located outside the region of breaking waves, however, profile change is more gradual under non-breaking waves, and the estimated bar speed should be more accurate.

Onshore and offshore bar movement were analyzed separately, and the inner (outer) bar moved onshore on 99 (122) and offshore on 92 (90) occasions. The average speed of onshore bar movement was 1.5 (0.6) m/day and the maximum onshore bar speed was 8.7 (6.1) m/day for the inner (outer) bar. Corresponding values for offshore bar movement were an average speed of 2.9 (1.1) m/day and a maximum speed of 18.0 (15.2) m/day. The outer bar exhibited considerably lower average speeds than the inner bar, both for onshore and offshore movement, whereas the maximum values were comparable. The average bar speed for the outer bar was approximately one third that of the inner bar. Because the inner bar is more frequently subjected to breaking waves than the outer bar, the average speed of movement is greater for the inner bar. However, if waves broke on the outer bar, the speed of movement was comparable to that of the inner bar, as shown by the similar maximum bar speed for the inner and outer bar.

### RELATIONSHIP BETWEEN BAR AND WAVE PROPERTIES

The average significant wave height for the entire measurement period was 1.1 m, and the average peak spectral wave period was 8.4 sec based on 29,098 individual recordings. Measurements of the incident wave angle were not available for the full 9-year observation period, and in the simultaneous analysis of bar and wave properties the influence of this variable was not quantified. Deep-water wave quantities were calculated from linear-wave theory including shoaling and omitting refraction. Wave quantities were determined from the time period preceding a specific profile survey, and averages were formed for the full record starting from the previous survey.
