# Coastal Engineering 1992

## Proceedings of the twenty-third international conference

October 4-9, 1992  
Venice, Italy

Conference held under the auspices of the  
Coastal Engineering Research Council of the  
American Society of Civil Engineers

Organized by the Ministry of Public Works and by  
Consiglio Nazionale delle Ricerche (CNR) with support of  
Veneto Region and of Venice local Government and  
co-sponsored by the International Association for  
Hydraulic Research (IAHR), by the Permanent International  
Association of Navigation Congresses (PIANC) and by the  
Associazione di Ingegneria Offshore e Marina (AIOM).

Edited by Billy L. Edge

Published by the  
American Society of Civil Engineers  
345 East 47th Street  
New York, New York 10017-2398

## ABSTRACT

This proceedings contains over 260 papers presented at the 23rd International Conference on Coastal Engineering which was held in Venice, Italy, October 4-9, 1992. The book is divided into seven parts: 1) Characteristics of waves and currents; 2) long waves and storm surges; 3) coastal structures; 4) the Italian coast; 5) coastal processes and sediment transport; 6) coastal, estuarine and environmental problems; and 7) case studies. The individual papers include such topics as the effects of wind, waves, storms and currents as well as the study of sedimentation and beach nourishment. Special emphasis is given to case studies of completed engineering projects. With the inclusion of both theoretical and practical information, these papers provide the civil engineer and related fields with a broad range of information on coastal engineering.

## FOREWORD

The Twenty-third International Conference on Coastal Engineering was a truly successful Conference. Its success was marked by the culmination of extensive planning and coordination. More than 678 abstracts were submitted for consideration, but only 321 could be accepted for presentation at the Conference. Moreover, owing to mechanical requirements of the printing process to keep the *Proceedings* in three volumes, papers were limited in pages and some contributions which should have been included could not be accepted for the final publication.

The Twenty-third Conference also marked a major milestone in the continuous contribution of Professor Robert L. Wiegel to the organization and conduct of these conferences; at this Conference he announced his retirement from the leadership of the Council. For forty-two years he has been directly involved with every conference since the first conference was held in Long Beach, California. He served as Vice-Chairman of the Council on Wave Research of the Engineering Foundation in the early years of the Conference and later as Chairman of the Coastal Engineering Research Council of the American Society of Civil Engineers. Because of his long and dedicated service and leadership of the coastal engineering community, the Council voted to dedicate the *Proceedings* of the Twenty-third Conference to Professor Robert L. Wiegel.

### *Robert L. Wiegel*

Professor Wiegel is Professor Emeritus of the Department of Civil Engineering of the University of California at Berkeley. He graduated from the University of California at Berkeley in 1943 with a degree in Mechanical Engineering. After serving in the Second World War, he returned to Berkeley where he obtained a Master of Science degree. He stayed on at Berkeley as a Research Engineer and later a Lecturer in Mechanical Engineering until he became a Professor in the Department of Civil Engineering. He subsequently served as Director of the State's Technical Services Program and also as Acting Dean of the College of Engineering. Most of the readers of this volume know many of the 26 Doctoral students he supervised who have gone on to become leaders in this area or one of the many Masters students he prepared to work in the area of coastal engineering. His teaching, research and professional contributions at Berkeley are well known and respected by his peers around the world.

Professor Wiegel has been bestowed many honors and awards in recognition of his outstanding accomplishments. He received the Research Prize from the American Society of Civil Engineers in 1962 and in 1969 he was invited to give the General Lecture at the Symposium to Dedicate the Delft Hydraulics Laboratory Facilities. In 1975, he was elected Member of the National Academy of Engineering. He is currently an Honorary Member and Fellow of the American Society of Civil Engineers and holds an extensive record of service to the Society. In 1977 he was elected to Senior Queens Fellow in Marine Science, Aus-

tralia. He received the Moffatt-Nichol Harbor and Coastal Engineering Award and International Coastal Engineering Award in 1978 and 1985, respectively, from the American Society of Civil Engineers.

During his active professional career, he has served on many boards, panels and commissions of the State of California, the United States, the United Nations, NATO and many individual nations. He has lectured in most countries with coastal resources and problems and many countries without these resources. Professor Wiegel has also been a Visiting Professor to The Polish Academy of Sciences and the University of Cairo. He received the Outstanding Civilian Service Medal from the U.S. Army Corps of Engineers in 1985. Professor Wiegel was the General Chairman and organizer of the *Symposium to Honor Morrrough P. O'Brien: Working Solutions*, which was sponsored by the American Shore and Beach Preservation Association and the Coastal Engineering Research Council, the ASCE Waterway, Port, Coastal and Ocean Engineering Division and the University of California's College of Engineering.

Professor Wiegel has authored more than 125 publications and 100 technical reports on various phases of coastal and ocean engineering, including the famous text *Oceanographical Engineering* which was published in 1964. He is currently the editor for *Shore & Beach*, the Journal of the American Shore and Beach Preservation Association.

Needless to say, it is with pleasure that the writer is able to dedicate the *Proceedings* of the Twenty-third International Conference on Coastal Engineering to Professor Robert L. Wiegel.

Billy L. Edge, Secretary  
Coastal Engineering Research Council  
American Society of Civil Engineers

# ACKNOWLEDGMENTS

## COMMITTEE OF HONOR

The Patriarch of Venice  
The president of Regione Veneto  
The Mayor of Venice  
The Chief of Staff of the Italian Navy  
The President of Magistrato alle Acque  
The Alderman for Culture of Venice  
The Superintendent to the Harbor of Venice  
The President of Cini Foundation  
The President of CNR  
The Minister of Public Works

## LOCAL ORGANIZING COMMITTEE

### Chairman:

Ugo Tomasicchio, Ministry of Public Works

### Organizing Committee:

Giuseppe Matteotti, University of Padua  
Attilio Adami, University of Padua  
Edoardo Benassai, University of Naples  
Fabio Capocaccia, Genoa Port Authority  
Leonardo Sarti, National Assoc. of Civil Engineering Contractors  
Alberto Tomasin, CNR, University of Venice  
Alberto Lamberti, Secretary, University of Bologna

### Scientific Committee:

Enrico Marchi, University of Genoa  
Eco W. Bijker, Delft University of Technology  
Giampaolo Di Silvio, University of Padua  
Hans F. Burcharth, Aalborg University  
Alberto Noli, University of Rome

## COASTAL ENGINEERING RESEARCH COUNCIL (ASCE)

WELCOME ADDRESS.....	1
<i>Ugo Tomasicchio</i>	
COASTAL ENGINEERING IN VENICE.....	4
<i>Enrico Marchi</i>	
A DESCRIPTION OF THE “ACQUA ALTA” EVENT ON 5TH OCTOBER.....	3496
<i>Organizing Committee</i>	

## PART I

### CHARACTERISTICS OF COASTAL WAVES AND CURRENTS

Chapter 1	
BREAKING WAVES PROPAGATING OVER A SHOAL.....	42
<i>J. A. Battjes, S. Beji</i>	
Chapter 2	
TRANSFORMATION OF NONBREAKING WAVES OVER A BAR.....	51
<i>S. Beji, T. Ohyama, J. A. Battjes, K. Nadaoka</i>	
Chapter 3	
PRACTICAL COMPARATIVE PERFORMANCE SURVEY OF METHODS USED FOR ESTIMATING DIRECTIONAL WAVE SPECTRA FROM HEAVE-PITCH-ROLL DATA .....	62
<i>Michel Benoit</i>	
Chapter 4	
THE MODELLING OF SHORT WAVES IN SHALLOW WATERS: COMPARISON OF NUMERICAL MODELS BASED ON BOUSSINESQ AND SERRE EQUATIONS .....	76
<i>M. Brocchini, M. Drago, L. Iovenitti</i>	
Chapter 5	
COMPUTATION OF BREAKING WAVES WITH A PANEL METHOD.....	89
<i>Jan Broeze</i>	
Chapter 6	
BAR/TROUGH EFFECTS ON WAVE HEIGHT PROBABILITY DISTRIBUTIONS AND ENERGY LOSSES IN SURF ZONES .....	103
<i>Maolong Cai, David R. Basco, Joe Baumer</i>	

Chapter 7	
THE MEDITERRANEAN SEA WAVE FORECASTING SYSTEM.....	116
<i>Luigi Cavaleri, Luciana Bertotti</i>	
Chapter 8	
CURRENT-DEPTH REFRACTION AND DIFFRACTION MODEL FOR IRREGULAR WATER WAVES.....	129
<i>Jang W. Chae, Shin Taek Jeong</i>	
Chapter 9	
TRANSIENT PROPAGATION OF WAVES IN A FLUME.....	142
<i>Kwok F. Cheung, Michael Isaacson, Etienne Mansard</i>	
Chapter 10	
IRREGULAR WAVE TRANSFORMATION PROCESSES IN SURF AND SWASH ZONES .....	156
<i>Daniel T. Cox, Nobuhisa Kobayashi, Andojo Wurjanto</i>	
Chapter 11	
NUMERICAL MODELLING OF WAVES AND CURRENTS WITH REGARD TO COASTAL STRUCTURES.....	170
<i>M. Fischer, J. Juhl, E. B. Rasmussen</i>	
Chapter 12	
ON THE TESTING OF MODELS IN MULTIDIRECTIONAL SEAS.....	3454
<i>E.R. Funke, E.P.D. Mansard</i>	
Chapter 13	
THE INTERACTION OF DEEP-WATER GRAVITY WAVES AND A CURVED SHEARING CURRENT.....	184
<i>Marius Gerber</i>	
Chapter 14	
TRANSFORMATION OF WAVE CREST PATTERN IN SHOALING WATER .....	199
<i>Yoshimi Goda</i>	
Chapter 15	
PARTICLE IMAGE VELOCIMETRY (PIV) IN THE COASTAL ENGINEERING LABORATORY.....	212
<i>C.A. Greated, D. J. Skyner, T. Bruce</i>	
Chapter 16	
DIRECTIONAL NEARSHORE WAVE PROPAGATION OVER A RIP CHANNEL: AN EXPERIMENT.....	226
<i>Luc Hamm</i>	

Chapter 17	
WAVE SETUP ON BEACHES AND IN RIVER ENTRANCES .....	240
<i>David J. Hanslow, Peter Nielsen</i>	
Chapter 18	
CHARACTERISTICS OF A SOLITARY WAVE BREAKING CAUSED BY A SUBMERGED OBSTACLE .....	253
<i>Masanori Hara, Takashi Yasuda, Yukio Sakakibara</i>	
Chapter 19	
EIGHT YEARS WAVE HINDCAST AND ANALYSIS OF WAVE CLIMATE .....	267
<i>Yoshio Hatada, Masataka Yamaguchi</i>	
Chapter 20	
CHARACTERISTICS OF ABSORBING DIRECTIONAL WAVEMAKER.....	281
<i>H. Hirakuchi, R. Kajima, T. Shimizu, M. Ikeno</i>	
Chapter 21	
A NEW NEARSHORE DIRECTIONAL WAVE GAGE .....	295
<i>Gary L. Howell</i>	
Chapter 22	
ENERGY DISSIPATION AND AIR BUBBLES MIXING INSIDE SURF ZONE .....	308
<i>H.H. Hwung, J.M. Chyan, Y.C. Chung</i>	
Chapter 23	
INSTRUMENTAL EVALUATION OF THE DEEP WATER DIRECTIONAL WAVE CLIMATE ALONG THE MEDITERRANEAN COAST OF ISRAEL .....	322
<i>Ya. A. Iosilevskii, D.S. Rosen, A. Golik, D.L. Inman</i>	
Chapter 24	
VARIATION OF POTENTIAL AND KINETIC WAVE ENERGY IN THE SURF ZONE .....	336
<i>Koichiro Iwata, Takashi Tomita</i>	
Chapter 25	
MODELLING OF WAVE-CURRENT BOUNDARY LAYER IN THE COASTAL ZONE .....	350
<i>Leszek M. Kaczmarek, Rafal Ostrowski</i>	
Chapter 26	
SPECTRAL EVOLUTION OF DIRECTIONAL FINITE AMPLITUDE DISPERSIVE WAVES IN SHALLOW WATER .....	364
<i>James M. Kaihatu, James T. Kirby</i>	

Chapter 27	
AN ADDITIONAL PARAMETER FOR THE ZERO CROSSING WAVE DEFINITION AND ITS PROBABILITY DISTRIBUTION .....	378
<i>A. Kimura, T. Ohta</i>	
Chapter 28	
TIME-DEPENDENT SOLUTIONS OF THE MILD-SLOPE WAVE EQUATION .....	391
<i>James T. Kirby, Changhoon Lee, Chris Rasmussen</i>	
Chapter 29	
NON-LINEAR WAVE-CURRENT INTERACTIONS IN THE SWADE RESEARCH PROGRAM .....	405
<i>S. P. Kjeldsen, H. C. Graber</i>	
Chapter 30	
TIME-DEPENDENT MILD SLOPE EQUATION FOR RANDOM WAVES .....	419
<i>Yasuhiro Kubo, Yasuo Kotake, Masahiko Isobe, Akira Watanabe</i>	
Chapter 31	
EVALUATION OF NUMERICAL MODELS ON WAVE-CURRENT INTERACTIONS .....	432
<i>Jung L. Lee, Hsiang Wang</i>	
Chapter 32	
WAVE TRANSFORMATIONS OVER A SUBMERGED BAR: EXPERIMENTS AND THEORETICAL INTERPRETATIONS .....	447
<i>Gianfranco Liberatore, Marco Petti</i>	
Chapter 33	
NONLINEAR TRANSFORMATION OF IRREGULAR WAVES IN SHALLOW WATER .....	460
<i>Per A. Madsen, Ole R. Sorensen, Hemming A. Schaffer</i>	
Chapter 34	
NUMERICAL VALIDATION OF DIRECTIONAL WAVEMAKER THEORY WITH SIDEWALL REFLECTIONS .....	3468
<i>E.P.D. Mansard, M.D. Miles, R.A. Dalrymple</i>	
Chapter 35	
HYBRID FREQUENCY-DOMAIN KDV EQUATION FOR RANDOM WAVE TRANSFORMATION .....	474
<i>Hajime Mase, James T. Kirby</i>	
Chapter 36	
BREAKING OF IRREGULAR WAVES ON A SLOPE .....	488
<i>Masaru Mizuguchi</i>	

Chapter 37	
OSCILLATING WATER COLUMN MODELLING .....	502
<i>Iain G. Morrison, Clive A. Greated</i>	
Chapter 38	
NEW APPROACH FOR ESTIMATING THE SEVEREST SEA STATE FROM STATISTICAL DATA .....	512
<i>Michel K. Ochi</i>	
Chapter 39	
MODELING THE TRANSFORMATION OF NONLINEAR WAVES PASSING OVER A SUBMERGED DIKE .....	526
<i>Takumi Ohyama, Kazuo Nadaoka</i>	
Chapter 40	
PROBABILISTIC CALCULATION MODEL OF DIRECTIONAL RANDOM WAVES .....	540
<i>Wi-Gwang Pae, Hajime Mase, Tetsuo Sakai</i>	
Chapter 41	
DIRECTIONAL WAVE MEASUREMENTS IN RIO DE JANEIRO COAST .....	551
<i>C.E. Parente, C.P. Hanse, R.M. Sampaio, J.M. Lima, J.L.B. Carvalho</i>	
Chapter 42	
ON THE ATTENUATION OF WAVES PROPAGATING WITH A CURRENT.....	563
<i>Michio Sato</i>	
Chapter 43	
A TWO-DIMENSIONAL SURF ZONE MODEL BASED ON THE BOUSSINESQ EQUATIONS.....	576
<i>H.A. Schaffer, R. Deigaard, P. Madsen</i>	
Chapter 44	
FIELD VERIFICATION OF NUMERICAL MODELS FOR CALCULATION OF NEARSHORE WAVE FIELD .....	590
<i>Takuzo Shimizu, Akiyuki Ukai, Masahiko Isobe</i>	
Chapter 45	
BOTTOM SHEAR STRESSES IN THE BOUNDARY LAYES UNDER WAVES AND CURRENTS CROSSING AT RIGHT ANGLES .....	604
<i>Richard R. Simons, Tony J. Grass, Mehrdad Mansour-Tehrani</i>	

Chapter 46	
THE EFFECT OF SHEARED CURRENTS ON WAVE KINEMATICS AND SURFACE PARAMETERS .....	618
<i>D.J. Skyner, W.J. Easson</i>	
Chapter 47	
LABORATORY STUDY ON WAVE TRANSFORMATION ON BARRED BEACH PROFILES .....	630
<i>Ernest R. Smith, Nicholas C. Kraus</i>	
Chapter 48	
ESTIMATION OF IRREGULAR WAVE KINEMATICS FROM A MEASURED RECORD .....	644
<i>Rodney J. Sobey</i>	
Chapter 49	
ON SPECTRAL INSTABILITIES AND DEVELOPMENT OF NON-LINEARITIES IN PROPAGATING DEEP-WATER WAVE TRAINS .....	658
<i>C.T. Stansberg</i>	
Chapter 50	
INTERACTION OF NONLINEAR WAVE AND CURRENT .....	672
<i>S. Supharatid, H. Tanaka, N. Shuto</i>	
Chapter 51	
A STREAM FUNCTION SOLUTION FOR WAVES ON A STRONGLY SHEARED CURRENT .....	684
<i>Christopher Swan</i>	
Chapter 52	
WAVE, TURBULENT AND MEAN MOMENTUM FLUXES ACROSS THE BREAKING WAVE TRANSITION REGION IN THE SURF ZONE .....	698
<i>R. J. Thieke</i>	
Chapter 53	
EFFECTS OF THE GULF STREAM ON WIND WAVES IN SWADE.....	712
<i>Hendrik L. Tolman</i>	
Chapter 54	
AN IMPROVED ARRANGEMENT FOR THE PROGRESSIVE WAVE ABSORBER .....	726
<i>S.W. Twu, C.C. Liu</i>	
Chapter 55	
INTERRELATION OF CNOIDAL WAVE THEORIES .....	737
<i>Masataka Yamaguchi</i>	

Chapter 56  
**FREAK WAVES IN UNIDIRECTIONAL WAVE TRAINS AND  
THEIR PROPERTIES** .....751  
*Takashi Yasuda, Nobuhito Mori, Kazunori Ito*

Chapter 57  
**A METHOD FOR ESTIMATING REFLECTION COEFFICIENT IN  
SHORT-CRESTED RANDOM SEAS** .....765  
*Hiromune Yokoki, Masahiko Isobe, Akira Watanabe*

Chapter 58  
**ESTIMATING INCIDENT AND REFLECTED WAVE FIELDS  
USING AN ARBITRARY NUMBER OF WAVE GAUGES**.....777  
*J.A. Zelt, James E. Skjelbreia*

**PART II**

**LONG PERIOD WAVES, STORM SURGES AND WAVE GROUPS**

Chapter 59  
**LABORATORY TESTS ON THE INTERACTION BETWEEN  
NONLINEAR LONG WAVES & SUBMERGED BREAKWATERS**.....792  
*Marco Petti, Piero Ruol*

Chapter 60  
**FIELD OBSERVATION OF SURF BEATS OUTSIDE THE  
SURF ZONE** .....804  
*Tsunehiro Sekimoto, Takuzo Shimizu, Kosuke Kondo, Yasuhiro Kubo*

Chapter 61  
**LOW FREQUENCY WAVES IN THE SURF ZONE** .....818  
*Gary Watson, D. Howell Peregrine*

Chapter 62  
**LOW FREQUENCY WAVES IN INTERMEDIATE WATER DEPTHS** .....832  
*E.C. Bowers*

Chapter 63  
**INFRAGRAVITY-FREQUENCY (0.005–0.05 HZ) MOTIONS  
ON THE SHELF** .....846  
*T.H.C. Herbers, Steve Elgar, R.T. Guza, W.C. O'Reilly*

Chapter 64  
**BREAKPOINT-FORCED AND BOUND LONG WAVES IN THE  
NEARSHORE: A MODEL COMPARISON**.....860  
*Jeffrey H. List*

Chapter 65	
THE EFFECT OF WAVES ON SURGES IN THE NORTH SEA .....	874
<i>C. Mastenbroek</i>	
Chapter 66	
DISTRIBUTION OF UNDERTOW AND LONG-WAVE COMPONENT VELOCITY DUE TO RANDOM WAVES.....	883
<i>Akio Okayasu, Hiroyuki Katayama</i>	
Chapter 67	
OCCURRENCE DISTRIBUTION OF MAXIMUM WAVE HEIGHT INCLUDING WAVE GROUPING EFFECT.....	894
<i>Kosuke Kondo, Tsunehiro Sekimoto, Takuzo Shimizu, Sumio Imai</i>	
Chapter 68	
AN EXPERIMENT AT SEA ON MECHANICS OF THE WAVE GROUPS .....	907
<i>Paolo Boccotti, Giuseppe Barbaro, Lucio Mannino</i>	
Chapter 69	
WAVE GROUP MODULATIONS IN CROSS-SHORE BREAKING PATTERNS.....	918
<i>T.C. Lippmann, R.A. Holman</i>	
Chapter 70	
PROBABILISTIC STRUCTURE OF RANDOM WAVE GROUPS .....	932
<i>Ke Yu</i>	
Chapter 71	
STATISTICS OF WAVE GROUP PARAMETERS.....	946
<i>Gerbrant Ph van Vledder</i>	
Chapter 72	
VERIFICATION OF A ONE-DIMENSIONAL SURFBEAT MODEL AGAINST LABORATORY DATA .....	960
<i>J.A. Roelvink, H.A.H. Petit, J.K. Kostense</i>	
Chapter 73	
INCIDENT WAVE GROUPS AND LONG WAVES IN THE NEARSHORE ZONE .....	974
<i>Y. Foote, D. Huntley, M. Davidson, P. Russell, J. Hardisty, A. Cramp</i>	
Chapter 74

THE BREAKING AND RUN-UP OF SOLITARY WAVES ON BEACHES .....	1461
<i>Ashwini Otta, Ib A. Svendsen, S.T. Grilli</i>	
Chapter 113	
IMPACT LOADING AND DYNAMIC RESPONSE OF CAISSON BREAKWATERS—RESULTS OF LARGE-SCALE MODEL TESTS .....	1475
<i>H. Oumeraci, H.W. Partenscky, S. Kohlhase, P. Klammer</i>	

Chapter 114	
WAVE FORCES ON CROWN WALLS.....	1489
<i>Jan Pedersen, Hans F. Burcharth</i>	
Chapter 115	
OPTIMAL DESIGN OF RUBBLE MOUND STRUCTURES UNDER THE IRREGULAR WAVE .....	1503
<i>Cheong-Ro Ryu, Yoon-Koo Kang, Jong-Wook Kim</i>	
Chapter 116	
NUMERICAL SIMULATION OF NONLINEAR WAVE INTERACTING WITH PERMEABLE BREAKWATERS .....	1517
<i>T. Sakakiyama, R. Kajima</i>	
Chapter 117	
WAVES ON PERMEABLE LAYERS .....	1531
<i>Toru Sawaragi, Ichiro Deguchi</i>	
Chapter 118	
IMPACT LOADS INDUCED BY PLUNGING BREAKERS ON VERTICAL STRUCTURES.....	1545
<i>R. Schmidt, H. Oumeraci, H.-W. Partenscky</i>	
Chapter 119	
PROFILE CHANGES OF ROCK SLOPES BY IRREGULAR WAVES.....	1559
<i>W. G. Smith, Nobuhisa Kobayashi, Shuji Kaku</i>	
Chapter 120	
WAVE-INDUCED UPLIFT CHARACTERISTICS ON CONCRETE BLOCK SLOPE REVETMENTS .....	1573
<i>Uwe Sparboom, Wolf Debus</i>	
Chapter 121	
FIELD MEASUREMENTS ON PLACED BLOCK REVETMENTS.....	1587
<i>Theo Stoutjesdijk, Ben Rieger, Adam Bezuijen</i>	
Chapter 122	
NUMERICAL DETERMINATION OF WAVE INDUCED FLOW IN RUBBLE MOUND BREAKWATERS .....	1599
<i>Z. C. Sun, A. F. Williams, N.W.H. Allsop</i>	
Chapter 123	
CHARACTERISTICS OF WAVE DISSIPATION BY FLEXIBLE SUBMERGED BREAKWATER AND UTILITY OF THE DEVICE.....	1613
<i>Masahiro Tanaka, Takumi Ohyama, Tetsushi Kiyokawa, Takaaki Uda, Atsushi Omata</i>	

Chapter 124	
FIELD EXPERIMENTS ON A DUAL CYLINDRICAL CAISSON BREAKWATER .....	1625
<i>Katsutoshi Tanimoto, Hiroshi Endoh, Shigeo Takahashi</i>	
Chapter 125	
PRESSURE OSCILLATIONS DURING WAVE IMPACT ON VERTICAL WALLS.....	1639
<i>M.E. Topliss, M.J. Cooker, D.H. Peregrine</i>	
Chapter 126	
WATER PARTICLE VELOCITIES ON A BERM BREAKWATER.....	1651
<i>Alf Torum, Marcel van Gent</i>	
Chapter 127	
RUBBLE-MOUND BREAKWATER STABILITY: RESULTS OF IN-SITU MEASUREMENTS.....	1666
<i>L. Van Damme, J. De Rouck, D. Vermeir</i>	
Chapter 128	
A UNIVERSAL ANALYSIS FOR THE STABILITY OF BOTH LOW-CRESTED AND SUBMERGED BREAKWATERS.....	1679
<i>C. Vidal, M.A. Losada, R. Medina, E.P.D. Mansard, G. Gomez-Pina</i>	
Chapter 129	
THE MAINTENANCE OF HYDRAULIC STRUCTURES.....	1693
<i>J.K. Vrijling, H. Kuiper, R.E. Jorissen, H.E. Klatter</i>	
Chapter 130	
FINITE ELEMENT SIMULATION OF WAVE-INDUCED INTERNAL FLOW IN RUBBLE MOUND STRUCTURES .....	1706
<i>H. Wibbeler, H. Oumeraci</i>	
Chapter 131	
THE PERMEABILITY OF RUBBLE MOUND BREAKWATERS. NEW MEASUREMENTS AND NEW IDEAS.....	1720
<i>A.F. Williams, H.F. Burcharth, H. den Adel</i>	
Chapter 132	
NEW METHODS TO EVALUATE WAVE RUN-UP HEIGHT AND WAVE OVERTOPPING RATE .....	1734
<i>Yoshimichi Yamamoto, Kiyoshi Horikawa</i>	
Chapter 133	
USE AND BEHAVIOR OF GABIONS IN COASTAL PROTECTION.....	1748
<i>Kees d'Angremond, Egbert J.F. van den Berg, Jan H. de Jager</i>	

Chapter 134  
 WAVE RUNUP AND OVERTOPPING ON COASTAL STRUCTURES ...1758  
*J.P. de Waal,, J.W. van der Meer*

Chapter 135  
 NUMERICAL SIMULATION OF WAVE MOTION ON AND IN  
 COASTAL STRUCTURES .....1772  
*J.W. van der Meer, H.A.H. Petit, P. van den Bosch, G. Klopman,  
 R.D. Broekens*

Chapter 136  
 IMPACT BREAKING WAVE PRESSURES ON VERTICAL WALLS .....1785  
*Masataro Hattori, Atsusu Arami*

Chapter 137  
 NUMERICAL MODELLING OF THE STABILITY OF  
 RUBBLE BASES .....1799  
*Wojciech Sulisz*

**PART IV**  
**THE VENETIAN COAST**

Chapter 138  
 DEVELOPMENT OF THE VENICE MORPHOLOGICAL SYSTEM.....1812  
*P. Silva, A. Mol*

Chapter 139  
 ON THE CHAOTIC STRUCTURE OF TIDE ELEVATION IN  
 THE LAGOON OF VENICE.....1826  
*Giovanna Vittori*

Chapter 140  
 THE ITALIAN WAVES MEASUREMENT NETWORK .....1840  
*M. DeBoni, L. Cavaleri, A. Rusconi*

Chapter 141  
 EVALUATION OF DESIGN WAVES ALONG THE COAST AND  
 AT THE INLETS OF THE VENICE LAGOON.....1851  
*Paolo De Girolamo, Giancarlo Passacantando, David Hurdle,  
 Alberto Noli*

Chapter 142  
 EFFECTS OF NON-UNIFORM SEDIMENT GRAINSIZE IN THE  
 LONG-TERM EVOLUTION OF TIDAL LAGOONS .....1865  
*G. Di Silvio, P. Teatini*

Chapter 143  
MIXING PROCESSES IN A SHALLOW LAGOON.....1867  
*Jorg Imberger, G. Di Silvio*

Chapter 144  
WATER FLOW MODELLING OF THE VENICE LAGOON .....1869  
*Enrico Marchi, Attilio Adami, Alfredo Caielli, Giovanni Cecconi*

Chapter 145  
HYDRAULIC AND MATHEMATICAL MODELLING OF HISTORICAL  
AND MODERN SEAWALLS FOR THE DEFENCE OF  
VENICE LAGOON.....1879  
*Leopoldo Franco, Giuseppe R. Tomasicchio*

## **PART V**

### **COASTAL PROCESSES AND SEDIMENT TRANSPORT**

Chapter 146  
OBSERVATIONS OF GRANULAR-FLUID MIXTURE UNDER AN  
OSCILLATORY SHEET FLOW.....1896  
*Toshiyuki Asano*

Chapter 147  
FINE-SCALE MEASUREMENT OF SEDIMENT SUSPENSION BY  
BREAKING WAVES AT SUPERTANK .....1910  
*Stephen F. Barkaszi, Jr., William R. Dally*

Chapter 148  
STATISTICALLY SIGNIFICANT BEACH PROFILE CHANGE WITH  
AND WITHOUT THE PRESENCE OF SEAWALLS.....1924  
*David R. Basco, Douglas A. Bellomo, Cheryl Pollock*

Chapter 149  
PREDICTION OF TURBIDITY CURRENTS WITH BOUSSINESQ  
VISCOSITY AND SECOND-MOMENT CLOSURE MODELS.....1938  
*Bard Brors, Karl J. Eidsvik*

Chapter 150  
CROSS-SHORE TRANSPORT MODELLING IN TERMS OF  
SEDIMENT CONCENTRATIONS AND VELOCITIES.....1947  
*Zhiwen Chen*

Chapter 151  
EVOLUTION OF A BEACH WITH AND WITHOUT A SUBMERGED  
BREAKWATER: EXPERIMENTAL INVESTIGATION.....1959  
*G. Chiaia, L. Damiani, A. Petrillo*

Chapter 152  
EQUILIBRIUM BEACH PROFILES WITH RANDOM SEAS.....1973  
*Christopher G. Creed, Robert A. Dalrymple, David L. Kriebel,  
James M. Kaihatu*

Chapter 153  
AN OVERVIEW OF THE BRITISH BEACH AND NEARSHORE  
DYNAMICS (B-BAND) PROGRAMME.....1987  
*M.A. Davidson, P.E. Russell, D.A. Huntley, J. Hardisty, A. Cramp*

Chapter 154  
LONGSHORE BAR GENERATION MECHANISMS .....2001  
*Robert G. Dean, Rajesh Srinivas, Trimbak M. Parchure*

Chapter 155  
SHEET FLOW UNDER NONLINEAR WAVES AND CURRENTS .....2015  
*Mohammad Dibajnia, Akira Watanabe*

Chapter 156  
ASSESSMENT OF COASTAL PROCESSES FOR THE DESIGN  
AND THE CONSTRUCTION OF THE ZEEPIPE LANDFALL  
IN ZEEBRUGGE .....2029  
*A. Eide, B. Malherbe, M. Mercanti, B. Lahousse*

Chapter 157  
A FIELD EXPERIMENT ON A NOURISHED BEACH .....2043  
*A.J. Fernandez, G. Gomez-Pina, G. Cuenca, J.L. Ramirez*

Chapter 158  
THIRTY YEAR EROSION PROJECTIONS IN FLORIDA:  
PROJECT OVERVIEW AND STATUS .....2057  
*Emmett R. Foster*

Chapter 159  
GRAIN-SORTING OVER RIPPLES INDUCED BY SEA WAVES .....2071  
*Enrico Foti, Paolo Blondeaux*

Chapter 160  
OSCILLATORY BEDLOAD TRANSPORT STUDIES BY IMAGING  
OF TRACERS .....2084  
*E.L. Gallagher, R.J. Seymour*

Chapter 161  
WAVE-INDUCED POREWATER PRESSURE AND SEABED  
STABILITY .....2095  
*A. Hattori, T. Sakai, K. Hatanaka*

Chapter 162	
INTERCOMPARISON OF COASTAL PROFILE MODELS .....	2108
<i>Ida B. Hedegaard, J.A. Roelvink, H. Southgate, P. Pechon, J. Nicholson, L. Hamm</i>	
Chapter 163	
OSCILLATORY FLOW BEHAVIOR IN THE VICINITY OF RIPPLE MODELS .....	2122
<i>Kiyoshi Horikawa, Suguru Mizutani</i>	
Chapter 164	
BERM FORMATION AND BERM EROSION .....	2136
<i>Kazumasa Katoh, Shin-ichi Yanagishima</i>	
Chapter 165	
COUPLING OF A QUASI-3D MODEL FOR THE TRANSPORT WITH A QUASI-3D MODEL FOR THE WAVE INDUCED FLOW .....	2150
<i>Irene Katopodi, Nukos Kitou, Huib J. de Vriend</i>	
Chapter 166	
FIELD OBSERVATION ON SAND RIPPLES UNDER ROUGH SEA STATE .....	2164
<i>Yoshiaki Kawata, Toru Shirai, Yoshito Tsuchiya</i>	
Chapter 167	
ABOUT CONDITIONS FOR THE WAVE RIPPLE EXISTENCE .....	2176
<i>Ruben K. Kos'yan, Alexander d. Kochergin</i>	
Chapter 168	
SUPERTANK LABORATORY DATA COLLECTION PROJECT .....	2191
<i>Nicholas C. Kraus, Jane McKee Smith, Charles K. Sollitt</i>	
Chapter 169	
A FIELD EXPERIMENT ON THE FORMATION OF BEACH CUSPS .....	2205
<i>Michio Sato, Keiji Kuroki, Tomoaki Shinohara</i>	
Chapter 170	
DYNAMICS OF LONGSHORE BARS .....	2219
<i>Magnus Larson, Nicholas C. Kraus</i>	
Chapter 171	
THE PUNTA UMBRIA (HUELVA) SPIT .....	2233
<i>Antonio Lechuga, Jose Maria Medina-Villaverde</i>	
Chapter 172	
COMPLEX PRINCIPAL COMPONENT ANALYSIS OF SEASONAL VARIATION IN NEARSHORE BATHYMETRY .....	2242
<i>Guoxiong Liang, Thomas E. White, Richard J. Seymour</i>	

Chapter 173	
TEMPORAL AND SPATIAL CROSS-SHORE DISTRIBUTIONS OF SEDIMENT AT “EL PUNTAL” SPIT, SANTANDER, SPAIN .....	2251
<i>M.A. Losada, R. Medina, C. Vidal, I.J. Losada</i>	
Chapter 174	
THREE-MODE PRINCIPAL COMPONENT ANALYSIS OF BATHYMETRIC DATA, APPLIED TO “PLAYA DE CASTILLA” (HUELVA, SPAIN) .....	2265
<i>Raul Medina, Cesar Vidal, Miguel A. Losada, Antonio J. Roldan</i>	
Chapter 175	
WAVE BREAKER TURBULENCE AS A MECHANISM FOR SEDIMENT SUSPENSION.....	2279
<i>G.P. Mocke, G.G. Smith</i>	
Chapter 176	
GRAIN-SIZE DISTRIBUTION OF SUSPENDED SEDIMENTS .....	2293
<i>Ryuichiro Nishi, Michio Sato, Kazuo Nakamura</i>	
Chapter 177	
BED BOUNDARY LAYERS.....	2307
<i>B.A. O'Connor, J.M. Harris, H. Kim, Y.K. Wong, H.U. Oebius, J.J. Williams</i>	
Chapter 178	
TIMESCALES OF BED RESPONSE IN A LOW ENERGY SURF ZONE .....	2321
<i>Philip D. Osborne, Christopher E. Vincent</i>	
Chapter 179	
SHORELINE CHANGE AT OREGON INLET TERMINAL GROIN .....	2332
<i>M.F. Overton, J.S. Fisher, W.A. Dennis, H.C. Miller</i>	
Chapter 180	
NUMERICAL SIMULATION OF SAND IN PLUNGING BREAKERS .....	2344
<i>C. Pedersen, R. Deigaard, J. Fredsoe, E.A. Hansen</i>	
Chapter 181	
SHINGLE BEACH PROFILES AND WAVE KINEMATICS.....	2358
<i>Keith A. Powell, Paul A. Quinn, Clive A. Greated</i>	
Chapter 182	
BEACH CHANGES AND SEDIMENT MOVEMENT IN THE SURF ZONE .....	2370
<i>Zbigniew Pruszk, Ryszard B. Zeidler</i>	

Chapter 183	
VELOCITY MEASUREMENTS CLOSE TO RIPPLED BEDS .....	2383
<i>K.I. Mahesha Ranasoma, J.F.A. Sleath</i>	
Chapter 184	
FIELD OBSERVATION OF WAVE-INDUCED POREWATER	
PRESSURES .....	2397
<i>T. Sakai, H. Mase, D.T. Cox, Y. Ueda</i>	
Chapter 185	
SAND TRANSPORT UNDER GROUPING WAVES .....	2411
<i>Shinji Sato</i>	
Chapter 186	
QUASI-TURBULENT BOUNDARY LAYER OF OSCILLATING	
FLOW OVER RIPPLES .....	2424
<i>Yukio Sato, Ken-ichiro Hamanaka</i>	
Chapter 187	
LONG PERIOD WAVE AND SUSPENDED SAND TRANSPORT IN	
THE SURF ZONE.....	2438
<i>Tomoya Shibayama, Akio Okayasu, Mikio Kashiwagi</i>	
Chapter 188	
OBSERVATION OF FORESHORE VARIATION IN IWO-JIMA .....	2450
<i>Toshiyuki Shigemura, Kenjiro Hayashi, Kojima Fujima</i>	
Chapter 189	
SHORE NOURISHMENT AND THE ACTIVE ZONE:	
A TIME SCALE DEPENDENT VIEW.....	2464
<i>Marcel J.F. Stive, Huib J. De Vriend, Robert J. Nicholls,</i>	
<i>Michele Capobianco</i>	
Chapter 190	
METHOD FOR ARTIFICIAL BEACH NOURISHMENT .....	2474
<i>Henk J. Verhagen</i>	
Chapter 191	
FIELD INVESTIGATION AT A MOUTH OF SMALL RIVER .....	2486
<i>Hitoshi Tanaka, Hobuo Shuto</i>	
Chapter 192	
ENTRAINMENT AND TRANSPORT OF FINE SAND BY COMBINED	
WAVES AND CURRENT:AN EXPERIMENTAL STUDY.....	2500
<i>C. Villaret, B. Latteux</i>	

Chapter 193	
A TIME-DEPENDENT NEARSHORE MORPHOLOGICAL RESPONSE MODEL.....	2513
<i>Hsiang Wang, Gang Miao, Li-Hwa Lin</i>	
Chapter 194	
TOTAL RATE AND DISTRIBUTION OF LONGSHORE SAND TRANSPORT.....	2528
<i>Akira Watanabe</i>	
Chapter 195	
COMBINED FLOW SAND TRANSPORT: FIELD MEASUREMENTS .....	2542
<i>Richard J.S. Whitehouse</i>	
Chapter 196	
NUMERICAL SIMULATION OF POCKET BEACH FORMATION .....	2556
<i>Takao Yamashita, Yoshito Tsuchiya</i>	
Chapter 197	
A CRITICAL REVIEW OF AVAILABLE DATA FOR CALIBRATION AND/OR VERIFICATION OF SEDIMENT TRANSPORT MODELS.....	2567
<i>Julio A. Zyserman</i>	
Chapter 198	
A FEASIBILITY STUDY OF A PERCHED BEACH CONCEPT IN THE NETHERLANDS .....	2581
<i>Joost H.M. de Ruig, Piet Roelse</i>	
Chapter 199	
ARTIFICIAL SAND FILLS IN WATER.....	2599
<i>J. van't Hoff, M.B. de Groot, J.C. Winterwerp, H. Verwoert, W.T. Bakker</i>	
Chapter 200	
SEDIMENT TRANSPORT BY CURRENTS AND WAVES .....	2613
<i>Leo C. van Rijn, Aart Kroon</i>	
Chapter 201	
A WAVE-CURRENT SEDIMENT BOUNDARY LAYER .....	2629
<i>Keith Bedford, Jongkook Lee</i>	
Chapter 202	
LONGSHORE CURRENT AND LATERAL MIXING IN THE SURF ZONE .....	2642
<i>Ichiro Deguchi, Toru Sawaragi, Masanobu Ono</i>	

Chapter 203  
LONGSHORE CURRENT INSTABILITIES: GROWTH TO FINITE  
AMPLITUDE .....2655  
*Nicholas Dodd, Edward B. Thornton*

Chapter 204  
PROFILE DEVELOPMENT OF DUNES DUE TO OVERFLOW .....2669  
*Henk J. Steetzel, Paul J. Visser*

Chapter 205  
THE CONTRIBUTION OF SUSPENSION EVENTS TO SEDIMENT  
TRANSPORT IN THE SURF ZONE .....2680  
*Bruce Jaffe, Asbury Sallenger, Jr.*

Chapter 206  
THE SHORT TERM PROFILE RESPONSE OF SHINGLE SPITS  
TO STORM WAVE ACTION .....2694  
*A.P. Bradbury, K.A. Powell*

**PART VI**

**COASTAL, ESTUARINE AND ENVIRONMENTAL PROBLEMS**

Chapter 207  
INTERACTION BETWEEN WATER WAVES AND VEGETATION .....2710  
*Toshiyuki Asano, Hirosh Deguchi, Nobuhisa Kobayashi*

Chapter 208  
PREDICTION OF CURRENT AND SEDIMENT DEPOSITION  
PATTERNS IN PUERTO MIRANDO OIL TERMINAL USING  
2-D MATHEMATICAL MODELS .....2724  
*Carlos Villoria, Reinaldo Garcia, Eduardo Valera*

Chapter 209  
DISPERSION PROCESS AND THE SETTLEMENT PATTERN OF  
MUD DUMPED IN OCEANS .....2735  
*Eiji Yauchi, Ken Katoh*

Chapter 210  
PORT OF LISBON-IMPROVEMENT OF THE ACCESS CONDITIONS  
THROUGH THE TAGUS ESTUARY ENTRANCE .....2745  
*I.B.M. Oliveira*

Chapter 211  
A MIXING MECHANISM IN THE NEARSHORE REGION .....2758  
*Uday Putrevu, Ib A. Svendsen*

Chapter 212	
FORMATION AND REDUCTION PROCESSES OF RIVER DELTAS: THEORY AND EXPERIMENTS.....	2772
<i>Hossam El-din A. Refaat, Yoshito Tsuchiya</i>	
Chapter 213	
THEORETICAL STUDY OF THE WAVE ATTENUATION IN A CHANNEL WITH ROUGHENED SIDES.....	2786
<i>A.J. Roldan, M.A. Losada, I.J. Losada</i>	
Chapter 214	
LOCAL SCOUR AROUND A LARGE CIRCULAR CYLINDER ON THE UNIFORM BOTTOM SLOPE DUE TO WAVES AND CURRENTS .....	2799
<i>Eiichi Saito, Tomoya Shibayama</i>	
Chapter 215	
VERTICALLY VARYING VELOCITY FIELD IN Q-3D NEARSHORE CIRCULATION.....	2811
<i>A. Sanchez-Archilla, F. Collado, A. Rodriguez</i>	
Chapter 216	
VERTICAL STRUCTURE OF THE NEARSHORE CURRENT AT DELILAH: MEASURED AND MODELED .....	2825
<i>Jane McKee Smith, Ib A. Svendsen, Uday Putrevu</i>	
Chapter 217	
A REVIEW OF WAVE/CURRENT-INDUCED SCOUR AROUND PIPELINES.....	2839
<i>B. M. Sumer, J. Fredsoe</i>	
Chapter 218	
TURBULENCE AND MUD SEDIMENTATION: A REYNOLDS STRESS MODEL AND A TWO-PHASE FLOW MODEL .....	2853
<i>C. Teisson, O. Simonin, J.C. Galland, D. Laurence</i>	
Chapter 219	
MECHANISM OF SEDIMENT TRANSPORT AROUND A LARGE CIRCULAR CYLINDER.....	2867
<i>Takao Toue, Hidehiro Katsui, Kazuo Nadaoka</i>	
Chapter 220	
SILTATION STUDY IN A LONG APPROACH CHANNEL ON LARGE SCALE MUDDY TIDAL FLAT .....	2879
<i>Hiroichi Tsuruya, Kazuo Murakami, Isao Irie, Kazumasa Katoh</i>	

Chapter 221	
MODELLING OCEAN WAVES IN THE COLUMBIA RIVER	
ENTRANCE.....	2893
<i>L.A. Verhagen, L.H. Holthuijsen, Y.S. Won</i>	
Chapter 222	
SEDIMENT TRANSPORT IN DREDGED TRENCHES.....	2902
<i>S.O. Vithana</i>	
Chapter 223	
MOTION OF MOBILE BEDS AT HIGH SHEAR STRESS.....	2917
<i>Kenneth C. Wilson, Fidelia N. Nnadi</i>	
Chapter 224	
PORT SITE SELECTION ON COAST WITH RADIAL SANDBANKS.....	2926
<i>Yixin Yan, Yen Kai</i>	
Chapter 225	
LIQUEFACTION AND EROSION OF CHINA CLAY DUE TO	
WAVES AND CURRENTS .....	2937
<i>P.J. de Wit, C. Kranenburg</i>	
Chapter 226	
CONSOLIDATION OF SOFT MARINE SOILS: UNIFYING	
THEORIES, NUMERICAL MODELLING AND IN SITU	
EXPERIMENTS.....	2949
<i>Alain Alexis, Philippe Bassoullet, Pierre Le Hir, Charles Teisson</i>	
Chapter 227	
EFFECTIVE STRESSES AND PERMEABILITY IN	
CONSOLIDATING MUD .....	2962
<i>Jean Berlamont, Lut Van de Bosch, Erik Toorman</i>	
Chapter 228	
COHESIVE PROFILE EROSION BY WAVES .....	2976
<i>Craig Bishop, Michael Skafel, Rob Nairn</i>	
Chapter 229	
THE KINEMATICS OF WAVE INDUCED FLOWS AROUND	
NEAR-BED PIPELINES .....	2990
<i>T. Bruce, W.J. Easson</i>	
Chapter 230	
MIXING BY SHEAR INSTABILITIES OF THE LONGSHORE	
CURRENT .....	2999
<i>J.C. Church, E.B. Thornton, J. Oltman-Shay</i>	

Chapter 231	
BOTTOM STRESS MODIFICATION BY BREAKING WAVES WITHIN A LONGSHORE CURRENT MODEL .....	3012
<i>J.C. Church, E.B. Thornton</i>	
Chapter 232	
HYDRODYNAMICS AND SEDIMENT CONCENTRATIONS AT WALKER BAY.....	3026
<i>R.C. Coppoolse, J.S. Schoonees, G.G. Smith, G.P. Mocke</i>	
Chapter 233	
WATER WAVE PROPAGATION IN JETTIED CHANNELS.....	3040
<i>Robert A. Dalrymple</i>	
Chapter 234	
DISPERSION MODEL OF DREDGE SPOIL DUMPED IN COASTAL WATERS .....	3054
<i>G. Drapeau, D. Lavallée, J.F. Dumais, G. Walsh</i>	
Chapter 235	
A MODIFIED METHOD OF CHARACTERISTIC TECHNIQUE COMBINED WITH GALERKIN FINITE ELEMENT METHOD TO SOLVE SHALLOW WATER MASS TRANSPORT PROBLEMS.....	3068
<i>A. Garzon, L. D'Alpaos</i>	
Chapter 236	
SEDIMENTATION AND EROSION PROBLEMS OF YAKAKENT FISHERY HARBOR.....	3081
<i>A.R. Gunbak, K. Tunc Gokce, Isikhan Guler</i>	
Chapter 237	
A STUDY ON MUD MASS TRANSPORT UNDER WAVES BASED ON AN EMPIRICAL RHEOLOGY MODEL.....	3093
<i>Masahiko Isobe, Trien N. Huynh, Akira Watanabe</i>	
Chapter 238	
SETTLING PROPERTIES OF COHESIVE SEDIMENTS IN A COOLING WATER INTAKE BASIN .....	3107
<i>Susumu Kanayama, Takuzo Shimizu, Kazuhiro Ueki</i>	
Chapter 239	
SEDIMENT TRANSPORT MODELLING IN A MACROTIDAL ESTUARY: DO WE NEED TO ACCOUNT FOR CONSOLIDATION PROCESSES? .....	3121
<i>Pierre Le Hir, Nancy Karlikow</i>	

Chapter 240	
WAVE-INDUCED PORE PRESSURE ACTING ON A BURIED SUBMARINE PIPELINE .....	3135
<i>Waldemar Magda</i>	
Chapter 241	
HYDRAULIC APPROACH TO DETERMINING OPTIMUM INTERVAL OF DISCHARGE SITES OF BARGE IN CONSTRUCTING RUBBLE FOUNDATION OF DEEP WATER BREAKWATER .....	3149
<i>Yoshiharu Matsumi, Akira Kimura</i>	
Chapter 242	
VORTEX TRAIN IN AN OFFSHORE ZONE.....	3163
<i>Nobuhiro Matsunaga, Kosei Takehara</i>	
Chapter 243	
THE VARIATION OF FLOC SIZES WITHIN A TURBIDITY MAXIMUM AT SPRING AND NEAP TIDES .....	3178
<i>J.C. McCabe, K.R. Dyer, D.A. Huntley, A.J. Bale</i>	
Chapter 244	
DISPERSION OF HEAVY SUSPENSIONS IN WAVE BOUNDARY LAYERS .....	3189
<i>Chiang C. Mei, Chimin Chian</i>	
Chapter 245	
COMBINED CONVECTION-DIFFUSION MODELLING OF SEDIMENT ENTRAINMENT .....	3202
<i>Peter Nielsen</i>	
Chapter 246	
MOVEMENTS OF MOORED SHIPS IN HARBOURS .....	3216
<i>Th. Elzinga, J.R. Iribarren, O.J. Jensen</i>	
Chapter 247	
WAVE AGITATION CRITERIA FOR FISHING HARBOURS IN ATLANTIC CANADA.....	3230
<i>Charles P. Fournier, Michael W. Mulcahy, K. Ander Chow, Otavio J. Sayao</i>	

## PART VII

### CASE STUDIES

Chapter 248	
EROSION OF THE DAMIETTA PROMONTORY, THE NILE DELTA .....	3246
<i>A.M. Fanos, A.A. Khafagy, P.D. Komar</i>	

Chapter 249	
NEARSHORE COASTAL CHANGES ALONG THE NILE DELTA SHORES.....	3260
<i>A.A. Khafagy, M.G. Naffaa, A.M. Fanos, R.G. Dean</i>	
Chapter 250	
NILE DELTA PROFILES AND MIGRATING SAND BLANKETS .....	3273
<i>Douglas L. Inman, M. Hany S. Elwany, Ahmed A. Khafaagy, Abraham Golik</i>	
Chapter 251	
DESIGN AND CONSTRUCTION OF THE BOSTON OUTFALL.....	3285

INTERVENTIONS ON THE COAST SOUTH OF BRINDISI.....	3413
<i>Giuseppe R. Tomasicchio, Fiore Uliana</i>	
Chapter 261	
SANDY BEACH STABILIZATION: PRESERVATION OF SHIRARAHAMA BEACH, WAKAYAMA .....	3426
<i>Yoshito Tsuchiya, Yoshiaki Kawata, Takao Yamashita, Teruo Shibano, Masahiko Kawasaki, Shin Habara</i>	
Chapter 262	
WAVE POWER CONVERSION BY A PROTOTYPE WAVE POWER EXTRACTING CAISSON IN SAKATA PORT.....	3440
<i>Shigeo Takahashi, Hiroaki Nakada, Hideaki Ohneda, Masazumi Shikamori</i>	
SUBJECT INDEX.....	3505
AUTHOR INDEX.....	3511

# WELCOME ADDRESS

**Prof. Ing. Ugo Tomasicchio**  
**Chairman of the Conference**

On On. Sottosegretario ai Lavori Pubblici, signora Vice Presidente della Regione Veneto, signor Sindaco, signor Presidente del Magistrato alle Acque, signor Capo di Stato Maggiore della Marina, signor Assessore alla Cultura, signor Provveditore al Porto, signor Presidente del Consiglio Nazionale delle Ricerche, signor Presidente del Coastal Engineering Council, grazie della vostra presenza.

All'on. Francesco Merloni oggi sono dovuti anche gli auguri onomastici, che tutti gli rivolgiamo con vivo sentimento.

Un benvenuto a tutti gli amici e collaboratori.

**Welcome**, welcome to you all, welcome to Italia and to Venezia!

It's with great pleasure that, in the name of the Organizing Committee of the 23rd International Conference on Coastal Engineering, I have the honour to give you, distinguished guests and colleagues, a warm welcome.

I thank very much all of the National District and City Authorities for their presence and especially the honourable Minister of Public Works, the Vice President of the Regione Veneto, the Mayor of Venezia, the President of National Council of Research, and the Superintendent of the Port, who have all in many ways supported us in organizing and funding this Conference.

I also thank the Coastal Engineering Research Council and its Chairman Prof. Robert L. Wiggel, eminent man of science, for choosing Italia and Venezia for this 23rd ICCE.

Also I give many thanks to the many private sponsors and especially to the Italian Contractors, without whose financial support we would not have been able to resolve the many organizational problems.

The tradition of the ICCE is to reduce as much as possible the time spent on the opening ceremony to give more prominence to the scientific sessions. Excellent tradition! So, as Master of Ceremony, according to the definition of Prof. Bijker, Chairman of the last Conference in Delft, I don't want to break the tradition. But, please, first let me express some brief considerations.

**Genesis** (5.1) talks about God who put Man in the garden of Eden "to cultivate and care for it". Giving the creation to the care of Man, God gave him special gifts: the word, intelligence and freedom, sparks of divine nature of the Creator. So, Man was named: mirror of God (B. Pascal) and *homo Dei*; the Italian Philosopher G. B. Vico uses the expression "*Simia Dei*".

Aristotle defined Man "*ζῷον λογος εχον*" as literally the animal who has the word. The word, the logos, the verbum, this exclusive feature of Man, is the first vehicle of communication of knowledge, of science. The word, the dialogue was the teaching method of philosophic and scientific truth as in Aristotle, Plato, Socrates, Pascal and innumerable other thinkers, but also it was that of Christian Revelation; the Evangelist John begins with the admirable words: "in principio erat Verbum et Verbum erat apud Deum et Deus erat Verbum".

Then came intelligence and freedom: two indivisible gifts to choose the best, that is making the best use of intelligence. In fact, it is intelligence which permits Man the knowledge of the things, starting from his own experience, according to Galilei and Bacon; the knowledge transforms itself in Science when it becomes common property of humanity. Human science, and particularly knowledge of physical phenomena, developed with incredible speed in the past and the fruit of Man's experience, always asks for more work, with the consequent necessity of repetitive and frequent exchanges of information among the scientists, researchers and technicians. That explains the usefulness, the necessity of the meetings of groups of specialists, meetings either to evaluate the state of art or to coordinate and to press for new research.

And history, nevertheless its cycles and recycles often contradictory, demonstrates that Man travels along the path of civilization, caring for and improving the natural environment in which he lives. It is possible to see, for example, many examples of hydraulic engineering in flood control, land reclamation, coastal defense.

To the **Hydraulic Engineer** we can certainly give the credit for taking care of the environment with which he was entrusted. Coastal Engineering has recently reached the level of a science; you can consider that it was only a few decades ago that Man was able to make a real model of the sea, an object of observation from the beginning of civilization. We can take 1950, the year of the first International Conference on Coastal Engineering, as the year of the official birth of the new hydraulic maritime science. Not without reason, we are finding, among the promoters of ICCE, the most famous names in coastal engineering.

From 1950 until today, the Proceedings of the 22 conferences already held illustrate the big development of this new science; consequently it seems that we could consider the ICCE the midwife of the new maritime hydraulics, according to the Socratic teaching. ICCE is today, without any doubt, the most important scientific international conference of civil maritime engineering; the high number of participants coming from over 50 countries, the number and the level of printed papers. Its growing reputation in the scientific world confirms this.

In this 23rd Conference 682 papers have been submitted (not including those arriving too late). The CERC has chosen about 330, which will take all the available time in the five sessions.

This is the first time in the history of ICCE that the Conference has been held in Italia. We believe that the choice was not casual, in that it is taking place in the fifth centenary of the discovery of America by the great Genoese Navigator Cristoforo Colombo.

Also the venue has a clear motivation connected with this anniversary. It is in fact in Venezia, the Serenissima Repubblica Marinara, that, at the beginning of the modern era, shone in all its brilliant light the Italian Renaissance, which has radiated throughout Europe and the whole world. In Venezia was designed the "Planimondo" which was used by Colombo and other intrepid Navigators of his time (as Amerigo Vespucci), to chart the route to the new world.

It was also in Venezia that you could admire, and you can still admire, the wonderful City, the masterpiece of Man's creation, built in a very poor physical environment. **The history of Venezia is**

also the history of man "homo faber", i.e. of the Engineer in constant confrontation with natural forces: sea-storms, flooding, subsidence, etc.

Venezia is the demonstration of how much Man, using intelligently his inventive ability, can achieve, caring for cultivating the garden which was entrusted to him. This attentive caring does not permit any respite. Furthermore, you know well the present problems of the defense of Venezia, for those hard working engineers. The problems of the defense of Venezia against the sea will be discussed in many of the papers in this Conference.

Meanwhile, admire and enjoy Venezia: a precious pearl of human engineering and art; Venezia: the most beautiful City in the water, admirable lighthouse of civilization.

And let me finish at this point with many good wishes for a successful Conference. The Organizing Committee apologizes if everything is not perfect, but we hope our hospitality will be acceptable.

Grazie e benvenuti a Venezia. Thank you again.

( Prof. Ing. Ugo Tomasicchio  
Chairman of the Conference )

ICCE'92 4-9 October 1992 VENICE  
THE FIRST 'ACQUA ALTA' OF THE YEAR

# Coastal Engineering in Venice

Enrico Marchi<sup>1</sup>

## 1 Introduction

Venice is well known in the world as a fantastic city, full of interest for visitors to its palaces, churches, art galleries and fascinating corners. However, there is more than this: the history of Venice (see, for example, Zorzi, 1980), its development as a refuge from invaders to an imperial marine city offers extraordinary examples of applications of coastal engineering.

Venice has always taken immense care of its Lagoon which completely surrounds it and has for centuries afforded protection for the city, a haven for its fleet and the gateway to the open sea. In order to defend this Lagoon the Venetians have had to face and overcome numerous risks: the aggradation of the basin, the erosion of the littoral barrier, the reduction in depth at the inlets due to the action of the sea waves, through to the recent risks caused by industrial and agricultural pollution and to the increasingly frequent submersion of vast areas and living quarters as a result of high tides combined with land subsidence and eustasy. A brief look at each of these problems and the ways in which they have been tackled could be an effective subject for thought on the part of the participants of this Congress.

## 2 Origin of the Lagoon

More than 10.000 years ago, in the era of the last great glaciation of the Quaternary, Italy had an emerged territory much larger than its present one especially in the Adriatic zone. At the end of the glaciation, the rise in sea level submerged a great part of the alluvial plains formed by the river Po and its affluents. The line of separation of *terraferma* from the North Adriatic Sea - as a result of the gentle declivity of the plane towards the sea, and probably

---

<sup>1</sup>Professor of Hydraulics, Head, Institute of Hydraulics, University of Genoa, Via Montallegro, 1 - 16145 Genoa, Italy

due to the combined effect of more moderate sea level variations as well as to the breaking of the waves - assumed an indented and irregular form. Long series of dunes parallel to the coast separated the open sea from the internal basins - the lagoons - that had a more or less narrow rectangular form with the greater side parallel to the sea. They received fresh water from the west and north-west estuaries and communicated with the sea towards the east by means of large inlets. Could we consider that the transverse dimensions of the adriatic lagoons have a connection with the length of the tidal waves which give them "life"? It is difficult to find proofs since many independent factors, sometimes of anthropic type, have successively conspired to modify the lagoon basin's size. However, a hypothesis proposed by Luigi De Marchi as far back as 1904 was taken up again by Di Silvio (1991) correlating the propagation time of the tide with the period of resonance of the lagoon basin.

The maximum flow through a lagoon inlet takes place when the length of the lagoon itself is such that the effective crossing time for the tidal wave becomes equal to the resonance time. The latter is about a quarter of the tidal period and turns out to be largely independent of the value of the flow resistance. The flow rates, and thus the tidal amplitudes, do not always increase with the dimension of the basin; when the crossing time of the tide is greater than the resonance one - meaning that the basin length is great enough to be larger than a quarter of the length of the effective tidal wave in the lagoon - the level oscillation can increase if the basin dimensions become reduced. In fact this is the case, for example, of the Zuiderzee (Ijsselmeer) when, after the damming reduced the notable original length of the basin, the tidal amplitudes have been clearly increased.

The Venice Lagoon originally consisted of shallower basins than the present ones and it is possible that its surface dimensions were commensurate with the resonance conditions. Now, the tidal propagation through each of the three basins in which the lagoon can be divided takes noticeably less time than that of resonance, if we exclude the extreme ramifications of the north-east zone where the tidal flow is controlled for the fishing areas. The Venice Lagoon behaves today substantially as a "short" basin. In fact, the tides - whose mean component has a period of 12 hours - have in most of the lagoon delays of less than 2 hours and slight amplitude attenuations that in general do not exceed 20% of the sea amplitudes.

### 3 Historical evolution

In Roman times the Lagoon had more or less the same form that it has today but with a larger open surface and at least eight inlets. The settlement of the "Veneti" in the small islands spread through the Lagoon happened after the fall of the Roman Empire, especially after the migration due to the invasion of the Lombards in Italy. The Torcello cathedral was built in the first part of the 7th century. The communities, settled in various small centers and in particular in Malamocco, made up the "Lagoon Province", formally linked to the

Byzantine Empire but really autonomous. Thus it was able to hold out against the pressure of the Franks in the IXth century and to establish at Venice-Rialto, the new capital, a community that was definitely detached from the land. One can say that Venice was born with the vocation to be, since that time, a bridge of communication and commerce between the East and the West. Gradually its independence became affirmed and so that power which brought it to its greatest splendour between the XIIIth and XVIth centuries. It was during the period of the mature Republic that the greatest problems of hydraulic and coastal engineering were faced, entrusting the responsibility for works to a single organization: the "Magistrato alle acque", an absolute water authority.

In that period the inlets of the Lagoon, called "mouths", were already the three present ones: Lido, Malamocco and Chioggia (Fig. 1) The mouths, however, do not have now the form shown in the figure; a point to be discussed later. Fig. 2 shows the present state of the Venice Lagoon. Note the characteristic network of submerged channels that ramify from each mouth and become progressively narrower and shallower; they represent the fastest ways for the tide to enter the Lagoon. The basin is moon-shaped and has a length of more than 50 km, a width that varies from 8 to 14 km and a mean depth of about 0.65 m (Rusconi, 1987).

Figure 1: The Lagoon in XVIth century with the three mouths.

In the Lagoon there are several inhabited islands, other than those on which Venice was built, such as the famous isles of Murano and Burano. Furthermore there exist - or existed - many low-lying lands, called "barene", which are regularly submerged during high tide since they have a level higher than the mean level of the sea but less than about +30 cm. These predominant green areas are typical of the lagoon scenery. They have undergone, especially during

the second half of the XXth century, a heavy surface reduction and they are also at present subject to border erosion.

The evolution of the Lagoon areas occupied by land and water is not easy to evaluate because the most precise surveys, carried out in 1950 and 1970, necessarily had different points of reference (Cavazzoni, 1977). According to the evaluation of the Hydrographic Office of the "Magistrato alle Acque" (Rusconi, 1987) the measurements are as follows (Tab. 1):

Tab. 1

Lagoon surfaces (km <sup>2</sup> )		
Years	1930	1970
Lagoon area not affected by tides	125.8	136.7
Barene	72.5	47.5
Water surface at 0 level	353.0	367.0

Today a project is underway for the morphological reconstruction of some of the "barene" and for the protection of existing ones in the context of the reclamation plan of the Lagoon on behalf of Consorzio Venezia Nuova (1992).

#### 4 Protection from aggradation

Aware of the importance of the lagoon basin for military use and of the convenience that its great size could have for the renewal of the inner water, the Venetians put the preservation of the lagoon before any other undertaking.

The first, and perhaps the most serious threat they had to face, was that of the basin silting up due to the sediment transport of the water courses entering the Lagoon. Even if the water discharges through the lagoon mouths have a maximum value in the range of 5,000 to 10,000 m<sup>3</sup>/s, as great as the highest flows of the river Po, the sediment movement within the lagoon - as well as in the internal network of submerged channels - is very slight. A slow but progressive lengthening of the river mouths took place, however, within the lagoon and the free surface of the basin was being reduced.

The first work dates from the XIVth century and consisted in the deviation of the mouth of the Brenta, which was in front of Venice, to a more southerly position. Many other works were carried out during the XVth and, above all, the XVIth century. The Brenta was finally excluded from the Lagoon in 1613 through the so-called "taglio nuovissimo" (the newest cut). The Bacchiglione was deviated to the sea in the middle of the XVIth century. The Piave was completely excluded from the Lagoon in 1639 and the Sile in 1683, using as well a stretch of the old bed of the Piave. Fig. 3 gives an idea of these enormous works carried out in more than two centuries.

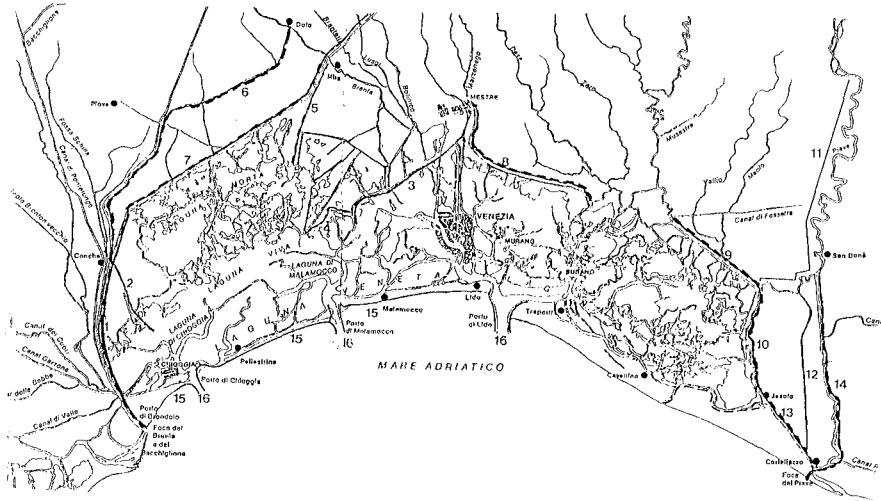

Figure 3. Deviation of the water courses entering the Lagoon (from Zorzi, 1980).

Particular mention should be made of a most important alteration that, although outside the Lagoon, was undertaken in 1598-1604 in order to remove the risks of sediment transport into the Lagoon caused by the mouths of the Po delta. This was the so-called "Taglio di Porto Viro" (the Porto Viro cut) by means of which the main mouth of the Po, which had the tendency to move northward, was deviated towards the East thus assuming its present form.

## 5 Protection of the Venetian littoral

From the earliest times of the Venetians' definitive settlement on the Lagoon islands many conservation works were carried out on the lagoon banks and sea shores. Typical embankments were built since the 11th century with willow branches and stones (Tomasicchio, 1983). This is an elastic and unsinkable protection also largely used to defend the banks of the river Po from erosion.

Timber was extensively used by the Venetians above all in the form of piers that, fixed into the muddy and sandy ground, compacted it so as to make it able to support the weight of massive structures, such as jetties and moles or even buildings.

In the XVII century the state of the littoral barrier which divides the lagoon from the sea was already particularly delicate. The sediment transport of the river Piave to the sea was lessened, probably because of the improvement to

Figure 4. The narrow stretch of land between Malamocco and Chioggia.

the middle and lower river bed. This fact rendered insufficient the renewal of sediments brought by the littoral currents that develop along the Venetian coast. The erosive action of the breaking sea waves therefore made the state of the narrow stretch of land and its littoral, especially that between the inlets of Malamocco and Chioggia (Fig. 4), particularly dangerous.

Until the end of the XVIIth and the beginning of the XVIIIth centuries attempts to protect the littoral using flexible systems of piers, branches and stones were repeated. At last, the Republic engaged Bernardino Zendrini, State Mathematician, and the experts Giovanni Filippini, Overseer to the Lidos, Matteo Lucchese, Overseer to the Lagoon, and Tommaso Ternanza, Overseer to the Rivers, in order to work on a project for stable defence. The Report ("Relazione" of June 1st, Zendrini, 1743) contained the design for the "murazzi" (Venetian massive walls). The primary idea is mainly traced back to Abbot Coronelli in about 1706 and the name was already current in Venice for protective works using pozzuolanic cement (Benigni, 1983). The original design of the "murazzi" attached to Zendrini's report is reproduced in Fig. 5. The "reinforcement plan" was carried out during a period of about 40 years and this protection has lasted up to the present time (Gottardo, 1976). However, some repairs have been necessary, particularly after the exceptional storm of 1825 and the recent one of 1966. We must bear in mind, though, that the construction of the long breakwaters defending the mouths, which took place between the end

Figure 5. Original design for the "murazzi" (Zendrini, 1743)

of the XIXth and the beginning of the XXth centuries cut down both northern and southern sediment transport to the physiographic unity confined by the Lido and Chioggia moles, including the narrow Caroman littoral.

The state of the "murazzi" deteriorated as a result of the erosion made by waves at the toe of the wall. The reinforcement was not limited to reconstructing and strengthening the rubble mound at the toe of the "murazzi", as shown in Fig. 6. It was necessary to consider the foreseeable possibility of isolating the lagoon from the sea, on different levels, in the case of exceptional tide. Therefore measures were taken to protect the foundation of the "murazzi" from the risk of siphoning using an impermeable diaphragm of reinforced concrete, sunk as far down as a layer of clay situated at about 20 m below sea level. Since this main diaphragm had to be constructed on the lagoon side, a second and shorter diaphragm was sunk at the toe of the "murazzi" in order to lessen the effects of underpressure waves reflected by the first diaphragm. Such an effect was experimentally observed *in situ* under the breakwater of Genoa harbour (Marchi e Stura, 1976). The cause, in that case, was attributed to the natural silting up of the internal porosity of the breakwater rubble mound.

Figure 6. Reinforcement of the "murazzi" after 1966.

## 6 Conservation of the Water Depth at the Mouths

The Venice Lagoon behaves, as already noted, like a "short" basin. Under this condition the tidal "prism", that is the volume entering the basin in one tidal cycle, is correlated with the basin surface. A relationship between the same tidal prism and the section area of the inlet was suggested by O'Brien (1969) and supported by others, in particular by Jarrett (1976), who based the result on a series of field measurements. The correlation form is analytically justifiable and the theoretical study (Marchi, 1990) has confirmed the experimental relationship between the area  $\Omega$  of the inlet section and the power 6/7 of the volume  $P$  of the tidal prism:  $\Omega = kP^{6/7}$  (Fig. 7). Furthermore, it has shown the factors on which the correlative coefficient  $k$  depends, in particular its functional dependence on the value of the shear stress at which the bed erosion begins and on the roughness of the bed itself.

Given the proportionality of the tidal prism  $P$  to the surface  $S$  of the basin, we could think that a simple relationship of the former type is valid also for  $S$ . However, it must be noted that the tidal prism is not only a linear function of the basin surface but also of the inside tidal amplitude which is still a function of the area  $\Omega$ . From this derives a more complex relationship between  $S$  and  $\Omega$ . Fig. 8 shows the curves relative to the three present mouths of the Lagoon. Note that if the opening has a value lower than a given limit (the asymptotic value of the left branch of the curve  $S = f(\Omega)$ ) the mouth cannot resist. Above such value the area  $\Omega$  increases by erosion until it arrives at the stability which depends on the balance between the maximum shear stress imposed at the bottom by the tidal current and the resistance to erosion of the bed surface. As  $\Omega$  increases, its influence on the tidal amplitude has the tendency to vanish and the relationship becomes of the previous type ( $\Omega = K_1 S^{6/7}$ ), as shown by the right branch of the curves in Fig. 8.

The conservation of the basin surface thus assures the conservation of the

Figure 7. Relationship between the tidal prism  $P$  and the inlet section  $\Omega$  (from Marchi, 1990).

Figure 8. Relationship between the basin surface  $S$  and the inlet section  $\Omega$  (from Marchi, 1990).

section area of the mouth if stable conditions have been reached (Bruun, 1978). However, the section area, by and large, can be maintained even if, as a result of the action of the sea waves, the water depth tends to diminish; for this it is enough for the width to increase accordingly. This can happen by the erosive action of the tidal currents. An example is represented in Fig. 9 by the evolution of the Lido mouth during the period 1552-1968 (Baroncini et al., 1983).

Figure 9. Evolution of the Lido mouth during the period 1552-1968 (from Baroncini et al., 1983).

In the XVIIth century shipping, especially through the Lido mouth, had already become difficult. Access to the Lagoon for loaded ships - although they were sailing ships with a small draught - was possible only during the hours of high tide and, in some cases, required a lightening of the load at sea. The situation rapidly became worse with the coming of steam ships which had a considerably larger draught.

In the first half of the XIXth century the Malamocco mouth was the only navigable inlet, since those of Lido and Chioggia had depths of only two meters. In order to conserve and increase the navigability of the Malamocco mouth, at the

Figure 10. Protective jetty to the North of the Malamocco mouth (from Tomasicchio, 1983).

beginning of the XIXth century a technical commission nominated by Napoleon proposed the construction of a protective jetty to the North of the mouth (Fig. 10). After many ups and downs, the work was carried out toward the middle of the century, as a result of the authoritative influence of Pietro Paleocapa (Noli, 1990). It was completed with the construction of the south jetty in 1872. With the width of the mouth limited in this way to about 500 m, the tidal currents began to erode the bottom and its deepening took place with different speeds according to the different resistance of the ground layers (Fig. 11) (Cavazzoni et al., 1983). This process continued until the middle of the present century and increased the depths to mean values of about 15 m, with an area of the minimal section of about 7300 m<sup>2</sup> that can now be considered stable (Consorzio Venezia Nuova, 1980).

The result obtained at Malamocco stimulated similar works at the mouths of Lido (1882-1910) and Chioggia (1911-13), which assumed the configurations visible in Fig. 2. Probably an overvaluation of the efficiency of the Lido mouth suggested a width of 900 m for this canal. In effect, the Lido water flow is hardly different from that of Malamocco and so the depth of the former mouth is established at 10 m for a large part of the section and is smaller near the north jetty.

If, on one hand, the construction of the mouth embankments has assured

Figure 11. Changes to the section of the Malamocco mouth following the construction of the jetties (Cons. Venezia Nuova, 1989).

the presence of great depths and thus continued navigability, on the other hand the seaward protrusion of the jetties has stopped the sediment transport by the littoral current. The present increase to the shores north of Lido and, partially, south of Chioggia is the evident result. On the contrary, the intermediate shores have become unstable and now require an artificial nourishment between Lido and Malamocco (Wallingford H.R. as consultant) and protection work to the "murazzi" between Malamocco and Chioggia, as earlier mentioned (Tomasicchio, 1983; Baroncini et al., 1983).

## 7 Protection against tidal effects

### 7.1 Tides

Venice arose on the group of islands around Rialto and so is in a central position with regard to the Lagoon but very close to the largest of its openings,

the Lido mouth. Therefore it has always been subject to floods, known by the name of "acque alte" (high waters), caused by the spreading out into the Lagoon of unusually high tides.

The ordinary Adriatic tides (Tenani, 1935; Polli, 1959; Defont, 1961) are of an astronomic nature and have a fairly small amplitude, around 0.60 m with a maximum of 0.90 m at the northern end of the Adriatic during the syzigial period. To the astronomic tide, characterized by a mean period of 12 hours and a secondary period of 24 hours, can be added the effect of atmospheric phenomena such as winds and low pressure. We can maintain that the action of the "sirocco", a southern wind, alone can cause a rise in the sea-level of as much as 0.90 m in exceptional conditions. A further factor in the increase of the maximum levels is represented by the seiche of the Adriatic around a transversal axis. These factors, when they act together, create tides of exceptional height and a non-periodic form, such as that illustrated in Fig. 12 which relates to the 1966 disaster.

Figure 12. Exceptionally high tide of 1966: a) measured level, b) astronomic forecast.

The tides enter the Lagoon through the three mouths and mainly propagate through a ramified system of submerged channels. The tidal elevations in Venice are usually referred to the tide gauge at Punta della Salute, on which the zero mark is still anchored to the mean level of the sea in 1897 (Comune di Venezia, Ufficio Idrografico del Magistrato alle Acque, CNR). The "acque alte" start at the 0.70 m mark, when water appears in St. Mark's Square, and so far have reached a maximum of 1.94 m in November 1966.

Table 2 shows the percentages of the flooded city which correspond to the various levels:

Tab. 2

Tide elevation at Punta della Salute	Flooding of the city
1.0 m	5%
1.1 m	15%
1.2 m	33%
1.3 m	62%
1.4 m	almost complete

A review of the highest tidal levels at Punta della Salute in Venice reveals a notable increase both in value and, above all, in the frequency of each level during this century.

Fig. 13 shows a tidal frequency curve at Venice in the decade 1975-1984 (Consorzio Venezia Nuova, 1989). Note that the 1.20 m mark, which until the last century was rarely reached (once every two or three years), has now been attained or surpassed twice every year. This worsening situation culminated in November 1966 when the highest tide in living memory covered St. Mark's Square with more than a meter of dirty water (Dorigo, 1969).

The causes of these changing phenomena, that seriously threaten the very survival of Venice, are to be found in three different factors (Ghetti et al., 1983):

- i) the eustasy, that is the rise in the mean sea-level;
- ii) the subsidence of the Lagoon territory and, particularly, the sinking of Venice;
- iii) the increase of the tidal amplitude in the Lagoon.

The aforesaid factors have various origins and different weights in the context of the phenomena being considered.

## 7.2 Eustasy

After the last glaciation the Adriatic sea level notably rose, to about 90 meters, and this obviously modified the coastal and lagoon morphology, as already said. During the last centuries, however, the sea level appears to be rather stable, at least so as not to reveal evident changes with regard to the level of the buildings. The traditional mark for the building level in Venice was that of the mean high tide. In fact, the oldest buildings (XIIIth-XVth centuries, see for example Fig. 14) seem nowadays to have thresholds and ground floors lower, in comparison to the sea level, than the buildings of the XVIth-XVIIth centuries (see for example Fig. 15). From these illustrations we cannot say if this is due

Figure 13. Frequency curve of "high water" in Venice in the decade 1975-84. The dotted line represents the same curve translated downstream by 25 cm.

only to a rise in the sea level or to a land subsidence as well. What is certain is that from the beginning of this century the rate of the rise in the sea level has increased and it has been possible to measure an average rise of 1.27 mm per year. Altogether we can consider, during the present century, a sea level increase of about 10 cm (Consorzio Venezia Nuova, 1989).

The forecast is not optimistic even for the immediate future. The change of the world climate due to the greenhouse effect shows a tendency to the increase of the mean temperature and so to a regression of the glaciers and to a sea level rise. Despite uncertainties that still exist about the interpretation and, above all, on the forecast of climate phenomena, there is a substantial agreement about a scenario which foresees a sea level rise of several centimeters already in the year 2000 and in the order of tens of centimeters up to more than 1 meter in the next century (Thomas, 1986).

In the project for safeguarding the lagoon environmental system eustasy values variable between 0 and 60 cm have been considered.

### 7.3 Subsidence

The Venice subsidence is a phenomenon determined first of all by a natural component of a geological type. The alluvial nature of the layers that make up the superficial area of the lagoon land and the tectonic deformations of

Figure 14. A XIIIth century palace (Ca' da Mosto).

Figure 15. A XVIth century palace (Grimani palace).

the substratum provoke a slow consolidation of deposits and a lowering of the Adriatic coast which can be a source of worry after several centuries. At present the mean rate of natural subsidence is estimated at 0.4 mm per year.

On the other hand, in the first half of the XXth century, and in particular from 1930 onwards, the subsidence was rapidly worsened by an anthropic component and the ground became lowered to values first of 2 mm/year and then, after 1950, up to 7 mm/year. The cause of this extraordinary increase in subsidence lies in the effect of overall heavy groundwater withdrawals in the Venice's surrounding region for the needs of Marghera's industry and also for civil and agricultural use. Between 1950 and 1970 this process of impoverishment of the groundwater layers and the consequent soil lowering continued indiscriminately. The alarm sounded late in conjunction with the increasing frequency of the "acque alte" (Carbognin et al., 1981). Accurate level surveys recorded the gravity of the risk (CNR, 1970; Consorzio Venezia Nuova, 1988) and the process was also mathematically simulated (Gambolati et al., 1973, 1974). Thus, between 1970 and 1975 pumping was gradually stopped. The artesian layers rapidly recovered the piezometric levels of 1950, but the soil lowering, at least up till now, appears to be irreversible. The mean level of the Venice land was lowered by 9 cm between 1952 and 1969 (Caputo et al., 1971) and during the entire century we can now estimate a total subsidence of 15 cm for the city.

If the two effects of eustasy and subsidence are added up one obtains a variation of the land level relative to the mean level of the sea at Venice of around 25 cm (Supino, 1978). Applying such a variation to the frequency curve plotted in Fig. 13 (see the dotted curve) it can be seen that the frequency increase of the "acque alte" caused by this change is truly impressive and corresponds to that observed over the last hundred years. The 80 cm mark, which without eustasy and subsidence would have had a frequency of 6 times per years, has been reached at present more than 45 times; the level of 1 m has passed from a frequency of 1 time to the present 9 times per year.

## 7.4 Amplitude of the lagoon tide

### 7.4.1 General remarks

The amplitude of the tides at Punta della Salute is roughly the same as that of the tides recorded at sea on the outer mole of the Lido mouth. The amplitude of the tide waves is scarcely reduced by their propagation through the inlets because of the slight resistance that is offered by the mouth canals. On the other hand, the speeds remain contained because they are correlated to the limit erosion values and, consequently, they model the form and area of the section. Obviously, this process depends on the nature of the bottom and on the distribution of sediment in the chanal. Thus, the probable silting up of the Lido mouth during the period of the last war (1940-45) resulted in a resistance increase and so in a small reduction of the tide amplitude between Lido and Punta della

Figure 16. Variations in tide amplitude during the century.

Salute (Adami, 1974); this reduction was of about 5% as seen in Fig. 16. On the contrary, the general lowering of the land during the '70s, increasing the depths of the inlets and of all the lagoon channels, slightly reduced the resistance and so increased a little the amplitude so as to make the Punta della Salute tide equal or even 1-2% superior to that of Lido (Gottardo, 1975).

These observations show the marginal influence of the considered factor - the variation of the tidal amplitude between the sea and Venice - on the phenomenon of the "acque alte" increase. Further confirmation has been provided with studies carried out using mathematical and physical models.

#### 7.4.2 Mathematical models

The tidal oscillations in the Lagoon have been studied with various types of mathematical models, which can be substantially reduced to three types: static model, one-dimensional propagation model and two-dimensional propagation model.

The *static models* study the relationship between marine oscillations and those in the Lagoon assuming the surface of the lagoon basin to be always

horizontal and considering effective only the flow resistance of the inlet. Numerous solutions have been reached after the original proposal by Poleni in 1717. A detailed review will be found in Ghetti's report of 1979 at the XVIII IAHR Congress in Cagliari (1979), and in his recent paper (1991) on Italian contributions to the lagoon hydraulics. A. Ghetti also promoted an eleven volume rich collection of studies on the Lagoon environment published by the Istituto Veneto di Scienze, Lettere ed Arti.

The results obtained using the static method are clearly confirmed by the tidal records at the Lido mouth (Adriatic Sea) and at Punta della Salute (centre of Venice). This type of model has been used to examine the effects on the Venice tidal levels caused by the artificial narrowing of the lagoon mouths. It has been observed that also very strong reductions, to the limits of the mouths' navigability, such as to lessen the section area to about one third of the present one, can reduce the maximum level of a periodic syzygial tide at Punta della Salute by about 20% (Ghetti et al., 1972). But such narrowings cease to be effective with regard to the long aperiodic tides, being able, for example, to lower by only 5% the maximum level of an exceptionally high tide like that of November 1966 (Fig. 17).

The propagation of tidal waves inside a lagoon was deeply studied by Supino (1955) and Pezzoli (1958) in the 1950's; contributions to knowledge of the process have been subsequently carried out by the same authors (1970) and also by the present writer (1986).

After the great flooding of 1966, the numerical mathematical models have become widely diffused.

The *one-dimensional propagation model* allows the study of the tidal flow into the Lagoon following the existing submerged channels, applying the de Saint-Venant equations to all stretches and satisfying the condition of volume and level conservation in the nodes. This type of model, originally proposed by Dronkers (1969, 1972) received substantial contributions from the research of Datei (1972), Di Silvio and D'Alpaos (1972) and Di Silvio (1978). Further improvements, both as regard the speed of computation and the more detailed description of the Lagoon, have been introduced in the recent model which has been developed by "Technital", with D'Alpaos as consultant, on behalf of "Consorzio Venezia Nuova" (1985). The consequences of certain modifications of the Lagoon basin have been examined with this model. The situations that have been compared are those before and after the digging of the "oil canal" and the filling up of some areas for industrial use. These two modifications, which bring opposite effects, have shown to have a slight influence on the volumes exchanged between Lagoon and sea: they have increased by some per cent at Malamocco and Chioggia and decreased by the same amount at Lido. Thus, the simulated opening of the fishing areas to the tides appeared to have very slight influence on the levels of "acque alte" at Venice. Despite a surface increase of about 80 km<sup>2</sup> (from 370 to 450 km<sup>2</sup>) the lowering of the maximum level in the central Lagoon and particularly at Punta della Salute turned out to be no more than a

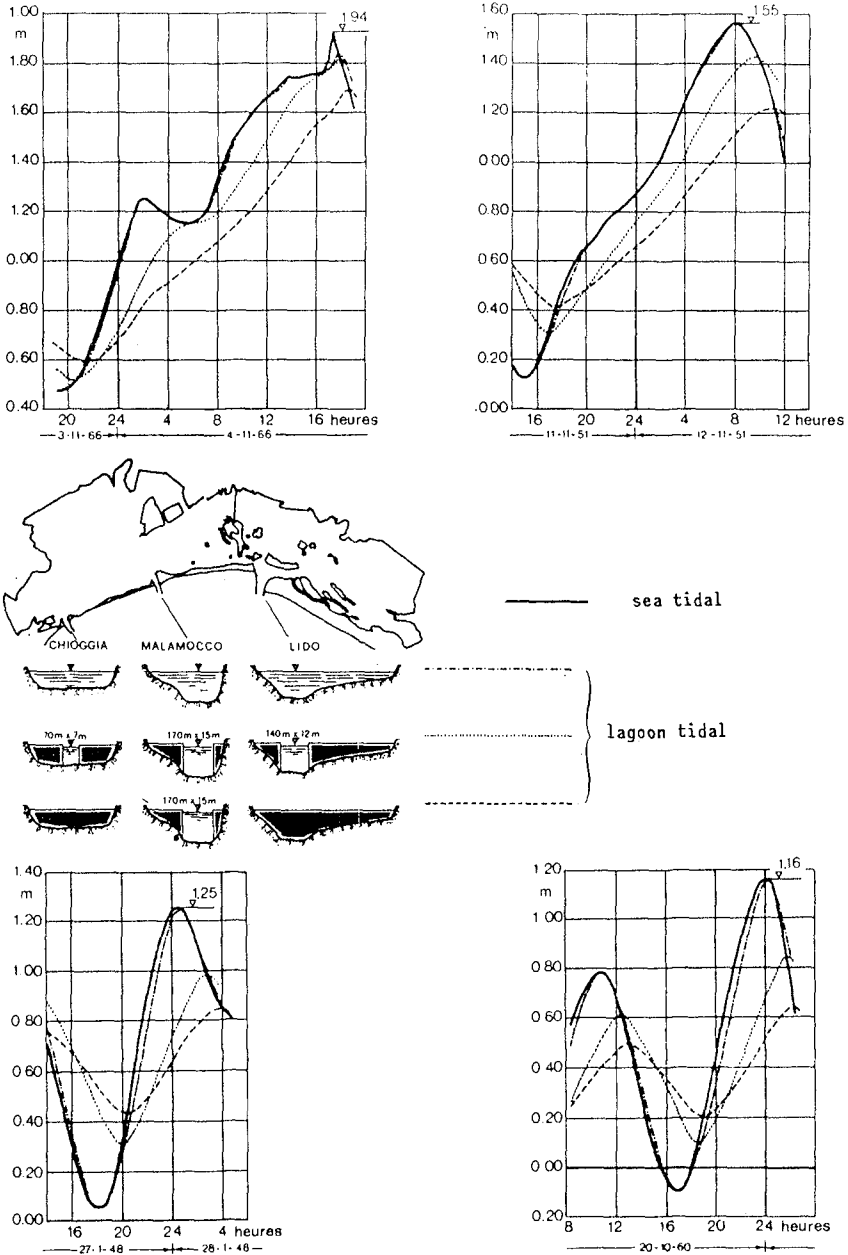

Figure 17. Tide reduction due to mouth narrowings (from Ghetti et al., 1972).

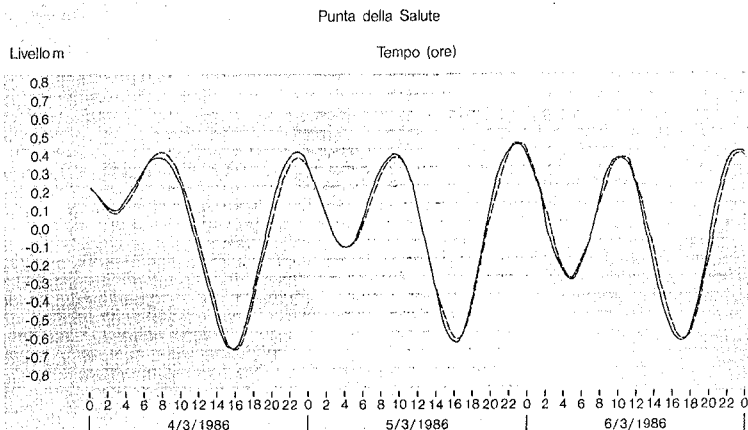

Figure 18. Calibration of the D.H.I. two-dimensional model (from Cons. Venezia Nuova, REA 1989).

few centimeters in the case of high tides with a level above 1 meter.

These observations have been confirmed by a more recent and sophisticated type of model, the *two-dimensional propagation model* based on the finite difference method and developed by the Danish Hydraulic Institute.

The mathematical procedure is the one originally proposed by Leendertse (1967) on the basis of the theory of low-water waves (Stoker, 1957) and it uses the continuity and momentum equations of the two-dimensional flow with quadratic resistance. The first application of such a model to the Venice Lagoon was carried out by the Venice IBM Center (Chignoli and Rabagliati, 1976) with a rather large grid. Further more refined developments have been undertaken by the same IBM Center. A grid size of 225 m has been used in the model prepared by the Rijkswaterstaat Laboratory collaborating with the Institute of Hydraulics of Padua University (D'Alpaos and Di Silvio, 1979) in order to study the behaviour of the central Lagoon.

The aforementioned DHI model (Consorzio Venezia Nuova, 1987-88) uses grid of 300 m size, reduced to 100 m in the areas surrounding the mouths. An example of calibration of the model by comparison with the March 1985 tide, recorded in various points of the Lagoon, is shown in Fig. 18.

Compared to the one-dimensional model, the two-dimensional one gives a better general picture of the deep water flow. A further improvement in the representation of such areas and also of the ramifications of the channel network can be obtained by the passage from the finite difference to the *finite elements model*. One gains in descriptive detail without an increase of, indeed with a reduction of, the total number of nodes.

The equations used and the resolution methods adopted for the finite elements model are those proposed by Backhaus (1976), Gray and Linch (1977), Duwe

Figure 19. The planimetric mesh of the finite elements model (from Cons. Venezia Nuova, REA 1989).

Andamento del campo di moto alle ore 19

Figure 20. Flow field simulated by the finite element model (4th Feb. 1985 tide; from Cons. Venezia Nuova, REA 1989).

and Hewer (1982). Fig. 19 shows the planimetric mesh and Fig. 20 gives an instantaneous representation of the flow field corresponding to the simulation of the 4th February 1985 tide (Consorzio Venezia Nuova, REA 1989).

Models of the same type were used to investigate the hydrodynamic behaviour of the mouths (Consorzio Venezia Nuova, REA 1989) and an example of the ebb current at the Lido mouth is represented by Fig. 21.

*Lagrangian models* were used to examine the so-called "residual" circulation in the lagoon (Datei, 1978; Cheng et al., 1982; Rinaldo et al., 1987) and to describe processes dominated by convective transport (D'Alpaos and Degan, 1977), while *dispersion models* have been developed on the basis of the diffusion equation (Fiorillo, 1978; Di Silvio et al., 1977, 1980, 1988; Dejak et al., 1984).

Figure 21. Example of the ebb current at the Lido mouth (from Cons. Venezia Nuova, REA 1989).

### 7.4.3 Physical models

The phenomenon of the hydrodynamics of the mouths has also been analysed by means of *physical models*, both aerodynamic and hydraulic. The *aerodynamic models* have been built to the planimetric scale 1:3,000 and the altimetric scale 1:1,000. Given the great reduction in size, the evaluation of the velocities and of the head losses was effective more for the comparison of the reactions in different possible projects than in absolute terms (Adami et al., 1981; Da Deppo et al., 1987; Consorzio Venezia Nuova, 1988).

The *hydraulic models* have been constructed at the Voltabarozzo Experimental Center run by the Ministero dei Lavori Pubblici (Italian Ministry

of Public Works). A general model of the Lagoon with a horizontal scale 1:250 and a vertical scale of 1:20 has been built with a stable bed covering an area of about 16,000 m<sup>2</sup> (Baroncini, 1983). Difficulties arising from its use, above all regarding the space and time distribution of tide among the three mouths and the adjusted reproduction of wall friction because of the very high distortion of the model, have slowed down its effective use. Nevertheless, some results enable us to understand the behaviour of the inner area of the Lagoon, where the three dimensional features of the flow become important. Greater use has been made of separate models of the three mouths, each built to the geometric scale of 1:60 (both horizontal and vertical). Such models, which are applied under steady conditions, have provided useful information about the flow field and the losses distribution of the tidal currents (Consorzio Venezia Nuova, 1986). They still have the task of selecting the best conditions for the projected solutions.

## 7.5 Surface waves

The Venetian Gulf is not subject to particularly heavy sea waves because it has an "effective" maximum fetch of 300 km in the "sirocco" direction 130°-140° N and of 80 km in the "bora" direction 70°-80° N. Furthermore, the depths remain fairly uniform; they do not go beyond 25 m in the bora direction and increase in the sirocco direction being under 40 m at 100 km from Venice.

The wind regime shows two directional modes that can be seen also in the waves. Information about significant heights and directions of the waves (Fig. 22) has been provided by the Hydrological Service of ENEL (the Italian general Electric Company) at a depth of about 25 m in front of the Po-Delta, and by CNR-IDGM (Dynamic Mass Institute of the National Research Council) and Consorzio Venezia Nuova on a platform placed at about 15 km in front of Malamocco at a depth of 16 m (Consorzio Venezia Nuova, 1987, 1988). In effect the two prevalent directions, around 70° N and 130° N, have been confirmed. Significant waves with a height  $H_s \geq 3$  m have a frequency of less than 1%, while the height  $H_s \geq 1$  m appears with a frequency of 10%.

Regarding wave propagation in the inlets, both direct measurements and evaluations using physical and mathematical models have been carried out. Various mathematical models have been commissioned by the Consorzio Venezia Nuova from the Wallingford Hydraulic Research Laboratory and the Delft Hydraulics (Consorzio Venezia Nuova, 1987), each model having a specific field of application: from the open sea to the mouths, and from the areas surrounding the jetties as far as the interior of the mouth canals.

## 7.6 The planned defense works

Protection from the "acque alte" must be carried out with the assurance of an exchange of the basin water that is sufficient to avoid worsening the ecological state in the lagoon. Even if the effects of new purification plants can be counted

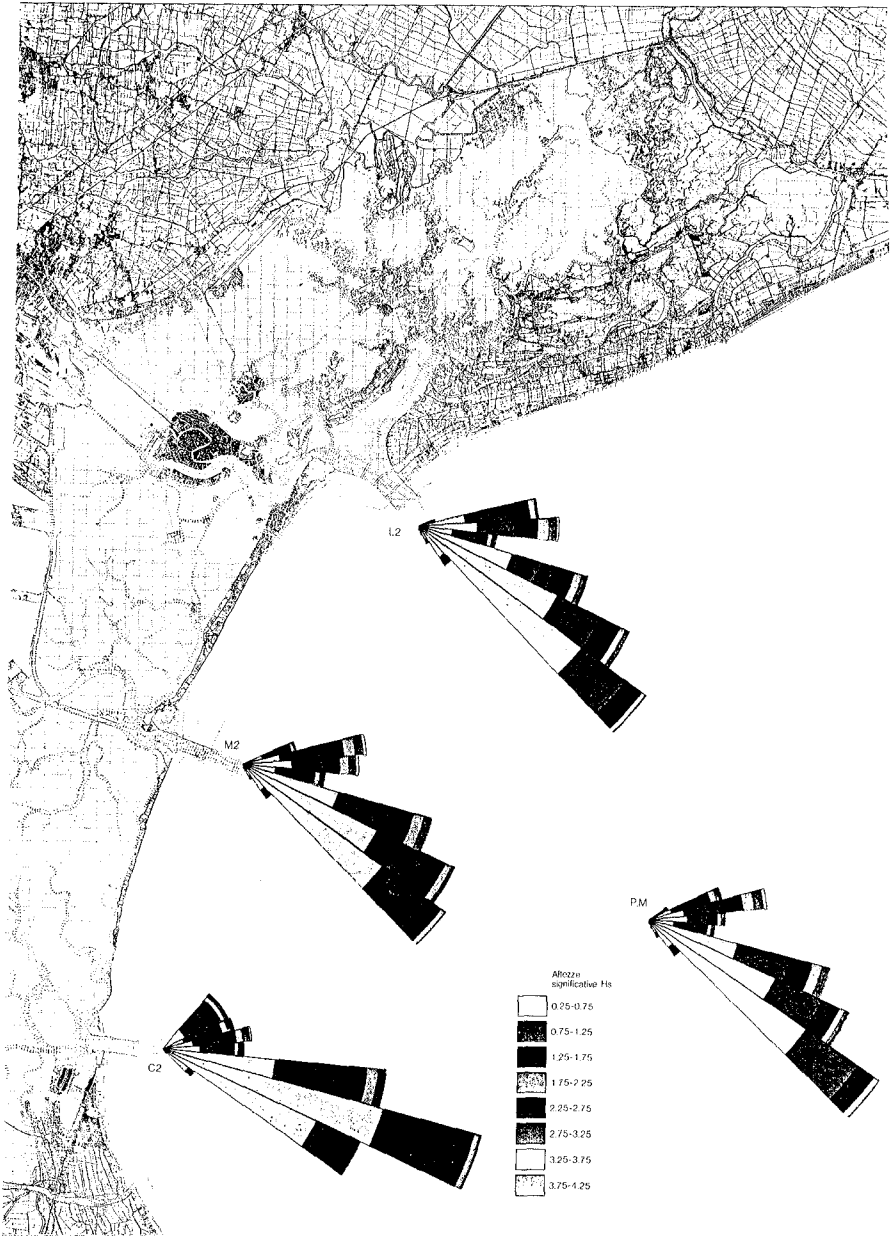

Figure 22. Sea wave directions and amplitudes (from Cons. Venezia Nuova, REA, 1989).

Figure 23. Experiments on the dispersion of pollutants in the sea caused by the ebb current (from Arato et al., 1983).

on as far as regards the reduction of industrial pollution, the agricultural and, partially, anthropic contribution is still high. Therefore, the ebb and flow of the tide into and out of the lagoon is still a factor essential for its vitality.

The process concerning the tidal currents around the openings of the inlets was studied by Blondeaux, De Bernardinis and Seminara (1982). The flow has been considered irrotational in the flood phase, while the shedding of vorticity in the ebb phase has been simulated by a discrete vortex technique. The resulting asymmetry of the flowfields during the different tidal phases justifies the dispersion of pollutants in the sea, also experimentally verified (Arato et al., 1983) (Fig. 23).

A second binding condition for the defence works is evidently to conserve the navigability of the mouths, with regard to the manoeuvrability of ships and the depth of the waterways and also to the duration of their possible use. Accordingly, current velocities must not exceed 2.00-2.50 m/s.

Furthermore, such works should not provoke erosion and, in general, not modify the morphological condition. Finally, they must not stand out in the lagoon landscape.

The planning studies, carried out by TECHNITAL on behalf of CONSORZIO VENEZIA NUOVA, have shown up the interconnections among the "acque alte" defence works and those of morphological re-equilibrium of the lagoon system and for the protection of littorals and the lagoon contours. The morphological evolution of the lagoon can be predicted on the basis of a long-term balance of sediment suspension and transport (Di Silvio and Gambolati, 1990). Thus, before carrying out the safeguarding works against high tides, some morphological modifications are being undertaken. These are the necessary works for the littoral protection, mentioned above, and the experimental ones (such as the reconstruction of the "barene") to halt the environmental deterioration of the Lagoon in danger of becoming a bay.

On the other hand, as regards the real safeguarding against the "acque alte", we had a choice between two ways (Agema et al., 1983).

- A) to have recourse to *permanent narrowings* of the mouths or, anyway, to concentrate resistances so as to provoke a considerable reduction of the tidal amplitude in the Lagoon, particularly in Venice;
- B) to install *mobile floodgates* at the mouths, able to interrupt completely the tidal flow when they are in use and which are not visible and do not interfere with the flow when they are open.

Figure 24. Comparison between the solutions A and B.

The differences between the two criteria are pointed out by Fig. 24. The first solution has the advantage of being simpler to construct and that of reducing the middle-high tides that are the most frequent. On the contrary the disadvantages are: the high tides of aperiodic kind are not sufficiently reduced, as already said, the currents become very fast in the narrowings and would therefore be dangerous for navigation and bottom erosion and, above all, the volume of sea-lagoon exchange would be permanently reduced. Such a reduction, in relative terms, would be greater or at least equal to the relative reduction of the tidal amplitude,

thus resulting in an equivalent relative increase of pollutant concentration in the Lagoon.

The *permanent narrowings* solution appears as a *defence system* against high tide whose efficiency is conditioned by the dynamics themselves of the tides.

The other solution, using *mobile floodgates*, behaves as a *control system* of the lagoon tides, able to limit the maximum levels to a given threshold, completely independent of the kind of tide. The influence on the water exchange is evidently limited to the periods when the gates are closed, periods that should now be relatively short in the course of a year.

The current project is based on this second criterion, having also rejected the possible use of partial permanent narrowings to support the mobile floodgates. This last choice is a result of the consideration that the benefit in the cost reduction seems lower than the disadvantages of the presence of obstructions, as sources of vorticity and as reducers of the mouth efficiency in the exchange of water. It is always possible, though, to reduce partially the openings even with the mobile gates.

## 7.7 The floodgates

The criterion of being able to close with moveable barriers wide passages at the mouths had already been adopted in 1981 by the group of Experts commissioned by the Ministero dei Lavori Pubblici (1981) to study the feasibility of the tidal protection of the Venice Lagoon. Since that time the chosen barriers were of the type with a hinge at the base, normally at rest on the bottom of the passage. The closure is obtained through the gate floating up due to the expulsion of water from its compartments by compressed air.

Such a choice is connected with the ability of the system to work in very wide canals without intermediate piers, with no superstructure and with an apparatus which can be hidden completely within the bottom. This type of mobile barrier exercises only a limited reflection of the open sea waves in so far as it oscillates with them.

Many variations of the modular barrier units have been proposed in recent years, both as to form, structure and foundations and, above all, as to the operative pneumatic system and position control.

Without going into further detail, Fig. 25 suffices to illustrate the transversal section of a component. An experimental prototype, called MOSE, was installed for a few years at the interior of the Lido mouth, towards Treporti. It provided useful information about the opening and closing operation and about the assembly and dismantling of the component, necessary for its maintenance and repair.

Figure 25. Section of a mobile floodgate.

## 7.8 The works at the mouths

The planimetric design of the floodgates at the mouths is almost complete today. It notably differs from the 1981 feasibility study above all because the present gates take up the entire opening of each inlet, without need of the fixed side barriers and without the breakwaters foreseen in the earlier design.

The above decision was the result of two principal motives. The first is the necessity of not reducing the flow through the openings in order to maintain the steady renewal of water, with the advantage of a flow without obstacles which cause dangerous vorticity. The second arises from the positive experiments carried out by Estramed (Roma) and in progress in Delft and in Voltabarozzo using physical models that prove the safe behaviour of the floodgates under attack from the sea waves.

Fig. 26 shows the design of the works planned for the Lido mouth, where an isle of support is foreseen in the center of the canal; Fig. 27 shows the works designed for Malamocco and Fig. 28 those for Chioggia. A refuge harbour is located on a side of each mouth.

I end my report with these images. They illustrate works of a new technology which must be absorbed into one of the richest areas in the world for nature and art. At the same time, however, they point out a way - perhaps the only way - of defending Venice against the assault of that very sea which is also its vocation and its life.

# CHAPTER 1

## BREAKING WAVES PROPAGATING OVER A SHOAL

J.A. Battjes<sup>a</sup> and S. Beji<sup>b</sup>

### Abstract

Spectral evolution of breaking and nearly breaking waves propagating over a submerged trapezoidal bar has been investigated in laboratory experiments. It is found that wave breaking itself does not play a crucial role in the evolution of the spectral shape, but contributes simply by extracting energy roughly in proportion to the local spectral density. For nonbreaking waves, a Boussinesq model with improved dispersion characteristics is found to simulate the wave evolution very well. On the basis of these findings, it is suggested to combine a semi-empirical model for the overall energy dissipation with a nondissipative Boussinesq model so as to obtain a model for simulation of spectral evolution of breaking waves.

### 1. Introduction

Harmonic generation in waves passing over submerged obstacles has long been known experimentally (Johnson et al., 1951; Jolas, 1960; Byrne, 1969; Young, 1989). On the theoretical side, Phillips (1960), Bretherton (1964), Mei and Unlüatta (1972) and Bryant (1973), among others, clarified the basic mechanisms of harmonic generation.

While for nonbreaking waves the generation of high-frequency energy may entirely be attributed to conservative nonlinear effects, the role of wave breaking in this process has not been clarified. The aim of the work reported here is to help resolve this question and to contribute to the development of capabilities for numerical modelling of the dominant processes involved.

A full account of the work reported here can be found in Beji and Battjes (1992a, 1992b) for the experimental and the numerical aspects, respectively.

## 2. Experiments

The experiments were carried out in a wave flume of the Department of Civil Engineering, Delft University of Technology. The flume is 37.7 m long and 0.8 m wide. In its midsection, a trapezoidal bar was built. See Figure 1. At the downwave end a gently sloping spending beach was present from previous experiments. The still-water depth was 0.4 m over the original, horizontal flume bottom and had a minimum of 0.10 m above the bar crest. Periodic and irregular input waves were used, the latter with a JONSWAP-type spectrum and a very narrow band spectrum. Peak frequencies were  $f_p=0.4$  Hz,  $f_p=0.5$  Hz and  $f_p=1.0$  Hz. Measurements of the free surface elevations were made with parallel-wire resistance gages at eight different locations as sketched in Figure 1.

Figure 1. Longitudinal sections of wave flume

### 3. Experimental Results

Experiments with three different wave conditions were done: steep but non-breaking waves, spilling breakers and plunging breakers.

In order to make direct comparisons of spectral evolutions for different wave conditions, spectral estimates obtained at stations 2, 4, 6, and 8 for JONSWAP type incident waves ( $f_p=0.4$  Hz), for non-breaking and plunging breakers, are normalized and plotted together. The normalization is such that the total area under the spectrum for every case is unity. Figure 2 shows these comparisons. Obviously, the spatial evolution of the spectral shape follows almost identically the same trend regardless of the occurrence of wave breaking. The same was observed in the case of narrow-banded incident waves with the same peak frequency (not shown here).

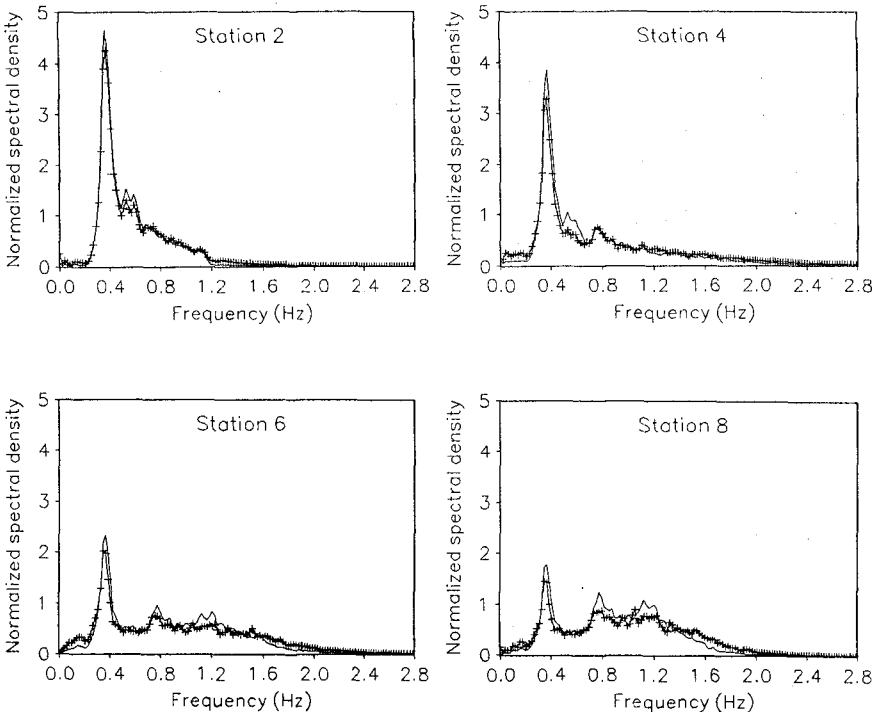

Figure 2. Normalized spectra at different stations; —: Non-breaking waves; +++: Plunging breakers. Incident waves: Jonswap-spectrum with  $f_p=0.4$  Hz.

The measurements with the short waves ( $f_p=1.0$  Hz) revealed little spectral shape evolution over the obstacle. See Figure 3. The shape of the input spectrum in every case remained nearly intact over the entire region and only a relatively small amount of high frequency energy was generated. For this reason we shall not pursue this case any further.

Figure 3. Normalized spectra at different stations; —: Non-breaking waves; +++: Plunging breakers. Incident waves: Jonswap-spectrum with  $f_p=1.0$  Hz.

#### 4. Numerical modeling

##### 4.1 Nonbreaking waves

A Boussinesq type model with improved dispersion characteristics was chosen as the wave propagation model. We used it in the following form:

$$u_t + uu_x + g\zeta_x = \frac{1}{3}h^2 u_{xxt} + hh_x u_{xt} + bh^2 (u_t + g\zeta_x)_{xx}$$

$$\zeta_t + [(h+\zeta)u]_x = 0$$

where  $\zeta$  denotes the surface displacement and  $u$  the vertically averaged horizontal velocity. For  $b=0$  the momentum equation reduces to its standard form as it was derived by Peregrine (1967) for mildly sloping bottoms. For  $b=1/15$  a major improvement for the dispersion characteristics is achieved. This extension to the original Boussinesq equations was first suggested by Witting (1984) and further elaborated by Madsen et al. (1991). A model with good dispersion characteristics is essential in this study because of the decomposition of the wavefield behind the submerged obstacle into free high frequency components which may be regarded as relatively deep water waves.

In the numerical treatment of the governing equations, we basically followed the guidelines given in Peregrine (1967), except for some minor but crucial adjustments.

In Figure 4, the left column gives measured and computed free surface elevations for nonbreaking but significantly nonlinear random waves at selected stations. The right column shows the comparisons for the measured and computed spectra at the same stations. The agreement is remarkable and justifies our choice of the governing equations.

#### 4.2 Breaking waves

The observation that in our experiments the evolution of the spectral shape is not significantly affected by wave breaking suggests the possibility of using a (non-spectral) model for the dissipation of total wave energy by breaking (e.g., Battjes and Janssen, 1978), in conjunction with a conservative (potential-flow) model incorporating nonlinear wave-wave interactions.

Results of a fully integrated model of the kind indicated here are not yet available. Nevertheless, to indicate the potential feasibility of this approach we show results for the plunging breaker case (JONSWAP spectrum,  $f_p = 0.4$  Hz) for which the initial surface elevations are reduced (in the calculations) with a factor 1.5 so as to ensure

Figure 4. Comparisons of measured (—) and computed (+++) surface elevations (Left) and spectra (Right) at different stations. Incident waves: Jonswap-spectrum with  $f_p=0.5$  Hz; No breaking.

non-diverging calculations, as in the case of the steep but non-breaking waves simulated at full strength. The idea behind this is that the strength of the nonlinearities in post-breaking waves is expected to be comparable to that in non-breaking waves of similar height.

Figure 5 compares the evolutions of the measured spectral shape for plunging breakers with those of the computations carried out with the down-scaled amplitudes. All the spectra shown have been normalized, as in Figure 2, so that their integral is unity. (Minor differences between the measured spectra in the two figures are due to the fact that the spectra in Figure 5 were calculated from a partly different set of time series, and with a coarser frequency resolution, than those shown in Figure 2.) It can be seen in Figure 5 that the spectrum, computed on the basis of an artificially reduced initial wave height, evolves in a similar manner as the observed spectrum does for the breaking waves.

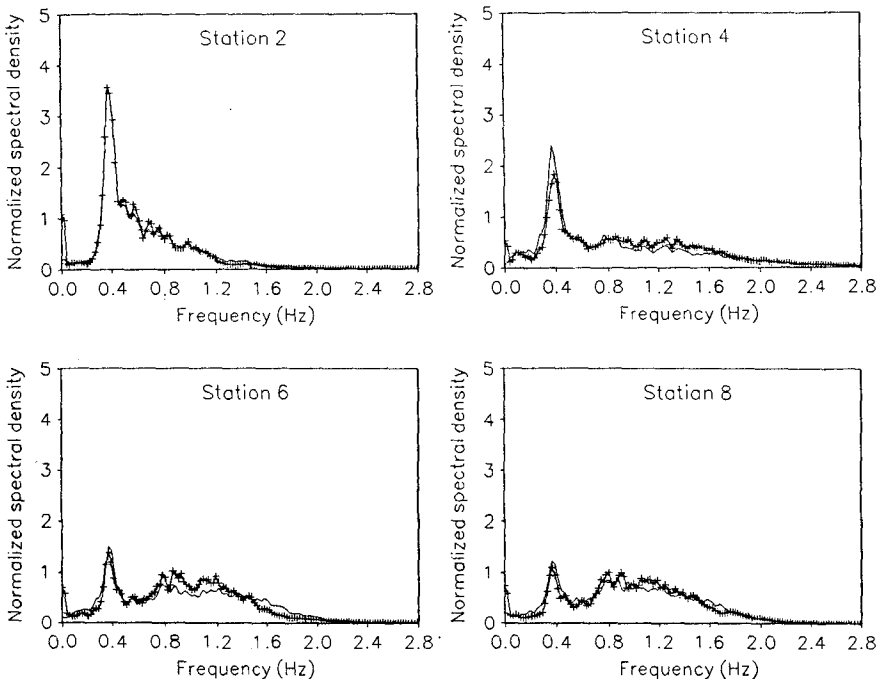

Figure 5. Comparison of measured (—) normalized spectra for plunging waves and normalized spectra computed with reduced initial values of surface elevations (+++). Incident waves: Jonswap-spectrum with  $f_p=0.4$  Hz.

This is taken as an indication that it is worthwhile to develop the combined modeling approach sketched above.

## 5. Conclusions

Energy spectra obtained from laboratory measurements are analyzed to clarify the effects of wave breaking on the inherently nonlinear phenomenon of high frequency energy generation and transfer in the spectra of waves traveling over submerged profiles. For the conditions in these experiments, it is found that wave breaking merely dissipates energy in averaged manner and does not introduce drastic alterations to the spectral shape.

A practical application of this finding is the possibility of combining a weakly nonlinear non-dissipative model with a semi-empirical dissipation formulation for the total energy.

## CHAPTER 2

### Transformation of nonbreaking waves over a bar

S. Beji<sup>1</sup>, T. Ohyama<sup>2</sup>, J.A. Battjes<sup>3</sup> and K. Nadaoka<sup>4</sup>

#### Abstract

Data collected from measurements performed in waves propagating over a trapezoidal bar on a horizontal bottom are used to test a fully nonlinear numerical model. The experiments include both regular and random waves. Wave form evolutions in the shoaling region, the near resonant wave-wave interactions over the bar, and finally the decomposition behind the bar are well predicted. The results provide assurance for the reliability of the numerical model.

#### 1. Introduction

Numerical modeling of evolving surface gravity waves based on the full nonlinear equations for irrotational motion was initiated by Longuet-Higgins and Cokelet (1976). Numerous alternative models have been presented since (Vinjé and Brevig, 1981; Dold and Peregrine, 1984). Surface profiles predicted by these models are in general quite realistic, even in the phases of profile steepening and turnover as in plunging breakers

(prior to impact). However, quantitative comparisons between predictions and observations are rarely given. The purpose of the present paper is to give such comparisons, for the demanding case of deformation and decomposition of near-breaking waves passing over a shallow bar.

It is known that relatively long waves passing over a bar or another submerged obstacle decompose into shorter components. In the shoaling region the amplitudes of the bound harmonics are initially relatively small. If the wave field continues to propagate into a shallower region, such that the medium becomes non-dispersive for this particular wave field, then the near resonance conditions for triplet-interactions are satisfied (Phillips, 1960). At this stage, a rapid energy flow from the primary wave components to the higher harmonics is observed and the amplitudes of higher harmonic components become appreciable.

The passage into deeper water results in the release of the bound harmonics followed by interactions taking place among these released wave components, which introduces drastic and rapid changes in wave forms. During this final stage, the amplitude of higher harmonics become comparable with, in some cases larger than, the primary wave amplitudes (Kojima, H. et al., 1990; Ohyama and Nadaoka, 1991; Beji and Battjes, 1992). Obviously, predicting the evolutions of a given incident wave field in such regions poses a real challenge; this suggests a good test case for a nonlinear numerical wave propagation model.

The paper presents a brief account of a comparison of results of simulations with a numerical nonlinear model with experimental data for conditions as described above. For details, reference is made to Ohyama et al. (1992).

## 2. Experiments

The measurements reported here were carried out as a subset of a larger program, an account of which can be found in Beji and Battjes (1992).

The experiments were performed in a wave flume of the Department of Civil Engineering, Delft University of Technology. The flume is 37.7 m long, 0.8 m wide, and 0.75 m high. It is equipped with a hydraulically driven, piston-type random-wave generator. The bottom profile is sketched in Figure 1.

Figure 1. Definition sketch of wave flume and locations of wave gages.

A submerged trapezoidal bar with an upslope of 1:20 and a 2 m horizontal crest followed by a 1:10 downslope was constructed. The still water depth was 0.4 m in the deeper region and 0.1 m in the shallowest part above the horizontal section. At the end of the flume opposite to the wave generator, a roughened plane beach with a 1:25 slope served as a wave absorber.

Measurements of the free surface displacements were made with parallel-wire resistance gages at 7 different locations as shown in Figure 1. The time history of the wave-board displacement was recorded also. In each run, data were recorded simultaneously from 8 separate channels at a sampling frequency of approximately 25 Hz.

Four different measurements were realized: two different spectral shapes (periodic waves with a spike spectrum and random waves with a JONSWAP target spectrum), and two different peak frequencies (0.5 Hz and 0.8 Hz, referred to as the "long" waves and the "short" waves, respectively). All the measurements reported here were for non-breaking waves. The following incident wave heights were selected for regular waves: 2.0 cm for 0.5 Hz, and 2.5 cm for 0.8 Hz. Irregular waves required somewhat smaller incident significant wave heights to prevent occasional breaking. Thus, for irregular waves the following incident significant waves heights ( $H_{1/3}$ ) were used: 1.8 cm for 0.5 Hz, and 2.3 cm for 0.8 Hz.

### 3. Numerical model

Computations have been carried out with a numerical model developed by Ohya and Nadaoka (1991). It is based on the time-dependent boundary element method for potential flow. The field equations outside the sponge layer at the downwave side (Bernoulli and Laplace) and the boundary conditions at the bottom and the free surface are standard and are not reproduced here.

Figure 2 is an illustration of the numerical "wave tank", specifying the geometry and the labelling of the contour around the computational domain.

Figure 2. Computational domain.

The original version of the model contains a non-reflective wave generator, which combines a vertically distributed wave-making source with a numerical filter. However, in the present calculations the same wave generating method (piston-type) is used as in the model experiments, as expressed by the following equation:

$$\frac{\partial \phi}{\partial x} = U(t) \quad (\text{on } S_2), \quad (1)$$

in which  $\phi$  is the velocity potential and  $U$  is the horizontal velocity of the wave board.

A numerical wave-absorption filter is located at the trailing end of the domain for the open boundary treatment. The filter is composed of a sponge layer, which absorbs the incoming wave energy by frictional damping according to the following equation:

$$\frac{\partial \phi}{\partial x} = -\frac{1}{\sqrt{gh_D}} \left( \frac{\partial \phi}{\partial t} + \mu \phi - \int_{x_3}^{x_4} \frac{\partial \mu}{\partial x} \phi \Big|_{on S_F} dx \right) \quad (on S_4), \quad (3)$$

in which  $\mu$  is the damping factor of the sponge layer, of which the magnitude is distributed linearly in the layer, as shown in Figure 2, in order to reduce the wave reflection at the leading side of the layer. In view of the results of a previous study (Ohyama and Nadaoka, 1991), the width of the sponge layer is set nearly equal to the incident wave length (corresponding to the peak frequency in case of random waves), and the maximum value of the damping factor in the sponge layers,  $\mu_{max}$ , is given as  $\mu_{max}(h_D/g)^{1/2}=0.25$ . At the leeside of the sponge layer, a Sommerfeld type radiation condition was applied to absorb whatever wave energy would be left after passing through the sponge layer.

Applying Green's theorem and the weighted residual method to the governing equations, integral equations can be derived; these are discretized spatially by using linear elements. In the discretized equations,  $\phi$  (on  $S_F$ ,  $S_V$ ,  $S_2$  and  $S_4$ ), and  $\partial \phi / \partial t$ ,  $\eta$  and  $\partial \eta / \partial t$  (on  $S_F$ ) are invoked as unknown variables. These variables are rewritten by using  $\Delta \phi$  and  $\Delta \eta$  which are the increments of  $\phi$  and  $\eta$ , respectively, during the time increment  $\Delta t$ . Linear algebraic equations to be solved for  $\Delta \phi$  (on  $S_F$ ,  $S_V$ ,  $S_2$ , and  $S_4$ ) and  $\Delta \eta$  (on  $S_F$ ) are consequently obtained.

In all the computations examined, the time increment,  $\Delta t$ , was set to 1/32 of the incident wave period (spectral peak period for random waves). The horizontal projection of the distance between the surface nodes,  $\Delta x$ , on the other hand, was varied in space. The values relative to the incident wave lengths,  $\Delta x/L$ , were 1/15 for the interval  $0 \leq x \leq 7.6m$  and 1/40 for  $x > 7.6m$  for the 0.5-Hz waves, and were 1/15 for  $0 \leq x \leq 10.0m$  and 1/20 for  $x > 10m$  for the 0.8 Hz-waves.

The only experimental data used as input to the numerical model are the bottom profile, the still-water level, and the time history of the wave-board displacement (used to calculate the wave-board velocity  $U(t)$  in eq. 1); on the downwave side, full absorption has been assumed. The initial condition for each case was the still-water condition, i.e.,  $\phi=\eta=0$ . Numerical results after 10 periods from the cold start are used for the subsequent discussion.

#### 4. Comparisons of measurements and computations

For the case of the long ( $f = 0.5$  Hz), monochromatic waves, Figures 3a-3d show the comparisons of measured and computed wave profiles at the stations 1, 3, 5, 7, and Figure 4 shows the spatial evolutions of the lowest three harmonics amplitudes of the surface displacement. The elevations have been normalized with  $H_0$ , the target value of the incident wave height.

Figure 3. Measured (—) and computed (ooo) wave profiles for monochromatic waves,  $f=0.5$  Hz, at stations 1, 3, 5 and 7 (a, b, c and d).

Figure 4. Measured (o:  $n=1$ )( $\cdot$ :  $n=2$ )( $\Delta$ :  $n=3$ ) and computed (—:  $n=1$ )(.....:  $n=2$ )(- - -:  $n=3$ ) spatial evolution of harmonic amplitudes for monochromatic waves,  $f=0.5$  Hz.

The overall agreement is excellent, especially in the upslope region and over the horizontal part. In the downslope region, some minor differences between measurements and computations are observed. These discrepancies are attributed mainly to the fact that the spatial resolution may not have been sufficient in the downslope region because in this region waves with smaller wavelengths become dominant (see Figure 4) and consequently the initially adopted resolution becomes relatively coarse.

Figures 5a-5d and Figure 6 show similar comparisons for the short monochromatic waves. The wave form in this case (short waves) does not evolve appreciably. The wave is closer to being a higher order Stokes type wave and does not behave as a shallow-water wave. Consequently, even in the shallowest region, the near resonant conditions for three-wave interactions are not satisfied and the growth rate of higher harmonics remains low.

The agreement between computations and observations for the short-wave case is not as good as that for the long waves. The reasons for this are believed to be as follows. First, the effect of wave energy dissipation is not taken into account in the numerical model. The error due to this is expected to increase with frequency, therefore should be more significant for the 0.8-Hz waves than it is for the 0.5-Hz waves. A second reason is related to the spatial resolution of the computation. The adopted relative resolution for the 0.8-Hz waves is less than for the 0.5-Hz waves, and may not have been sufficient, especially for the higher harmonics.

For the random incident waves, comparisons are given only for the "long" waves ( $f = 0.5$  Hz) at the odd-numbered stations. The results are shown in Figure 7 (time records) and Figure 8 (spectra). (The surface elevations in Figure 7 have been normalized with  $H_p$ , the target value of  $H_{1/3}$ .) The spectral evolution is substantial and so is the amount of high frequency energy generation.

For the shorter waves (results not shown here), a negligible amount of high frequency energy generation was observed. The spectral shape was found to remain nearly intact at all stations.

Figure 5. Measured (—) and computed (ooo) wave profiles for monochromatic waves,  $f=0.8$  Hz, at stations 1,3,5,7 (a,b,c,d)

Figure 6. Measured ( $\circ$ :  $n=1$ )( $\cdot$ :  $n=2$ )( $\Delta$ :  $n=3$ ) and computed ( $\text{---}$ :  $n=1$ )( $\text{.....}$ :  $n=2$ )( $\text{---}$ :  $n=3$ ) spatial evolution of harmonic amplitudes for monochromatic waves,  $f=0.8$  Hz.

Figure 7. Measured (—) and computed (---) surface elevations for random waves,  $f=0.5$  Hz, at stations 1,3,5,7 (a,b,c,d,)

Although the overall evolution of the random wave forms and energy spectra are well predicted by the numerical model, detailed inspection of the time domain records shows significant differences in amplitude and phases, even in the constant-depth region between wave generator and slope. These are ascribed to insufficient resolution; the normalized mesh size  $\Delta x/L$  was set to  $1/15$  in the initial propagation domain. This may not have been sufficient to reproduce the propagation of the higher-frequency components in the (incident) waves.

Figure 8. Measured (—) and computed (---) energy density spectra of random waves,  $f=0.5$  Hz, at stations 1, 3, 5, 7 (a, b, c, d)

It may further be noticed that the observed energy levels are overestimated in the computations (see e.g. the spectra at station 5 and 7 in Figure 8); the differences increase with propagation distance. This is ascribed to viscous dissipation, which is absent in the computations.

## 5. Conclusions

General agreement between the measurements and the computations is quite satisfactory, provided the computations are done with sufficient resolution. For the long waves the numerical model performs very well, the discrepancies are usually small. The performance of the model is less for the short waves, but still acceptable.

The comparisons presented here show some discrepancies due the absence of dissipation in the

computational model, but that is not considered a serious shortcoming for the intended applications, i.e. near-field computation of strongly non-uniform and steep wave fields near localised topographical features. In such cases, the dissipation plays a minor role, particularly at full-scale (high Reynolds number) instead of the small-scale laboratory situation of the observations discussed here.

Summarising, the results presented here confirm the reliability of the numerical model. As the cost of computing becomes lower, numerical models such as the one tested here will find wider use in engineering applications.

## CHAPTER 3

### PRACTICAL COMPARATIVE PERFORMANCE SURVEY OF METHODS USED FOR ESTIMATING DIRECTIONAL WAVE SPECTRA FROM HEAVE-PITCH-ROLL DATA

Michel BENOIT <sup>1</sup>

#### Abstract

Twelve methods used for estimating the directional wave spectrum from heave-pitch-roll data are compared on realistic numerical simulations. These methods are based on different modelling approaches including simple and sophisticated ones : Fourier Series decomposition, Fit to unimodal or bimodal parametric models, Variational fitting technique, Maximum Likelihood Methods, Eigenvector Methods, Maximum Entropy Methods and Bayesian approach. The comparison is performed in terms of practical aspects such as estimation error, computation time, implementation difficulty... This study must be regarded as a preliminary step devoted to the choice of optimal methods for operational in situ measurements.

#### **1. Introduction :**

The knowledge of directional properties of waves is of greatest interest in ocean and coastal engineering and the directionality of waves has appeared to have a great influence for offshore situations : moored vessels, oil-platforms,... as for nearshore problems : stability of coastal structures, harbour agitation, coastline morphodynamic evolution... A great effort has been devoted in the recent years to the determination of the directional wave spectrum. Several measurement techniques have been proposed for in situ or laboratory applications. They can be divided into several groups depending on the way they proceed :

- the single-point systems that measure at the same location several properties of waves. From this type of sensors one can mention the heave-pitch-roll buoy (Kobune *et al.*, 1985 ; Lygre and Krogstad, 1986 ; Mardsen and Juszko, 1987), the two-component current meter associated with a pressure sensor (Briggs, 1984) and the cloverleaf buoy (Mitsuyasu *et al.*, 1975).
- the gauge arrays that are composed of several sensors set up at various locations. The sensors may be either identical or of various types including for instance current meters and pressure sensors (Hashimoto *et al.*, 1987)
- the remote-sensing systems including active microwave radars (Jackson *et al.*, 1985), aerial stereo-photography techniques...

EDF - Laboratoire National d'Hydraulique, 6, quai Watier 78400 CHATOU, FRANCE

Among these systems the heave-pitch-roll buoy is probably the most widely employed for operational use because it is a compact single-point measurement system of moderate cost and easy keeping. In the meantime the sampling of wave statistics is limited to three properties : the sea-surface elevation (heave) and two orthogonal slopes of sea-surface (pitch and roll). Starting with only three measured quantities the estimation of the directional wave spectrum is a difficult inverse problem for which no unique method can be exhibited. To take maximum advantage of these rather limited information, several methods based on various modelling approaches have then be proposed.

The aim of this study is to compare a large number of these methods on numerical representative sea-state simulations. In this study we are interested in evaluating the ability of the methods to estimate the simulated directional spectra (estimation error) and studying practical aspects of their use (implementation problems, computing time). This preliminary work aims to exhibit practical recommendations for the choice of optimal methods that could then be applied in laboratory or in the field.

## 2. Problem formulation

The directional wave spectrum  $S(f,\theta)$  is a function of wave frequency  $f$  and direction of propagation  $\theta$ . The following classical decomposition is used :

$$S(f,\theta) = E(f).D(f,\theta) \quad (1)$$

in which  $E(f)$  is the one-sided frequency spectrum that may be estimated by a single record of sea-surface elevation. It is related to the directional spectrum by :

$$E(f) = \int_0^{2\pi} S(f,\theta) d\theta \quad (2)$$

$D(f,\theta)$  is the directional spreading function satisfying two important properties :

$$D(f,\theta) \geq 0 \text{ over } [0, 2\pi] \quad \text{and} \quad \int_0^{2\pi} D(f,\theta) d\theta = 1 \quad (3)$$

The following pseudo-integral relation may be written between the directional spectrum and the sea-surface elevation  $\eta$  :

$$\eta(x,y,t) = \int_0^{\infty} \int_0^{2\pi} \sqrt{2.S(f,\theta).df.d\theta} \cdot \cos[2\pi ft - k.(x.\cos\theta+y.\sin\theta) + \varphi] \quad (4)$$

In the present study we assume that the buoy is able to measure the sea-surface elevation and two orthogonal slopes on the sea-surface :

$$\begin{aligned} \eta(t) &= X_1(t) \\ \frac{\partial \eta}{\partial x}(t) &= \eta_x(t) = X_2(t) \\ \frac{\partial \eta}{\partial y}(t) &= \eta_y(t) = X_3(t) \end{aligned} \quad (5)$$

By applying spectral analysis procedures it is possible to compute the cross-spectra  $G_{ij}(f)$  between each couple  $(X_i, X_j)$  of the three measured properties :

$$G_{ij}(f) = 2 \cdot \int_{-\infty}^{+\infty} R_{ij}(\tau) e^{-i2\pi f\tau} d\tau \quad \text{with } R_{ij}(\tau) = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T X_i(t) \cdot X_j(t+\tau) dt \quad (6)$$

The cross-spectra or spectral cross-correlation coefficients are in the general case complex quantities which are often written in the following form :

$$G_{ij}(f) = C_{ij}(f) - i \cdot Q_{ij}(f) \quad (7)$$

$C_{ij}(f)$  is called "coincident spectral density function" or "co-spectrum" and  $Q_{ij}(f)$  is called "quadrature spectral density function" or "quad-spectrum".

By using (4) and the linear relationship between the elevation and the slopes of sea-surface it may be shown that the cross-correlation coefficients for the heave-pitch-roll buoy take the following expressions :

$$\left. \begin{aligned} C_{11}(f) &= \int_0^{2\pi} S(f, \theta) d\theta = E(f) & Q_{11}(f) &= 0 \\ C_{22}(f) &= E(f) \cdot k^2 \int_0^{2\pi} D(f, \theta) \cdot \cos^2(\theta) d\theta & Q_{22}(f) &= 0 \\ C_{33}(f) &= E(f) \cdot k^2 \int_0^{2\pi} D(f, \theta) \cdot \sin^2(\theta) d\theta & Q_{33}(f) &= 0 \\ C_{12}(f) &= 0 & Q_{12}(f) &= E(f) \cdot k \int_0^{2\pi} D(f, \theta) \cdot \cos(\theta) d\theta \\ C_{13}(f) &= 0 & Q_{13}(f) &= E(f) \cdot k \int_0^{2\pi} D(f, \theta) \cdot \sin(\theta) d\theta \\ C_{23}(f) &= E(f) \cdot k^2 \int_0^{2\pi} D(f, \theta) \cdot \cos(\theta) \cdot \sin(\theta) d\theta & Q_{23}(f) &= 0 \end{aligned} \right\} \quad (8)$$

From the twelve real cross-correlation coefficients only six are non equal to zero. Furthermore  $C_{11}(f)$  does not carry any information about the directional distribution and  $C_{11}(f)$ ,  $C_{22}(f)$ ,  $C_{33}(f)$  are tied by the following relation :

$$C_{22}(f) + C_{33}(f) = k^2 \cdot C_{11}(f) \quad (9)$$

that we can use for the calculation of the wave number expression :

$$k = \sqrt{\frac{C_{22}(f) + C_{33}(f)}{C_{11}(f)}} \quad (10)$$

As established so far it is possible to compute by spectral analysis only five independent coefficients at each frequency from which one is devoted to the estimation of the frequency spectrum  $E(f)$  and the four others may be used for the computation of the directional spreading function  $D(f, \theta)$  at this frequency. The problem of directional spectrum estimation is then to determine a continuous function over  $[0, 2\pi]$  satisfying (3) with only four independent integral properties from (8). It is clear that finding a solution to this difficult inverse problem can not be proceeded in an unique way because of the too feeble number of constraints.

### 3. Review of methods used for estimating the spreading function

Among the theoretical modelling approaches proposed in the literature to solve the above exposed problem, twelve operational methods have been selected and implemented in the software **PRD-WAS 1.0** (Pitch and Roll Data - Wave Analysis Software) developed at LNH (Benoit, 1991). Only a short description of the theoretical background of each method is reported below. Further information may be found in the mentioned references.

1. Truncated Fourier Series (TFS): the directional spreading function is expressed as a truncated series whose first four coefficients are easily computed from the spectral cross-correlation coefficients :

$$D(f, \theta) = \frac{1}{\pi} \left( \frac{1}{2} + a_1(f) \cdot \cos \theta + b_1(f) \cdot \sin \theta + a_2(f) \cdot \cos 2\theta + b_2(f) \cdot \sin 2\theta \right) \quad (11)$$

2. Weighted truncated Fourier Series (WFS): Following Longuet-Higgins *et al.* (1963) a weighting function is used to avoid negative values of the former method :

$$D(f, \theta) = \frac{1}{\pi} \left( \frac{1}{2} + \frac{2}{3}(a_1(f) \cdot \cos \theta + b_1(f) \cdot \sin \theta) + \frac{1}{6}(a_2(f) \cdot \cos 2\theta + b_2(f) \cdot \sin 2\theta) \right) \quad (12)$$

3. Fit to Unimodal Gaussian Model (1MF): A unimodal parametric model of gaussian type (Borgman, 1969) is used whose two unknown parameters  $\alpha$  et  $\sigma$  are computed from the first two Fourier coefficients of the spreading function :

$$D(f, \theta) = \frac{1}{\sqrt{2\pi} \sigma} \exp\left(-\frac{(\theta - \alpha)^2}{2\sigma^2}\right) \quad (13)$$

4. Fit to Bimodal Mitsuyasu Model (2MF): A bimodal parametric model obtained from linear combination of two unimodal Mitsuyasu-type models is used:

$$D(f, \theta) = \frac{\lambda}{\Delta(s_1)} \cos^{2s_1}\left(\frac{\theta - \theta_1}{2}\right) + \frac{1 - \lambda}{\Delta(s_2)} \cos^{2s_2}\left(\frac{\theta - \theta_2}{2}\right) \quad (14)$$

Its five unknown parameters are calculated from the spectral cross-correlation coefficients by using a method based on the least-square method (Benoit, 1991).

5. Variational Fitting Technique: Long-Hasselmann Method (LHM): Long and Hasselmann (1979) developed this method by which an initial simple estimate is iteratively modified to minimize a "nastiness" function that takes into account the various conditions on the spreading function.

6. Maximum Likelihood Method (MLM): By this method the spreading function is regarded as a linear combination of the cross-spectra :

$$D(f, \theta) = \sum_{i=1}^3 \sum_{j=1}^3 w_n^*(\theta) \cdot w_m(\theta) \cdot G_{ij}(f) \quad (15)$$

The weighting coefficients  $w_n$  are calculated with the condition of unity gain of the estimator in the absence of noise (Oltman-Shay and Guza, 1984).

7. Iterative Maximum Likelihood Method (IMLM): The estimator obtained by the former method is not consistent with the data cross-spectra. It is also iteratively modified to let its spectral cross-correlation coefficients become closer to the ones obtained from the data (Oltman-Shay and Guza, 1984).

8. EigenVector Method (EVM): Mardsen and Juszko (1987) proposed a refinement of the MLM in which the data are partitioned into signal and noise through the calculation of the eigenvalues of the spectral cross-correlation matrix.

9. Iterative EigenVector Method (IEVM): the same iterative improvement as proposed for the MLM is applied to the Eigenvector Method.

10. Maximum Entropy Method - Version 1 (MEM1): Lygre and Krogstad (1986) proposed to find an estimate of the spreading function by maximizing :

$$\chi = - \int_0^{2\pi} \ln (D(f,\theta)) d\theta \quad (16)$$

under the constraints given by the spectral cross-correlation coefficients.

11. Maximum Entropy Method - Version 2 (MEM2): The same approach may be considered by using Shannon's definition for entropy (Nwogu *et al.*, 1987) :

$$\chi = - \int_0^{2\pi} D(f,\theta) \ln (D(f,\theta)) d\theta \quad (17)$$

With the former version the expression of the directional estimate is easily obtained, but with the latter a non-linear system of equations has to be solved.

12. Bayesian Directional Method (BDM): With this statistical technique used for regression analysis (Hashimoto *et al.*, 1987), no *a priori* assumption is made about the spreading function which is considered as a piecewise-constant function over  $[0, 2\pi]$ . The unknown values of  $D(f,\theta)$  on each of the  $K$  segments dividing  $[0, 2\pi]$  are obtained by considering the constraints of the spectral cross-correlation coefficients and an additional condition on the smoothness of  $D(f,\theta)$ .

#### 4. Description of the performed tests

Numerical sea-state simulations are performed by following the single direction per frequency method (Miles, 1989) based on a discretization of (4) :

$$\eta (x,y,t) = \sum_{n=1}^N A_n \cos (2\pi.f_n.t - k_n(x.\cos \theta_n + y.\sin \theta_n) + \varphi_n) \quad (18)$$

$$\left. \begin{aligned} \text{with : } A_n &= \sqrt{2 S (f_n, \theta_n) \Delta f_n \Delta \theta_n} \\ \varphi_n &= 2 \pi U [0,1] \quad (\text{random phase}) \\ f_n &= (n - 1) \Delta f \quad \text{with } \Delta f = \frac{f_c}{N} = \frac{1}{T} \\ \theta_n &\text{ are of the form } k.\Delta\theta, \text{ but randomly distributed over } [0, 2\pi] \end{aligned} \right\} \quad (19)$$

The frequency spectrum  $E(f)$  is a classical JONSWAP spectrum with a significant wave height of 4 m, a peak frequency of 0.1 Hz and a peak-factor  $\gamma = 3.3$ .

The directional spreading function is of the form :

$$\Pi_{p1,\alpha1,p2,\alpha2,\lambda}(\theta) = \lambda.\Pi_{p1,\alpha1}(\theta) + (1-\lambda).\Pi_{p2,\alpha2}(\theta) \quad \text{with } 0 \leq \lambda \leq 1 \quad (20)$$

$$\left. \begin{aligned} \text{with : } \Pi_{p,\alpha}(\theta) &= \frac{1}{\Lambda(p)} \cos^2 p(\theta-\alpha) \quad \text{if } \theta \in \left[ \alpha - \frac{\pi}{2}; \alpha + \frac{\pi}{2} \right] \\ \Pi_{p,\alpha}(\theta) &= 0 \quad \text{if } \theta \in \left[ \alpha - \pi; \alpha - \frac{\pi}{2} \right] \cup \left[ \alpha + \frac{\pi}{2}; \alpha + \pi \right] \end{aligned} \right\} \quad (21)$$

$\Lambda(p)$  is a normalizing constant to ensure the properties (3).

A Gaussian real white noise is added to the simulated time series. Its spectral density is constant from zero to the Nyquist frequency  $f_c$ . The noise level is expressed in terms of a percentage of the RMS (root mean square) amplitude of sea-surface elevation as proposed by Nwogu *et al.* (1987).

The simulated time series have a time step of 0.5 s and a duration of 4096 s (8192 points per signal). This represents a record of around 410 waves with 20 points per wave (at peak frequency).

The spectral estimator is based on the technique of the averaged periodogram on the whole simulated sequence partitioned in segments of 1024 points. An overlapping of 25% between adjacent segments is used and a parabolic data window is applied to the common part of two adjacent segments. The resulting frequency resolution is 0.002 Hz.

Three test cases are performed with the following characteristics for the directional spreading function :

- case 1 : Unimodal Broad Spreading Function ( $\lambda=1 \mid p_1=1 \mid \alpha_1=120^\circ$ )
- case 2 : Unimodal Thin Spreading Function ( $\lambda=1 \mid p_1=10 \mid \alpha_1=70^\circ$ )
- case 3 : Bimodal Spreading Function ( $\lambda=0.5 \mid p_1=2 \mid \alpha_1=130^\circ \mid p_2=6 \mid \alpha_2=240^\circ$ )

The first case rather represents a wind-sea with a large spread around a main direction of propagation. In the second case the spread around the main direction of propagation is much lower indicating a rather "old" swell. In the third case we have a crossed-sea with two main directions of propagation. The three directional spreading functions are presented on figure 1.

Figure 1: The three Directional Spreading Functions

To perform the comparison of the methods five criterion are taken into account :

a) **the error of the estimate**  $\hat{D}(\theta)$  produced by the method versus the simulated spreading function  $D(\theta)$ . This error is measured by the Weighted Average Percent Error (WAPE) as proposed by Olman-Shay and Guza (1984) :

$$\text{WAPE} = \frac{\sum_{\theta} |\hat{D}(\theta) - D(\theta)|}{\sum_{\theta} D(\theta)} \times 100 \quad (22)$$

- b) **the sensitivity to the shape of the spreading function**
- c) **the computation time** measured on an IBM 3090 Computer
- d) **the noise sensitivity**
- e) **the difficulty of implementation**

## 5. Presentation and discussion of the results

The spreading functions estimated at peak frequency by the various methods on the three cases with a noise level of 20% are reported on figures 2, 3 and 4 respectively. On these figures the target function is represented by a dashed line and the spreading functions estimated at both the frequency surrounding the theoretical peak frequency are represented by continuous lines with different marker symbols. The WAPE and CPU Time are also reported on the same figures. An overview for the comparison of the various methods on the three cases is presented on figure 5 where performance is visualized by points representing WAPE versus CPU Time.

Because on the great volume of results to be presented in such a comparative study only nine methods appear on these figures. Both the Fourier Series methods (TFS and WFS) are not reported because it is now well known that they do not give good results although they are fast and easy to implement. The former often produces negative values which are not acceptable for a spreading function. For the latter the suppression of negative values by a weighting function results in an important smoothing of the curve and strongly under-estimates the peaks of the spreading function. The Iterative Eigenvector Method IEVM is not reported because it has sometimes failed to converge during these tests (in particular on case 2) and produced spurious peaks.

The IMF method (Fit to Unimodal Gaussian Model) is the fastest one and produces good results on the two first cases where the target spreading function is unimodal, but as expected do not give a reliable estimate on case 3.

The extension of this approach to Bimodal Model Fitting (2MF) is very satisfactory on the three cases, more especially as one has to keep in mind that it is tried to determine five model parameters from only four data coefficients. Even if more validation cases are needed for this method currently developed at LNH, the results on these three cases are very promising. Furthermore the computing time may be considered as very short.

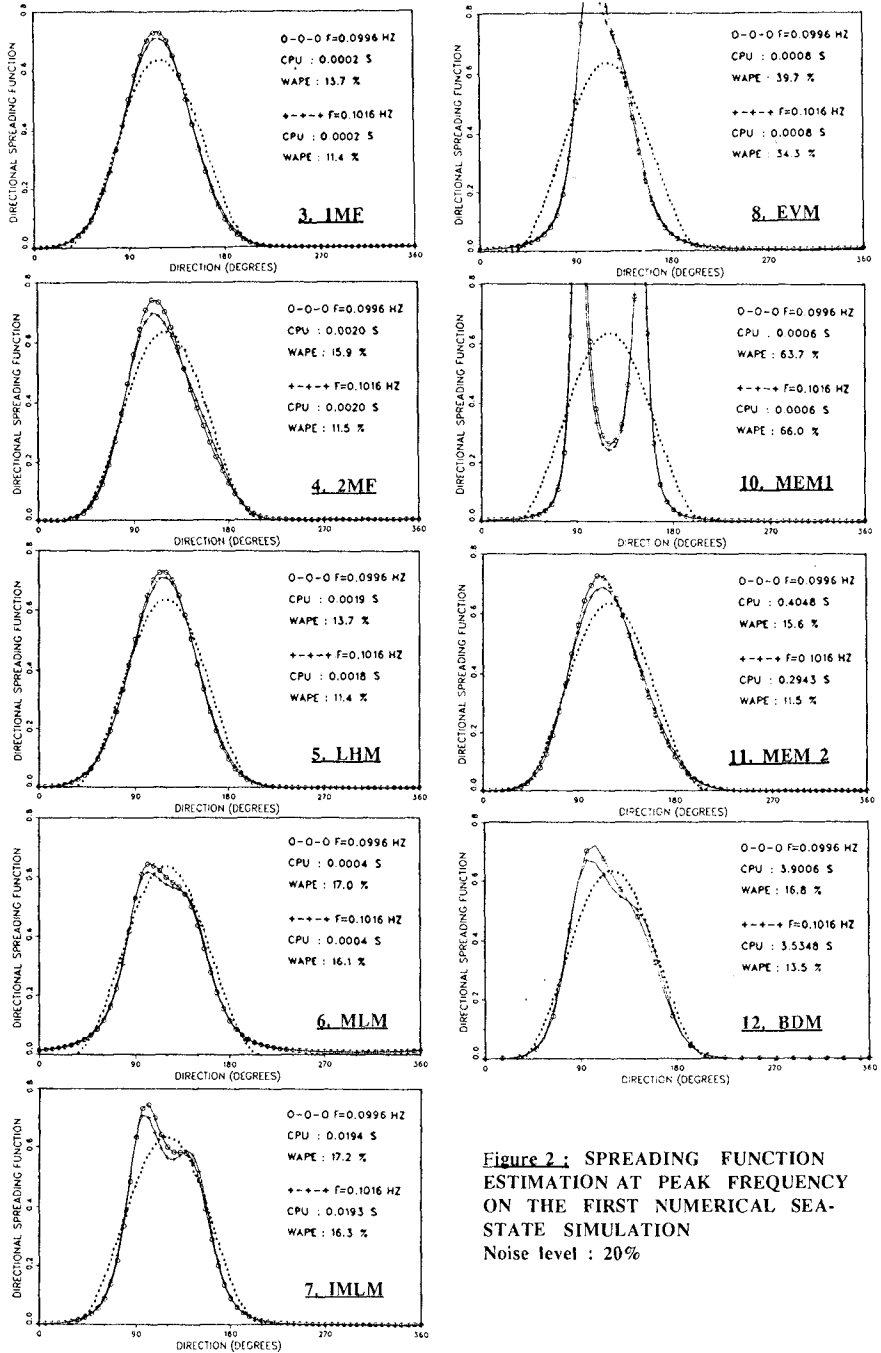

The Variational Fitting Technique of Long and Hasselmann gives good results on the unimodal cases because the initial model (based on IMF method) is already close to the target model, but in the third case when the iterative algorithm has to be activated, the computing time increases rapidly for an estimate that still produces 50% WAPE. At this point of validation this method has not shown definite advantages compared to its rather long and difficult implementation.

The Maximum Likelihood Method produces rather good estimates on all the cases with a very short CPU Time. As it is furthermore rather easy to implement we understand why it is so widely used for operational measurement. Its iterative refinement IMLM improves the estimation on case 3, but also shows a trend to split the peak on unimodal cases. Nevertheless it appears better than the MLM on figure 5 even if the CPU Time is clearly higher. During these tests 10 iterations were performed but further tests are required to optimize this value.

The Eigenvector Method does not reveal here a particular interest : the method is fast but on these cases the estimates are not very accurate. This method should be probably more interesting on cases where the noise level is much higher.

The first version of the Maximum Entropy Method (MEM1) is easy to implement and needs very little CPU time, but the estimate is not reliable and split the peak on unimodal cases. On case 3 the directional spreads are under-estimated.

The MEM version 2 (MEM2) is clearly superior and gives very good estimates on the three cases. On the other hand the CPU time is high and the implementation of this method is not simple.

**Figure 2: SPREADING FUNCTION ESTIMATION AT PEAK FREQUENCY ON THE FIRST NUMERICAL SEA-STATE SIMULATION**  
Noise level : 20%

**Figure 3: SPREADING FUNCTION ESTIMATION AT PEAK FREQUENCY ON THE SECOND NUMERICAL SEA-STATE SIMULATION**  
Noise level : 20%

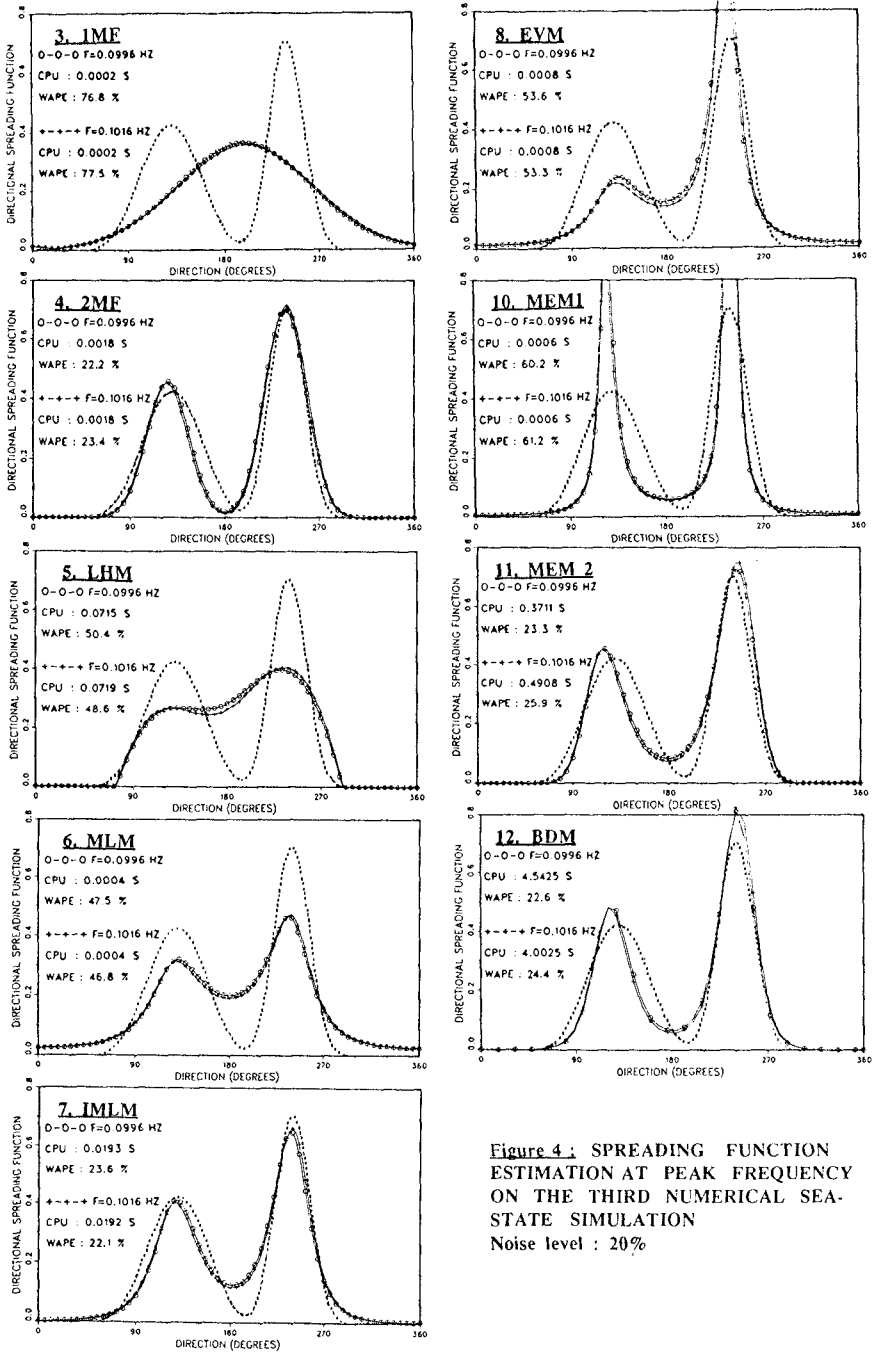

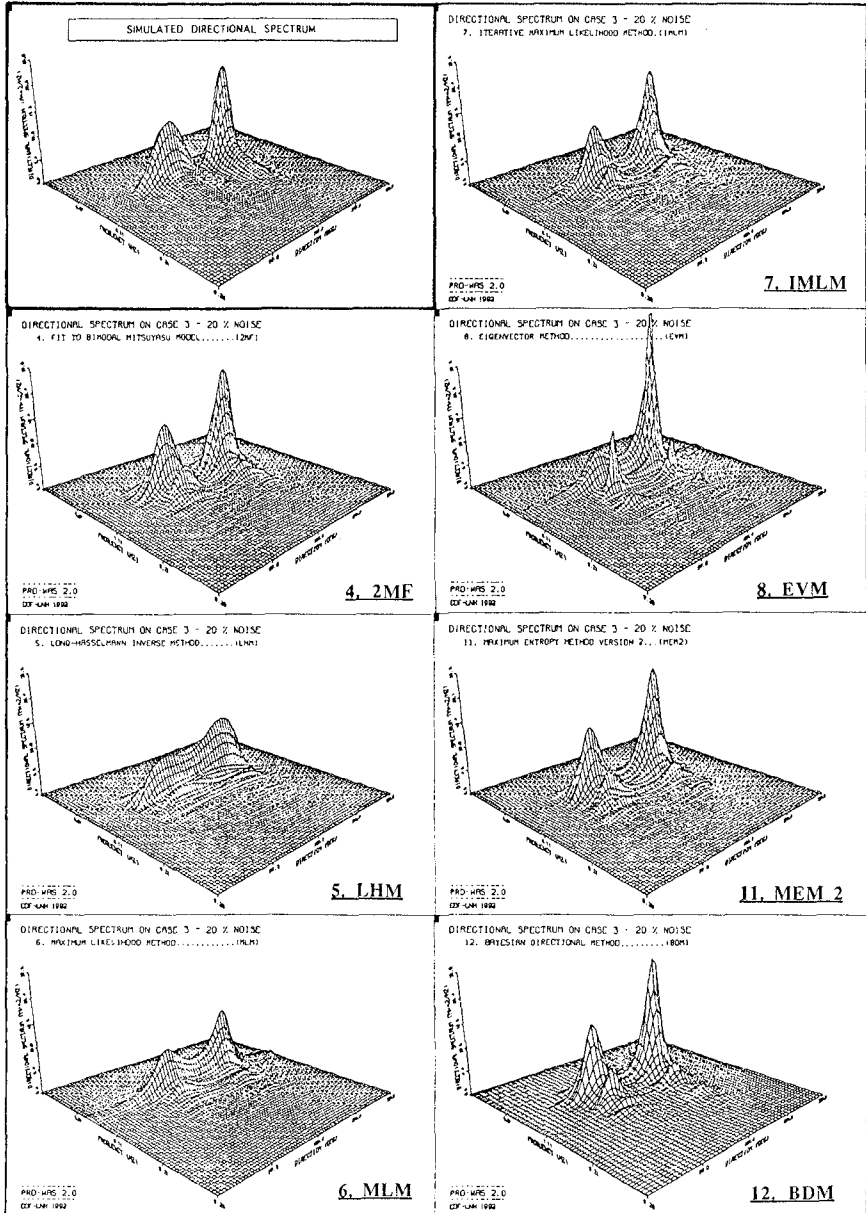

Figure 4 : SPREADING FUNCTION ESTIMATION AT PEAK FREQUENCY ON THE THIRD NUMERICAL SEA-STATE SIMULATION  
Noise level : 20%

**Figure 5 :** PERFORMANCE COMPARISON OF THE VARIOUS METHODS ON THE THREE NUMERICAL SEA-STATE SIMULATIONS

Spreading Function estimated at Peak Frequency - Noise level : 20%

**Figure 7 :** COMPARISON OF DIRECTIONAL SPECTRUM SHAPES ON THE THIRD NUMERICAL SEA-STATE SIMULATION (Bimodal Spreading Function) - Noise level : 20%

The Bayesian Direction Method also produces good estimates on these cases although there are very few information on input. This is also an extreme application of this sophisticated method and the resulting CPU Time is very high. Following its authors we can not affirm this method will always produce reliable estimates for so little amount of data.

From the analysis of figure 5 four methods giving less than 25% WAPE on the three cases may be identified : 2MF, IMLM, MEM2 and BDM (ordered following increasing CPU Time). These methods are rather stable in the sense that the CPU Time is rather constant and the WAPE do not vary in a great manner from a case to an other. Meanwhile the CPU Time is changing in a ratio of around 10 from a method to the following one.

The effect of noise is sensitive as soon as we try to compute the spreading function too far from the peak frequency. As example the variation of directional spread with noise level is reported on figure 6. Following Nwogu *et al.* (1987) who obtained the same conclusions about noise effect study, we would advise not to compute the spreading function out of the range  $[0.75 f_p, 1.5 f_p]$ .

Figure 5 : Effect of Noise Level on Directional Width  
(Case 2 : Unimodal Thin Spreading Function)

Figure 7 shows 3D-plots of the directional spectra estimated by seven of these methods on case 3. The most accurate estimates are clearly given by the above identified four methods : 2MF, IMLM, MEM2 and BDM. The MLM spectrum may be regarded as acceptable. The LHM and EVM spectra are of relative poor quality.

## 6. Conclusion

As major conclusions the following points have to be highlighted :

- the determination of the spreading function from heave-pitch-roll data is a critical problem that should be undertaken only around peak frequencies while on the other hand representative parameters such as main direction, directional spread, etc... may be computed over a much larger frequency range.
- Simple methods as Fourier Series Decomposition (TFS, WFS) or Unimodal Fitting (1MF) are not recommended because their estimates are of poor quality.
- the Maximum Likelihood Method (MLM) may be advised because it is fast and rather easy to implement. Its iterative refinement (IMLM) clearly improves the method and appears as an acceptable compromise between error and CPU Time.
- the Maximum Entropy Version version 2 (MEM2) seems to give the most reliable estimate but its computing time is rather high.
- the Bimodal Fitting (2MF) in its form developed at LNH seems very promising but has to be validated on more simulations.
- Sophisticated refinements as Variational Model Fitting (LHM) or Bayesian Directional Method (BDM) are not interesting for the case of the buoy where only few information are available.

Of course these preliminary conclusions have then to be confirmed or altered by applying the methods to laboratory or field data. Nevertheless guidelines for the choice of *a priori* optimal methods may be extracted from this study.

## CHAPTER 4

The modelling of short waves in shallow waters.  
Comparison of numerical models based  
on Boussinesq and Serre equations.

M. Brocchini<sup>†</sup>, M. Drago<sup>†</sup> and L. Iovenitti<sup>†</sup>

### Abstract

Two different flow models of the surf zone wave-current dynamics based on Boussinesq and Serre equations have been implemented and tested. Good results were obtained while testing the models against many different wave and current data sets. A preliminary calibration was tried but further activities are required to define the proper parameters.

### Introduction

The research in coastal hydrodynamics recently focused its attention on the mathematical and numerical modelling of the water flows in that region where wave breaking takes place.

This was to fill the gap that shallow water wave theories suffered up to now: they could no longer predict wave-current characteristics while approaching the surf zone. This was a very serious limit to the application of predictive models to coastal engineering and to environmental problems.

The latest trend in the modelling of such phenomena is to develop flow models that work at space-time scales much smaller than the wave length and period. Those models are based on the solution of the equations derived from the continuity and approximated Navier-Stokes equations. Of particular interest are the Boussinesq equations, the Su-Gardner equations and a particular approximation called the Serre equations. The presence of turbulence and energy dissipation in the breaking region is introduced by the concept of the 'surface roller'.

---

<sup>†</sup> Snamprogetti S.p.A. - Offshore Division

The roller is the upper turbulent region of the wave. The main hypothesis is that the water mass of the roller does not take part in the wave motion, but only contributes to the internal pressure field. Its main action is, then, to extract energy from the wave motion acting on it, as a first approximation, through an hydrostatic pressure contribution in the momentum equations.

### The Boussinesq equations

In the following an irrotational (the velocity is the derivative of a potential  $\phi$ ), inviscid fluid with constant density  $\rho$  is considered. The water depth is  $h$  and the surface waves are characterized by an amplitude  $A$  and a wave number  $k$ . For shallow waters (the depth to wavelength ratio is smaller than one), considering weakly non linear and moderate long waves the Boussinesq approximation is valid:

$$O(\epsilon) = O(\mu^2) < 1,$$

where  $\mu = kh$  and  $\epsilon = A/h$ . In the following the unidimensional equation including terms in the order of  $O(\epsilon)$  and  $O(\mu^2)$  is considered:

$$\eta_t + [(h + \eta)\bar{u}]_x = 0, \quad (1)$$

$$\bar{u}_t + \bar{u}\bar{u}_x + g\eta_x = \frac{h}{2}[(h\bar{u})_{xxt}] - \frac{h^2}{6}(\bar{u}_{xxt}), \quad (2)$$

where

$$\bar{u} = \frac{1}{h + \eta} \int_{-h}^{\eta} \nabla \phi dz \quad (3)$$

is the horizontal depth-averaged velocity and where the subscripts represent partial derivatives. The velocity vertical profile is related to the mean velocity through a parabolic equation depending on the vertical coordinate  $z$ :

$$u(z) = \bar{u} - \frac{h}{2}(h\bar{u})_{xx} + \frac{h^2}{6}\bar{u}_{xxx} - z(h\bar{u})_{xx} - \frac{z^2}{2}\bar{u}_{xxx}. \quad (4)$$

These equations have a dispersive behaviour as the phase velocity depends on the wave number  $k$ :

$$C = (gh)^{1/2} \left( 2 - \frac{k^2 h^2}{3} \right)^{1/2} \quad (5)$$

This depedance has been introduced by the  $O(\mu^2)$  term. It may be noticed that the same term causes the pressure field not to be hydrostatic:

$$P = \rho g (\eta - z) + \frac{\rho}{2} (z^2 + 2zh) \nabla \cdot \bar{u}_t. \tag{6}$$

The Serre equations

Using the same procedure of Su and Gardner (1969), expanding the Navier-Stokes equations up to the order  $O(\epsilon\mu^2)$  and considering a slowly varying water depth (the horizontal derivatives of the water depth are neglected at the higher order) the Serre approximation is obtained for  $O(\epsilon) = 1$ , and  $O(\mu^2) < 1$ :

$$\eta_t + [(h + \eta)\bar{u}]_x = 0, \tag{7}$$

$$\begin{aligned} \bar{u}_t + g\eta_x + \bar{u}\bar{u}_x = & hh_x\bar{u}_{xt} + \frac{h^2}{3}\bar{u}_{xxt} + \\ & + h\eta_x\bar{u}_{xt} + \frac{2}{3}h\eta\bar{u}_{xxt} + \frac{h^2}{3} [\bar{u}\bar{u}_{xx} - (\bar{u}_x)^2]_x. \end{aligned} \tag{8}$$

The presence of higher order approximation makes the solution (solitary or cnoidal solutions for example) to be less peaked with respect to the Boussinesq's one (see fig.1)

Fig.1 - Solitary solution for Boussinesq and Su-Gardner equations.

The 'Surface Roller'

The description of the breaking process based on the concept of the 'surface roller' was developed by Deigaard (1989). The roller is considered to be that portion of water mixed with air that is formed on the front region of the wave after breaking. The main assumption is that both vertical and horizontal acceleration within the roller are negligible as compared to its other effects on the water beneath. This also means that the pressure field within the roller may be considered hydrostatic. The roller follows the wave crest at a celerity  $C = \sqrt{gh}$ . On these bases the roller may be considered as a solid body that does not take part in the water motion within the wave but only extracts energy from it. This sort of description fits well the spilling breaking process as the overturning of the wave crest and the air-entrainment play a minor role. On the other hand the roller doesn't provide a good representation of a plunging breaker: the overturning of the wave crest generates a too strong jetting within the whole wave to be neglected. Being  $\delta$  the roller elevation above the wave crest and  $\eta$  the wave elevation, the shear stress  $\tau_s$  present at the wave crest-roller interface (Deigaard and Fredsoe (1989)) is:

$$\tau_s dx = -\rho g \delta (\delta_x + \eta_x) dx. \tag{9}$$

It may be deduced that the energy dissipated through a shear stress term in the wave-roller interface is provided by the whole water columns. Considering the spatial derivative  $P_x$  of the Boussinesq pressure vertical profile and neglecting terms in the order of  $O(\epsilon\mu^2)$ :

$$P_x = \epsilon(\eta_x + \delta_x) + \epsilon\mu^2 \left( z h_{xx} \bar{u}_t + 2z h_x \bar{u}_{xt} + \frac{z^2}{2} \bar{u} - xxt \right). \tag{10}$$

This gradient is averaged over the depth giving:

$$\bar{P}_x = \epsilon(\eta_x + \delta_x) + \frac{\epsilon\delta}{h + \epsilon\eta} (\eta_x + \delta_x) - \epsilon\mu^2 \frac{h}{2} (hu)_{xxt} + \epsilon\mu^2 \frac{h^2}{6} \bar{u}_{xxt}. \tag{11}$$

It may be noticed that the Boussinesq equations are obtained neglecting the terms proportional to  $\delta$  and  $\delta_x$ . The dimensional terms due to the roller alone are:

$$\bar{P}_x = -\rho g \left[ \delta_x + \frac{\delta}{h + \eta} (\delta_x + \eta_x) \right]. \tag{12}$$

In the following numerical application this quantity will be multiplied by a factor  $K$  that globally accounts for other energy dissipating phenomena and is calibrated as one of the three 'driving parameters' used in the models. Finally, including the presence of the roller in the mass balance the continuity equation becomes

$$(\eta_x + \delta_x) + [(h + \eta)\bar{u} + \delta C_x]_x = 0, \quad (13)$$

where  $C_x$  is the x-component of the wave celerity.

#### The Roller detection and growth

More consideration is given to correctly represent the surface roller growth from the breaking point toward the shore. Raichlen and Papanicolau (1988) pointed out that the bubble mass on the front face of the wave grows from zero, reaches a maximum and then decreases. Moreover the maximum size of the roller is reached at different distances  $X/h_{br}$  after breaking in dependence on the seabed slope and the breaker type (spilling or plunging). This relative distance ranges between one and ten. In the present model the growth of the roller is governed by the empirical relationship:

$$\delta'(x) = \delta(x) \left[ \frac{\tanh(X/h_{br}) + \tanh(\beta)}{1 + \tanh(\beta)} \right], \quad (14)$$

where  $X$  = distance from the breaking point,  $h_{br}$  = breaking point water depth,  $\beta$  = calibration parameter.

#### The numerical model

Generally speaking, along the curve  $C$  bounding a certain domain  $D$  both open and closed boundary conditions may be encountered. The latter covers all those situations ranging from total reflection to complete absorption. At the open boundaries radiation conditions are applied. They are schematized according to the following relationship:

$$f_{n1} - C\eta = -2C\eta_I f(\alpha), \quad (15)$$

$$u(h + \eta) = f_{n1}, \quad (16)$$

where

$$\begin{aligned} f_{n1} &= \text{outgoing normal flux} \\ \eta &= \text{actual sea surface elevation} \\ \eta_I &= \text{elevation of the incident wave} \end{aligned}$$

$C$  = wave celerity  
 $\alpha$  = the angle between the incident  
 wave and the boundaries

The wave celerity  $C$  is calculated by the appropriate theory: second order cnoidal wave theory. On the other hand the linear theory for shallow waters is applied to determine the celerity for irregular waves. The function  $f(\alpha)$  was firstly evaluated as  $f(\alpha) = 1 + \sin \alpha$ . A numerical analysis carried out with unidimensional and bidimensional models showed that the validity of the above relationship is limited to angles  $\alpha$  close to  $90^\circ$ . The function  $f(\alpha)$  is now considered a calibration parameter of the model, and is empirically evaluated depending on the value of  $\alpha$ . For closed boundaries two different schematizations are used. Total or partial reflection is schematized by the relationship

$$f_{n2} - C(1 - \gamma)\eta = 0, \quad (17)$$

$$u(h + \eta) = f_{n2},$$

where

$f_{n2}$  = incident normal flux  
 $\gamma$  = reflection coefficient ( $\leq 1$ ; 1 for total reflection).

In this case, too, the wave celerity  $C$  is calculated by the appropriate theory: cnoidal for monochromatic waves and linear for irregular waves. Complete absorption is schematized according to a 'sponge layer' approach (Larsen and Dancy, 1983). The 'sponge layer' is simulated by an extension of the model behind the absorbing boundary. In this extension, after each integration time step, the surface elevations and the fluxes are divided by a dumping factor  $\mu(x)$  which is a function of the distance  $x$  from the boundary:

$$\mu(x) = \exp \left[ \left( 2^{-(x_s - x)/\Delta s} - 2^{-x_s/\Delta s} \right) \ln(a) \right], \quad (18)$$

where  $\Delta s$  is the size of the grid mesh and  $a$  is a constant that depends on the number of the grid lines in the 'sponge layer'. As for the behaviour of the roller at the boundaries, it is assumed that there are no incoming rollers from the open boundaries and that they are completely absorbed at the closed boundaries. The basic equations are numerically integrated by a semi-implicit multistep finite difference technique (Brocchini, Cherubini and Iovenitti, (1991)).

The variables are defined on a space-staggered square or rectangular grid. The integration too is staggered in time as the elevations and fluxes are evaluated at half time steps  $(2n + 1)\Delta t/2$ . From the continuity equation (explicit scheme) the water elevation  $\eta$  is calculated, then from the water surface profile a test on the local slope defines the location and thickness of the surface roller. The fluxes are evaluated through the momentum equation (roller contribution included) by a semi-implicit technique made of three different calculation steps.

### Test cases and preliminary calibration

The model has been widely applied to many data sets made available from different European Institutes (Brocchini, Drago and Iovenitti (1992), Drago (1992)). The data sets are relative to wave elevation (Liberatore and Petti (1988), Schaffer (1991), Dette and Oelerich (1991)) and velocity (Quinn et al. (1991)) flume measurements. The waves used in the tests are both monochromatic and irregular; wave breaking occurs over different bottom profiles (sloping or barred). In table 1 a scheme on the analyzed data sets within the validation activities is reported:

Institute	Profile	Type/(Number of tests)	$\frac{H_0}{L_0}$
Padua Un.	Slope 1/30	Irregular (4)	0.0310 ÷ 0.0380
D.H.I.	Barred	Regular (3)	0.0212 ÷ 0.0522
Hannover Un.	Slope 1/20	Irregular (4)	0.0316
Edinburgh Un.	Slope 1/30	Regular (2)	0.0220 ÷ 0.0330

Tab. 1 - Validation data sets.

Table 2 summarizes the percent error  $(H_{exp} - H_{comp})/H_{exp}$  from outside the breaking region to the shore for both Boussinesq and Serre equations.

$\frac{D}{D_b}$	Bouss.	Serre
1.5	+5	+8
1.0	+7	+11
0.6	-15	-8

Tab. 2 - Average percent (%) error on wave height.

Fig.2 - Wave elevations comparison.  
(Data shifted for better comprehension).

Figure 2 shows an example of computed and measured wave elevation comparison (inside the surf zone) while figures 3 and 4 represent, respectively, a typical comparison of the wave spectra and of the decay pattern for the wave height over a barred profile.

Fig.3 - Wave spectra comparison.

Fig.4 - Wave height decay pattern.

Comparison on velocity data has been worked out both on mean velocity spatial series and on vertical profiles. In fig.5 a typical pattern for mean velocity is shown.

Fig.5 - Mean velocity comparison.

Table 3 sums up the percent error  $(V_{exp} - V_{comp})/V_{exp}$  between experimental and computed velocity profile for two different wave phases and for both Boussinesq and Serre model.

Dist. from bottom(cm)	Crest		Trough	
	Bouss.	Serre	Bouss.	Serre
4.0	-15	-2	-20	-13
6.0	-14	-1	-10	-3
8.0	-9	+3	-5	-5
10.0	-13	-2	+40	+50
12.0	-8	+3		
14.0	-5	+6		

Tab. 3 - Percent error on velocity profiles.

It may be seen that for the maximum phase the Serre model oscillates around the experimental pattern with errors of about 5% while the Boussinesq model gives an almost constant overestimation of the velocity of about 10%. Within the calibration activity typical relationships between wave-seabed characteristics and model breaking parameters ( $\alpha_{br}, K, \beta$ ) were looked for. Thirteen monochromatic wave decay patterns were modelled and compared against the experimental data (Liberatore and Petti (1991)). The experimental waves were characterized by a deep water wave steepness ranging from 0.03 to 0.07 and broke over a submerged bar while eight wave gauges recorded the free water surface from the breaking point to the shoreline. Moreover video camera recordings all along the flume were taken to better evaluate the roller area and the breaking point location.

Fig.6 - Adimensional wave height at breaking.

The adopted methodology was to minimize both the differences between the experimental and the computed wave shape and to reproduce the wave height decay pattern all along the flume within a percent error of about 15%. Once the best representation of the wave decay pattern obtained, a first comparison of the results against those coming from wide data sets (Easson et al.(1988)) was tried (see fig.6).

Fig.7 - Preliminary calibration curve for  $\alpha_{br}$ .

Fig.8 - Preliminary calibration curve for  $K$ .

The underestimation of the  $H/h$  ratio (mainly for the Boussinesq

model) is related to the adopted experimental set-up where the gauges were spaced too far apart to exactly determine the breaking point location. The preliminary calibration curves for the breaking slope  $\alpha_{br}$  and the dissipation factor  $K$  are shown in figures 7 and 8. The correlation factors are not so high as to suggest that the performed calibration is sufficiently reliable. Anyway it is clear that the Boussinesq model needs much higher values for the dissipation parameter with respect to the Serre model to obtain the same energy decay. This is due to the presence of terms proportional to  $O(\epsilon\mu^2)$  which act as a smoothing factor within the surf zone.

### Conclusions

A quite good fit of the experimental wave elevation and spectra has been obtained through the model based on both Boussinesq and Serre equations. A satisfactory description of the wave height decay process in the surf zone was reached (errors of about 15%). The Serre equations give a much better representation of the velocity field than the Boussinesq's. A preliminar calibration of the main parameters was tried but some uncertainties in the determination of the experimental breaking point force a more accurate evaluation on the basis of the camera recordings.

### Acknowledgements

This work was undertaken as part of the MAST-G6 Coastal Morphodynamics Research Programme. It was funded by the Commission of the European Communities, Directorate General for Science, Research and Development, under MAST contract N° 0035-C. The authors wish to thank Mr.Liberatore, Mr.Petti, Mr.Schaffer, Mr.Oelerich, Mr.Dette, Mr.Greated, Mr.Quinn for having provided the data used for models testing and calibration.

## CHAPTER 5

# COMPUTATION OF BREAKING WAVES WITH A PANEL METHOD

Jan Broeze<sup>1</sup>

### Abstract

Some basic properties and computational results are presented of a solution method for potential flow problems, with nonlinear waves at the free surface. The results show that stable and accurate results can be obtained for nonlinear wave propagation problems, up to the stage of breaking waves, though no numerical smoothing is applied. Also the interaction with constructions on the bottom can be computed well.

For efficient usage of the available CPU-time, a suitable condition for the time increments in nonlinear computations is given.

### 1. Introduction

In this paper we will consider the description of propagating and breaking waves with a potential model for the fluid flow.

For the description of potential flow problems in two-dimensional and three-dimensional domains, we have developed an accurate panel method. One of the boundaries of the domain is the free surface, on which nonlinear boundary conditions are imposed for the description of the solution in time.

For accurate descriptions of highly nonlinear wave evolution in complex three-dimensional regions, a model should be used that includes the behaviour of

---

<sup>1</sup>Delft Hydraulics, P.O. Box 152, 8300 AD Emmeloord, The Netherlands.

the solution in vertical direction. This can be achieved by discretizing the whole fluid domain. Such an approach makes computations on extreme problems like the development of breaking waves possible.

For incompressible potential flow problems, the field equation reduces to Laplace's equation for the potential. This is an elliptic equation, so that solving the problem on the boundaries of the domain is sufficient. Green's third identity provides a boundary integral relation for the solution on the boundary.

Boundary element methods and panel methods are based on a discretization of Green's third identity in the physical domain. That is why they can be used for modelling the fluid flow in domains with arbitrary boundary shapes.

Time dependence comes into the problem by the time-dependent boundary conditions. These give expressions for the evolution of the free surface position and the velocity potential in time.

Many computations on breaking waves have been discussed in literature (see Peregrine, 1990). However, due to restrictions of the numerical methods, in most cases the chosen initial solution is not physical. For example, an exact solution of a periodic high wave is imposed on a geometry with a smaller depth. In such situations, the numerical results are useful for studying the local solution near the tip of the wave. However, the global solution is not valid in physical situations.

Computations on highly nonlinear wave problems in three-dimensional domains are still very rare. One example can be found in the work by Xü & Yue (1992). They computed the evolution of a breaking wave with a three-dimensional method. A breaking wave was generated by prescribing a non-physical pressure distribution at the surface. However, for practical applications, a method for computing wave evolution due to interactions with a bottom profile is more useful.

Romate has developed a higher order panel method for the computation of three-dimensional potential flow problems with a free surface. As far as the results were presented in his thesis (see Romate, 1989), the method was very well capable of computing the evolution of linear wave solutions and weakly nonlinear waves. However, stable computations of highly nonlinear waves were not possible yet.

On the basis of Romate's work, we have further developed the method for the evolution of highly nonlinear waves. By the improvements, stable results can be obtained for highly nonlinear wave problems up to the stage of the development of breaking waves. For an extensive analysis of algorithms used in the method, the reader is referred to Romate (1989) and Broeze (1993a, 1993b).

In this paper we will briefly describe the method of computation. Furthermore we will show some numerical results on three-dimensional wave propagation problems, including the development of a breaking wave.

## 2. Numerical solution method

The fluid motion is modelled with a higher order panel method. This method is based on the assumption of a potential flow, i.e. the velocity can be derived from a potential  $\phi$ :

$$\underline{v} = \nabla \phi \quad (1)$$

Due to incompressibility, the velocity potential satisfies Laplace's equation:

$$\nabla^2 \phi = 0 \quad (2)$$

In our panel method, the field equation problem is solved by using a boundary integral equation formulation, where Green's third identity is applied:

$$\frac{1}{2} \phi(\underline{x}) = \int_{\partial\Omega} [\phi(\underline{\xi}) G_n(\underline{x}, \underline{\xi}) - \phi_n(\underline{\xi}) G(\underline{x}, \underline{\xi})] dS \quad (\underline{x} \text{ on } \partial\Omega) \quad (3)$$

For the discretization of this equation, the boundary of the domain is divided into a number of smooth panels, with one collocation point near the centre of each panel. Values in the collocation points of a number of adjacent panels are used to determine tangential derivatives.

Green's identity is solved in the physical domain. Up to quadratic variations of the velocity potential and linear variations of its normal derivative are assumed in the discretization of the boundary integral equation. Also contributions due to curvature of the panels are included in the expressions for the influence coefficients. This provides very accurate solutions of the field equation.

Time dependence comes into the problem by the time-dependent boundary conditions.

In our Lagrangian method, at the free surface  $S_f$  we have the kinematic condition, expressing that a fluid particle remains at the free surface:

$$\frac{Dx_f}{Dt} \equiv \underline{v} = \nabla \phi \quad \text{at } S_f \quad (4)$$

and the dynamic boundary condition, expressing zero pressure:

$$\frac{D\phi}{Dt} = -gz + \frac{1}{2}(\nabla \phi)^2 \quad \text{at } S_f \quad (5)$$

where  $g$  is the gravitational acceleration, and  $z$  is the vertical coordinate.

On the bottom  $S_b$ , on fixed constructions and on symmetry boundaries, the no-flux condition should be satisfied:

$$\phi_n = 0 \quad \text{at } S_b \quad (6)$$

where  $\underline{n}$  is the outward directed normal with respect to the fluid domain.

On a moving structure  $S_s$ , or a wave maker, the normal velocity is prescribed according to the motion velocity  $\underline{V}$  of the structure:

$$\phi_n = \underline{V} \cdot \underline{n} \quad \text{at } S_s \quad (7)$$

In order to represent large physical domains with a small computational domain, we can truncate the domain with artificial boundaries  $S_a$ . Radiation boundary conditions, that only allow waves travelling out of the domain with minimal reflections, are needed on these boundaries. A simple example is Higdon's (1987) first order condition:

$$\frac{\partial \phi}{\partial t} = - \frac{c}{\cos \alpha} \frac{\partial \phi}{\partial n} \quad \text{on } S_a \quad (8)$$

where  $\underline{n}$  is the normal with respect to the vertical boundary, positive in outward direction. This condition perfectly radiates waves that travel at phase speed  $c$  and at an angle  $\alpha$  with the normal  $\underline{n}$ . For second order conditions (that can perfectly radiate waves from different directions) the reader is referred to Romate (1992) and Broeze & Romate (1992).

The above described boundary conditions provide values for the time derivatives of the potential and the positions of the collocation points as a function of spatial derivatives of the potential and the vertical coordinate.

Various methods can be used for integrating the problem in time. We have considered the classical fourth order Runge-Kutta method, a third order Taylor method and a 2-stage 2-derivative Runge-Kutta method (that uses first and second order time derivatives on the original and one intermediate time level). We have concluded that the latter method is most favourable for our problem, because it provides accurate results in relatively short CPU times.

An adaptive grid evolution technique was used to obtain desirable grid distributions in time. This is especially important in 3-D computations, where a strongly deformed grid on the lateral boundaries may have negative influences on the accuracy of the solution.

Our method is very suitable for computations of the interaction of highly nonlinear waves with constructions, because there are no restrictions on the shape of the boundaries of the domain. Another favourable property is the stability of the

method, so that no artificial dissipation or smoothing terms need to be added (which may have a large influence on the solution during breaking).

### *Time-step restrictions*

One important aspect that we want to discuss here is the chosen time increment in the numerical computations.

We found that stability restriction based on linear theory (see e.g. Dommermuth et al., 1988) are not suitable in computations on highly nonlinear wave propagation problems.

Another frequently applied condition is that the highest order terms in the Taylor time integration method should be below a given value (see e.g. Nakayama, 1990). Such condition is rather arbitrary, and lacks a theoretical basis.

We have derived a more appropriate condition for the full nonlinear problem.

From a perturbation analysis of the solution around the nonlinear solution, the following evolution equations for small disturbances  $(\varepsilon, \zeta)$  in the potential  $\phi$  and elevation  $\eta$  can be derived:

$$\frac{d}{dt} \begin{bmatrix} \varepsilon \\ \zeta \end{bmatrix} = \begin{bmatrix} -i\phi_s k & -g \\ |k| \cos\gamma & 0 \end{bmatrix} \begin{bmatrix} \varepsilon \\ \zeta \end{bmatrix} \quad (9)$$

where  $s$  represents a tangential coordinate to the surface,  $k$  is the wave number of the disturbance and  $\gamma$  is the local angle of inclination of the free surface.

For stability of the numerical method for nonlinear problems, the eigenvalues of the matrix in eq.(9) should be in the stability region of the domain:

$$\frac{i}{2} \left( -\phi_s k \pm \sqrt{(\phi_s k)^2 + 4g|k|\cos\gamma} \right) \Delta t \in R_{\text{stab.}} \quad \forall k \in [0, \pi/\Delta x] \quad (10)$$

This is a straightforward condition for the time increment. From numerical test computations we found that it is very appropriate: satisfying this condition provides a stable evolution of the solution, whereas instabilities occur if it is violated. For an extensive description of the derivation of condition (10), the reader is referred to Broeze (1993a, 1993b).

Eq. (10) can reduce the required amount of CPU time in highly nonlinear computations with large velocities and fine grids. A maximal time increment can be chosen then.

### 3. Computational results on periodic wave propagation problems

The panel method provides stable and very accurate results for linear (see e.g. Broeze and Romate, 1992), mildly nonlinear and highly nonlinear wave problems (see Broeze, 1993a, 1993b and Broeze et al., 1993). Computations can be performed on highly nonlinear steady propagating waves near the maximum wave height without instabilities, with errors in the elevation of only a few percents after a large number of wave periods.

Fig. 1 shows results of computations on a typical highly nonlinear propagating plane wave problem. The wave height is 5m on 10m water (over 80% of the maximum), with wave length 60m and Eulerian period 6.5s. This figure shows the results of the computations after 0, 1, 2 and 4 Lagrangian periods. The errors in the elevation are within 2% of the wave height.

The results illustrate that the method is well-capable of accurately describing highly nonlinear propagation.

In order to analyze the accuracy of the method for three-dimensional problems, we have computed the same wave solution, where the propagation direction of the wave is at an angle  $\pi/6$  with one of the grid lines.

Fig. 2 shows the numerical boundary shape from 0 to 6s at intervals 2s. Again the results illustrate that no large growing errors occur in the solution.

### 4. The interaction of a solitary wave with a mild slope

A solitary wave is generated on a numerical wave flume with depth 5m. A weak slope (1:10) truncates the domain in horizontal direction. The solitary wave has a height 3.5m (84% of the maximum) and a phase velocity of 9.0m/s. Initially the fluid is at rest. We computed the interaction of the solitary wave and the slope with a two-dimensional variant of our panel method.

The shape of the domain boundaries after 2s, 4s and 6s is given in Fig.3. This figure shows how the wave starts deforming on the slope. When the wave approaches the end of the slope, it starts to break, and a plunging breaker develops. The shape of the jet from  $t=6.6s$  to  $7.3s$  is given in Fig.4. A finer grid would be needed to further continue the computations.

It is noted that in our method, no collocation points occur at the intersection. Also no special condition is applied at the intersection of the slope with the free surface.

In order to analyze the quality of the numerical results of these computations, we have considered a number of theoretical models for the description of breaking waves.

A few theoretical models exist for the evolution of the tip of a breaking wave and the surface region below the jet (see e.g. Longuet-Higgins (1980) and New (1983)). These models were developed for breaking waves on deep water. They cannot be applied to our situation, because of the influence of the slope on the solution.

Peregrine (1990) suggested to check the motion of the tip of the wave (it should be in free fall).

Fig.5 shows the evolution of the coordinates of the tip of the wave during the final stage of computation. Obviously, the free-fall model holds very well from  $t=6.95s$  (when the jet has developed) to  $7.3s$ .

## **5. Results on breaking wave computations with the three-dimensional method**

We have used the three-dimensional panel method to compute the interaction of the highly nonlinear solitary wave with a smooth construction the bottom. Fig.6 shows the bottom profile in these computation.

Fig.7 shows the grid on surface and on the lateral boundaries of the domain when the wave front has started to overturn. Obviously, the method is capable very well to compute the evolution of the solution so far. The well-arranged grid on the lateral boundaries illustrates the suitability of our adaptive grid motion algorithm. The forming of the jet is more clearly illustrated in Fig. 9.

In order to show the height of the construction in comparison with the domain dept, in Fig. 8 the bottom profile and the surface are depicted.

The computations on this wave cannot be further continued due to the small number of panels near the tip of the wave. A large number of extra panels would be needed to increase the grid density near the jet. However, this cannot be achieved due to memory restrictions on our supercomputer.

## **6. Conclusions**

In this paper we have seen that highly nonlinear waves can be very well described with an accurate panel method. Also real three-dimensional effects can be computed. Efficient solution methods for the spatial problem, for the time integration and for the grid motion are of crucial importance for the success of the method.

The results show that even extreme problems like the development of breaking waves due to a construction on the bottom can be modelled. We think that such models offer new possibilities for studies on nonlinear wave propagation problems in complex three-dimensional domains.

## Acknowledgements

The investigations were supported by the Netherlands Technology Foundations (STW). Supercomputer usage was financed by the Dutch National Computing Facilities Foundation (NCF). Professor P.J. Zandbergen is greatly acknowledged for his support and advise.

## CHAPTER 6

### BAR/TROUGH EFFECTS ON WAVE HEIGHT PROBABILITY DISTRIBUTIONS AND ENERGY LOSSES IN SURF ZONES

Maolong Cai<sup>1</sup>, David R. Basco<sup>2</sup> (Member, ASCE)  
and Joe Baumer<sup>3</sup>

#### Abstract

Laboratory measurements of irregular wave heights across a bar/trough beach profile are being studied to develop improved probability distributions including the subset of breaking waves. The energy dissipation in breaking waves modeled as a periodic bore is inversely proportional to the wave period and this may explain why the bore model appears to underestimate measured average energy dissipation rates. The study is ongoing and preliminary results for one wave period are presented in this paper.

#### 1. Introduction

The transformation of irregular waves across surf zones is dominated by wave breaking. In contrast to regular (single frequency) waves, irregular (multiple frequency) waves can break almost anywhere depending upon the wave characteristics (heights, periods) and the water depth. Thus some waves break because of their steepness, i.e., they behave as if in "deep" water while others break due to a depth limiting criteria for "shallow" water. The nearshore bathymetry, especially the presence of bars dominates the wave transformation process.

The traditional, wave transformation method assumes a slowly-varying, quasi-uniform wave field as represented by the time averaged and depth-integrated wave energy flux per unit surface area and the wave energy balance equation including rate of energy dissipation per unit area. For irregular waves, two different approaches are possible for solving the multiple frequency, wave

<sup>3</sup> Coastal Engineer, Shoreline Programs Bureau, Commonwealth of Virginia, Gloucester Point, Virginia (USA)

energy balance equation.

One approach randomly selects offshore waves from a known joint (height, period) distribution, transforms individual waves with the energy balance equation and then reassembles the wave heights into probability distributions across the surf zone. This approach is called the wave-by-wave or Monte-Carlo method and requires computation for hundreds of waves. Dally (1990,1992) presents an excellent review paper and application to field data of this approach.

A second approach, herein called the probability density function (pdf) approach, assumes *a priori*, the wave height distribution functions for all the waves and the subsets of breaking waves. The energy balance equation is then solved only once for the transformation of a single, statistical descriptor wave through the surf zone.

This paper focus on the pdf approach. For coastal engineering applications, especially for two-dimensional wave transformations, it is felt that this approach is more practical. Section 2 briefly reviews the literature and summarizes the objectives of an ongoing study to learn more about the pdf's for bar/trough beach profiles and methods to estimate the breaking wave energy dissipation rates. The laboratory facilities and experimental design is presented in Section 3. Early test results are presented in Section 4. Section 5 gives some conclusions and future directions for the research.

## 2. The Probability Density Function(pdf) Approach

### 2.1. Literature Review

Battjes and Janssen(1978) were the first to integrate the energy flux balance equation using the pdf approach and calculate wave heights over non-monotonic bottom profiles. Previous random wave transformation models (see Thornton and Guza, 1983 for review) used a cut-off model for the pdf when waves broke so that calculated wave heights depended only on the local water depth. On bar/trough beaches this produced physically unrealistic lower energy levels over the bar and energy gains in the adjacent trough.

Thornton and Guza(1983) extended the work of Battjes and Janssen(1978) by including a semi-empirical expression for the breaking wave distribution,  $p_b(H)$  that was a *subset* of the theoretical, Rayleigh distribution,  $p(H)$  for all the waves. The average rate of energy dissipation  $\bar{e}_b$ , in each breaking wave is modeled after a periodic bore (Stoker, 1956) in both these models. However, Thornton and Guza (1983) derived an analytical expression for the ensemble average,  $\langle \bar{e}_b \rangle$  for an irregular wave train by integrating the product  $\bar{e}_b * p_b(H)$  for all the waves. The final expression for  $\langle \bar{e}_b \rangle$  includes two coefficients ( $\gamma$ , B) that require field verification as discussed later in this paper. The ensemble

average,  $\langle \bar{e}_b \rangle$  is also inversely proportional to the wave period and the implications of this result are also reviewed at the end of this paper.

These modelers use the root-mean-square wave height,  $H_{rms}$  as the statistical, descriptor wave and both models give good predictions for the  $H_{rms}$  transformations occurring over real (field) beach profiles (see Battjes and Stive, 1985 for laboratory and field calibrations with Northsea waves,  $T_{max} < 8.7$  sec; and Thornton and Guza, 1983 for West Coast swell waves,  $T = 13-17$  sec). However, this agreement between calculated and observed  $H_{rms}$  required the use of physically unrealistic coefficients as discussed below and also does not mean that the underlying pdf's are correct as noted by these researchers.

## 2.2. Research Objectives

A laboratory study is underway that focuses on the wave height probability distributions for all the waves,  $p(H)$  and the breaking waves as a subset,  $p_b(H)$  as they pass over a synthetic, bar/trough beach profile. One objective is to compare the measured pdf's with those predicted by the Thornton and Guza (1983) theory and to make improvements in the theory, if warranted.

The second objective is to investigate the apparent *underestimation* of the average rate of wave breaking energy dissipation when using the periodic bore model as claimed by some researchers (Svendsen et al., 1978; Stive, 1984).

## 3. Laboratory Facility and Experiments

Experiments are being conducted in the new 18m long by 0.9m deep by 0.9m wide wave tank in the Coastal Engineering Laboratory at Old Dominion University. This facility is equipped with a random wave generator as designed by the Danish Hydraulic Institute (DHI) that includes an automatic wave absorption system at the wave board to remove reflected wave energy in the tank. Wave generation, recording, and analysis is accomplished through a special software package also developed by DHI. Wave heights up to 30cm and a period range between 0.7-3.5sec is possible in this facility.

Fig. 1 schematically shows the 1:20 beach slope with 1:10 artificial bar and dimensions such that the bar crest lies 22cm below the SWL in 60cm water depth. Seven wave gauges are positioned as shown across this synthetic bar/trough beach profile with all dimensions in meters. Four additional locations for wave gauges are shown in the trough region (vertical dashed lines) to provide details in this location.

A JONSWAP spectrum with standard shape parameters is generated at the wave board. The irregular wave train is constructed by a random number generator that always begins with the same seed to permit repetition of the time history of sea surface variation. For the results reported in this paper, the

FIG 1. SCHEMATIC OF BEACH PROFILE AND TEST ARRANGEMENT

FIG 2. MEASURED WAVE PROFILES & BREAKING WAVE SIGNALS

spectral significant wave height,  $H_{m0}$  was 15.0cm with peak period,  $T_p = 1.30$ sec. These input conditions were verified at wave gauge no. 1 and convert to a relative water depth ( $d/L$ ) ratio of 0.249 and wave steepness of 0.0569 at this position as given from linear wave theory.

Waves were generated for six minutes and approximately 300 were distinguished by the zero-down-crossing method. The number of waves passing each wave gauge was relatively constant. A spectral analysis of the sea surface at each wave gauge location produced similarly-shaped spectrums with reduced energy content. Therefore, the bar/trough shape, position, water depth and wave spectrum chosen did *not* generate higher frequency wave energy after the bar.

Fig. 2 shows an example of the wave train measured over a 30 second interval with an enlargement below it for a 4 second span. Also shown is the impulse voltage signal generated manually into the record by an observer whenever a breaking or broken wave event passed the gauge. This somewhat subjective observation of which waves were classified as "breaking waves" was confirmed by running replicate sets and using different observers. A special, software program has been developed to automatically distinguish the broken waves as a subset of all the waves identified in the record. Note that the largest waves are not always the breaking/broken waves identified in the record.

#### 4. Test Results

##### 4.1. Probability Distributions - All Waves

Wave height histograms were calculated using the DHI software package and checked with specially developed software that also computed histograms for the breaking waves identified as a subset of all the waves. Fig. 3 shows the measured histograms for *all the waves* at four, representative gauge locations, namely: Gauge 2 on the horizontal bottom before the beach slope; Gauge 4 near the bar crest; Gauge 5 in the trough; and Gauge 7 on the plane beach slope.

Also shown are the theoretical, probability distribution functions for all the waves,  $p(H)$  as given by the Rayleigh distribution (dotted line) and the Beta-Rayleigh distribution (solid line). Thornton and Guza (1983) showed that the Rayleigh distribution produced an reasonable description of all surf zone waves (mean period about 14 seconds) transforming over a monotonically decreasing profile (Torry Pines, CA). These authors also reviewed the works of others attempting to explain why the Rayleigh distribution *overpredicts* the number of large waves in the tail when compared with observations.

The Beta-Rayleigh distribution has been offered by Hughes and Borgman, 1989 to ". . . better characterize the wave height distributions for shallow water waves." It is semi-empirical and requires that the  $p(H)$  be bounded by  $H_{max}$ ; be

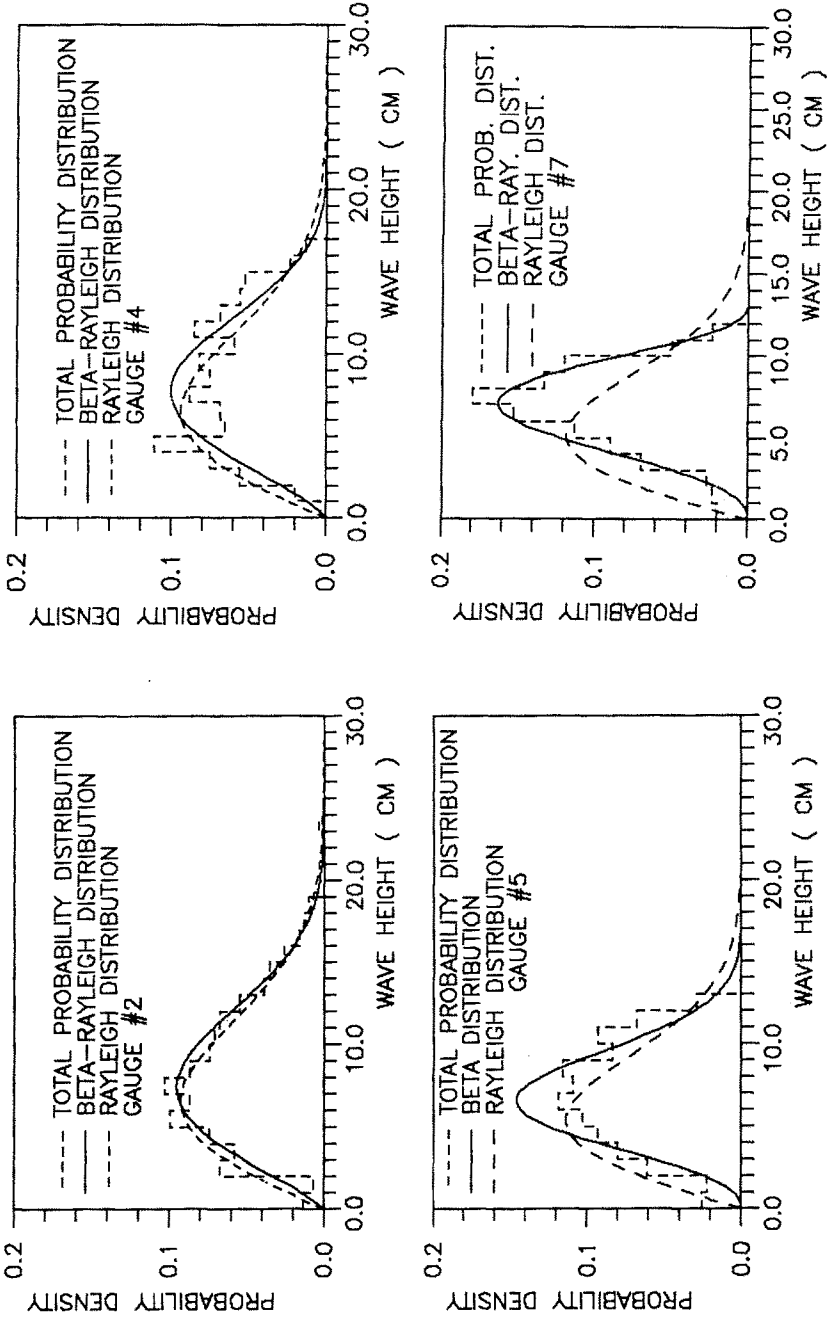

FIG 3. WAVE HEIGHT PROBABILITY DENSITY DISTRIBUTION OF ALL WAVES

skewed toward the larger waves; become the Rayleigh distribution in deep water and; be physically justified. Using the calibration parameters identified by Hughes and Borgman, 1989, we have also presented the Beta-Rayleigh,  $p(H)$  distributions in Fig. 3.

At Gauge 2 in "deep" water, the Rayleigh distribution is found to give a good fit to the measured data. Near the bar crest (Gauge 4) the measured distribution flattens out (or becomes double peaked) and both theoretical curves give a reasonably good fit. In the trough (Gauge 5) both theories give a relatively inaccurate shape compared with the measured distribution, but in different ways. Finally, on the plane beach slope, the Beta-Rayleigh distribution is found to give an excellent fit to the measured histogram, especially for the peak value and in the tail where the Rayleigh distribution *overpredicts* the number of larger waves as discussed above.

#### 4.2. Probability Distributions - Breaking Waves

The measured, breaking wave histograms are plotted in Fig. 4 for the same four gauge location (2, 4, 5, and 7) as discussed above. The scales are constant for each location and reveal that most waves break near the bar and on the plane beach, as expected. Many waves breaking on the bar *continue* through the trough region as broken waves to account for the totals displayed at Gauge 5.

The theoretical, breaking wave distributions,  $p_b(H)$  shown have been computed from the theory of Thornton and Guza (1983). Here,  $p_b(H) = W(H) \cdot p(H)$  where  $p(H)$  is the Rayleigh distribution and  $W(H)$  is a semi-empirical, weighting distribution (model M2) that includes two coefficients ( $\gamma$ ,  $n$ ). Field calibration values of these coefficients ( $\gamma = 0.42$ ,  $n = 2$ ) are used to determine the theoretical curves shown in Fig. 4. Except for Gauge 7 on the plane beach where the shape of  $p_b(H)$  is satisfactory but too large, the theoretical  $p_b(H)$  appears to *under predict* the large wave heights that are measured to be breaking. However, ensemble average, breaking wave energy dissipation,  $\langle \bar{e}_b \rangle$  is determined from the integration of the  $p_b(H)$  distribution so that, at least qualitatively, the areas under the distributions are modeled correctly, except for Gauge 7 on the plane beach.

The length of the test run was doubled to 12 minutes giving approximately 600 waves but no significant difference in the measured histograms for all the waves and the breaking wave subsets were noted.

#### 4.3. Energy Dissipation and $H_{rms}$ Distribution

The measured variation of the root-mean-square wave height,  $H_{rms}(x)$  for eleven positions across the bar/trough profile is shown in Fig. 5(a). The  $H_{rms}(x)$  variation is relatively flat up to the bar crest (near Gauge 4), drops rapidly in the trough region, then recovers again and afterwards drops again as all the wave

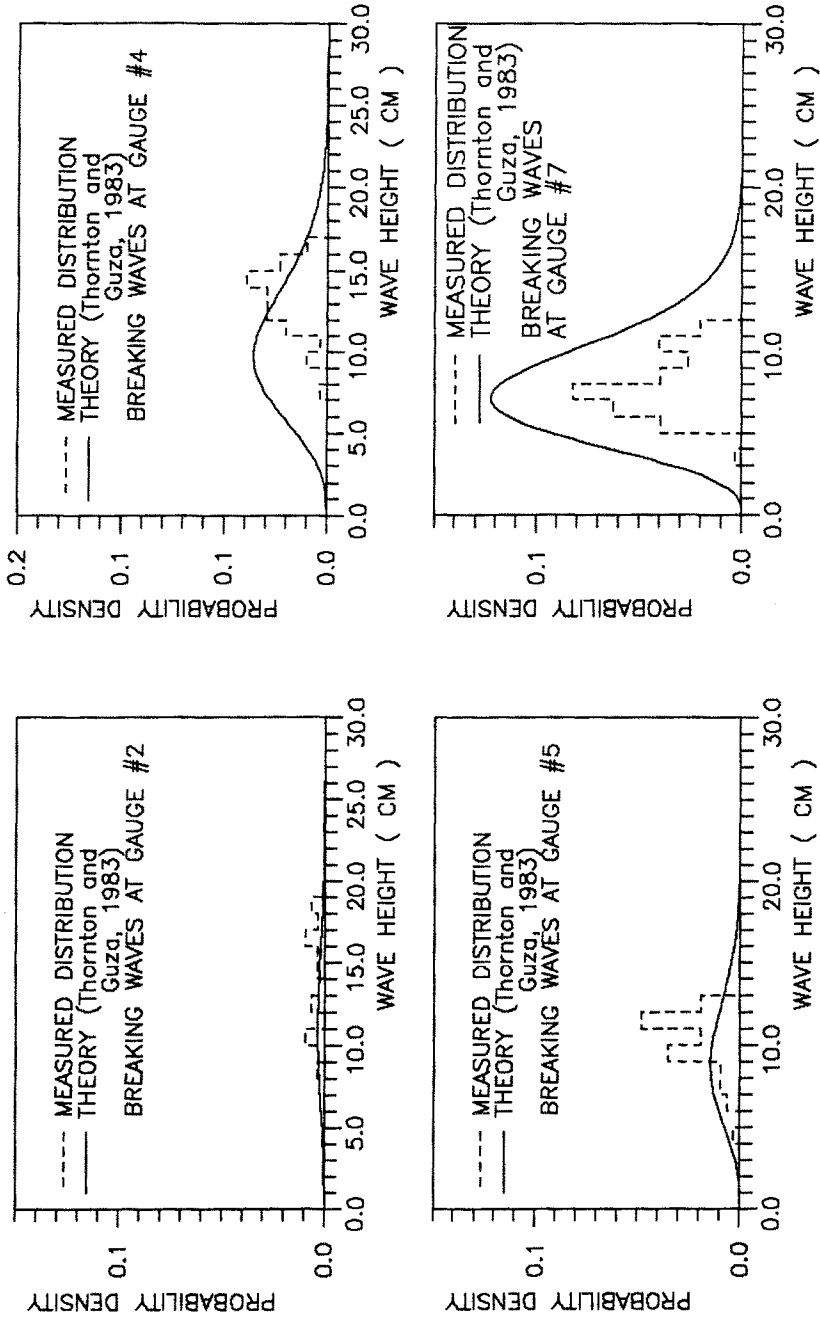

FIG 4. WAVE HEIGHT PROBABILITY DENSITY DISTRIBUTION OF BREAKING WAVES

FIG 5b. WAVE ENERGY DISSIPATION ACROSS BEACH

FIG 5a. WAVE HEIGHT DISTRIBUTION ACROSS BEACH

energy is dissipated on the plane beach. Shoaling of individual waves on the slope approaching the bar takes place but so does wave breaking for some of the waves so that the  $H_{rms}(x)$  variation actually decreases slightly as the waves approach the bar crest.

Numerical integration of the energy flux balance equation by a simple, finite-difference approximation using the ensemble average, breaking wave energy dissipation,  $\langle \bar{e}_b \rangle$  from Thornton and Guza (1983) gives the theoretical curve (dotted line) also shown in Fig. 5(a) for the laboratory bar/trough beach profile. The coefficient chosen to give the fit shown for this laboratory data is  $B = 0.8$  where  $B$  is the ratio of the broken wave height to the height of turbulence on the front of the broken wave. Thus  $B \leq 1$  is physically realistic for this laboratory-scale model. Local wave energy flux is computed from linear wave theory for both the average wave energy,  $E$  per unit surface area (i.e.  $\frac{1}{8}\rho g H_{rms}^2$ ) and the group celerity,  $C_g$  for the local water depth. The theory with  $B = 0.8$  and all other approximations ( $\gamma = 0.42$ ,  $n = 2$ ) gives a "smoothed" fit to the data for  $H_{rms}(x)$  but misses the more rapid changes occurring in the trough and wave recovery region on the plane beach. Therefore, even though the theories for the probability distributions  $p(H)$  and  $p_b(H)$  were somewhat inadequate, the results translated into the  $H_{rms}(x)$  distribution are fairly representative of the measured data.

Fig. 5(b) shows the calculated distribution of  $\langle \bar{e}_b \rangle$  across the bar region. The large spike in energy loss at the bar is apparent. The modeled energy loss term then drops way off again in the trough region, as physically expected. However, the theory as presently formulated does not appear to permit the  $H_{rms}(x)$  variation to *increase* again in the trough region as wave shoaling takes place on the plane beach. The  $\langle \bar{e}_b \rangle$  theory extracts too much wave energy in the inner surf zone region on the plane beach and this is postulated to be due to the excessively large area beneath the  $p_b(H)$  theory (see Fig. 4, Gauge 7) as compared to that actually measured.

## 5. Future Directions

### 5.1. Bores and Breaking Waves

Following LeMehauté (1962) many researchers use the theory for the energy dissipation across a moving hydraulic jump (bore) to approximate the rate of energy dissipation in a single breaking wave,  $e_b$  per unit width. Thornton and Guza (1983) took

$$e_b = \frac{1}{4} \rho g C_b \frac{(BH)^3}{d} \quad (1)$$

where  $C_b$  is the wave celerity,  $B$  is the breaker coefficient as discussed above and  $d$  is the local water depth. The average rate of energy dissipation per unit surface area of each wave of length  $L$  is then determined as

$$\bar{e}_b \equiv \frac{e_b}{L} = \frac{1}{4} \rho g \frac{C_b}{L} \frac{(BH)^3}{d} \quad (2)$$

or since  $c \equiv L/T$

$$\bar{e}_b = \frac{1}{4} \rho g \frac{1}{T} \frac{(BH)^3}{d} \quad (3)$$

so that  $\bar{e}_b$  is inversely proportional to wave period,  $T$ .

Consider three waves all of equal height but with periods,  $T$  of 5, 10, and 15 seconds. After breaking in shallow water due to depth-limiting effects, Equation (3) says average wave energy is dissipated but only at one-third the rate for the 15 second wave compared with the 5 second wave. This seems physically unrealistic because the energy dissipation is concentrated between the trough and crest regions and for trough Froude numbers relative to a moving observer, the lengths of hydraulic jumps,  $L_j$  are far less than the wave length,  $L$ .

Fig. 6 is taken from the field calibration efforts of Thornton and Guza (1983) for their theory discussed above. Long period swell waves ( $T = 13 - 18.2$  seconds) were present and each required a different calibration coefficient,  $B$  ranging between 1.3 - 1.7 to get the best fit between measured  $H_{rms}(x)$  in the field and their model computation. In essence, the longer period waves reduced  $\bar{e}_b$  in (3) and consequently require a larger  $B$  coefficient to extract enough energy to get a proper fit for  $H_{rms}(x)$ . Note also that  $B$  values greater than unity are physically unrealistic by definition and that  $B^3$  values needed for "calibration" ranged from 2.2 to 4.9 for these field results. Thornton and Guza (1983) also report setting  $B = 0.8$  to calibrate the laboratory measurements of Battjes and Janssen (1972). For laboratory wave periods,  $L_j$  is closer to  $L$ .

Svendsen, et al. (1978), Stive (1984) and others have argued that the bore model *underestimates* the actual rate of energy dissipation in breaking waves because pressure, momentum and energy distribution coefficients are neglected along with the flux of turbulent energy into and out of the control volume. These factors may account for some of the discrepancy in the use of the bore theory, but using  $L$  to define  $\bar{e}_b$  may be the most important reason.

## 5.2. Current Research

Tests are being conducted with a peak wave period of 2.3 seconds to study longer period effects on  $\bar{e}_b$  and hence  $B$  in the theory. The ratio ( $L/L_j$ ) used as

FIG 6. Variation of Calibration Coefficient,  $B$ , with Wave Period (from Thornton & Guza, 1983)

a coefficient (keeping  $B \approx 1$ ) will remove the strong dependency of  $\bar{e}_b$  on the wave period. Various ways to estimate  $L_j$  are being investigated.

Modifications to the probability density functions for all the waves and the breaking waves are also being made to more closely represent shallow water effects on  $p(H)$  and deep water effects (wave steepness) on  $p_b(H)$ .

Field data sets from Duck, NC at the Corps', Field Research Facility (Ebersole and Hughes, 1987) are also being used in this effort.

**6. Summary and Conclusions**

The transformation of an irregular wave train across a bar/trough beach profile by using the (1) energy flux balance equation including the bore model for breaking waves and (2) a single, statistical wave height,  $H_{rms}$ , together with probability functions for all the waves and those breaking as a subset, is a powerful tool for coastal engineers. Laboratory measurements reveal that refinements in the underlying theories are necessary to improve the  $H_{rms}(x)$  prediction especially in the wave height recovery region in the trough. These improvements include incorporating physically realistic coefficients for both laboratory and field data sets that are used to modify and verify the theory.

The completed results will be reported in the Proceedings of the next Conference on Coastal Engineering.

## CHAPTER 7

### THE MEDITERRANEAN SEA WAVE FORECASTING SYSTEM

Luigi Cavaleri, Luciana Bertotti

#### Abstract

We describe the sea wave forecasting system presently operational at ECMWF. After a short description of the meteorological and wave models, we address specifically the problems connected to their application to the Mediterranean Sea. We consider in particular two storms, a Mistral and an African storm, whose results provide clear indication of the present forecasting capability in this area.

#### Background

Following the opening to Optional Projects by the Council of the European Centre for Medium Range Weather Forecasts, Reading, U.K. (henceforth referred to as ECMWF), a project for real time forecast of the sea wave conditions has been proposed and approved by the Centre in May 1991. The aim is to make use of the daily meteorological forecast to produce a corresponding wave forecast on a global basis by means of an advanced wave model. Due to the lack of sufficient resolution the Mediterranean Sea cannot be properly represented on a global grid. Consequently a separate version of the model, with a sufficiently high spacial resolution but otherwise the same physics and numerics of the global version, has been implemented in this basin.

-----  
Istituto Studio Dinamica Grandi Masse, S.Polo 1364, 30125 Venice, Italy

In this paper we briefly describe the meteorological and wave models used for the forecast. Then we point out the problems specifically connected to the Mediterranean area. These are well illustrated by the analysis and forecast of two storms of different characteristics, a Mistral and an African storm. We conclude with an outlook on the expected future developments of the models and their effect on the actual forecast.

### The meteorological and wave models

A 213 components spectral meteorological model is daily run at ECMWF on a global basis for analysis and up to days forecast (Tiedtke et al, 1988). The results are provided at 6 hour interval. Among a wide variety of products the model provides U10, the 10 m height wind, with an effective resolution of approximately 80 km. This wind is used as input to the wave model.

The third generation WAM wave model is used for wave evaluation. The model (amply described in the literature, see e.g. The WAMDI Group, 1988 and Cavaleri et al, 1991) is based on the energy balance equation, and on the physical description of the processes that affect the growth and decay of wind waves. In the present version 300 components, 12 directions and 25 frequency bins, are considered. For each component and at each integration step the balance equation is solved at the knots of a spherical grid with 3 degree resolution, both in latitude and longitude, providing information on the two-dimensional spectrum at each grid point. For application to the Mediterranean Sea a limited area geographical grid, with 0.5 degree resolution, is used. The grid includes 930 sea points. With  $0.3 \times 10^3$  CPU second for each point and each integration step, a 5 day forecast in the Mediterranean Sea requires about 100 second of CPU on a CRAY C90.

### Application to the Mediterranean Sea

The main problem for a correct evaluation of wind wave conditions is the correctness of the input wind field. This is particularly true in basins with complicated geographical shape, as it is the case for the Mediterranean Sea. Limited shift of location or direction of an intense wind distribution can lead to substantial change of fetch in a certain area, and consequently to drastically

different wave conditions. The practical difficulties are also increased by the presence of a complicated orography. Cavaleri et al (1991) and Dell'Osso et al (1992) have discussed the problem of an accurate description of the wind field in the Mediterranean Sea, and they have clearly shown the fundamental role of the surrounding orography in shaping the meteorological situation, in particular the wind field, inside the basin. The present resolution of the ECMWF meteorological model has been shown to be the minimum required for a proper description of the surface wind fields in the Mediterranean basin.

In the following we show different applications of the WAM model, both with analysis and forecast wind. We call attention to the fact that for a wave model there is no difference if operating in hindcast (analysis) or forecast mode. An input wind, however produced, is just an "input wind", and the wave model reacts accordingly, independently of where the wind information comes from. Given the basic characteristics and the intrinsic accuracy of a wave model, its results plainly reflect the accuracy of the input wind fields.

The wave measurements used to verify the results discussed in this paper have been obtained with the Italian network of directional buoys. The network is described in a companion paper in this conference (De Boni et al, 1992).

#### Mistral case

On 17 November 1991 (see figure 1) a strong Mistral wind was blowing across the Western Mediterranean Sea. The Mistral wind is a cold north-westerly wind that, associated to energetic flows from the Atlantic Ocean, enters the Mediterranean Sea across the Carcassone Passage, north of the Pyrenees between Spain and France. The analysis at 12 UTC 17 November 1991 is shown in figure 1a. Figure 2a shows the corresponding wave field. The peak conditions are reached on the west coast of Sardinia, with significant wave height  $H_s$  larger than 6 metre. Figure 3a compares the WAM output at Alghero, indicated with a dot (A) in figure 2a, with the data obtained from the WAVEC wave measuring buoy. The closest grid point to the measurement location was chosen for comparison. Given this approximation and the time variability of the  $H_s$  record, the comparison is quite satisfactory.

Figure 1b,c,d shows the corresponding wind fields evaluated as forecast at day N-1, N-2, N-3 respectively. Remarkably we see that the storm was well described

till 3 days in advance. The associated wave forecasts stress further this point. They are shown in figure 2b,c,d. We note only a limited (a few hours) anticipation of the storm in figure 2d, with wave energy already protruding into the Tyrrhenian Sea.

Note that the actual ECMWF forecast would be much better than this. In routine operations a wave forecast uses as input the analysis wind until time 0 (beginning of the forecast), and then the wind forecast at +1d (day), +2d, etc. We have used a different technique. Considering p.e. the +1d wave forecast (one map of which is shown in figure 2b), for each day N of the run the input wind has been

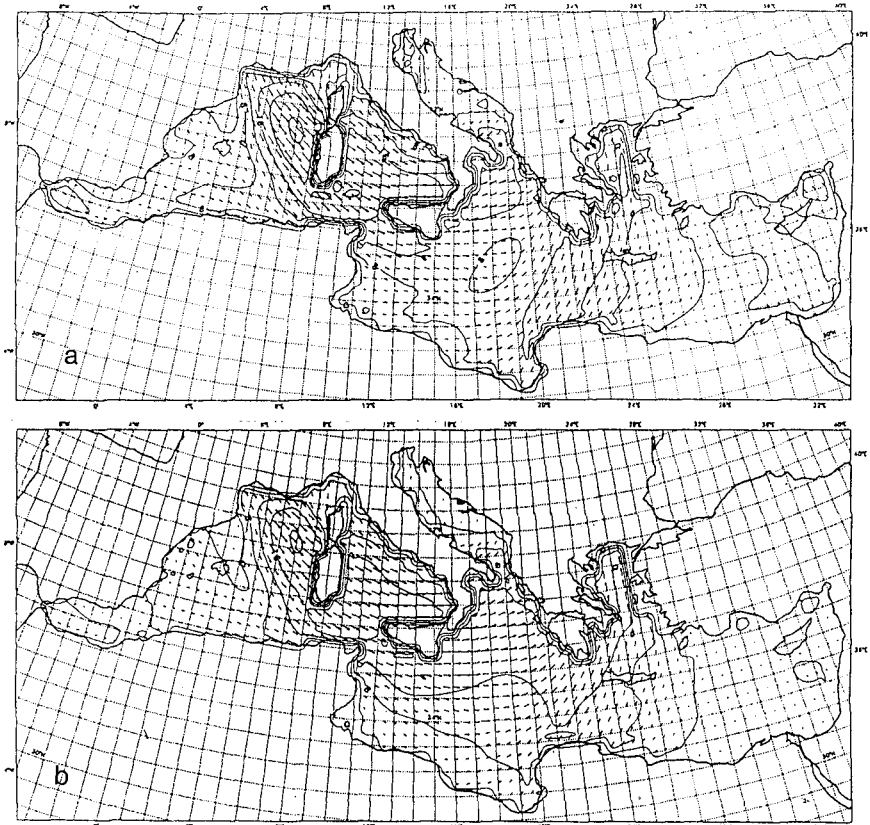

Figure 1 - Wind field on the Mediterranean Sea at 12 UTC 17 November 1991. 10 m height wind; speed is given as m/s. a) analysis, b) 1 day forecast.

given by the wind forecast produced at day N-1. So doing, the wave forecast becomes very sensitive to even small but permanent error in the wind forecast, certainly much more than in the standard routine operation. This leads to a better appreciation of the wave forecast shown in figure 2 and figure 3.

#### African storm

A week after the Mistral case a different condition arose, characterised by an intense African storm. The main feature of African storms is a small minimum that, born over the Sahara desert, moves then northward. When entering the Mediterranean Sea the minimum rapidly intensifies, producing a very localised but deep low. The dominant characteristics of the African storms, at least for what

Figure 1 - (cntd) c) as b), but for 2 day forecast, d) 3 day forecast.

concerns the evaluation of wind waves, are the extremely strong winds and the large spacial and temporal gradients. Mutatis mutandis, they resemble small hurricanes.

The meteorological situation at 00 UTC 24 November 1991 is shown in figure 4a. The minimum is located on the western end of Sicily, producing a strong southerly wind on the whole Ionian Sea, south of Italy. The associated wave conditions are represented in figure 5a. Large waves, with  $H_s$  larger than 5 metre, affect the south-eastern coast of Italy.

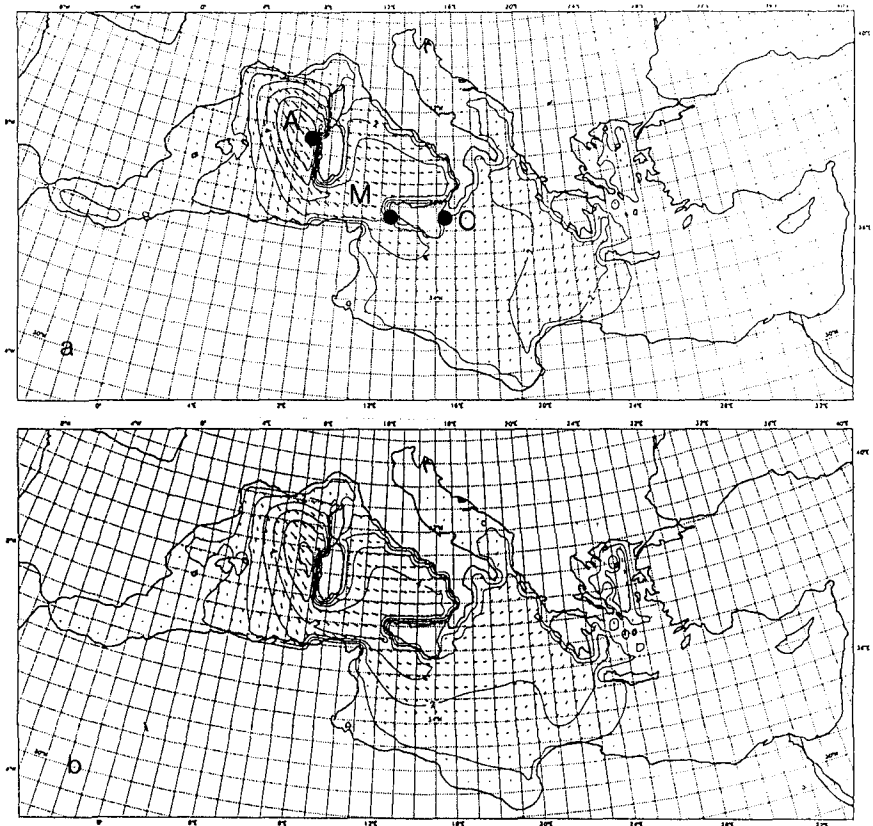

Figure 2 - Wave field on the Mediterranean Sea at 12 UTC 17 November 1991. Significant wave height, in m. a) analysis, b) 1 day forecast. The dots in a) show the position of the wave measuring stations at Alghero (A), Mazara (M), Catania

The comparison of the WAM model output with the measured  $H_s$  at Mazara and Catania (points M and C in figure 2a, respectively) reveals several interesting aspects. The underestimate of  $H_s$  at Mazara and the overestimate at Catania suggest that the analysis has misplaced the actual track of the low to the East. Also, as discussed by Dell'Osso et al (1992), the strength of these storms is often underestimated. The main reason for this is the limited resolution of the meteorological models, consequently unable to resolve the details of the storm and to correctly represent its physics. The limited dimensions of the African storms, and the substantial lack of information on the African territory where they come from, make their prediction a very difficult task. This is apparent in the 1d, 2d, 3d wind forecast in figure 4b,c,d. The storm is present, but weaker and misplaced

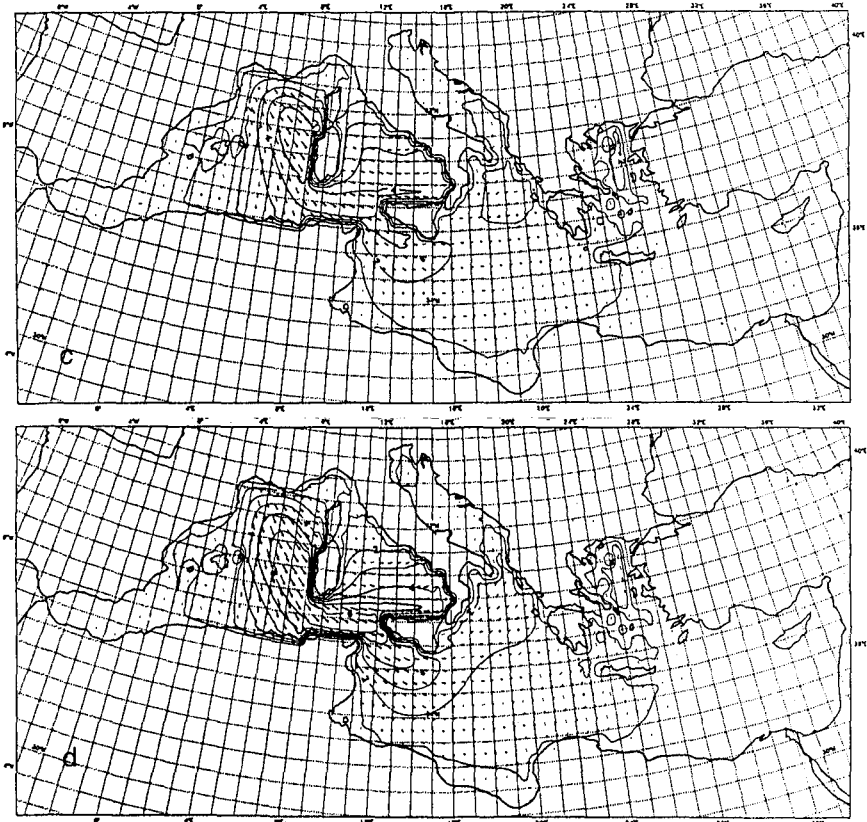

Figure 2 - (cntd) c) as b), but for 2 day forecast, d) 3 day forecast.

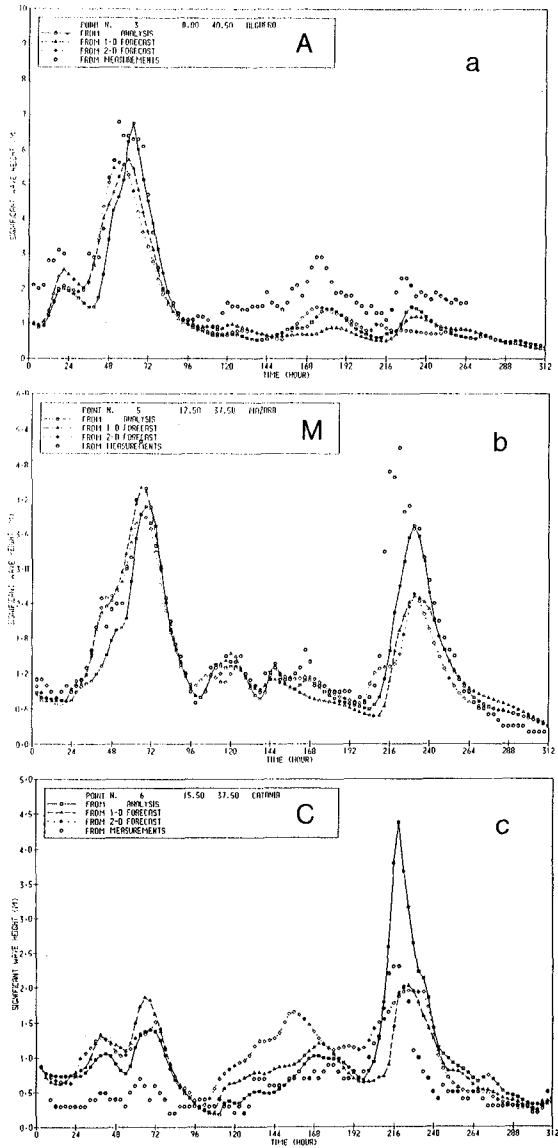

Figure 3 - Timeseries of the significant wave height (m) at the three locations shown in figure 2a. Measured data, and wave model output for analysis wind and 1 and 2 day forecast are shown.

in b, barely discernible in c, absent in d where the minimum over Sardinia has a different genesis. As previously said, the consequences of these poor forecasts are stressed by the corresponding wave forecast (shown in figure 5b,c,d). There is virtually no resemblance with the analysis field in figure 5a. This conclusion is backed by the  $H_s$  comparison in figure 3b,c. Note that the 3d forecast has not been drawn to avoid an unnecessarily large number of diagrams in the figure.

### Conclusions and outlook

The tests carried out until now suggest that in most of the cases the T213 spectral

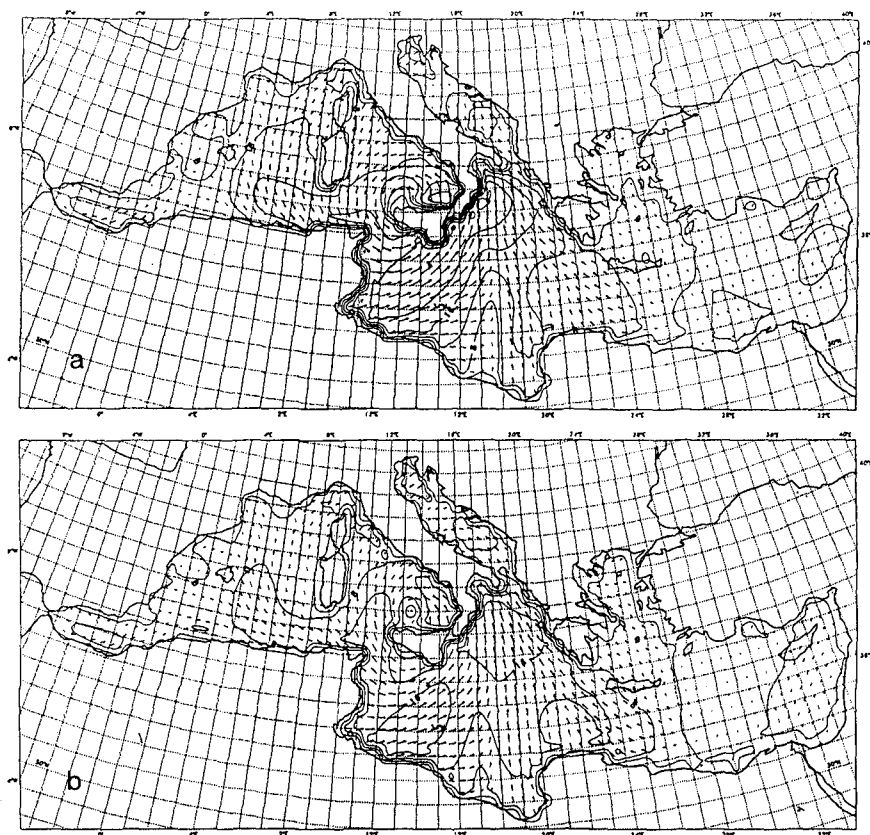

Figure 4 - As figure 1, but at 00 UTC 24 November 1991.

meteorological model presently used at ECMWF provides acceptable surface winds on the Mediterranean Sea. This is true for extended storms with a well defined shape and distribution. It is not the case for small storms, e.g. the African storms, whose structure cannot be resolved in the present resolution of the meteorological model. A similar argument holds for the predictability of the storms, with the further point that the western storms are well documented from several days in advance, while in practice the African storms are not detected by the scarce and scattered meteorological network present on the North-African continent.

In general terms the meteorological and wave predictability is expected to improve in the future, both for the increase of resolution of the models, and for the large

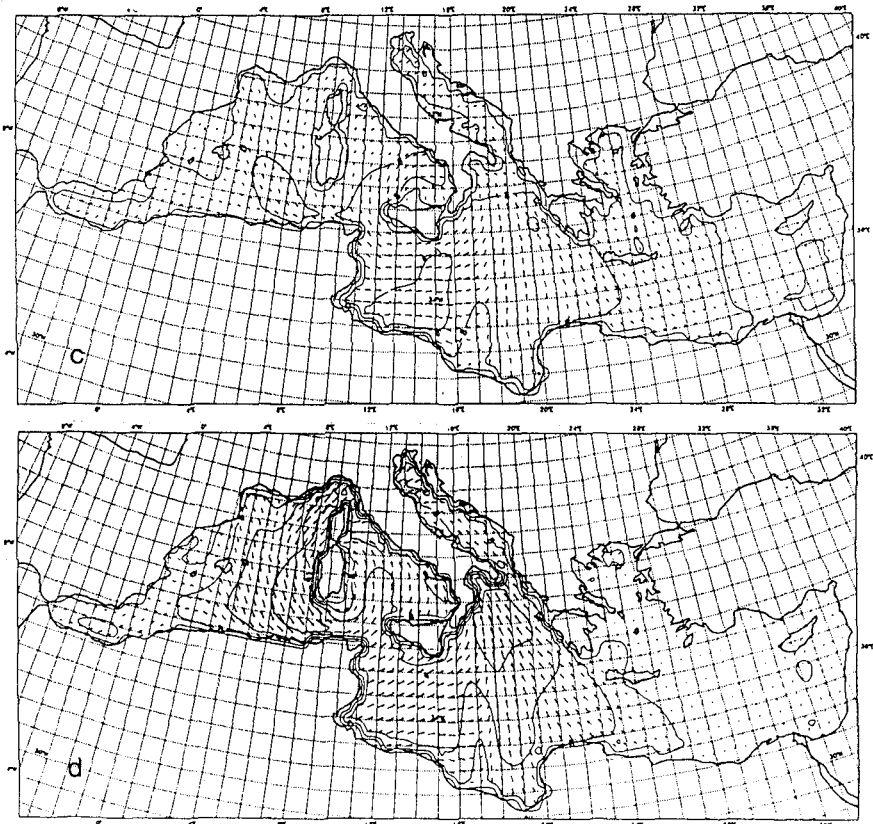

Figure 4 - (cntd).

amount of information provided by the satellite like ERS-1. However, once more the argument is much weaker for the African storms, because of the lack of sufficient information (the ERS-1 scatterometer and altimeter provide estimates of the wind distribution only on the sea). It is true that a better definition of the global meteorological situation will help in detecting the conditions that are at the origin of the African storms. However, the surface observations, providing the truth for the short term accurate forecasts, will still be missing. Similar conditions are found in many parts of the world (Bengtsson, 1991). If the general forecast, and the one on the Mediterranean Sea in particular, is to be substantially improved in the near future, this problem will have to be addressed with will and decision.

## CHAPTER 8

### Current-Depth Refraction and Diffraction Model for Irregular Water Waves

Jang Won Chae<sup>1</sup> and Shin Taek Jeong<sup>2</sup>

#### Abstract

A numerical model is presented for the prediction of combined refraction-diffraction of waves propagating in the region of slowly varying current and topography. For steady waves, two elliptic-type model equations are derived from the mild-slope equation which can be solved in a similar way to an initial value problem without stability restriction. Therefore, the present model appears to be an efficient tool for irregular wave propagation problem in a large coastal area. Some examples of numerical computations are given for the cases concerning wave-current interaction on a sloping beach and over a mound.

#### Introduction

Waves propagating near a tidal inlet will be transformed due to currents and irregular water depths. The wave-current interaction is one of the most interesting and important phenomena for the prediction of wave climate and resultant sediment transport in coastal areas. The approximation of irregular waves by a monochromatic wave in modeling of wave transformation in coastal areas often introduces large errors in wave heights. There is a definite need for an efficient method for the calculation of irregular wave transformation over large coastal area(Panchang et al., 1990).

<sup>2</sup> Senior Res. Engr., Coast. Engrg. Lab., Korea Ocean Res. & Dev. Inst. Ansan P.O. Box 29, Seoul 425-600, Korea.

Recently, a number of studies have been made for the analysis of wave-current system. Booij(1981), Liu(1983), and Kirby(1984) proposed hyperbolic wave equations governing the propagation of waves in water of varying depth and currents in the mild-slope approximation. They used parabolic approximation in order to circumvent the difficulty in calculation of elliptic equations for regular waves. Ohnaka et al.(1988) provided a set of mild-slope equations based on Kirby's equation, which consists of two first-order equations describing the water surface elevation and flow rate. This model includes partially reflective boundary condition.

The models mentioned above employ parabolic- or hyperbolic-type differential equations which are in general not so efficient to use in large area (order of hundreds of wave length). In shallow water they need fine grid resolution to meet sufficient accuracy of numerical results, which is more crucial condition for the high frequency components of wave spectrum.

In the present study, a new set of mild-slope equations describing the deformation of regular waves by a large-scale current field in water of irregular depth is derived, and an efficient numerical method is also presented. The elliptic type governing equations are solved in a similar way to an initial value problem. The accuracy of the numerical method does not greatly depend on grid size and computation time is comparatively short. Therefore, this method is extensively applied to several spectral components in order to simulate irregular wave transformation due to combined refraction-diffraction. Linear superposition of monochromatic-wave calculation is made to obtain spectral estimates. Some results of the computation are compared with analytical solutions, and numerical examples concerning the interactions between waves and currents over a mildly sloping beach and also over a mound are presented.

### Derivation of Governing Equations

The mild-slope equation has been used successfully as a model equation for describing surface water waves propagating over a seabed of mild slope(eg. Berkhoff, 1972). For a wave-current interaction Kirby(1984) derived a general equation. Recently Chae et al.(1990) and Jeong(1990) have rederived the mild-slope equation using variational principle and Green's theorem for linear water waves following Booij's method(1981). The equation can be written as

$$\frac{D^2\Phi}{Dt^2} + (\nabla \cdot \underline{U}) \frac{D\Phi}{Dt} - \nabla \cdot (CC_g \nabla \Phi) + (\sigma^2 - k^2 CC_g)\Phi + W \frac{\partial \Phi}{\partial t} = 0 \quad (1)$$

where  $D/Dt = \partial/\partial t + \underline{U} \cdot \nabla$ ,  $\nabla = [(\partial/\partial x) \mathbf{i}, (\partial/\partial y) \mathbf{j}]$ , and  $\underline{U} = (u, v)$ ,  $\Phi$  the complex velocity potential at the mean surface level,  $\sigma$  the intrinsic

angular frequency,  $k$  wave number,  $C$  and  $C_g$  are the phase and group velocity respectively, which are defined according to  $C = \sigma/k$ ,  $C_g = \partial\sigma/\partial k$ ,  $\sigma^2 = gk \tanh kh$ , and  $W$  dissipation coefficient,

$$\omega = \sigma + \mathbf{k} \cdot \mathbf{U} \quad (2)$$

where  $\omega$  is absolute angular frequency. The velocity potential at an elevation  $z$  is given by

$$\Phi(\mathbf{x}, z, t) = f(z) \phi(\mathbf{x}, t) \quad (3)$$

where  $f(z) = (\cosh k(z+h))/(\cosh kh)$ . Since the bottom is mildly sloping, the derivative of  $f$  with respect to  $\mathbf{x}$  will be small.

For purely periodic waves the velocity potential is given by

$$\phi(\mathbf{x}, t) = \text{Re} \left[ \hat{\phi}(\mathbf{x}) e^{-i\omega t} \right] \quad (4)$$

Substitutions of eq.(4) into eq.(3), and further them into eq.(1) produce an elliptic equation as follows:

$$\begin{aligned} & -i\omega \left[ 2\mathbf{U} \cdot \nabla \hat{\phi} + \hat{\phi} (\nabla \cdot \mathbf{U}) \right] + (\mathbf{U} \cdot \nabla) (\mathbf{U} \cdot \nabla \hat{\phi}) + (\nabla \cdot \mathbf{U}) (\mathbf{U} \cdot \nabla \hat{\phi}) \\ & - \nabla \cdot (CC_g \nabla \hat{\phi}) + (\sigma^2 - \omega^2 - k^2 CC_g) - i\omega W \hat{\phi} = 0 \end{aligned} \quad (5)$$

If  $\mathbf{U} = (0, 0)$ , eq.(5) reduces to Berkhoff's(1972) mild-slope equation.

Here the complex velocity potential  $\hat{\phi}$  can be written in terms of the amplitude  $a$  and the phase  $S$  as

$$\hat{\phi} = -ig \frac{a}{\sigma} e^{iS} \quad (6)$$

where  $g$  is acceleration due to gravity, and  $S(\mathbf{x})$  phase function given by

$$S(\mathbf{x}) = \mathbf{k} \cdot \mathbf{x} - \omega t \quad (7)$$

Then eq.(5) with the substitution of eq.(6) reduces to a set of elliptic equations by separating the resulting equation into real and imaginary parts as follows

$$\nabla \cdot \left[ \mathbf{U} \frac{a^2}{\sigma^2} (\omega - \mathbf{U} \cdot \nabla S) + CC_g \frac{a^2}{\sigma^2} \nabla S \right] + W \frac{a^2}{\sigma} = 0 \quad (8)$$

$$\begin{aligned} & CC_g \frac{a}{\sigma} (\nabla S)^2 - (\mathbf{U} \cdot \nabla S - \omega)^2 \frac{a}{\sigma} + (\sigma^2 - k^2 CC_g) \frac{a}{\sigma} \\ & - \nabla \cdot (CC_g \frac{a}{\sigma}) + (\nabla \cdot \mathbf{U}) (\mathbf{U} \cdot \nabla \frac{a}{\sigma}) + \mathbf{U} \cdot \nabla (\mathbf{U} \cdot \nabla \frac{a}{\sigma}) = 0 \end{aligned} \quad (9)$$

These are the final forms of the wave equation for this numerical model study. In the present paper, we are concerned with the problems where  $W$

is assumed zero for simplicity and the mean current is in the following condition

$$|\underline{U}|^2 \ll CCg \quad (10)$$

Eq.(9) then can be simplified as follows:

$$CCg \frac{a}{\sigma} (\nabla S)^2 - (\underline{U} \cdot \nabla S - \omega)^2 \frac{a}{\sigma} + (\sigma^2 - k^2 CCg) \frac{a}{\sigma} - \nabla \cdot (CCg \nabla \frac{a}{\sigma}) = 0 \quad (11)$$

If we set  $\underline{U} = (0, 0)$ , eqs.(8) and (11) reduce to the Ebersole's(1985) model equations for depth refraction-diffraction. Further, the equation of wave action conservation for steady waves can be simply obtained from eq.(8).

The main wave direction  $\theta$  can be given from eq.(12) with the combination of eqs.(8) and (11). The irrotationality condition of wave number vector is

$$\frac{\partial(|\nabla S| \sin \theta)}{\partial x} = \frac{\partial(|\nabla S| \cos \theta)}{\partial y} \quad (12)$$

### Numerical Computation

Both eqs.(8) and (11) are of the elliptic type and can generally be solved as a boundary value problem using finite element method. If we neglect wave reflections from boundaries, and also if approximate intermediate values of wave properties can be provided at all grid points using a refraction model, the problem can be converted into an initial value problem for the wave diffraction (eg. Ebersole, 1985).

Finite difference method is adopted to solve the governing equations (8), (11) and (12). The coordinate and grid systems as shown in Figure 1 are employed. Forward difference scheme is used in x-direction and centered scheme in y-direction to approximate the eq(8), which yields the following difference equations.

$$(a_j^i)^2 b_j^i = (a_j^{i+1})^2 b_j^{i+1} + \frac{\Delta x}{2\Delta y} [(a_{j+1}^i)^2 b_{j+1}^i - (a_{j-1}^i)^2 b_{j-1}^i] \quad (13)$$

where

$$b_j^i = \left\{ \frac{1}{\sigma^2} \right\}_j^i \left[ U(\omega - \underline{U} \cdot \nabla S) + CCg |\nabla S| \cos \theta + V(\omega - \underline{U} \cdot \nabla S) + CCg |\nabla S| \sin \theta \right]_j^i$$

$$(a_j^{i+1})^2 b_j^{i+1} = \tau (a_{j-1}^{i+1})^2 b_{j-1}^{i+1} + (1 - 2\tau) (a_j^{i+1})^2 b_j^{i+1} + \tau (a_{j+1}^{i+1})^2 b_{j+1}^{i+1}$$

where  $\tau$  is Abbott's dissipative interface factor ( $0 \leq \tau \leq 0.5$ ).

Figure 1. Definition of coordinate system, grid cell and wave angle conventions.

Eq(11) can be rearranged in the standard form of quadratic equation

$$P(|\nabla S|)^2 + Q(|\nabla S|) + R = 0 \tag{14}$$

The solution at a point (i , j) is given as follows

$$|\nabla S|_j^i = \left[ \frac{-Q + (Q^2 - 4PR)^{\frac{1}{2}}}{2P} \right]_j^i \tag{15}$$

where details of P, Q, R are given in Jeong(1990).

Differentiation eq(12) for wave direction  $\theta$  can be written as

$$\theta_j^i = \sin^{-1} \left\{ \frac{1}{|\nabla S|_j^i} \left[ \tau(|\nabla S| \sin \theta)_{j-1}^{i+1} + (1 - 2\tau) (|\nabla S| \sin \theta)_j^{i+1} + \tau(|\nabla S| \sin \theta)_{j+1}^{i+1} - \frac{\Delta x}{2\Delta y} \left\{ (|\nabla S| \cos \theta)_{j+1}^i - (|\nabla S| \cos \theta)_{j-1}^i \right\} \right] \right\} \tag{16}$$

Boundary conditions are now discussed to solve the governing equations. Input wave conditions are to be given along the offshore boundary, which are wave height, period and direction. At the side boundaries waves will be transmitted without reflection. Near the land boundary wave will break and be fully absorbed. Wave breaking criteria  $H_b = 0.78h_b$  is used for simplicity, where  $H_b$  is breaker height and  $h_b$  breaker depth.

Initial wave field is defined at all grid points using the Snell's law. For the calculation of wave diffraction we need intermediate values of wave heights and directions over the modelled area. These can be provided from a refraction model based on energy balance equation for the waves propagating on currents (eg. Chae and Song, 1986).

The computation is made row by row and proceeds toward the shoreward direction as in the method for an initial value problem.

As we use steady-wave iteration approach, the simple iterative method for the solution of the equations may have no stability restrictions (Roach, 1982). From the sensitivity analysis for the waves propagating over a circular shoal, variation of computed wave heights is less than 10% for relative grid sizes ( $L_o/\Delta x$ ) from 4 to 32 and  $L_o/\Delta x = 4$  gives the best fit to the experimental data. It can be said that the grid size of the present model does not significantly depend on wave length. However the restriction is strictly applied to parabolic models. This is one of the major advantages of the present model.

Iterative solution procedure is carried out until the solutions converge to the criterion given as follows

$$\max_{i,j} \left| \frac{(X_j^i)_{\text{new}} - (X_j^i)_{\text{old}}}{(X_j^i)_{\text{old}}} \right| < 0.005 \quad (17)$$

where  $X_j^i$  is the computed value at a grid point (i, j). Then the solutions become coupled ones with three governing equations.

The validity and accuracy of the above mentioned numerical scheme have been proved in Chae et al. (1990) through the comparison with experimental data for depth refraction-diffraction problem of monochromatic waves.

### Calculation of Wave Spectral Changes

As the present monochromatic wave model is computationally fast and stable especially for short period waves, it may be valuable to simulate spectral transformation of irregular waves propagating in water of complex bathymetry and with ambient currents. Input spectrum  $S_o(f, \theta)$  is given as below

$$S_o(f, \theta) = S_o(f) G(f, \theta) \quad (18)$$

where

$$S_o(f) = 0.25 H_{1/3}^2 T_{1/3} (T_{1/3} f)^{-5} \exp[-1.03 (T_{1/3} f)^{-4}] \quad (19)$$

is the Bretschneider-Mitsuyasu(B-M hereafter) frequency spectrum, and the directional spreading function  $G(f, \theta)$  is given by

$$G(f, \theta) = \left\{ \frac{1}{\pi} 2^{2s-1} \frac{\Gamma^2(s+1)}{\Gamma(2s+1)} \right\} \cos^{2s} \left\{ \frac{\theta}{2} \right\} \quad (20)$$

$\Gamma$  : gamma function

$$s = \begin{cases} S_{\max} \cdot (f/f_p)^5 & : f \leq f_p \\ S_{\max} \cdot (f/f_p)^{-2.5} & : f \geq f_p \end{cases} \quad (21)$$

$f_p$  : Peak frequency of  $S(f)$ , ( $f_p = 1/1.05 T_{1/3}$  used)

The frequency spectrum and directional spreading function are divided into equal segments. The lower and upper frequency limits of the spectrum are 0.07Hz and 0.37Hz.  $\Delta f = 0.02$ Hz(15 frequency bins) and  $\Delta \theta = 10^\circ$ (17 directional bins) are used.

The input wave amplitude for a particular frequency-directional component is  $a_o = [2S_o(f, \theta) \Delta f \Delta \theta]^{1/2}$ . The resulting wave amplitude at any location can be computed using the model, and then the transformed spectrum  $S(f, \theta)$  can be obtained as

$$S(f, \theta) = [a/a_o]^2 S_o(f, \theta) \quad (22)$$

### Computation Results and Analysis

To demonstrate the applicability of the model numerical computations are made for two cases. The first case is for the refraction-diffraction due to rip-current in a mildly sloping beach as shown in Figure 2(studied by Arthur, 1950).

The computational domain is divided into square grids ( $\Delta x = \Delta y = 10$  m) and numerical calculations are performed. Normal incident waves of  $H_o = 1$  m,  $T = 8$  s are used as an incident wave condition at the offshore boundary. The background(of initial and intermediate) wave field are specified using the Snell's law and the refraction routine in the program, respectively. The dimensionless wave heights  $H/H_o$  for two transections are plotted in Figure 3. For the purpose of comparison, parabolic model results(Kirby, 1984) are also shown in the same figure. A comparison of the figures shows that they are in good agreement.

Figure 2. Rip-current field.

Figure 3. Wave height relative to incident wave for waves interacting with rip current.

The second case is for irregular wave propagation over a shoal as shown in Figure 4, which was recently simulated in a hydraulic laboratory equipped with multi-directional random wave generators (Hiraishi, 1991). The shoal is similar to that used in the experiments of Ito and Tanimoto (1972) with a minimum water depth of 0.05 m at the center of the shoal and constant depth (0.15 m) in the region outside the shoal. B-M spectrum is used for the input spectrum for which  $H_{1/3} = 0.1$  m,  $T_{1/3} = 1.5$  s, and  $S_{\max} = 75$  (narrow directional spectrum) are used. The grid sizes used are  $\Delta x = \Delta y = 0.1$  m. The results are presented in Figure 5, in the form of normalized wave height against the input wave height. The computations agree very well with experimental data which are for the case of non-breaking waves. As the frequency and directional spectra are not available, the comparison for those spectra between computation and experiment can not be made. However, the spectrum can be simulated by linear superposition of monochromatic wave components (eg. Panchang et al, 1990). From those comparisons, the present model appears to be used effectively for the calculation of irregular wave propagation with respects to computation accuracy and time (26 min. with IBM 386 PC).

The present model is used for the analysis of irregular wave transformation due to combined refraction-diffraction while the waves propagate over a circular shoal (Ito and Tanimoto, 1972). The input spectrum is discretized into segments of  $\Delta f$  and  $\Delta \theta$ .  $H_{1/3} = 1.0$  m and  $T_{1/3} = 5.0$  s are used for the frequency spectrum (Figure 6) and angular spreading parameter  $S_{\max} = 25$  and 75 for the broad and narrow directional spectra, respectively. Current velocity fields are generated using

Figure 4. Experimental configuration(Hiraishi, 1991).

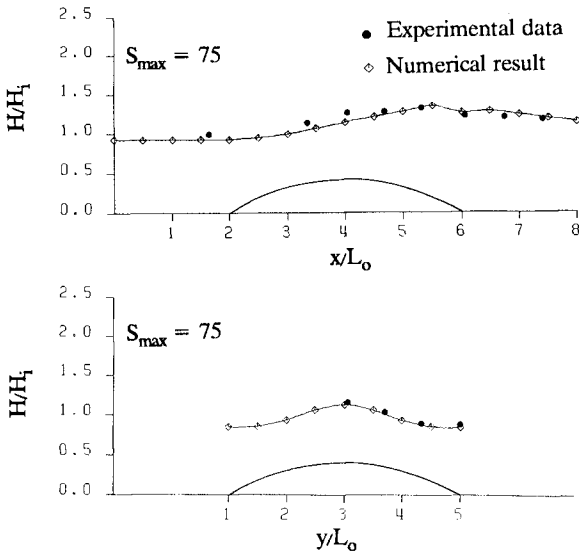

Figure 5. Comparisons between present model results and observed data.

a standard depth-averaged flow model, and assumed frozen during the wave propagation over the field. A uniform current field is assumed at the incoming boundary where the maximum velocity is 0.5 m/s.

The results are shown in Figures 6 and 7. The frequency and frequency-directional spectra are for opposing and following current conditions, and also for broad and narrow directional spreading conditions at a specified point ( $x/L_0 = 7, y/L_0 = 3$ ) behind the circular shoal.

As shown in Figure 7, we can clearly see the differences in spectral shapes of input  $S_0(f, \theta)$  depending on the value of  $S_{max}$ . The smaller value of  $S_{max}$  yields less peaky spectral shape and broader band of energy distribution than those with larger  $S_{max}$ . When the waves propagate on a current field, the wave height and direction are strongly dependent on the magnitude and direction of the current.

In the following current field the velocities over the shoal are generally larger than those in other region. This will increase the celerity and decrease focusing effect of wave rays propagating over that region, but in the opposing current the effect will be adverse. Such a wave-current interaction causes a large peak around centered direction in the opposing current field and a small peak with side humps in the following current. The waves with directionally narrow banded spectrum will produce very sharp peak, which is contributed mainly from the peak region.

Figure 6. Input frequency spectra( $S_0(f)$ ) and output frequency spectra( $S(f)$ ) at  $x/L_0 = 7, y/L_0 = 3$ .

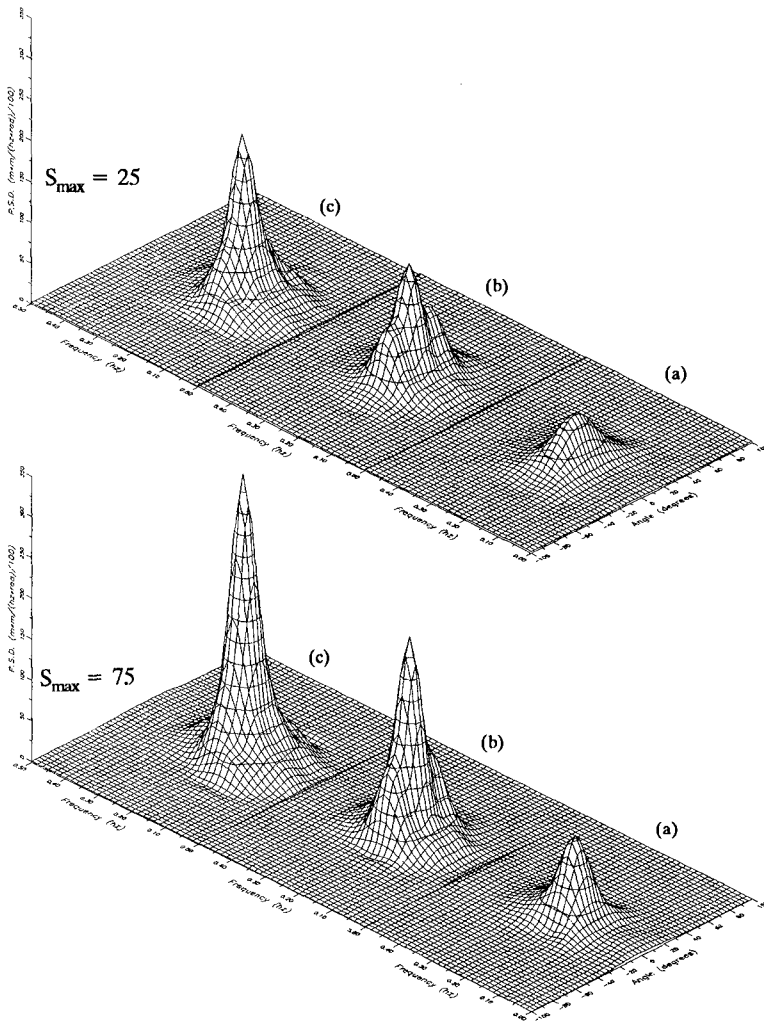

Figure 7. Input directional spectra( $S_o(f, \theta)$ ) and output directional spectra( $S(f, \theta)$ ) at  $x/L_o = 7, y/L_o = 3$  for different  $S_{\max}$  and current conditions. (a)  $S_o(f, \theta)$ , (b)  $S(f, \theta)$  with following current, (c)  $S(f, \theta)$  with opposing current.

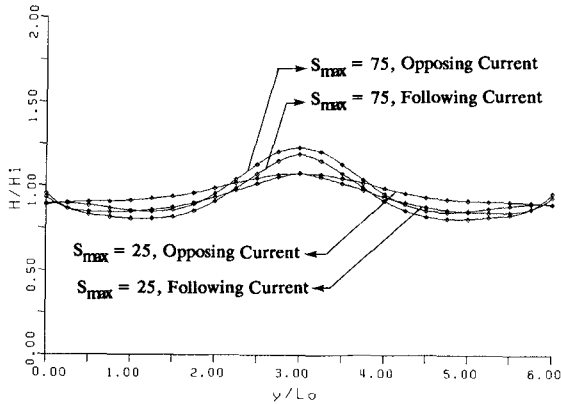

Figure 8. Wave height comparisons, for narrow and broad directional spectra.

The computed frequency spectra are shown in Figure 6. The spectral peaks are almost at the same frequency, the amplification is prominent in the peak frequency region, where the current effects are also dominant.

The propagation of wave spectra with narrow or broad directional spread shows a little difference between the wave heights in the following and opposing current conditions. The wave heights in the opposing current field are generally larger than those in the following current field (Figure 8).

### Conclusions

A set of elliptic type mild-slope equations has been derived for wave-current interactions over a slowly varying topography. Numerical computation method to solve the equations has been presented. The model solves the elliptic equations in a way similar to an initial value problems. Accuracy of numerical computation does not greatly depend on grid size. It can be said that the present model is efficient for wave propagation problems in a large coastal area. Numerical results are shown for transformation of the waves propagating on a rip-current in a mildly sloping beach. They are in good agreement with published ones (Kirby, 1984).

It is also shown that spectral transformation of irregular waves can be satisfactorily simulated by summing up the results from a monochromatic refraction-diffraction model for component waves of a spectrum. From the analysis of frequency-directional spectrum for waves propagating on currents flowing over a mound we can see large differences in spectra

depending on current directions, but there is a little difference in wave heights. When the waves propagate on strong currents in shallow water, non-linearity of the waves and wave breaking will be significant, and therefore this model should not be applied.

## CHAPTER 9

### TRANSIENT PROPAGATION OF WAVES IN A FLUME

Kwok Fai Cheung<sup>1</sup>, Michael Isaacson<sup>2</sup>, Member ASCE, and Etienne Mansard<sup>3</sup>

#### ABSTRACT

A recently developed numerical method is applied to the study of transient, nonlinear wave propagation in a flume. The nonlinear free surface boundary conditions and the wave generator boundary condition are expanded about the corresponding equilibrium positions by perturbation expansions. The boundary conditions are then satisfied to second order by a numerical integration in time, and the field solution at each time step is obtained by an integral equation method based on Green's theorem. The propagation characteristics of regular, bichromatic and irregular waves are studied numerically, and the significance of nonlinear effects is highlighted.

#### 1. INTRODUCTION

The numerical prediction of transient wave propagation in a flume has been the subject of investigation for a number of years. To a first approximation, linear wave theory may be used to describe the transient wave field. However, there are a number of shortcomings associated with this approach, which are mainly due to the neglect of higher order forced and free wave components. Although the amplitudes of these higher order components are generally small, these may become important for wave flume and basin tests involving wave interactions with harbours, floating breakwaters or moored vessels.

To account for nonlinear effects, the transient wave problem may be treated numerically by a time-stepping procedure, in which the full nonlinear free surface boundary conditions are applied on the instantaneous free surface and a new system of simultaneous equations is generated and solved at each time step as the free surface

moves to a new position (e.g. Longuet-Higgins and Cokelet, 1976; Kim et al., 1983; and Brorsen and Larsen, 1987). On the other hand, a second-order model defined on fixed boundaries can be obtained by the application of a perturbation expansion so that a solution to the system of simultaneous equations is required only once rather than at each time step. The boundary conditions to second order are then satisfied on the corresponding equilibrium positions by a numerical integration in time. Based on this approach, Isaacson and Cheung (1991, 1992) have treated the second-order diffraction problems in two and three dimensions respectively.

The theoretical treatment for the extension of the second-order diffraction method in two dimensions to include the effects of a moving wave generator has been described by Isaacson et al. (1993). The computed free surface elevations have been validated through comparisons with experimental results. The present paper summarizes the theoretical and numerical formulations of the method, and places emphasis on numerical results for the propagation of various transient wave trains and wave packets.

## 2. THEORETICAL FORMULATION

A description of the theoretical and numerical formulations has been given in detail by Isaacson et al. (1993) and only a brief outline of the method is given here. With reference to Fig. 1, the two-dimensional problem is defined with respect to a right-handed Cartesian coordinate system  $(x,z)$ . The wave generator is located above a fixed vertical plate and extends from a distance  $h$  above the floor of the flume to the water surface. The generator may produce a combined piston/paddle motion defined by the generator's horizontal displacement  $\delta$  at the still water level together with a rotation  $\theta$  measured clockwise from the  $z$  axis. With the fluid assumed incompressible and inviscid, and the flow irrotational, the fluid motion is described by a velocity potential  $\phi$  which satisfies the Laplace equation within the fluid domain and which is subject to boundary conditions on the generator surface  $S_w$ , the instantaneous free surface  $S_f$  at  $z = \eta$ , the flume floor  $z = -d$ , and a radiation surface  $S_c$ .

When the amplitude of the wave generator displacement is small compared to the height of the generator, and the water depth is not small compared with a typical wavelength, it is possible to apply Taylor series expansions to reduce the wave generator and free surface boundary conditions, originally derived on the instantaneous surfaces, to conditions evaluated at the corresponding equilibrium positions. The problem may then be defined with respect to a time-independent domain  $D$  which is bounded by the equilibrium generator surface  $S_g$ , the still water surface  $S_0$ , the flume floor and the control surface  $S_c$ . The first-order and second-order quantities in the formulation are further separated by introducing perturbation expansions for  $\phi$  and  $\eta$  and taking the specified generator motion variables  $\delta$  and  $\theta$  to be first-order quantities:

$$\phi = \varepsilon \phi_1 + \varepsilon^2 \phi_2 + \dots \quad (1)$$

$$\eta = \varepsilon \eta_1 + \varepsilon^2 \eta_2 + \dots \quad (2)$$

$$\delta = \varepsilon \delta_1 \quad (3)$$

$$\theta = \varepsilon \theta_1 \quad (4)$$

where  $\varepsilon$  is a perturbation parameter related to the amplitude of the horizontal displacement of the wave generator which is small.

Substituting the power series representations for  $\phi$ ,  $\eta$ ,  $\delta$  and  $\theta$  into the Laplace equation and the boundary conditions, including the expanded generator and free surface boundary conditions, separate boundary value problems may be developed for each of the  $\varepsilon$  and  $\varepsilon^2$  terms in the power series. In the  $k$ -th order problem ( $k = 1, 2$ ), the potential  $\phi_k$  satisfies the Laplace equation

$$\nabla^2 \phi_k = 0 \quad \text{in } D \quad (5)$$

and is subject to the boundary conditions applied on the flume floor, the equilibrium generator surface and the still water surface. These are given respectively as

$$\frac{\partial \phi_k}{\partial z} = 0 \quad \text{at } z = -d \quad (6)$$

$$\frac{\partial \phi_k}{\partial n} = f_k \quad \text{on } S_g \quad (7)$$

$$\frac{\partial \phi_k}{\partial z} - \frac{\partial \eta_k}{\partial t} = f'_k \quad \text{on } S_o \quad (8)$$

$$\frac{\partial \phi_k}{\partial t} + g \eta_k = f''_k \quad \text{on } S_o \quad (9)$$

Here  $t$  denotes time,  $g$  is the acceleration due to gravity and  $n$  is distance in the direction of the unit normal vector  $\mathbf{n}$  directed outward from the fluid region. Each of the terms  $f_k$ ,  $f'_k$  and  $f''_k$  represents known expressions which can be evaluated from the specified motion of the wave generator and the solution at first order. In addition, the potential has to satisfy a radiation condition

$$\frac{\partial \phi_k}{\partial t} + c \frac{\partial \phi_k}{\partial n} = 0 \quad \text{on } S_c \quad (10)$$

where  $c$  is the time-dependent celerity of the radiated waves on the control surface (see Orlanski, 1976; and Isaacson and Cheung, 1991). With the boundary conditions on each of the boundaries properly defined, the solution to the boundary-value problem is obtained by the application of a boundary integral equation involving a Green's function.

Initial conditions correspond to a stationary generator and still water in the computational domain. A wave train is subsequently generated by applying a prescribed time series for the generator motion. The generator boundary condition, the free surface boundary conditions and the radiation condition, which together govern the development of the flow, are satisfied by a numerical integration in time. Since the boundaries are invariant in time, the matrix equation obtained through a discretization

of the integral equation need be inverted only once rather than at each time step, with variations in time only affecting the input vector of the matrix equation. The maximum time-step size for a given discretization and excitation wave frequency can be determined by the Courant criterion,  $c\Delta t/\Delta S \leq 1$ , where  $\Delta t$  and  $\Delta S$  denote respectively the time-step and facet sizes. This criterion has been tested numerically in the context of the second-order diffraction problem, and has been found to provide reasonable estimates (Isaacson and Cheung, 1991).

### 3. EXPERIMENTAL SET-UP AND PROCEDURE

In order to verify the present numerical model, a series of physical experiments were performed at the Hydraulics Laboratory of the National Research Council of Canada. The experiments were carried out in a flume of dimensions  $1.2 \times 1.2 \times 67$  m. A beach of uniform slope 1:25 was located at one end of the flume, and consisted of a sub-layer of coarse sand covered by a 10-cm layer of sharp stones (2-3 cm). Earlier measurements of wave reflection by the beach indicated that the reflection coefficient was below 5% over the wave frequency range 0.3 to 1.3 Hz. However, long waves with a frequency range 0.04 to 0.05 Hz encounter a relatively high degree of reflection, corresponding to reflection coefficients of the order of 40 to 50%.

The flume is equipped with a hydraulically driven wave generator which was operated in piston mode only. In the experiments described here, waves were generated in a water depth of 0.7 m and the free surface elevations at 12 different locations along the flume were monitored using twin wire capacitance wave probes. Data acquisition and analysis were performed using the Generalized Experiment control and Data Analysis Package (GEDAP; Miles and Funke, 1989) and the Real-Time Control (RTC) software packages (Crookshank, 1989). These allow all required probes to be sampled simultaneously. The sampling rate was chosen to be 0.05 sec, while the total sampling time for a typical test was chosen to be 100 sec.

### 4. RESULTS AND DISCUSSION

In the numerical and experimental results presented, a generator surface extending from the flume floor to the water surface has been adopted (i.e.  $h = 0$  in Fig. 1) and the piston mode of the generator motion has been applied (i.e.  $\theta = 0$ ). The computation was performed on an IBM 3090/150S computer at the University of British Columbia and double precision was used throughout. The variations of the free surface profiles in time and space are presented and the propagation characteristics of various transient wave trains are described. For the case of an irregular wave packet, simulated nonlinear free surface elevations at twelve different locations along the flume are compared with experimental results.

In the development of a regular or bichromatic wave train, there is a continuous influx of energy from the generator. In order to avoid an abrupt initial condition and allow a gradual development of the wave field, the periodic generator displacement is multiplied by a modulation function  $F_m$  such that the generator develops its motion gradually from zero to the prescribed amplitude over a specified modulation time  $T_m$ . For the case of regular wave diffraction to second order, testing by Isaacson and Cheung (1991) has indicated that, as a suitable choice,  $T_m$  may be taken to be equal to a typical wave period.

#### 4.1 Regular Wave Train

Prior to an examination of results for irregular waves, the development and propagation of a regular wave train in time and space are first examined. For the case considered, the wave generator undergoes a sinusoidal displacement defined by  $\delta(t) = \Delta \sin(\omega t) F_m$ , where  $\omega = 2\pi/T$  is the angular frequency,  $T$  is the wave period and  $\Delta$  is the amplitude of the generator displacement. For a given wave frequency and water depth, the value of  $\Delta$  can be related to the wave height by linear wave generation theory. Figs. 2 and 3 show the variations of the linear and nonlinear free surface profiles in space and time respectively. The incident wave conditions correspond to  $kd = 2$  and  $H/L = 0.08$ , where  $k$ ,  $H$  and  $L$  are respectively the wave number, the wave height and the wavelength of the resulting regular wave train. In the figures,  $A = H/2$  is the wave amplitude. To ensure stability of the simulation, the facet and time-step sizes were taken respectively as  $\Delta S = L/30$  and  $\Delta t = T/60$ , which correspond to a Courant number,  $c\Delta t/\Delta S = 0.5$ .

Fig. 2 shows linear and nonlinear free surface profiles along the flume at selected instants. At  $t = 0$ , the initial condition corresponds to still water everywhere in the computational domain. With the imposition of the generator motion over the first cycle, incident waves are gradually generated and propagate away from the generator at the corresponding group velocity. A steady state solution is developed near the generator after the first cycle, while the flow further from the generator takes somewhat longer to reach a steady state. It is noted that the initial waves of the wave train are unsteady with elongated lengths and smaller amplitudes, and appear to propagate at faster speeds. Without a radiation condition applied at the control surface, the reflection of these elongated initial waves would affect the flow near the test section well before a steady state solution has been developed.

Fig. 3 shows the time histories of the linear and nonlinear free surface elevations at four different locations along the length of the flume. For the location nearest to the wave generator, a stable steady-state solution for the free surface elevation is obtained for the entire period of simulation after a short duration of transient effects. Further down the flume, the duration of transient effects increases, and the initial waves are found to have longer periods as indicated above. It is also observed that a modulation is induced to the initial portion of the wave height envelope for the records at locations far away from the wave generator. At the last record, corresponding to a location 7 wavelengths away from the generator, a slight fluctuation of the free surface elevation is observed immediately after the modulation. These phenomena of wave front modulation and fluctuation have been examined analytically and similar results have been discussed by Mei (1983).

The numerical data also indicates that a system of second-order free waves at twice the incident frequency is also generated at the wave generator and propagates into the computational domain at the corresponding group velocity. These high frequency free waves are due to nonlinear interactions between the second-order free surface and the wave generator, and have also been observed in laboratory tests. Generally, the amplitude of these second-order free waves is small and does not have a significant effect on the overall wave profile. Since the numerical model is based on a second-order approach, the most obvious nonlinear effect in a regular wave train is to give rise to wave profiles with steeper crests and flatter troughs, whereas nonlinear effects on the celerity and group velocity are of higher order and cannot be reproduced here.

## 4.2 Bichromatic Wave Train

A bichromatic wave train at first order is composed of two primary harmonics propagating independently of each other, and each with a behaviour identical to a regular wave train. At second order, cross-interactions between the two harmonics give rise to a wave field which is modified to a greater extent.

Figs. 4 and 5 show the development of a bichromatic wave train in space and time respectively. The driving signal of the bichromatic wave train is obtained by adding a side-span harmonic signal to the excitation described in Section 4.1, such that the resulting signal is given by  $\delta(t) = \Delta [\sin(\omega t) + \sin(0.8\omega t)] F_m$ . Similar to the regular wave train, the bichromatic wave train develops its steady state solution rapidly. In Fig. 4, after a steady state solution has been developed, the same free surface profile repeats itself at an interval of  $5T$  near the generator, which corresponds to the beat frequency of the signal. The free surface profile is also shown to repeat itself along the flume at a fixed interval. In Fig. 5, the time histories of the free surface elevation at selected locations along the flume are found to be virtually identical after an initial duration of a transient signal, which is greater for locations further along the flume.

Nonlinear effects associated with the super-harmonic interactions are indicated in Figs. 4 and 5 at locations where the amplitude of the free surface elevation is high, giving rise to steeper crests and flatter troughs than the linear theory predictions. However, a more careful inspection of the numerical results also indicates the presence of a second-order sub-harmonic component, which is phase-locked to the wave group structure, with troughs beneath the high waves and crests in between the wave groups. In addition, low-frequency spurious free waves which are generated nonlinearly through the second-order boundary conditions are also present in the numerical solution. Although the amplitudes of these second-order components are generally small, the correct reproduction of the second-order wave field is critical in the testing of systems with relatively low natural frequencies. Such considerations have given rise to research into the development of suitable second-order control signals (e.g. Barthel et al., 1983).

## 4.3 Regular Wave Packet

The examples studied so far represent a steady-state influx of energy at the wave generator. Despite a short duration of transient effects associated with the propagation of the initial waves, a steady-state solution near the wave generator can be developed rapidly in time and space. To further illustrate transient effects in wave propagation, the development a regular wave packet is considered here.

The modulation function applied to the regular and bichromatic wave trains is modified to incorporate a gradual decline from unity to zero during the fourth cycle. The regular wave packet is then generated by applying this modulation function to the regular wave signal described in section 4.1. Figs. 6 and 7 show the development of the regular wave packet in space and time respectively. In Fig. 7, immediate adjacent to the generator at  $x/L = 1$ , the amplitude of the wave packet is quite uniform and corresponds to that of a regular wave train. Further away from the generator, the amplitude of the packet increases slightly and then decreases gradually with time and distance away from the generator. The decrease in wave amplitude is associated with an increase in the length of the wave packet as the energy is dispersed to a greater extent.

Despite the changing wave amplitude, the period and wavelength in the core of the wave packet remain relatively constant. In addition to the elongated initial waves, a trail of short waves is also observed to lag behind the packet. Nonlinear effects associated with the superharmonics are more obviously observed, especially at locations of high waves. Due to the decrease in wave amplitude, nonlinear effects also decrease with distance away from the wave generator. On the other hand, the forced and free sub-harmonic components associated with the wave packet is not clearly observed here.

#### 4.4 Irregular Wave Packet

To verify the present numerical procedure, the model has been applied to the simulation of a wave flume experiment performed at the Hydraulics Laboratory of the National Research Council of Canada. The experiment was carried out with a still water depth of 0.7 m. The generator was operated in piston mode and was used to generate an irregular wave packet by applying the generator displacement time history shown in Fig. 8. A spectral analysis of the displacement time history indicated two dominant peaks at 0.48 and 0.64 Hz. For the specified water depth of 0.7 m, these two frequency groups correspond to relative water depths  $kd = 0.92$  and  $1.32$  respectively, and to celerities  $c = 2.30$  and  $2.12$  m/s respectively. In the numerical model, the time-step and facet sizes were selected as 0.025 sec and 0.1 m respectively. On the basis of the Courant criterion, these values correspond to the capability of simulating celerities of up to about 4 m/s.

The measured and simulated nonlinear free surface elevations at twelve different locations along the flume are plotted as functions of time in Fig. 9. In general, comparisons between the numerical and experimental results indicate good agreement with respect to both the amplitude and phase, except for the portions of the records after the occurrence of the maximum amplitude. This may possibly be due to wave breaking that occurred near the generator in the experiment after the highest wave was generated. The discrepancies are first observed in the record corresponding to a location 4.11 m from the generator, with the simulated free surface elevation found to be higher than the measured elevation near time  $t = 25$  sec. These differences appear to spread to a greater extent in the records for locations further down the flume. The discrepancies between the simulated and measured free surface elevations appear to be in the form of high frequency waves which travel at slower speeds, and appear to affect the later part of the records more significantly.

Even though the high and low frequency components in the applied displacement function are generated simultaneously, in the results presented the lower frequency components with higher amplitudes and celerities propagate ahead of the higher frequency components, so that the randomness of the wave profiles as shown in Fig. 9 appears to decrease with time. Although the frequency content of the entire record (100 seconds long) measured at various locations along the flume remains basically the same, the time-histories of the free surface elevations at different locations as shown in Fig. 9 are modified more significantly. Since components of similar frequencies propagate at approximately the same speed, after a long duration of simulation the free surface profile and elevation are characterized by a series of beat phenomena with successive frequencies and amplitudes. The overall decline in wave amplitude with distance from the generator is partly attributed to the segregation of the different frequency components and partly to the amplitude dispersion of a wave packet as discussed in section 4.3.

In addition to predicting the linear and nonlinear wave fields, the present numerical model provides a useful alternative approach in the study and analysis of the various transient, nonlinear wave phenomena. A potential application of the method is to the calculation of suitable first and second-order generator control signals which may be required prior to carrying out particular flume tests.

## 5. CONCLUSIONS

A time-domain second-order method for the simulation of transient, nonlinear wave propagation in a flume is summarized. The boundary conditions are satisfied to second order by a time-stepping procedure, and the field solution at each time step is obtained by an integral equation method based on Green's theorem. Since the boundaries are invariant in time, the solution to the matrix equation obtained through a discretization of the integral equation is required only once and can be applied to different time histories of generator motion. The method is applied to a study of the transient propagation of various wave trains and wave packets.

Free surface profiles along the flume and time histories of the free surface elevation are obtained for a regular wave train, a bichromatic wave train, and regular and irregular wave packets. For the case of a regular wave train, the numerical model is shown to be stable and robust, and is capable of maintaining a steady state condition for a sufficiently long duration of simulation. The propagation of a bichromatic wave train is similar to that of a regular wave train, but includes an additional second-order sub-harmonic component. The propagation of the regular and irregular wave packets is found to be unsteady and transient, given its varying wave profile along the length of the flume. For the case of an irregular wave packet, time histories of the water surface elevation along a wave flume are compared with those predicted by the numerical model and these indicate favourable agreement. Second-order effects in transient wave propagation have been highlighted and potential applications of the second-order wave model are indicated.

## CHAPTER 10

### Irregular Wave Transformation Processes in Surf and Swash Zones

Daniel T. Cox<sup>1</sup>, Nobuhisa Kobayashi<sup>1</sup> and Andojo Wurjanto<sup>2</sup>

**ABSTRACT:** A frequency-domain model is developed for elucidating the nonlinear transformation processes of the Fourier amplitudes and phases of normally incident random waves in surf and swash zones. The vertically-integrated continuity and momentum equations which have been used to describe a turbulent bore on a beach are rearranged to derive the equations expressing the cross-shore variations of the Fourier components of normally incident random waves. The derived equations are solved numerically using forcing terms computed from a previously developed time-domain model. The frequency-domain model attempts to quantify the importance of the nonlinear forcing due to the cross-shore variations of instantaneous radiation stress and bottom shear stress as well as the seaward boundary condition related to incoming low frequency waves for generating two-dimensional surf beat in the surf and swash zones.

#### Introduction

The quantitative understanding of the transformation processes of breaking or broken irregular waves is essential for predicting wave-induced currents and sediment transport in the surf and swash zones. A number of researchers (*e.g.*, Guza and Thornton, 1985) have observed that the low-frequency wave components are dominant near the shoreline of gently sloping beaches. The mechanisms by which these oscillations are generated is not fully understood. Guza and Thornton (1985) explained their observations with a standing wave model on the basis of correlations of the incident wave to measured free surface elevations and velocities in the nearshore region. Their analysis was inconclusive, however, regarding the detail mechanisms by which the incident wind waves are modulated to produce the low frequency motions. Symonds *et al.* (1982) explained the generation of low frequency waves with a time-varying breakpoint model; that is, fluctuations in surf zone width and wave setup lead to the surf beat motions. This model results in a standing wave shoreward of the breakpoint and a progressive wave radiated seaward. More recently, List (1992) proposed a model for two-dimensional surf beat to separate the contributions to the low frequency band by the bound long wave of the wave group envelope and the breakpoint-forced long wave.

In the work presented herein, a frequency-domain model is developed to quantify the importance of the nonlinear forcing due to the cross-shore variations of

<sup>2</sup> Department of Civil Engineering, Bandung Institute of Technology, Jalan, Ganesha 10, Bandung 40132, Indonesia

instantaneous radiation stress and bottom shear stress as well as the seaward boundary condition related to incoming low frequency waves.

First, the time-domain model (TDM) is briefly introduced, including the specification of the incident wave train at the seaward boundary. Next, the computed results are compared with the measured data of Cox *et al.* (1991) to show that the TDM reasonably predicts the cross-shore variation of the free surface oscillation in the shoaling and surf zones, including the generation of the low-frequency components as well as the shoreline oscillation on a mild slope for irregular waves. The formulation of the frequency-domain model (FDM) is presented in detail, including the model domain, governing equations and boundary conditions. The continuity and momentum equations used in the TDM are rearranged to obtain a linear ordinary differential equation for each Fourier component with nonlinear forcing terms resulting from the interaction of Fourier components. The linear boundary value problem for each harmonic is solved using the nonlinear forcing terms computed by the TDM to avoid solving nonlinear simultaneous equations for Fourier amplitudes and phases. The computed cross-shore variations of low-frequency Fourier amplitudes and phases of the FDM are shown to match those of the TDM. The FDM is then used to examine the effects of each of the nonlinear terms as well as the seaward boundary condition related to incoming low-frequency waves.

### Time-Domain Model

A numerical model based on the nonlinear shallow water equations including the effect of bottom friction (Kobayashi *et al.*, 1989) is probably the simplest one-dimensional, time-dependent model for predicting the nonlinear time-dependent irregular wave characteristics in the surf and swash zones. Kobayashi and Wurjanto (1992) showed that the TDM could predict available field data on shoreline oscillations fairly well. Moreover, Wise *et al.* (1991) compared the numerical model with the laboratory data of Roelvink and Stive (1989) and obtained reasonable agreement except for undertow and odd velocity moments probably because the model does not account for the vertical velocity variation and is not accurate enough to predict small values of the odd moments.

Cox *et al.* (1991) conducted a hydraulic model test in a wave flume to obtain detailed data on the cross-shore variations of the free surface oscillations and shoreline oscillation on a 1:20 smooth impermeable slope. Six wave gages were positioned in the shoaling and swash zones at  $d' = 15.0, 12.5, 10.0, 7.5, 5.0$  and  $3.0$  cm, where  $d'$  is the depth below the still water level (SWL). Additionally, a runup meter provided the time series of the shoreline oscillations. The target spectrum was based on the Pierson-Moskowitz spectrum, and the waves were generated without regard to nonlinear effects or wave reflection. The data were collected at a sampling interval of 0.04 s with a duration sufficient to include roughly 600 waves.

The seaward boundary of the time-domain model was taken at the location of the most seaward gage at  $d' = 15.0$  cm, immediately outside the breaker zone. The TDM requires that the incident wave time series and not the total time series be specified, where reflection can be significant even for mild slopes, particularly at the lower harmonics. The standard spectral technique of separating incident and reflected waves using an array of gages was not employed since the experiment was originally intended for other purposes (Cox *et al.*, 1991). Instead, the incident wave train to be specified was determined by an iterative technique based on a modification of the measured time series at  $d' = 15.0$  cm as follows. From previous work on this data set, it was estimated that the reflection coefficient was near unity for harmonics less than

half of the peak frequency and near zero for harmonics greater than half of the peak frequency. As a first approximation, the Fourier coefficients of the measured time series were modified as follows:

$$(a_n)_{\text{mod}} = \begin{cases} \frac{1}{\sqrt{2}} a_n; & n=1, 2, \dots, N_{p/2} \\ a_n; & n=N_{p/2}+1, \dots, N_{nyq} \end{cases} \quad \text{and} \quad (b_n)_{\text{mod}} = \begin{cases} \frac{1}{\sqrt{2}} b_n; & n=1, 2, \dots, N_{p/2} \\ b_n; & n=N_{p/2}+1, \dots, N_{nyq} \end{cases}$$

where  $a_n$  and  $b_n$  are the real and imaginary parts, respectively,  $N_{p/2}$  indicates the harmonic corresponding to half of the peak frequency, and  $N_{nyq}$  indicates the harmonic corresponding to the Nyquist frequency. The modified time series,  $\eta'_{\text{mod}}$ , was recovered by an inverse Fourier transform. To begin the iterative procedure, the modified time series  $\eta'_{\text{mod}}$  was specified as the incident wave time series,  $\eta'_i$ . For subsequent iterations, the computed reflected wave time series was subtracted from the assumed (modified) wave time series to obtain the new incident wave time series. After the second iteration, an incident wave time series was obtained that when added to the computed reflected wave time series nearly equaled the total measured time series at  $d' = 15.0$  cm. This incident wave time series after the second iteration is used in the following.

The reference wave height,  $H'$ , and period,  $T'$ , for normalization of the TDM computations (Kobayashi and Wurjanto, 1992) were chosen as  $H' = 6.094$  cm and  $T' = 1.72$  s, respectively, based on the spectral estimate of the significant wave height and spectral peak period of the incident wave train,  $\eta_i = \eta'_i/H'$ , at the seaward boundary. The prime denotes a dimensional quantity unless otherwise stated. The duration of the time series specified to the TDM was  $-20 \leq t \leq 520$ , where  $t$  is the time normalized by  $t = t'/T'$  and  $t = -20$  is the start of the computation. To eliminate transitional effects in evaluating the TDM and FDM, the initial part of all the time series was truncated for  $-20 \leq t < 0$ . All spectral calculations in this paper are based on the truncated time series for  $0 \leq t \leq 520$ . The corresponding band width of the normalized frequency,  $f^*$ , is  $\Delta f^* = .00192$ , where  $f^* = 1$  corresponds to the spectral peak of the incident wave spectrum. The spectra presented herein are smoothed using ensemble averaging to give 40 degrees of freedom and corresponding band width of  $\Delta f_{\text{sm}}^* = .0384$ .

The friction factor,  $f'$ , is the only empirical parameter specified to the TDM. The value  $f' = 0.01$  was used in the computed results presented herein. The model was not sensitive to  $f'$  for the range  $0.01 \leq f' \leq 0.05$  for most of the shoaling and surf zones, although it did have some effect in the swash zone where frictional effects are noticeable (Kobayashi and Wurjanto, 1992).

Figs. 1a to 1f compare the normalized spectral densities,  $S_\eta$ , of the measured and computed free surface elevation,  $\eta$ , plotted for the frequency range  $\Delta f_{\text{sm}}^* \leq f^* \leq 3.5$  at the six locations in the shoaling and surf zones. The normalized horizontal coordinate,  $x$ , is defined as  $x = x'/(T'\sqrt{gH'})$ , and the still water shoreline is at  $x = 2.26$ . The agreement in Fig. 1a, located at the seaward boundary, indicates the necessity and partial justification of the iterative technique to specify the incident wave train. It is noted that the computed results using the measured time series as the incident wave train showed an overprediction of the lower harmonics by a factor of roughly two in a figure similar to Fig. 1a. Figs. 1b to 1f show that the TDM can be used to predict the free surface oscillations of irregular waves over a mild slope, including the low frequency components. The disagreement in Figs. 1e and 1f in the low frequency components may be partly due to the measurement difficulties at small

water depths. Fig. 2 shows the measured and computed cross-shore variation of setback or setup,  $\bar{\eta}$ , as well as the node locations where the TDM output was stored. The storage of the TDM output is discussed in further detail in the next section.

Fig. 3 shows the normalized spectral densities,  $S_z$ , of the measured and computed shoreline elevation above SWL for the range  $\Delta f_{\text{min}}^* \leq f^* \leq 3.5$ . The shoreline oscillations are well predicted by the TDM over the entire frequency range of interest, and Fig. 3 shows the dominance of the low-frequency motion. The friction factor  $f' = 0.01$  is used for Fig. 3, and the computed shoreline oscillations for  $f' = 0.02$  and 0.05 were somewhat smaller than that shown in Fig. 3.

### Frequency-Domain Model

A frequency-domain model for normally incident irregular waves on a beach of arbitrary geometry but alongshore uniformity is developed herein to examine the nonlinear wave interactions and elucidate the generation mechanisms of low-frequency waves in the surf and swash zones. The FDM is based on the same continuity and momentum equations as the TDM of Kobayashi and Wurjanto (1992). These equations, where the primes indicating the dimensional variables are omitted for brevity, are rearranged as

$$\frac{\partial(\eta - \bar{\eta})}{\partial t} + \frac{\partial q}{\partial x} = 0 \quad (1)$$

$$\frac{\partial q}{\partial t} + g \bar{h} \frac{\partial(\eta - \bar{\eta})}{\partial x} + g(\eta - \bar{\eta}) \frac{\partial \bar{\eta}}{\partial x} = -g \bar{h} \frac{\partial \bar{\eta}}{\partial x} - \frac{\partial S}{\partial x} - \frac{\tau_b}{\rho} \quad (2)$$

with

$$S = qu + \frac{1}{2} g (\eta - \bar{\eta})^2 \quad (3)$$

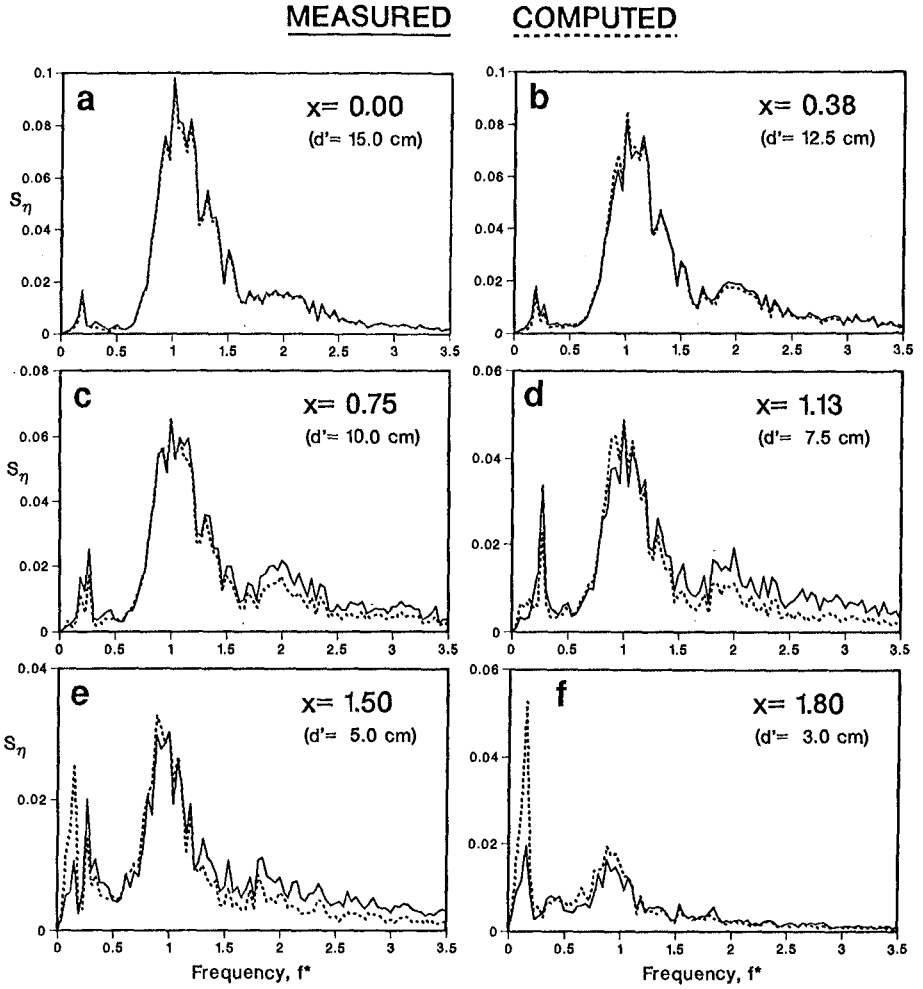

and

$$\tau_b = \frac{1}{2} \rho f' |u| u \quad (4)$$

where  $t$  = time;  $x$  = horizontal coordinate taken to be positive in the landward direction;  $\eta$  = free surface elevation above the SWL;  $q$  = volume flux per unit width;  $g$  = gravitational acceleration;  $h$  = total water depth given by  $h = (\eta + d)$  with  $d$  = water depth below the SWL;  $u$  = depth-averaged horizontal velocity defined as  $u = q/h$ ;  $\tau_b$  = bottom shear stress;  $\rho$  = fluid density; and  $f'$  = empirical bottom friction factor. The overbar in Eqs. 1–3 denotes time averaging.  $S$  defined by Eq. 3 may be termed the instantaneous cross-shore radiation stress since  $\bar{S}$  is the usual radiation stress for the adopted momentum equation (Kobayashi *et al.*, 1989). The time-averaged continuity equation obtained from Eq. 1 yields  $\bar{q} = 0$ . The time-averaged momentum equation obtained from Eq. 2 is the standard equation used to predict the wave setup  $\bar{\eta}$  where  $\bar{\tau}_b$  is normally neglected.  $\bar{\tau}_b$  is retained herein since the computed low-frequency wave motions in the swash zone may be sensitive to the bottom friction. Subtraction of the time-averaged momentum equation from Eq. 2 yields

$$\frac{\partial q}{\partial t} + g \bar{h} \frac{\partial(\eta - \bar{\eta})}{\partial x} + g(\eta - \bar{\eta}) \frac{\partial \bar{\eta}}{\partial x} = -\frac{\partial(S - \bar{S})}{\partial x} - \frac{\tau_b - \bar{\tau}_b}{\rho} \quad (5)$$

If the water depth  $\bar{h}$  below the mean water level is known, Eqs. 1 and 5 are linear in terms of the oscillatory components  $(\eta - \bar{\eta})$  and  $q$  with zero mean except for the nonlinear terms on the right hand side of Eq. 5, which account for the wave-wave interaction effects.

**Figure 1:** Smoothed spectral densities of normalized free surface elevation,  $\eta$ , as a function of normalized frequency,  $f^*$ , at six locations.

Figure 3: Smoothed spectral density  $S_z$  of normalized shoreline elevation above SWL,  $Z$ , as well as corresponding time series.

Figure 2: Cross-shore variation of normalized mean free surface elevation,  $\bar{\eta}$ , and location of nodes for storage of TDM output.

The time series  $q$ ,  $\eta$ ,  $S$  and  $\tau_b$  represented by  $v(t,x)$  in the following equation are expressed as Fourier series, viz.,

$$v(t,x) = \bar{v} + \sum_{n=1}^N \left\{ \text{Re}[v_n(x)] \cos(\omega_n t) + \text{Im}[v_n(x)] \sin(\omega_n t) \right\} \quad (6)$$

in which  $v_n(x)$  = complex Fourier coefficient with Re and Im indicating the real and imaginary parts of  $v_n$ ;  $\omega_n$  = angular frequency where  $\omega_n = 2\pi n \Delta f^*$ , for  $n = 1, 2, \dots, N$  and  $\Delta f^*$  is the frequency band width without any smoothing; and  $N$  is the number of harmonics. For the FDM proposed herein, Eqs. 1 and 5 are rewritten in terms of the complex Fourier coefficients as follows:

$$-i \omega_n \eta_n + \frac{dq_n}{dx} = 0 \quad (7)$$

$$-i \omega_n q_n + g \bar{h} \frac{d\eta_n}{dx} + g \eta_n \frac{d\bar{h}}{dx} = -\frac{dS_n}{dx} - \frac{\tau_n}{\rho} \quad (8)$$

Eliminating  $q_n$  from Eqs. 7 and 8 gives

$$g \bar{h} \frac{d^2 \eta_n}{dx^2} + g \frac{d(\bar{h} + \bar{\eta})}{dx} \frac{d\eta_n}{dx} + (\omega_n^2 + g \frac{d^2 \bar{\eta}}{dx^2}) \eta_n = -\frac{d}{dx} \left( \frac{dS_n}{dx} + \frac{\tau_n}{\rho} \right) \quad (9)$$

The resulting ordinary differential equation for each harmonic is solved using  $\bar{h}(x)$  and the complex Fourier coefficients of  $(S - \bar{S})$  and  $(\tau_b - \bar{\tau}_b)$  obtained from  $q(t,x)$  and  $h(t,x) = [d(x) + \eta(t,x)]$  computed by the TDM. As a result, the FDM in this paper is not an independent model but supplements the TDM in interpreting the computed results. For the boundary conditions,  $(\eta - \bar{\eta})$  is assumed to be given at the seaward boundary  $x = 0$ , while  $(\eta - \bar{\eta})$  is taken to be zero at the location of  $\bar{h} = 0$ . Since  $\bar{h} \geq 0$  in the region wetted by water,  $\bar{h}$  approaches zero asymptotically such that  $\bar{h} = 0$  at the maximum runup location during the specified computation duration. This formulation allows the FDM to be evaluated throughout the swash zone, past the still water shoreline (SWSL) to the point of maximum runup, *i.e.* from  $x = 2.26$  to  $x = 3.46$  in the subsequent figures. Further, Eq. 9 can be solved efficiently using a finite difference method of constant grid spacing and a tridiagonal matrix solver (*e.g.*, Press *et al.*, 1989).

The TDM was run twice. First, the model was run to locate the furthest node wetted by water and to determine the locations of the nodes where the output of  $q(t)$  and  $h(t)$  should be stored with the same sampling rate as the data collection. For the work presented here, there were 461 computational nodes in  $x$  with a spatial resolution of  $\Delta x = 0.00752$ . The model was run a second time storing  $q(t)$  and  $h(t)$  at every four nodes or 116 locations as shown in Fig. 2. Cubic splines were used to interpolate the numerical output from 116 to 461 nodes, and a standard IMSL subroutine was employed to compute the derivatives in Eq. 9.

To evaluate the FDM, a large number of harmonics were chosen from the low-frequency band. The computed results for  $f^* = 0.198$  and  $f^* = 0.258$  are shown as examples in the following. The frequency  $f^* = 0.198$  represents a harmonic for which  $x = 0$  appears to be an antinode of the cross-shore variation of  $|\eta_n|$ ; and the frequency  $f^* = 0.258$  represents a harmonic for which  $x = 0$  is nearly a node. It is noted that the FDM did not agree with the TDM for frequencies higher than about  $f^* = 0.3$ , probably due to difficulties in computing the cross-shore derivatives of the instantaneous radiation stress at higher frequencies. In the figures to follow, comparisons are made of the magnitude  $|\eta_n|$  and phase,  $\theta_n$ , where Eq. 6 for  $\eta(t,x)$  is rewritten

$$\eta(t,x) = \bar{\eta}(x) + \sum_{n=1}^N |\eta_n(x)| \cos[\omega_n t + \theta_n(x)] \quad (10)$$

with

$$|\eta_n| = \left\{ \text{Re}[\eta_n(x)]^2 + \text{Im}[\eta_n(x)]^2 \right\}^{\frac{1}{2}} \quad (11)$$

and

$$\theta_n = \tan^{-1} \left\{ \frac{-\text{Im}[\eta_n(x)]}{\text{Re}[\eta_n(x)]} \right\} \quad (12)$$

where Eq.12 is computed such that  $-\pi \leq \theta_n \leq \pi$ .

Fig. 4 shows the cross-shore variation of  $|\eta_n|$  and  $\theta_n$  from the TDM and FDM solutions with the measured data for (a)  $f^* = 0.198$  and (b)  $f^* = 0.258$ . The ability of the TDM to simulate the free surface elevations of irregular wave in the surf and swash zones is further exemplified by the agreement between the TDM solutions and measured data. It is emphasized that the TDM and FDM yield continuous solutions landward of the SWSL located at  $x = 2.26$ . The agreement between the TDM and FDM solutions shows the ability of the FDM to compute the free surface variation of lower harmonics from the nonlinear forcing of the radiation stress and bottom shear stress terms calculated by the TDM. In Fig.4a, the seaward boundary,  $x = 0$ , appears to correspond to an antinode of the free surface for a standing wave in the nearshore, with a phase shift of  $\pi$  at the nodal location near  $x = 1.3$ . Similarly, Fig. 4b shows that the TDM, FDM and measured data are in good agreement. Further, the seaward boundary nearly corresponds to a node of the free surface but the non-zero value of  $|\eta_n|$  and gradual phase shift near  $x = 1.8$  indicates that the low frequency motions are not purely standing in the inner surf zone. The FDM was reformulated to solve for the volume flux,  $q_n$ , instead of the free surface displacement,  $\eta_n$ , from Eqs.7 and 8. The reformulation was also intended to examine the sensitivity of the solutions to the number of differentiations of  $S_n$  and  $\tau_n$  with respect to  $x$ . Solutions for the cross-shore variation of the magnitude  $|\eta_n|$  and its phase  $\theta_n$  from the TDM and FDM for  $f^* = 0.258$  are shown in Fig. 5. Figs.4b and 5 further exemplify the apparent standing wave pattern with nodes of the volume flux corresponding to antinodes of the free surface displacement.

To assess the importance of the nonlinear forcing terms on the right hand side of Eq. 9, the magnitudes of the instantaneous radiation stress and bottom shear stress are examined. Fig. 6 shows the cross-shore variations of  $|S_n|$  and  $|\tau_n|$  for input to FDM for (a)  $f^* = 0.198$  and (b)  $f^* = 0.258$ . The maximum value of instantaneous radiation stress occurs in the breaker zone while the bottom shear stress may become as large as the radiation stress in the swash zone. The oscillations in Fig. 6 are probably caused by the spurious numerical oscillations in the TDM.

A primary purpose of the FDM is to assess the relative importance of the seaward boundary condition and the nonlinear forcing terms. Fig.7 shows the cross-shore variations of  $|\eta_n|$  and  $\theta_n$  from the FDM for the solutions without and with modifications to the seaward boundary condition and to the nonlinear forcing for (a)  $f^* = 0.198$  and (b)  $f^* = 0.258$ . In Fig. 7a, the FDM solution modified by specifying  $\eta_n = 0$  at  $x = 0$ , is greatly affected since  $x = 0$  corresponds to the antinode. Interpretation is somewhat limited, however, because both incident and reflected waves are affected by this boundary condition. It is interesting to note that this solution in the swash zone for  $x \geq 2.5$  is not affected by the boundary condition at  $x = 0$ , suggesting the dominance of the nonlinear forcing terms in the swash zone.

This result is consistent with all other lower harmonics examined. The FDM solution modified by zeroing both of the nonlinear forcing terms is basically unaffected except in the swash zone. This implies that the wave motion at  $f^* = 0.198$  is essentially a standing wave except in the swash zone. In Fig. 7b, the FDM is modified similarly for  $f^* = 0.258$ . Because  $x = 0$  roughly corresponds to a node of the free surface, the solution is affected only slightly by imposing the condition  $\eta_n = 0$  at  $x = 0$ . It is noted that the solution in the swash zone for  $x \geq 2.5$  is unaffected by the seaward boundary condition. By zeroing the nonlinear forcing terms,  $|\eta_n|$  is reduced, but the basic standing wave pattern is apparent with only a slight shifting of the nodal location near  $x = 1.8$ . As a whole, Fig. 7 suggests that the wave motion in the swash zone is dominated by the nonlinear forcing rather than the seaward boundary condition and that the relative importance of these two throughout the surf zone depends on the frequency.

In a further attempt to quantify the relative importance of the radiation stress and bottom shear stress, the FDM is evaluated with modifications to these two terms separately. Fig. 8 shows the cross-shore variations of  $|\eta_n|$  and  $\theta_n$  from the FDM for the three solutions without and with modification to the  $S_n$  and  $\tau_n$  terms. Fig. 8a for  $f^* = 0.198$  shows that the forcing terms do not affect the solution much, consistent with Fig. 7a. Hence, the solutions for  $S_n = 0$  or  $\tau_n = 0$  are similar except that  $S_n$  seems to be the more important of the two in the swash zone. Fig. 8b for  $f^* = 0.258$  shows that the forcing terms individually increase the magnitude  $|\eta_n|$  over most of the surf zone, whereas in Fig. 7b their combined effect is to reduce the magnitude  $|\eta_n|$  by roughly a factor of two. Additionally, Fig. 8b shows that  $\tau_n$  affects the magnitude  $|\eta_n|$  but not the phase  $\theta_n$ . For this frequency,  $S_n$  affects the phase  $\theta_n$  somewhat more.

## Conclusions

Accurate prediction of the low-frequency motions in the surf and swash zones requires specification of incident low frequency waves immediately outside the breaker zone. At present, no reliable theory is available to predict incident bound long waves immediately outside the surf zone except for the simplified model by List (1992). The TDM was shown herein to predict the temporal and cross-shore variations of the free surface elevation in the surf and swash zones fairly well; however, it does not reveal how and where low-frequency waves are generated or transformed in the surf and swash zones. Additional analyses are hence needed to interpret the computed results. The FDM was proposed to elucidate the nonlinear transformation and generation processes of the low-frequency waves in the surf and swash zones. Important to the formulation of this model was the use of  $\bar{h}$ , eliminating the singularity problem of the free surface elevation in the swash zone. The limited computation for one test run suggests that the low-frequency wave motions in the surf and swash zones appear to be standing waves, qualitatively consistent with the field data and analysis of Guza and Thornton (1985), but modified by the forcing terms associated with the instantaneous radiation stress and bottom shear stress. The degree of modifications depends on specific frequencies.

## CHAPTER 11

### Numerical Modelling of Waves and Currents with regard to Coastal Structures

M. Fischer  
J. Juhl  
E.B. Rasmussen<sup>1</sup>

#### Abstract

This paper describes a two-dimensional numerical model capable of simulating non-stationary flows. Special emphasis has been put on wave motion on and in porous structures, e.g. a rubble mound breakwater. Comparisons of numerical simulations with analytical solutions and model test results have confirmed the applicability of this model for studies of waves and currents with regard to coastal structures.

#### Introduction

In the past coastal structures such as breakwaters mainly have been studied by means of physical modelling and simplified numerical calculations. Recent developments in numerical techniques and methods, however, have implied that advanced numerical tools may be adopted in such studies. These numerical models dedicated to coastal structures are still in their infancy but likewise other branches of the hydraulics it is envisaged that numerical models will play an increasing role in future studies.

In the present paper, a special 2D (x-z) version of Danish Hydraulic Institute's three-dimensional model is described. Details on the three dimensional model

---

<sup>1</sup> Danish Hydraulic Institute, Agern Allé 5,  
DK-2970 Hørsholm, Denmark

adapted here are given in Rasmussen et al. The x-z version is designed especially for flow with regard to coastal structures and porous media. The numerical model is based on the Reynolds-averaged Navier-Stokes equations and the equation for conservation of mass. The equations are discretized into a finite difference scheme imposed on a rectangular, space-staggered grid. The finite difference equations are solved through a non-iterative ADI (Alternating Directions Implicit) technique using the artificial compressibility method.

The energy loss due to both laminar and turbulent effects in porous media is included through the Forchheimer equation. Furthermore, an inertia term has been included in the Forchheimer equation for the case of non-stationary flow.

The free surface boundary in the model has been described applying a subgrid modelling in which the instantaneous position is calculated for each time step by use of linearized momentum equations and kinematic boundary conditions. This implies that the computational domain varies from time step to time step.

The numerical model is applicable to a large range of both dynamic and stationary flow problems with regards to coastal structures such as flows in breakwaters consisting of layers with different porosity, flows through and/or beneath dams and stability of slopes etc. protected by impermeable surface layers likewise.

Model simulations have been compared with both analytical solutions and physical model tests.

### Description of Flows in Porous Media

It is common to apply a macroscopic point-of-view of a porosity layer by describing the porous matrix through characteristic constants. These properties are related both to the fluid and to the granular material in order to describe the penetration of the fluid. This implies that the basic problem is reduced to establish a relation between the pressure gradient and the bulk velocity.

It can be argued as to whether this description is suitable or a microscopic point-of-view is needed. However, such an approach would imply the necessity of a description of each stone with connected geometry and roughness factors. Furthermore, highly sophisticated

turbulence descriptions would be required. This leads to unrealistic demands to both model set-up for a simulation of flow in porous media and to the performance of the model itself, since the computational grid should be very fine in order to produce the required resolution of the geometry.

A breakwater normally consists of three porous layers, i.e. core, filter, and armour layer. This implies the necessity of a porosity description, in which multiple layers with different properties can be specified. Physical model tests have shown the necessity of a description of the energy dissipation including both laminar and turbulent flow as well as energy dissipation due to dynamic effects.

The relation between the bulk velocity,  $u$ , and the pore velocity,  $V$ , is given by

$$u = V \cdot n$$

where  $n$  is the porosity.

#### Forchheimer equation

The Forchheimer equation consists of two terms expressing the hydraulic gradient due to both laminar and turbulent flow, respectively

$$i = a \cdot u + b \cdot u^2$$

where,

- $i$  is the hydraulic gradient
- $a$  is the laminar dissipation factor
- $b$  is the turbulent dissipation factor

Since the linear term,  $a$ , accounts for the laminar effects, it depends on the viscosity. The non-linear term,  $b$ , represents the fully turbulent flow and is only dependent on the granular matrix material.

Several relationships of  $a$  and  $b$  have been proposed in the literature, of which many have been based on a dimensional analysis. In the presented model the relationship proposed by Engelund has been adopted. The laminar and turbulent dissipation terms are described by the constants  $a$  and  $b$ :

$$a = \alpha \cdot \frac{(1-n)^3 \cdot \nu}{n^2 g d^2}$$

$$b = \beta \cdot \frac{(1-n)}{n^3 g d}$$

where

$\nu$  is the viscosity of the fluid  
 $g$  is the gravity  
 $d$  is the stone diameter  
 $\alpha$  is an empiric constant  
 $\beta$  is an empiric constant

The formulation of the hydraulic gradient presented above is only valid for a steady state flow. A model for unsteady flow would be to add a time dependent term to the Forchheimer expression

$$i = a \cdot u + b \cdot u^2 + c \cdot \frac{\partial u}{\partial t}$$

The factor  $c$  can be expressed in the following way:

$$c = \frac{\left(1 + \gamma \cdot \frac{(1-n)}{n}\right)}{g}$$

where  $\gamma$  is the inertia coefficient.

### Implementation of porosity description

The model presented solves the Reynolds-averaged Navier-Stokes equations and the continuity equation in a staggered finite difference grid. The prognostic variables are the three velocity components together with the fluid pressure. The adopted porosity description is based on macro parameters of porosity, stone size and dissipation factors. The implementation of this macro scale porosity description involves two changes to the original balance equations

- 1) Redefinition of terms including velocity with respect to the influence of the porosity.

- 2) Adding of dissipation terms due to the microscopic flow resistance, i. e. flow between stones. The expression given by Forchheimer together with an additional term for the dynamic effect is applied.

The continuity equation reads

$$\frac{1}{\rho \cdot c_s^2} \cdot \frac{\partial p}{\partial t} + \nabla \cdot V_i = 0$$

where,

$\rho$  is the density  
 $c_s$  is the speed of sound  
 $p$  is the excess pressure  
 $V$  is the pore velocity

The momentum equation reads after introduction of the bulk velocity:

$$c \cdot \frac{\partial u_i}{\partial t} + \frac{1}{n^2} \cdot u_j \cdot \frac{\partial u_i}{\partial x_j} =$$

$$-\frac{1}{\rho} \cdot \frac{\partial p}{\partial x_i} - g_i - g \cdot a \cdot u_i - g \cdot b \cdot |u_i| \cdot u_i + \frac{1}{n} \cdot \frac{\partial}{\partial x_j} \left( E \cdot \frac{\partial u_i}{\partial x_j} \right)$$

where E is the eddy viscosity

### Free Surface Description

The applied free surface description of waves is presented in the following. The method is inspired by the VOF method proposed by Nichols and Hirt but splits the volume fraction into space increment fractions in the three coordinate directions, and can as such be considered as a surface tracking method rather than a volume tracking method.

The presented description includes three dependent variables in addition to the velocity components and the fluid pressure. The variables noted  $\alpha$ ,  $\beta$  and  $\gamma$  represent fractions of space increments in the x-, y- and z-direction, respectively, and thus describe the location of the free surface within the current grid cell, see Fig. 1. In the present model the instantaneous position of the water is directly calculated, which is the main difference to the VOF method. The fraction of volume in each cell can be found as

$$V = \alpha \cdot \beta \cdot \gamma$$

A free surface cell is identified as a cell containing a non-zero value of  $V$  and having at least one neighbouring cell that contains a zero value of  $V$ . Cells with zero  $V$  values are empty cells whereas cells with non-zero  $V$  values are treated as full or interior fluid cells.

Fig. 1 Description of the free surface by a fraction of volume of fluid technique. The corners represent pressure nodes. For the two-dimensional description  $\beta = dy$ .

Briefly, the basic procedure for advancing a solution in time consists of three steps:

- 1) From the previous time step the dependent variables form the basis for a new discretisation of the conservation of mass and the conservation of momentum equations. The system is solved implicitly taking into account closed boundaries, open boundaries and free surface boundaries.
- 2) By use of the fractions calculated in the previous time step and on the basis of the newly found dependent variables the fractions  $\alpha$ ,  $\beta$  and  $\gamma$  are computed.
- 3) Finally, the fractions defining fluid regions must be used to update the fluid taking into account the fluid in the adjacent cells and the boundaries of the computational domain.

The theory presented in the following is developed in three dimensions. For reasons of simplicity the implementation of the free surface into the three-dimen-

sional model has been done in two dimensions only - one horizontal and one vertical direction.

### The Continuity Equation

In general the continuity equation reads

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x} (u\rho) + \frac{\partial}{\partial y} (v\rho) + \frac{\partial}{\partial z} (w\rho) = 0$$

where  $\rho$  is the density and  $u$ ,  $v$  and  $w$  are the velocity components.

In order to obtain a hyperbolicly dominated system the pressure is introduced into the continuity equation through an equation of state.

$$\frac{1}{\rho c_s^2} \cdot \frac{\partial p}{\partial t} + \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0$$

where  $c_s$  is the speed of sound and  $p$  the excess pressure. In the top layer of the computational domain a cell may not be full of fluid. To obtain the continuity equation for the computational cell at the surface an integration over the fraction of fluid volume is done:

$$\frac{1}{\alpha \beta \gamma} \int_0^\gamma \int_0^\beta \int_0^\alpha \left( \frac{1}{\rho c_s^2} \cdot \frac{\partial p}{\partial t} + \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} \right) dx dy dz = 0$$

The result of this integration is the continuity equation described in terms of the fractions of volume

$$\frac{1}{\rho c_s^2} \cdot \frac{\partial p}{\partial t} + \frac{\partial u}{\partial \alpha} + \frac{\partial v}{\partial \beta} + \frac{\partial w}{\partial \gamma} = 0$$

The compressibility of the fluid is expressed by the speed of sound  $c_s$ . In order to make the coefficient matrix of the system diagonally dominated, an artificial value of  $c_s$  should be used.

### The Momentum Equations

The conservation of momentum reads:

$$\frac{\partial u_i}{\partial t} + \frac{\partial(u_i \cdot u_j)}{\partial x_j} = -\frac{1}{\rho} \cdot \frac{\partial P}{\partial x_i} + g_i + \frac{\partial}{\partial x_j} \left( E \cdot \frac{\partial u_i}{\partial x_j} \right)$$

where  $u$  is the velocity,  $P$  the total pressure,  $\rho$  the density,  $g$  the gravity and  $E$  the eddy viscosity of the fluid.

For reasons of simplicity regarding the space and time discretisation only the linear momentum equations are modelled in the surface cells.

The applied momentum equation for a cell containing a free surface in the  $x$ -direction reads

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho} \cdot \frac{\partial}{\partial x} (p + \rho gh)$$

where  $h$  is the local, vertical distance to the surface.

#### Wave Boundary Condition

In order to make simulations of wave impacts on coastal structures an open boundary condition forming propagating waves in the simulation area has been developed. The wave boundary is a mixture of the general Dirichlet type boundary conditions of velocity and level boundaries in the sense that both the level and the velocity are specified. This is presently done by applying a first order wave theory.

#### Verifications and Simulations

A number of simulations have been performed in order to verify and study the applicability of the model. A few examples are shown in the following:

##### Simulation of Steady State Flow in Porous Media

Verification of the porosity description in the case of steady state flow is carried out by a comparison to experimentals made by Burcharth. The characteristic flow properties, such as the hydraulic gradient and the discharge velocity, have been measured in the case of penetration of water through three different gravel materials. For all three cases the principle model set-up both for the experimentals and for the numerical simulations is shown in Fig. 2.

Fig. 2 Model set-up for steady state flow through a porous layer.

The comparison is done in accordance with the following description:

- 1) Since the hydraulic gradient is given as

$$i = a \cdot u + b \cdot |u| \cdot u$$

where,

- $i$  is the hydraulic gradient
- $a$  is the laminar dissipation factor
- $b$  is the turbulent dissipation factor
- $u$  is the bulk velocity

a straight line is expected when  $(i/u)$  is plotted against  $u$ . The slope of the line equals  $b$  and the intersection with the  $(i/u)$ -axis equals  $a$ .

- 2) For the experimentals  $a$  and  $b$  are deduced as described above. In accordance with the Forchheimer expression and by use of the properties of the gravel material measured by Burcharth the dissipation factors  $\alpha$  and  $\beta$  are deduced. For the case of steady state flow the dynamic dissipation term equals zero.
- 3) With the properties of the gravel material and the fluid, simulations of the flow through a porous layer is carried out. Velocity boundaries with a constant value are imposed at both ends of the model area. For each of the three gravel materials the boundary velocity is varied in order to obtain a suitable number of points. The simulations are made with "full slip" closed boundaries, which implies that the pressure gradient is zero outside the porous layer. For all the simulations the kinematic viscosity of the fluid equals  $1.34 \cdot 10^{-6}$

$m^2/s$ , which is in accordance with the viscosity of the water used by Burcharth.

- 4) The comparisons of the experimentals and the numerical simulations for two of the gravel materials are shown in Fig. 3.

Fig. 3 Comparisons of experimentals and numerical simulations for two cases of steady state flow.

The comparisons show that the model, including a bulk description of the porosity layer, is able to reproduce the measurements for the case of steady state flow.

Simulation of a dam break

Testing of the free surface description is done by simulation of a dam break. Initially a column of water is confined between two vertical walls. When the calculation starts the right wall is removed, and gravity forces the fluid to propagate along the dry floor.

At the beginning of the simulation the fluid is described by  $20 \times 20$  cells with a size of 0.1 m in both the vertical and horizontal direction. The applied time step is 0.01 sec. Examples of results showing the fluid position and the velocity is presented in Fig. 4.

Experimental results for a dam break test case have been reported by Martin and Moyce and form a basis for a comparison to the model generated results.

Fig. 4. Example of results for the dam break test. The plots represent the surface location and the velocity for each grid node at time 0.3 sec. and 0.7 sec.

A comparison between model generated results and the experimental results of the toe position vs time is shown in Fig. 5. The largest deviation from the experimental results is everywhere less than one grid spacing.

Fig. 5 Comparison of a numerical simulation with experimental data for a dam break.

Wave Run-Up on a Permeable Structure

The combination of porosity layers and a free surface is tested by simulation of wave run-up on a rubble mound breakwater. The breakwater has a sea side slope of 1:2.0 and consists of three porosity layers with the following characteristics:

- a = 14.4, 4.9, 2.0 s/m
- b = 1820.0, 109.0, 50.0 (s<sup>2</sup>/m<sup>2</sup>)
- c = 0.0, 0.0, 0.0
- n = 0.35, 0.37, 0.39

The model grid consists of 100 x 3 x 50 nodes and the general parameters of the simulation are:

$$\Delta x = \Delta y = \Delta z = 0.015 \text{ m}$$

$$\Delta t = 0.002 \text{ sec}$$

At the right end of the model area a wave boundary is applied with the following parameters:

$$H = 0.06\text{m}, T = 1.0\text{s}$$

The still water depth for the simulation is 0.3 m.

An example from a model simulation is shown in Fig. 6. Time series plots of horizontal velocities in three points (as defined in Fig. 6) are shown in Fig. 7.

Fig. 6 Example of surface position and velocities during wave run-up on a permeable breakwater. After t = 1.8 s.

Fig. 7 Time series of horizontal velocities (m/s) at three locations, one outside the breakwater, one at the edge of the breakwater and one in the coarsest porosity layer as shown in Fig. 6.

### Conclusions

A 2D (x-z) numerical model has been developed for description of flows on and in coastal structures. The model includes a description of the energy loss in porous media taking into account both laminar and turbulent effects as well as the inertia effect. Comparisons with analytical solutions and measurements from physical model tests with waves and currents have shown promising results.

In order to correctly simulate the flow on and in porous coastal structures, it will be necessary to establish a better knowledge of the coefficients involved in the energy loss equation and to describe the energy loss due to wave breaking on a slope which implies a formulation of the hereby induced air entrainment.

### Acknowledgement

The research project which started in 1988 has been funded by the Danish Council of Technology through grant no. 880440. The verification of the porosity description has partly been co-sponsored by the Commission of the European Communities under the MAST-programme, contract 0032.

## CHAPTER 13

### THE INTERACTION OF DEEP-WATER GRAVITY WAVES AND A CURVED SHEARING CURRENT

MARIUS GERBER<sup>1</sup>

#### 1. ABSTRACT:

The interaction of steady deep-water gravity waves with a pre-existing large-scale curved current has been investigated. In order to investigate the influence of the curvature of the current on the wave field, the current field was represented by a section of an annular current with a particular non-dimensional radius  $R$ .

As a first approximation the interaction of a family of linear axi-symmetrical waves and the current was investigated. Exact linear ray solutions were obtained which, in the limit when  $R \rightarrow \infty$ , reduce to the analytical straight current solutions of Longuet-Higgins and Stewart (1961).

#### 2. INTRODUCTION:

The emphasis of this paper is on the linear theory of the interaction of deep-water waves, generated on still water, and pre-existing large scale currents. Longuet-Higgins and Stewart (1960, 1961) were the first to give an accurate description of linear wave-current interactions and introduced the concept of radiation stress. Further contributions in our understanding of the interaction of linear waves and large scale currents came from, among others, Whitham(1962), Bretherton and Garrett(1968) and Peregrine (1976), who examined a number of different situations.

In almost all of the above studies the analysis was confined to two special situations of steady currents, namely (i) straight currents, varying with distance along the stream or (ii) straight

---

<sup>1</sup>Department of Applied Mathematics  
Stellenbosch University  
STELLENBOSCH, SOUTH AFRICA

currents varying across the stream. Exact linear solutions for these situations were derived by Longuet-Higgins and Stewart (1960, 1961).

The purpose of this paper is to extend the linear theory of the interactions of waves with a large scale current to more general current situations. Here we extend the range of known linear solutions by considering the simplest formulation of interaction with a curved current, namely steady axi-symmetrical waves on an axi-symmetrical annular current. This restriction simplifies the mathematics, but even so, solutions have been found for a wide range of cases.

### 3. MATHEMATICAL FORMULATION

Consider, in polar co-ordinates, an annular current of the form

$$\underline{U} = U_{\theta}(r) \underline{e}_{\theta} , \quad (3.1)$$

where  $r$  and  $\theta$  are the polar coordinates and  $\underline{e}_{\theta}$  is a unit vector in the  $\theta$  direction. Equation (3.1) describes an axi-symmetric current with arbitrary velocity profile which is only a function of the radial distance.

For the annular current (3.1) the basic equations of wave kinematics are given by:

DISPERSION:

$$\sigma^2 = gk \text{ or } c^2 = g/k, \quad k = |\underline{k}| \quad (3.2)$$

where  $\sigma$  is the intrinsic frequency of the waves and  $k$  is the corresponding wavenumber. The celerity of the waves is denoted by  $c$ .

DOPPLER SHIFT:

The apparent frequency, i e the frequency of waves passing a fixed point, is

$$\begin{aligned}\omega &= \sigma(\underline{k}) + \underline{k} \cdot \underline{U} \\ &= \sigma + k \sin \alpha U_\theta \\ &= k[c + U_\theta \sin \alpha],\end{aligned}\quad (3.3)$$

where  $\alpha$  is the angle between the wavenumber  $\underline{k}$  and the unit vector  $\underline{e}_r$  in the radial direction (see figure 1).

ANGULAR WAVENUMBER:

$$m = rk \sin \alpha, \quad (3.4)$$

with  $m$  a constant.

Non-dimensional variables may now be introduced to simplify the solutions. Consider a wave ray initially outside the influence of the current and denote, when  $U_\theta = 0$ , the wavenumber  $k$  by  $k_0$  and the wave celerity  $c$  by  $c_0$ . A scaled wavenumber  $K = k/k_0$ , as well as a scaled celerity  $C = c/c_0$ , may then be introduced. Also let  $V = U_\theta/c_0$  denote the scaled current velocity.

In order to depict the outside (or inside) radius of the annulus at the point of entry of the ray, let the radius of the current at this point be  $r_0$ . Assume further that  $U_\theta = 0$  just outside (or inside) the annulus, i e where  $r \rightarrow r_0$ . This suggests a logical choice for the non-dimensional radius is  $R = r/r_0$ .

From the symmetry of the current it is clear that, without loss of generality, a polar angle  $\theta_0 = 0$  can be selected for the point of entry  $r_0$ . Since  $\alpha = \phi - \theta$ , where  $\phi$  is the angle between  $\underline{k}$  and  $\underline{e}_1$ ,  $\alpha_0 = (\phi - \theta)_0$ , and the angle between  $\underline{k}$  and the x-axis at  $r_0$  is then  $\phi_0$  (see figure 1).

figure 1 : Definition diagram of rays interacting with an annular current.

Equations (3.3) and (3.4), by using (3.2), then become:

$$C = \frac{R \operatorname{cosec} \phi_0}{R \operatorname{cosec} \phi_0 - V} \quad (3.5)$$

$$K = \left[ \frac{R \operatorname{cosec} \phi_0 - V}{R \operatorname{cosec} \phi_0} \right]^2 \quad (3.6)$$

$$\sin \alpha = \frac{R \operatorname{cosec} \phi_0}{[R \operatorname{cosec} \phi_0 - V]^2} \quad (3.7)$$

so that, for a current field given by  $V(R)$ , the wave properties may be found from (3.5), (3.6) and (3.7).

We now also introduce the description that for rays initially outside the annulus, which then penetrate the circular current at  $R = 1$ , so that  $R < 1$  within the annulus where  $V \neq 0$ , the term convex current (to the direction of wave approach) will be used. Conversely, concave currents have waves that originate inside the annulus before they penetrate the annulus at  $R = 1$ .  $R$  will then become greater than unity within the annulus where  $V \neq 0$ . Figure 2 is a schematic representation of convex and concave currents as defined above.

#### 4. SPECIAL SOLUTIONS

It is clear that the right hand side of equation (3.7) can have a magnitude greater than one for a range of  $V$  values. This defines upper and lower limits to  $V$  for which solutions exist.

The critical velocities bounding the region without waves are:

$$V = R \operatorname{cosec} \phi_0 \pm (R \operatorname{cosec} \phi_0)^{\frac{1}{2}} \quad (4.1)$$

At these critical velocities  $\alpha = 90^\circ$  so that the waves travel parallel to the current. In practise the rays are tangent to a caustic curve, concentric with the eddy, and reflection of the rays result. It is important to note that with this model the wave motion along rays is entirely reversible. Note also that "reflection" in this paper imply  $\alpha = 90^\circ$  and  $V \neq 0$ . The

Convex currents

(a)  $R = 1$  ;  $\phi_0 < 90^\circ$

(b)  $R = 1$  ;  $\phi_0 > 90^\circ$

Inside annulus :  $R < 1$ .

Concave currents

(a)  $R = 1$  ;  $\phi_0 > 90^\circ$

(b)  $R = 1$  ;  $\phi_0 < 90^\circ$

Inside annulus :  $R > 1$ .

Figure 2 : Definition diagram for concave and convex currents.

corresponding circular caustic curve is thus at a fixed radius from the origin within the current. For axi-symmetrical wave fields caustics can, however, also occur in the absence of "reflection". This is when the wave rays cross within the core of the annulus and although  $\alpha = 90^\circ$ ,  $V = 0$ .

For currents opposing the direction of wave approach two other refraction configurations, at other  $\alpha$  angles, may also be identified. "Blocking" is when the component of the group velocity in the direction of  $\underline{e}_\theta$ ,  $C_g \sin \alpha$ , becomes equal to  $|U_\theta|$

$$C_g \sin \alpha + U_\theta = 0 \quad (4.2)$$

and the waves are blocked in the  $\underline{e}_\theta$  direction. As in the case of "reflection" a fixed "blocking" radius from the origin may also be identified.

The second, or "stopping", configuration results when the local group velocity of the waves becomes equal and opposite to the convection velocity of the current:

$$C_g + U_\theta \sin \alpha = 0 \quad (4.3)$$

The crests of the waves are refracted to be parallel to the ray direction and the waves are stopped in the  $\underline{k}$  direction. As before, a fixed "stopping" radius from the origin may be identified.

By using equation (3.7) the resultant  $\alpha$  values may be contoured in the  $(R \operatorname{cosec} \phi_0, V)$  plane. Superposition of the current profile, as a function of the radius and the initial angle,  $V(R \operatorname{cosec} \phi_0)$ , then provides an easy mechanism to study the variation of the waves. For equation (3.7) the contours of figure 3 are obtained. The intersection of the various contours with the  $R \operatorname{cosec} \phi_0$  axis then indicate the cosec  $\phi_0$  values of the initial  $\phi_0$  entry angles, that is where  $R = 1$  and  $V = 0$ . As before, since for concave (convex) currents  $R > 1$  ( $R < 1$ ), the abscissa values in figure 3 will be increasing (decreasing) from the initial cosec  $\phi_0$  value when rays penetrate the annulus from the concave (convex) side.

The  $\alpha = 90^\circ$  contour in figure 3 is of particular interest since it represents the linear caustic curve where reflection of the wave rays take place. Other important contours in figure 3 are those

Figure 3 : Contours of  $\alpha$  on the  $(R \operatorname{cosec} \phi_0, V)$  plane.

which indicate where the rays are blocked or stopped by the current. These contours were obtained from equations (4.2) and (4.3). It is clear that only the lower branch of the blocking contour in figure 3 is relevant. Figure 3 also shows that for waves initially on still water, for both concave and convex currents, the blocking condition will always occur before the stopping condition can be satisfied. Furthermore, in practical application the linear stopping velocity condition will only be satisfied for waves of relatively short period. This is due to the relatively large opposing current values needed for (4.3) to apply.

## 5. NUMERICAL RAY SOLUTIONS

Waves interacting with a shearing current can, in general, exhibit four different types of behaviour. That is, the waves can (i) penetrate the current, (ii) be reflected by the current, (iii) become blocked by the current or (iv) are stopped by the current. Whereas all four these types of behaviour can be expected from waves opposed to the flow direction of the current, waves that propagate in the same direction as the current can not be blocked or stopped by the current.

The information contained in figure 3 is very useful since it allows us to illuminate the different features of straight, concave and convex shearing currents. For example, for given initial angle of incidence,  $\phi_0$ , different annular current distributions of the form (3.1) may be superimposed on the  $(R \operatorname{cosec} \phi_0, V)$  plane and the variation of the waves followed graphically. Various numerical ray simulations of an axis-symmetrical wave field interacting with an annular current of the form (3.1) are shown in figures 5 - 11. The point of entry of the rays in each of these figures is marked by "E" while the maximum current velocity within the annulus is indicated by a dashed line. The wave crests are also shown in some of these figures. For each of these figures the corresponding parabolic current profile is shown in figure 4. In particular instances where the waves are reflected by the current the relevant part of the current profile is indicated by a bold line. Also, the position on the ray where the waves are blocked, reflected and stopped by the current are shown by the filled circles marked "B", "F" and "S" in figures 5 - 11.

Figure 5 shows a family of rays penetrating the following concave annular current marked (a) in figure 4. The initial angle between the ray and the x-axis,  $\phi_0$ , was taken as  $45^\circ$ , corresponding to  $R \operatorname{cosec} \phi_0 = 1.41$ . The maximum value of the parameter  $V$  occurs at the dashed centerline-radius of the annulus and for this example  $V_{\max} = 0.28$ .

Figure 6 is an example of two rays interacting with the opposing convex current marked (b) in figure 4. The initial angle  $\phi_0 = 120^\circ$

so that  $R \operatorname{cosec} \phi_0 = 1.15$ . Only the bold part of the profile is relevant since the waves are reflected by the current. The filled circles in figure 6 correspond to the positions where the waves are blocked before being reflected by the current. Since the wave motion along the rays are reversible, the blocking contour is crossed twice (figure 4) before the waves exit the annulus.

It is interesting to note that on a straight opposing current, such as the current marked (c) in figure 4, reflection of the waves is not possible. This is also shown in figure 7. As before, the filled circles indicate the positions where the waves are blocked and stopped by the current. The waves are only stopped at relatively large values of  $V$ ; in this example  $V_{\max} = -0.96$ .

Figure 8 is another example of waves interacting with an opposing convex current. Here the dimensionless current velocity,  $V$ , is such that the waves are both blocked and stopped before they reflect. The initial angle of incidence is, similar to that of figure 6, taken as  $\phi_0 = 120^\circ$  and the relevant current profile is marked (d) in figure 4. The value of  $V_{\max} = -0.96$ .

The current profile marked (e) in figure 4 was used to generate the rays in figure 9. This profile is similar to that used in figure 8, except that here the waves approach the opposing current from the concave side.

Waves may also be trapped by an annular current. Waves generated on still water, before interacting with a concave current, may undergo multiple reflections within a certain radius and thus become trapped inside the annulus. Figure 10 is a trapped ray solution corresponding to the current profile marked (f) in figure 4. The angle of initial incidence  $\phi_0 = 45^\circ$  while  $V_{\max} = 0.64$ .

For this annular configuration, and for waves initially inside the annulus, while propagating in the same direction as the current, it can also be seen from figure 4 that profiles that reach up to the upper branch of the caustic line  $\alpha = 90^\circ$  may have trapped waves on them for chosen initial conditions. Figure 11 is an example of such a single trapped ray. The bold part of the current profile marked (g) in figure 4 corresponds to the ray solution shown in figure 11. It is clear that relatively large  $V$  values are needed to trap the waves. In this example  $V_{\max} = 1.4$ .

## 6. CONCLUSIONS

Exact linear solutions for the interaction of steady, axis-symmetric deep-water gravity waves and an axis-symmetric annular current have been derived. Two important non-dimensional parameters, namely a current velocity parameter,  $V = U_0/c_0$ , and a radius-angle parameter,  $R \operatorname{cosec} \phi_0$ , where  $R = r/r_0$ , were

Figure 4 : The annular current configurations used to generate the wave ray examples of figures 5 - 11.

Figure 10 :

identified. For  $R > 1$  concave currents were considered while convex currents have  $R < 1$ .

Wave reflections, as well as blocking and stopping of the waves by the current, were investigated. Both positive convex currents and positive concave currents admit reflections, but reflections are only possible for negative convex currents. Reflections may also occur on opposing convex currents before the waves are blocked. On negative concave currents the linear waves may also be stopped by the current. However, very large opposing current velocities are required to do so. Furthermore, reflections on an adverse convex current will occur more frequently than the "stopping" velocity criterion can be satisfied. This is so since large negative values of  $V$  are needed to stop the waves.

Wave rays may also be trapped within the boundaries of the current. Waves that are generated on still water inside the annulus, and which penetrate the annulus, while travelling in the same direction as the concave current, may undergo multiple reflections and remain trapped within a certain reflection radius of the current. Only waves generated within the boundaries of the annulus can be trapped so as to remain within the annulus. The theory presented in this paper limits the waves, and therefore also the current distributions, to cases where  $R \csc \phi_0 > 1$ . Figure 4 then shows that it is not possible to construct an adverse current configuration which can trap waves.

## CHAPTER 14

# TRANSFORMATION OF WAVE CREST PATTERN IN SHOALING WATER

Yoshimi Goda<sup>1</sup>

### Abstract

Spatial distributions of wave crests are examined through numerical simulations of directional random sea surface. As the directional spreading of wave energy becomes narrow, the wave crests become long and the spread of individual crest directions become narrow. Simulations are extended to waves propagating into a planar beach. The areas of wave breaking are identified as the zone of surface elevation higher than the breaking threshold. The lateral spreading speed of breakers is analyzed from consecutive scenes of breaker crest patterns. It is about 30% of the forward advance speed of breakers.

### Introduction

Directional random sea waves are generally described with the directional wave spectrum. The wave field is represented as the superposition of an infinite number of infinitesimal component waves, as illustrated by Pierson, Neumann, and James (1955). The theoretical expression for the root-mean-square wave number in an arbitrary direction has been given by Longuet-Higgins (1957), who introduced the long-crestedness parameter as the ratio of the smallest to the largest wave numbers in the directions 90° degree apart. Isobe (1988) introduced a theory of the joint distribution for the direction, height, and period of individual waves, based on the orbital velocities of water particles on the surface. Such statistics on individual wave directions are the subject to be examined in more details in the present paper.

A direct approach to the statistics of individual wave directions is to analyze the spatial distributions of sea surface elevations. The data of real sea surface elevations are hard to obtain, but the simulation technique can provide as many data as necessary. The contours of simulated wave surface make it possible to identify the areas of wave crests, on which the lengths, heights, and directions of wave crests are examined. The information on the statistics of wave crests will be utilized for the analysis of surfing climate, the necessity of which has been pointed out by Dally (1990).

---

<sup>1</sup> Prof., Yokohama National Univ., Dept. Civil Eng., Hodogaya-Ku, Yokohama 240, Japan, M. ASCE

Analysis of wave crest statistics has been undertaken by Goda and Tokiwa (1991) and by Goda and Mizusawa (1992), but the results are reported in Japanese. The present paper introduces the directional characteristics of wave crests in both uniform and shoaling waters. The aspect of crest length statistics will be reported elsewhere (Goda 1993).

### Directional Wave Spectrum Employed for Simulation

A combination of the modified JONSWAP frequency spectrum and the Mitsuyasu-type directional spreading function was employed as the directional spectrum for numerical simulations. For a given wave height  $H_{1/3}$  and spectral peak period  $T_p$ , the modified JONSWAP spectrum is expressed by Goda (1988) as

$$S(f) = \beta_J H_{1/3}^2 T_p^{-4} f^{-5} \exp[-1.25(T_p f)^{-4}] \gamma^{\exp[-(T_p f - 1)^2 / \sigma^2]} \quad (1)$$

where

$$\beta_J = \frac{0.0624[1.094 - 0.01915 \ln \gamma]}{0.230 + 0.0336\gamma - 0.185(1 + \gamma)^{-1}} \quad (2)$$

$$\sigma = \begin{cases} 0.07 & : f \leq f_p \\ 0.09 & : f > f_p \end{cases} \quad (3)$$

Throughout the simulations, the following height, period, and peak enhancement factor were employed:

$$(H_{1/3})_0 = 2.0 \text{ m}, \quad (T_p)_0 = 8.01 \text{ s}, \quad \gamma = 3.3 \quad (4)$$

where the subscript 0 indicates the values of deepwater waves. The spectral peak period of 8.01 s corresponds to the deepwater wave length of  $(L_p)_0 = 100.0$  m. The significant wave period is estimated as  $T_{1/3} = 7.59$  s. Because the wave linearity is assumed and the results are all presented in dimensionless forms, the above values of height and period merely indicate the input conditions for simulations.

The Mitsuyasu-type directional spreading function is expressed as

$$G(f; \theta) = G_0 \cos^{2S}(\theta/2) \quad (5)$$

where

$$G_0 = \left[ \int_{\theta_{\min}}^{\theta_{\max}} \cos^{2S}(\theta/2) d\theta \right]^{-1} \quad (6)$$

$$S = \begin{cases} (f/f_p)^5 S_{\max} & : f \leq f_p \\ (f/f_p)^{-2.5} S_{\max} & : f > f_p \end{cases} \quad (7)$$

The directional spreading parameter  $S_{\max}$  was given the values of 10, 25, and 75 to represent wind waves, medium-distance swell, and long-distance swell.

### Simulations of Directional Random Wave Profiles in Water of Uniform Depth

The surface elevation of directional random waves  $\eta(x, y)$  is computed by means of double series of the following form:

$$\eta(x, y) = \sum_{m=1}^M \sum_{n=1}^N a_{m,n} \cos(k_m x \cos \alpha_n + k_m y \sin \alpha_n + \epsilon_{m,n}) \quad (8)$$

where  $a_{m,n}$  denotes the amplitude of component wave,  $k_m$  the wave number,  $\alpha_n$  the directional angle,  $x$  and  $y$  the cartesian coordinates, and  $\epsilon_{m,n}$  the random phase angle which is uniformly distributed between 0 and  $2\pi$ . The time  $t$  is dropped in Eq. 8, because the wave profiles in steady state condition is examined in the water of uniform depth.

The number of frequency components was set at  $M = 50$ , while that of directional components was  $N = 30$ . The wave number  $k_m$  was computed by the small amplitude wave theory for the following frequency  $f_m$  :

$$f_m = 1.007 T_1^{-1/3} \{\ln[2M/(2m-1)]\}^{-1/4} \quad (9)$$

The directional angle  $\alpha_n$  was set by equally dividing the directional range between  $[(\alpha_p)_0 - 90^\circ]$  and  $+90^\circ$  in deepwater, where  $(\alpha_p)_0$  denotes the incident wave angle to the depth contour in deepwater. In shallow water, the directional range was reduced by considering the wave refraction effect.

Wave simulations were carried out in deepwater and also in shallow water with the depth  $h = 20, 10,$  and  $5$  m, which corresponded to the relative water depth  $h/L_0 = 0.2, 0.1,$  and  $0.05$ , respectively. The shoaling and refraction effects were taken into account in wave simulations in shallow water, by assuming the depth contours being parallel and straight lines. The bottom slope was assumed nearly horizontal so that the area of computation could be considered of the uniform depth.

The computation area was a square with the side length equal to  $20(L_p)_0$ , and the grid spacing of  $\Delta x = \Delta y = 0.1(L_p)_0$  was employed. For a given condition of wave simulation, 25 surface wave profiles were created by changing the initial phase angle by means of a pseudo random number generating program.

### Detection and Definition of Wave Crests

Wave crests can be defined in many ways. In this paper a wave crest is defined as an enclosed area above a certain threshold elevation. The outermost boundary of this wave crest area defines the length, width, direction of the wave crest. The procedure to detect and define the outermost boundary is as follows.

First, the surface elevation at every grid point in the computed space is checked if it is above the threshold level, and the grid point is marked accordingly. The closed circles in Fig. 1 indicate the point being below the threshold level, while the open circles being equal to or above the threshold level.

Second, a search is made for a change from the open to closed circles or vice versa between the adjoining grid points. The search is made from the left to the right and from the top to the bottom along every grid line. When the change from a closed circle to an open circle takes place, the numeral 1 is assigned to the section of grid line there. The change from an open circle to a closed circle is marked with the numeral 2. No change is marked with N.

Third, a line is drawn by connecting the sections of grid lines marked either with 1 or 2. When such lines are drawn, they are numbered as ①, ②, ③, and so on. These lines are examined if they encounter the peripheries of the computation area. When a line does not form a closed loop by ending up at the peripheries, it is not considered as a complete boundary of wave crest and discarded in the following analysis.

Fourth, the exact location of the wave crest line is determined at each grid line section by a linear interpolation between the surface elevations at the adjoining grid points. The information of the locations of grid-line-crossings is stored for each wave crest line for further analysis.

The threshold elevation for defining wave crests was selected as  $\eta_{\text{thres.}} = 0.1(H_{1/3})_0$  after several examinations. This threshold level is employed throughout this paper except for the case when the breaker area is defined.

Fig. 1 Explanatory Sketch for Detection of Wave Crest Boundary Line

**Wave Crest Patterns and Crest Lengths in Water of Uniform Depth**

Figure 2 exhibits examples of wave crest areas defined by the above procedure. The four diagrams shown here represent directional random waves with the spreading parameter  $(S_{\text{max}})_0 = 25$  in water of uniform depth. The upper left diagram is for deepwater waves, and the other three diagrams are for waves with the relative depth  $h/L_0 = 0.2, 0.1,$  and  $0.05$ . The incident wave angle is  $(\alpha_p)_0 = 30^\circ$ . As the relative depth decreases, wave crest patterns approach toward the pattern of monochromatic waves, because of the wave refraction and shoaling effects. The apparent long-crestedness of wave patterns in shallow water regions is caused by the shortening in wave length: the absolute lengths of wave crests remain unchanged from deep to shallow water for the same value of directional spreading parameter.

The directional spreading affects the wave crest length. As the range of directional spreading becomes narrow, the crest length increases. Figure 3 shows the relation between the relative crest length  $\lambda/L_p$  and the directional spreading parameter  $S_{\text{max}}^*$ . The crest lengths are measured for crests with the top elevation  $\eta_c$  higher than  $0.75(H_{1/3})_0$ , and the mean length and the upper quartile length have been calculated from the data of 25 wave crest patterns for each condition. The crest lengths are normalized with the local wave length  $L_p$  corresponding to the spectral peak frequency. For waves in the intermediate to shallow water, the directional spreading becomes narrow owing to the wave refraction effect. This causes an apparent increase in the value of  $S_{\text{max}}$  as shown in Fig. 4 (Goda and Suzuki 1975), which is called the equivalent spreading parameter in this paper. The closed symbols in Fig. 3 refer to waves with  $(S_{\text{max}})_0 = 25$  in the intermediate to shallow water. As shown in Fig. 3, the relative crest length is well described as the function of equivalent spreading parameter  $S_{\text{max}}^*$  regardless of water depth.

**Spreading of Individual Crest Directions**

The crest direction is defined as the direction normal to the straight line connecting the two outermost points of a wave crest area. Figure 5 shows the joint distribution of the crest direction  $\theta$  and the relative crest length  $\lambda/(L_p)_0$  of the random waves with  $S_{\text{max}} = 10$  in deep water, while Fig. 6 is for waves with  $(S_{\text{max}})_0 = 25$  in shallow water with  $h/L_0 = 0.05$ . The numerals in Figs. 5 and

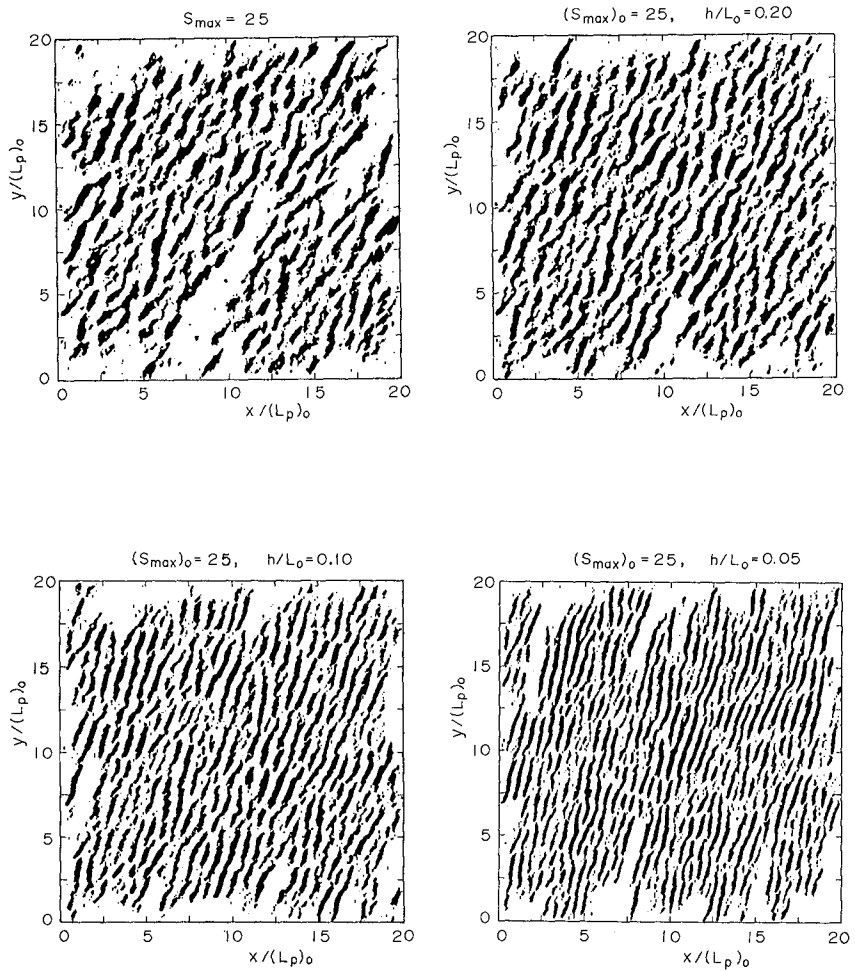

Fig. 2 Wave Crest Patterns in Water of Uniform Depth

Fig. 3 Mean and Quartile Crest Lengths of Wave Crests Higher than  $0.75(H_{1/3})_0$

Fig. 4 Equivalent Spreading Parameter  $S_{max}^*$  in Shallow Water Area (after Goda and Suzuki 1975)

6 are the numbers of wave crests within respective blocks of relative crest length and crest direction. The data with crest lengths less than  $(L_p)_0$  are omitted because of inherent errors in assessing the crest direction (the positions of wave crest lines are determined on the  $x$  and  $y$  grid lines only).

The incident wave angle in deep water is  $(\alpha_p)_0 = 30^\circ$ . The mean angle of crest direction in Fig. 5 is  $27.8^\circ$ , and a small difference is probably due to the method of defining crest direction. The mean angle of crest direction in Fig. 6 is  $13.0^\circ$ , which is slightly smaller than the mean direction  $15.0^\circ$  estimated by the calculation of wave refraction with the directional spectrum.

Fig. 5 Joint Distribution of Individual Crest Direction and Relative Crest Length in Deepwater with  $S_{max} = 10$

The spread of individual crest directions is represented with their standard deviations. They are plotted against the equivalent spreading parameter  $S_{max}^*$  in Fig. 7, where the standard deviation of crest direction for the wave crests longer than  $(L_p)_0$  and that of crests higher than  $0.75(H_{1/3})_0$  are shown.

### Simulation of Directional Random Wave Patterns in Shoaling Water

Waves propagating in shoaling water can be simulated by paying due account to the change in phase angle. For the case of one-dimensional waves, the phase angle advances by the amount  $k dx$  over a distance  $dx$ . When waves propagate from  $x_0$  to  $x_I$  and reach to the  $I$ -th grid section, the wave profiles there can be computed by using the following equation:

$$\eta(x_I, t) = a(x_I) \cos[2\pi ft + \epsilon + \sum_{i=0}^{I-1} k(x_i) dx] \quad (10)$$

Fig. 6 Joint Distribution of Individual Crest Direction and Relative Crest Length in Shallow Water at  $h/L_0 = 0.05$  with  $(S_{max})_0 = 25$

Fig. 7 Standard Deviation of Individual Crest Directions of Wave Crests Longer than  $(L_p)_0$  and Those of Crest Lengths Higher than  $0.75(H_{1/3})_0$

in which  $i$  denotes the order number of the grid section and  $\epsilon$  is the initial phase angle. The amplitude  $a$  is a function of the location  $x_I$  due to the shoaling effect.

Waves propagating toward the shore of coast with parallel straight contours are depicted in Fig. 8. The coordinate  $x$  is set parallel to the shoreline and thus the water depth is constant in the  $y$  direction. The lines with arrows indicate the direction of wave propagation and the dashed lines normal to the arrow lines represent the wave crest lines. The phase angle at each grid point is determined as follows. First, the phase angle at  $(x_0, y_1)$  is greater by the amount  $k(x_0)dy \sin \alpha(x_0)$  than that at the origin  $(x_0, y_0)$ . The advance of phase angle at  $(x_0, y_J)$  is  $J$  times that amount. Along the line  $y = y_J$  the phase angle increases by the amount  $k(x_i) \cos \alpha(x_i)$  when waves propagate from the  $i$ -th section to  $(i + 1)$ -th section. This increase of phase angle is common for all the  $y$ -lines. Thus, the wave profile at the grid section  $(x_I, y_J)$  can be calculated by the following equation:

Fig. 8 Explanatory Sketch for Grid System of Planar Beach

$$\eta(x_I, y_J) = a(x_I) \cos[-2\pi ft + \epsilon + k(x_0)Jdy \sin \alpha(x_0) + \sum_{i=0}^{I-1} k(x_i)dx \cos \alpha(x_i)] \quad (11)$$

Wave simulation in shoaling water has been carried out by using Eq. 11, and wave crest areas have been marked out as exemplified in Fig. 9. The bottom slope is assumed as 1/100, and the wave crest pattern in the water depth from 20 m to 0.1 m are shown there. The incident wave conditions are the same as those in Fig.2.

**Spatial Behavior of Breaking Waves in the Surf Zone**

The area in which waves are breaking can be detected through examination of the spatial surface elevations of random waves. It is done by setting the threshold level of wave crest definition at some breaking crest elevation instead of a fixed value such as  $\eta_{thres.} = 0.1(H_{1/3})_0$ . The threshold level of breaking crest area is set in this paper as one-half the breaker height formulated by Goda (1975), i.e.:

$$\eta_b = \frac{1}{2}H_b = 0.085L_0 \left\{ 1 - \exp \left[ -1.5 \frac{\pi h}{L_0} (1 + 15 \tan^{4/3} \theta) \right] \right\} \quad (12)$$

where  $\tan \theta$  denotes the bottom slope. The threshold level varies with the  $x$  coordinate, but the technique of defining the breaking crest area is the same as before. However, the crest lines crossing the peripheries of the simulation area have been kept as the boundary of breaking area.

Fig. 9 Wave Crest Pattern in Shoaling Water of Planar Beach with  $(S_{max})_0 = 25$  and  $(\alpha_p)_0 = 30^\circ$

A check on the reliability of simulating random surface elevations has been made by comparing the ratio of breaking wave crest areas to the total water area in a given water depth. From the simulated surface elevations, the total length of breaking wave crests along a given grid line at a constant  $x$ -value (constant water depth) was tabulated and this process was repeated at each grid line. The total length of breaking crest areas when divided by the length  $20(L_p)_0$  provides the breaker ratio at a given water depth. The raw data of breaker ratio has been averaged over 25 diagrams of random wave profiles in order to reduce the effect of statistical variability. The dashed line in Fig. 10 is a result of such analysis.

The theoretical prediction of breaker ratio has been made through the computation of shoaling and refraction of directional random waves. The root-mean-square value of deepwater waves has been transformed to that of shallow water waves by being multiplied with the shoaling and refraction coefficients of directional spectral waves. Because the wave simulation is based on the linear superposition of component waves, the simulated wave elevations should follow the normal distribution. Then the probability of surface elevation exceeding the breaker threshold level by Eq. 12 is simply estimated from the probability table of the normal distribution. The predicted value is shown with the solid line in Fig. 10, and it fits with the result of simulation analysis as expected.

The effect of incident angle upon the breaker ratio is demonstrated in Fig. 11. As the incident angle increases, the breaker ratio at a given depth decreases slightly; the start of wave breaking becomes closer to the shoreline and the surf zone becomes a little narrow. This is due to the more conspicuous decrease in the local wave height by the wave refraction effect in the case of oblique wave incidence than that of the normal wave incidence. The difference between the breaker ratios of different incident angles have also been predicted by theoretical

Fig. 10 Comparison of Theoretical and Simulated Ratios of Breaker Areas

Fig. 11 Effect of Incident Wave Angle on Breaker Ratio

calculation, though not shown in Fig. 11.

**Growth of Wave Breaking Areas in Shoaling Water**

Wave simulations can also reveal the change of individual breaking crest areas. Figure 12 exhibits an example of such analysis. A simulation of wave profiles in the nearshore is made with a certain set of initial phase angles. Then the transformation of that wave profiles is followed from  $t = 0$  to  $t = 9T_p$  with the time step  $\Delta t = T_p$  by using the same set of initial phase angles and by changing the time  $t$  in Eq. 11. Among these consecutive scenes of wave profiles, visual search is made for conspicuous breaking areas which appear in the locations far from the shoreline. Once they are picked up, further search is carried out on the locations of the same breaking areas in the preceding and following scenes. The breaking crest area marked with ② in Fig. 12, for example, has been noted in all of ten simulated wave profiles and its growth has been well observed, whereas the rest of breaking crest areas have appeared at later scenes. In the analysis of the time-sequence change of breaking crest areas, the grid distance  $\Delta x = 5$  m was adopted for finer resolution. The number of grid lines and the bottom slope were the same as before so that the offshoreward water depth was 10.0 m.

The shoreward advances of conspicuous breaking crest areas have been plotted on tracing papers, and the lateral spread lengths of these crest area have been measured on the tracing papers. The lateral spreading speed  $V_s$  of the breaking crest area has been calculated from these data. Figure 13 shows the results of the analysis of the lateral spreading speed of breaking crest area. The abscissa is the forward advance speed  $C_b$  of breaker, which has been approximated as  $\sqrt{gh}$  with the water depth  $h$  at the corresponding locations. The analysis has been carried out for the deepwater directional spreading parameter of  $(S_{max})_0 = 10, 25,$  and  $75$ , but the effect of directional spreading parameter on the lateral spreading speed is insignificant. As seen in Fig. 13, the lateral spreading speed shows a large scatter, but it remains in the range between 0 and  $C_b$ . The regression line

Fig. 12 Time Sequence Change of Breaker Areas with Time Step  $\Delta t = T_p$

Fig. 13 Lateral Spreading Speed versus Forward Speed of Breaking Crests  
 $\square$ :  $(S_{max})_0 = 10$ ,  $+$ :  $(S_{max})_0 = 25$ ,  $\times$ :  $(S_{max})_0 = 75$

between  $V_s$  and  $C_b$  under the condition that the line should pass through the origin yields the relation  $V_s = 0.30C_b$ .

**Conclusions**

Numerical simulation of directional random sea surface has succeeded in visualizing the wave crest patterns and clarifying the statistics of wave crest lengths and directions. Major conclusions of the present paper can be summarized as follows:

1. The mean crest lengths and the standard deviation of crest directions are governed by the directional spreading parameter  $S_{max}$  of the Mitsuyasu-type directional function.
2. In shoaling water, the effect of relative water depth on the crest statistics can be incorporated by using the equivalent spreading parameter  $S_{max}^*$  shown in Fig. 4.
3. The portion of breaking area within wave crests in shoaling water can be identified by setting the threshold surface level at the breaking crest elevation at respective water depth.
4. The lateral spreading speed of breaking crest area shows a wide scatter, but the average speed is assessed as 0.3 times the forward advance speed of breaker.

The numerical simulations reported hereinabove have been carried out by Messrs. Yasuhiro Tokiwa and Tatsuya Mizusawa as their thesis works at the Department of Civil Engineering, Yokohama National University. The author wishes to express his deep appreciation for their cooperations.

## CHAPTER 15

### Particle Image Velocimetry (PIV) in the Coastal Engineering Laboratory

C.A.Greated<sup>1</sup>, D.J.Skyner<sup>2</sup> & T.Bruce<sup>3</sup>

#### ABSTRACT

The Particle Image Velocimetry (PIV) technique is reviewed, with special reference to its application to coastal engineering problems. The basic principles are described, and strengths and weaknesses of different implementations considered. Examples of some applications of PIV at Edinburgh are described to illustrate the practicalities of its implementation in a hydrodynamics laboratory. Finally, the limitations to the accuracy of PIV in these applications are reviewed and an outline of some new developments in this area is given.

#### INTRODUCTION

Non-intrusive flow measurement techniques are becoming an increasingly familiar part of laboratory experiments in applied hydrodynamics and coastal engineering. Since its inception in 1966, Laser Doppler Anemometry (LDA) has progressed, and aided by developments in other technologies, notably in lasers, fibre-optics and computing, it is now a most useful tool under a wide range of conditions. LDA is, however, fundamentally a point measurement technique; the time evolution of flow velocity can be measured with great accuracy at a point, but if a map of an area of the flow is to be obtained, it must be built up point by point. Thus the flow must be steady or accurately repeatable. PIV gives a quantitative map of instantaneous flow velocities over a large field. An attractive feature of PIV analysis is that the velocity measurements come out on a regular grid and thus post-processing is relatively straightforward.

PIV is sometimes compared to streak photography where the path lengths of individual marker particles in the fluid are measured. Streak photography suffers two major disadvantages. Firstly, only a very few marker particles can be

<sup>2</sup>Research Associate, Dept Physics (D.Skyner@ed.ac.uk)

<sup>3</sup>Research Associate, Dept Mech Eng (T.Bruce@ed.ac.uk)

used, otherwise their paths overlap too often and the individual particle motions cannot be separated. Secondly, when used with sheet illumination, the particles may move out of the measurement plane, artificially shortening the streak lengths and causing errors in the velocity measurement.

## PARTICLE IMAGE VELOCIMETRY

The basis of PIV is to stroboscopically illuminate a two-dimensional plane of a flow containing small *seeding* particles. A double (or multiple) exposure photograph of this plane is taken. The spacing between the images of each particle on the film gives the local velocity. This photograph is then analysed to obtain the local flow velocities over a grid of points covering the whole field. PIV is normally considered as a two stage process: the acquisition and the analysis of the image.

Figure 1: Schematic diagram of PIV acquisition

Figure 1 shows schematically the acquisition stage in a typical application of PIV. The enlarged area shows a portion of the film containing multiple particle images: the optimum form of this area is dictated by the requirements of the subsequent analysis. The acquisition and analysis phases are therefore inextricably linked. The following sections consider the stages of the PIV process: acquisition, ie. illumination and photography, and the automated analysis of the image.

## PIV ILLUMINATION

In general, the two-dimensional plane within the flow is defined by a thin sheet of pulsed laser light. Two different techniques are available for producing this light sheet. In the first of these, a continuous wave (CW) laser is deflected off a

rotating multi-facet mirror so that the beam is scanned through the measurement area, as illustrated in figure 2. In the illustration, the parabolic mirror collimates the beam to give a more even intensity distribution. The shutter opening time on the camera is normally set to be four to six times the period of the beam scan, in order that this number of exposures are recorded on each negative. In the second technique, a pulsed laser, typically a Nd Yag, is used to produce double pulses, the beam being spread out into a sheet using a cylindrical lens as shown in figure 3.

Figure 2: Scanning beam illumination system

A comparison of the illumination techniques shows that the scanning beam method [Gray et al, 1991] is usually the best for use within the velocity ranges normally encountered in the coastal engineering laboratory, i.e. up to a few metres per second. It gives a sufficiently even illumination over a large area and has the advantage that more than two images per particle can easily be obtained, which improves the signal strength in subsequent analysis. For measurement regions of about  $1\text{m}^2$  and flow velocities up to  $2\text{ms}^{-1}$  a  $10\text{W}$  Argon Ion laser is suitable. The upper limit on velocities which can be measured with the scanning beam system can be proportionally increased by, for example, reducing the width of the scanned area. Above about  $10\text{ms}^{-1}$  it is necessary to use a pulsed laser; in this case the energy per pulse is almost constant, so that measuring higher velocities does not require a proportional increase in laser power. However, the use of pulsed lasers has certain drawbacks: such systems are inherently more dangerous; it is harder to obtain an even illumination over the measurement zone; the optical alignment is more difficult. Additionally, with a single laser only two pulses per negative

Figure 3: Pulsed sheet illumination

can be obtained easily. It is possible to obtain a four pulse sequence by coupling two lasers, but this is a costly option.

If the surface flow of a fluid is to be measured, then illuminating the measurement zone can be accomplished without the use of lasers. The surface defines the two dimensional plane for measurement and the stroboscopic illumination may be achieved by means of standard flash units. Thus PIV may often be simply and inexpensively applied to such flows.

### Practical Implementation of Illumination

In the fluid dynamics laboratories at Edinburgh the wave flumes and water channels have been designed with the application of PIV in mind. All the tanks are made of glass, giving optical access from the sides and below. The beam from a single laser serves three experimental rigs, considerably saving on the cost. Most of the time involved in carrying out PIV experiments is in setting up the apparatus. When the laser is in use for one experiment, another can be in the preparation stage.

For water channel experiments a 15W argon ion laser is used with scanning beam illumination. The beam from such a high powered laser is potentially very hazardous. For safety reasons, the laser is mounted rigidly in an enclosed area and its beam is directed through pipes to the appropriate experiment by a series of mirrors. With this arrangement the beam is totally enclosed up until the point where it enters the water tank and no longer represents a safety hazard. The scanning beam illumination system is mounted on rails beneath each of the water

channels so that the position of the measurement area can be easily moved.

## PIV PHOTOGRAPHY

The process of acquiring good PIV photographs involves two major stages. The first is selecting appropriate hardware for the application (eg, illumination, seeding, camera and film), and the second is using this hardware to best effect. This section addresses both of the above stages.

### Hardware

The hardware considerations may be divided into four broad and interdependent areas: illumination (already discussed), flow seeding, camera and film. Here the practices adopted in the study of water waves in the Fluid Dynamics Unit (FDU) at Edinburgh are detailed. However, most of the issues covered are also relevant to the application of PIV to other flows.

#### *Seeding*

The selection of a suitable flow seeding is crucial. The seeding used is conifer pollen which meets the most important criteria: it is almost exactly neutrally buoyant, quite reflective at the wavelength of the Argon Ion laser and small enough to follow the flow patterns (typical particle diameters are  $\sim 60\mu\text{m}$ ). It is also quite inexpensive — the cost of seeding a flume containing three tonnes of water is about the same as the cost of the film in the camera.

#### *Camera & Lens*

The choice of the camera and lens is also important. A flat-field lens should be used to minimise distortions of the image plane. Choosing a lens of longer focal length will reduce the apparent effect of any out-of-plane motions of particles in the field, but will increase the difficulty of achieving a sharp focus and make the process more susceptible to vibrations. A Hasselblad 500 *EL/M* camera with 80mm lens has proved suitable for many PIV applications at the FDU.

#### *Film*

The choice of film is generally straightforward, since there are a number of good, high resolution black and white films available at reasonable cost. Kodak TMax is one such film and is well suited to the green light of the Argon Ion laser.

### Taking the Photographs

The important issues remaining are the choice of camera position, achieving the correct seeding density, optimising the focus and optimising the exposure parameters to give good, high contrast photographs. Resolving all these issues involves

making compromises, and the aim of the following paragraphs is to outline the most important considerations. Figure 4 shows a well optimised image.

Figure 4: A photographically obtained PIV image

### *Seeding Density*

The optimum seeding density is determined by considering the subsequent analysis of the photograph. In the Edinburgh system, the local flow velocity at a point on the photograph is averaged over a 1mm diameter interrogation region. The seeding density should be high enough that there will always be several particle image pairs in each interrogation area, as shown in figure 1. Experience also plays a large part in getting an optimum level of seeding, and once good results have been obtained, the successful level of seeding can be repeated.

### *Illumination Interval*

As with optimising seeding density, the choice of illumination interval is dictated by consideration of the subsequent analysis. The interval should be set such that the largest velocity in the flow gives particle image separation on the photograph which is the largest resolvable by the analysis system,  $200\mu\text{m}$  for the FDU system. Normally an estimate of the largest velocity can be made, but its often necessary to take a test film trying different intervals in order to optimise the choice.

### *Shutter Speed*

Once the illumination interval has been chosen, the shutter speed is selected to give the required number of exposures. Typically, four to six exposures are used, but it is important to consider whether the flow changes over the exposure time.

### *Focus*

Achieving a sharp focus is vital if good PIV photographs are to be obtained, and can be quite difficult, especially when a large lens aperture or long focal length lens are being used. Again, a test film in which the focus is varied is the usual route to its optimisation.

### *Photographic Magnification*

The magnification from the measurement zone to the film depends upon the focal length of the lens and the distance from the camera to the measurement zone. Its selection is another compromise. It is often desirable to measure as large a region as possible, but the analysis phase must be considered. The implicit assumption is that particle image displacement over the interrogation region is uniform: if there is a strong displacement gradient present, errors are introduced and the resulting data point may be at best inaccurate and at worst, spurious. Therefore the size of the area imaged onto the photograph is typically limited to that which will result in displacement gradients of less than 3% over any 1mm diameter interrogation area.

### *Exposure*

Once the illumination interval and magnification have been established, the only factors left governing the exposure of the film are the lens aperture, the laser power and the film speed (ie, ASA rating). In general, a test film covering various settings of aperture and laser power is required for a new application. The quality of the resulting photographs may then be assessed on the analysis system and the best settings finalised.

If there is scope for choosing an aperture setting, it should be remembered that the largest apertures (smallest  $f$  numbers) give the poorest depth of field, so focussing is more difficult. However, if the particle image size is diffraction limited, the smaller apertures (larger  $f$  numbers) will result in larger particle images. Using  $f/4$  or  $f/5.6$  is usually a good compromise.

In general, the lower the ASA rating of the film, the finer the grain, so it is preferable to work with 100 ASA film. However, if the maximum available laser power and the largest aperture still give insufficient film exposure, then faster film may be used — 400 ASA TMax is widely used in the FDU, and has, on occasion, been *push processed* to as much as 3200 ASA, though this does result in a reduction in resolution.

## PIV ANALYSIS

There are a number of different approaches to extracting the velocity information from the flow photograph. The objective in this phase of the PIV process is to extract the local velocity at an array of positions on the negative from the most correlated separation of the particle images near that point. For high seeding densities, this is most commonly achieved by obtaining the autocorrelation of the intensity distribution within each interrogation area and locating the strongest correlation peak, which yields the average displacement and hence the velocity.

The autocorrelation function can be conveniently calculated using Fourier transforms (Wiener-Khintchine theorem)

$$A(x, y) = FT^{-1}\{[FT\{a(x, y)\}]^2\} \quad (1)$$

where  $a(x, y)$  is the image intensity distribution of the chosen portion of film,  $FT$  is a forward Fourier transform and  $A(x, y)$  is the autocorrelation function of the area.

Fast Fourier transform (FFT) routines are computationally very efficient. Nevertheless, with a fine grid the amount of computation is still considerable and an alternative approach is to produce optical transforms. Three types of analysis system are therefore possible. Both transforms can be performed digitally, both optically, or one of the transforms can be optical and the other digital. The last approach is the one which has been adopted in the FDU [Gray,1989], and is commonly known as the Young's fringe method, since the result of the optical transform is diffraction fringes. This gives adequate processing speed, whilst keeping the optical system relatively simple.

If the transformations are to be carried out purely digitally, white light illumination is used and the image of the particles is captured directly on a CCD array. This approach requires two digital transforms it is more computationally intensive than the fringe method. There are certain advantages, one of the most important being that boundaries can be indentified directly during the analysis phase without the need for additional optics.

A complete optical analysis of the PIV records is the most rapid of all, although the techniques for implementing this have not yet been fully developed. The best approach is probably to use an optically addressed spatial light modulator (SLM) as described by Jakobsen et al [1992].

### Practical Implementation of Analysis

Figure 5 shows the layout of the Edinburgh analysis rig. The negative is mounted onto a two-axis translation stage in the path of the beam from a low power laser. The illuminated area defines the point where the velocity is to be measured. Behind the negative is the "Fourier transforming" lens which images the fringe pattern onto a CCD array in its back focal plane. For a perfect transform the object should be in the front focal plane of the lens, but in practice it is placed

much closer to the lens than this in order to avoid vignetting caused by the finite aperture of the lens.

Figure 5: The Edinburgh PIV analysis system

For a typical PIV negative the fringe pattern is shown figure 6. The spacing between the fringes is inversely proportional to the particle spacing, and hence velocity, and their orientation gives the direction of the flow at that point. This fringe pattern is digitised and transferred to the PC. The inverse Fourier transform is then performed using an FFT algorithm.

Figure 6 also shows the computed autocorrelation function, containing two symmetrically placed peaks. The analysis program uses a peak detection routine to locate the position of the correlation peaks; the coordinates of the peaks define the magnitude and direction of the velocity vector at that point. An advantage of the fringe method is that the user can see immediately whether clear fringes are formed at any particular point in the flow. If they are, then the analysis procedure will almost certainly give a reliable velocity reading.

To obtain velocity values on a grid of points in the flow, the translation stage moves the negative relative to the interrogating laser beam. At each point, the analysis takes about 4 seconds, so that a 35mm format negative is analysed on a 1mm grid in under an hour.

Figure 6: Fringe pattern and autocorrelation function

### Data Validation

In the Edinburgh system, each velocity measurement is accompanied by a value which gives a measure of its reliability. This is determined by strength of the correlation peak compared to the background noise level. Velocity vectors whose “quality” factor lies below a specified threshold can either be discarded or checked individually.

### PIV ERRORS

As with LDA, PIV gives an absolute measurement of velocity, provided that the system is calibrated correctly for known particle displacements. Distortions can also occur in the photographic process, for example by refraction at side walls. The extent of these can easily be checked by inserting a grid into the measurement area and photographing this in place of the illuminated sheet.

The accuracy of PIV data is determined by the uncertainties introduced in the two distinct phases of the process; the photographic recording of the flow, and the analysis of this photograph. The specific problems in the case of PIV applied to wave motion have been considered in detail. For the most reliable results, the flow must be well seeded, and the photographic acquisition parameters selected to ensure that the velocity range present corresponds to the full range measurable in the analysis and that the velocity gradients on the film are not too great. If these conditions are satisfied, then the final error bound on measurements can be less than  $\sim 2\%$  of the maximum velocity measured.

### EXAMPLES OF PIV MEASUREMENTS

In this section the results from applications of PIV at the FDU are presented. Other recent studies using the technique are described in [Powell et Al,1992,

Morrison & Greated,1992, Bruce & Easson,1992, Skyner & Easson,1992(b)].

Figure 7: Vector field within a breaking wave

The results of the analysis of a PIV photograph can be displayed as a set of velocity vectors or, alternatively, iso-velocity contours may be plotted. Figures 7 and 8 show matching plots of velocity vectors and iso-velocities for a breaking wave; this type of plot is particularly useful for illustrating wave motions. Further details of this work are given in [Skyner,1992(a)].

For studies of vortex shedding or turbulence, vorticity contours may be the best method of display. Vorticities can be computed at each point by taking central differences in the two coordinate directions. Figure 9 shows a typical vorticity map recorded in the wake of an oscillating cylinder using PIV.

### Other Applications

PIV is potentially applicable to the measurement of two-phase flows and has been used successfully to study particle transport in air streams [McCluskey et al,1989]. It is anticipated that it will give good results in the study of sediment movement in water channels when the sediment density is low.

### FUTURE DEVELOPMENTS

Two new areas of development in PIV are particularly relevant to the coastal engineering laboratory. One is the use of stereoscopic photography to measure

Figure 8: Iso-velocity contours of a breaking wave. Contour interval  $0.1\text{ms}^{-1}$

all three velocity components and the other is the development of on-line PIV using acquisition systems based on a CCD camera.

### Stereoscopic Measurements

In stereoscopic photography the normal methods of illumination are used but the illuminated sheet in the flow is photographed from two different positions at the same time. There are two fundamental optical arrangements. In one of these, two cameras are angled to image the same field. The problem here is that different parts of the sheet are at different distances from the lens so it is difficult to achieve a sharp focus. Secondly, there is a distortion of the image. The other approach is to have both cameras aligned normal to the measurement plane. The problem in this case is that only part of the two images overlap and are usable for measurement. Most researchers have chosen the second method.

Two separate photographs may be taken and analysed and the resulting velocity vector plots combined by triangulation to produce the three components of velocity in a plane. For practical purposes the use of two cameras presents alignment difficulties because the resulting negatives need to be matched very precisely. To overcome this difficulty a number of systems have been developed which use just a single lens and produce the two images on a single piece of film. One such system has been devised by Arroyo and Greated [1991]. Instead of having two separate lenses in front of a single piece of film the two images are formed through the same lens. This is achieved by removing the lens from a

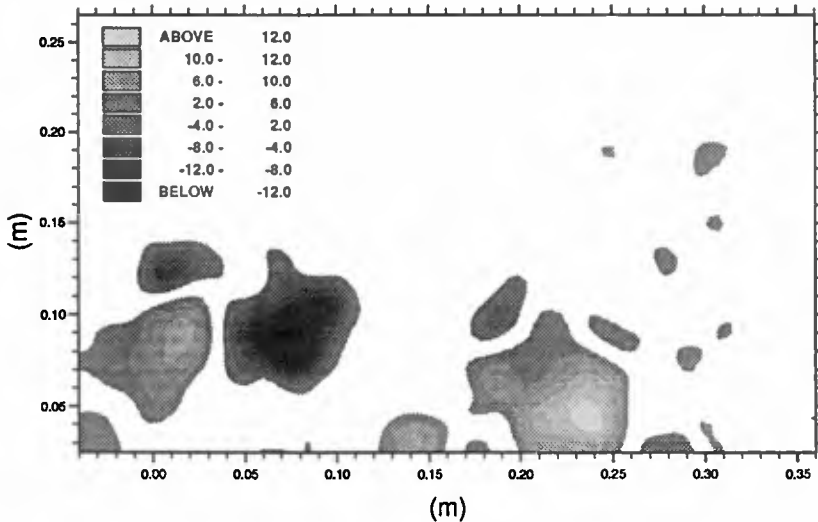

Figure 9: Vorticity in the wake of an oscillating cylinder

conventional camera and placing two parallel mirrors between the lens and the film. Two further parallel mirrors are also placed on the other side of the lens. After alignment, this system can be operated as a conventional camera.

### On-line PIV

It would be attractive if the photographic process could be eliminated completely. This can in fact be done by replacing the film camera with a CCD camera which simply captures an image electronically. Again, with multiple exposures on the same frame, the matrix of pixels needs to be subdivided and correlations carried out digitally. If different frames are used for consecutive exposures or two separate cameras are used, then the autocorrelation can be replaced by crosscorrelation, in which case directional ambiguity is resolved. Systems of this type have been implemented but in the present state of the art they are limited to extremely low velocities and the resolution is extremely poor compared to film.

### Fibre Optic Delivery

Considerable developments have been made in fibre optics in recent years and it is now possible to channel powers of up to 4W through monomode fibres. The use of monomode fibres allows the light to be recollimated back into a narrow beam of light at the other end; with the multimode fibres this is difficult to do. Powers of greater than about 4W can in theory be transmitted by splitting the

beam. Fibre optic linkage makes the PIV system very much more flexible and may be essential where access to the working area is severely constricted. Fibre transmission of pulsed laser beams is much more difficult due to the very high peak power densities.

## CHAPTER 16

### Directional nearshore wave propagation over a rip channel: an experiment

Luc HAMM\*

#### ABSTRACT

The aim of these tests was to study wave propagation on a beach, including the surf zone, and nearshore circulation produced by breakers in the presence of a rip channel. The tests were carried out in a multidirectional wave tank. The initial series of tests concerned the case of a plane beach sloping at 1 in 30. The second series was performed with a rip channel excavated in the beach. Conventional wave measurements were taken at 50 different points. Measurements of the multidirectional waves and rip current were taken at 7 points along the channel centre line. During the tests, various types of wave (monochromatic, random monodirectional and multidirectional) were tested and the results obtained were compared with identical starting conditions.

#### 1. INTRODUCTION

Wave tanks capable of simulating real multidirectional (short-crested) waves are a relatively common means of studying offshore structures, but they are less frequently used in the field of coastal engineering. Nevertheless, this field is rapidly developing at the present time and many shallow-water, multidirectional wave tanks have been built in recent years in Europe and North America. Mention should be made of three recent studies conducted in tanks of this type, which have been devoted to the study of wave propagation in the nearshore area, including the surf zone. Dingemans et al. (1986) studied the propagation of breaking waves on a submerged bar creating a rip current. In this case, where the energy slope is very localised, directional effects do not appear to affect the results to any great extent. Vincent and Briggs (1989) studied the effect of directional spectrum width on the concentration of wave

---

\* Senior engineer, SOGREAH Ingénierie, 6 rue de Lorraine, 38130 ECHIROLLES, France

disturbance behind a shoal. They showed that the results were highly sensitive to this parameter in the case of non-breaking waves. Lastly, Briggs and Smith (1990) and Elgar et al. (1992) have presented results for propagation on a plane beach with a slope of 1 in 30, including a wide range of unimodal and bimodal frequency spectra.

The main interest of these tests was to provide data sets that can be used to validate numerical models of real wave propagation (Dingemans, 1986; Grassa, 1990; Panchang et al., 1990). The tests described here were carried out in line with this philosophy. The bed configuration adopted aims at combining a moderately sloping beach with the creation of a water circulation cell produced by breaking waves.

## 2. EXPERIMENTAL SET-UP

The model was built in a wave tank at the Laboratoire d'Hydraulique de France in Grenoble. The tank measures 30 m by 30 m and is fitted with a multidirectional wave generator consisting of 60 paddles, each 0.5 m wide and 1.40 m high. The sea bed consists of a plane beach sloping at 1 in 30, with a rip channel excavated in the centre (fig. 1).

Direct OXYZ co-ordinates are defined as follows. The OX axis is perpendicular to the generator and forms the axis of symmetry of the wave tank. OY is parallel to the generator and marks the foot of the beach. OZ is vertical, running from the bottom to the top, with its origin at 0.50 m above the flat bed of the wave tank.

The bathymetry may be represented by the following analytical expression (Noda, 1974):

$$Z_f(x,y) = 0.1 - \frac{X}{30} \left[ 1 + 3 \exp\left(-\frac{X}{3}\right) \cos\left(\frac{\pi y}{30}\right) \right] \quad (1)$$

with  $X = 18 - x$

$x$  varies between 0 and 18 m and  $y$  between -15 and +15 m. The longitudinal profile along the centre line of the channel is shown on fig. 2d.

During construction of the sea bed, the channel was temporarily filled in order to carry out prior tests on the plane beach. It should also be noted that the beach only starts at a distance of about 5 m from the generator. This makes for better wave generation and for clear access to the tank.

Fig. 1 Experimental set-up

### 3. INSTRUMENTATION

Ten standard wave gauges and a wave direction gauge were installed in the tank. Visual observations (comprising photographs and video films) were also made under rather poor lighting conditions, which it was impossible to improve during the study.

The wave gauges are accurate to within 2%, with 1-5% linearity and very little drift. They were calibrated once a week. The direction gauge consists of a classic resistive wave gauge coupled to an electromagnetic current meter capable of making two-directional horizontal measurements. The main drawbacks encountered with resistive gauges, namely lack of stability, drift and linearity of measurement, were largely offset by using a small platinum electrode that compensates for deviations. In this way, linearity was 0.5% and calibration only had to be performed during maintenance operations.

The electromagnetic current meter is a disk 40 mm in diameter and 18 mm thick, accurate to within about 1%, and covering a measurement range of 0 to 1 m/s. It is calibrated during maintenance operations.

#### 4. MEASUREMENT POSITIONS

The ten wave gauges and wave direction gauge were installed in two groups in the wave tank.

The first group (comprising the direction gauge and six wave gauges) was fixed on a mobile beam running along the axis of the wave tank. These gauges scan an area between  $y = 8.3$  m to  $y = +1$  m and  $x = 1.0$  m to  $x = 15.30$  m. This last position ( $x = 15.30$  m) was only reached by certain gauges when the depth of water was sufficient for the measurement to be taken.

The other four gauges were arranged in a fixed pattern over the tank. They were used to check the repeatability of the measurements and replace any gauges on the beam that might prove to be defective during the tests.

In practice, the beam was moved along 7 axes during each test. This meant that wave disturbance was measured at 53 points in the case of the plane beach and 50 with the channel. The positions of the measuring points are shown on fig. 1 for the tests carried out with a channel.

The electromagnetic current meter was placed at 0.05 m above the bed, except at the last point near the coast, where the distance was reduced to 0.03 m.

#### 5. INCIDENT WAVE CONDITIONS

The wave generator is of the piston type and each paddle is controlled independently by a hydraulic system. The paddle control signal is generated by a program that uses the white noise filtering technique described by Gilbert and Huntington (1991). This method can only be used for waves that are perpendicular to the generator. With oblique waves, the superimposed sinusoidal wave method must be used. During this study, only frontal waves were generated with the white noise filtering technique. 17 wave conditions were selected in order to cover a wide range of steepness values and frequency and direction spectrum widths.

The spectra generated were of the form:

$$S(f, \Theta) = S_{\gamma}(f) \cos^n \Theta \quad (2)$$

$S_{\gamma}(f)$  corresponds to the Jonswap spectrum dependent on the parameter  $\gamma$ , with a value of 3.3 or 7. The angular distribution function depends on the exponent  $n$ , which has the value 2 or 6 in this case. Table no. 1

lists the theoretical incident wave conditions. Wave measurements in front of the generator gave values between 0.95 and 1.15 times the set height. No adjustment was made to correct these deviations.

Each wave condition was generated by identical repetitive cycles. A cycle had a period equal to 260 times the peak period, corresponding to about 320 waves. Repeatability of the waves was found to be very good at the fixed offshore gauges (variance less than 1% in most cases).

Table 1 Incident wave conditions

## 6. TEST PROCEDURE

This comprised three main phases, as described below:

Preparation of the test: The water surface at rest was measured at each measurement point in order to determine the reference level for subsequent calculation of the set-up and mean rip current. This procedure was essential as the gauges were submerged at different depths from one measurement line to another so as to be adapted to decreasing water depths. The generator was then started up and allowed to run for about 15 minutes in order to achieve a stable rip current pattern.

Measurements: Measurements were made simultaneously on the 13 channels over a period equal to one generation cycle (i.e. about 320 waves) with a frequency of between 20 and 25 Hz depending on the peak period. The trolley was then moved to the following measurement line and the gauges submerged at a suitable level for the water depth in this new position. These operations were repeated seven times during each test, without stopping the generator. They lasted about three hours.

End of test: At the end of the test, all the measurements were checked and any incidents during acquisition noted. Certain tests were repeated when serious incidents had occurred. An initial statistical analysis of measurements from the fixed gauges was also made to check the reproducibility of the wave conditions during the test. The recorded data were then stored on magnetic tape, translated into ASCII and stored on PC-compatible floppy disks.

## 7. STANDARD DATA PROCESSING

The mean values from each measurement point were first of all calculated by comparison with the measurements at rest. The set-up and mean current values were estimated in this way.

Standard processing then involved performing a statistical analysis of all the recordings. The main characteristics ( $H_{1/3}$ ,  $H_{1/10}$ ,  $H_{\max}$  and associated periods and  $H_{\sigma}$ ) were then gathered in the summary tables shown in the complete report (Hamm, 1992).

Graphic representation of these values revealed acquisition anomalies on certain channels. Generally speaking, the checks carried out showed that 90% of the measurements were reliable. Figures 2 to 4 show examples of the results obtained for three series of tests. These figures show a comparison between the significant wave height values ( $H_{1/3d}$ ) and an estimate made on the basis of the variance of the free-surface elevation ( $H_{\sigma}$ ) for unidirectional and multidirectional waves.

These figures are divided into four parts, designated a) to d). Figures a) present the results obtained on the plane beach and b) those obtained in the centre line of the rip channel. Figures c) give the mean rip current measured near the bed in the centre line of the channel. Lastly, figures d) recall the bed contour profiles. It can be seen that there is little difference between  $H_{1/3}$  and  $H_{\sigma}$  except in the case of waves with low steepness (fig. 2) in the surf area. Similarly, there is little difference between unidirectional and multidirectional wave cases. This result appears a little surprising at first, in the presence of the channel, as the rip current tends to generate wave concentrations which should be more attenuated in the case of a multidirectional wave (Vincent and Briggs, 1989). Indeed, the opposite trend may be observed on figure 3b). This may be due to the breaking process.

Figures 5a) and b) give an overall view of the wave heights measured in the case of waves of low steepness. Figure 5a) shows an abnormal value along the channel centre line (line D), which had already been observed on figure 2a). These abnormal results are currently being analysed.

## 8. SPECTRUM ANALYSIS

Measurements with the wave direction gauge were subjected to a conventional spectrum analysis and directional spectrum analysis using the maximum entropy method (MEM) published by Sand and Mynett (1987). This method is one of the most accurate currently available (Benoit, 1992). However, it is not always easy to interpret the results (Van de Meer, 1990) and detailed analysis is currently in progress.

By way of example, figure 6 shows the frequency spectra obtained with unidirectional waves of low steepness in front of the generator and in the surf zone on the plane beach and in the channel centre line. The results are comparable and show a classic type of evolution with the development of sub- and super-harmonics during propagation towards the coast.

Figures 7 and 8 show the change in directional spectrum for these same waves between offshore and the coast, on the plane beach. There is similarity with the change in frequency spectrum observed previously and a marked narrowing of the directional distribution.

## 9. GENERAL COMMENTS AND CONCLUSIONS

The tests presented here represent a valuable data set for validating numerical models of wave transformation and rip current generation. The huge amount of data is still under analysis and the first results presented here tend to show that the directional spreading does not seriously affect the magnitude of the return current and the significant wave heights.

On the other hand, in spite of the large number of recording points (53), the impression given is one of a fairly loose measuring network, particularly in the channel. Indeed, the instability of the rip current could be observed visually in most of the tests. This is clearly demonstrated by the dissymmetry of the wave crests on either side of the channel centre line, and in particular a shift in the breaking point, which varied with time. A denser measuring network would have been needed to quantify this instability. A possible alternative, which is currently being tested, would be to use a video technique of the type used in the field by Holman and Lippmann (1991) in addition to the conventional isolated measurements.

10 ACKNOWLEDGEMENTS

This work was undertaken as part of the MAST G6 Coastal Morphodynamics research programme. It was funded jointly by the Service Technique Central des Ports Maritimes et des Voies Navigables and by the Commission of the European Communities Directorate General for Science, Research and Development, under contract no. ## CHAPTER 17

### WAVE SETUP ON BEACHES AND IN RIVER ENTRANCES

David J. Hanslow<sup>1</sup> & Peter Nielsen<sup>2</sup>

#### Abstract

This paper investigates the phenomenon of wave setup both on beaches and within river entrances. Field measurements of the mean water surface through the Brunswick River Entrance on the North Coast of NSW, Australia and on the beach immediately south of the entrance are presented for a variety of incident wave conditions. These include wave heights up to 4m (Deepwater RMS). Data collected show very little setup in the river entrance even though wave breaking occurs across the entrance under relatively small wave conditions. At the same time significant wave setup was measured on the adjacent beach. This resulted in the super-elevation of the beach shoreline level above the mean water level of the adjacent river. This super-elevation has been observed to result in large scour holes as the water finds its way through the entrance training walls.

#### Introduction

The super-elevation or setup of river entrance water levels by wave breaking is a subject of great importance for the modelling of flood inundation levels in coastal rivers and for floodplain management in general. However, very little is known about wave setup within river entrances. Current practice in estimating river entrance setup has been to use either beach shoreline setup or to calculate the likely setup at the point of minimum depth using simple models like that of Bowen et al. (1968).

2. Senior Lecturer, Department of Civil Engineering, University of Queensland, Queensland 4072, Australia.

Bowen's model gives the setup as a linear function of depth and is based on an assumption of constant wave height to water depth ratio and linear wave theory. Recent field studies have shown, however, that setup versus depth profiles tend to be upward concave steepening considerably near the shoreline (eg. Nielsen, 1988, 1990). This means that while the model of Bowen et al. (1968) tends to under-estimate the shoreline setup it over-estimates the setup across much of the surf zone. These results suggest that both of the above mentioned approaches to the estimation of river entrance setup are likely to be inappropriate. In any case, the application of 'beach results' to river entrances must be subject to considerable uncertainty because of the difference in breaking processes as a result of the current.

The aim of the present project is to investigate wave setup within a river entrance and to compare this with wave setup observed on beaches under similar conditions.

### Concepts & Definitions

Beach and river entrance water levels fluctuate over various time scales. When the local water surface elevation  $\eta(x, t)$  is averaged over a time span longer than the incident wave and surf beat periods but shorter than the tidal period, the result is the local, mean water level  $\bar{\eta}(x)$  which traces the mean water surface (MWS).

Far offshore the mean water level (MWL) approximates the still water level (SWL) which is the level of the still water surface (ie, the sea surface in the hypothetical situation of no waves). The still water level for practical purposes is taken as the mean water level offshore from the surfzone.

The local setup  $B(x)$  is the super-elevation of the mean water level above the still water level.

$$B(x) = \bar{\eta}(x) - SWL$$

Set-down corresponds to the situation where  $B(x) < 0$ .

Beach shoreline setup has in the past been used to approximate likely river entrance setup. The shoreline elevation and the shoreline setup  $B_s$  are defined by the intersection of the mean water surface and the beach sand surface.

### Field Sites

Data for the present study have been obtained from several sites along the New South Wales coast. These include Brunswick Heads, Dee Why Beach, Palm Beach and Seven Mile Beach (figure 1).

The NSW coast is exposed to a moderate to high energy east coast swell environment. Dominant swell direction is from the south-east and deep water significant wave heights at Sydney exceed 1.5m at least 50% of the time and 4m, 1% of the time. The tidal regime is micro-tidal, diurnal with a semi diurnal inequality. Tidal range varies from about 2m at springs to less than 1m at neaps. The tidal regime is uniform along the whole NSW coast.

The main field site used in the present study was Brunswick Heads on the north coast of NSW (figure 2). This site was used to collect river entrance as well as beach setup data. The coastline at Brunswick Heads is oriented north-south and fully exposed to the regional wave climate. The Brunswick River enters the ocean at Brunswick Heads. This river entrance is regulated by rubble mound training walls. The channel width near the end of the training walls is approximately 40m and the mid tide depth is normally 4-5m but can be as shallow as 1-2m on the offshore bar which experiences wave breaking even under relatively small wave conditions (figure 3).

The tidal prism of the Brunswick River is approximately  $4.8m \times 10^6 m^3$  corresponding to spring tidal peak velocities of about 1.8m/s at the entrance.

The setup monitoring installation at Brunswick Heads comprised two lines of manometer tubes, one through the river entrance extending from 300m upstream of the entrance to 150m offshore of the entrance; and the other spanning the surfzone on the beach 150m to the south. This line was 500m long and extends from the beachface to a depth of approximately 10m. The beachface here is relatively flat and the surfzone is characterised by a well developed bar/trough system. Mean swash zone grain size is 0.22mm.

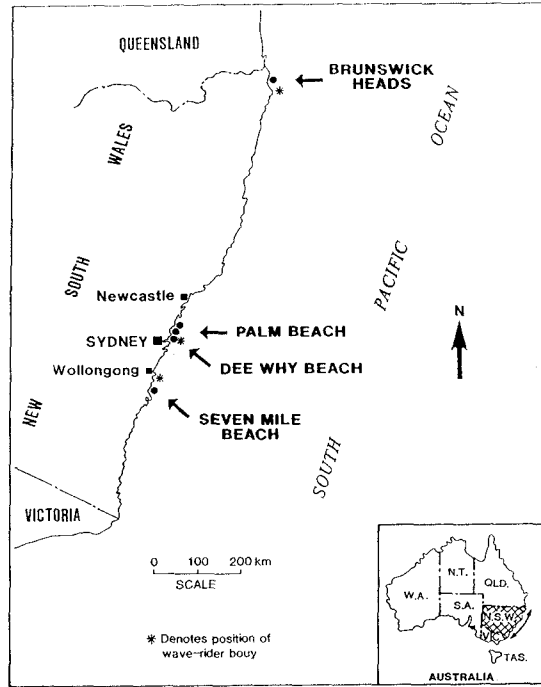

Figure 1: Location of field sites

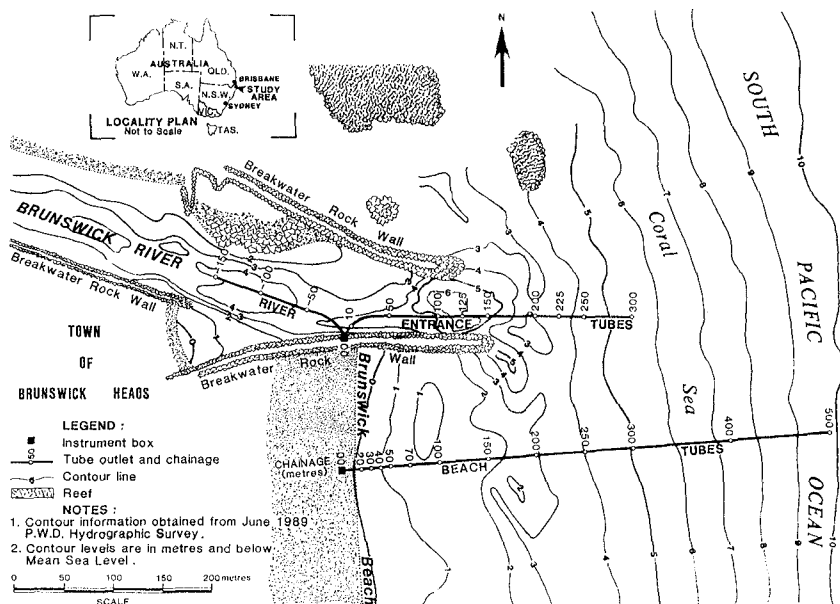

Figure 2: Setup monitoring installation at Brunswick Heads

Subsidiary field sites include Dee Why Beach, Palm Beach and Seven Mile Beach. These locations were used to obtain beach setup measurements from various beach types. Characteristics of these beaches are shown in table 1. A more detailed description of these sites is given in Nielsen & Hanslow (1991).

### Equipment

The equipment and techniques used at the Brunswick Heads field site are in part similar to those described by Davis & Nielsen (1988) and Nielsen (1988).

TABLE 1.

Field Site	Beach Type During Experiments	Swash Zone Grain Size (MEAN)	Range of Beachface Slope During Experiments
Seven Mile Beach	Dissipative	0.18mm	$0.03 < \tan \beta_f < 0.05$
Dee Why Beach	Intermediate/ Reflective	0.5mm	$0.06 < \tan \beta_f < 0.16$
Palm Beach	Intermediate	0.4mm	$0.08 < \tan \beta_f < 0.12$
Brunswick Beach	Dissipative	0.22mm	$0.04 < \tan \beta_f < 0.08$

**Figure 3:** Wave breaking occurs at the Brunswick River entrance even during small to moderate wave conditions

Measurements of the mean water surface elevation were obtained at various points through the river entrance and on the adjacent beach via a system of manometer tubes which are permanently deployed. These tubes are made of hard but flexible nylon material and open to water pressure at their seaward ends. They are attached to a steel chain and became buried shortly after deployment.

At the landward end of each line, each tube is connected to a glass riser tube. The glass riser tubes are closed to the atmosphere but interconnected, so that the air pressures inside are at all times identical. Partial evacuation of the system enables relative water levels at the tube outlets to be monitored. Absolute levels can be obtained by connecting one of the riser tubes to a known (surveyed) water level.

The system facilitated measurements of the mean water surface at fixed locations through the river entrance and across the surfzone on the adjacent beach. Measurements of the mean water surface closer to the beachface at Brunswick Heads as well as the other field sites were obtained using an array of stilling wells. During individual experiments, wells were placed with 2-5m spacing along shore normal transects. The wells were made of clear polycarbonate tubing of 25-35mm internal diameter. The bottom end of each well was covered with geotextile filter cloth to prevent the entry of sand, and were damped with foam to eliminate fluctuation by individual waves and infragravity oscillations. The wells were sunk to at least 20-30cm below the lowest level of the local watertable.

Well top levels were surveyed and measurements taken from the well top to the water surface and to the beach sand surface. This enabled fairly accurate definition of the intersection point between the mean water surface and the beachface otherwise known as the shoreline.

Wave Setup on Beaches

Data collected for the present study confirmed earlier results by Nielsen (1988), (1990) regarding the nature of the mean water surface on natural beaches. That is, as seen in Figure 4, the mean water surface displays an upward concave profile, steepening considerably near the shoreline. Here relative setup is plotted versus still water depth for several data collection exercises at Brunswick Heads. Nielsen's data suggest that Bowen's model

Figure 4: Relative setup plotted versus still water depth for 3 different experiments at Brunswick Heads

may over-estimate setup across much of the surfzone while under-estimating setup at the shoreline.

The elevation of the shoreline above the still water line is plotted as a function of wave height in Figure 5. As seen in this plot a relationship of the form

$$B_s \approx 0.38 H_{orms}$$

Figure 5: Shoreline setup plotted as a function of wave height ( $H_{orms}$ ) for all data

fits the data fairly well with scatter between  $0.2 H_{orms}$  and  $0.65 H_{orms}$ .

A slightly better relationship is obtained by including wave length as seen in Figure 6. Here the line of best fit is given by

$$B_s = 0.048 (H_{orms} L_0)^{0.5}$$

Figure 6: Shoreline setup plotted as a function of  $(H_{orms} L_0)^{0.5}$  for all data

River Entrance Setup

Mean water surface data collected during the present investigation were obtained under widely varying conditions. These included wave heights up to 4m (deepwater RMS), all stages of the tide and two minor flood events.

An example of the mean water surface data collected is given in Figure 7. Here mean water surface profiles through the Brunswick River entrance during an ebbing tide on 17 March, 1992 are presented. The river flow during these observations was assisted by considerable fresh water input. Drogue velocities in the entrance recorded at 11.30 were between 2.0 and 2.5ms<sup>-1</sup> offshore RMS wave height varied between 2.0 and 2.4m while wave period was approximately 8 seconds. Most wave breaking occurred 50–100m seawards of the end of the breakwaters, a distance of 200–250m from the instrument box. The furthest offshore data point in this graph (chainage 500) is the ocean tide level calculated by averaging the recorded tide levels at Coffs Harbour and Sydney Harbour, both corrected for barometric effects. These tide gauges are well removed from the study site but have been included as a check on the level of the offshore manometer tube.

Figure 7: Mean water surface profiles through the Brunswick River entrance during an ebbing tide on 17-3-92

The elevation of the mean water surface increases by an average of 0.05m from the breakpoint (250m) to the 150m or 200m point. There is a small decrease in the mean water surface elevation at (150m) or just landwards of (125m) the end of the breakwaters. Landwards of this region the mean water surface slopes upstream with a maximum gradient of 0.0024.

This data suggests there is very little setup occurring (less than  $0.03 H_{orms}$ ) in the river entrance.

All measurements of the river entrance setup obtained at Brunswick Heads are presented in Figure 8. Here super-elevation of the mean water surface at the river entrance ( $\bar{\eta}_{150m}$  tube —  $\bar{\eta}_{300m}$  tube) is plotted as a function of wave height.

The data presented in this figure show very little wave setup in the Brunswick River entrance under any conditions.

#### All Data

Figure 8: River entrance setup versus wave height for all data

#### Combined Data

The collection of simultaneous river entrance and beach water level data was made difficult during severe weather conditions, thus measurements of this type were limited. However, one data set was collected on 22 June, 1989. Figure 9 presents a mean water surface profile and bed profile through the river entrance and across the surfzone on the adjacent beach, both taken at 1600 hrs on this day. Offshore RMS wave height at this time

was around 2.4m with a period of 11.1/s. This figure illustrates the absence of setup in the river entrance during conditions which produce significant setup on the adjacent beach.

**Figure 9:** Mean water surface through the Brunswick River entrance and across the adjacent beach at 1600hrs on 22-6-89

Comparison between the beach shoreline setup and the water level in the river entrance on 22 June, 1989 is presented in figure 10. On this occasion the offshore RMS wave height increased from 2m at 1500hrs to 3.2m at 2400hrs, while the period averaged 12 seconds. Elevation of the mean water surface at the 10m and 300m stations in the river entrance are plotted together with the shoreline elevation on the adjacent beach over part of a tidal cycle.

The 10m and 300m tubes in the entrance are on opposite sides of the breaker zone in (and offshore from) the entrance. The difference in elevation between the 10m tube and 300m tube suggest there is very little wave setup through the river entrance, in fact their relative elevation changes with the tide suggesting tidal gradients may be more important than any wave induced slopes. At the same time the shoreline on the adjacent beach was consistently about 1m above the offshore water levels.

The setup of the shoreline on the beach above the levels in the river, has been observed to result in large scour holes where water from the beach found its way through the entrance training walls (fig. 11).

## BRUNSWICK HEADS 22·6·1989

**Figure 10:** Time series of water levels in the Brunswick River Entrance (22-6-89) (10m tube and 300m tube) and on the southern beach (shoreline). Offshore RMS wave height increased from 2.4m at 1500hrs to 3.2m at 2400hrs, while wave period averaged 12 seconds.

### Conclusions

Measurements of the mean water surface through the Brunswick River entrance show very little wave setup. This is in spite of the fact that wave breaking occurs across the entrance even under relatively small wave conditions. At the same time measurements of the mean water surface on the adjacent beach show significant setup. This setup occurs mostly close to the beach, and results in the super-elevation of the shoreline above the level of the river. This super-elevation has been observed to result in large scour holes as the water finds its way through the entrance training walls.

Figure 11: Scour hole formed on the beach next to the southern breakwater on 22-6-89

### Acknowledgements

The present study was funded by the Public Works Department of NSW. The authors wish to thank Greg Davis and the other members of the Public Works Department who have helped to collect the data presented in this paper. Thanks are also due to Rolyn Sario and Tim Ruge for their help with the data reduction and analysis, Krystyna Starmach for the drafting and Caroline Harrington for her desktop publishing services.

## CHAPTER 18

### CHARACTERISTICS OF A SOLITARY WAVE BREAKING CAUSED BY A SUBMERGED OBSTACLE

Masanori HARA<sup>1</sup>, Takashi YASUDA<sup>2</sup> and Yukio SAKAKIBARA<sup>3</sup>

#### ABSTRACT

This study aims to make quantitatively clear the breaking wave characteristics of a solitary wave incident to a submerged obstacle by performing intensive numerical simulations using a boundary integral method. The incident critical wave height, the break point and the breaker height are formulated through regression analyses based on the simulated results and are shown to be determined uniquely by using the regression equations.

#### INTRODUCTION

A sound knowledge on breaking wave characteristics of coastal waves over a submerged obstacle is clearly important for designing coastal structures. Although many investigations have been made on the characteristics, most of them are concerned with waves on uniformly sloping bottoms. Smith and Kraus(1991) performed laboratory experiments to measure macro-scale properties of breaking waves on barred beaches but simply showed that wave-breaking properties differed on a barred profile. Very little quantitative knowledge is hence available on the breaking wave caused by a submerged obstacle.

It is widely recognized that steep waves on beaches resemble solitary waves. They are in fact representable as a train of solitary waves[Tuchiya & Yasuda, 1984]. It may be hence better to consider each individual wave of coastal waves over a submerged obstacle as an independent solitary wave and to investigate its breaking characteristics, rather than to examine directly those of the waves. Further, considering a submerged step and dike as submerged obstacles, we could reduce the breaking wave problem of the steep coastal waves over a submerged obstacle to that of a solitary wave incident to the step or dike.

In this study, we focus our attention on the relation of the geometric quantities of the incident wave and obstacle to the breaking wave characteristics and investigate the following three items and their governing law; i)Critical incident wave height  $H_c$  which gives the limiting wave height of the incident wave passing through a obstacle without breaking, ii)Break point and iii)Breaker height. For this purpose, we perform the intensive numerical simulation using a computational model[Yasuda et al.,1990] to describe the time evolution of a solitary wave propagating on a step or dike and formulate three items mentioned above based on the simulated results. The model used here can solve numerically but almost exactly the hydrodynamic equations for fully nonlinear two-dimensional irrotational flows over uneven bottoms and can describe accurately the deformation up to overturning of a solitary wave incident to a step or dike. Its validity has been already verified by comparing the computed results with the experimental measurements[Yasuda et al., 1992]. It could therefore be stated that the results obtained here through the numerical simulation have sufficient accuracy.

### MODIFIED SURF-SIMILARITY PARAMETERS

It is well-known that the breaker height and type of periodic waves on a plane slope with the gradient of  $\tan\theta$  are described by the surf-similarity parameter  $\xi = \tan\theta/(H_0/L_0)^{0.5}$ , where  $H_0$  and  $L_0$  are respectively the wave height and wave length of incident waves in deep water. This parameter can be derived as the ratio of the perturbation term due to depth change to the nonlinear term of incident periodic waves from the variable coefficient KdV equation.

We now regard periodic waves with the incident wave height  $H_1$  on a plane bottom with the still water depth  $h_1$  as a train of solitary waves with the same wave height  $H_1$  and rewrite the nonlinear term by using the lowest order solution of the solitary wave on the plane bottom,  $\eta = H_1 \text{sech}^2[\sqrt{(3/4)(H_1/h_1)}x/h_1]$ , instead of that of the sinusoidal wave,  $\eta = (H_0)/2 \cos(2\pi x/L_0)$ . As a result, we can obtain the following parameter for the solitary wave on a plane slope with the same gradient  $\tan\theta$ ,

$$\xi_s = \tan\theta/(H_1/h_1)^{0.4}. \quad (1)$$

If we then consider the depth change perturbation due to a submerged solid step with the crown height  $R$  (Fig.1) instead of that due to the plane slope and rewrite the perturbation term, we obtain, through some trial and error, the following modified surf-similarity parameter for the solitary wave which has the initial wave height  $H_1$  and is incident to the submerged step.

$$\xi_s^* = (R/h_1)^{0.1}/(H_1/h_1)^{0.4}. \quad (2)$$

The slope gradient  $\tan\theta$  is omitted in eq.(2) because its influence on the breaking characteristics is almost negligible as explained afterwards.

Further, considering the depth change due to a submerged symmetric trapezoidal dike with the crown height of  $R$ , the crown width of  $B$  and the slope gradient of  $\tan \theta$  schematically shown in Fig.2, we can obtain another modified surf-similarity parameter,

$$\xi_s'' = [B/h_1 + (R/h_1)/3.5 \tan \theta]^{0.2} (R/h_1) / (H_1/h_1)^{0.4}, \quad (3)$$

for the solitary wave with the initial wave height  $H_1$  incident to the rectangular trapezoidal dike. This parameter can be rewritten into the parameter  $\xi_s' = (B/h_1)^{0.2} (R/h_1) / (H_1/h_1)^{0.4}$  for the solitary wave incident to a rectangular dike by putting the value of the slope gradient  $\tan \theta$  in eq.(3) as infinity. The parameter  $\xi_s''$  can thus be regarded as a unified parameter applicable to both the dikes.

Fig.1 Schematic illustration of solitary wave over a submerged step

Fig.2 Schematic illustration of solitary wave over a submerged dike

## BREAKING CHARACTERISTICS OF A SOLITARY WAVE INCIDENT TO A STEP

### Wave profiles

Figure 3 describes representative examples of the propagation process of a solitary wave propagating on a bottom containing a solid step. It is easily found that the stage of the deformation caused by the step clearly depends on the value of  $\xi_s^*$ . Run 1 shows the propagation process of a solitary wave passing over a step without breaking. Not only a reflected wave but also a shelf is generated by the depth change due to the step. The shelf is not indefinitely carried behind the transmitted wave, but separates from it and finally turns to a secondary solitary wave. This means that when an incident solitary wave is perturbed by a step, it tries to be stable by generating a reflected wave and a shelf turning to a secondary solitary wave and distributing the excess energy to them. Both of Run 2 and 3 show the propagating process leading to wave breaking. The onset of wave breaking is defined here as the instant when the front face at the top of the solitary wave becomes just vertical. The validity of this definition is experimentally confirmed by the fact that the onset almost agrees with the time when the

(a) Run1 [ $H_1/h_1 = 0.2, R/h_1 = 0.3, \xi_s^* = 0.57$ ]

(b) Run2 [ $H_1/h_1 = 0.58, R/h_1 = 0.2, \tan \theta = 1/5, \xi_s^* = 1.06$ ]

(c) Run3 [ $H_1/h_1 = 0.5, R/h_1 = 0.6, \xi_s^* = 1.25$ ]

**Fig.3** Time evolution of water surface profile of a solitary wave incident to a submerged step

formation of a jet at the crest is initiated in the real fluid[Yasuda et al.,1992]. While the breaker profile of Run 2( $\xi_s^* = 1.06$ ) seems to be a spilling breaker, that of Run 3( $\xi_s^* = 1.25$ ) could be regarded clearly as a plunging breaker because of its remarkably vertical asymmetry. Although the shelf is generated in both the cases, it runs just behind the transmitted main wave until the transmitted wave begins to break. This means that these depth change perturbations caused by the step are too strong for the excess energy distribution by exciting the reflected wave and shelf to prevent the breaking.

Figure 4 shows the comparison with the wave profile at the onset of the wave breaking among a solitary wave incident to a rectangular step and those incident to trapezoidal steps with a face slope of gradient  $\tan\theta = 1/5$  and  $1/10$ . The breaker profiles almost agree with one another except for the reflected waves and shelves. We could hence say that the gradient of the face slope very little affects the breaking characteristics and its influence is negligible, although it affects on the height of the reflected wave and shelf.

Fig.4 Comparison of water surface profiles of breaking wave between solitary waves over steps with a vertical face and a slope

### Critical incident wave height

When some investigations are made on the characteristics of breaking of a solitary wave caused by a step, it is required at first to answer the question whether the solitary incident to the step breaks or not and make clear the presence of wave breaking. If the value of the critical incident wave height  $H_c$  is available for each dike, the answer to the question can be easily obtained because the value of  $H_c$  gives the limiting wave height of the incident solitary wave which can pass through the step without breaking, that is, the solitary wave of which incident wave height  $H_1$  exceeds  $H_c$  necessarily breaks on the step.

Figure 5 shows the relation of the presence of wave breaking due to a rectangular step to the relative wave height  $H_1/h_1$  and the relative step height  $R/h_1$ .

The circles  $\circ$  indicate the solitary waves that break on the step and the crosses  $+$  indicate other solitary waves that progress on the step without breaking. The solid line is given by the regression equation,

$$H_c/h_1 = 1.012 - 1.063(R/h_1)^{0.46}, \quad 0.2 \leq R/h_1 \leq 0.6, \quad (4)$$

and indicates the relation of the relative critical wave height  $H_c/h_1$  to the relative step height  $R/h_1$ . Although eq.(4) are based on the computed results concerning a solitary wave incident to a rectangular step, it can directly be applied to that incident to a step with the slope gradient over 1/10. Hence, we can now easily answer the aforementioned question almost independently of the slope gradient, only if we substitute the values of the still water depth  $h_1$ , the incident wave height  $H_1$  and the crown height  $R$  of the step into eq.(4) and examine whether the value of  $H_1/h_1$  exceeds that of  $H_c/h_1$  or not.

Fig.5 Relation of the presence of breaking caused by a step to the relative wave height  $H_1/h_1$  of an incident solitary wave and the relative step height  $R/h_1$

### Break point

We here aim to establish the method to predict the break point of the solitary wave incident to the step and reply to the question, 'Where the incident wave breaks?'. The break point is defined as the location just under the main crest at the onset of wave breaking and indicated by the break distance  $X_b$  from the top corner of the step to the location.

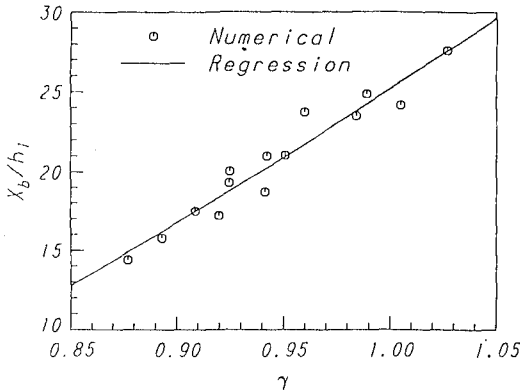

Figure 6 shows the relation between the ratio  $X_b/h_1$  of the break distance to the still water depth and the following parameter  $\gamma$  derived as a function of  $H_1/h_1$  and  $R/h_1$  by a regression analysis,

$$\gamma = (0.78 - H_1/h_1)/(R/h_1)^{-0.83}. \quad (5)$$

The solid line is given by the regression equation,

$$X_b/h_1 = -27.292 + 52.495\gamma^{1.664}, \quad 0.87 \leq \gamma \leq 1.03. \quad (6)$$

The circles  $\circ$  denote the results computed for the solitary wave incident to the rectangular dike. The computed results scatter along the regression curve and hence could be regarded to agree considerably well with it. It is found that the break distance  $X_b$  naturally becomes short and the break point tends to approach the top corner of the step as the values of  $H_1/h_1$  and  $R/h_1$  approach 0.78 and 1, respectively. However, the break distance  $X_b$  is still greater than ten times of the still water depth  $h_1$  under the present condition ( $0.87 \leq \gamma \leq 1.03$ ). This states that the incident waves never break at once after the perturbation due to depth change has affected them but require propagation distances up to breaking. The results shown in Fig.6 demonstrate that the location of the break point approximately obeys eq.(6) and is determined by the value of  $\gamma$  alone. We can thus easily predict the break point of a solitary wave incident to a step by using eqs.(5) and (6) although not exactly.

**Fig.6** Relation between the break distance  $X_b$  from the top corner of a step to the break point and the parameter  $\gamma$

**Breaker height**

Breaker height  $H_b$  is the wave height at the onset of wave breaking and is given here as the wave height at the instant when the top front face of the main crest becomes just vertical. The breaker height usually indicates the maximum value during the propagation process. On the other hand, the breaker depth  $h_b$  is equal to the submerged crown depth of the step and is given as  $h_1 - R$ .

Figure 7 shows the relation between the relative breaker height  $H_b/h_1$  of the solitary wave incident to a step with the slope gradient of  $\tan \theta = 1/5, 1/10$  and  $\infty$ (vertical) and the modified surf-similarity parameter  $\xi_s^*$  defined in eq.(2). The circles  $\circ$ , triangles  $\Delta$ , asterisks  $*$  and squares  $\square$  in Fig.7 denote the computed results for the step with vertical slope and the slope gradient of  $\tan \theta = 1, 1/5$

and 1/10, respectively. The solid line is given by the regression equation,

$$H_b/h_1 = 5.885 - 5.090\xi_s^{*0.133}, \quad 0.2 \leq \xi_s^* \leq 1.1. \quad (7)$$

It is found that all the relative breaker heights  $H_b/h_1$  agree well with the regression curve independently of the slope gradient ( $\tan \theta = 1/10 \sim \infty$ ) and that the values of them are uniquely determined by the parameter  $\xi_s^*$  alone. We can hence easily estimate the breaker height of a solitary wave incident to a step with arbitrary slope gradient by substituting the value of  $\xi_s^*$  into eq.(7). Further, the so-called breaker depth index  $H_b/h_b$  is derived by multiplying the relative breaker height  $H_b/h_1$  into  $h_1/(h_1 - R)$ .

Fig.7 Relation of the breaker height of a solitary wave incident to the submerged step having the slope gradient of  $\tan \theta = 1, 1/5, 1/10$  and  $\infty$ (vertical) to the parameter  $\xi_s^*$

## BREAKING CHARACTERISTICS OF A SOLITARY WAVE INCIDENT TO A DIKE

### Wave profiles

Figure 8 describes the time evolution of a solitary wave propagating on a bottom containing a solid submerged dike. Run 4 shows the propagation process of a solitary wave passing through the rectangular dike without breaking as well as Run 1 shown in Fig.3. Reflected waves of two types are generated in this case; one is a positive reflected wave due to the depth decreasing and another is a negative one due to the depth increasing. However, it is similar with Run 1 that the shelf is generated and finally turns to a secondary solitary wave. This could be said to be a common feature of the solitary wave perturbed by depth change. The breaker profile of Run 2 seems to be a typical spilling breaker, while those of Run 3 and Run 4 could be regarded clearly as plunging breakers because of their vertically asymmetric profiles. However, all of them are in common forward

(a) Run 1

(b) Run 2

(c) Run 3

Fig.8 Temporal changes of water surface profiles of a solitary wave passing over a submerged dike

(d) Run 4

(e) Run 5

(f) Run 6

Fig.8 (Continued)

breakers in which the main crests break forward after they have passed through the dike. Whereas the case of Run 5 is remarkably different from them at the point that the surface of the wave on the shelf breaks backward onto the dike. This breaking was firstly found by Cooker et al.(1990) and was called a backward breaker. It is characterized by the backward breaking that occurs before any other breaking event. However, its influence is conjectured to be small and negligible because the height of shelf itself is considerably small in comparison with that of the main crest. Run 6 seems to be the composite type of the backward breaker and the spilling breaker, but this should be strictly classified as a spilling breaker because the forward breaker of the transmitted wave occurs a little faster than the backward breaker of the shelf.

### Critical incident wave height

In order to answer the question whether a solitary wave to a submerged dike breaks or pass through without breaking, we investigate its critical incident wave height  $H_c$  to the trapezoidal dike with the relative crown height  $R/h_1$ , the relative crown width  $B/h_1$  and the slop gradient  $\tan \theta$ . Here, rectangular dikes are included in the trapezoidal ones, because they are regarded as trapezoidal dikes with the vertical slope as mentioned above.

Figure 9 shows the relation between the critical incident wave height  $H_c/h_1$  to each dike and the following parameter  $\gamma$  derived as a function of its geometric quantities,  $R/h_1, B/h_1$  and  $\tan \theta$ , by a regression analysis.

$$\gamma = [(B/h_1) + (R/h_1)/2 \tan \theta]^{0.4} (R/h_1), \quad (8)$$

The symbols of triangle  $\Delta$ , asterisk  $*$  and square  $\square$  respectively denote the values of  $H_c/h_1$  to the trapezoidal dikes with the slop gradient of  $\tan \theta=1, 1/5$  and  $1/10$  and the circles  $\circ$  denote those to the rectangular dikes. These values are obtained by examining the limiting incident wave height of the solitary wave that comes onto each dike and can pass through without breaking. The solid line is given by the regression equation,

$$H_c/h_1 = 0.952 - 0.591\gamma^{0.76}, \quad 10.2 \leq \gamma \leq 1.4. \quad (9)$$

The computed results agree well with the regression curve and could be said to obey almost eq.(10). This states that the critical incident wave height  $H_c/h_1$  to a dike uniquely relates to a single parameter  $\gamma$  and its value is uniquely determined by  $\gamma$  alone. We can hence easily answer the aforementioned question, only if we calculate the value of  $H_c/h_1$  by substituting the geometric quantities of the dike,  $R/h_1, B/h_1$  and  $\tan \theta$ , into eqs.(9) and (10) and examine whether the value of the incident wave height  $H_1/h_1$  exceeds the value of  $H_c/h_1$  or not.

### Break point

All of the forward breakers simulated here occur behind dikes. If a incident wave breaks on a dike before passing through it, the breaking should hence be

treated as the breaker due to the step and is thereby excluded here. As well as the case of the rectangular step, we investigate here the relation between the relative break distance  $X_b/h_1$  from the top corner of the rectangular dike to the break point and the following parameter  $\mu$  derived as a function of  $H_1/h_1$ ,  $R/h_1$  and  $B/h_1$  by regression analysis,

$$\mu = (0.78 - H_1/h_1)^{0.5} (R/h_1)^{-1.2} (B/h_1)^{-0.13} \tag{10}$$

Figure 10 shows the relation of the break distance  $X_b/h_1$  to the parameter  $\mu$ . The circles  $\circ$  denote the results computed in this study and the solid bent line is given by the regression equations,

$$\left. \begin{aligned} X_b/h_1 &= 10.78\mu - 4.14, & 0.6 \leq \mu \leq 1.03 \\ X_b/h_1 &= 1.94\mu + 5.01, & 1.03 \leq \mu \leq 2.2 \end{aligned} \right\} \tag{11}$$

It is noticed that the break point of the solitary wave incident to a dike is shorter compared with that of the step(see Fig.4). This cause is conjectured to be the influence of the twice depth change due to the dike on the incident wave. Since the computed results agree well with the regression curve, the relation governed by eq.(11) seems to hold approximately between the incident wave height and the geometric quantities of the dike. We can hence predict the location of the break point of a solitary wave incident to a rectangular dike by using eqs.(10)and (11).

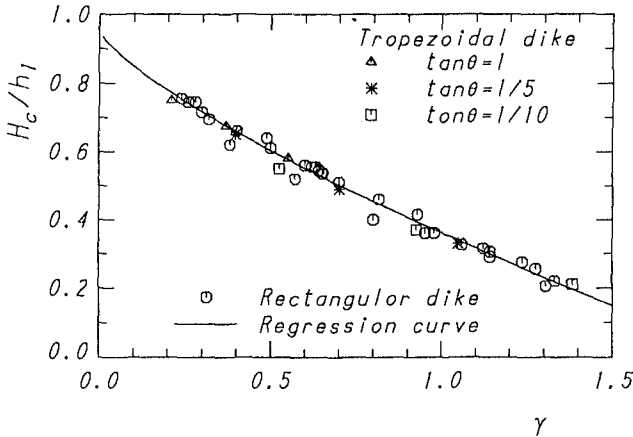

Fig.9 Relation of the critical wave height  $H_c/h_1$  of a solitary wave incident to a submerged rectangular and trapezoidal dike to a parameter  $\gamma$

Fig.10 Location of the onset of breaking of a solitary wave caused by a submerged rectangular dike

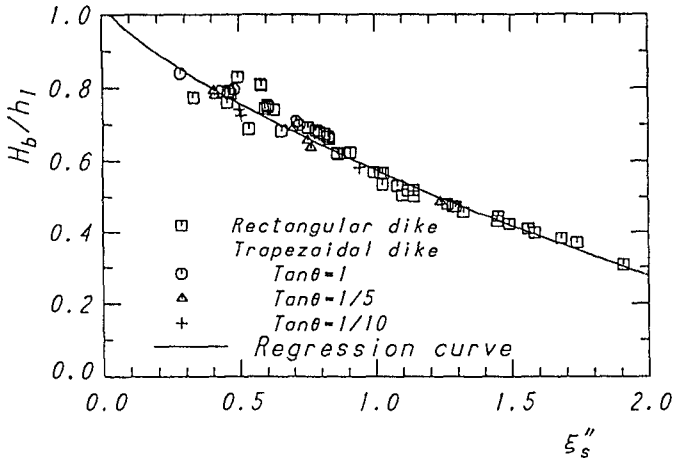

Fig.11 Relation of the parameter  $\xi_s''$  to the breaker height of a solitary wave passing over a rectangular submerged dike or trapezoidal one with face slopes of  $\tan \theta=1, 1/5$  and  $1/10$ .

**Breaking wave height**

Figure 11 shows the relation between the relative breaker height  $H_b/h_1$  of the solitary wave incident to a submerged dike and the modified surf-similarity parameter for the dike  $\xi_s''$  defined in eq.(3). The symbols of circle  $\circ$ , triangle  $\triangle$  and cross  $+$  denote respectively the values of solitary waves incident to the trapezoidal dikes with the slope gradient of  $\tan \theta=1, 1/5$  and  $1/10$  and squares  $\square$  indicate the values of solitary waves incident to the rectangular dike with vertical slope. The solid line is given by the regression equation,

$$H_b/h_1 = -0.463\xi_s''^{0.133} + 1.039, \quad 0.2 \leq \xi_s'' \leq 2.0. \quad (12)$$

All the breaker heights are obtained from the computed surface profiles at the break point and they agree very well with the regression curve. This states that the relative breaker height  $H_b/h_1$  of the solitary wave incident to the dike uniquely relates to the modified surf-similarity parameter  $\xi_s''$  and its value is determined by the parameter  $\xi_s''$  alone. We can hence easily know the breaker height  $H_b/h_1$  only if calculating the value of the parameter  $\xi_s''$  to the given incident wave and dike. Further, the breaker depth  $h_b$  is equal to the still water depth  $h_1$  because the transitted main crest breaks after passing through the dike. The relative breaker height  $H_b/h_1$  is thereby equal to the breaker depth index  $H_b/h_b$ .

## CONCLUSIONS

Intensive numerical simulations using a boundary intergral method were performed to make quantitatively clear the breaking wave characteristics of a solitary wave incident to a submerged step or dike. As a result, the critical incident wave height, the location of the break point and the breaker height were formulated as functions of the incident wave height and the geometric quantities of the step or dike through regression analyses based on the simulated results. Further, their values were shown to be determined almost uniquely by the regression equations. It is thus now possible to determine accurately the persence of the wave breaking, the break point and the breaker height by using the regression equations, as far as concerned with a solitary wave incident to a step or dike. Further study is recommended to establish a unified governing law of the breaking wave characteristics of not only a solitary wave but also periodic waves incident to submerged obstacles having arbitrary shapes.

## CHAPTER 19

### Eight Years Wave Hindcast and Analysis of Wave Climate

Yoshio Hatada<sup>1</sup> and Masataka Yamaguchi<sup>2</sup>

#### Abstract

This paper deals with 8 years of wave hindcast at 11 wave observation points along the coast of the Japan Sea using a long-term shallow water wave hindcast system, and investigation of its applicability to the estimation of wave climate. Comparison with observations for not only time variations of significant waves but also long-term sea state indices such as yearly-averaged wave height and period. The availability of the present system and the advantages over the deep water wave hindcast system previously developed by the authors are verified by close and more reasonable agreement with the observed data including mean wave direction.

#### 1. Introduction

Quantitative estimation of long term wave conditions over several years, so-called wave climate is a subject of great importance for the mitigation of wave-caused disaster and efficient utilization of wave energy. Up to now, the analysis of wave climate has relied on the observed wave data or wave data hindcasted with a simple wave prediction model such as the SMB method. In the former case, data of wave direction which are crucial to analysis of shore processes have seldom been observed and wave gauges have often broken down during severe wave conditions. In the latter case, conventional methods do not always give a satisfactory accuracy for hindcasted

waves and tremendous efforts are needed for hindcasting long term wave conditions.

Yamaguchi et al.(1990) developed a long term wave hindcast system which makes it possible to consecutively follow wave conditions over several years with reasonable accuracy. The system was applied to compute wave characteristics over 2 years every hour at 14 selected points along the coast of the Japan Sea. Close agreement between computation and observation for time variations of significant waves and wave direction as well as long term wave statistics verified the validity of the system. But the hindcast period of 2 years is too short to properly evaluate the wave climate when variability of the sea states is taken into account, and the wave model used is a deep water model with an approximate correction for shallow water effect.

The aim of this paper is to re-examine the applicability of a newly-revised system based on the comparison between computation and observation over 8 years at 11 wave observation points along the coast of the Japan Sea.

## 2. Outline of Long-Term Wave Hindcast System

### (1) Wind hindcast model

The system consists of a wind estimation model and a wave estimation model. The wind model produces time variations of wind distribution over sea by spatial interpolation onto a regular grid of atmospheric pressure observed at irregularly-distributed points surrounding the sea area and the application of the wind model proposed by Bijvoet(1957). Either of  $-1^{\circ}\text{C}$  or  $0^{\circ}\text{C}$  or  $1^{\circ}\text{C}$  every year on the entire region was given for data of air-water temperature difference which determines coefficients in the Bijvoet wind model, so that hindcasted results agree with observed results to the best possible degree, because it is hard to acquire long-term data of air and water temperatures.

Fig. 1 is a grid system divided into 28 by 41 with a grid distance of 80 km for the computation of atmospheric pressure and wind distributions over the Japan Sea, which includes 43 pressure observation points with the WMO location number. Surface atmospheric pressure data at the observation points and central positions of lows or highs over 8 years ranging from 1982 to 1989 every 3 hours are acquired from the magnetic tapes of meteorological data prepared by the Japan Meteorological Agency and direct inspection of the weather charts. Extraordinary values of observed pressure data are corrected by checking time series of the data and inspecting the corresponding

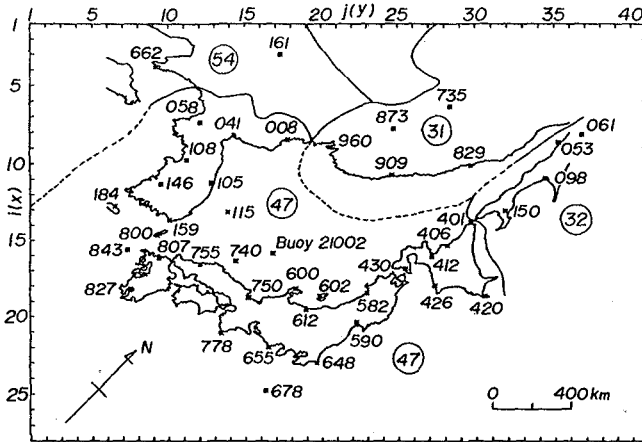

Fig. 1 Grid for computing wind distribution, and input points of observed atmospheric pressure.

weather charts. Before the wind computation, the pressure data interpolated on grids are smoothed three times, making use of a weighted smoothing formula with data of the surrounding 9 grid points in order to avoid overestimation of wind speed.

## (2) Wave hindcast model

Wave estimation is due to a shallow water wave model (Yamaguchi et al., 1987) which belongs to a decoupled propagation model, tracing the change of directional spectrum along a refracted ray of each component focused on a hindcast point. The basic equation in the model is the radiative transfer equation in shallow water and is given by

$$\frac{\partial F}{\partial t} + c_g \cos \theta \frac{\partial F}{\partial x} + c_g \sin \theta \frac{\partial F}{\partial y} + \frac{c_g}{c} \left( \sin \theta \frac{\partial c}{\partial x} - \cos \theta \frac{\partial c}{\partial y} \right) \frac{\partial F}{\partial \theta} = c c_g S(f, \theta) \quad (1)$$

where  $F = c c_g E(f, \theta)$ ,  $c$  is the celerity of a wave component,  $c_g$  the group velocity of a wave component,  $E(f, \theta)$  the directional spectrum,  $f$  the frequency,  $\theta$  the direction and  $S(f, \theta)$  the source function. Source function consists of linear growth term by the Phillips mechanism, exponential growth term by the Miles mechanism and energy dissipation terms by pseudo-viscosity, bottom friction and opposing winds. Energy dissipation due to wave breaking is evaluated by imposing the condition that directional spectrum at growth stage can not exceed beyond an equilibrium directional spectrum in shallow water. This equilibrium spectrum is given by the product of the Pierson-Moskowitz spectrum with the correction term proposed by Thornton (1977) for shallow water effect and  $\cos^4 \theta$

angular spreading function.

Eq. (1) is solved by a fractional time step method which computes propagation equation, and growth or decay equation alternately in each time step. At the first step, the propagation equation setting the right hand side of Eq. (1) to zero is solved by a full ray method or a piecewise ray method, which is a kind of the characteristic method. Full ray method is used for the computation of low frequency components satisfying the condition of  $kh < 4$  at a hindcast point which can be regarded as shallow water waves, where  $h$  is the water depth at a hindcast point and  $k$  the wave number of the corresponding component, and piecewise ray method is used for the computation of high frequency components with  $kh > 4$  which can be regarded as deep water waves. At the second step, the computation of growth or decay equation, which sets the propagation term in Eq. (1) to zero is conducted with the analytical solution using the results of propagation step as an initial value. When the directional spectrum computed at growth stage exceeds the shallow water equilibrium spectrum, it is reduced so as to get equal to the equilibrium spectrum.

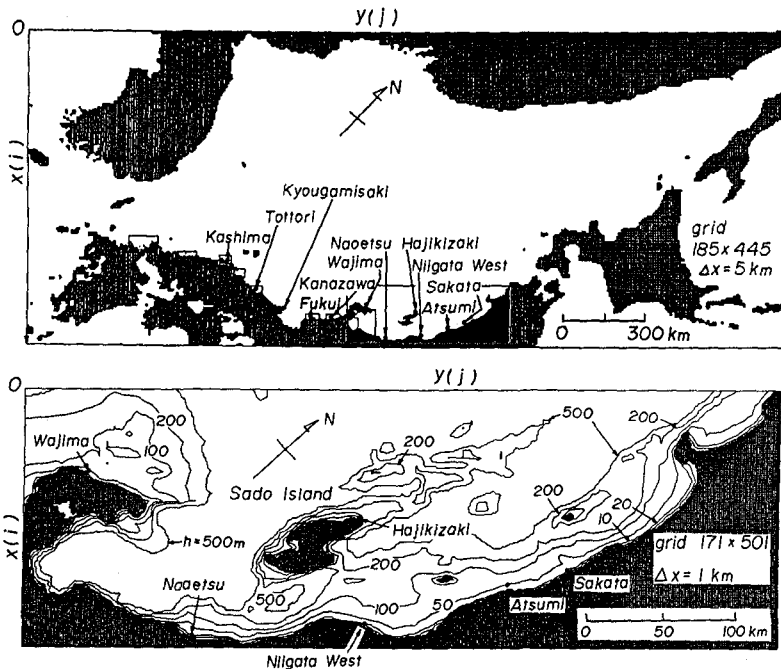

Fig.2 Medium and fine grid systems used in wave hindcast and location of hindcast points.

Wave ray is traced on the nesting grid system composed of the Japan Sea area divided into 185 by 445 with a medium grid size of 5 km and a small sea area surrounding the hindcast point with a fine grid size of 1 km. Fig. 2 shows the medium grid system covering the Japan sea and an example of the fine grid system covering the coastal area off the Hokuriku District, which are used in wave ray computation. The figures also include the locations of 11 wave hindcast points and contour plot of water depth. The numbers of frequency and direction data are 25 and 20 to 25 respectively, and the time step in wave hindcasting is 1 hour. Wind speeds and directions at wave computation points along a wave ray are estimated by applying a bilinear interpolation formula to wind data at 4 wind grid points surrounding the wave computation point. Boundary around the computational sea area is assumed to be land, where the directional spectrum is zero.

Since it is assumed to be three days after the start of computation that the influence of initial condition of calm sea vanishes, the wave hindcasting is carried out every hour for about 8 years from 4 a.m., December 29th, 1981 until 12 p.m., December 31st, 1989.

Fig. 3 is an example of refraction diagram. Directional range of wave rays reaching a hindcast point rather changes every hindcast point due to geographical situation in the vicinity of the hindcast point.

Fig. 3 Examples of refraction diagram at wave hindcast point.

### 3. Applicability of Long-Term Wave Hindcast System

#### (1) Comparison for time variations of significant waves

Spiky noises are often found in the time series of significant wave period data observed during the calm sea state. In general, data observed during the low wave condition are less reliable compared to those during the high wave condition, because of measuring and statistical errors. Thus, wave observation data to be used for comparison with hindcasted results are limited to those which satisfy the condition such as  $H_{1/3\text{obs}}/1.56T_{1/3\text{obs}}^2 > 0.003$ , where  $H_{1/3}$  is the significant wave height,  $T_{1/3}$  the significant wave period, and subscripts 'obs' and 'cal' indicate the observed and hindcasted results respectively. The threshold value of 0.003 is conveniently adopted only for excluding unfavorable observation data and does not have any physical meaning.

Fig. 4 is two examples of the 3 month comparison between hindcast and observation for the time variations of wave height, period and wave direction at Wajima and Tottori indicated in Fig. 2. Wave hindcast was carried out with both the shallow water wave model and the deep water wave model. Both models follow the time variations of

Fig. 4 Comparison between hindcast and observation for time variations of significant waves over 3 months at Wajima and Tottori.

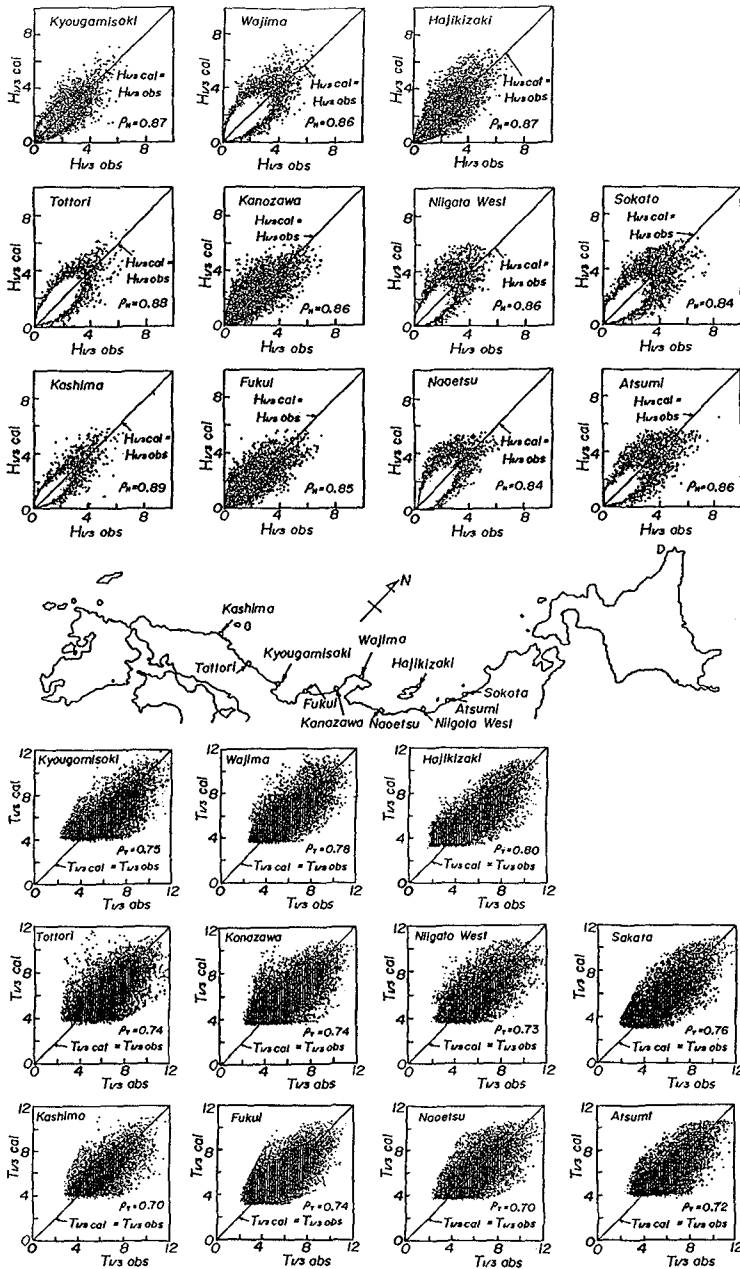

Fig. 5 Scatter diagrams between hindcast and observation for significant waves.

observed waves with acceptable accuracy, and the shallow water wave model gives better estimation than the deep water model during the high wave condition. Hereafter wave hindcast with the shallow water wave model is used for the comparison with wave observation, where no reference is made.

High reliability of the present system is also confirmed in Fig. 5 indicating the scatter diagrams of individual significant wave height and period observed every 2 or 3 hours over 8 years at 11 points along the coast of the Japan Sea. Plotted points almost symmetrically distribute around the line which means the perfect correlation between hindcast and observation, but plotted data for wave period show wider scatter than those for wave height. Accordingly, the correlation coefficient for wave height  $\rho_H$  ranges from 0.84 to 0.89, while the correlation coefficient for wave period  $\rho_T$  shows smaller value of 0.70 to 0.80 than those for wave height.

(2) Comparison for wave climate

Fig. 6 shows the error statistics on yearly-averaged wave height and period at 11 wave observation points along the coast of the Japan Sea, in which  $\bar{H}_{1/3}$  and

Fig. 6 Error statistics on significant waves hindcasted consecutively over 8 years at 11 points along the coast of the Japan Sea.

$\overline{T_{1/3}}$  are the yearly-averaged significant wave height and period,  $\sigma_H$  and  $\sigma_T$  the root-mean square errors of wave height and period and  $p$  is the occurrence rate of high waves exceeding wave height of 2 m. Overall agreement between hindcast and observation is found in the figure, although wave period is nearly consistently underestimated by about 0.3 s, and the shallow water wave model gives higher correlation coefficient and smaller root-mean square error for both wave height and wave period than the deep water wave model. As for the occurrence rate of high waves, the shallow water wave model has a tendency of underestimation, whereas the deep water wave model has a tendency of overestimation.

Fig. 7 is the monthly variations of mean significant wave height and period and occurrence rate of the high

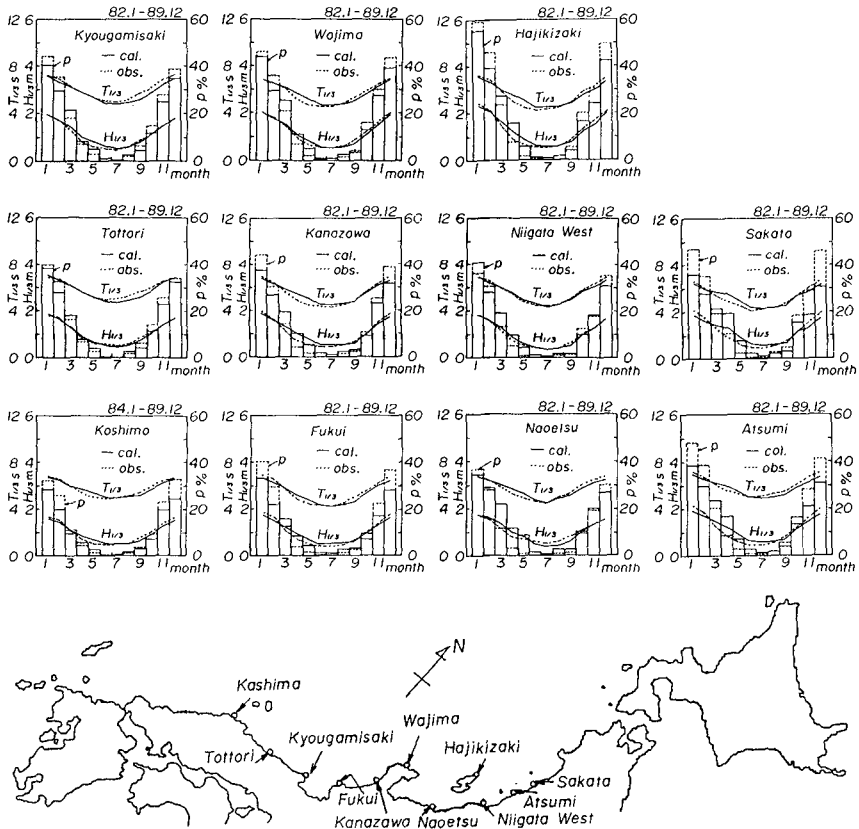

Fig. 7 Comparison of hindcast and observation for monthly variations of mean significant waves and occurrence rate of high waves.

waves at 11 points which are indices representing wave climate. The model reproduces fairly well the seasonal change of wave climate in the Japan Sea where high wave conditions occur in winter and autumn, and calm sea states continue in summer and spring. More precisely, the model tends to overestimate the wave conditions during April to September and to underestimate the one during September to December.

Fig. 8 shows the comparison between computation and observation for histograms of wave height grouped every 0.5 m and wave period grouped every 1 s. The model reproduces well overall distribution of the histograms again. But, underestimation for the occurrence rate of wave height with 0 to 0.5 m and overestimation for the occurrence rate of wave height with 0.5 to 1 m or the contrary tendency are found in the hindcast points located in the northern part of the coast of the Japan Sea such as Naoetsu and Sakata. The model also tends to overestimate the occurrence rates of wave period with 4 to 6 s and to underestimate those of the other ranges.

The above-mentioned applicability of the model is also confirmed in Fig. 9 which shows the comparison for contour plot of correlation between significant wave height and period. As the Japan Sea is almost closed, being surrounded by land boundaries, wind waves are predominant, which have high correlation between wave height and wave period. The model reproduces fairly well the feature of observed data which is described by contour lines extending in the right-upward direction.

Fig. 10 illustrates the comparison of hindcast and observation for the directionally-grouped occurrence rates of high wind speed exceeding 10 m/s and those of wave height exceeding 2 m at 5 observation points. The number of observation data of mean wave direction is much smaller than that of hindcast data used in the analysis, because of the reasons such as undeployment of wave direction measurement device and its break-down by severe sea states. The period of wind observation data used in the analysis is 8 years from 1982 to 1989 at Wajima, 2 years from 1986 to 1987 at Sakata, Hajikizaki and Fukui, and 1 year of 1986 at Niigata West.

At Hajikizaki facing open sea directly, high correlation for the directionally-grouped occurrence rates of both high winds and high waves is found and the distributions of hindcasted data agree well with those of observed data. Difference between the distributions by both shallow water wave model and deep water wave model is small, because water depth of 50 m at Hajikizaki gives almost deep water wave condition even for high waves with

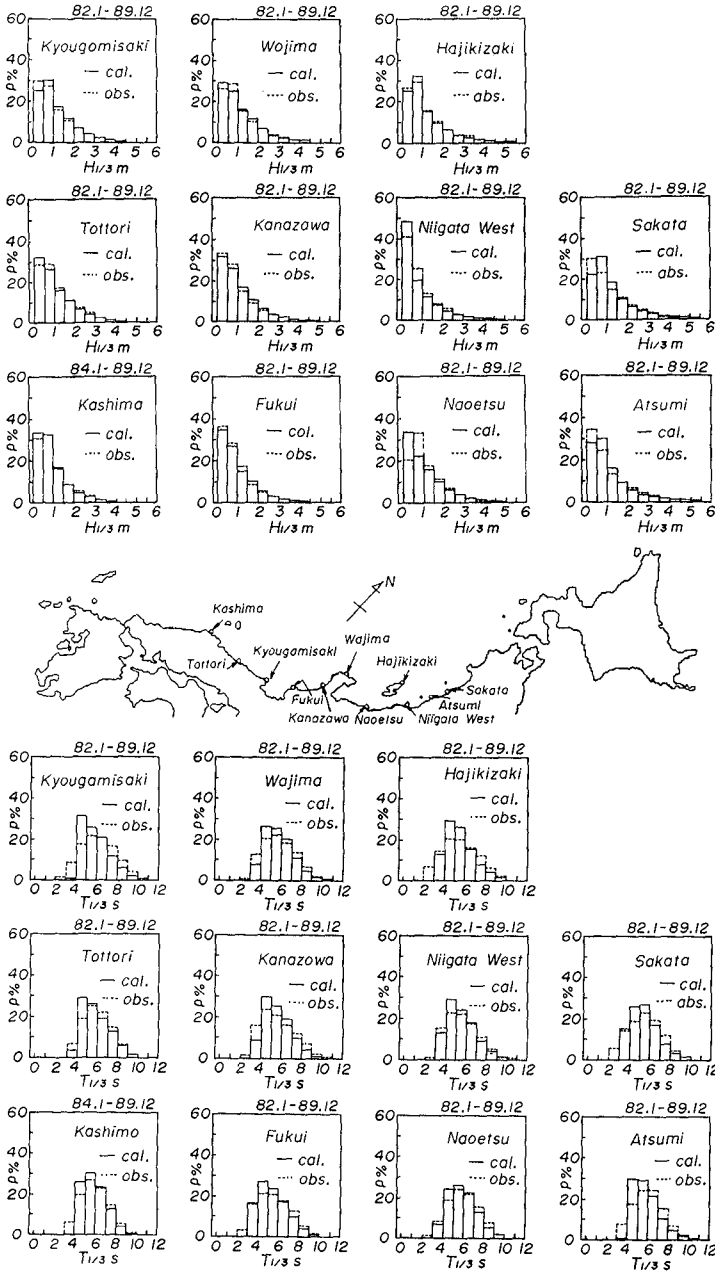

Fig. 8 Comparison of hindcast and observation for histograms of significant wave height and period.

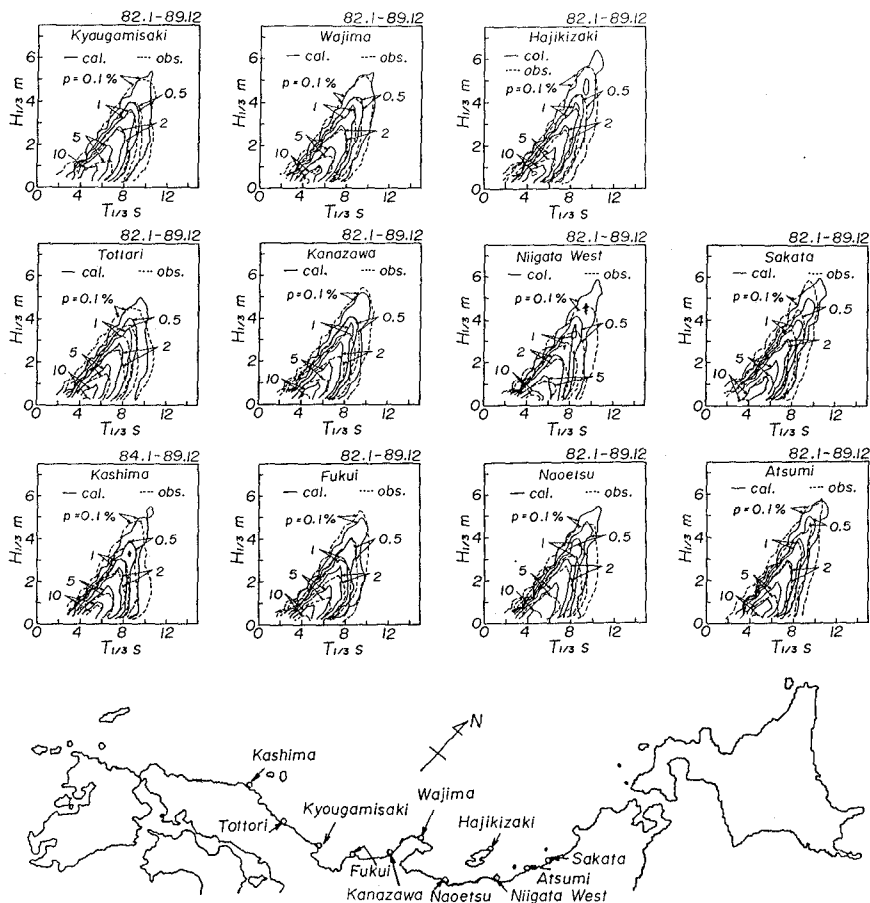

Fig. 9 Comparison of hindcast and observation for correlation diagram between wave height and wave period.

wave period shorter than about 10 s. On the other hand, predominant wave directions estimated by both shallow and deep water wave models at Wajima, where is in observation conditions similar to Hajikizaki are biased against observed wave direction clockwise by about 10 degrees, as estimated predominant wind direction is biased against observed wind direction to similar extent. Observation points at Sakata, Niigata West and Fukui are located in shallow water where water depths are less than 30 m. At Niigata West, predominant wave directions hindcasted with both models are close to the observed direction in

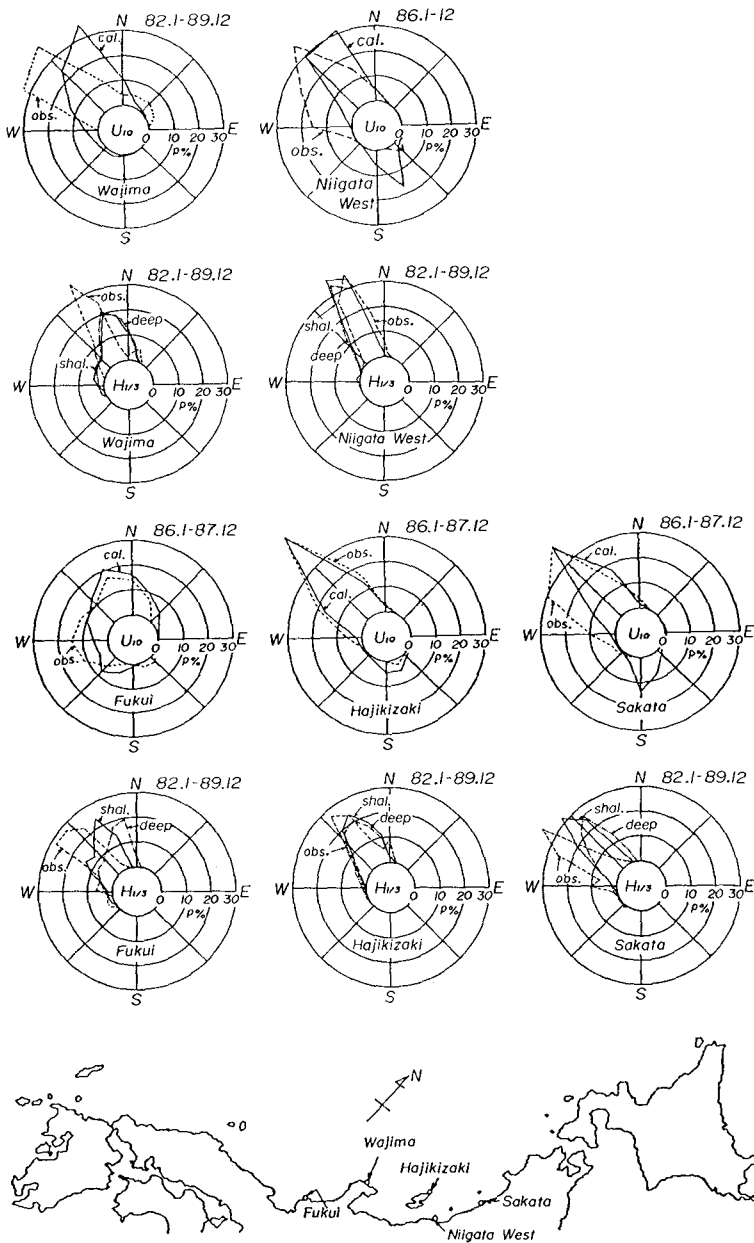

Fig. 10 Comparison of hindcast and observation for directionally-grouped occurrence rates of high winds and high waves.

spite of the difference of predominant wind direction. This suggests that sheltering effect of Sado Island is greater than refraction effect at Niigata West. At Fukui and Sakata, the shallow water wave model gives better estimation to observed predominant wave direction than the deep water wave model, but discrepancy of about 20 degrees still exists.

#### 4. Conclusions

Applicability of the long term wave hindcast system was verified by reasonable agreement between computation and observation over 8 years at 11 wave observation points along the coast of the Japan Sea. Although the shallow water wave model requires more than three times computer processing time compared to the deep water wave model, higher reliability over the deep water wave model leads us to use the shallow water wave model for the estimation of wave climate including wave direction.

#### 5. Acknowledgements

The authors thank the Bureaus of Harbor Construction, Ministry of Transportation and the Prefectural Offices for kindly offering the valuable wind and wave data. Thanks are also due to Mr. M. Ohfuku, Technical Officer of Civil and Ocean Engineering, Ehime University and Mr. T. Hioki, graduate student of Ocean Engineering, Ehime University for their sincere assistance during the study.

## CHAPTER 20

# Characteristics of absorbing directional wavemaker

H. Hirakuchi <sup>1</sup>, R.kajima, T.Shimizu, M.Ikeno

### ABSTRACT

In order to maintain realistic and expected incident waves, an absorbing directional wavemaker has been developed and its performance is examined experimentally. The directional spectrum of the generated waves in the progressive wave field is analysed by the Bayesian Model (BDM), and the directional spectrum of the incident waves in the combined wave field is separated by the Modified Bayesian Model (MBM). Good agreement is shown between the BDM result and the MBM result. In order to make a further check on the angular spreadings of the directional waves in the progressive and combined wave fields, coherence function of the cross spectrum is measured and compared with the target one derived theoretically.

## 1 Introduction

Hydraulic model tests have often been conducted to solve the various problems associated with the planning and the design of coastal structures. It is very important to reproduce realistic ocean surface waves in a laboratory basin. Major hydraulic laboratories in the world have built the directional wavemakers during the last decade.

To generate short-crested waves by the directional wavemaker, several different random wave synthesis methods have been developed. All of these synthesis methods are based on the simulation of the irregular waves which have the specific directional spectrum. For evaluating the performance of the directional wavemaker, the directional spectrum analysis becomes of importance. Several analysis models are proposed and used for this purpose.

---

<sup>1</sup>Abiko Research Laboratory, Central Research Institute of Electric Power Industry, 1646 Abiko, Abiko-shi, Chiba, JAPAN 277-11

However, it is well known that each model gives the different result, although the same data are used. Therefore, it is very important to use another analysis method except for the directional spectrum analysis method as well as to select the best directional analysis model.

When a model structure is highly reflective and occupies a large part of a width of a basin, re-reflected waves at a paddle affect the incident waves. In the case of the 2-D experiment, an absorbing wavemaker has been developed and used in a wave channel (Hirakuchi et al., 1990b). In order to maintain better controlled wave conditions in a incident and reflected combined wave field, an absorbing directional wavemaker has been developed. To evaluate the absorption performance of the developed wavemaker, it is important to separate the directional spectrum of the incident waves from the combined wave field. For this purpose, Isobe and Kondo(1986) modified the MLM technique, and Hashimoto et al.(1987a) proposed the Modified and the Extended Bayesian Model (MBM and EBM). The separated result would be also affected by the resolution power of each model.

The purpose of this study is to examine the performance of the absorbing directional wavemaker experimentally. We first consider some aspects of the usefulness of the coherence function of the cross spectrum, for evaluation of the wave angular spreadings. Next, we carry out the several experiments in the progressive wave field and the combined wave field with regular and irregular waves, and make comparison of the wave height and the directional spectrum. A further check on the wave spreadings of the generated waves are obtained by comparing the coherence distribution in space and frequency domain.

## 2 Coherence function of directional wave field

Directional wave field used in a wave modelling is usually represented by the following form:

$$S(f, \theta) = P(f) \cdot G(\theta; f) \quad (1)$$

where  $S$ ,  $P$  and  $G$  are the directional spectrum, the frequency spectrum and the angular spreading function, respectively. In the case of Mitsuyasu-type spreading function,  $G$  is:

$$G_M(\theta) = \frac{(2s)!!}{2\pi (2s-1)!!} \left( \cos \frac{\theta - \theta_0}{2} \right)^{2s} \quad (2)$$

where  $\theta_0$  is the mean wave angle, and  $s$  is the angular spreading parameter. In this paper,  $s$  is defined as:

$$s = \begin{cases} s_{max} (f/f_p)^5 & ; f \leq f_p \\ s_{max} (f/f_p)^{-2.5} & ; f \geq f_p \end{cases} \quad (3)$$

where  $f_p$  is a peak frequency of the power spectrum and  $s_{max}$  is a maximum value of the spreading parameter at  $f_p$ .

The general relationship between the directional spectrum and the cross spectrum can be expressed as:

$$\phi_{mn}(\sigma) = \int_{\mathbf{k}} H_m(\mathbf{k}, \sigma) H_n^*(\mathbf{k}, \sigma) S(\mathbf{k}, \sigma) \exp(-i\mathbf{k} \cdot \mathbf{r}_{mn}) d\mathbf{k} \quad (4)$$

where  $\phi_{mn}$  is the cross-spectrum between the point  $\mathbf{x}_m$  and  $\mathbf{x}_n$ ,  $\mathbf{r}_{mn}$  is a space vector ( $\mathbf{r}_{mn} = \mathbf{x}_n - \mathbf{x}_m = (R \cos \alpha, R \sin \alpha)$ ),  $H$  is the complex transfer function relating the water surface elevation to any wave quantity, and  $*$  represents the complex conjugate value.

When the wave quantities measured are wave surface elevations,  $H$  is  $H_m = H_n^* = 1.0$ . In this case, the cross spectrum can be expressed as:

$$\phi_{mn}(\sigma)/P(\sigma) = C_1 - i Q_1 \quad (5)$$

$$C_1 = J_0(kR) + 2 \sum_{j=1}^{[s/2]} \frac{s! s! (-1)^j J_{2j}(kR)}{(s-2j)! (s+2j)!} \cos(2j\delta) \quad (6)$$

$$Q_1 = -2 \sum_{j=0}^{[(s-1)/2]} \frac{s! s! (-1)^j J_{2j+1}(kR)}{(s-2j-1)! (s+2j+1)!} \cos(2j+1)\delta \quad (7)$$

where  $C_1$  and  $Q_1$  are co-spectrum and quadrature spectrum, respectively,  $J$  is a Bessel function and  $\delta$  is:

$$\delta = \alpha - \pi - \theta_0 \quad (8)$$

The cross spectrum is often expressed by the coherence and the phase:

$$coh = \frac{|\phi_{mn}|^2}{\phi_{mm} \phi_{nn}} \quad (9)$$

$$phs = \tan^{-1} \left( \frac{\text{Imag}(\phi_{mn})}{\text{Real}(\phi_{mn})} \right) \quad (10)$$

Fig.1 is an example of the spacial distribution of the coherence function between the origin and any other position in the directional wave field with the spreading parameter of  $s=10$  and  $75$ . It is shown that the coherence value along the main wave direction from the origin keeps very high value, although the coherence value along the wave crest line from the origin decreases very rapidly. In the case of uni-directional waves, the coherence value should be 1.0 all over the field. Therefore, it can be said that the decreasing rate of the coherence value in space domain reflects the angular spreadings of the directional wave field.

In Fig.1, the coherence value along the crest line from the origin becomes less than 0.1 over the range of  $R/L > 2$ , where  $L$  is a wave length. It means

(a)  $s = 10$

(b)  $s = 75$

**Fig.1** Coherence distribution in the progressive wave field.

(a)  $s = 10$

(b)  $s = 75$

**Fig.2** Coherence distribution in the combined wave field.

that the data measured at two points with the distance of  $R/L > 2$  along the wave crest line are statistically independent. It also means that it is possible to get the ststistically independent cross spectra by arranging the several wave arrays, each of which is located with the distance of  $R/L > 2$  along the wave crest line.

The relationship between the crosss and directional spectrum in the incident and reflected combined wave field is derived by Isobe and Kondo(1986):

$$\begin{aligned} \phi_{mn}(\sigma) = & \int_{\mathbf{k}} H_m(\mathbf{k}, \sigma) H_n(\mathbf{k}, \sigma) S(\mathbf{k}, \sigma) \times \\ & [ \exp\{-\mathbf{k} \cdot (\mathbf{x}_n - \mathbf{x}_m)\} + r^2 \exp\{-\mathbf{k} \cdot (\mathbf{x}_{nr} - \mathbf{x}_{mr})\} + \\ & r \exp\{-\mathbf{k} \cdot (\mathbf{x}_{nr} - \mathbf{x}_m)\} + r \exp\{-\mathbf{k} \cdot (\mathbf{x}_n - \mathbf{x}_{mr})\} ] d\mathbf{k} \quad (11) \end{aligned}$$

where  $r$  is the reflection coefficient,  $\mathbf{x}_{nr}$  and  $\mathbf{x}_{mr}$  are symmetrical space vectors of  $\mathbf{x}_n$  and  $\mathbf{x}_m$  against the reflecting boundary, and  $\mathbf{k}$  is a wave number vector of the incident waves defined in a half domain.

The coherence function in the combined wave field can be calculated by the above equation. Fig.2 is an example of the coherence distribution in space domain between the origin and any other position in the half domain under the condition of  $r = 1.0$  and  $\theta_0 = \pi$ . In Fig.2, the coherence value along the wave direction changes very rapidly at the nodal position and gives the maximum value at the anti-nodal position. This figure shows that the coherence distribution in space domain would be useful to evaluate the wave spreadings in the combined wave field.

### 3 Experimental set-up

The dimension of the wave basin is 45m wide, 35m long and 1.1m deep (Fig.3). The absorbing directional wavemaker consists of 48 wave paddles, each of which is controlled independently and is 40cm wide and 120cm high (Hirakuchi et al., 1990a). To detect the reflected waves, a capacitance wave gauge is mounted on the front side of each paddle. It is possible to switch the absorption loop in or out of the control circuit, so this wavemaker also work as a conventional wavemaker. The absorbing principle and its performance for the uni-directional irregular waves in a wave channel have been described and examined by Hirakuchi et al.(1990b).

To examine the performance of wave generation and reflected wave absorption, all four combinations of the following alternatives are considered in the experiments: 1) either with or without the absorption loop, and 2) either with or without the remarkable reflected waves in the basin (with the vertical wall in Fig.4, with absorbing beach in Fig.3).

Regular and irregular wave experiments are carried out at the water

depth of 50cm. The wave height and period used for regular wave experiments are  $H=4\sim 5$ cm and  $T=1.0\sim 1.5$ s. For the directional wave experiments, the Mitsuyasu-type angular spreading function and the Bretschneider-type power spectrum are used as a target spectrum. The significant wave height and period for  $s_{max}=10$  and 75 are  $H_{1/3}=5.0, 4.0$ cm and  $T_{1/3}=1.0, 1.25$ s, respectively. The double-summation model are used for the wave synthesis.

The star arrays in Fig.3 and the linear array in Fig.3 and 4 are used for the directional spectrum analysis. The linear array in Fig.3 and 4 are also used to evaluate the coherence distribution in space and frequency domain.

## 4 Results for progressive wave fields

### 4.1 Regular waves

Firstly, experiments on oblique regular waves were carried out (see Fig.3), and the generated waves were compared with the numerical and analytical results. Fig.5 is an example of the wave height distribution at  $y=9$ m in Fig.3. The black circle is the experimental result, and the break line and the solid line are analytical result proposed by Takayama(1982) and the numerical result calculated by the mild slope equation, respectively. The mild slope equation used in this study is:

$$\left. \begin{aligned} \frac{\partial \mathbf{Q}}{\partial t} + C^2 \nabla \zeta &= 0 \\ \frac{\partial \zeta}{\partial t} + \frac{1}{n} \nabla \cdot (n \mathbf{Q}) + \frac{f_d}{n} \zeta &= 0 \end{aligned} \right\} \quad (12)$$

where  $C$  is the wave velocity,  $\zeta$  is the surface elevation,  $f_d$  is a coefficient for energy dissipation, and  $n$  and  $\mathbf{Q}$  are defined as:

$$n = C_g / C = \frac{1}{2} \left( 1 + \frac{2kh}{\sinh 2kh} \right) \quad (13)$$

$$\mathbf{Q} = \int_{-h}^0 \mathbf{U} dz \quad (14)$$

in which  $\mathbf{U}$  is the water particle velocity.

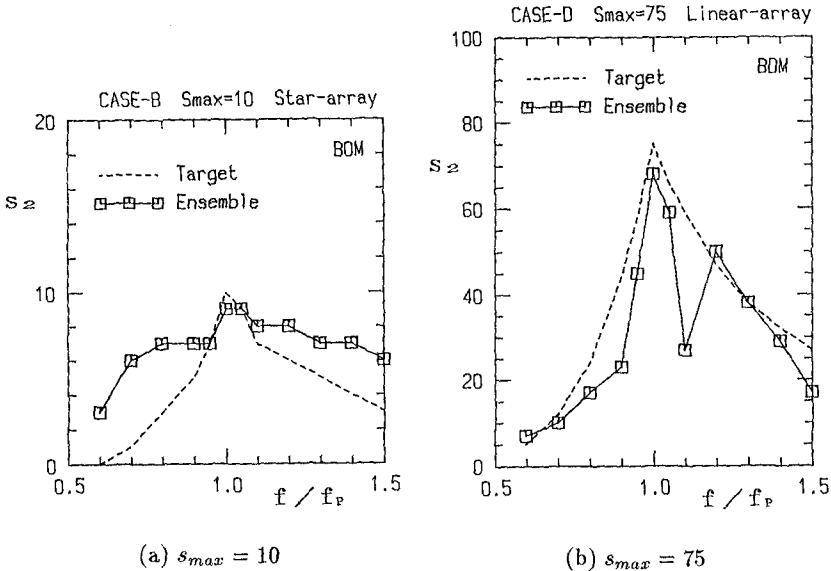

Eq.(12) is equivalent to the mild slope equation with the dissipation term  $f_d$  (Dalrymple, Kirby et al., 1984):

$$\nabla \cdot (nC^2 \nabla \zeta) + n\sigma^2 \zeta + i\sigma f_d \zeta = 0 \quad (15)$$

Fig.5 shows good agreement between the measured wave heights and the numerical results calculated by Eq.(12). It is notified that the analytical result proposed by Takayama is not satisfied with the experimental boundary condition illustrated in Fig.3.

**Fig.5** Wave height distribution of oblique waves in the progressive wave field. ● represents the measured value at  $Y=9m$ , the dotted line is the analytical value by Takayama and the solid line is the numerical value calculated by the mild slope equation.

**Fig.6** Comparison between estimated angular spreading parameter and target one. □ is estimated by Eq.(16) using the directional spectrum analysed by BDM. For the BDM analysis, the averaged cross spectrum for 6 experiments are used.

### 4.2 Directional waves

Directional wave experiments with  $s_{max}=10$  and  $75$  are carried out. In order to reduce the statistical variation, six experiments are carried out, each of which has the same wave parameters but has different random phases. Using the averaged cross spectrum for the six experiments, the directional spectrum is analysed by the Bayesian Model (BDM) proposed by Hashimoto and Kobune(1987b). The spreading parameter of the analysed directional spectrum is calculated by the following form:

$$s = \left( \frac{1}{\gamma^2} - \frac{1}{2} \right) + \left( \frac{1}{\gamma^4} - \frac{3}{4} \right)^{1/2} \tag{16}$$

where  $\gamma$  is a long-crested parameter at a frequency  $f$

$$\gamma(f) = \left[ \frac{(M_{20} + M_{02}) - \sqrt{(M_{20} - M_{02})^2 + 4M_{11}^2}}{(M_{20} + M_{02}) + \sqrt{(M_{20} - M_{02})^2 + 4M_{11}^2}} \right]^{1/2} \tag{17}$$

$$M_{pq}(f) = P(f) \int_0^{2\pi} (k \cos \theta)^p (k \sin \theta)^q G(f, \theta) d\theta \quad ; p, q = 0, 1, 2 \tag{18}$$

Fig.6 is the estimated results of  $s$ , where the dotted line is the target one defined in Eq.(3) and  $\square$  is the measured one calculated by Eq.(16). The estimated values of  $s$  show good agreement with the target ones, although the some results for  $s_{max}=75$  show the small values.

The coherence distribution between P1 and P2~P11 (in Fig.3) are measured. Fig.7(a) gives the result along the crest line ( $\alpha = 0^\circ$ ) at the peak frequency of the long-crested waves: the target value of  $s$  at the peak frequency is  $s=75$ . The solid line is the coherence function of the target waves,  $\square$  is the coherence value of the averaged cross spectrum, and the other six marks represent the coherence values of the six experiments. The agreement between the averaged value and the target value is very good, although the measured value for each experiment varies from  $s = 30 \sim 150$ .

The coherence distribution in frequency domain are also calculated. Fig.7(b) gives the coherence between P1 and P3 along the crest line with the distance of 60cm. The solid line is the coherence value of the averaged cross spectrum, and the dotted line with  $\bullet$  is the coherence value of the target wave with the Mitsuyasu-type spreading function. The averaged coherence value shows good agreement with the expected one.

Fig.7 Coherence value measured in progressive wave field ( $s_{max} = 75$ ).

Fig.8 Time histories of generated oblique waves ( $\theta = 105^\circ$ ) with and without the absorption loop in the combined wave field. P1 and P21 are shown in Fig.4

## 5 Results for combined wave fields

### 5.1 Regular waves

To reproduce the incident and reflected combined wave field, a vertical wall with the reflection coefficient of 1.0 are settled as shown in Fig.4. 21 wave gauges (P1~P21) are arranged parallel to the wall and 6 wave gauges are arranged perpendicular to the wall.

Experiments on oblique regular waves were carried out with and without the absorption loop. The time history measured at P1 and P21 are shown in Fig.8. The upper and lower two graphs represent the result with and without the absorption loop, respectively. The waves generated without the absorption loop are unstable, and the multi-reflected waves between the wall and the wavemaker are apparently remained over the range of  $t > 125s$ .

Fig.9 is the result of the wave height distribution along the parallel and perpendicular line to the wall, generated with the absorption loop.  $\square$ ,  $\circ$  and  $\triangle$  are the mean wave heights during several wave periods (T).  $\square$  is the early result of the combined wave field, which may not be affected by the multi-reflected waves. The break line and the solid line are the numerical results of the expected combined wave field calculated by Eq.(12). Fig.9 shows that the wave heights along the both lines are rather stable in time and agree to the expected results.

### 5.2 Directional waves

Directional wave experiments with  $s_{max}=10, 75$  and  $\infty$  are carried out with and without the absorption loop, and the combined wave fields are reproduced. The significant wave height along the perpendicular line to the wall are shown in Fig.10. This figure shows that the results with the absorption loop are not affected by the reflected waves. Since the reflection coefficient at the vertical wall is 1.0, the ratio of the significant wave height ( $H/H_0$ ) may be equal to 2.0 at the wall and to  $\sqrt{2}$  at large distances from the wall, and the minimum value may be occurred at  $Y \approx 8m$  ( $L/4$  away from the wall). The agreement with the measured results with the absorption loop and the theoretical values mentioned above is also excellent.

Fig.11 gives the comparison of the directional spectrum with and without the remarkable reflected waves in the basin: Fig.11(a) and (b) are the power spectrum and the directional spreading function, respectively. These results show that the directional spectrum of the incident waves in the combined wave field is not affected by the re-reflected waves at the paddles.

Fig.12 is an example of the coherence distribution along the parallel line (P1~P21) in Fig.4.  $\circ$  represents the coherence value between P11 and

(a)  $Y = 6.5 \text{ m}$   
 (parallel to the wall)

(b)  $X = -3 \text{ m}$   
 (perpendicular to the wall)

**Fig.9** Comparison between wave height in the combined wave field generated with the absorption loop and numerical results of the mild slope equation (solid and dotted lines).

□, ○ and △ are measured values.

**Fig.10** Comparison of the significant wave height in the combined wave field ( $s_{max} = 10, 75, \infty$ ).

The white and black marks represent experimental results with and without the absorption loop, respectively.

(a) power spectrum

(b) angular spreading function

**Fig.11** Comparison of directional spectrum with and without the remarkable reflected waves in the basin.  $\square$  and  $\blacktriangle$  represent the power spectrum of the incident waves in the combined wave field. These two results are estimated by MBM using the data measured at the different position.

(a)  $s_{max} = 10, f/f_p = 1.0$

(b)  $s_{max} = 75, f/f_p = 1.1$

**Fig.12** Comparison of coherence distribution in space domain in the combined wave field.  $\circ$  represents the observed coherence value between P11 ( $x=-3m$ ) and P1~P21( $x=-6\sim 0m$ ), and solid line represents the theoretical value of the target combined wave field.

P1~P21, so the coherence at P11 ( $x = -3\text{m}$ ) is equal to 1.0. Fig.12(a) is the result for  $s_{max}=10$  at  $f/f_p=1.0$ , and Fig.12(b) is the result for  $s_{max}=75$  at  $f/f_p=1.1$ . The measured coherence value agrees very well to the expected value.

## 6 Conclusion

The absorbing directional wavemaker has been developed, and its performance is examined experimentally. Several experiments were carried out either with or without the absorption loop in the progressive wave field and in the combined wave field. From the comparison of the wave height, the directional spectrum and the coherence function of the cross spectrum, it is shown that the absorbing directional wavemaker has excellent performance to absorb the reflected waves. The wavemaker can reproduce the short- and long-crested waves with the specific directional spectrum, and can maintain the better controlled incident wave field.

## CHAPTER 21

# A New Nearshore Directional Wave Gage

Gary L. Howell<sup>1</sup>

## 1 Introduction

A field directional wave gage has been developed for requirements in coastal, port, and harbor engineering. Uses include planning and design studies, long term wave climatology, and post construction monitoring. The gage provides high quality directional wave spectra measurements from a compact, easily installed instrument. Stand alone installation with long term internal data recording is provided. Real time data access may be simultaneously provided by connecting a cable.

The gage is completely bottom mounted with no surface components. Optimized for shallow and intermediate water depths required by coastal engineers, the gage may be reliably deployed in water depths too shallow for buoys or acoustic instruments. The sensors are three high resolution pressure transducers that permit the mounting frame to be resistant to fishing activities.

Reliable data storage and long term deployment are achieved by performing preliminary data analysis within the instrument. Intermediate analysis results are recorded on reliable non-volatile solid state memory. The recorded data may be post processed to obtain simple estimates of mean water level, wave height, period, and direction. If desired, the Fourier series coefficients of the directional spectrum may be computed from the intermediate data. Optionally, modern high resolution methods may be used.

## 2 Background

### 2.1 Motivation

*Deep ocean directional wave measurement has progressed rapidly during the last*

---

<sup>1</sup>U S Army Corps of Engineers, Coastal Engineering Research Center, Waterways Experiment Station Vicksburg, Mississippi 39180-6199 USA

twenty years. In-situ buoy measurements are routinely collected by the industrialized nations. Commercial directional buoys are available for site specific studies. The development of satellite technology has provided deep water measurements assumed to be homogeneous over the large range cells of satellite sensors.

Unfortunately for coastal engineers, progress in nearshore measurements has lagged. The typical coastal regime, characterized by shoaling, refraction, diffraction, and reflection, makes the use of large spatial averaging remote sensors, inappropriate. Data are often required in areas subject to large breaking waves and strong currents. These conditions capsize directional buoys, and aerate the water column, blinding acoustic sensors.

## 2.2 Requirements

Modern coastal engineering practice requires use of increasingly sophisticated models. Properly calibrated and verified, models can yield accurate information on waves at a project site. Frequently data are not available, and models must be employed with only deep water data, or shallow water data from a distant or unrepresentative site. In undeveloped areas, models may be applied without any calibration or verification. The goal of this development is to make high quality, site specific wave data commonplace.

A requirements based design approach was employed to guide development efforts. First, engineering data requirements were identified:

- Wave height
- Wave period
- Wave direction
- Wave spectrum
- Radiation stress
- Water level

While many other statistics could be added, routine availability of these parameters constitutes a useful parameter set. This paper will focus on the key parameter of wave direction, in particular mean wave direction.

## 2.3 Measuring wave direction with arrays

In-situ directional wave gages can be generalized as arrays of sensors that spatially and temporally sample the *true* directional wave spectrum over a section of the sea surface. The estimated directional spectrum is the convolution of the *true* directional spectrum with the transfer function of the sensor array. Isobe et al. (1984) expressed this using the cross power spectra,  $\Phi_{mn}$ , between arbitrary

measured wave parameters and the directional wave spectrum  $S(\vec{k}, \sigma)$ , where  $\vec{k}$  is the wave number vector, and  $\sigma$  is angular frequency.

$$\Phi_{mn} = \int_{\vec{k}} H_m(\vec{k}, \sigma) H_n^*(\vec{k}, \sigma) e^{-i\vec{k}(x_n - x_m)} S(\vec{k}, \sigma) d\vec{k} \tag{1}$$

The  $H_m$  is the hydrodynamic transfer function between the water surface and the  $m$ th sensor and  $x_m$  is the sensor's location vector.

Common practice for engineering applications assumes linear wave theory for the transfer functions  $H_m$ , and a linear dispersion relationship between wave length and frequency expressed as

$$\sigma^2 = (2\pi f)^2 = gk \tanh kd \tag{2}$$

where  $d$  is the water depth.

Equation 1 can then be expressed in the frequency domain as

$$\begin{aligned} \Phi_{mn}(f) = & \int_0^{2\pi} H_m(f, \theta) H_n^*(f, \theta) \{ \cos(k[x_{mn} \cos \theta + y_{mn} \sin \theta]) \\ & - i \sin(k[x_{mn} \cos \theta + y_{mn} \sin \theta]) \} S(f, \theta) d\theta \end{aligned} \tag{3}$$

where  $\theta$  is the wave direction,  $f$  is wave frequency,  $S(f, \theta)$  is the wave frequency directional spectrum, and

$$x_{mn} = x_n - x_m \tag{4}$$

$$y_{mn} = y_n - y_m \tag{5}$$

Directional wave analysis is the method of estimating solutions to the integral equation 3. Horikawa (1988) provides a summary of current methods. For many engineering applications, mean wave direction is sufficient. Note that  $\Phi_{mn}(f)$ , the cross-spectral matrix, is sufficient information to employ any directional analysis technique.

## 2.4 Existing instrumentation

Existing instrumentation and field procedures were reviewed to identify required improvements. The following types of in-situ, nearshore directional measurement instrumentation systems are being used, or have been evaluated in the past.

**PUV** Co-located EM current meter and absolute pressure gage. Both real-time, cable connected, and self recording versions are used routinely.

**Borgman array** Shore parallel array of absolute pressure transducers with spacing comparable to wave lengths (Panicker and Borgman, 1970). This array is capable of high resolution and is routinely used at research facilities.

**$S_{xy}$  array** A 6m right triangle, absolute pressure transducer array, analyzed as a slope array (Higgins, et al., 1981).

**DPG** Differential Pressure Gage. Two orthogonal short base line differential pressure gages, and one absolute gage. Developed and successfully tested by Bodge and Dean (1984).

**ADCP** Acoustic Doppler Current Meter. Measures three components of current velocity at several range cells in the middle part of the water column. The data analysis is similar to a *PUV*.

**Short base-line slope array** A real time, cable connected, 1.6 m equilateral triangle, absolute pressure transducer array, analyzed as a slope array. This gage was developed as a precursor to the gage reported here and has been in routine use by CERC since 1989.

Economy and reliability are the most needed improvements. Measurement and analysis techniques were less so. When the total costs of obtaining an analyzed data report are considered, instrument cost was less important than costs associated with field operations, maintenance, and data analysis.

An integrated approach addressed the entire function from sensor to analyzed data report. Instrument requirements were part of the overall systems analysis. Existing instruments require improvement in one or more of the following areas:

**Directional resolution** Most important for sediment transport formulae, but benefits all applications.

**Gage orientation accuracy** Errors or suspected errors in the orientation of directional gages can render data useless.

**Site selection flexibility** Often sites must be selected based on survivability or operational requirements, rather than engineering data needs.

**Deployment period** Frequent service requirements are a principal cause of high costs. At many sites, weather permits servicing only during the summer.

**Measurement interval** Shallow water wave conditions can change rapidly. Instrument limitations force sub-sampling.

**Reduce total cost of analyzed data** Site specific data costs must be within the budget of a typical engineering project.

## 3 New Developments

### 3.1 Principles of operation

The enabling development is the very short baseline absolute pressure transducer array (Figure 1). Traditional directional wave gages using pressure transducers have relied on arrays with dimensions on the order of water wave lengths (Panicker and Borgman, 1970).

Figure 1: DWG-1 ready for deployment. Base version uses 3 transducers in a 1.6 m equilateral triangle array.

Scripps Institute of Oceanography developed slope gages using absolute pressure transducers in a 6 m right triangle array. Higgins, et al. (1981) analyzed the errors due to length of the baseline. Error was reduced by making the baseline as short as possible, limited only by the noise of the absolute pressure transducers.

Bodge and Dean (1984) demonstrated that differential pressure transducer arrays could employ very short base lines. The differential transducer array requires a fluid filled tubing system to transmit the pressure to the transducer. Construction and maintenance of the tubing system requires care.

The new gage has the advantages of the short baseline array, yet still uses absolute pressure sensors. An absolute pressure sensor using a quartz crystal transducer and a specially designed digitization circuit was developed. The combination provides pressure samples with an order of magnitude less noise than previous strain gage based transducers. The sampling period for this resolution is less than 180msec.

Numerical simulation of various directional wave spectra measurements using the noise characteristics of the new transducer examined the effect of baseline dimension on error in mean wave direction. Results were very encouraging. To verify these results a field experiment was conducted. Figure 2 shows the layout of a seven transducer array of transducers arranged to provide multiple baseline lengths. The array was placed in 8m of water at the CERC Field Research

Figure 2: Array layout used at the DUCK 85 field test to evaluate the effect of the baseline length of slope arrays on mean wave direction measurement error.

Facility, Duck, N.C.

A total of 1567 wave records from October to December 1986 were analyzed. Significant wave height ranged to 4 m, and spectral peak periods ranged from 4 to 20 sec. Data from sensor number 1 was discarded due to excessive noise. Virtual sensors 8, 9, and 10 were created by linear interpolation of data from sensors 1 and 4. Figure 3 is an example of a scatter plot of mean direction from a slope analysis of effective 1.2 m and 1.8 m arrays. As predicted by the simulation, the reduction in base line length has little effect on the mean direction estimate.

The new gage has a base configuration of a 1.6 m equilateral triangle, absolute transducer array. This array will give accurate mean direction estimates at low cost. Figure 1 shows the geometry of the standard installation pod. The hexagonal shape allows the minimum configuration triangular array to be augmented with additional transducers. Numerical simulations using the Bayesian analysis method (Hashimoto and Kobune, 1988) have been performed using 4 and 6 transducers. Directional resolution is improved over the minimum three transducers. Directional resolution performance of the new gage will be reported when planned field tests of the four and six transducer versions have been completed.

The short base line reduces construction costs and simplifies installation and recovery. Problems of spatial homogeneity in the complex bathymetry of coastal projects are eliminated. The hexagonal array facilitates design of a high strength, trawler resistant pod.

Figure 3: Correlation of mean wave direction estimates from Array (5,7,8) and Array (6,7,9).

### 3.2 Gage design

The performance requirements were translated into the following design specifications.

#### Specifications.

**Internally recorded data:** Mean water level, cross-spectral matrix, and calendar date and time.

**Post-processed data:** Water level, significant wave height, spectral peak period, mean wave direction, and directional spectrum.

**Internal data storage:** Removable EPROM modules.

**Real time option:** Simultaneous with internal recording and analysis, calibrated pressure time series data are available in real time. Adds a standard 7-conductor well logging cable up to 1.7 km length and a shore located PC or modem.

**Principle:** 3-transducer pressure array. 1.6 m equilateral triangle.

**Sampling interval:** Acquires and analyzes 30 min data record every hour.

**Deployment period:** Records hourly data for 13 months.

**Operational depth:** Bottom mounted in water depths from 2 to 20 m.

**Accuracy:** Water level, wave height, and spectral energy error - 1 cm rms. Mean wave direction error - 2 degrees rms.

Implementation of the gage is achieved through very low power microcomputer design and custom firmware. Firmware controls data acquisition, quality control, calibration, analysis, and storage functions. The most difficult specification is simultaneous 13 month deployment, 1 hour continuous record interval, and 30 min record length. Existing instrumentation requires compromise of one or more of these requirements.

Achieving 13 month deployment requires internal data analysis. The cross spectral matrix is computed internally and stored. These data provide the maximum data compacting while still permitting various analysis techniques for post processing. For the base level gage is treated as a space array. To reduce the amount of information saved, redundant information in the cross spectral array is eliminated.

Expressing the cross spectral matrix as real and imaginary parts, the usual definitions of Co (real) and Quad (imaginary) spectra are defined as

$$\Phi_{mn}(f) = C_{mn}(f) - iQ_{mn}(f) \quad (6)$$

Figure 4: DWG-1 cylinder containing the electronics and batteries. The three pressure transducers connect to the main cylinder.

and for 3 sensors

$$\Phi_{mn} = \begin{bmatrix} C_{11} & C_{12} & C_{13} \\ C_{21} & C_{22} & C_{23} \\ C_{31} & C_{32} & C_{33} \end{bmatrix} - i \begin{bmatrix} Q_{11} & Q_{12} & Q_{13} \\ Q_{21} & Q_{22} & Q_{23} \\ Q_{31} & Q_{32} & Q_{33} \end{bmatrix} \quad (7)$$

Observing that each  $nm$  term is the complex conjugate of the corresponding  $mn$  term, three each Co and Quad spectra are eliminated from storage. By definition  $Q_{11} = Q_{22} = Q_{33} = 0$ , and for the case of a space array,  $C_{11} = C_{22} = C_{33}$  except for statistical variability. Substituting

$$\hat{C} = \frac{C_{11} + C_{22} + C_{33}}{3} \quad (8)$$

and

$$\hat{C}_{nm} \approx \sqrt{\hat{C}^2 - Q_{nm}^2} \quad (9)$$

allows the saved parameters to be reduced to  $\hat{C}$ ,  $Q_{12}$ ,  $Q_{13}$ , and  $Q_{23}$ . These assumptions are sufficient for accurate mean direction estimates. High resolution directional estimates require that Co-spectra terms also be saved, resulting in a small cost increase.

The mean water level computed during the first and last six minutes of each measurement interval are also saved. All data are calibrated in engineering units and tagged with UCT time. Each gage permanently stores its sensor calibrations, identification, location, quality control, and status information in the removable EPROM modules.

A prototype diverless deployment and recovery system has been developed to reduce operation cost and improve the gage directional orientation measurement. The unit is operated from a boat using a PC interface. The fixture contains a remotely operated air jetting controls and release, depth and attitude read outs, and a gyrocompass for orientation measurement.

## 4 Field test results

The completed gage has been field tested at two sites. Both gages functioned successfully, obtaining better than 99% data return. A comparison of the gage results with a 15-element linear array at the Coastal Engineering Research Center (CERC), Field Research Facility (FRF) in Duck, North Carolina was independently conducted by William Birkemeier of the FRF. The linear array is composed of 9 shore parallel and 6 shore normal sensors. Figures 5 and 6, prepared by Mr. Birkemeier, summarize the results. The comparison data represent 1090 records during the period February 1 - March 31, 1992. Records with  $H_s < 0.4 m$  or  $T_p < 4 sec$  were not included. An unexplained time difference of 1 hour between the two data sets was compensated. No manual editing or quality control was applied to data from the new gage.

Both gages rely on the autospectrum of a pressure transducer to estimate significant wave height and peak period. The agreement shown in Figure 5 is expected for properly calibrated and analyzed gages. Fig. 6 compares mean direction estimates. For these data the new gage's mean direction was obtained from a space array analysis. Agreement is quite good. Outliers result from bimodal spectra where approximately equal peaks can cause a different  $T_p$  to be picked by the analysis codes. Agreement is best near shore normal angle of 70 degrees. Waves at oblique angles to the beach are underestimated by the linear array compared to the new gage. Similar differences were observed with comparisons of the linear array to a *PUV* gage.

## 5 Conclusions

The new gage is a high quality, directional wave gage, capable of simple installation, and year long deployment. The low cost availability of nearshore directional wave data will impact the planning, engineering, and maintenance of coastal projects. Wave measurements will be possible in most locations. Stand-alone internally recording gages will be more economical than real-time, cable connected gages. Low cost and site selection flexibility will permit multiple gages

Figure 5: Linear regression of  $H_s$  of DWG-1 and the FRF Linear Array. Outer dashed lines are 95% prediction limits. The correlation coefficient is 0.987.

Figure 6: Linear regression of mean wave direction at the spectral peak period of DWG-1 and the FRF Linear Array. Outer dashed lines are 95% prediction limits. The correlation coefficient is 0.931

at a project site. Routine monitoring for engineering requirements will increase. New monitoring objectives of environmental assurance and litigation prevention will emerge.

## Acknowledgments

The author gratefully acknowledges the contributions, discussions, and review of many colleagues. In particular William E. Grogg, Joon P. Rhee, William M. Kucharski, and Michael D. Carpenter of CERC made major contributions. Noriaki Hashimoto of the Japan Port and Harbor Research Institute provided valuable suggestions and comments. Data from the FRF linear array was provided by Charles E. Long. The work described here was performed under the Nearshore Directional Wave Measurement Technology work unit, of the U.S. Army Corps of Engineers, Coastal Research Program. Permission to publish this paper was granted by the Chief of Engineers, U.S. Army Corps of Engineers.

## CHAPTER 22

# ENERGY DISSIPATION AND AIR BUBBLES MIXING INSIDE SURF ZONE

Hwung Hweng Hwung<sup>1</sup> Jih Ming Chyan<sup>2</sup> Yeong Chyang Chung<sup>3</sup>

### Abstract

In order to understand the relationship between entrained air bubbles and energy transfer inside surf zone, a special technique of He-Ne laser and 2D LDV were employed to investigate the characteristics of air bubbles concentration and velocity fields, respectively. The experimental results shows that the concentration profiles of air bubbles decay hyperbolically in the vertical direction and exponentially in the horizontal direction. With appropriate parameter groups, the distributions of air bubbles show a characteristics of similarity. The potential energy, kinematic energy and total energy decrease with the horizontal distance except that the kinematic energy slightly increases between the impinging point and the maximum penetration. Within this region, the energy loss of potential energy and kinematic energy is almost transferred to the air bubbles to merge into the water body.

### Introduction

The wave breaking in the nearshore area is a very important and fascinating phenomenon of wave hydrodynamics. In the instant of wave

<sup>3</sup> Graduated Student of Hydraulic and Ocean Engineering Department, National Cheng Kung University, Tainan, Taiwan, ROC

breaking, air entrainment destroys the original flow structure, resulting in dissipation of wave energy. With the admixing of air bubbles, the flow fields of broken wave are turbulent and complicated. Although the energy dissipation and air bubbles mixing after wave breaking have been extensively studied in the past thirty years, its mechanism is not fully understood, due to the complex flow fields are essentially beyond the capacity of measuring equipments during that period. From theoretical and experimental studies, Horikawa and Kuo (1966) obtained an exponential decay function of wave height inside surf zone. Führböter (1970) assumed that the wave breaking provided the total dissipation energy to the air bubbles entraining into the water body, and derived the decay functions of wave height for spilling and plunging breakers respectively. Jansen (1986) employed the flow visualization technique and photochromism method to observe the turbulent flow fields of aerated layer in the outer region of surf zone. Recently, Nadaoka (1986) detected the turbulent intensity distributions in the nearshore zone by LDV. In the previous efforts, the connections of air bubbles entrainment with the turbulent energy dissipation had not been fully investigated. In order to understand this relationship, a special technique of He-Ne laser was employed to detect the entrainment process of air bubbles, and a LDV system was used to examine the spatial distributions of two dimensional velocity in wave flume respectively.

### Experiments

It is very difficult to observe the kinematic phenomenon of air bubbles merged in water body. A special installation of He-Ne laser was developed, as depicted in Fig. 1. According to our experience, the transformed voltage signal from the He-Ne laser appears a drop-out when the laser beam is deflected by air bubbles. Such a phenomenon can be used to represent the variations of air bubbles. However, an appropriate threshold of background air concentration obtained in still water has to be determined before the data analysis process. A typical example is shown in Fig. 2 in which both the dash and solid line respectively denote the threshold value and drop-out signal. Furthermore, Lin & Hwung (1992) found out that the broken wave was a three dimensional flow field. Under this circumstance, air bubbles across the test section at the same phase of wave motion can't be identified by the laser beam. It is because that only the first bubble deflects the beam and the rest are hidden in the drop-out signal. Based on this conclusion, to determine a proper test width is very important in this experiment. From the results of total air concentration ( $C_t$ ) with different test widths, as shown in Fig. 3a, it is obvious that a wider one possesses a higher concentration

Figure 1. Experimental installation of air bubbles measurements; (a) top view, (b) front view

which doesn't linearly increase with the test width. When they are expressed in air concentration per unit width ( $C_u$ ), as seen in Fig. 3b, the results of both of 3 and 4 cm test width are almost consistent, so that we adopt these two test widths for all of the experiments. In addition to the measurements

Figure 2. Drop-out signal induced by entrained air bubbles

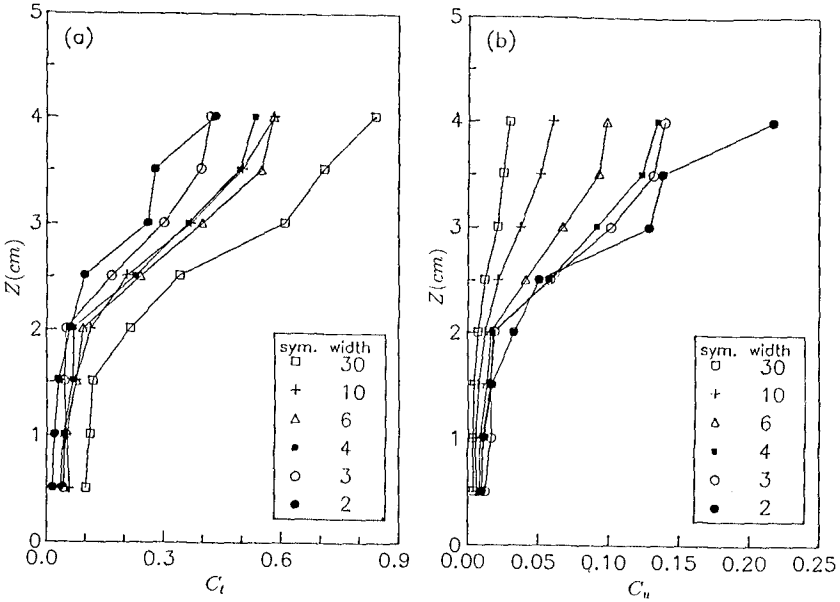

Figure 3. Concentration profiles of various test width; (a) total air bubbles concentration ( $C_t$ ), (b) air bubbles concentration per unit width ( $C_u$ )

Figure 4. Schematic description of coordinate system and measuring points

Table 1. Experimental conditions

Case	$T$ (sec)	$h_i$ (cm)	$H_i$ (cm)	Breaking type	$H_b$ (cm)	$H_o/L_o$	$h_b$ (cm)	$H_b/h_b$
1	1.29	33.0	6.11	plunging	8.08	0.0259	8.10	0.998
2	0.90	33.0	5.72	spilling	6.57	0.0483	7.00	0.925

of bubbles concentration, the turbulent flow fields in the surf zone was also detected by LDV (TSI—9100-8) of being capable to determine the variations of two dimensional velocity.

Two typical wave breaking were generated in the wave flume and the experimental conditions are tabulated in Table 1; in which  $T$  is the wave period in seconds,  $h_i$  the water depth at the horizontal portion of the flume,  $H_i$  the wave height produced by the wave generator,  $H_b$  the breaking wave height,  $H_o/L_o$  the converted wave steepness at deep water,  $h_b$  the water depth at breaking point, and finally  $H_b/h_b$  the relative water depth at the point of wave breaking. The bed slope of wave flume is 1/15. Fig. 4 shows the coordinate system and the distribution of measuring points. The first test section was positioned at the wave breaking point and the distances between measuring points in  $X$  and  $Z$  directions were 7.5 cm and 0.5 cm respectively.

## Results and discussion

From the elaborate measurements, the vertical distributions of the concentration of entrained air bubbles for the plunging and spilling breakers are plotted in Fig. 5 and Fig. 6, respectively, in which  $L_o$  denotes the wave length in deep water. The concentration of air bubbles hyperbolically decreases with the water depth for both of the plunging and spilling breakers. As shown by Lin & Hwung (1992), the formation of water tongue by the plunging breaker, which violently impinges the water body, enhances the entrainment process of air bubbles. The maximum concentration of it, 18%, is larger than that of a spilling breaker, 12%. The plunging breaker also induces a deeper penetration of air bubbles and a higher concentration within the aerated layer. When normalized by appropriate parameter groups, there exists a similarity function for different profiles and cases, which is shown in Fig. 7 and can be written as;

$$\frac{C}{C_o} = 0.56 \left[ \tanh \left( 5.36 \frac{Z_a}{\eta^+ + h_a} - 1.56 \right) + 1 \right] \quad (1)$$

where  $C$  is the air bubble concentration per unit width,  $C_o$  the air bubble concentration at still water level,  $\eta^+$  the water surface elevation above the still water level.  $h_a$  denotes the penetration depth of air bubble based on the location where the duration of drop-out signal is 10% of total sampling period.  $Z_a$  is the distance from the origin located at the penetration depth of  $h_a$ , and it is positive upward.

The longitudinal distributions of air concentration averaged on the aerated layer for cases of plunging and spilling breakers decrease with the dimensionless distance ( $X/L_o$ ), as shown in Fig. 8. By the comparison with Kuo (1972), it shows that the theoretical prediction coincides with the experimental results of spilling breaker. However, it has much differences between the theoretical and experimental results due to the nonlinearity and strong impingement of plunging breaker. From a non-dimensionalized process, the cross-sectional average of air concentration shows a characteristic of similarity in Fig. 9. The similarity function can be expressed as;

$$\frac{\bar{C} - \bar{C}_{ha.max}}{\bar{C}_{imp} - \bar{C}_{ha.max}} = 2.85 \exp(-1.72X/L_o) - 0.72 \quad (2)$$

where  $\bar{C}$  represents the averaged concentration within the aerated layer,  $\bar{C}_{imp}$  the averaged concentration at the impinging point of breaking wave,

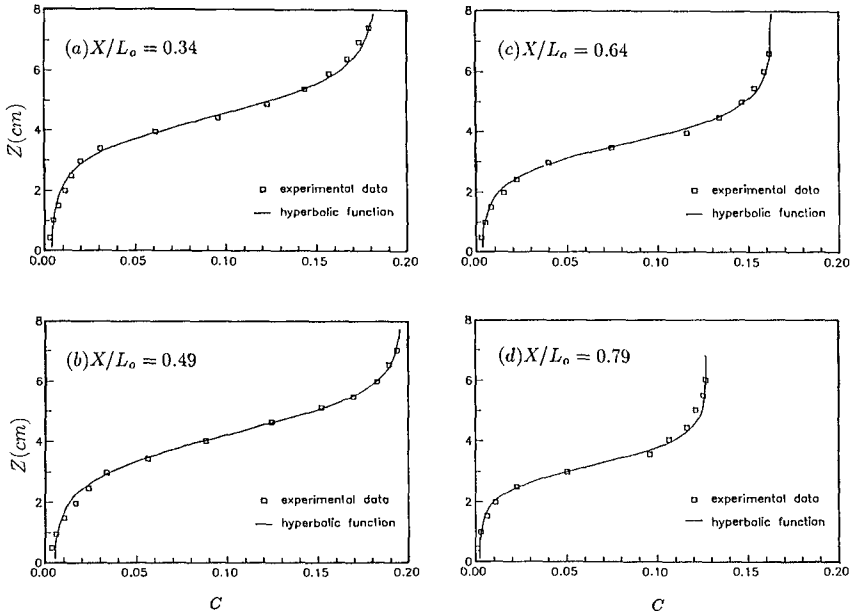

Figure 5. Vertical distribution of air bubble concentration (plunging breaker)

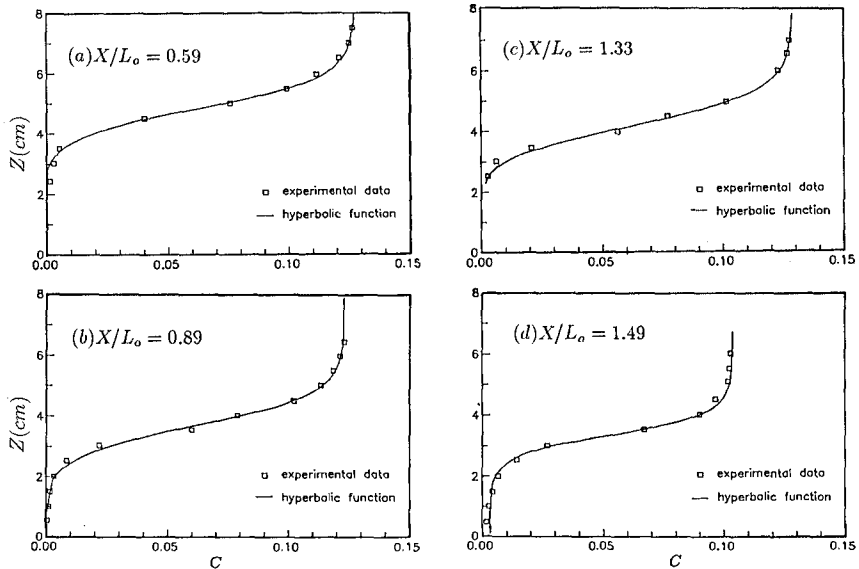

Figure 6. Vertical distribution of air bubble concentration (spilling breaker)

Figure 7. Similarity of vertical distribution of air bubble concentration

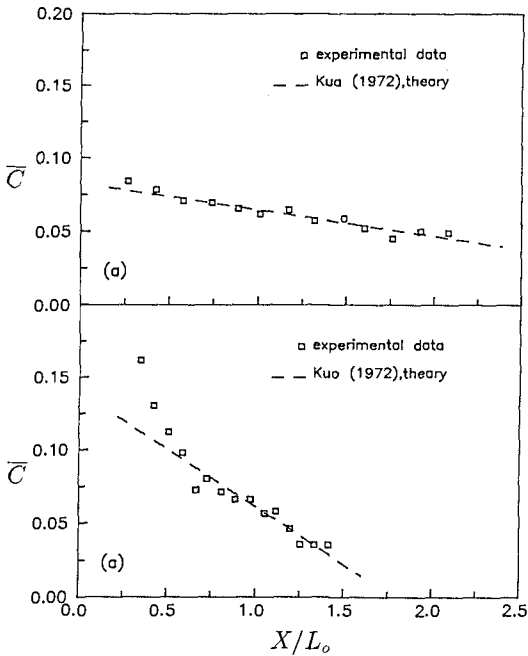

Figure 8. Average concentration along the longitudinal direction; (a) spilling breaker, (b) plunging breaker

Figure 9. Similarity of cross-sectional averaged concentration of air bubbles

$\bar{C}_{ha,max}$  the averaged concentration at the maximum penetration section of air bubbles.

In order to understand the effect of air entrainment process on the turbulent flow fields after wave breaking, LDV was also employed to measure both of the horizontal velocity ( $u$ ) and vertical velocity ( $w$ ). According to IFFT (inverse fast Fourier transformation) method proposed by Hwung et al.(1989), the spatial distributions of air concentration, turbulent velocity intensities ( $\sqrt{u'^2}$ ,  $\sqrt{w'^2}$ ) and Reynolds stress ( $-\overline{u'w'}$ ) are shown in Fig. 10 and Fig. 11 for cases of plunging and spilling breakers. It is obvious that the maximum of turbulent velocity intensities locate at the maximum penetration of air bubbles and so does the Reynolds stress. However, the positions of the maxima of velocity and its turbulent intensity don't coincide with each other. The former reaches the peak value in the impinging point. It is because that, when the wave breaking, there forms a water jet mixed with air bubbles impinging and penetrating into a deeper water depth. In the maximum of penetration section, the air bubbles begin to ascend due to the buoyancy effects and generate well-correlated velocity fluctuations. It enhances the energy transfer between different dimensions and results in the maximum of turbulent velocity intensities and Reynolds stress.

Figure 11. Spatial distribution of air concentration, turbulent velocity intensities and Reynolds stress (spilling breaker)

According to Führböter (1970), the potential energy of air bubbles inside surf zone can be expressed by;

$$E_{air} = \gamma \frac{h_a^2(x)}{2} \frac{\bar{C}}{1 - \bar{C}} \quad (3)$$

where  $\gamma$  is the specific weight of water. In addition to the energy of air bubbles, the potential and kinematic energy ( $E_p$ ,  $E_k$ ) of the broken wave can be written as;

$$E_p = \frac{\gamma}{2} \frac{1}{T} \int_0^T \eta^2 dt \quad (4)$$

$$E_k = \frac{\rho}{2} \int_0^{h+\eta} \left[ \frac{1}{T} \int_0^T (u^2 + w^2) dt \right] dz \quad (5)$$

where  $T$  and  $\eta$  are the sampling duration and the variations of water surface, respectively, while  $\rho$  denotes the water density. From Eq. (3) ~ Eq. (5), the relationships between the energy of air bubbles and that of the turbulent flow fields for both of plunging and spilling breakers are plotted in Fig. 12 where the experimental results are non-dimensionalized by the total energy ( $E_b$ ) at the breaking point of wave motion and  $E$  represents the summation of  $E_p$  and  $E_k$ . By the comparisons of experimental results, it shows that the variations of energy transfer can be divided into three stages in characteristics. The energy rapidly decreases before the impinging point of broken waves. Between the impinging point and the maximum penetration, the energy loss of the flow fields has been almost transferred into the potential energy of air bubbles since the summation of  $E_{air}$  and  $E$  nearly conserves. The kinematic energy slightly increases in the same region. Due to the buoyancy, the air bubbles ascend and induce the turbulence. The total energy of  $E + E_{air}$  gradually decays in the rest region. The decaying tendency for the plunging breaker is faster than that of the spilling breaker since the entrainment of air bubbles is weaker for the spilling breaker.

Figure 12. Variations of air bubbles energy, potential energy and kinematic energy ; (a) plunging breaker,(b) spilling breaker

## Conclusion

According to the present study, the most important step in measuring air bubbles is to determine the significant width of detecting section which is 3~4 cm in our experiments. From the experimental results, the profiles of averaged air bubbles concentration decay hyperbolically and exponentially in the vertical and the horizontal directions. There exist similarity functions of air bubbles profiles if the experimental results are non-dimensionalized by appropriate parameter groups. For both of the plunging and spilling breakers, the turbulent velocity intensities and the Reynolds stress reach their maximum at the maximum penetration. The total energy shows multi-stages variations of rapid decrease, conservation and gradual decay in the region divided by the impinging point and the maximum penetration. The energy required for the air bubbles to merge into the water body is almost provided by the potential and kinematic energy.

## CHAPTER 23

Instrumental evaluation of the deep water directional wave climate along the Mediterranean coast of Israel

Ya. A. Iosilevskii<sup>1</sup>, D. S. Rosen<sup>1</sup>, A. Golik<sup>1</sup>, and D. L. Inman<sup>2</sup>

### Abstract

The frequency-directional deep water wave climate along the Mediterranean coast of Israel was evaluated for the first time by computer numerical analysis using *instrumental shallow water measurements*. The shallow water data underlying the study were gathered within the period from 1984 through 1991 by two CAS (Cassette Acquisition System) wave measuring stations located off Haifa (North) and Ashkelon (South) along the Mediterranean coast of Israel. The paper includes a brief description of the data gathering, analysis, and processing methods, and it also includes main results of the study.

### 1. Introduction

It is both expensive and technically complicated to acquire accurate instrumental deep water data needed for computing the respective height, frequency, and direction of water waves. A quite cheap and commonly available practical way to evaluate frequency-directional spectra of water waves in deep water is to reconstruct those spectra from appropriate shallow water measurements. This approach is adopted in this study.

<sup>1</sup>National Institute of Oceanography: Israel Oceanographic and Limnological Research, Tel Shikmona P. O. Box 8030, Haifa 31080, Israel

<sup>2</sup>CCS, Scripps Institution of Oceanography, University of California, San Diego, La Jolla, Ca. 92093, U.S.A

In studying or simulating the wave climate in the offshore region, the coastal engineer typically employs the method which may be called '*the representative monochromatic wave method*'. In the framework of this method, the coastal engineer approximates the offshore irregular sea state by the corresponding *representative* (e.g., characteristic) *monochromatic wave*; and he investigates the refraction transformation of this monochromatic wave as it propagates shoreward. Although the representative monochromatic wave method is widely used in coastal engineering practice, the coastal engineer is usually unaware of the degree of accuracy of that method.

In contrast to the representative monochromatic wave method, the method of refraction transformation, which is used in this study, may be called '*the spectral decomposition method*'. It consists of three steps: (i) decomposition of the measured shallow water sea surface displacement from equilibrium into monochromatic wave components (say, by the FFT method); (ii) refraction transformation of each component; (iii) computation of the linear superposition of the component results. The spectral decomposition method is more consistent than the representative monochromatic wave method. Also, from the standpoint of both physical and numerical analysis, the latter method is a particular case of the former method. The two methods are compared in this study.

As contrasted to the evaluations of the present study, none of the previous wave climate evaluations at the Mediterranean coast of Israel, which were reported by Rosen & Kit (1981), Goldsmith & Sofer (1982), Rosen (1982), Carmel *et al* (1985b), had the property to be directional, deep water, and instrumental all together.

The term '*wave weather*', as contrasted to '*wave climate*', is used in this paper interchangeably with the presently common term '*sea state*'. The term '*shallow water*' is used as a class synonym of the term '*not deep water*'.

## 2. Data gathering

The raw data used in this study were collected by two similar CAS (Cassette Acquisition System - see Boyd & Lowe (1985)) wave measuring stations located off Haifa (North) and Ashkelon (South) along the Mediterranean coast of Israel. Each station is composed of a linear array of three pressure gauges with spacings of 12 m and 24 m between two successive gauges. Both arrays are installed at a mean depth of 8.5 m, 0.95 m above the sea bottom. Consequently, the wind water waves of typical periods, say, from 4 sec. to 14 sec., i. e. of wavelengths from approximately 24 m to approximately 124 m

at the station location, undergo refraction due to bathymetry effects before they reach the station.

The wave measuring station located at Ashkelon was intermittently operational from March 1984 through May 1987 and from August 1989 through February 1990. The wave measuring station located at Dado Beach, Haifa, was intermittently operational from March 1984 through April 1987 and from April 1989 through May 1991. Wave measurements have been carried out by each station for 34 min. 8 sec. every 6 hours, at a sampling rate of 2 Hz. A single whole phenomenon of the above duration when a CAS station samples with the rate of 2 Hz is said to be a *fast mode event* (briefly, an FME).

### 3. Physical and mathematical prerequisites

A description of the physical and mathematical concepts underlying the results reported in this paper is beyond its scope. Still, in order to discuss those results conveniently, we will make explicit some elementary physical and mathematical notions, - largely, by introducing the appropriate notation.

#### 3.1. A coordinate system

A local working right-handed rectangular rectilinear coordinate system is chosen in such a way that its XY-plane coincides with the equilibrium sea surface, and its Z-axis is directed vertically upward. The origin of the coordinate system is located somewhere in deep water area, the X-axis is directed shoreward, and the Y-axis is, in a crude sense, parallel to the local shoreline.

#### 3.2. General notation

's' and 'd' are subscript acronyms for 'shallow water' and 'deep water', respectively; '\*' is a subscript ellipsis for 's' or 'd';  $P_*$  is a point on the equilibrium sea surface;  $P_s$  is the shallow water point on the equilibrium sea surface under which the water wave measuring station is located;  $\rho$  is the mass density of sea water, ( $1028.8 \text{ kg/m}^3$ );  $g$  is the acceleration of gravity ( $9.81 \text{ m/sec}^2$ ).

#### 3.3. Parameters characterizing continuous spatiotemporal Fourier transform of the sea surface displacement equilibrium at the point $P_*$

$\nu$  = a monochromatic water wave frequency (Hz);  
 $\tau(\nu) = 1/\nu$  = the period of a monochromatic water wave of frequency  $\nu$  (sec);

- $\vec{n}_*(\nu)$  = the propagation vector of a plane monochromatic water wave of frequency  $\nu$  at  $P_*$  ( $\text{cm}^{-1}$ );  
 $\vartheta$  = the direction of  $\vec{n}_*(\nu)$  relative to the positive direction of the axis  $X$ , positive in the counterclockwise direction (degree or radian);  
 $C_{g*}(\nu)$  = the group celerity of a quasi-monochromatic wave packet of frequency  $\nu$  at  $P_*$  ( $\text{m}/\text{sec}$ );  
 $\mathcal{E}_*(\nu, \vartheta)$  = the continuous frequency-directional energy density per unit area, per unit frequency, and per unit angle at  $P_*$  [ $\text{joule}/\text{cm}^2 \cdot \text{Hz} \cdot \text{deg}$ ];  
 $\mathcal{E}_{*0}(\nu) = \int_{-\pi}^{\pi} \mathcal{E}_*(\nu, \vartheta) d\vartheta$   
 = the continuous frequency-directional energy density per unit area and per unit frequency at  $P_*$  [ $\text{joule}/\text{cm}^2 \cdot \text{Hz}$ ];  
 $\mathcal{F}_*(\nu, \vartheta) = \mathcal{E}_*(\nu, \vartheta) C_{g*}(\nu)$   
 = the continuous frequency-directional energy flux density across unit length, per unit time, per unit frequency, and per unit angle at  $P_*$  [ $\text{joule}/(\text{cm} \cdot \text{sec} \cdot \text{Hz} \cdot \text{deg}) = \text{newton}/\text{deg}$ ];  
 $\mathcal{F}_{*0}(\nu) = \int_{-\pi}^{\pi} \mathcal{F}_*(\nu, \vartheta) d\vartheta$   
 = the continuous frequency-directional energy flux density across unit length, per unit time, and per unit frequency at  $P_*$  [ $\text{joule}/(\text{cm} \cdot \text{sec} \cdot \text{Hz}) = \text{newton}$ ];  
 $\mathcal{R}(\nu, \vartheta)$  = the wave ray of frequency  $\nu$ , which passes through the point  $P_\vartheta$  at the angle  $\vartheta$  relative to the positive direction of the axis  $X$ ;  
 $P_d = \mathcal{P}_d(\nu, \vartheta)$  = the first deep water point on the backward path of  $\mathcal{R}(\nu, \vartheta)$ ;  
 $A_d(\nu, \vartheta)$  = the deep water direction angle of  $\mathcal{R}(\nu, \vartheta)$ ;  
 $K(\nu, \vartheta)$  = the refraction-and-shoaling coefficient (the product of refraction and shoaling coefficients) of  $\mathcal{R}(\nu, \vartheta)$  at  $P_\vartheta$  relative to  $\mathcal{P}_d(\nu, \vartheta)$ ;

3.4. Integral sea weather parameters computed via  $\mathcal{E}_*$   
 versus integral sea weather parameters computed via  $\mathcal{F}_*$

$$m_{E*n}(\nu_1, \nu_2) = \int_{\nu_1}^{\nu_2} \nu^n \mathcal{E}_{*0}(\nu) d\nu$$

= the  $n$ th moment of  $\mathcal{E}_{*0}$  between  $\nu_1$  and  $\nu_2$ ;

$$\nu_{E^*}(\nu_1, \nu_2) = m_{E^*1}(\nu_1, \nu_2) / m_{E^*0}(\nu_1, \nu_2)$$

= the mean wave frequency between  $\nu_1$  and  $\nu_2$   
via  $\xi_{O^*}$  (Hz);

$$\tau_{E^*}(\nu_1, \nu_2) = 1 / \nu_{E^*}(\nu_1, \nu_2)$$

= the mean wave period between  $\nu_1$  and  $\nu_2$   
via  $\xi_{O^*}$  (sec);

$$m_{E^* \rho g}(\nu_1, \nu_2) = \int_{\nu_1}^{\nu_2} \int_{-\pi}^{\pi} \xi_{O^*}(\nu, \theta) |z_{O^*}(\nu)|^{p+q} \cos^p \theta \sin^q \theta d\theta d\nu :$$

$$\vartheta_{E^*}(\nu_1, \nu_2) = \arctan (m_{E^*01}(\nu_1, \nu_2) / m_{E^*10}(\nu_1, \nu_2))$$

= the mean wave direction between  $\nu_1$  and  $\nu_2$   
via  $\xi_{O^*}$  (radian).

The overall mean wave frequency  $\bar{\nu}_{E^*}$ , period  $\bar{\tau}_{E^*}$ , and direction  $\bar{\vartheta}_{E^*}$ , and also the characteristic wave height  $\bar{H}_{E^*}$ , at the point  $P_*$  are defined via  $\xi_{O^*}$  by

$$\bar{\nu}_{E^*} = \nu_{E^*}(0, \infty), \quad \bar{\tau}_{E^*} = \tau_{E^*}(0, \infty), \quad \bar{\vartheta}_{E^*} = \vartheta_{E^*}(0, \infty),$$

$$\bar{H}_{E^*} = H_{*mo} = 4 \sqrt{2 m_{E^*}(0, \infty) / (\rho g)},$$

respectively, in accordance with IAHR (1989).

Let  $\gamma \in (0, 1)$  be a given real number, and  $\nu_{E^*M}$  be the frequency at which  $\xi_{O^*}(\nu)$  reaches its absolute maximum. Let  $\nu_{E^*L}(\gamma)$  be the lowest, and  $\nu_{E^*G}(\gamma)$  be the greatest frequency with the property that

$$\xi_{O^*}(\nu_{E^*L}(\gamma)) / \xi_{O^*}(\nu_{E^*M}) = \xi_{O^*}(\nu_{E^*G}(\gamma)) / \xi_{O^*}(\nu_{E^*M}) = \gamma.$$

Then the overall centroidal  $\gamma$ -peak wave frequency  $\hat{\nu}_{E^*}$ , period  $\hat{\tau}_{E^*}$ , and direction  $\hat{\vartheta}_{E^*}$  at the point  $P_*$  are defined via  $\xi_{O^*}$  by

$$\hat{\nu}_{E^*} = \nu_{E^*}(\nu_{E^*L}(\gamma), \nu_{E^*G}(\gamma)), \quad \hat{\tau}_{E^*} = \tau_{E^*}(\nu_{E^*L}(\gamma), \nu_{E^*G}(\gamma)),$$

$$\hat{\vartheta}_{E^*} = \vartheta_{E^*}(\nu_{E^*L}(\gamma), \nu_{E^*G}(\gamma)),$$

respectively. In this study, we have set  $\gamma = 0.8$ , in accordance with IAHR (1989).

All the above definitions of this subsection, except for the definition of ' $\bar{H}_{E^*}$ ', apply with 'F' and ' $\mathcal{F}$ ' in place 'E' and ' $\xi$ ', respectively.

3.5. Parameters characterizing discrete spatiotemporal Fourier transform of the sea surface displacement from equilibrium at the point  $P_*$

- $\nu_m$  = the low cutoff wave frequency (Hz);  
 $\nu_M$  = the high cutoff wave frequency (Hz);  
 $I$  = the total number of discrete frequencies in the interval  $[\nu_m, \nu_M]$ ;  
 $\Delta\nu$  = the wave frequency increment (Hz);  
 $f(i) = \nu_m + (i - 1)\Delta\nu$   
 = the discrete wave frequency of index  $i \in \{1, 2, \dots, I\}$ ;  
 $\vartheta_{*m}$  = the least (low cutoff) wave ray direction angle at the point  $P_*$  (radian or degree);  
 $\vartheta_{*M}$  = the greatest (high cutoff) wave ray direction angle at the point  $P_*$  (radian or degree);  
 $J_*$  = the total number of discrete wave ray direction angles in the interval  $[\alpha_{*m}, \alpha_{*M}]$ ;  
 $\Delta\vartheta_*$  = the shallow water wave ray direction angle increment (radian or degree);  
 $\vartheta_{*}(j) = \vartheta_{*m} + (j - 1)\Delta\vartheta_*$   
 = the wave ray direction angle of index  $j$  at the point  $P_*$  relative to the positive direction of the X-axis (radian or degree);  
 $E_{*}(i, j) = \mathcal{E}_{*}(f(i), \vartheta_{*}(j))\Delta\nu\Delta\vartheta$   
 = the discrete energy density of indices  $i$  and  $j$  per unit area at  $P_*$  (joule/m<sup>2</sup>).  
 $F_{*}(i, j) = F_{*}(f(i), \vartheta_{*}(j))\Delta\nu\Delta\vartheta$   
 = the discrete energy flux density of indices  $i$  and  $j$  across unit length and per unit time at  $P_*$  [joule/(m·sec) = newton/sec].

4. Expressions for the frequency-directional energy density and energy flux density in deep water in terms of those in shallow water

The general idea of how to express  $E_d$  or  $F_d$  in terms of the respective  $E_s$  or  $F_s$ , is based on this hypothesis:

**Hypothesis 1:** [During a storm caused by a distant source,] the wave pattern in deep water is statistically

(ergodically) uniform over an area of the sea surface whose linear dimensions are small as compared to the distance from the storm source.

The most important specific factors which influence the character of most frequency-directional spectra of sea waves during the winter storms off the Mediterranean coast of Israel are (i) a single narrow window for deep water wave approach and (ii) a fetch of approximately 2200-2300 km in length (see Goldsmith & Golik (1978, p. 22), Carmel et al (1985a, 1985b)). We therefore adopt the following hypothesis:

**Hypothesis 2:** [During a storm caused by a distant source,] for each point  $P_*$  along the Mediterranean coast of Israel, the spatiotemporal discrete Fourier decomposition of the sea surface displacement during an FME contains exactly one plane monochromatic wave whose direction is uniquely determined by its frequency.

To be able to analyze all available data uniformly, we have, in accordance with common practice, extended Hypotheses 1 and 2 by omission of the phrase enclosed between square brackets. Thus, by Hypothesis 2, for each for FME, each  $i \in \{1, 2, \dots, I\}$ , there is exactly one  $j \in \{1, 2, \dots, J\}$  such that  $\theta_*(i) = \vartheta_*(k_*(i))$ , i.e.  $\theta_* = \vartheta_* \cdot k_*$ , where  $k_*$  is a certain integer-valued function of an integer argument, and  $\theta_*$  is a composite real-valued function defined herewith. Hence,

$$E_*(i, j) = E_{o*}(i) \delta_{j, k_*(i)}, \quad E_{o*}(i) = \sum_{j=0}^{J_*} E_*(i, j), \quad (1)$$

where  $\delta$  is the unit diagonal matrix. By Hypothesis 1, we then have

$$E_{od}(i) = E_{os}(i) [K(f(i), \theta_s(i))]^{-2}, \quad (2)$$

$$\theta_d(i) = A_d(f(i), \theta_s(i)). \quad (3)$$

By the respective definitions of Sections 3.3, and 3.5, the variant of (1) with 'F' in place of 'E' is semantically sound. Under Hypothesis 2, equations (2) and (3) solve the problem of expressing  $E_d$  in terms of  $E_s$ , whereas  $F_d = E_d C_{gd}$  and  $F_{do} = E_{do} C_{gd}$ .

### 5. Data processing

Broadly speaking, the data processing underlying this study comprises four steps.

1). The first step of data processing was accomplished with the aid of a package of original FORTRAN programs recently developed by Iosilevskii & Iosilevskii (1991). At this step, each time series of raw shallow water pressure data, gathered by each wave measuring station during the corresponding FME was tested on reliability in accordance with certain criteria, and, if reliable, it was Fourier transformed with the purpose to obtain the respective table  $\langle f, E_{os}, F_{os}, \theta_s \rangle$ . Among some other results, the programs also compute the cumulative longshore energy density flux across unit length over any given span of time; such a flux is commonly associated with the respective longshore sediment transport.

2). The second step of the data processing was accomplished with the aid of *Multi-frequency and multi-ray FORTRAN program for backward and forward refraction of water waves* (briefly, BFRFP) recently written by Iosilevskii (1992). Using the bottom topography data for the neighborhood of the wave measuring station, the program computes, among some other wave ray parameters, the matrix  $A_d$  of deep water wave propagation angles and the matrix  $K$  of products of refraction and shoaling coefficients. The size  $I \times J_s$  of each matrix is specified by the user of the program. Once computed, the matrices  $A_d$  and  $K$  become universal attributes of the neighborhood of the wave measuring station independent of any specific wave weather or wave climate.

In this study, we have used the following values:

$$\begin{aligned} \nu_m &= 6.0 \times 2^{-10} \text{ Hz}, \quad \nu_s^M = 0.25 \text{ Hz}, \quad \Delta\nu = 1024^{-1} \text{ Hz}, \\ \vartheta_{sm} &= -45^\circ, \quad \vartheta_{sM} = 45^\circ, \quad \Delta\vartheta_s = (90/89)^\circ, \\ I &= 251, \quad J_s = 90. \end{aligned}$$

3). The third step of the data processing was accomplished with the aid of *Deep water spectrum FORTRAN program* (briefly, DWSFP) which was recently written by Ya. A. Iosilevskii (to be published). At the first place, the program transforms a sequence of tables  $\langle f, E_{os}, F_{os}, \theta_s \rangle$ , obtained at the first step, into the respective sequence of tables  $\langle f, E_{od}, F_{od}, \theta_d \rangle$ . This is done with the aid of the matrices  $A_d$  and  $K$  obtained at the second step. Then using  $E_{so}, F_{so}, E_{do}$ , and  $F_{do}$  as statistical

weights, the program computes, for each individual FME, the following mean and peak sea state parameters:

$$E_{so} \Rightarrow \bar{H}_s, \bar{\tau}_{Es}, \bar{\vartheta}_{Es}, \hat{\tau}_{Es}, \hat{\vartheta}_{Es}; \quad (4)$$

$$F_{so} \Rightarrow \bar{\tau}_{Fs}, \bar{\vartheta}_{Fs}, \hat{\tau}_{Fs}, \hat{\vartheta}_{Fs}; \quad (5)$$

$$E_{do} \Rightarrow \bar{H}'_d, \bar{\tau}'_{Ed}, \bar{\vartheta}'_{Ed}, \hat{\tau}'_{Ed}, \hat{\vartheta}'_{Ed}; \quad (6)$$

$$F_{do} \Rightarrow \bar{\tau}'_{Fd}, \bar{\vartheta}'_{Fd}, \hat{\tau}'_{Fd}, \hat{\vartheta}'_{Fd}. \quad (7)$$

Most of the parameters listed in (4) and (5) are also computed by the programs used at step 1. The parameters listed (6) and (7) are the desired deep water sea state parameters computed by the *spectral decomposition method*.

$\bar{H}_s$ ,  $\bar{\tau}_{Es}$ , and  $\bar{\vartheta}_{Es}$  can be regarded as the wave height, period, and propagation vector direction of an imaginary monochromatic wave at the point  $P_s$ , and  $\bar{H}'_d$ ,  $\bar{\tau}'_{Ed}$ , and  $\bar{\vartheta}'_{Ed}$  as the similar characteristics of another imaginary monochromatic wave. With the aid of the appropriate matrix elements of the matrices  $A_d$  and  $K$ , the program computes the deep water wave height  $\bar{H}'_{Ed}$  and direction  $\bar{\vartheta}'_{Ed}$  corresponding to the triple  $\langle \bar{H}_s, \bar{\tau}_{Es}, \bar{\vartheta}_{Es} \rangle$ , and it also computes the similar characteristics  $\bar{H}'_{Fd}$  and  $\bar{\vartheta}'_{Fd}$  corresponding to the triple  $\langle \bar{H}_s, \bar{\tau}_{Fs}, \bar{\vartheta}_{Fs} \rangle$ .

$\bar{H}'_{Ed}$ ,  $\bar{\tau}'_{Ed}$ , and  $\bar{\vartheta}'_{Ed}$  are conventional deep water characteristics of sea state computed in the framework of the presently common *representative monochromatic wave method*.  $\bar{H}'_{Fd}$ ,  $\bar{\tau}'_{Fd}$ , and  $\bar{\vartheta}'_{Fd}$  form a similar set of deep water sea state parameters, but this set is not in common usage - it is suggested here for the first time.

4). The fourth step of the data processing comprises statistical analysis and graphic and table presentation of the results obtained. The statistical analysis was done with the aid of programs prepared by the second author. The graphic and table presentation was done with the aid of Quattro Pro Software of Borland Intl.

## 6. Results

The results of this study can be summarized as follows.

1). There is both deterministic and statistical correlation between the deep water sea weather parameters at Haifa and of the respective parameters at Ashkelon, with the exception of the directional parameters. The latter parameters are correlated statistically and,

to a lesser extent, mainly during storms, they are also correlated deterministically.

2). The prevailing wave direction is from West-North-West at Haifa, and it is from West at Ashkelon.

3). For the same place (Haifa or Ashkelon), there is deterministic and statistical correlation between the deep water sea weather parameters computed via  $E_{do}$  and the respective parameters computed via  $F_{do}$ . In this case, the values of ' $\bar{\tau}_{Ed}$ ' and ' $\hat{\tau}_{Ed}$ ' sometimes differ from the respective (simultaneous) values of ' $\bar{\tau}_{Fd}$ ' and ' $\hat{\tau}_{Fd}$ ', whereas  $\bar{\phi}_{Ed}$  and  $\hat{\phi}_{Ed}$  are, as a rule, close to  $\bar{\phi}_{Fd}$  and  $\hat{\phi}_{Fd}$ , respectively.

4). There is both deterministic and statistical correlation between values of the deep water sea weather parameters computed by the spectral decomposition method and the respective parameters computed by the representative monochromatic wave method, although during a storm the former values seem to be more stable (more smooth) in time than the latter.

5). Comparison of the present estimates of the prevailing wave direction at Ashkelon, based on *instrumental measurements*, with the previous estimates of the prevailing wave direction at Ashdod (Rosen (1982)), 15 km North of Ashkelon, based on *visual observations*, shows that the two estimates are grossly different.

Some of the results of this study are illustrated in Figures 1 - 6.

#### Acknowledgements

The research underlying this paper was partly sponsored by the Agency for International Development, U.S.A. BFRFP was written by Ya.A.Iosilevskii under the sponsorship of Israeli Ministry of Energy and Infrastructure. The authors thankfully acknowledge the sponsorship of the above two bodies.

The bathymetry survey to collect the raw data for preparing the two depth grids covering wide regions off Haifa and off Ashkelon along the Mediterranean coast of Israel, where our CAS wave measuring stations are located, was made by Mr. G.Amit and by Mr. A.Golan who also prepared the grids. Mr. P.Artsztein and Mr. A.Cohen digitalized the continuous bathymetric records. Mr. G.Amit and Mr. D.Ramot maintained the wave measuring equipment. The authors are deeply indebted to all the above persons for their cooperation.

## CHAPTER 24

### VARIATION OF POTENTIAL AND KINETIC WAVE ENERGY IN THE SURF ZONE

Koichiro IWATA\* and Takashi TOMITA\*\*

#### ABSTRACT

This paper is to investigate experimentally variation of the potential and kinetic wave energy in the surf zone. First, a cantilever-type velocimeter is newly devised to measure water particle velocities in an air-entrained water body above as well as below the wave trough. Laboratory experiments are carried out, and it is revealed that the kinetic wave energy is larger than the potential one and that some of the potential wave energy can be transferred to the kinetic one at the early stage of wave breaking.

#### 1. INTRODUCTION

Prediction of variation of the wave energy such as potential, kinetic and total wave energy and elucidation of wave dissipation mechanism in the surf zone is one of very important problems for coastal hydraulics as well as coastal engineering. A lot of knowledge about wave breaking and wave deformation after breaking have been accumulated, but it is still unknown how the potential and kinetic wave energy change and how we estimate them well in the surf zone. In particular, an accurate evaluation of the kinetic wave energy is very useful for prediction of the nearshore current system.

---

\* M. ASCE, D. Eng., Professor, Dept. of Civil Eng., Nagoya Univ., Nagoya 464-01, Japan

\*\* D. Eng., Research Associate, ditto

With this background, this paper discusses experimentally the variation of potential and kinetic wave energy in the surf zone. First of all, a cantilever-type velocimeter is newly devised in order to measure the kinetic wave energy as well as particle velocities in the air-entrained wave body above and below the wave trough. Secondly, laboratory experiments are conducted on the uniform slopes of 1/10 and 1/30, using an indoor wave tank which can generate regular and irregular waves. Based on the laboratory experiments, characteristics of variation of the potential and kinetic wave energy, the wave energy dissipation and the propagation velocity of the total wave energy in the surf zone are discussed in relation to breaker types and breaker-caused turbulence.

## 2. CANTILEVER-TYPE VELOCIMETER

A cantilever-type velocimeter based on the "dynamic pressure principle" is newly devised in order to measure accurately the water particle velocity, especially above the wave trough in the surf zone, since we have no reliable velocimeter which enables us to measure wave kinematics above wave trough including air-bubble and turbulence.

The cantilever-type velocimeter is comprized of two cantilevers, as shown schematically in Fig.1, one of which only responds to a vertical component of the dynamic force and another responds only to a horizontal component of the dynamic force. Each cantilever is constructed with a small-sized sensing rod and a plastic plate which is rigidly fixed to a supporting rod. Two semi-conductor strain gauges are pasted on the plastic plate to convert the wave force acting normally to the cantilever into an electrical signal. The plastic plate and end part of the sensing rod is protectively shielded so as not to be affected by direct attack of waves. The diameter of the sensing rod was carefully designed to 0.9mm in order to respond to the fluid drag force and to be almost insensitive to the fluid acceleration force.

Figure 2 shows that the wave force acting on the sensing element is proportional to square of the velocity. Therefore, the water particle velocities,  $u$  and  $w$  are calculated with

$$u|u| = \left(\frac{X_o}{K_x}\right) \left|\left(\frac{X_o}{K_x}\right)\right| / \sqrt{\left(\frac{X_o}{K_x}\right)^2 + \left(\frac{Z_o}{K_z}\right)^2}$$

$$w|w| = \left(\frac{Z_o}{K_z}\right) \left|\left(\frac{Z_o}{K_z}\right)\right| / \sqrt{\left(\frac{X_o}{K_x}\right)^2 + \left(\frac{Z_o}{K_z}\right)^2}$$
(1)

where,  $u$  and  $w$  are the horizontal and vertical velocities of water particle, respectively,  $X_o$  and  $Z_o$  are the output voltages of horizontally and vertically sensing cantilevers, respectively, and  $K_x$  and  $K_z$  are the correction factors to  $X_o$  and  $Z_o$  which are determined by calibration tests, respectively. High accuracy of this cantilever-type velocimeter has

been confirmed by comparing with data obtained with electromagnetic-type velocimeter, as shown in Fig.3 (Iwata et al., 1983 and Koyama and Iwata, 1986).

## 3. LABORATORY EXPERIMENT

Laboratory experiments were carried out using an indoor wave tank at Nagoya University, the dimension of which is 25m in length, 0.7m in width and 0.95m in height. At one end of the wave tank we installed a flap-type wave generator controlled by an oil-pressure servo system. The water was perfectly shut out from the area behind the wave board; therefore, the input electrical signal can be converted smoothly to wave board motion. At the other end of the wave tank was constructed a wave-absorbing beach to keep wave reflection to a minimum. The uniform slopes of 1/10 and 1/30 were adopted and three kinds of breakers such as spilling, plunging and heavy plunging were produced on each slope (see Table 1).

Water surface profiles and particle velocities were, respectively, measured with capacitance-type wave gauges and cantilever-type velocimeters. The measuring locations of water particle velocities were more than 126, as listed in Table 1. The measuring region was from near bottom up to near free surface in vertical direction and from before the wave breaking point to near shoreline in horizontal direction. In the experiments, the same wave was generated repeatedly in order to measure particle velocities at so many locations. One example of the measuring locations is shown in Fig.4. For each experimental run, using a 16mm high speed cine camera (50 frames/s), breaking region was filmed through a grid on glass wall of the channel. Analyzing the films, the breaking point, domain of horizontal roller, and region of air-entrainment were determined. Time profiles of water surface and particle velocities were all recorded on a magnetic tape over 2 minutes.

Table 1 Experimental conditions

CASE	BREAKER	SLOPE	T(s)	Ho(cm)	Ho/Lo	Hb(cm)	$h_b$ (cm)	M

T: wave period, Ho:deep water wave height, Ho/Lo:wave steepness in deep water, Hb:breaking wave height,  $h_b$ :breaking water depth  
M: measuring locations of water particle velocity

## 4. DATA PROCESSING AND ANALYSIS

Time profiles of the water surface profile and particle velocities were divided into 20 discrete values for one wave

cycle to evaluate the potential and kinetic wave energy.

The mean water level  $\bar{\eta}$  is estimated with

$$\bar{\eta} = \frac{1}{T} \int_0^T \eta dt \quad (2)$$

in which, T is the wave period and  $\eta$  is the water surface profile.

The potential wave energy per unit time averaged over one wave period,  $E_p$  and kinetic wave energy per unit time averaged over one wave period,  $E_k$  are, respectively, defined with

$$E_p = \frac{\rho g}{2T} \int_0^T \eta^2 dt \quad (3)$$

$$E_k = \frac{\rho}{2T} \int_0^{h+\eta} ds \int_0^T (u^2 + w^2) dt \quad (4)$$

in which,  $\rho$  is the density of water,  $g$  is the gravitational acceleration,  $h$  is the still water depth,  $s$  is the vertical distance taken upward positive with its origin being on the bottom,  $u$  and  $w$  are the horizontal and the vertical of water particle, respectively. The total wave energy per unit time averaged over one wave period,  $E_T$  is given by

$$E_T = E_k + E_p \quad (5)$$

The energy flux,  $F$  and the energy dissipation rate,  $\Phi$  are evaluated with the following equations;

$$\frac{\partial}{\partial x} (F) = -\Phi \quad (6)$$

$$F = \frac{1}{T} \int_0^T dt \int_0^{h+\eta} u \left( \frac{\rho}{2} (u^2 - w^2) + \rho g \eta \right) ds \quad (7)$$

where,  $x$  is the horizontal distance, and Eq.(7) is derived for the second-order approximation of wave pressure,  $P$ . The calculations of  $E_p$ ,  $E_k$  and  $F$  were performed by applying the trapezoidal formula to Eqs.(3),(4) and (7), respectively, using measured values of  $\eta$ ,  $u$  and  $w$ .

Analysing 16mm motion films by means of a film motion analyzer, the breaking point, air-entrained region, plunging point, domain of horizontal roller, splash zone were determined. The breaking point is defined just as the inception of curling of wave crest. Therefore, the breaking point corresponds to the maximum wave height.

### 3. EXPERIMENTAL RESULTS AND DISCUSSION

#### 3.1 Water particle velocity

Figures 5 and 6 show two examples of water particle velocities before and after wave breaking. It is seen that measured velocities are well predicted with Dean's stream

Fig.4 Measuring locations of water particle velocity for case 1-1

Fig 6 Time histories of water particle velocities (after breaking)

function method (Dean,1965). However, Airy's linear wave theory cannot well evaluate the water particle velocities. Figure 7 shows the time profile of water particle velocities measured at 5cm above the still water level. The particle velocity profiles are quite similar to those of the solitary wave above wave trough (Lee et al.,1982). Figure 8 shows examples of the vertical distribution of the horizontal steady-velocity component,  $\bar{u}$  at three different locations such as before breaking, breaking point and after breaking. The steady-velocity component  $\bar{u}$  is the velocity which is averaged over one wave period both above and below the wave trough. From the figures, it is seen that the on-shore mass transport takes place above the wave trough and offshore mass transport occurs below the wave trough and that conservation of mean mass flux is established. The magnitude of the steady-velocity component (mass transport velocity) corresponds well to foregoing researches (Nadaoka et al.,1982). Thus, as described above, the cantilever type velocimeter devised in this study can safely be said to be highly reliable to measure water particle velocities.

Fig. 7 Time histories of water particle velocities measured at 5cm above the still water level

Fig. 8 Some examples of vertical distribution of horizontal steady-velocity component,  $\bar{u}/\sqrt{gh_b}$  ( $h/h_b=1.57$ ; before breaking,  $h/h_b=1$ ; breaking point,  $h/h_b=0.73$ ; after breaking)

3.2 Variation of potential and kinetic wave energy

Figures 9 shows the variation of the wave height after breaking. Both figures show that the wave height decreases almost monotonously toward the shoreline, as have been pointed out by foregoing researches (Horikawa and Kuo, 1966; Sawaragi and Iwata, 1974).

Figures 10, 11 and 12 show the variation of the potential and kinetic wave energy after breaking in cases of the spilling, plunging and heavy plunging breaker, respectively. In the figures,  $X^*=(x-x_b)/\sqrt{g(h+\bar{\eta})T}$ ,  $x_b$  is the breaking location of  $x$  ( $X^*=0$ ; breaking point),  $E_{tb}$  is the total wave energy at breaking point,  $X_a$  is the location of deepest air entrainment,  $X_o$  is the location of air bubble's disappearance below wave trough,  $X_p$  is the plunging point,  $X_s$  is the location of horizontal roller's disappearance and  $X_v$  is the location at which air bubble covers the front face from crest

Fig.9 Variation of the wave height after breaking

to trough. The symbols,  $\circ$ ,  $\blacksquare$  and  $\Delta$  are experimental values of  $E_T/E_{Tb}$ ,  $E_k/E_{Tb}$  and  $E_p/E_{Tb}$ , respectively.

(a) Spilling breaker:

The potential wave energy  $E_p$  decreases monotonously from  $X^*=0$  to  $X=X_a$  at which the entrained air depth is maximal for both slopes of 1/10 and 1/30. The potential wave energy  $E_p$  at  $X^*=X_a$  is almost  $0.3E_{pb}$  ( $E_{pb}; E_p$  at  $X^*=0$ ). This indicates that almost 70% of the potential wave energy at breaking point is dissipated from  $X^*=0$  to  $X^*=X_a$ . On the other hand, decay of  $E_p$  in the range of  $X^*>X_o$  is seen to be very small.

The kinetic wave energy  $E_k$  is clearly seen to be larger than the potential one, and  $E_k$  increases at an early stage of wave breaking and then decreases toward the shoreline. This is quite different from the change of  $E_p$  with  $X^*$ . The kinetic wave energy  $E_k$  around  $X^*=0.2$  becomes larger than that at  $X^*=0$ . This fact would indicate that some of the potential wave energy is transferred to the kinetic one, since the potential wave energy continuously decays around  $X^*=0.2$ . The attenuation of  $E_k$  in the range of  $X^*>X_o$  is very small and  $E_k$  is almost equal to  $E_p$ . The magnitude of difference between  $E_k$  and  $E_p$  increases with  $X^*$  in the range of  $X^*<X_a$  and  $E_k/E_p$  becomes maximal around  $X^*=X_a$ ;  $E_k/E_p=2.7$  for case 1-1 and  $E_k/E_p=2.4$  for case 2-1. The value of  $E_k/E_p$  at breaking point is 1.15 for case 1-1 and 1.08 for case 2-1. These values are smaller than those measured on gentler slope of 1/150 by Tsuchiya and Tsutsui (1982).

The total wave energy  $E_T$  decays monotonously from  $X^*=0$  to  $X^*=X_o$ , although  $E_k$  increases around  $X^*=0.2$ . Figure 10 shows that 70% ~ 80% of  $E_{Tb}$  (total wave energy at breaking point) are dissipated between  $X^*=0$  and  $X_o$ .

(b) Plunging breaker:

Rapid decay of the potential wave energy  $E_p$  takes place from  $X^*=X_p$  to  $X^*=X_a$ , and  $E_p$  at  $X^*=X_a$  attenuates to  $0.6E_{pb}$  for case 1-2 and  $0.3E_{pb}$  for case 2-2. The magnitude of attenuation of  $E_p$  on  $S=1/10$  is larger than that on  $S=1/30$ , where  $S$  is the bottom slope.

The kinetic wave energy  $E_k$  after breaking is seen to be smaller than that at breaking point  $E_{kb}$ . In case of 2-2 ( $S=1/30$ ),  $E_k$  attenuates monotonously and the magnitude of decay of  $E_k$  between  $X^*=0$  and  $X_a$  is much larger than that in the range of  $X^*>X_a$ . On the other hand, in case of 1-2 ( $S=1/10$ ),  $E_k$  once increases around  $X^*=X_a$ . The reason of this is thought to be that the energy of splash and horizontal roller is transferred to the kinetic energy. Then, the total wave energy  $E_T$  becomes also larger around  $X=X_a$  in case of run 1-2.

(c) Heavy plunging breaker:

The potential wave energy  $E_p$  decreases rapidly after breaking and  $E_p$  around  $X^*=X_s$  becomes  $0.25E_{pb}$ . The potential wave energy once increases around  $X^*=X_a$ . This is thought to be caused by the combination of splash with main

Fig.10 Variation of potential and kinetic wave energy after breaking (Spilling breaker)

Fig.11 Variation of potential and kinetic wave energy after breaking (Plunging breaker)

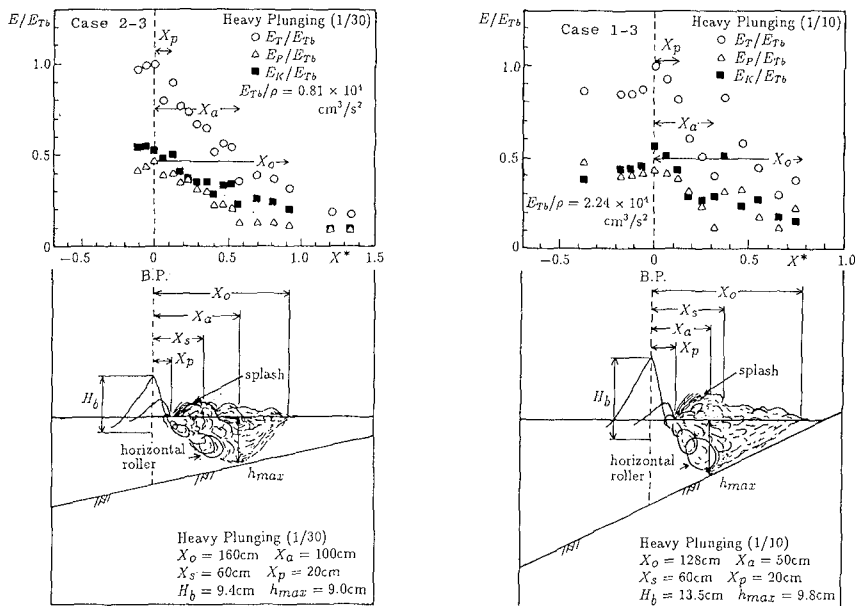

Fig.12 Variation of Potential and kinetic wave energy after breaking (Heavy plunging breaker)

wave body.

The kinetic wave energy  $E_k$  decays rapidly within the short distance between  $X^*=0$  and  $X^*=X_p$ , and 50% and 25% of  $E_{kp}$  are dissipated, respectively, in the cases of 1-3 and 2-3 in this range. The kinetic wave energy  $E_k$  once increases between  $X^*=X_a$  and  $X^*=X_s$  where the splash and horizontal roller's energy seem to be combined with the main wave body. The attenuation of  $E_k$  in the range of  $X^*>X_o$  is very small, like the spilling and plunging breakers.

The total wave energy  $E_T$  decreases rapidly after breaking and once increases between  $X^*=X_a$  and  $X^*=X_s$ , like the plunging breaker. Attenuation of  $E_T$  from  $X^*=X_a$  is small, like the spilling and plunging breakers. The kinetic wave energy  $E_k$  is generally larger than the potential wave energy  $E_p$  and the ratio of  $E_k/E_p$  becomes larger with  $X^*$  and takes a maximum value between  $X^*=X_s$  and  $X^*=X_a$  and then decreases to 1, like other types of breakers. The maximum value of  $E_k/E_p$  in case of 1-3 is 1.62.

As stated above, regardless of breaker types, most of the potential and kinetic wave energy are dissipated from breaking point ( $X^*=0$ ) to  $X^*=X_o$ , especially rapid energy dissipation takes place between  $X^*=0$  and  $X^*=X_a$  at which the depth of entrained air bubble becomes maximum. Thus, it seen that quantity of air bubble is an index of wave energy dissipation.

3.3 Variation of energy flux

Figures 13 and 14 show changes of the nondimensional energy flux  $F/F_b$  with  $X^*$ , where  $F_b$  is the energy flux at breaking point. The magnitude of changes of  $F/F_b$  with  $X^*$  depends on breaker types and bottom slopes. The figures show that  $F/F_b$  attenuates in the order of spilling, plunging and heavy plunging breakers and that the decay of  $F/F_b$  in the range of  $0 \leq X^* \leq X_a$  is much larger than that in the range of  $X^* \geq X_a$ . The splash and horizontal roller are only formed in cases of plunging and heavy plunging breakers and their scale of the heavy plunging breakers are larger than those of the plunging breakers. This causes the most rapid decay of  $F/F_b$  of the heavy plunging breaker among the three breakers. Figure 15 shows the relationship between  $F/\rho$  and  $d (=h+\bar{n})$ , in which the solid and dotted lines indicate, respectively, Eq.(8) and Eq.(9).  $\gamma$  in Eq.(8) and  $\gamma$  and  $\beta$  in Eq.(9) were determined by a least square method, and they

Fig.13 Variation of  $F/F_b$  with  $X^*$  ( $S=1/10$ )

Fig.14 Variation of  $F/F_b$  with  $X^*$  ( $S=1/30$ )

Fig.15 Relationship between  $E/\rho$  and  $d (=h+\bar{n})$

are given in Table 2.

Table 2 Values of  $\beta$  and  $\gamma$

$$\frac{F}{\rho} = \frac{1}{8} g^{\frac{3}{2}} \left(\frac{H}{d}\right) \gamma (d)^{\frac{5}{2}} \quad (9)$$

$$\frac{F}{\rho} = \frac{1}{8} g^{\frac{3}{2}} \left(\frac{H}{d}\right) \gamma (d) \beta \quad (10)$$

	$\beta$	$\gamma$	$\beta$	$\gamma$
Spilling(1/10)	5/2	0.48	2.18	0.75
Plunging(1/10)	5/2	0.78	2.12	1.23
H. Plunging(1/10)	5/2	0.76	2.63	0.63
Spilling(1/30)	5/2	0.50	2.82	0.30
Plunging(1/30)	5/2	0.62	2.64	0.51
H. Plunging(1/30)	5/2	0.54	3.44	0.16

$\gamma=2$  and  $\beta=5/2$  are derived for the linear long wave theory (Ishii,1990). Table 2 shows that  $\gamma$  is much smaller than 2, therefore the linear wave theory cannot be applied to evaluate the wave energy flux in the surf zone. However,  $\beta$  is between 2 and 3.5, and then it can be said that  $\beta=2.5$  is well approximated value. The value of  $\gamma$  changes according to breaker types and bottom slopes, and larger values of  $\gamma$  on steeper slope agree well with the foregoing studies.

3.4 Wave energy dissipation rate

Figure 16 shows variations of the nondimensional wave energy dissipation rate,  $\Phi/\Phi_{max}$  with  $X^*$ , where  $\Phi_{max}$  is the maximum value of wave energy dissipation rate. The wave energy dissipation rate  $\Phi$  is not constant, but it changes with  $X^*$ , depending on breaker types and the bottom slope.

In case of spilling breakers,  $\Phi$  is small at the inception of wave breaking, but it gradually increases and becomes maximum around  $X^*=0.8Xa$  ( $X^*=0.45$  for case 1-1 and  $X^*=0.8$  for case 2-1).

In the cases of plunging and heavy plunging breakers, different from spilling breakers, the wave energy dissipation rate  $\Phi$  becomes larger at the inception of wave breaking, and takes a maximum value around  $X^*=Xp$ . The wave energy dissipation rate  $\Phi$  becomes small in the range of  $X^*>Xa$ . As shown in Fig.16, rapid energy dissipation takes place in the order of spilling, plunging and heavy plunging breakers.

Fig.16 Variation of wave energy dissipation rate

3.5 Velocity of wave energy transport

Figure 17 shows two examples of variation of the non-dimensional velocity of wave energy transport  $C_e/C_{eb}$  with  $X^*$ , in which  $C_{eb}$  is the value of  $C_e$  at  $X^*=0$ , and  $C_e$  is defined with

$$C_e = F/E_T \quad (11).$$

The group velocity  $C_g$  and the wave celerity  $C$  given by Airy wave theory are also drawn as solid and dotted lines, respectively, for comparison.

$$C_g = \frac{1}{2} \left( 1 + \frac{2kh}{\sinh 2kh} \right) C \quad (12) \quad C = \frac{gL}{2\pi} \tanh \frac{2\pi h}{L} \quad (13)$$

The velocity of wave energy transport  $C_e$  is, in general, in good agreement with the group velocity  $C_g$  before wave breaking takes place, as shown in Fig.17. On the other hand, the velocity of energy transport  $C_e$  after breaking becomes smaller than the group velocity  $C_g$  and the difference between  $C_e$  and  $C_g$  becomes maximum around  $X^*=0.8X_a \sim X_a$ , in which the kinetic wave energy is much larger than the potential one, as already shown in Figs.10,11 and 12. This discrepancy of  $C_e$  from  $C_g$  is possibly caused by increasing of the offshore steady-velocity below the wave trough as in Fig.8.

The velocity of wave energy transport  $C_e$  is seen to close to the group velocity  $C_g$  in  $X^* > X_o$ , especially in the case of spilling breaker. Since the kinetic energy is almost equal to the potential one in  $X^* > X_o$ . It seems that wave energy is transported with the group velocity under the condition that the kinetic is almost equal to the potential one. The same facts are seen in other experimental cases such as case 1-1,1-2,1-3 and 2-2.

Fig.17 Relationship between  $C_e/C_{eb}$  and  $X^*$

4. CONCLUSION

The variation of the potential, kinetic and total wave energy after breaking has been discussed experimentally in relation to breaker types and bottom slopes. The main results obtained in this study are summarized as follows:

- (1) The kinetic wave energy is larger than the potential

one in the surf zone. The ratio of the kinetic wave energy to the potential one is changed according to breaker types and bottom slopes. The location of the deepest air-entrained depth  $X_a$ , plunging point  $X_p$ , and location of air bubble's disappearance from wave body  $X_o$  can be indexes to the ratio of the kinetic wave energy to the potential one, from macroscopic viewpoint.

(2) Some of the potential wave energy can be transferred to the kinetic one at an early stage of wave breaking in the spilling breaker. The splash and the horizontal roller play an important role to the transfer mechanism between the kinetic and potential wave energy in plunging and heavy plunging breakers.

(3) The attenuation of the kinetic, potential and total wave energy becomes larger in the order of spilling, plunging, heavy plunging breakers. The magnitude of the attenuation increases with steepening of the bottom slope.

(4) The most of wave energy are dissipated in the region between the breaking point and the location of air bubble's disappearance from wave body ( $X^*=X_o$ ).

(5) The wave energy dissipation rate increases in the order of spilling, plunging and heavy plunging breakers. The location at which the maximum wave energy dissipation rate takes place approaches the breaking point in the order of spilling, plunging and heavy plunging breakers.

## CHAPTER 25

### Modelling of Wave-Current Boundary Layer in the Coastal Zone

Leszek M. Kaczmarek & Rafał Ostrowski <sup>1</sup>

#### Abstract

A 2-D numerical model of bottom turbulent boundary layer is described. The nonlinear effects associated with wave asymmetry and the nonlinear interaction of waves and currents are taken into account. The model provides a relatively simple procedure for determination of both instantaneous and time-averaged quantities of velocity and friction inside the boundary layer.

#### 1 Introduction

The interaction of current and nonlinear waves is characteristic for a coastal zone behind and ahead of surf line because of the balance of wave asymmetry and effects bound with time-averaged current, called a return flow. Inter alia, it is possible that a time-averaged flow is offshore in the entire outer region while in the boundary layer, due to wave asymmetry, onshore flow occurs.

The problem of interaction of waves and currents will be dealt with in two regions: in a potential oscillatory flow with superimposed current and in a boundary layer, with the continuity laws satisfied at the interface of the two regions. The solution in the boundary layer is conditioned by the knowledge of the flow in the outer region.

The model takes into account nonlinear effects (i.e. wave asymmetry and those due to  $\overline{Uw_\infty}$ ). Two steps have been proposed:

- Step *I* — an iterative scheme providing the slip velocity, with  $\overline{Uw_\infty}$  term due to energy dissipation in the boundary layer
- Step *II* — a procedure yielding instantaneous and time-averaged velocity distributions in the boundary layer due to wave asymmetry.

## 2 Wave nonlinearity

### 2.1 Wave input asymmetry

Within nonlinear approximation the equation of motion in boundary layer has the form:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} = \frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} + \frac{\partial}{\partial z} \left( \nu_t \frac{\partial u}{\partial z} \right) \quad (1)$$

where  $u(z, t)$  i  $U(t)$  are the velocities inside and at the upper limit of boundary layer, respectively.

Assuming that the velocity  $u$  does not depend on a variable  $x$ , one may neglect the convective terms and simultaneously take the nonlinearity into account by expressing the velocities of bottom oscillations  $U(t)$  in potential motion by nonlinear Stokes approximation. In this way the *asymmetry* of wave with respect to still water level, defined according to the order of nonlinear approximation, is considered.

The linearized equation of motion (Eq. 1) in boundary layer reads:

$$\frac{\partial}{\partial t}(u - U) = \frac{1}{\rho} \frac{\partial \tau}{\partial z} \quad (2)$$

where  $\tau(z, t)$  is the shear stress and  $\rho$  is water density.

To define time distribution of bottom friction velocity  $u_f(t)$ , the assumptions of Fredsoe's model (1981) formulated for sinusoidal wave and the suggestion of Fredsoe, Andersen & Silberg (1985) concerning the possibility of adaptation of the model for nonlinear wave case have been employed.

Integrating Eq. 2 over the thickness of boundary layer  $\delta$  and assuming the logarithmic distribution of velocity one obtains the following differential equation:

$$\frac{dz_1}{d(\omega t)} = \frac{30\kappa^2 U(\omega t)}{k_s \omega e^{z_1}(z_1 - 1) + 1} - \frac{z_1(e^{z_1} - z_1 - 1)}{e^{z_1}(z_1 - 1) + 1} \frac{1}{U} \frac{dU}{d(\omega t)} \quad (3)$$

in which:

$$z_1 = \frac{U\kappa}{u_f} \quad (4)$$

and:

$$\delta = \frac{k_s}{30}(e^{z_1} - 1) \quad (5)$$

where  $k_s$  is Nikuradse roughness parameter and  $k_s/30$  is the theoretical bed level above  $z = 0$ .

It is necessary to point out that the solution of Eq. 3 bases on an assumption that the boundary layer develops anew every time the flow reverses. This implies the neglect of memory effects.

As a result of numerical solution of Eq. 3, the function  $z_1(t)$  is obtained and the temporal distributions of friction velocity  $u_f(t)$  and boundary layer thickness  $\delta(t)$  can be calculated thereafter on the basis of Equations 4 and 5.

The asymmetry of bottom velocity oscillations  $U(t)$  brings about non-uniform growth of boundary layer thickness in crest and trough phases, thus non-uniform friction.

The presented computational procedure permits the determination of the characteristics of bottom friction ( $\delta$  and  $u_f$ ) practically for any input  $U(t)$ .

Making use of the definition of friction velocity:

$$u_f = \sqrt{\frac{\tau}{\rho}} \quad (6)$$

one may determine the mean shear stress within wave period  $T$ :

$$\tau_c = \frac{1}{T} \int_0^T \rho |u_f(t)| u_f(t) dt \quad (7)$$

and the corresponding mean friction velocity:

$$u_{fc} = \sqrt{\frac{\tau_c}{\rho}} \quad (8)$$

On the basis of computations one finds out that the mean friction velocity for an arbitrary nonlinear input is a positive value although the resultant water velocity at the top of the boundary layer is zero. In the computations carried out for a typical nonlinear wave in small scale laboratory tests, represented by 2nd or 3rd Stokes approximation, the quantity  $u_{fc}^2$  has represented about 5% of the maximum shear stress  $u_{fmax}^2$ , where  $u_{fmax} = \max[u_f(t)]$ .

The non-zero mean shear stress reflects the existence of a certain resultant current inside boundary layer, directed accordingly to wave propagation.

All earlier attempts of *theoretical* description of the resultant current induced inside a boundary layer have led to the identification of wave-induced mass flux caused by the displacement in a boundary layer. The flux arises because a phase shift exists between the horizontal and vertical flow velocities at the top of the boundary layer in non-uniform water waves. This effect will be discussed in the next section.

## 2.2 Discussion of vertical momentum transfer induced by the energy dissipated in a wave boundary layer

The non-zero vertical velocity  $w$  in the boundary layer results from continuity equation in the solution of Longuet-Higgins (1953) for the laminar boundary layer. The existence of this velocity indicates that an additional mean (over wave period) shear stress  $\overline{uw}$  is generated inside the boundary layer. This stress attains the maximum value at the upper limit of the layer. It causes the disturbances in the region of potential flow, because there is no vertical momentum exchange represented by the term  $\overline{uw}$  in linear wave motion. The approach of Longuet-Higgins implies that the form of vertical velocity  $w$  induced by the vorticity depends on the linear solution of the equation of motion. Moreover, it can be easily shown that the shear stress induced outside the boundary layer is oriented in the direction of wave propagation and the velocity is smaller by one order of magnitude than its linear counterpart.

In the case of turbulent motion, the determination of the additional shear stress generated inside the boundary layer requires, as in laminar motion, the knowledge of the linear solution of Eq. 2. This solution depends on the distribution of eddy viscosity  $\nu_t$ .

Using the continuity equation and assuming:

$$\frac{\partial}{\partial x} = -\frac{1}{c} \frac{\partial}{\partial t} \tag{9}$$

where  $c$  is a phase velocity of wave, one may determine the additional vertical velocity  $w_\infty$  outside the boundary layer:

$$w_\infty = -\frac{\partial}{\partial x} \int_{\frac{k_s}{30}}^{\frac{k_s}{30} + \delta} (u - U) dz = \frac{1}{c} \int_{\frac{k_s}{30}}^{\frac{k_s}{30} + \delta} \frac{\partial}{\partial t} (u - U) dz \tag{10}$$

After taking into account Eq. 2 integrated over the boundary layer thickness, Eq. 10 transforms into the form:

$$w_\infty = -\frac{\tau_0}{c\rho} = -\frac{u_f |u_f|}{c} \tag{11}$$

The considerations of Deigaard & Fredsoe (1989) reveal that the nonlinearities bound with the generation of an additional vertical velocity  $w_\infty$  at the top of boundary layer i.e. the nonlinearities linked with the terms  $\overline{UW}$  are closely associated with the dissipation of wave energy. If the energy dissipation is neglected one may skip the additional stresses generated at the top of the boundary layer (the current induced by these stresses does not exist).

Finally it is worthwhile pointing out that the stress  $\overline{uw_\infty}$  equals zero at the bottom and reaches the maximum value at the top of boundary layer while the effects of wave asymmetry play the key role very close to the bottom.

The above conclusions will be helpful for formulation of a model in Section 3.

### 3 Wave and current interaction

Integrating Eq. 2 over the thickness of boundary layer in the similar manner as in Section 2.1 and assuming  $\tau(\delta) = -\rho u_{f0}^2$  and  $\tau_0 = \rho |u_f| u_f$ , cf. Fredsoe (1984), one obtains the following differential equation:

$$\frac{dz_1}{d(\omega t)} = \frac{30z_1^2 \left[ \left| \frac{\kappa U}{z_1} - u_{f0} \right| \left( \frac{\kappa U}{z_1} - u_{f0} \right) + u_{f0}^2 \right]}{\omega k_s U [e^{z_1}(z_1 - 1) + 1]} - \frac{z_1(e^{z_1} - z_1 - 1)}{e^{z_1}(z_1 - 1) + 1} \frac{1}{U} \frac{dU}{d(\omega t)} \tag{12}$$

in which:

$$z_1 = \frac{\kappa U}{u_f + u_{f0}} \tag{13}$$

and:

$$\delta = \frac{k_s}{30} (e^{z_1} - 1) \tag{14}$$

In Equation 12 the *nonlinear wave input*  $U(t)$  can be involved, given by any Stokes approximation (for instance of 2nd or 3rd order). Both the current friction velocity  $u_{f0}$  and the variable  $z_1$  are unknown. Therefore the use of iteration method in the first stage of solution is proposed.

Introducing the defect velocity  $u_d(z, t) = u(z, t) - U(t)$  one has the equation of motion (Eq. 2) in the form:

$$\frac{\partial u_d}{\partial t} = \frac{\partial}{\partial z} \left( \nu_t \frac{\partial u_d}{\partial z} \right) \quad (15)$$

The following approximate initial condition is assumed:

$$u_d(z, t_0) = 0 \quad (16)$$

and the boundary conditions are:

$$u_d\left(\frac{k_s}{30}, \omega t\right) = -U(\omega t) \quad (17)$$

$$u_d\left(2\delta_m + \frac{k_s}{30}, \omega t\right) = 0 \quad (18)$$

Eq. 15 is solved numerically by an implicit method involving the Crank – Nicholson scheme. Because the approximate initial condition (Eq. 16) has been assumed, the computations have had to cover the time corresponding to a few wave periods until the compatibility between  $u_d(z, t_0 + N \cdot T)$  and  $u_d[z, t_0 + (N + 1) \cdot T]$  is reached. The number of required runs  $N$  depends on wave parameters and is three to five.

Within the first stage of the solution, an interaction of a *sinusoidal* wave and the steady current is considered. A simple iterative procedure presented by Kaczmarek & Ostrowski (1991) ensures the determination of the current friction velocity  $u_{f0}$  by matching the mean shear stress at the top of boundary layer. Mean velocities are also matched at the upper limit of boundary layer: the slip velocity calculated from equations governing in the outer region and the mean velocity at the top of boundary layer (see Appendix).

Within the second stage of the solution, the temporal distribution of total friction velocity  $u_f$  is determined on the basis of Eq. 12 for the quantity  $u_{f0}$  computed previously and for nonlinear oscillatory input  $U(t)$ .

As a result of numerical solution of Eq. 12, the function  $z_1(\omega t)$  is obtained and the temporal distributions of friction velocity  $u_f(\omega t)$  and boundary layer thickness  $\delta(\omega t)$  are determined from Eqs. 13 and 14, respectively. Then one can easily calculate the root mean square friction velocity  $u_{fc}$  from Eqs. 7 and 8.

The following distribution of eddy viscosity  $\nu_t$  is assumed:

$$\begin{aligned} \nu_t(z) &= \kappa \hat{u}_f z & \text{for } \frac{k_s}{30} \leq z \leq \frac{\delta_m}{4} + \frac{k_s}{30} \\ \nu_t(z) &= \kappa \hat{u}_f \left( \frac{\delta_m}{4} + \frac{k_s}{30} \right) & \text{for } z > \frac{\delta_m}{4} + \frac{k_s}{30} \end{aligned} \quad (19)$$

Let us notice that the above distribution is based on the friction velocity  $\hat{u}_f$ , which couples the effects of a current and wave asymmetry (determined within the two-stage approach). The equivalent friction velocity  $\hat{u}_f$  has been assumed as:

$$\hat{u}_f = \max(|u_f(\omega t)|) \quad (20)$$

while the mean boundary layer thickness the authors propose to determine as:

$$\delta_m = \max(\delta_1, \delta_2) \tag{21}$$

where  $\delta_1$  and  $\delta_2$  are the boundary layer thicknesses at the moments corresponding to maximum and minimum total (oscillatory and current) input  $U(t) + V$ , respectively.

The equation of motion for the case of linear wave and current may be solved separately with separate boundary conditions. As it was pointed out by Kaczmarek & Ostrowski (1991), the assumption of time-independence of eddy viscosity  $\nu_t$  in the boundary layer allows one to treat the combined wave and current motion by separate equations. The effect of nonlinear interaction between waves and a current is incorporated in the eddy viscosity, thus modelling of the turbulent viscosity  $\nu_t$ .

Hence the determination of instantaneous velocities  $u(z, t)$  may be the sum of the solution of equation of motion for wave only with the oscillatory velocity at the top of boundary layer as a boundary condition and the current described by equations:

$$\kappa \hat{u}_f z \frac{\partial u_c}{\partial z} = u_{fc} |u_{fc}| \tag{22}$$

in the range  $< k_s/30; \delta_m/4 + k_s/30 >$  and

$$\kappa \hat{u}_f \left( \frac{\delta_m}{4} + \frac{k_s}{30} \right) \frac{\partial u_c}{\partial z} = u_{fc} |u_{fc}| \tag{23}$$

in the range  $(\delta_m/4 + k_s/30; \delta_m/2 + k_s/30 >$ .

The friction velocity  $u_f(\omega t)$ , the boundary layer thickness  $\delta(\omega t)$  and the root time-mean square friction velocity  $u_{fc}$  are determined from the solution of Equation 12.

Integrating Eqs. 22, 23 and taking advantage of the condition  $u_c(z = k_s/30) = 0$  and the condition of continuity of  $u_c$  at  $z = \delta_m/4 + k_s/30$  one comes up with the formulas:

$$u_c(z) = \frac{u_{fc} |u_{fc}|}{\kappa \hat{u}_f} \ln \frac{z}{\frac{k_s}{30}} \tag{24}$$

in the range  $< k_s/30; \delta_m/4 + k_s/30 >$  and

$$u_c(z) = \frac{u_{fc} |u_{fc}|}{\kappa \hat{u}_f \left( \frac{\delta_m}{4} + \frac{k_s}{30} \right)} \left( z - \frac{\delta_m}{4} - \frac{k_s}{30} \right) + \frac{u_{fc} |u_{fc}|}{\kappa \hat{u}_f} \ln \frac{\frac{\delta_m}{4} + \frac{k_s}{30}}{\frac{k_s}{30}} \tag{25}$$

in the range  $(\delta_m/4 + k_s/30; \delta_m/2 + k_s/30 >$ .

The nonlinear wave on a steady current is the most interesting case from a practical point of view, as the resultant shear stress direction controls the direction of the resultant flow in the combined boundary layer. Therefore the quantity  $u_{fc}$  is of a great importance: if it is positive, the effects of wave asymmetry will prevail and the mean flow in the wave-current boundary layer will be directed shorewards; if  $u_{fc}$  is negative, the steady current will prevail, and the resultant flow in the boundary layer will be directed seawards. For both situations the mean velocity profile can be calculated from of Eq. 24 in the range  $< k_s/30; \delta_m/4 + k_s/30 >$

Fig. 1. Mean current velocity distributions in boundary layer as a result of interaction between nonlinear (solid line) or sinusoidal (dashed line) waves and a current

and Eq. 25 in the range  $(\delta_m/4 + k_s/30; \delta_m/2 + k_s/30 >$  as in the case of nonlinear wave and current interaction the shear stress is assumed as constant in the range  $< k_s/30; \delta_m/2 + k_s/30 >$ . The choice of the upper limit where the shear stress is constant is rather arbitrary but it follows an assumption made with respect to wave boundary layer. The authors have proposed the upper limit of this region as the ordinate corresponding to the level at which the maximum (or minimum) velocity profile reaches the free stream velocity. In accordance with Jonsson & Carlsen (1976)  $\delta_m/2 + k_s/30$  is the most consistent measure. In the range  $(\delta_m/2 + k_s/30; 2\delta_m + k_s/30 >$  the mean velocity profile is assumed to change linearly upwards and to attain the value of slip velocity at the top of boundary layer. To analyse and distinguish the two major types of waves propagating against a current, sample computations have been carried out for the wave parameters corresponding to the laboratory experiment by Jonsson & Carlsen (1976):  $h = 10$  m,  $H = 5.3$  m,  $T = 8.39$  s. The wave has been approximated by Stokes theory of 2nd order. Additionally three currents of different slip velocities have been assumed:  $V = 0.20$  m/s,  $V = 0.35$  m/s and  $V = 0.70$  m/s. The resultant mean velocity distributions (solid line) in comparison with the profiles obtained for sinusoidal wave and current interaction (dashed line) are depicted in Fig. 1.

Having solved the equation of motion in boundary layer (Eq. 15) one may superimpose the instantaneous velocity profiles on the mean current distribution given by Eqs. 24 and 25 in the range  $< k_s/30; \delta_m/2 + k_s/30 >$ . In the range  $(\delta_m/2 + k_s/30; 2\delta_m + k_s/30 >$  the mean velocity profile changes linearly upwards and attains the value of slip velocity at the top of boundary layer. This mean current velocity is also superimposed on the instantaneous velocity distributions.

#### 4 Comparison between theory and measurements

##### 4.1 Velocity in wave-current bottom boundary layer

Results of computations have been compared with the laboratory measurements by Hwang & Lin (1990). The experiments were carried out in a  $9.5 \times 0.7 \times 0.3$  m wave tank in which the bottom was adjusted on one-fifteenth slope. The velocities

Fig. 2. Measured (●) and calculated (—) water surface elevation (left) and wave input (right)

of water were measured in 13 testing sections (including the boundary layer) situated along the flume. The comparison of computed data and measurements concern *Case 2* of experimental wave parameters: initial depth  $h = 0.33$  m, initial wave height  $H = 6.6$  cm, wave period  $T = 1.23$  s.

Although it is possible to provide a complex solution in the outer region using one of the models dealing with return flow and in the boundary layer using the present approach, it is well worth focusing attention on the precision of solution in the boundary layer, being a major topic of the paper. Therefore the value of the slip velocity  $V$  has been taken from the measurements of Hwung & Lin (1990) to obtain the best fit of the boundary condition at the upper limit of boundary layer.

The computed and measured instantaneous velocity profiles have been compared for the testing section *P4*. The water surface elevation  $\zeta(\omega t)$  and the wave input  $U(\omega t)$  have been determined by the theory of Borgman and Chappelair (Stokes approximation of 3rd order), Fig. 2. The assumed time distributions of  $\zeta(\omega t)$  and  $U(\omega t)$  have been a little bit shifted to obtain the best fit with respect to the recorded ones.

The instantaneous and mean velocity profiles have been computed using the procedure presented in the previous section. The parameter of equivalent roughness  $k_s$  has been estimated as 2 mm. The instantaneous velocities are given in Fig. 3. The agreement of computed and measured instantaneous velocity profiles is satisfactory, especially at the moments corresponding to the best fit between recorded and assumed wave inputs  $U(\omega t)$ .

The calculated mean velocity profiles for the testing sections *P1*, *P3*, *P4* and *P6* are given in Fig. 4. In general, they all correspond to the measured ones very

Fig. 3. Measured (●) and computed (—) instantaneous velocity distributions

well. As the testing section *P1* lies in the range of application of Stokes 2nd order theory, the velocity has also been determined with this approximation (dashed line).

#### 4.2 Undertow combined with a bottom boundary layer

The case of the wave propagating perpendicularly to the shoreline is considered. The oscillatory motion is accompanied by the undertow which compensates the mass flux carried shoreward by the breaking waves. The eddy viscosity model (Eqs. 19) in the bottom boundary layer is assumed. The eddy viscosity  $\nu_{tc}$  in outer region is assumed vertically constant. As shown by Svendsen (1984) the inclusion of a conceptually realistic depth-variation of  $\nu_{tc}$  has the effects of secondary importance when compared to the effects of incorporating alternative boundary conditions at the bottom.

The vertical distribution of the mean current velocity in the outer region  $U_c(z)$  may be estimated by the following formula, cf. Svendsen (1984):

$$U_c(z) = \frac{1}{2} \alpha (z+h)^2 + \left( 2 \frac{U_m - V}{d_{tr}} - \frac{1}{3} \alpha d_{tr} \right) (z+h) + V \quad (26)$$

in which

$$\alpha = \frac{\alpha_1(x)}{\nu_{tc}} \quad (27)$$

$$\alpha_1(x) = \frac{\partial}{\partial x} \left( \overline{u_w^2} + g\bar{\eta} \right) \quad (28)$$

where  $U_m$  is the total mean mass flux below the wave trough,  $d_{tr}$  is the distance between sea bottom and wave trough,  $\overline{u_w^2}$  is mean square oscillatory horizontal velocity,  $\bar{\eta}$  is the set-up and  $g$  is the acceleration of gravity. The coordinate system begins at mean water level in this case and  $z$  axis is directed upwards.

Fig. 4. Measured (●) and computed (-) mean velocity profiles at testing sections P1, P3, P4, P6

The derivative of Eq. 26 reads:

$$\frac{\partial U_c(z)}{\partial z} = \alpha (z + h) + \left( 2 \frac{U_m - V}{d_{tr}} - \frac{1}{3} \alpha d_{tr} \right) \tag{29}$$

The shear stress at the lower limit of the undertow region is given by the formula:

$$\tau_e = \rho \nu_{tc} \left. \frac{\partial U_c(z)}{\partial z} \right|_{z=-h} \tag{30}$$

Basically, the slip velocity  $V$  which corresponds to the one at the top of the boundary layer is unknown and that is the reason of iteration in our solution of the problem. The quantity  $V$  must match the mean velocity at the top of boundary layer as well as  $\tau_e$  must be equal to the mean shear stress at the top of boundary layer calculated on the basis of instantaneous velocity profiles from Eq. 15.

The comparisons between the measurements of Stive & Wind and Hansen & Svendsen experiments (Stive & Wind 1986) and the results obtained with the use of proposed method are shown in Figs. 5 and 6.

As it is seen the slip velocity obtained with the use of presented procedure does not differ much from that which would exist if an assumption was made of  $\tau_e(z = -h)$  equal zero. This confirms experimental observations of Stive & Wind (1986). The above conclusion is of great importance for calculating the undertow velocity distribution in practical use. Thus assuming  $\partial U_c(z)/\partial z|_{z=-h} = 0$  in Eq. 29 one obtains the simplified formula for slip velocity:

$$V = U_m - \frac{1}{6} \alpha d_{tr}^2 \tag{31}$$

Fig. 5. Measured and calculated undertow; tests by Stive & Wind (1986)

Fig. 6. Measured and calculated undertow; tests by Hansen & Svendsen (Svendsen 1984)

Fig. 7. The  $\overline{Uw_\infty}$  contribution to undertow profile

In the computations  $k_s$  was assumed as 1 mm for all sets of data after Svendsen & Hansen (1988).

It is worthwhile remembering that the  $\overline{UW}$  term originating from the organized orbital motion vanishes at the top of boundary layer, while the  $\overline{Uw_\infty}$  associated with the energy dissipated in a wave boundary layer possesses a certain value, cf. the discussion in section 2.2. It is interesting to evaluate the contribution of this term to the undertow distribution near the bottom. To this end the  $\overline{Uw_\infty}$  term has been estimated from Eq. 11 and incorporated in the iterative scheme by superposition with the undertow shear stress at the top of boundary layer. The effect of  $\overline{Uw_\infty}$  on the undertow distribution has been evaluated for one of the cases of Hansen & Svendsen's (1984) experiment and is depicted in Fig. 7 (solid line) in comparison with the undertow profile without this effect (dashed line). Additionally, the undertow distribution computed with the assumption of zero undertow shear stress at the top of boundary layer is given (dotted line). As one could have expected, the contribution of  $\overline{Uw_\infty}$  is very small and the proposed formula for slip velocity (Eq. 31) obtained with the assumption of zero undertow shear stress at the bottom is sufficient for practical engineering purposes.

## 5 Conclusions

The theoretical model describing both instantaneous and time-averaged quantities of velocity and friction inside the turbulent boundary layer generated by the interaction of nonlinear wave and current has been presented. The treatment of the paper is restricted to the two-dimensional flow, in which the intersection angle between the direction of wave propagation and that of the steady current is either  $0^\circ$  or  $180^\circ$ . The model takes into account nonlinear effects, i.e. wave asymmetry and the effects associated with  $\overline{Uw_\infty}$ .

The results of computations of velocities inside the boundary layer under nonlinear wave and current have been compared with the laboratory data of Hwung

& Lin's (1990) experiment. The agreement of computed and measured, both instantaneous and mean, velocity profiles is satisfactory.

The effect of  $\overline{U}w_\infty$  (associated with energy dissipation in the wave boundary layer) on the undertow distribution has been evaluated for one of the cases of Hansen & Svendsen's (1984) experiment. The contribution of this term has been found out to be very small. This implies that the proposed formula for slip velocity obtained with the assumption of zero undertow shear stress at the bottom is sufficient for practical engineering purposes.

## CHAPTER 26

### Spectral Evolution of Directional Finite Amplitude Dispersive Waves in Shallow Water

James M. Kaihatu and James T. Kirby <sup>1</sup>

#### Abstract

Two different aspects of nearshore wave modelling are discussed. The first section details a model valid in deeper water than the usual shallow water wave models. We derive a mild-slope equation in which nonlinearity is retained to second order in  $\epsilon$  and dispersion is retained to all orders. The resulting parabolic model is then simplified for expedient calculation. This simplified model is compared to the data of Whalin (1971) with favorable results. The second section concerns the role of vector-sum interactions as compared to colinear, near-resonant interactions. We use the angular spectrum model of Kirby (1990) to determine which sort of interaction is dominant in the nearshore wavefield. A steady wave solution of the model and a case of unsteady wave evolution were investigated. Two simplified data sets with different amounts of directional spread were then run through the model. All three tests indicate that vector-sum interactions contribute significantly to wave field evolution.

#### Introduction

A number of frequency-domain models of nearshore wave evolution have appeared in the literature. Many of these models are based on the Boussinesq equations of Peregrine (1967) or closely-related variants; examples include Freilich and Guza (1984) and Liu, et.al. (1985). All these models calculate the wavefield in the frequency domain by factoring out the time periodicity of each frequency component, and treat the nonlinear terms in the governing equations by three-wave resonant interaction theory, making explicit the energy exchange between frequencies. Directional characteristics of the wavefield, if considered at all, are usually treated by the parabolic approximation (see Liu, et.al. (1985) for an example of this).

This paper is divided into two parts. The first part contains the development of a finite-depth spectral evolution model which can be used in deeper water than the Boussinesq-type models. A slightly simplified version of this model is compared to data, and the

---

<sup>1</sup>Center for Applied Coastal Research, Department of Civil Engineering, University of Delaware, Newark, DE 19716

effect of the simplification discussed. The second part of the paper details an investigation of directional spectral interaction. Specifically, we use the angular spectrum model of Kirby (1990) to determine whether detuned vector-sum interactions are as important in the wavefield as resonant (or near-resonant) colinear interactions.

## Finite Depth Evolution Model

Spectral models based on the Boussinesq equations (Peregrine (1967)) have existed for some time (Friedrich and Guza (1984); Liu, et.al. (1985)). They work well within their range of validity ( $kh \ll 1$ , where  $k$  is the wavenumber and  $h$  the water depth). However, the shoaling mechanism for these models in their lowest-order variants is Green's Law:

$$\frac{A}{A_0} = \left(\frac{h}{h_0}\right)^{\frac{1}{2}} \quad (1)$$

which overpredicts the shoaling of higher-frequency spectral components. Some dispersiveness has been added to the shoaling terms of Boussinesq-type models (e.g., the "dispersive shoaling model" of Friedrich and Guza (1984); Madsen, et.al. (1992)). This added dispersiveness is of at most  $O(kh)^2$ , and is thus only a small correction to the shoaling term.

## Theoretical Formulation

In this paper we seek a model which is valid for all orders of  $kh$ , and retain terms to  $O(\epsilon^2)$ , where  $\epsilon$  is the ratio of wave amplitude to water depth. The derivation follows the method of Bryant (1973, 1974). A similar model, but truncated to two components, was detailed by Keller (1988).

We begin from the boundary value problem:

Governing equation ( $-h < z < 0$ ):

$$\nabla^2 \phi = 0 \quad (2)$$

Combined free surface boundary condition (to  $O(\epsilon^2)$ ) at  $z = 0$ :

$$\phi_z = -\frac{1}{g} \left( \phi_{tt} + \frac{1}{2} (\nabla_h \phi)_t^2 + \frac{1}{2} (\phi_z)_t^2 - \frac{1}{2g} (\phi_t)_{zt}^2 + \nabla_h \cdot (\phi_t \nabla_h \phi) \right) \quad (3)$$

Bottom boundary condition at  $z = -h$ :

$$\phi_z = -\nabla_h h \cdot \nabla_h \phi \quad (4)$$

We then assume the solution for  $\phi$  in terms of a superposition of components:

$$\phi = \sum_{n=1} f_n(k_n, h, z) \bar{\phi}_n(x, y, k_n, \omega_n, t) \quad (5)$$

where the  $f_n$  are the depth dependencies for each mode:

$$f_n = \frac{\cosh k_n(h+z)}{\cosh k_n h} \tag{6}$$

and the  $k_n$  are found using the linear dispersion relation:

$$\omega_n^2 = g k_n \tanh k_n h \tag{7}$$

Following the method of Smith and Sprinks (1975), we obtain the following mild-slope equation modified by nonlinearity:

$$\begin{aligned} \ddot{\phi}_{tt} - \nabla_h \cdot ((CC_g)_n \nabla_h \ddot{\phi}_n) + \omega_n^2 \left(1 - \frac{C_{gn}}{C_n}\right) \ddot{\phi}_n = \\ \frac{1}{2} \left( \sum_l \sum_m \left[ \frac{\omega_l^2 + \omega_m^2}{g^2} (\ddot{\phi}_l \ddot{\phi}_{m,t})_t - \frac{\omega_l^2 \omega_m^2}{g^2} (\ddot{\phi}_l \ddot{\phi}_m)_t \right] \right. \\ \left. - \sum_l \sum_m \left[ (\nabla_h \ddot{\phi}_l \cdot \nabla_h \ddot{\phi}_m)_t + \nabla_h \cdot (\ddot{\phi}_l \nabla_h \ddot{\phi}_m) + \nabla_h \cdot (\ddot{\phi}_{m,t} \nabla_h \ddot{\phi}_l) \right] \right)_n \end{aligned} \tag{8}$$

where the  $l$ ,  $m$  and  $n$  are related according to three-wave interaction conditions. Introducing time periodicity and slow  $x$ -variation in amplitude:

$$\ddot{\phi} = \frac{-ig}{2\omega_n} A_n e^{i(\int k_n dx - n\omega t)} + \frac{ig}{2\omega_n} A_n^* e^{-i(\int k_n dx - n\omega t)} \tag{9}$$

yields an elliptic equation for the evolution of the complex amplitude  $A_n$ . Using the parabolic approximation:

$$((CC_g)_n A_{n,x})_x \ll 2i(kCC_g)_n A_{n,x} \tag{10}$$

and making use of a reference phase function (Kirby and Dalrymple (1983)) to redress the lack of phase dependence on  $y$ ,

$$A_n = a_n e^{(\int k_{n_o}(x) dx - \int k_n(x) dx)} \tag{11}$$

where  $k_{n_o}(x)$  is a  $y$ -averaged wavenumber, gives us:

$$\begin{aligned} 2i(kCC_g)_n a_{n,x} - 2(kCC_g)_n (k_{n_o} - k_n) a_n + i(kCC_g)_{n,x} a_n + ((CC_g)_n (a_n)_y)_y = \\ \frac{1}{4} \left( \sum_{l=1}^{n-1} R(\omega_n, \omega_{n-l}, -\omega_l, k_{n-l}, k_l) a_l a_{n-l} e^{i(\int k_{l_o}(x) + k_{n-l_o}(x) - k_{n_o}(x) dx)} + \right. \\ \left. 2 \sum_{l=1}^{N-n} R(\omega_n, \omega_{n+l}, \omega_l, k_l, k_{n+l}) a_l^* a_{n+l} e^{i(\int k_{n+l_o}(x) - k_{l_o}(x) - k_{n_o}(x) dx)} \right)_n \end{aligned} \tag{12}$$

where:

$$R(\omega_n, \omega_{n+l}, \omega_l, k_l, k_{n+l}) = \frac{g}{\omega_l \omega_{n+l}} (\omega_n^2 k_l k_{n+l} + (k_{n+l} - k_l)(\omega_{n+l} k_l + \omega_l k_{n+l}) \omega_n) - \frac{\omega_n^2}{g} (\omega_l^2 - \omega_l \omega_{n+l} + \omega_{n+l}^2) \quad (13)$$

and all wavenumbers are calculated from full linear theory. Preliminary testing of (12) has demonstrated that the interaction coefficients  $R$  require a large amount of computer time to calculate. Thus we simplified the model somewhat by taking the coefficients to the shallow-water limit (Ukai, et.al. (1990); Abreau, et.al. (1992); Mase and Kirby (1992)), and using the shallow water wavenumber as the reference phase function in (11). Thus we obtain:

$$2i(kCC_g)_n a_{nx} - 2(kCC_g)_n (k'_{no} - k_n) a_n + i(kCC_g)_{nx} a_n + ((CC_g)_n (a_n)_y)_y = \frac{3gn^2 k_1'^2}{4} \left( \sum_{l=1}^{n-1} a_l a_{n-l} + 2 \sum_{l=1}^{N-n} a_l^* a_{n+l} \right)_n \quad (14)$$

where  $k'_n = \frac{n\omega}{(gh)^{\frac{1}{2}}}$ .

### Comparison to Data

To see whether this simplification causes any loss of accuracy, one-dimensional versions of (12) and (14) were compared to flume data from Mase and Kirby (1992); the reader is referred to their paper for details on the experiment. Experimental results for Case 1 are compared to the two one-dimensional models at a depth  $h = 15cm$  (Figure 1), and it is apparent that, save for some slight deviation at the tail of the spectrum, both models compare equally well to the data. However, (14) required roughly 12 percent of the computing time of (12). This indicates that retaining full dispersion in the shoaling terms is the dominant improvement of these models over the Boussinesq equations, and that little is lost in simplifying the nonlinear coefficients as we have done here. The one-dimensional version of (14) is equivalent to that of Mase and Kirby (1992), except for a different dispersion term. Kaihatu and Kirby (1991) have shown that (12) fits experimental shoaling data better than the "consistent model" of Freilich and Guza (1984), particularly in the higher frequency ranges.

We use the data of Whalin (1971) to verify the two-dimensional model equation (14). This particular data set has been used on numerous occasions to evaluate numerical models (e.g. Liu, et.al. (1985); Rygg (1988); Madsen, et.al. (1992)). The experiment consisted of a long channel with bathymetry resembling a cylinder tilted along its longitudinal axis; the experimental layout is shown in Figure 2. Sinusoidal waves of one, two and three second periods were generated at three different amplitudes for each period; higher harmonics were allowed to grow from zero amplitude. The amplitudes of the first

Figure 2: Topography of Whalin's (1971) experiment. From Liu, et.al. (1985)

three Fourier components were recorded along the centerline of the channel.

In this study we used the 3 second case for model-data comparison. This was done to facilitate a fair comparison between (14) and the Kadomstev-Petviashvili (KP) model of Liu, et.al. (1985). The KP model is essentially a lowest-order parabolic Boussinesq model, with a non-dispersive shoaling term and frequency dispersion retained up to  $O(kh)^2$ . Figures 3(a,b,c) show the Fourier amplitudes of the models compared to data along the centerline of the tank. For the most part the present model performs better than the KP model, especially in reproducing the higher harmonics. This is possibly due to the improved dispersion characteristic of the present model, where each mode is shoaled using full linear theory.

## Discussion

To conclude this section, it appears that the simplified fully-dispersive model (14) performs well in both combined refraction-diffraction and in pure shoaling. One drawback of the model is the lowest-order parabolic formulation. This not only restricts the model to small angle of incidence, also gives equal weight to all interactions no matter the direction of approach. This can be remedied by using the angular spectrum approach (Kirby (1990)), as explained in greater detail in the next section.

## Directional Spectra

This section of the paper discusses the role of directional spectral interaction in an evolving wave field. Specifically, we wish to address two recently-published viewpoints concerning whether detuned, vector-sum interactions play as large a role in the evolution of nearshore waves as near-resonant, colinear interactions. Vector-sum interactions place the energy exchanged between two spectral components approaching at different directions at the sum frequency and the vector-sum-wavenumber direction, while the colinear interactions only take place between components travelling in the same direction. This sort of interaction is seemingly stronger, since the two interacting components are very nearly in resonance. However, Freilich, Guza and Elgar (1990, hereafter referred to as FGE) maintain that vector-sum interactions may be as important as colinear interactions, especially when the interactions come from very energetic spectral peaks approaching at different directions. They used field data taken at Torrey Pines Beach, California, where directional arrays were placed at 10m and 4m water depth. Figure 4 is taken from their paper, and shows a contoured frequency-direction plot of waves at the 4m depth. Freilich, et.al. contended that the spectral peak located at  $(0.06Hz, -4^\circ$  from beach normal, marked "A"), interacted with the peak at  $(0.10Hz, +10^\circ$  from beach normal, marked "B"), to produce a peak at  $0.16Hz$  approaching at a direction that was within one degree of the vector-sum wavenumber direction (marked "C").

In direct opposition to this, Abreau, et.al. (1992) argue that only resonant colinear interactions are important. They formulated a collision integral to obtain a wave Boltzmann equation where only colinear interactions were allowed. They compared their results to the data of Freilich, et. al. (1990), and demonstrated qualitatively good agreement. Abreau, et.al. stated that the peak at  $f = 0.16Hz$  in the field data was not due to noncolinear interaction between highly energetic peaks as stated by FGE, but rather to near-resonant, colinear interactions between significantly less energetic

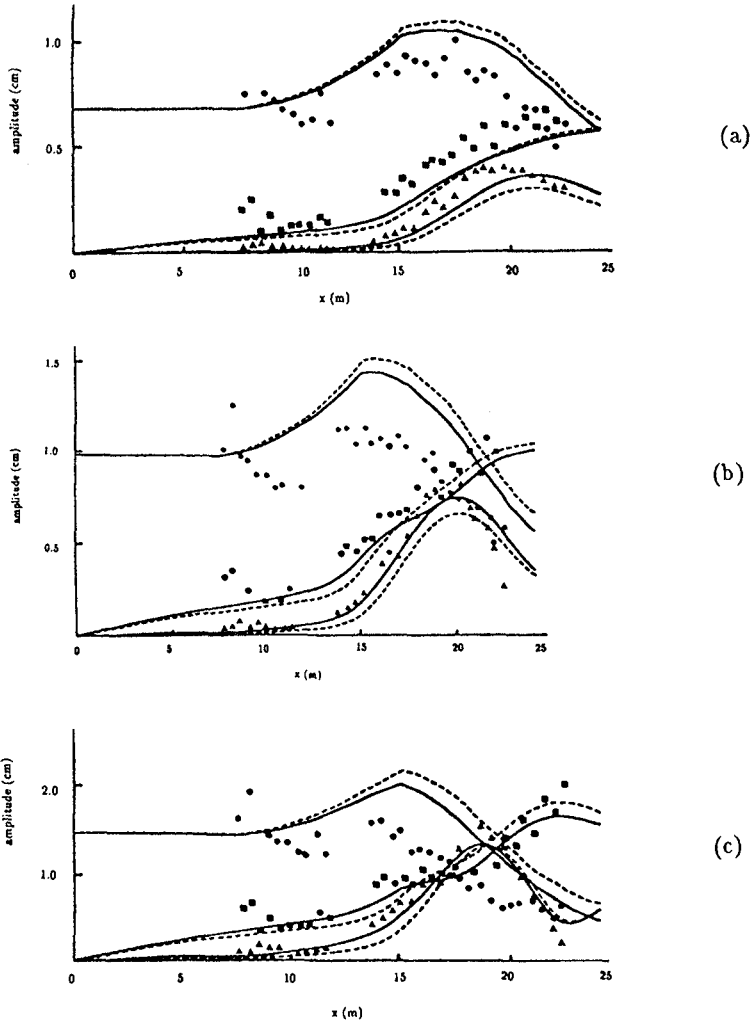

Figure 3: Comparison of equation (14) and KP model of Liu, et. al. (1985) to data of Whalin (1971) along centerline of tank. Solid line is equation (14), dashed line is KP model, and discrete points are data: dots are first harmonic Fourier amplitudes, squares are second harmonic amplitudes and triangles are third harmonic amplitudes. (a):  $a_0 = 0.68\text{cm}$ , (b):  $a_0 = 0.98\text{cm}$ , and (c):  $a_0 = 1.46\text{cm}$

components of the two directional spectra. They stated that this interaction occurred because of the directional overlap between the two spectra in deep water.

### Angular Spectrum Boussinesq Model

We wish to ascertain whether the vector-sum interactions are as important as the colinear interactions in wavefield evolution. The Boussinesq equation is used to serve as the diagnostic tool. We have three options concerning the form of the Boussinesq model used: a time-dependent model, a parabolic model and an angular spectrum model. The time-dependent formulation (e.g., Wu and Wu (1982)) treats both the resonant and non-resonant interactions in a non-explicit manner, making it difficult to discern between them. Parabolic models (e.g., Liu, et.al. (1985)) are not helpful in this situation since they treat nonlinear interactions with equal weight regardless of direction. Thus we use the angular spectrum model of Kirby (1990).

The angular spectrum approach consists of decomposing the governing equation into  $2M + 1$  components of the longshore wavenumber  $\lambda (= k \sin \theta)$  as well as  $N$  components of the frequency  $\omega$ . Thus the free surface elevation, for instance, can be written as:

$$\eta_n(x, y, t) = \sum_{n=1}^N \sum_{m=-M}^M A_n^m(x) e^{i(n \int k \tilde{\gamma}_n^m dx + m \lambda_0 y - n \omega t)} + c.c. \quad (15)$$

where :

$$\tilde{\gamma}_n^m = \left(1 - \left(\frac{m}{n}\right)^2 \left(\frac{\lambda_0}{k}\right)^2\right)^{1/2} \quad (16)$$

In contrast to the parabolic approach, where  $N$  coupled partial differential equations

Figure 5: Steady-wave solution of angular spectrum Boussinesq model. Solid lines are amplitudes of vector-sum components, dashed lines are amplitudes of colinear second harmonics.

were solved, the angular spectrum approach computes  $N \times (2M + 1)$  ordinary differential equations. Further details of the derivation of the angular spectrum Boussinesq model can be found in Kirby (1990), along with the governing equations.

We have used the model in two preliminary investigations to determine the relative strength of the vector-sum interaction. For the case of a steady wave field, we generated permanent form solutions using five amplitudes: two primary harmonics of equal amplitude separated by an angle  $2\theta$ , two second harmonics travelling in the same direction as their respective primary harmonics, and one component at the sum frequency and moving at the vector-sum direction. Figure 5 shows a comparison of vector-sum amplitudes to those of the in-line second harmonic for permanent-form solutions and for several values of  $\theta$  and  $\epsilon$ . It is apparent that the vector-sum harmonic amplitude is larger than that of the in-line second harmonic for  $\theta$  up to  $25^\circ$ . This corresponds to a separation angle of  $50^\circ$  between primary components, much larger than the  $14^\circ$  separation between the spectral peaks in the field data of FGE. We also used the model to investigate unsteady wave evolution. We created an initial condition for the model using the same five components as the steady wave example, but the higher harmonics were given zero amplitude. This condition was then run through the model. Figure 6 shows a comparison of the primary amplitude to the vector-sum harmonic and the in-line second harmonic amplitudes. We see that the vector-sum amplitude dominates the in-line second harmonic for much of the domain. We also see evidence of recurrence, whereby the system evolves back into its original state. Recurrence has been shown to be unstable to broad-banded noise (Elgar, et.al. (1990)), so results of this analysis is only moderately applicable to events in the ocean. However, these two investigations do show that vector-sum interactions make non-negligible contributions to wave field evolution.

Figure 6: Recurrence test of angular spectrum Boussinesq model for  $\epsilon = 0.1$ ,  $(kh)^2 = 0.36$ ,  $\theta = 10^\circ$ . Solid line is amplitude of primary harmonic, short dashed line is amplitude of vector-sum component, and long-dashed line is amplitude of colinear second harmonic.

## Results

We at first considered using the model directly on the field data, after the appropriate re-mapping into  $(f, \lambda)$  space. We encountered some difficulty in doing so, primarily due to the random-phase assignments to the components of the field data. This attempt is continuing; however, its successful completion would not demonstrate how vector-sum interactions contribute to wave field evolution. This is because the two directional spectra of FGE overlap in direction, making it difficult to determine whether energy at the sum frequency originated from vector-sum interaction at the two peaks or from colinear interaction by directionally overlapped components.

We then decided to create an artificial wave field, one which would demonstrate the importance of vector-sum interactions for both non-overlapping and overlapping spectra but with fewer components. Two cases, both with the same total variance, were considered: one with two non-overlapping spectra, and one where two spectra overlap in direction. Figure 7a shows two spectra in  $(f, \lambda)$  space, each consisting of one frequency component and six longshore wavenumber components. The frequencies and peak  $\lambda$  chosen correspond to the frequencies and directions of the spectral peaks in FGE. This condition was run through (17) using the same bathymetry as FGE. The result at 4m water depth is shown in Figure 7b. The in-line second harmonic for the  $0.06Hz$  peak (marked "A"), the in-line third harmonic for the same peak (marked "B"), the in-line second harmonic for the  $0.10Hz$  peak (marked "C"), and the vector-sum peak (marked "D") and vector-difference peak (marked "E") have all been generated by nonlinear interaction. It is clear that the vector-sum peak is of the same order of magnitude as the in-line second harmonic of the  $0.06Hz$  spectral peak.

The second case is shown in Figure 8a. Two directional spectra with only one frequency component each are positioned at the same frequencies as the first case, but the number of  $\lambda$  components was increased to 20 to allow directional overlap. The result of the

calculation is shown in Figure 8b. Here we see very little energy at the vector-sum peak (marked "D"). Energy in this location was generated by detuned interactions between the spectral peaks, and by colinear interactions between the overlapping components. It is apparent that the colinear interactions between the less-energetic directionally overlapping components did not transfer as much energy to peak "D" as noncolinear detuned interactions between two more energetic spectral peaks did in the non-overlapping case. This shows that, for these cases, the vector-sum detuned interactions are responsible for a significant part of nonlinear energy transfer.

## Discussion

In this section we used the angular-spectrum Boussinesq model of Kirby (1990) to show that vector-sum detuned interactions play an important role in nonlinear energy transfer. This is shown in the two preliminary investigations of steady and unsteady wave evolution discussed herein. Actual input of the field data to the model has proved to be problematic, so we used two simplified wave fields. These simplified wave fields retain much of the character of the actual field data with fewer components. The results show that the vector-sum interactions can be as prominent in wavefield evolution as the colinear interactions. Model investigations using field data, however, are continuing.

It can be argued that the field data of FGE was actually in deeper water than is valid for lowest-order Boussinesq theory. Therefore, future work will focus on the use of a more dispersive Boussinesq-type model than that of Kirby (1990). This model will be similarly cast in the angular-spectrum format. Additional work will also include the use of a directional bispectrum, which is derivable from the model equation. This will allow us to investigate the strength of the different interactions.

## CHAPTER 27

### AN ADDITIONAL PARAMETER FOR THE ZERO CROSSING WAVE DEFINITION AND ITS PROBABILITY DISTRIBUTION

by A. Kimura<sup>1</sup> and T. Ohta<sup>2</sup>

#### ABSTRACT

In this paper, the distance from the mid point between a wave trough and a consecutive wave crest of a zero-crossing wave (a position of wave height bisection) to the still water level is proposed to be an important zero-crossing wave property. Its roles on certain physical properties of the zero-crossing waves are shown through experimental data in the first part of the paper. Its probability distribution is introduced, in the second part, from the combined probability distribution of the amplitudes of consecutive wave trough and crest of irregular waves. In the last part, the theoretical probability distribution for this property is verified with numerically simulated data for many types of wave spectra.

#### 1. INTRODUCTION

The zero-crossing method has been used to split the irregular wave profile into zero-crossing waves. The overall physical property of irregular waves is evaluated by connecting the relevant physical properties of individual waves and the probability of wave heights and periods. For example, the probability distribution of random wave forces (Kimura et al., 1983) is given as

$$p(f) df = \int_S p(H, T) dHdT \quad (1)$$

$p(H, T)$  is the combined distribution of wave height  $H$  and period  $T$ .  $S$  is the region in which

$$f \leq g(H, T) \leq f + df \quad (2)$$

where  $g(H, T)$  gives the wave force  $f$  of a periodic wave for the wave with  $H$  and  $T$ .

1 Prof., Dept. of Social Systems Eng., Faculty of Eng., Tottori Univ., 4-101 Koyama Minami, Tottori, Japan

2 Research Associate, Dept. of Social Systems Eng., Faculty of Eng., Tottori Univ., 4-101 Koyama Minami, Tottori, Japan

The physical properties of the zero-crossing wave are approximated usually by those of a periodic wave with the same wave height and period. The draw back of this method, some times, is that the two properties H and T are not sufficient to express the overall physical wave properties, since the measured and calculated probabilities have shown apparent differences in some physical properties. Therefore some studies have tried to apply supplemental wave properties such as slope of the fore-side face of waves in the examination of wave breaking (Holthuijsen and Herbers, 1986, for example). Among these, important parameters which may affect the physical properties of the zero-crossing wave are listed by the PIANC working group (list of sea state parameters; 1987). The parameter proposed in this study is not involved in the list but may exert an important effect on the waves in a shallow water region. That is a position of wave height bisection (mean position between the wave crest and trough of a zero-crossing wave).

Two waves in Fig.1 have the same wave height and period but different crest heights. In the ordinary definition, these two waves are recognized as having the same property. Figure 2(a) shows the wave height at the breaking point on 1/20 slope (Scyama et al., 1988). H,  $L_0$  and h are the wave height, deep water wave length and still water depth. Subscript b shows the value measured at the breaking points. The same data ( $H/H_b$ ) are plotted against  $h^*$  in Fig.2(b) instead of h, in which  $h^*$  is the distance from the bottom to the center between wave crest and trough (Fig.1). The scattering of data in Fig.2(a) reduces very much in this figure, therefore,  $h^*$  works more effectively as a water depth than h. This  $h^*$  is given by the sum of the still water depth h and the distance d from the still water level to the position of wave height bisection (PWHB; Fig.1). In the next section, the probability distribution for d is introduced theoretically and the result is verified through numerically simulated irregular waves.

2. The definition of d and its characteristics

2.1 Definition

The distance d from the mean water level to PWHB is given by

$$d = (\eta_1 - \eta_2) / 2 \tag{3}$$

in which  $\eta_1$  and  $\eta_2$  are the amplitudes of the wave trough and the consecutive wave crest, respectively. From a definition of the zero-crossing wave, we got  $-H/2 < d < H/2$ .

2.2 Characteristics of d

The numerically simulated values of d are shown first. The FFT method is used to calculate irregular wave profiles for the Wallops type wave spectrum which is given by

$$S(f) = (f/f_p)^{-m} \exp \left[ m/4 \left\{ 1 - (f/f_p)^{-4} \right\} \right] \tag{4}$$

where  $f_p$  is 1.0Hz and the interval of the calculated wave profile,  $\Delta t$  is 0.05s. in the numerical simulations. The 7 different values for the shape parameter m (4, 5, 6, 8, 10, 15, 20) in eq.(4) are used in the calculations. The zero-down-cross method is applied in the irregular wave definition. d is calculated applying eq.(3) for each wave. Figures 3 (a), (b) and (c) show the calculated relations between d/H and  $H/H_m$  ( $H_m$  is the mean wave height) for three values of m (5, 10, 20) in this order. While the spectrum is wide (m=5) d/H distributes up to its limit (-H/2, H/2) where  $H/H_m$

Fig. 1 Zero down cross waves with common H and T

Fig. 2(a) Breaking limit

Fig. 2(b) Breaking limit (modified water depth)

<1.0. However the fluctuation decreases at the larger values of  $H/H_m$ . When  $m$  is large ((b),(c)) the fluctuation decreases except for the very small wave height region. From these, the larger the wave height or the narrower the wave spectrum, the more zero-down-cross waves tend to have symmetric profiles.

3. The probability distribution of  $d$

3.1 Two-dimensional Rayleigh distribution

As shown in eq.(3),  $d$  is half the difference between  $\eta_1$  and  $\eta_2$ . If these two values are independent (no correlation), the probability distribution for  $d$  is easily given as

Fig. 3 Distribution of  $d/H$

$$p(d) = \int p\left(\frac{h_1}{2} + d\right) p\left(\frac{h_1}{2}\right) dh_1 \quad (5)$$

where  $p(\cdot)$  is the probability distribution. The time interval between consecutive wave trough and crest is about half the mean wave period on the average. Two values on the wave profile with such a distance inevitably have a correlation. Therefore, this correlation property has to be taken into account when the probability distribution for  $d$  is considered. However the theoretical probability distribution of  $\eta_i$  ( $i=1,2$ ) has not yet been determined. The amplitude of the envelope for the wave profile at the same position of  $\eta_i$  has been used instead (Tayfun et al., 1989) with an error of order  $\nu$  in the noise theory, where  $\nu$  is given by

$$\nu = (m_0 m_2 / m_1^2 - 1)^2 \quad (6)$$

and

$$m_n = \int_0^\infty f^n S(f) df \quad (7)$$

in which  $S(f)$  is the power spectrum of waves.

The present study also used the above approximation. Since the theoretical probability distribution for envelopes is the Rayleigh distribution (Rice, 1945), the combined distribution for  $\eta_1$  and  $\eta_2$  is given by the 2-dimensional Rayleigh distribution (no non-linearity of the wave is considered in the present study). Expressing the amplitudes of wave envelopes at the position of  $\eta_1$  and  $\eta_2$  as  $A_1$  and  $A_2$  respectively, Eq.(3) is approximately expressed as,

$$d = (A_1 - A_2) / 2 \quad (8)$$

The probability distribution for the normalized amplitude  $\xi_i = A_i / A_m$  ( $i=1,2$ ), where  $A_m$  is a mean amplitude, is the Rayleigh distribution.

$$p(\xi_i) = \frac{\pi}{2} \xi_i \exp\left[-\frac{\pi \xi_i^2}{4}\right] \quad (9)$$

The combined probability distribution of the numerically simulated  $\xi_1$  and  $\xi_2$  agrees well with the 2-dimensional Rayleigh distribution,

$$p(\xi_1, \xi_2) = \frac{\pi^2 \xi_1 \xi_2}{4(1-\kappa^2)} \exp\left[-\frac{\pi^2(\xi_1^2 + \xi_2^2)}{4(1-\kappa^2)}\right] I_0\left[\frac{\pi \kappa \xi_1 \xi_2}{2(1-\kappa^2)}\right] \quad (10)$$

in which  $I_0$  is the 0-th order modified Bessel function of the first kind, and  $\kappa$  is the correlation parameter which is calculated as follows,

$$\kappa = \sqrt{(\rho^2 + \lambda^2)} / m_0 \quad (11)$$

where

$$\rho = \int_0^\infty S(f) \cos 2\pi(f - \bar{f}) \frac{1}{2} df$$

$$\lambda = \int_0^\infty S(f) \sin 2\pi(f - \bar{f}) \frac{1}{2} df$$

$$\bar{f} = m_1 / m_0 \tag{12}$$

$t/2$  is the time interval between  $A_1$  and  $A_2$ .  $T_m/2$  is used for this interval in this study where  $T_m$  is the mean wave period. This parameter is explained briefly in 3.3.

Figure 4 shows the comparison between numerically simulated combined frequency distributions of  $\xi_1$  and  $\xi_2$  and eq.(10) (solid line). The values for  $m$  in eq.(4) is (a) 5, (b) 10, and (c) 20 respectively. When  $m=5$  the spectrum is that for a fully developed sea condition. Excellent agreements are obtained for all cases.

3.2 The probability distribution of  $d$

Since  $A_1$  and  $A_2$  are amplitudes of the envelope at the consecutive wave trough  $\xi_1$  and crest  $\xi_2$ , the wave height is given approximately as,

$$H = A_1 + A_2 \tag{13}$$

Both sides of eq.(13) are divided by  $H_m (=2A_m, A_m$ ; mean amplitude of the envelope) to normalize,

$$\zeta = (\xi_1 + \xi_2) / 2 \tag{14}$$

in which  $\xi_i / 2 = A_i / H_m (i=1,2)$  and  $\zeta = H / H_m$

From eq.(14),

$$\xi_2 = 2\zeta - \xi_1 \tag{15}$$

Substituting eq.(15) into eq.(10), the combined distribution of  $\xi_1$  and  $\zeta$  is obtained.

$$p(\xi_1, \zeta) = \frac{\pi^2 \xi_1 (2\zeta - \xi_1)}{2(1 - \kappa^2)} \exp \left[ -\frac{\pi^2 \left\{ \xi_1^2 + (2\zeta - \xi_1)^2 \right\}}{4(1 - \kappa^2)} \right] I_0 \left[ \frac{\pi \kappa \xi_1 (2\zeta - \xi_1)}{2(1 - \kappa^2)} \right] \tag{16}$$

Integration of eq.(16) brings the probability distribution for  $\zeta$

$$p(\zeta) = \int_0^{2\zeta} p(\xi_1, \zeta) d\xi_1 \tag{17}$$

Since the analytical expression of this integration is difficult, a numerical calculation is used. The region of the integration is given from the definition of  $\xi_1, \xi_2 > 0$ . To normalize the region,

Fig. 4 Combined probability distribution of  $\xi_1$  and  $\xi_2$

eq.(8) is divided by  $H_m$ .

$$\delta = (\xi_1 - \xi_2) / 4 \tag{18}$$

Substitution of eq.(15) into eq.(18) brings

$$\delta = (\xi_1 - \zeta) / 2 \tag{19}$$

then

$$\xi_1 = 2\delta + \zeta \tag{20}$$

Substituting this relation in eq.(16), the combined distribution of  $\delta$  and  $\zeta$  is obtained.

$$p(\delta, \zeta) = \frac{\pi^2 (\zeta^2 - 4\delta^2)}{1 - \kappa^2} \exp\left[-\frac{\pi (\zeta^2 + 4\delta^2)}{2(1 - \kappa^2)}\right] I_0\left[\frac{\pi \kappa (\zeta^2 - 4\delta^2)}{2(1 - \kappa^2)}\right] \tag{21}$$

From the definition,

$$-H/2 < d < H/2 \tag{22}$$

we obtain

$$-\zeta/2 < d < \zeta/2 \tag{23}$$

Since  $\delta$  in eq.(21) changes the range following the change of  $\zeta$ , the new parameter which is given in the next equation is introduced.

$$\epsilon = \delta / \zeta \quad (=d/H) \tag{24}$$

$\epsilon$  takes the value only from -1/2 to 1/2 regardless of  $\zeta$ . Substitution of this parameter in eq.(21) we obtain,

$$p(\epsilon, \zeta) = \frac{\pi^2 \zeta^3 (1 - 4\epsilon^2)}{1 - \kappa^2} \exp\left[-\frac{\pi \zeta^2 (\zeta + 4\epsilon^2)}{2(1 - \kappa^2)}\right] I_0\left[\frac{\pi \kappa \zeta^2 (1 - 4\epsilon^2)}{2(1 - \kappa^2)}\right] \tag{25}$$

The conditional distribution of  $\epsilon$  for given  $\zeta$ , is calculated as

$$p(\epsilon | \zeta) = p(\epsilon, \zeta) / p(\zeta) \tag{26}$$

### 3.3 Time interval between $A_1$ and $A_2$

$\kappa$  which is calculated by eq.(11) plays a very important role in this theory. The representative frequency  $\bar{f}$  is usually given by eq.(12) and the time interval  $t/2$  between  $A_1$  and  $A_2$  is approximately given by the mean wave period. Two definitions for the mean wave period have been used. They are

$$\begin{aligned} T_{01} &= m_0 / m_1 \\ T_{02} &= \sqrt{m_0} / m_2 \end{aligned} \tag{27}$$

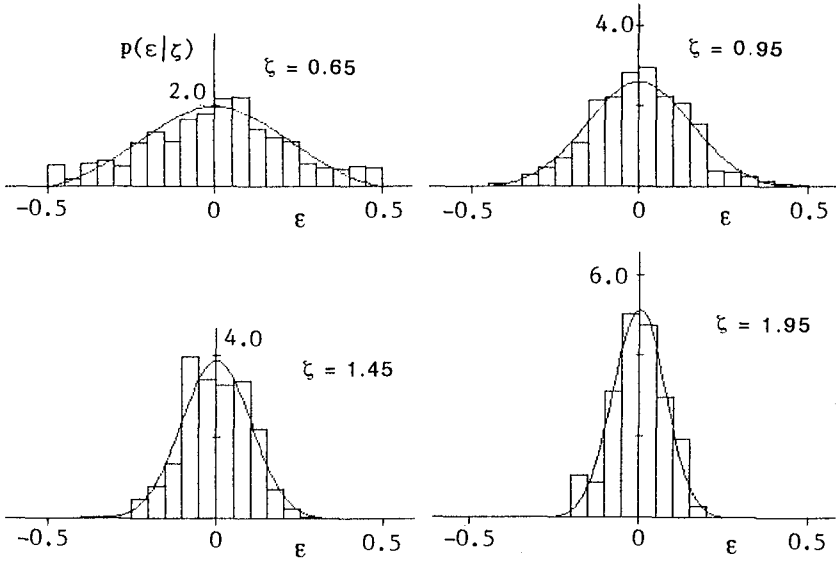

Fig. 5(a) Conditional probability distribution for  $\epsilon$  ( $m=5$ )

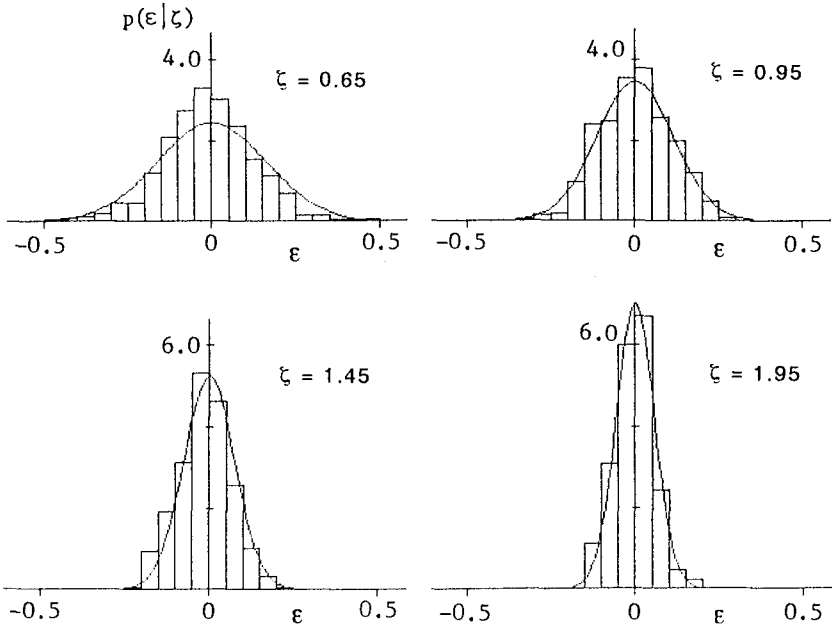

Fig. 5(b) Conditional probability distribution for  $\epsilon$  ( $m=10$ )

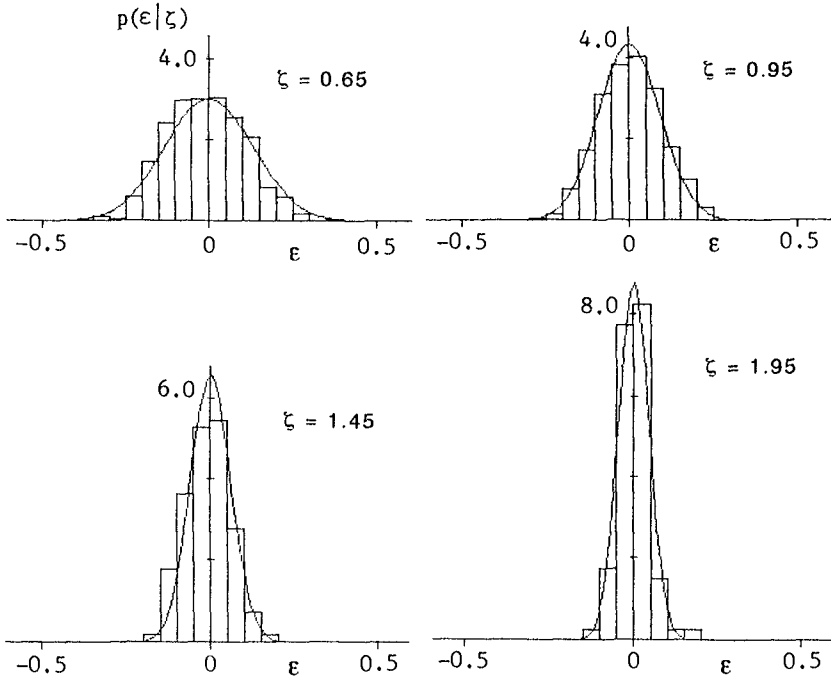

Fig. 5(c) Conditional probability distribution for  $\epsilon$  ( $m=20$ )

The numerical calculations with different values of  $m$  in eq.(4) show that  $T_{02}$  is always closer to the calculated mean zero-crossing wave period than  $T_{01}$ . Therefore  $T_{02}$  is used for  $T_m$  in this study.

4. Verification of the theoretical distribution

Figure 5 shows the comparison between  $p(\epsilon | \zeta)$  and the numerically simulated values of  $\epsilon$  for the several different wave spectra (a)  $m=5$ , (b)  $m=10$ , (c)  $m=20$ . The solid curves shows the theoretical distributions and the columns are the frequency distributions of the numerically simulated data of  $\epsilon$ . Calculated values of  $\epsilon$  which fall in the shown intervals of  $\zeta$  are sorted into ranks of width  $\Delta\epsilon=0.05$  from  $\epsilon=-0.5$  to  $0.5$ . The agreement between the theory and the simulated data are good in all cases except for the very small part of  $\zeta$ . This discrepancy in the region of small  $\zeta$  may be induced by the value of  $\kappa$  used in the calculation of eq.(12), since the time interval between the consecutive wave trough and crest for a small wave is smaller than the average value. However when  $\zeta$  is larger than  $0.6\sim 0.7$ , the theoretical distributions always show good agreements with the data. Fig. 6 shows the comparison between the theoretical standard deviation (solid line) for  $\epsilon$  which is given by

$$\sigma = \left\{ \overline{\epsilon^2} - (\overline{\epsilon})^2 \right\}^{1/2} \tag{28}$$

Fig. 6 Standard deviations of  $\epsilon$

Fig. 7 Comparison between  $p(\epsilon|\zeta)$  and the normal distribution ( $m=5$ ) (solid line;  $p(\epsilon|\zeta)$ , dotted line; the normal distribution)

Fig. 8 Theoretical standard deviation for  $p(\epsilon|\zeta)$

where

$$\overline{\epsilon^2} = \int_{-1/2}^{1/2} \epsilon^2 p(\epsilon | \zeta) d\epsilon \quad (29)$$

$$\overline{\epsilon} = \int_{-1/2}^{1/2} \epsilon p(\epsilon | \zeta) d\epsilon$$

and the standard deviations of the numerically simulated data (white circle). Except for the smaller part than  $\zeta = 0.6 \sim 0.7$  their agreements are good. As can be observed in fig. 5, the theoretical distribution  $p(\epsilon | \zeta)$  has a very close form to the normal distribution. Fig.7 shows the comparisons between  $p(\epsilon | \zeta)$  (solid line) and the normal distribution (dotted line) of the zero mean and the standard deviation calculated from eq.(28). The probability distribution  $p(\epsilon | \zeta)$  used in the calculation is that for  $m=5$  (eq.12) in this case. The agreements between  $p(\epsilon | \zeta)$  and the normal distribution always agree well regardless of the spectrum width when the calculated value of the standard deviation by eq.(28) is used beside zero mean. Fig.8 shows the theoretical standard deviation for  $p(\epsilon | \zeta)$  for the several different spectra (eq.4).

## 5. Conclusion

Additional property for the zero crossing wave is proposed newly in this study. That is the distance from the mean water level to the mean position between the consecutive wave trough and crest. Its theoretical distribution is introduced and compared with the numerically simulated data. The theoretical distribution shows excellent agreement with the numerically simulated data regardless of the spectrum width. The theoretical distribution has a very close form to the normal distribution and can be approximated with that distribution, if the standard deviation shown in Fig.8 and the zero mean is applied.

## CHAPTER 28

### Time-Dependent Solutions of the Mild-Slope Wave Equation

James T. Kirby, Changhoon Lee <sup>1</sup> and Chris Rasmussen <sup>2</sup>

#### Abstract

Time dependent forms of the mild-slope wave equation are applied to the propagation of regular and irregular wave trains over variable bathymetry. The model equation of Smith and Sprinks is found to be a robust predictor of irregular waves, if the frequency spread for a single component calculation is not made too large. The model is extended to include forced, low-frequency components, and some preliminary results for bound and free long wave computation are shown.

#### Introduction

Based on the work of Smith and Sprinks (1975), the mild-slope wave equation for linear waves with a dominant carrier frequency  $\omega$  and small frequency spread may be written as

$$\tilde{\phi}_{tt} - \nabla_h \cdot (CC_g \nabla_h \tilde{\phi}) + (\omega^2 - k^2 CC_g) \tilde{\phi} = 0 \quad (1)$$

where  $\tilde{\phi}$  is the value of the velocity potential at the mean surface  $z = 0$ . This equation reduces to Berkhoff's (1972) elliptic equation when the time dependence of purely periodic waves is extracted.

In the past, many solutions of the elliptic problem for open coastal zones have been obtained using a parabolic approximation, which treats the forward-propagating portion of the wave field only. This step has often been taken because of its computational efficiency. The applicability of parabolic approximations is limited, however, to regions without complicated structural boundaries. In particular, complex entrance channels and interiors of harbors are not good candidates for this modelling technique, since the wave field is built up by a number of reflections and re-reflections of waves within the enclosed domains. For these applications, full solutions to the complete boundary-value problem must be found. Progress in obtaining efficient solutions using sophisticated pre-conditioning schemes has been made by Panchang et al (1991).

As an alternative to the elliptic equation approach, several authors (Ito and Tanimoto, 1972; Copeland, 1985; Madsen and Larsen, 1987) have obtained solutions to time-dependent, three-equation models using time-stepping techniques based on equations which are first-order in time. These models are essentially numerical analogs to the more familiar shallow water equations. The model solutions are computed until

<sup>1</sup>Center for Applied Coastal Research, Department of Civil Engineering, University of Delaware, Newark, DE 19716

<sup>2</sup>New York District, U.S. Army Corps of Engineers, New York, NY

the amplitude envelopes reach a steady state. The final solutions are only valid for purely periodic wave trains, since the three-equation models used are, for the most part, equivalent to the second order model

$$\tilde{\phi}_{tt} - \frac{C}{C_g} \nabla_h \cdot (CC_g \nabla_h \tilde{\phi}) = 0. \quad (2)$$

This model differs from the correct form (1), and is non-dispersive in the sense that modulations of the carrier wave train propagate at the wave phase speed, rather than at the group velocity, as would be required in a correct time-dependent model.

Since the application of time-stepping solutions to the mild-slope equation is a reasonably efficient line of approach, and since it is desirable to provide a model which is valid for unsteady wave trains, it would be advantageous to use a set of model equations which preserves the proper wave group behavior for non-periodic, narrow-banded wave trains. Such a model would be useful in computing effects such as second-order oscillations forced by wave groups.

In section 2, we derive the time-dependent mild-slope equations. In section 3, the dispersiveness of the resulting model is verified by studying wave group propagation over a flat bottom. In section 4 we consider the propagation of linear and weakly nonlinear waves over an elliptic shoal. Section 5 considers two-dimensional propagation of waves over an elliptic shoal using monochromatic and random waves. Finally, in section 6, we discuss the forcing of long wave components at difference frequencies due to non-resonant wave-wave interactions.

## Derivation of the time-dependent model equations

The model equations are derived here using Hamilton's variational principle. The Lagrangian for irrotational motion is given by

$$L = -\rho \int_{-h}^{\eta} [\phi_t + \frac{1}{2}(\nabla_h \phi)^2 + \frac{1}{2}(\phi_z)^2 + gz] dz \quad (3)$$

The  $z$  dependence is extracted from  $\phi(x, y, z, t)$  according to

$$\phi(x, y, z, t) = \tilde{\phi}(x, y, t) f(z) \quad (4)$$

where

$$f(z) = \frac{\cosh k(h+z)}{\cosh kh} \quad (5)$$

From the variational principle the change of the integral of the Lagrangian,  $L$ , over all time and space must be equal to zero:

$$\delta \int_t \int_y \int_x L(x, y, t, \phi, \nabla_h \phi, \phi_t, \eta) dx dy dt = 0 \quad (6)$$

Substituting (3) into (6) and retaining the terms to the second order in  $\phi$  and  $\eta$  gives

$$-\rho L = \eta \tilde{\phi}_t + \frac{1}{2} g \eta^2 + \frac{1}{2} \frac{CC_g}{g} (\nabla_h \tilde{\phi})^2 + \frac{1}{2} \frac{(\omega^2 - k^2 CC_g)}{g} (\tilde{\phi})^2 \quad (7)$$

Varying the Lagrangian  $L$  with respect to  $\tilde{\phi}$  and  $\eta$  gives

$$\eta_t = -\nabla_h \cdot \left( \frac{CC_g}{g} \nabla_h \tilde{\phi} \right) + \frac{(\omega^2 - k^2 CC_g)}{g} \tilde{\phi} \quad (8)$$

$$\tilde{\phi}_t = -g\eta \quad (9)$$

which are the time-dependent mild-slope equations. The surface displacement may be eliminated from (8) and (9) in order to obtain the model equation (1). In this study, we have employed a number of numerical methods fairly interchangeably, including a second-order, centered-time centered-space finite difference approximation for (1), and a fourth-order accurate Adams-Bashforth-Moulton method for (8) and (9). (Use of this latter method was motivated by a parallel effort for the Boussinesq equations, which will be reported separately.)

As in Madsen and Larsen (1987), it is convenient to remove the fast time behavior from the dependent variables by means of the transformation

$$\eta, \tilde{\phi} = (\hat{\eta}, \hat{\phi})e^{-i\omega t} \quad (10)$$

where  $\omega$  is the frequency used to evaluate the model coefficients. The resulting model equations are

$$\hat{\eta}_t = i\omega\hat{\eta} - \nabla_h \cdot \left( \frac{CC_g}{g} \nabla_h \hat{\phi} \right) + \frac{(\omega^2 - k^2 CC_g)}{g} \hat{\phi} \quad (11)$$

$$\hat{\phi}_t = i\omega\hat{\phi} - g\hat{\eta} \quad (12)$$

instead of (8) and (9), and

$$\hat{\phi}_{tt} - 2i\omega\hat{\phi}_t - \nabla_h \cdot (CC_g \nabla_h \hat{\phi}) - k^2 CC_g \hat{\phi} = 0 \quad (13)$$

instead of (1). The same set of numerical schemes are also used for the revised model.

## Wave group propagation

The basic ability of the model to propagate dispersive linear waves is tested by examining wave group propagation over constant depth. Two numerical experiments were performed. An initial wavelength of  $10m$  was specified, with shallow and deep water depths of  $0.25m$  and  $9m$ , respectively. The initial conditions are  $\eta$  and  $\tilde{\phi} = 0$ . A narrow-banded groupy wavetrain is generated at the boundary according to

$$\tilde{\phi}_x = u_0 \sin(\omega t) \sin\left(\frac{\omega}{20}t\right); \quad t \geq 0 \quad (14)$$

The results shown in figure 1 are water surface elevations plotted at a sequence of twenty time levels spaced one wave period apart. These results were obtained using the Euler Predictor-Corrector method with second-order accurate finite differences (Kirby and Rasmussen, 1991). Two lines are shown on each graph; one following the maximum amplitude of a specific wave group, and the other following a zero crossing of a specific wave. Visually, it appears that in shallow water  $C_g \approx C$ , and in deep water  $C_g \approx C/2$ , which shows the validity of the models to predict wave group velocity. Examination of the wave records and computed envelopes using cross-correlation techniques shows that the phase and group velocities are accurately predicted to within 1% for the differencing resolutions used here.

## Berkhoff, Booij and Radder shoal experiment

As an example of the application of the models in two-dimensions, we study the focussing of waves by a shoal, using the geometry and experimental parameters given in Berkhoff et al. (1982). It is known from parabolic model computations (Kirby and Dalrymple,

Figure 1: Propagation of wave groups in deep and shallow water.

1984) that the waves in this example are significantly affected by wave nonlinearity. Following the appendix in Kirby and Dalrymple (1984), we provide a heuristic extension to the mild-slope equation that is appropriate only for progressive Stokes waves. The resulting modification to (8) is given by

$$\eta_t = -\nabla_h \cdot \left( \frac{CC_g}{g} \nabla_h \tilde{\phi} \right) + \frac{(\omega^2 - k^2 CC_g + \omega C_g K' |\eta|^2)}{g} \tilde{\phi} \tag{15}$$

where

$$K' = \frac{k^3 C \cosh 4kh + 8 - 2 \tanh^2 kh}{8 \sinh^4 kh} \tag{16}$$

We apply both the linear and nonlinear model equations to the shoal described by Berkhoff et al. (1982). The data on wave amplitude was obtained over the entire vicinity of a refractive focus. The Ursell parameter remains of a reasonably small size over the entire domain of interest, thus indicating that Stokes theory should be a valid representation of the experiment.

In the model test, normally incident waves are generated at a period of 1.0s at the deep end of the wave tank, and are dissipated by a breaking process on a gravel beach at the shallow end. At sections 1 through 8 (see Berkhoff et al) there are arrays of resistance type wave gages spaced 0.5m apart which record time series of water surface elevations.

In order to dissipate wave energy at downwave boundaries, we presently use a wave damping layer at the downwave boundary. Equation (9) is modified to

$$\tilde{\phi}_t = -g\eta - w\tilde{\phi} \tag{17}$$

where

$$w = \begin{cases} 0, & x \leq x_{sponge} \\ \omega \left( \frac{e^{F^n} - 1}{e - 1} \right), & x \geq x_{sponge} \end{cases} \tag{18}$$

$$F = \frac{x - x_{sponge}}{x_{max} - x_{sponge}}, \quad (19)$$

and the sponge length  $x_{sponge}$  is specified as 2.5 times the initial wave length.

Following a method of line approach, the model equations (8) and (17) (linear), or (15) and (17) (nonlinear) are solved using the A-B-M predictor-corrector method. The grid sizes are  $\Delta x = \Delta y = 0.25m$  and  $\Delta t = 1/40s$ . Input wave period is 1s. We run the models until  $t = 80s$  and compute average wave heights between  $t = 70s$  and  $t = 80s$ , after the waves reach steady state.

Referring to figure 2, where model results are compared to measured data along transects 1 through 8, we see that the linear model tends to overpredict maximum amplitudes in the vicinity of focused waves, where wave steepness may become large and nonlinear effects become important. In these regions the nonlinear models give better results. The nonlinear model results appear to contain some spurious amplitude modulations. These are not a manifestation of instability, and the effect may be suppressed by a suitable lagging of the nonlinear term in the numerical scheme.

## Vincent and Briggs shoal experiment

A further study of monochromatic and random wave propagation over a shoal has been performed by Vincent and Briggs (1989). These tests are used here as a validation of the present numerical scheme as a model for irregular wave propagation.

For a random wave train, the water surface elevation may be written as

$$\eta(x, y, t) = \sum_{l=1}^L \sum_{m=1}^M A_{lm} \cos\{k_l \cos \theta_m x + k_l \sin \theta_m y - 2\pi f_l t + \psi_{lm}\} \quad (20)$$

where  $A_{lm}$  is wave amplitude;  $f_l$  is wave frequency;  $\theta_m$  is wave direction; and  $\psi_{lm}$  is random phase independent of frequency and direction. Instead of using a discrete set of wave angles, we use here a discretization of the longshore wavenumber spectrum. The longshore wavenumber  $\lambda_m$  is defined as

$$\lambda_m = k_l \sin \theta_m \quad (21)$$

which determines the wave direction  $\theta_m$  at each frequency. At the upwave boundary ( $x = 0$ ), the water surface elevation is given by

$$\eta(y, t) = \sum_{l=1}^L \sum_{m=1}^M A_{lm} \cos\{\lambda_m y - 2\pi f_l t + \psi_{lm}\} \quad (22)$$

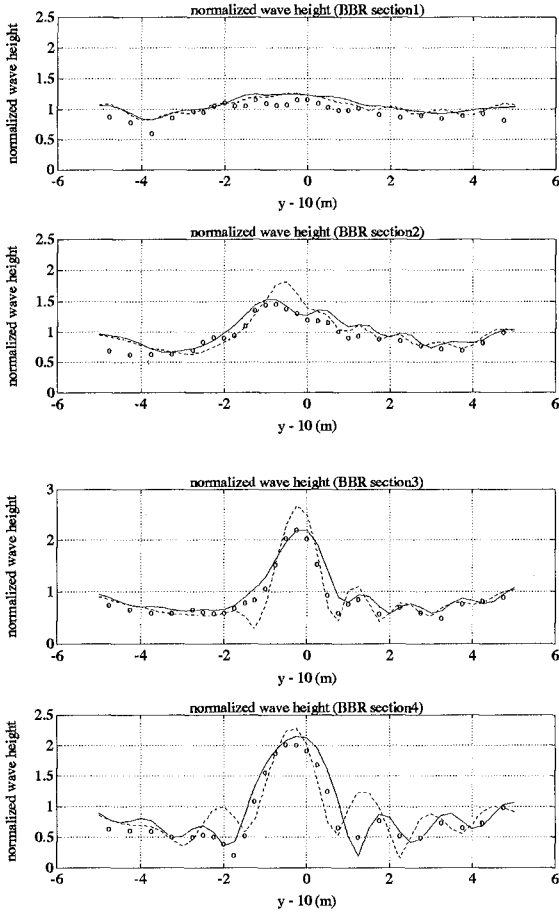

For given frequency  $f_l$  and longshore wavenumber  $\lambda_m$ , we get the amplitude of the water surface elevation

$$A_{lm} = \sqrt{2S_l(f)\Delta f \frac{S_m(\lambda)}{2\pi} \Delta \lambda} \quad (23)$$

where  $S_l(f)$  is the spectral density dependent on the frequency  $f$  and  $S_m(\lambda)$  is the directional spreading function dependent on the longshore wavenumber  $\lambda$ . We can get  $S_m(\lambda)$  from  $D_m(\theta)$  (which is the spreading function dependent on the direction  $\theta$ ) by the condition

$$\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} D(\theta) d\theta = \int_{-k}^k \frac{S(\lambda)}{2\pi} d\lambda = 1, \quad (24)$$

caption on following page

Figure 2: Comparison among linear model (dashed lines), nonlinear model (solid lines), and experimental data of Berkhoff et al. (1982)

and so,

$$\frac{S(\lambda)}{2\pi} = D(\theta) \frac{d\theta}{d\lambda} = \frac{D(\theta)}{k \cos \theta} \quad (25)$$

The  $x$ -component of fluid velocity at  $x, z = 0$  can be obtained from the velocity potential and is given by

$$\tilde{\phi}_x = \sum_{l=1}^L \sum_{m=1}^M B_{lm} \cos\{\lambda_m y - 2\pi f_l t + \psi_{lm}\} \quad (26)$$

where the amplitude  $B_{lm}$  is given by

$$B_{lm} = A_{lm} \frac{g \sqrt{k_l^2 - \lambda_m^2}}{2\pi f_l} \quad (27)$$

When the spectral density  $S(f)$  and the directional spreading function  $D(\theta)$  are given, we can get the amplitude of the wave velocity  $B_{lm}$ . Using a 2-dimensional inverse FFT from the frequency and longshore wavenumber domain to time and  $y$  space domain, we can generate the velocity  $\tilde{\phi}_x$ .

Since the model equation (1) is not valid for an arbitrarily large range of frequencies, we proceed by separating the whole spectrum into several bands. In each frequency band, we then construct a wavemaker or offshore boundary condition using the spectral information falling within that band. The time-dependent mild slope equation is then solved for the narrow-banded irregular sea lying within each frequency band. The final solution is obtained by adding the different bands.

Following Vincent and Briggs (1989), we use the TMA spectrum as the target frequency spectrum and a wrapped normal function as the directional spreading function. The TMA spectrum is given by

$$S(f) = \alpha g^2 (2\pi)^{-4} f^{-5} \exp\{-1.25(\frac{f_p}{f})^4 + (\ln \gamma) \exp[-\frac{(f - f_p)^2}{2\sigma^2 f_p^2}]\} \phi(f, h) \quad (28)$$

$S(f)$  depends on the parameters  $\alpha$  (Phillip's constant),  $f_p$  (peak frequency)  $\gamma$  (peak enhancement factor) and  $\sigma$  (shape parameter). The factor  $\phi(f, h)$  incorporates the effect of the depth  $h$  and may be approximated by

$$\phi = \begin{cases} 0.5\omega_h^2, & \omega_h < 1 \\ 1 - 0.5(2 - \omega_h)^2, & 1 \leq \omega_h \leq 2 \\ 1, & \omega_h > 2 \end{cases} \quad (29)$$

where  $\omega_h = 2\pi f(h/g)^{1/2}$ . The parameter  $\gamma$  is assigned values of 2 (broad frequency) and 20 (narrow frequency). For the cases studied here,  $\gamma$  was assigned a value of 20. The directional spreading function  $D(\theta)$  is obtained by assigning the values of either  $10^\circ$  (narrow spreading) or  $30^\circ$  (broad spreading) to the spreading parameter  $\sigma_0$ :

$$D(\theta) = \frac{1}{2\pi} + \frac{1}{\pi} \sum_{n=1}^N \exp[-\frac{(n\sigma_0)^2}{2}] \cos n(\theta - \theta_0) \quad (30)$$

where  $\theta_0$  = mean wave direction ( $= 0^\circ$ ) and  $N$  = number of terms in the series ( $= 20$ ).

Vincent and Briggs (1989) present a number of cases with a combination of monochromatic, narrow-banded or broad-banded frequency spectra and unidirectional, narrow-banded or broad-banded directional spreads. Here, we show results for three typical

cases: a monochromatic unidirectional sea (M2), a sea with narrow frequency and narrow directional spreading (N4), and a sea with narrow frequency and broad directional spreading (B4). All three cases involve non-breaking waves. Wave period (M2) and peak period (N4, B4) are 1.30s. Wave height (M2) and rms wave height (N4, B4) are 2.54cm. Phillip's  $\alpha$  is taken to be 0.00047.

We separate the whole frequency spectrum into five components with equal band widths. The five components of the frequency spectra cover 95 percent of the total spectral density, and, using the grid spacings chosen below, the ratio of minimum wavelength to spatial grid size is 4.54. We use a weighted average of the frequencies in each frequency band to determine the representative frequency used to compute the model coefficients for each band. The band width is 0.267 Hz (see figure 3). The grid size is  $\Delta x = \Delta y = 0.1905m$  and time step is  $\Delta t = 1.3/80s$ . We compute until  $t = 260s$ . Variances of water surface elevation,  $m_0$  are computed between  $t = 65s$  and  $t = 260s$  and, by the assumption of the Rayleigh distribution of the wave height, significant wave heights are computed according to

$$H_s = 4\sqrt{m_0} \quad (31)$$

In figures 4-6, the water surface elevations in the whole spatial domain at  $t = 260s$  are shown for cases M2, N4, and B4. The figure for Case M2 shows that the waves are long-crested and symmetric along the line crossing the center of the shoal parallel to  $x$  axis. After the waves pass the shoal they become short-crested because of refractive focusing. When we compare the cases with directional spreading (N4 and B4) we clearly see that the wave field with broad directional spreading (B4) is more short-crested than the wave field with narrow directional spreading (N4).

In figure 7, the computed normalized wave heights along the section 4 are compared with measured data for cases M2, N4, and B4. For case M2, the normalized wave height near the centerline is greater than 2, which shows the considerable effects of refractive focusing over the shoal. For case N4, the computed results show underestimation near the centerline and overestimation away from the centerline. For case B4, the computed results show overestimation all along the section. The model results and data indicate that increasing directional spreading leads to much less spatial wave height variation induced by localized topographic irregularities. This result is seen in all spectral wave studies, and is a manifestation of the fact that the local minimums and maximums in the diffraction pattern for each spectral component overlap and experience mostly destructive interference.

Roughly, all three cases show that the model yields reasonably accurate results compared with the measured data. It is found that for directionally broad spreading case (B4) the refractive focussing effects are not noticeable behind the shoal.

## Forced long waves

The forcing of long waves at difference frequencies is of particular interest in coastal design due to the influence of long waves in low frequency harbor seicheing and forces on moored ships. Kirby (1983) extended the linear mild-slope equation to include forced low-frequency components, using the Stokes expansion to second order in the Lagrangian. The model for the additional low-frequency components is given by forced long wave equations, which for variable depth are given by

Figure 3: TMA frequency spectra (narrow frequency band) and directional spreading functions (solid lines :  $\sigma_0 = 10^\circ$ , dashed lines :  $\sigma_0 = 30^\circ$ )

Figure 4: Water surface elevations at  $t = 260$  seconds (case M2)

Figure 5: Water surface elevations at  $t = 260$  seconds (case N4)

Figure 6: Water surface elevations at  $t = 260$  seconds (case B4)

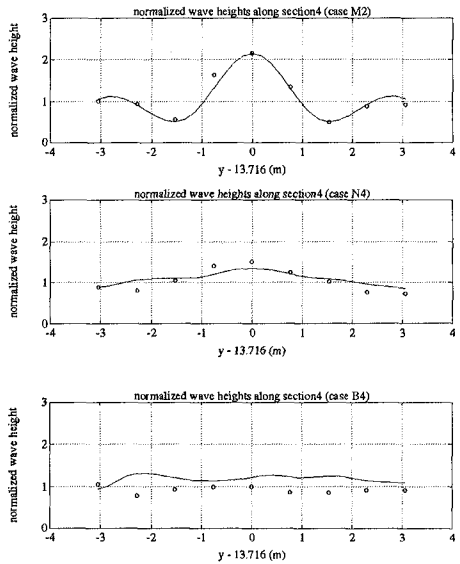

Figure 7: Measured and predicted normalized wave heights on section 4

$$\eta_{2,t} + \nabla_h \cdot \{h \nabla_h \phi_2\} = -\nabla_h \cdot \{\overline{\eta \nabla_h \phi}\} \quad (32)$$

$$\phi_{2,t} + g \eta_2 = \frac{\omega^2}{g^2} \overline{\phi_t^2} - \frac{1}{2} \overline{(\nabla_h \phi)^2} - \frac{\omega^4}{2g^2} \overline{\phi^2} \quad (33)$$

where  $\overline{(\quad)}$  denotes a time average. The correct method for computing time averages in an unsteady wave train is unclear. If the wave train is narrow-banded, we may use the extraction of the dominant frequency in section 2 as the basis for isolating the slowly-varying amplitudes. Following this strategy, (32) and (33) may be further reduced to

$$\eta_{2,t} + \nabla_h \cdot \{h \nabla_h \phi_2\} = -\frac{1}{2} \text{Re} \left( \nabla_h \cdot [\hat{\eta}^* \nabla_h \hat{\phi}] \right) \quad (34)$$

$$\phi_{2,t} + g \eta_2 = \frac{\omega^2}{2} \hat{\eta} \hat{\eta}^* - \frac{1}{4} \left( \nabla_h \hat{\phi} \cdot \nabla_h \hat{\phi}^* \right) - \frac{\omega^4}{4g^2} \hat{\phi} \hat{\phi}^* \quad (35)$$

These equations may also be written as a single second-order equation, analogous to (13), after elimination of  $\eta_2$ . The numerical schemes are again identical to those used for the basic linear equations.

Figure 8 shows a plot illustrating the generation of a single wave group and the associated bound and free long waves in a one-dimensional wave flume. The wavemaker motion used does not compensate for the decrease in total volume (at second order) associated with the entrance of the wave group into the wave channel. There is thus a free long wave generated whose net positive volume compensates for the negative volume associated with the setdown under the wave group. This positive wave propagates away from the wavemaker as a free wave, and thus leads the short wave group in the tank.

Additional results for long wave generation and harbor resonance in 2-D will be reported separately.

## Conclusions

We have developed models for the numerical solution of time-dependent mild-slope equations, and applied the models to the study of irregular and regular wave propagation in the coastal environment. Linear and nonlinear versions of the model were applied to Berkhoff shoal, and, as expected, we found that the nonlinear model showed better results than the linear model. We also applied the linear version of the model to study irregular wave refraction and diffraction by a submerged shoal, and compared model results to experimental data given by Vincent and Briggs (1989). Finally, the models were extended to include additional low frequency components which are forced by the primary wave envelopes, and some preliminary results on long wave generation were shown.

## CHAPTER 29

### NON-LINEAR WAVE-CURRENT INTERACTIONS IN THE SWADE RESEARCH PROGRAM.

S. P. Kjeldsen. \*

H. C. Graber. \*\*

#### Abstract.

This publication gives an introduction to the SWADE experimental programme. It presents examples of results of directional ocean wave spectra in polar format obtained by the third generation met/ocean buoy WAVESCAN. Then focus is made on a new algorithm "CUWA" that simulates non-linear Stokes waves propagating through regions of strong surface current.

#### Introduction.

The surface wave dynamics experiment SWADE was initiated by the Office of Naval Research in U.S.A. as an accelerated research initiative. A large field experimental program was carried out in the fall of 1990 through the spring of 1991 offshore the coast of Virginia. The measurement systems and a team of investigators are funded by the U.S. Office of Naval Research and the National Aeronautics and Space Administration (NASA).

SWADE is concerned primarily with the evolution of the directional wave spectrum in both time and space, and the goal is to provide improved understanding of wind forcing and wave dissipation, and the effects of breaking waves on the air-sea coupling mechanisms. It is well known that this energy transport is strongly coupled to dissipation in breaking waves. Actually 33 % of momentum transferred from the wind to the large scale ocean current systems is due to wave breaking, LONGUET-HIGGINS (1969). Further a particular goal was to

investigate the effects of waves on various airborne radar systems such as the surface contour radar (SCR), the remote ocean wave spectrometer (ROWS), and the synthetic aperture radar (SAR). Therefore it became very important in this experiment to have the best available directional wave buoys to provide the sea surface truth, and make it possible to calibrate air-borne radar instruments. The company SEATEX from Trondheim in Norway funded the deployment of such a buoy.

### Field Experiment.

The experiment was performed 100 nautical miles east of the coast of Virginia between Cape Hatteras and Cape Cod. This was an area where the Gulf Stream developed large eddies or rings, and thus interacted strongly with the waves. Fig 1 shows the location of some of the instruments that were deployed in SWADE. Five directional wave buoys were selected for this task, among them the third generation WAVESCAN Met/ocean buoy from SEATEX in Norway. Also a large spar buoy was brought into the experiment but unfortunately the spar buoy was lost in a severe storm that occurred at the site in late October 1990. Therefore a SWATH-ship "FREDERICK G. CREED" from Canada was brought into the experiment. A SWATH is a small waterplane area twin hull catamaran. This ship was equipped with an array of wave gauges that permitted the ship to move to several positions on the site and measure the directional spectra there, see DONELAN et al. 1992. The comparison between directional spectra measured at sea and directional spectra measured with air-borne SAR-radars had a high priority. 5 airplanes from NASA, NADC, CRPE, CCRS and NRL participated, and during the most intensive measuring period, these aircrafts flew over the sea area with a SCR (Surface Contour radar), a ROWS (Radar Ocean Wave Spectrometer), a SAR (X- and C-band Side Looking Real Aperture Radar) and finally a 3-frequency SAR radar. During two intensive weeks not less than 41 flying missions were taken.

Fig 2 shows the site where the experiment took place, and Fig 3 and Fig 4 show examples of directional spectra obtained with the WAVESCAN buoy. The spectra are shown in polar format. Such a format was also used extensively in the Labrador Sea Extreme Waves Experiment LEWEX program, see BEAL (1990). After termination of the LEWEX-experimental program it was recommended by the 8 participating countries to use the polar format as an international standard for directional spectra in order to make practical applications more easy, in particular for ships navigating with access to forecasted directional wave spectra, see KJELSDSEN (1990 c). Also comparisons with satellite and airborne directional wave spectra becomes

Fig. 1. The SWADE arrays and aircraft.  
 ( From WELLER, DONELAN, BRISCOE, HUANG 1990.)

more convenient when all spectra are referenced to true North.

Fig 5 shows the increase in mean temperature on earth and in carbon dioxide in the period from 1860 to 1985. It is in particular in the two last decades that the carbon dioxide content in the atmosphere has a steep increase. Interaction between oceans and atmosphere are very important in this exchange of carbon dioxide and here the breaking waves plays an important role.

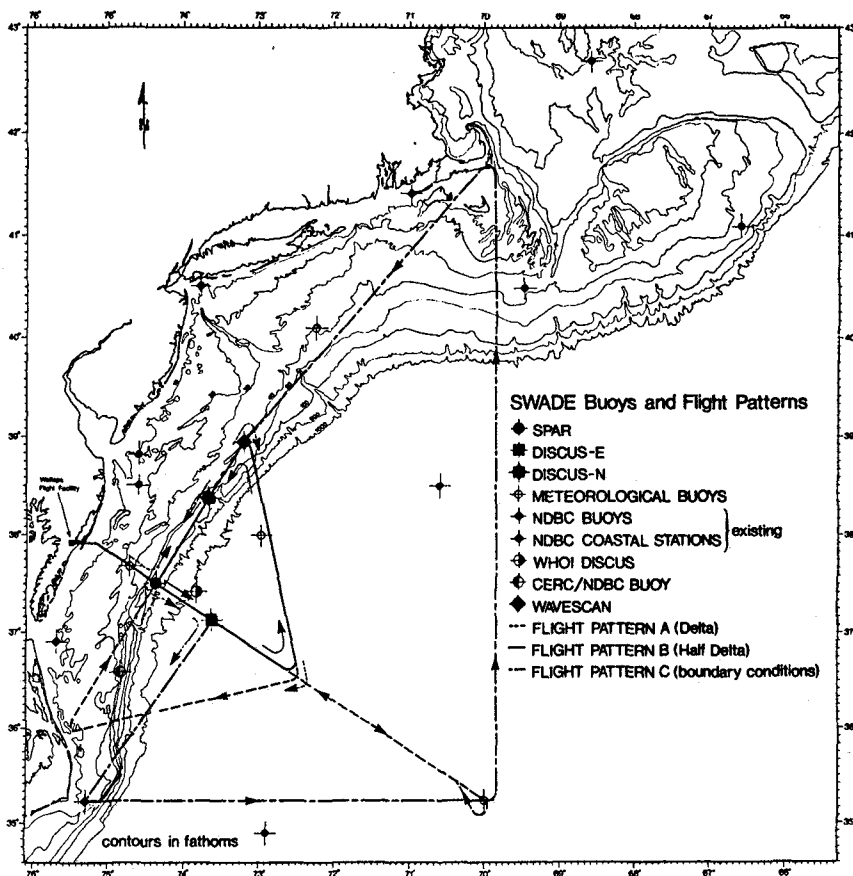

Fig. 2. SWADE buoys and flight patterns.  
( From WELLER, DONELAN, BRISCOE, HUANG 1990.)

Fig 6 shows the third generation met/ocean WAVESCAN buoy. The WAVESCAN system consist of :

1. The met/ocean data buoy which automatically collects the raw data which is then processed onboard before transmission to the end user. A particular feature is the onboard wave directional analysis.
2. A telemetry system which can be used with satellite links and/or UHF radio links.
3. A data presentation system with RTscan software for communication, control and data presentation.

The data is available to the end user in realtime from anywhere in the world's oceans. The system can make use of satellite systems, such as Service Argos, Inmarsat C, Meteosat or GOES, to provide the telemetry link. Locally, UHF radio may be used to provide a two way link to the shore based RTscan receiver/controller station. The data is organised and presented by the RTscan software which also provides the means to control and manage a network of buoys.

For further details see BARSTOW et al. (1991).

The buoy can be configured with sensors for :

- Wave characteristics, (heights, frequencies, directions).
- Wind speed and direction.
- Air temperature, pressure and humidity.
- Solar radiation.
- Current profile, velocity and direction.
- Water temperature.
- Dissolved oxygen.
- Ph-value.
- Salinity.
- Conductivity.
- Redox.

Fig 7 shows the WAVESCAN with an acoustic doppler current profiler, (ADCP) installed below. However this current meter is an additional option and it was not used in the SWADE experiment.

WAVESCAN was found to be the ideal buoy to use in connection with weather routing applications for ships.

#### Comparisons between results obtained with WAVESCAN and results obtained with SAR-radars.

It has been observed that directional ocean wave spectra obtained from wave buoys in some cases were wider than directional wave spectra obtained for the same situation with SAR-radars. A possible explanation is that the buoys are moving in the sea in yaw motion during data acquisition. However the WAVESCAN buoy was calibrated in a large wave calibration project WADIC performed at the EKOFISK field in Norway. Here an array with lasers were used to measure the directional wave spectrum. WAVESCAN calibration equations were then obtained in which yaw motion was eliminated, see ALLENDER et. al. (1989). The WAVESCAN buoy has therefore been used extensively as a key sensor, and used for comparisons both with airborne and with satellite-borne SAR-radars. This was in particular the case during the LEWEX experiment.

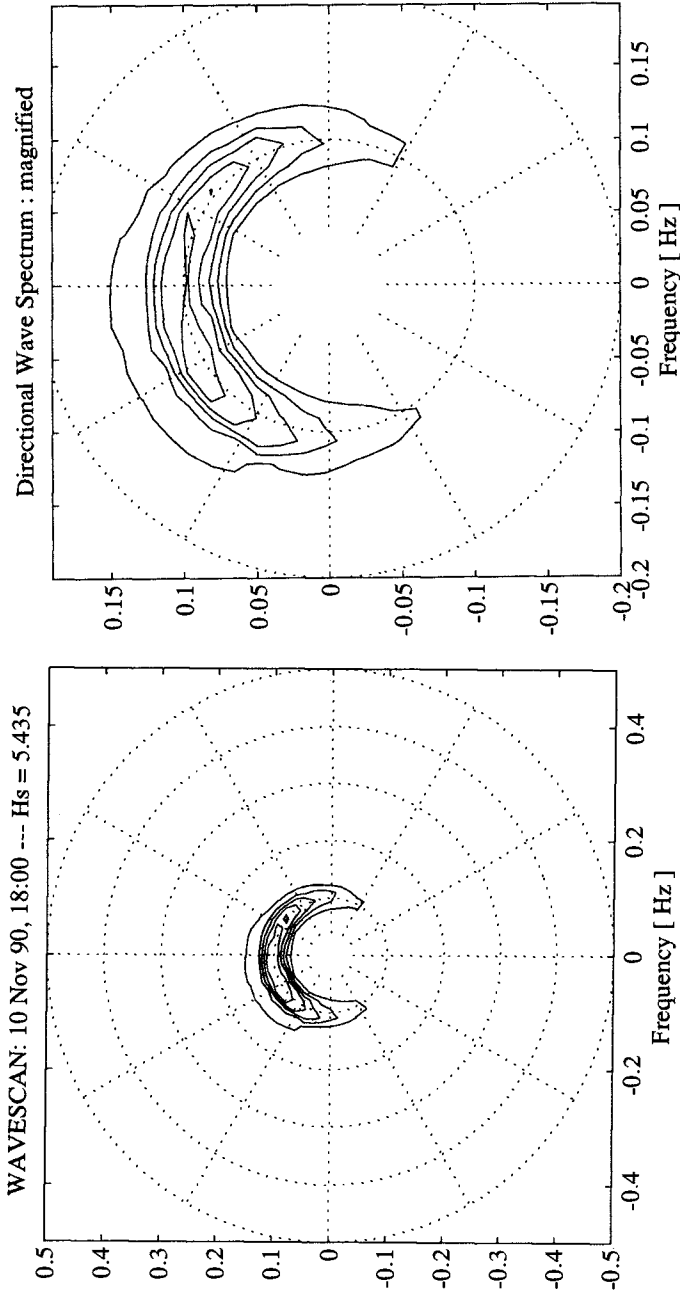

Fig. 3. Directional spectra in polar format obtained from the WAVESCAN Met/ocean buoy during the storm the 10th november 1990 at 1800.

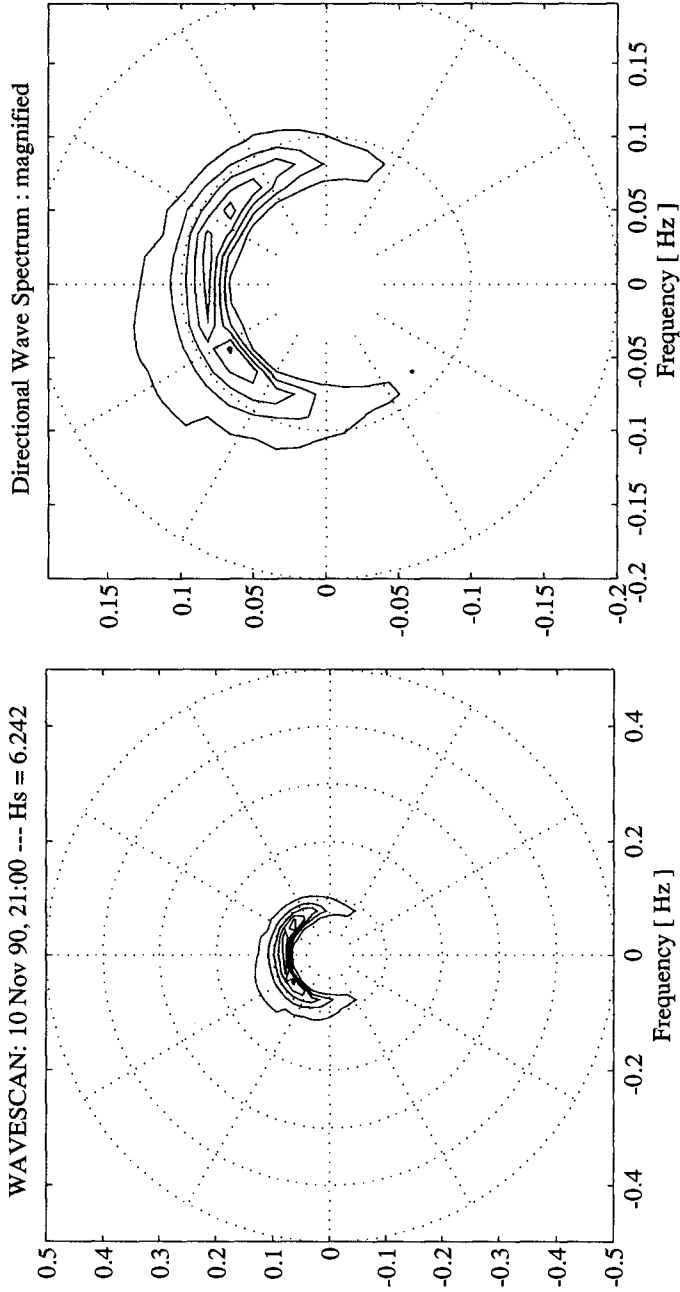

Fig. 4. Directional spectra in polar format obtained from the WAVESCAN Met/ocean buoy during the storm the 10th november 1990 at 2100.

There are various methods that can be used to derive the 3-dimensional spectra such as :

- The Fourier Series Expansion Method.
- The Maximum Likelihood Method.
- The Maximum Entropy Method.
- The Variational Method.
- The Direct Integral Method.

An example of an algorithm used to derive directional spectra from the WAVESCAN buoy is given by KJELDEN, KROGSTAD, OLSEN 1988.

The idea to use data from several directional buoys installed at the same position simultaneously in order to establish a statistical weighted directional spectrum to represent the best estimate to sea surface truth was used both in the WADIC and in the Labrador Sea Extreme Waves Experiment LEWEX, see KJELDEN (1990 b).

**Mathematical Algorithm.**

Interaction between non-linear waves and strong surface currents such as the Gulf Stream is an important problem to consider with many practical applications. The Gulf Stream varies slowly in time and space and large vortex rings develop. In a study of waves on slowly varying currents it is natural to start with specifying the current field in space and time. However, in general, this is not possible. There is an ambiguity in the definition of still water when finite amplitude water waves propagate into the current. This is important because finite amplitude water waves often develop into breaking waves and thus the energy dissipation is governed by this non-linear wave-current interaction. The ambiguity is caused by the Stokes drift velocity. Thus superposition of waves upon a current changes the current and its determination becomes part of the problem.

Let us consider the two equations that governs the problem. First we have the equation for the wave action flux B:

$$B = \frac{\rho g A^2 (U + C_g)}{2\sigma}$$

Here B is the wave action flux,  
 A the wave amplitude  
 U the surface current velocity  
 $C_g$  the group velocity relative to the water  
 $\sigma$  the intrinsic wave frequency  
 $\rho$  the sea water density  
 g the gravity acceleration.

The cyclic wave frequency  $\omega$  is given by the equation :

$$\omega = k(C + U) = \frac{g(C + U)}{C^2}$$

Here k is the wave number and  
 C is the phase velocity relative to the water.

Both the wave action flux and the cyclic wave frequency must be conserved. The problem can then be solved as two equations with two unknowns, namely the wave action and the surface current. When the equations are solved the following conditions must be taken into consideration. The non-linear dispersion relation for the waves is given by :

$$C^2 = \frac{g}{k} (1 + f(A^2 k^2))$$

and the Stokes drift  $S$  is given by :

$$S = 0.5 * k A^2 C$$

A new algorithm "CUWA"-(current-wave-interaction) is developed. Here a test simulation with non-linear Stokes waves propagating against a strong opposing current is considered.

Also a case with linear waves is simulated for comparison. However the linear theory is not valid in this case as the amplitude of the linear waves tends towards infinity.

The performed analysis showed that non-linear wave-current interactions are very important and deserves further attention. The research has many practical applications, such as forecasting of breaking waves, prediction of wave kinematics, pollution control and management of coastal areas and in particular navigation in coastal waters.

#### Further work.

There is a need not only to consider directional ocean wave spectra but also to analyse single waves. In particular measured extreme wave heights and wave groupiness should be analysed from the storm data obtained in november 1990.

Further results obtained from the algorithm "CUWA" should be compared with measurements obtained at positions where strong wave-current interactions have taken place.

An analysis of wave groups and single extreme waves has been initiated in other sea areas, see KJELDEN (1989), KJELDEN (1990 a) and KJELDEN (1991).

**Conclusions.**

1. The final conclusions that are derived from the SWADE experimental programme will not be published by single scientists but will appear as a joint publication from all participants.

2. In nature it is often observed, that a current opposing the waves leads to a significant amount of whitecapping. The energy dissipation is then increased. It is necessary to consider non-linear wave-current interaction computed by an algorithm such as "CUWA" in order to compute dissipation in breaking waves under such circumstances.

3. Directional ocean wave spectra obtained with the WAVESCAN buoy is calibrated against a laser array installed on a fixed platform. Thus movements of this particular buoy during data acquisition is eliminated. The WAVESCAN buoy has therefore been used extensively, in order to establish sea surface truth used in assesment of results with airborne SAR-radars.

**Acknowledgement.**

A special acknowledgement is given to the company SEATEX A/S in Trondheim, Norway for support to the SWADE experimental programme.

## CHAPTER 30

# Time-Dependent Mild Slope Equation for Random Waves

Yasuhiro Kubo,<sup>1</sup> Yasuo Kotake<sup>2</sup>, Masahiko Isobe<sup>2</sup>  
and Akira Watanabe<sup>2</sup>

A time-dependent mild slope equation is derived to simulate the deformation of irregular waves due to refraction, diffraction and breaking. It is based on Berkhoff's mild slope equation, but the resulting model is capable of simulating the time evolution of irregular wave profiles. The validity of the model is verified through comparisons with experimental data in a wave flume. Application examples for two-dimensional problems are given.

### 1 Introduction

The mild slope equation derived by Berkhoff (1972) has widely been used in the numerical calculation of refraction and diffraction of regular waves. However, it is well known that the randomness of sea waves has a significant effect on the wave height distribution due to refraction and diffraction.

In this paper a governing equation for calculating the time evolution of random waves due to refraction and diffraction is derived on the basis of the mild slope equation. An energy dissipation term is added to model the wave breaking. To examine the validity of the equation, the results of calculation are compared with measurements in a wave flume. Examples of model application to two-dimensional random wave computation are also given.

---

<sup>2</sup>Dept. of Civil Eng. , Univ. of Tokyo ,Bunkyo-ku , Tokyo , 113 , Japan

## 2 Derivation of Governing Equation

The mild slope equation derived by Berkhoff (1972) is written as

$$\nabla(cc_g \nabla \hat{\eta}) + k^2 cc_g \hat{\eta} = 0 \quad (1)$$

where  $c$  is the wave celerity,  $c_g$  the group velocity,  $k$  the wave number, and  $\nabla$  the horizontal gradient operator. The quantity  $\hat{\eta}$  denotes the complex amplitude of the water surface elevation, by which the water surface elevation  $\eta$  is expressed as  $\eta = \text{Re}[\hat{\eta}e^{-i\omega t}]$  ( $\omega$ : the angular frequency). In the above equation, the quantities  $cc_g$  and  $k^2 cc_g$  depend on the frequency, which restricts the applicability of the mild slope equation to waves with a single frequency.

For random waves, the water surface elevation is expressed as the superposition of component waves :

$$\eta = \text{Re}\left[\sum_{m=1}^{\infty} \hat{\eta}_m e^{-i\omega_m t}\right] \quad (2)$$

where  $\omega_m$  is the angular frequency and  $\hat{\eta}_m$  the complex amplitude of the  $m$ -th component waves.

To apply the mild slope equation to the analysis of random wave transformation, we define a variable  $\tilde{\eta}$  such that

$$\eta = \text{Re}[\tilde{\eta}e^{-i\bar{\omega}t}] \quad (3)$$

where  $\bar{\omega}$  is a representative angular frequency such as the peak frequency. Comparing this with Eq. (2), we have

$$\eta = \text{Re}\left[\sum_{m=1}^{\infty} \tilde{\eta}_m e^{-i\bar{\omega}t}\right] \quad (4)$$

and

$$\tilde{\eta}_m = \hat{\eta}_m e^{-i\Delta\omega_m t} \quad (5)$$

where  $\Delta\omega_m = \omega_m - \bar{\omega}$ . The variable  $\tilde{\eta}_m$  is a function of time  $t$ , for which

$$\frac{\partial \tilde{\eta}_m}{\partial t} = -i\Delta\omega_m \tilde{\eta}_m \quad (6)$$

The quantity  $\tilde{\eta}_m$  is a function of time  $t$ , it is a solution of Eq. (1) as well as  $\hat{\eta}_m$ . Therefore, we can rewrite Eq. (1) as

$$\nabla[(cc_g)_m \nabla \tilde{\eta}_m] + (k^2 cc_g)_m \tilde{\eta}_m = 0 \quad (7)$$

Since the quantities  $(cc_g)_m$  and  $(k^2 cc_g)_m$  depend on the angular frequency  $\omega_m$ , it is not possible to superimpose Eq. (7) for all component waves and calculate  $\tilde{\eta}$

directly. Therefore, we modify Eq. (7) and change the quantities  $cc_g$  and  $k^2cc_g$  into constants independent of component angular frequencies.

If we expand the quantities  $(cc_g)_m$  and  $(k^2cc_g)_m$  into Taylor series of  $\Delta\omega_m$  and eliminate powers of  $\Delta\omega_m$  using relations such as  $-i\Delta\omega_m\tilde{\eta}_m = \partial\tilde{\eta}_m/\partial t$  and  $(-i\Delta\omega_m)^2\tilde{\eta}_m = \partial^2\tilde{\eta}_m/\partial^2t$ , we can obtain an equation in which all the quantities can be determined from the representative frequency only.

For example, by truncating the Taylor series at the first order, the first and second terms in Eq. (7) are expressed as

$$(cc_g)_m \nabla \tilde{\eta}_m = [\overline{cc_g} + \frac{d(\overline{cc_g})}{d\omega} \Delta\omega_m] \nabla \tilde{\eta}_m = \overline{cc_g} \nabla \tilde{\eta}_m + i \frac{d(\overline{cc_g})}{d\omega} \nabla \left( \frac{\partial \tilde{\eta}_m}{\partial t} \right) \quad (8)$$

$$(k^2cc_g)_m \tilde{\eta}_m = [\overline{k^2cc_g} + \frac{d(\overline{k^2cc_g})}{d\omega} \Delta\omega_m] \tilde{\eta}_m = \overline{k^2cc_g} \tilde{\eta}_m + i \frac{d(\overline{cc_g})}{d\omega} \frac{\partial \tilde{\eta}_m}{\partial t} \quad (9)$$

where all the quantities  $\overline{cc_g}$ ,  $\overline{d(\overline{cc_g})/d\omega}$ ,  $\overline{k^2cc_g}$  and  $\overline{d(\overline{k^2cc_g})/d\omega}$  are constants. Substitution of Equations (8) and (9) into Eq. (7) yields

$$\nabla(\bar{\alpha} \nabla \tilde{\eta}_m) + i \nabla[\bar{\beta} \nabla(\frac{\partial \tilde{\eta}_m}{\partial t})] + \bar{k}^2 \bar{\alpha} \tilde{\eta}_m + i \bar{\gamma} \frac{\partial \tilde{\eta}_m}{\partial t} = 0 \quad (10)$$

$$\bar{\alpha} = \overline{cc_g} \quad (11)$$

$$\bar{\beta} = \frac{\bar{c}}{\bar{k}} [-2(1 - \bar{n}) + \frac{1}{2\bar{n}}(2\bar{n} - 1)\{1 - (2\bar{n} - 1) \cosh 2\bar{k}d\}] \quad (12)$$

$$\bar{\gamma} = \bar{k}\bar{c}[2\bar{n} + \frac{1}{2\bar{n}}(2\bar{n} - 1)\{1 - (2\bar{n} - 1) \cosh 2\bar{k}d\}] \quad (13)$$

$$\bar{n} = 1/2(1 + 2\bar{k}d/\sinh 2\bar{k}d) \quad (14)$$

Then, superposition of Eq. (10) for an infinite number of component waves yields

$$\nabla(\bar{\alpha} \nabla \tilde{\eta}) + i \nabla[\bar{\beta} \nabla(\frac{\partial \tilde{\eta}}{\partial t})] + \bar{k}^2 \bar{\alpha} \tilde{\eta} + i \bar{\gamma} \frac{\partial \tilde{\eta}}{\partial t} = 0 \quad (15)$$

which is termed as a time-dependent mild slope equation for random waves. For random incident waves,  $\tilde{\eta}$  along the boundary is determined by Eq. (4), and then  $\tilde{\eta}$  in the calculation domain can directly be calculated by Eq. (15).

The above expansion of the quantities  $cc_g$  and  $k^2cc_g$  into the first-order Taylor series of  $\Delta\omega_m$  is equivalent to approximating them as linear functions of  $\omega$ . Fig. 1 illustrates the accuracy of the approximation. As seen in Fig. 1, the error is insignificant when the deviation of the frequency from the representative value is small.

Fig. 1: Accuracy of the approximated quantities

### 3 Modeling of Wave Breaking

To incorporate energy dissipation due to wave breaking, an empirical energy dissipation term based on the model presented by Isobe(1986) is added to Eq. (15):

$$\nabla(\bar{\alpha}\nabla\bar{\eta}) + i\nabla[\bar{\beta}\nabla(\frac{\partial\bar{\eta}}{\partial t})] + \bar{k}^2\bar{\alpha}(1 + if_D)\bar{\eta} + i\bar{\gamma}(1 + if_D)\frac{\partial\bar{\eta}}{\partial t} = 0 \quad (16)$$

where  $f_D$  is the energy dissipation coefficient.

It is convenient to evaluate  $f_D$  by using spatial wave profiles because time series of the spatial profile are obtained as a solution of Eq. (16). In the procedure, we first divide the spatial wave profiles into individual waves by the zero-up crossing method from offshore to onshore as shown in Fig. 2.

To judge the breaking of individual waves, the amplitude to water depth ratio,

Fig. 2: Evaluation of energy dissipation function due to wave breaking

$\gamma$ , is introduced as follows:

$$\gamma = |\tilde{\eta}|/d \quad (17)$$

where  $|\tilde{\eta}|$  is the amplitude at the wave crest and  $d$  the water depth. If  $\gamma$  is greater than  $\gamma_b$  which is a critical value of wave breaking and determined by Eq. (18), the individual wave is judged to be breaking.

$$\gamma_b = 0.8\gamma'_b \quad (18)$$

$$\gamma'_b = 0.53 - 0.3 \exp(-3\sqrt{d/L_0}) + 5 \tan^{\frac{3}{2}} \beta \exp\{-45(\sqrt{d/L_0} - 0.1)^2\} \quad (19)$$

where  $L_0$  is the representative wavelength in deep water and  $\tan \beta$  the bottom slope. The value 0.8 in Eq. (18) is introduced to consider that random waves are easier to break than regular waves. After breaking, if  $\gamma$  becomes smaller than  $\gamma_r$  which is a critical value of wave recovery determined by Eq. (20), the individual wave is judged to have recovered.

$$\gamma_r = 0.135 \quad (20)$$

To evaluate the spatial distribution of the energy dissipation coefficient, we first determine  $f_{D\max}$  at each crest of breaking waves by Eq. (21), then obtain the energy dissipation coefficient  $f_D$  by interpolating  $f_{D\max}$  linearly as shown in Fig. 2, and finally calculate the water surface profile at the next time step.

$$f_{D\max} = \frac{5}{2} \tan \beta \sqrt{\frac{1}{k_0 d}} \sqrt{\frac{\gamma - \gamma_r}{\gamma_s - \gamma_r}} \quad (21)$$

$$\gamma_s = 0.4 \times (0.57 + 5.3 \tan \beta) \quad (22)$$

where  $k_0$  is the representative wave number. The same procedure is repeated for arbitrary time steps.

## 4 Boundary conditions

The open boundary condition, which allows outgoing waves to propagate freely, is not easy to implement. In addition, along the offshore boundary, the incident waves should be introduced.

We apply a method presented by Ohya *et al.* (1990) to the open boundaries. In the method, the energy of outgoing waves is absorbed in the energy dissipation layer which is added outside of the boundary. To introduce the incident waves from the offshore boundary, terms due to an exciting force are added on the right hand side:

$$\begin{aligned} & \nabla(\bar{\alpha} \nabla \tilde{\eta}) + i \nabla[\bar{\beta} \nabla(\frac{\partial \tilde{\eta}}{\partial t})] + \bar{k}^2 \bar{\alpha} (1 + i f_D) \tilde{\eta} + i \bar{\gamma} (1 + i f_D) \frac{\partial \tilde{\eta}}{\partial t} \\ & = \nabla(\bar{\alpha} \nabla \tilde{\eta}_{in}) + i \nabla[\bar{\beta} \nabla(\frac{\partial \tilde{\eta}_{in}}{\partial t})] + \bar{k}^2 \bar{\alpha} (1 + i f_D) \tilde{\eta}_{in} + i \bar{\gamma} (1 + i f_D) \frac{\partial \tilde{\eta}_{in}}{\partial t} \quad (23) \end{aligned}$$

where  $\tilde{\eta}_{in}$  is the complex amplitude due to the incident waves. The above equation is obtained by substituting component,  $\tilde{\eta}_{out} = \tilde{\eta} - \tilde{\eta}_{in}$ , due to outgoing waves for  $\tilde{\eta}$  in Eq. (16).

## 5 Application and Results

Time-evolutional solutions can be obtained from Eq. (16) by using a finite difference method.

Numerical calculations for the present equation are carried out for one-dimensional cases by using Crank-Nicholson method. Figures 3 and 4 show the result for two component waves with slightly different frequencies,  $0.9\bar{\omega}$  and  $1.1\bar{\omega}$  ( $\bar{\omega}$ : the mean angular frequency). Fig. 3 is for deep water and Fig. 4 for shallow water. Spatial wave profiles are shown at four time steps from the top to the

Fig. 3: Propagation of two-component waves (deep water)

Fig. 4: Propagation of two-component waves (shallow water)

Fig. 5: Wave flume and bottom configuration

bottom with an interval of a half of the mean period. It seems in Fig. 3 that waves propagate with the wave celerity  $c$ , while wave groups propagate with the group velocity  $c_g$ . This can not be reproduced by the previous time-dependent mild slope equation.

Results of numerical calculations are compared with experiments for the wave transformations on a slope to confirm the validity of the present equation. The data were obtained by Watanabe *et al.*(1988) in a wave flume shown in Fig. 5. Figures 6 and 7 compare the measured and calculated wave height variations of random waves on a beach with a slope of  $1/30$ . The offshore boundary condition is given at  $x = -40\text{cm}$  and the shoreline is located at  $x = 1000\text{cm}$ . Fig. 6 is for the plunging-breaker (case 1), while Fig. 7 for the spilling-breaker (case 2).

The peak frequency  $f_p$  and the significant wave height  $H_{1/3}$  of the incident waves are  $0.5\text{Hz}$  and  $5.4\text{cm}$  for case 1, and  $0.75\text{Hz}$  and  $9.2\text{cm}$  for case 2. In the numerical calculations, the incident waves are given by synthesizing component waves with frequency  $0.25f_p \sim 2.5f_p$ , which were extracted from the measured water surface elevation at the offshore boundary by using FFT. The grid size  $\Delta x$  is  $10\text{cm}$  and the time interval  $\Delta t$  is  $0.02\text{s}$ .

In Fig. 6, the calculated significant wave height variations does not agree well with the measured one near the breaking point since the present equation is linear. However, the root mean square of the water surface variation is predicted well due to the empirical formulation of the dissipation term.

Fig. 8 compares the measured and calculated water surface fluctuations for the case 2. Fig. 8 (a) is for the offshore boundary, Fig. 8 (b) for the offshore zone, Fig. 8 (c) for the average breaking point and Fig. 8 (d) for the surf zone. As seen in Fig. 8 (b), a good agreement is obtained in the offshore zone, but in Fig. 8 (d) the difference is large. Owing to the linearity of the equation, the

Fig. 6: Comparison of the measured and calculated wave height variations (case 1:  $H_{1/3} = 5.4\text{cm}$ ,  $f_p = 0.5\text{Hz}$ )

Fig. 7: Comparison of the measured and calculated wave height variations (case 2:  $H_{1/3} = 9.2\text{cm}$ ,  $f_p = 0.75\text{Hz}$ )

present equation can not reproduce the non-linear properties such as skewness of the wave profile. However, the transformation of wave groups is well reproduced.

As examples of application to two-dimensional problems, wave fields on a uniform slope and around a detached breakwater are calculated by the present equation. For two-dimensional problems, the ADI method is used because it reduces the memory size and computation time.

Fig. 9 shows the calculation domain. The contour lines are shown for the energy dissipation coefficient  $f_D$  in the energy dissipation layer. The layer is taken thicker along the offshore boundary than along the onshore boundary because of the difference in wavelengths. The grid size  $\Delta l$  is 2m and the time interval  $\Delta t$  is 0.02s.

Fig. 8: Comparison of the measured and calculated wave surface fluctuations (case2)

Numerical calculations are carried out for two cases: for regular waves and multidirectional irregular waves. The wave period or significant wave period is 6s, and the wave height or significant wave height is 1m in deep water.

The frequency spectrum of the incident irregular waves is of the Bretshneider-

Fig. 9: Calculation domain

Fig. 10: The frequency spectrum of incident waves

Mitsuyasu spectrum and the Mitsuyasu-type directional distribution function is used with  $S_{max} = 10$ . The incident irregular waves are given by the double summation method in which 13 frequency components and 15 directional components are used. High frequency components are cut as shown in Fig. 10, because the applicability range of the present equation is restricted within a narrow band.

Figures 11 (a) and 11 (b) compare the analytical and numerical solution of wave height variations of component waves due to refraction. Fig. 11 (a) is for the longest wave period 8.09 s and Fig. 11 (b) for the shortest wave period 3.89s. In these figures, the calculated solutions agree well with the analytical ones.

Figures 12 (a) and 12 (b) show the results of the numerical calculation of the wave field around a detached breakwater for regular and irregular waves, respectively. Figures 13 and 14 show the wave height variations along the X- and Y-axis. As seen in these figures, the distribution of wave height is smoother

(a) the longest wave period 8.09s

(b) the shortest wave period 3.89s

Fig. 11: Comparison of the analytical and calculated wave height variations of component wave

(a) regular wave field

(b) irregular wave field

Fig. 12: Comparison of the regular wave field and irregular wave field around a detached breakwater

for the irregular waves because of the frequency and directional distribution. For the regular waves, nodes and anti-nodes are clearly seen. The asymmetrical distribution of wave height for irregular waves is due to a statistical variation because the significant wave height is obtained by using  $H_{1/3} = 4.004\eta_{rms}$ , where  $\eta_{rms}$  is the root mean square of the water surface elevation.

## 6 Conclusion

A time-dependent mild slope equation for random waves was derived from Berkhoff's mild slope equation. An advantage of the present equation is that it allows to calculate the time evolution of the random wave transformation due to refraction and diffraction and can easily incorporate a breaking wave model. The results of numerical calculations were compared with theoretical predictions and laboratory data, which confirmed the validity of the present equation.

## CHAPTER 31

### EVALUATION OF NUMERICAL MODELS ON WAVE-CURRENT INTERACTIONS

Jung L. Lee<sup>1</sup> and Hsiang Wang<sup>2</sup>

#### Abstract

Five contemporary numerical models on wave-current interactions are evaluated in this paper. The bases of evaluation are mathematical exactness, degree of computational difficulty and practical applicability in terms of the abilities of handling shoaling, refraction, diffraction, reflection and wave-current interaction. Recommendations are given in matrix form on the relative merit of each model.

#### 1 Introduction

In the past two decades, we have witnessed remarkable progress in modeling nearshore hydrodynamics by numerical techniques. Prediction of nearshore waves took a new dimension with the introduction of the mild slope equation by Berkhoff (1972) which is capable of handling the combined effects of refraction and diffraction. Since then significant progress has been made in computational techniques as well as model capabilities, notably by Radder (1979), Copeland (1985), Ebersole (1986), Yoo and O'Connor (1986a), and Dalrymple et al. (1989).

Prediction of nearshore, wave-induced currents has also advanced considerably since some of the earlier development by Noda et al. (1974) and Ebersole and Dalrymple (1979). Both of these earlier models were driven by a wave refraction model but with no current feed back. More recently, Yoo and O'Connor (1986b) developed a wave-induced circulation model based upon what could be classified as a hyperbolic-type wave equation; Yan (1987) and Winer (1988) developed their interaction models based upon parabolic approximation of the wave equation.

Five wave and current coupled models were selected for evaluation. Of the five wave models, four were selected from existing literature and one was developed by the authors. The main differences among the 5 models are their governing wave equations and the as-

---

<sup>1</sup>Graduate Assistant, Coastal and Oceanographic Engineering Department, Univ. of Florida

<sup>2</sup>Professor, Coastal and Oceanographic Engineering Department, 336 Weil Hall, University of Florida, Gainesville, FL 32611, USA

sociated numerical methods; they include two hyperbolic types, two elliptic types, and one parabolic type. Each can be derived from the mild slope equation given by Kirby(1984), with varying degrees of approximations. The current model is governed by the depth-integrated momentum and continuity equations, much the same as given by Ebersole and Dalrymple (1979).

In this paper, the emphasis is on evaluating wave models and their suitability for wave-current interaction modeling. Thus, the current condition is given as input rather than coupled with the circulation model. The evaluation of fully coupled models has been presented in Lee and Wang (1992).

## 2 Wave equations

The governing equations of the 5 models are all derivable from the linearized mild slope wave-current interaction equation given by Kirby (1984) as follows:

$$\frac{D^2\hat{\phi}}{Dt^2} + (\nabla \cdot U) \frac{D\hat{\phi}}{Dt} - \nabla \cdot (CCg\nabla\hat{\phi}) + (\sigma^2 - k^2CCg)\hat{\phi} = 0 \tag{1}$$

- where,  $\hat{\phi}$  is the surface velocity potential
- $C$  is the relative phase velocity ( $\sigma/k$ )
- $Cg$  is the relative group velocity ( $\partial\sigma/\partial k$ )
- $\sigma$  is the intrinsic angular frequency ( $\sigma^2 = gk \tanh kh$ )
- $\omega$  is the apparent angular frequency
- $k$  is the wave number
- $h$  is the water depth
- $U$  is the steady current velocity vector ( $u, v$ ).

The intrinsic frequency and wave number for progressive waves are determined by the Doppler equation

$$\omega = \sigma_d + U \cdot \mathbf{K}$$

where  $\sigma_d$  and  $\mathbf{K}$  are, respectively, the intrinsic angular frequency and wave number vector with the inclusion of diffraction effect. Ignoring the mean surface gradient in the above equation yields the conventional Doppler equation (see Eq.(9)). If any reflective wave exists in the current field, the intrinsic frequency and wave number of the reflected wave should be determined by a separate Doppler equation. Therefore, wave reflection effects may be included by superposition.

### 2.1 Hyperbolic-type model I (HM I) [Ohnaka et al., 1988]

The governing equations are a pair of first-order equations which constitute a hyperbolic system similar to the shallow water wave equations. Ito and Tanimoto (1972) first proposed the approach and Copeland (1985) completed the formulation through the application of the mild slope equation. Ohnaka et al. (1988) extended the formulation to a wave and current coexisting field to obtain:

$$\left[1 + \frac{\sigma}{\omega} \left(\frac{Cg}{C} - 1\right)\right] \frac{\partial\eta}{\partial t} + \nabla \cdot (U\eta) + \nabla \cdot \left(\frac{CCg\nabla\hat{\phi}}{g}\right) = 0 \tag{2}$$

$$\frac{\partial\nabla\hat{\phi}}{\partial t} + \omega g \nabla \frac{\eta}{\sigma} = 0 \tag{3}$$

The unknowns to be solved are the wave surface elevation,  $\eta$ , and the gradient of surface velocity potential,  $\nabla\hat{\phi}$ . It can be shown that in the presence of strong currents these equations will lead to conditions inconsistent with the conservation equation of wave action given by Bretherton and Garrett (1968).

### 2.2 Hyperbolic-type model II (HM II) [Yoo et al., 1986b]

In this second model the governing equations are based on kinematic and dynamic conservation equations of wave properties averaged over both a wave period and a wave length; they are of the following forms:

$$\frac{\partial \mathbf{K}}{\partial t} + (Cg \frac{\mathbf{K}}{k} + U) \cdot \nabla \mathbf{K} + \mathbf{K} \cdot \nabla U + \frac{k\sigma}{\sinh 2kh} \nabla h - \frac{CCg}{2a} \nabla [\nabla^2 (\frac{a}{\sigma})] = 0 \quad (4)$$

$$\frac{\partial}{\partial t} (\frac{a^2}{\sigma}) + \nabla \cdot [(Cg \frac{\mathbf{K}}{k} + U) \frac{a^2}{\sigma}] = 0 \quad (5)$$

Eqs.(4) and (5) are used to solve for  $\mathbf{K}$  and  $a^2/\sigma$ .

### 2.3 Elliptic-type model I (EM I)

The surface velocity potential is now assumed to be a harmonic function of time expressed as:

$$\hat{\phi}(\mathbf{x}, t) = \tilde{\phi}(\mathbf{x})e^{-i\omega t}$$

where  $\tilde{\phi}(\mathbf{x})$  is the surface potential in steady state. Substituting the above equation into Eq.(1) gives,

$$\begin{aligned} -i\omega \{2U \cdot \nabla \tilde{\phi} + \tilde{\phi}(\nabla \cdot U)\} + (U \cdot \nabla)(U \cdot \nabla \tilde{\phi}) + (\nabla \cdot U)(U \cdot \nabla \tilde{\phi}) \\ - \nabla \cdot (CCg \nabla \tilde{\phi}) + (\sigma^2 - \omega^2 - k^2 CCg)\tilde{\phi} = 0 \end{aligned} \quad (6)$$

The above equation together with the Doppler equation permits us to solve for  $\tilde{\phi}(\mathbf{x})$ .

### 2.4 Elliptic-type model II (EM II) [Jeong, 1990]

The surface velocity potential is approximated by wave-period and wave-length averaged quantity as,

$$\hat{\phi}(\mathbf{x}, t) = A(\mathbf{x})e^{i\psi} = A(\mathbf{x})e^{i(\int \mathbf{K} \cdot d\mathbf{x} - \omega t)} \quad (7)$$

Substituting the above equation into the linearized free surface boundary conditions, we obtain

$$A = -i \frac{g}{\sigma_d} a \quad (8)$$

$$\sigma_d^2 = \sigma^2 - \frac{g}{A} \nabla A \cdot \nabla \bar{\eta} \quad (9)$$

Where  $\sigma_d$  is the intrinsic angular frequency with diffraction effect as mentioned earlier, and  $\bar{\eta}$  is the mean surface elevation. The second term in Eq.(9) can be usually be neglected. Substituting Eqs.(7-9) into Eq.(1) and after some manipulation the real and imaginary parts yield two equations; the real part is the energy conservation equation of elliptic type,

$$\nabla \cdot [(Cg \frac{\mathbf{K}}{k} + U) \frac{a^2}{\sigma}] = 0 \quad (10)$$

and the imaginary part is the Eikonal equation,

$$CCg \frac{a}{\sigma} K^2 - \nabla \cdot (CCg \nabla \frac{a}{\sigma}) - k^2 CCg \frac{a}{\sigma} = 0 \tag{11}$$

Since there are 3 unknowns,  $a$ ,  $K_x$  and  $K_y$ , another equation expressing the irrotationality of wave number is introduced.

$$\nabla \times \mathbf{K} = 0 \tag{12}$$

2.5 Parabolic-type model (PM) [Winer, 1988]

The parabolic approximation to the elliptic-type equation of harmonic wave motion (Eq.6) is derived by 1) splitting the surface potential into two components ( $\tilde{\phi} = \tilde{\phi}^+ + \tilde{\phi}^-$ ) and 2) assuming that the waves are oriented in the x-direction, thus, allowing  $k_y \cong 0$ . There were several approaches with varying degrees of approximations to arrive at various terms of parabolic equation. The version suggested by Winer (1989) has the final form,

$$\begin{aligned} \sigma(Cg_x + u) \frac{\partial A'}{\partial x} + i(k_o - k_x)(Cg_x + u)A' + \frac{1}{2} \frac{\partial}{\partial x} [\sigma(Cg_x + u)]A' = \\ \frac{i}{2} \frac{\partial}{\partial y} (CCg \frac{\partial A'}{\partial y}) - \frac{\omega}{2} \frac{\partial v}{\partial y} A' - \omega v \frac{\partial A'}{\partial y} \end{aligned} \tag{13}$$

where

$$A' = \tilde{\phi}^+ e^{-ik_o x}, \quad Cg_x = Cg \frac{k_x}{k}$$

3 Numerical schemes

The numerical methods of all models fall under the category of finite difference method (FDM). Table 1 summarizes the numerical schemes as well as the unknowns of each model. The downwave and side boundary conditions are summarized in Table 2. A brief description of the numerical scheme of each model is given here.

Table 1

Model	Unknowns	Numerical scheme
HM I	$\eta$ and $\nabla \tilde{\phi}$	FDM on a staggered grid system
HM II	$a$ and $\mathbf{K}$	FDM on a staggered grid system
EM I	complex $\tilde{\phi}$	Combined Gragg's method-FDM
EM II	$a$ , $K$ and $\theta$	Generalized Lax-Friedrich FDM
PM	complex $A'$	Crank-Nicholson FDM

Table 2

Model	Downwave B.C.	Side B.C.
HM I	Method of characteristics	$\mathcal{D}_y \eta = ik_y \eta$
HM II	$\mathcal{D}_x a = 0, \mathcal{D}_x K_x = 0$	$K_y$ given by Snell's law
EM I	-	$\mathcal{D}_y \tilde{\phi} = ik_y \tilde{\phi}$
EM II	$\mathcal{D}_x a = 0, \mathcal{D}_x \theta = 0$	$\theta$ given by Snell's law
PM	-	$\mathcal{D}_y A' = ik_y A'$

$\mathcal{D}$ =finite difference operator

### 3.1 Hyperbolic model I

The numerical technique is based on Ohnaka et al. (1988). However, the technique of treating boundary conditions and calculating wave angles has been improved by the introduction of the complex variables as given in Table 2. For details see Lee and Wang (1992).

In the case of wave-current interaction, the determination of wave angle is very important because phase speed, group velocity and intrinsic frequency are determined through the dispersion equation which contains the scalar product of the current vector and the wave number vector. The wave angle is calculated at the center of each grid location by the approximation

$$\theta \cong \tan^{-1} \left[ \frac{\mathcal{R}e(\nabla_y \hat{\phi} / \eta)}{\mathcal{R}e(\nabla_x \hat{\phi} / \eta)} \right]$$

and the wave height is calculated by

$$H = 2\sqrt{\mathcal{R}e\{\eta\}^2 + \mathcal{I}m\{\eta\}^2}$$

### 3.2 Hyperbolic model II

The numerical scheme used here is the same as detailed in Yoo and O'Connor (1986a). The wave amplitude is specified at the center of the grid whereas the wave number vector is situated at the side of the grid.

The wave angle is calculated at the center of each grid location

$$\theta = \tan^{-1} \left( \frac{K_y}{K_x} \right)$$

where the wave number vector indicates the value at the center of each grid and the wave angle is measured from the x-axis.

### 3.3 Elliptic model I

The numerical scheme was developed by the authors. Here, Eq.(6) is treated as an ordinary differential equation in x while letting the y-direction differential operator,  $\mathcal{D}$ , be approximated by a finite difference scheme,

$$\begin{aligned} & (u^2 - CCg)\tilde{\phi}_{xx} + \{-2i\omega u + 2uu_x + u_y v + uv_y - (CCg)_x\}\tilde{\phi}_x \\ & + 2uv\mathcal{D}_y(\tilde{\phi}_x) + \{-2i\omega v + 2vv_x + uv_x + u_x v - (CCg)_y\}\mathcal{D}_y(\tilde{\phi}) \\ & + (v^2 - CCg)\mathcal{D}_{yy}(\tilde{\phi}) + \{-i\omega(u_x + v_y) + \sigma^2 - \omega^2 - k^2 CCg\}\tilde{\phi} = 0 \end{aligned}$$

in which subscripts indicate the differentiations.

The above equation is then converted into a pair of first-order equations by the simple expediency of defining the derivative as a second function.

$$\begin{aligned} \tilde{\phi}_x &= \tilde{\phi}_1 \\ \tilde{\phi}_{1x} &= \frac{1}{u^2 - CCg} \{ \{-2i\omega u + 2uu_x + u_y v + uv_y - (CCg)_x\}\tilde{\phi}_1 \\ & + 2uv\mathcal{D}_y(\tilde{\phi}_1) + \mathcal{F}(\tilde{\phi}) \} \end{aligned}$$

where

$$\mathcal{F}(\tilde{\phi}) = \{-2i\omega v + 2vv_x + uv_x + u_xv - (CCg)_y\} \mathcal{D}_y \tilde{\phi} + (v^2 - CCg) \mathcal{D}_{yy} \tilde{\phi} + (-i\omega(u_x + v_y) + \sigma^2 - \omega^2 - k^2 CCg) \tilde{\phi}$$

These ordinary differential equations are solved numerically using Gragg's method for which the main algorithm for a differential equation  $\phi'(x) = f(x, \phi(x))$  is given as

$$\begin{aligned} y_1 &= \phi_{i-1} + hf(x_{i-1}, \phi_{i-1}) \\ y_{j+1} &= y_{j-1} + 2hf(x_{i-1} + jh, y_j) \quad j = 1, 2, \dots, n-1 \\ \phi_i &\cong (y_n + y_{n-1} + hf(x_i, y_n))/2 \end{aligned}$$

where  $h$  is a subgrid space defined as  $h = \Delta x/n$ .

The upwave boundary condition is merely the specified complex  $\tilde{\phi}$  determined by the incident wave amplitude and wave angle. The side boundary conditions are either non-reflective or reflective. The non-reflective boundary condition can be specified by Snell's law in the absence of diffraction,

$$\tilde{\phi}_y = ik_y \tilde{\phi} \quad \text{where } k_y = k \sin \theta = k_o \sin \theta_o$$

The reflective boundary condition is expressed as

$$\tilde{\phi}_y = 0 \quad \text{i.e. } k_y = 0$$

If there is any reflective structure posed in the  $y$ -direction, the direction of the reflected waves is the mirror image of that of the incident wave. Since the unknown in this model is the complex surface potential, the reflected wave field can be easily specified as the conjugate by tracing the computation backward.

The wave angle is calculated by

$$\theta = \tan^{-1} \left( \frac{K_y}{K_x} \right)$$

where

$$K_x = \mathcal{I}m \left\{ \frac{\tilde{\phi}_1}{\tilde{\phi}} \right\}, \quad K_y = \mathcal{D}_y^\pm S$$

with

$$\begin{aligned} S &= \mathbf{K} \cdot \mathbf{x} = \tan^{-1} [\mathcal{I}m(\tilde{\phi})/\mathcal{R}e(\tilde{\phi})] \\ \mathcal{D}_y^\pm S &= [S_{j+1} - S_j]/\Delta y \quad \text{or} \quad [S_j - S_{j-1}]/\Delta y \end{aligned}$$

The wave height is calculated easily by

$$H = 2\sqrt{\mathcal{R}e\left\{\frac{\sigma}{g}\tilde{\phi}\right\}^2 + \mathcal{I}m\left\{\frac{\sigma}{g}\tilde{\phi}\right\}^2}$$

### 3.4 Elliptic model II

By introducing wave angle,  $\theta$ , Eq.(11) can be expressed as,

$$AK^2 - C = 0$$

where,

$$A = CCg\frac{a}{\sigma}, \quad C = \nabla \cdot (CCg\nabla\frac{a}{\sigma}) + k^2CCg\frac{a}{\sigma}$$

The solution of  $K$  is simply,

$$K = \sqrt{\frac{C}{A}}$$

The generalized Lax-Friedrich method is employed to solve Eqs.(10) and (12). Both unknown,  $\theta$  and  $a$ , are solved row by row using an explicit FDM (Ebersole et al. (1986) or Jeong (1990)).

**3.5 Parabolic model**

Eq.(13) is solved by the Crank-Nicolson scheme using a double sweep approach. The first sweep is required to approximate the x-directional component of group velocity.

The wave angle is calculated by

$$\theta = \tan^{-1}\left(\frac{K_y}{K_x}\right)$$

where

$$K_x \cong k\sqrt{1 - (K_y/k)^2}, \quad K_y = D_y^\pm S$$

with

$$S = \int K_x dx - k_0 x + K_y y = \tan^{-1}[\text{Im}(A')/\text{Re}(A')]$$

$$D_y^\pm S = [S_{j+1} - S_j]/\Delta y \quad \text{or} \quad [S_j - S_{j-1}]/\Delta y$$

The wave height is calculated by,

$$H = 2\sqrt{\text{Re}\left\{\frac{\sigma}{g}A'\right\}^2 + \text{Im}\left\{\frac{\sigma}{g}A'\right\}^2}$$

**4 Comparisons of wave models**

**4.1 Basic equation**

The nature and the exactness of the basic equations in each model are evaluated in terms of dynamics (energy conservation) and kinematics (Eikonal equation). The comparisons are summarized in Table 3. For details see Lee and Wang (1992).

Table 3

Model	Assumption	Energy eq.	Eikonal eq.	Violating cond.
HM I	$g\eta \cong i\sigma\phi$	approx.	exact	strong current
HM II	$\nabla(CCg) \cong 0$	exact	approx.	steep slope
EM I	-	exact	exact	-
EM II	-	exact	exact	-
PM	$k_y \cong 0$	approx.	approx.	wide angle

4.2 Computational difficulty

The degree of computational difficulty is measured in terms of stability as well as CPU time. The stability criteria given below are obtained for ideal cases only. Therefore, they are not general as well as not vigorous.

Table 4

Model	Stability
HM I	$\Delta t \leq T / [(L_{max} / \Delta x)^2 + (L_{max} / \Delta y)^2]^{1/2}$
HM II	$\Delta t \leq T / [(n_a L_{max} / \Delta x)^2 + (n_a L_{max} / \Delta y)^2]^{1/2}$
EM I	$\Delta y \geq L_{max} / \pi$ for central difference method
EM II	$\Delta y \geq L_{max} / \pi$ for $\tau = 0$
PM	stable

$n_a = Cg_a / C_a$  (with subscript *a* indicating the absolute)

The comparison for the computational time is also not general. Rather, a specific configuration as shown in Fig.1 is used as the test bench mark. This configuration is a circular shoal used by Ito and Tanimoto (1972) in their laboratory experiment to study combined diffraction and refraction. This configuration has been cited by many authors for verification purposes. Here, the same grids and same accuracy criteria are used in all models. Wave heights along three cross-sections as shown in Fig.2 are compared with the laboratory data of Ito and Tanimoto. The CPU time on a VAX-8350 computer and the values of the agreement parameter are given below.

Table 5

Model	CPU time	<i>d</i> (Sec.1)	<i>d</i> (Sec.2)	<i>d</i> (Sec.3)
HM I	15 min	0.98	0.97	0.95
HM II	12 min	0.97	0.97	0.96
EM I	24 sec	0.96	0.97	0.94
EM II	5 min	0.98	0.97	0.96
PM	17 sec	0.97	0.97	0.95

The agreement is based on an index, *d*, given here as an agreement parameter (Willmott, 1981):

$$d = 1 - \frac{\sum_i^N (P_i - O_i)^2}{\sum_i^N (|P_i - \bar{O}| + |O_i - \bar{O}|)^2}$$

where *P<sub>i</sub>* is the numerical value, *O<sub>i</sub>* is the theoretical or observed value and  $\bar{O}$  is the mean of the variates *O<sub>i</sub>*. The values for *d* vary between 0 and 1.0, with 1.0 indicating perfect agreement.

4.3 Wave shoaling and refraction

To test wave shoaling and refraction, numerical results were compared with the analytical solutions based on the energy conservation equation and Snell's law for waves propagating over a uniform slope. The input data are uniformly given to each model as follows:

Figure 1: Shoal configuration for comparison of CPU time (concentric circular contours of  $h/L_i$ ).

Figure 2: Comparison with the laboratory data of Ito and Tanimoto (1972).

Figure 3: Comparison of wave shoaling and wave refraction.

NX	NY	$\Delta x(m)$	$\Delta y(m)$	T(sec)
101	21	0.02	0.14	0.8

The time step in the hyperbolic models is fixed at 0.01 sec.

As shown in Figure 3, all models except hyperbolic model I produce results of good agreement. Hyperbolic model I, on the other hand, induces periodical fluctuations. The numerical error appears to be related to the ratio of grid size to wave length. As the wave length shortens towards shoreline the error becomes larger and also propagates up-wave as time progresses. The numerical results were taken along a center grid line in x- axis.

#### 4.4 Wave diffraction

Wave diffraction was evaluated by comparing wave height with the analytical solution given by Wiegel (1962) for a semi-infinite breakwater. The input data are uniformly given as NX=91, NY=75,  $\Delta x=0.04 m (=0.1 L)$ ,  $\Delta y=0.08 m$  for  $T=0.511 sec$  except elliptic model II where NY=38 and  $\Delta y=0.16 m$  were used to avoid numerical instability. The time step is 0.01 sec in the hyperbolic models.

Figure 4 shows the comparisons for waves approaching normal to the breakwater axis. All models appear to agree well with the analytical result. For 30° angle to the normal, however, only hyperbolic model I and elliptic model II perform adequately (Fig.5). The performance in general can be improved by reducing  $\Delta y$ , except elliptic model II which is almost stable regardless the size of  $\Delta y$ .

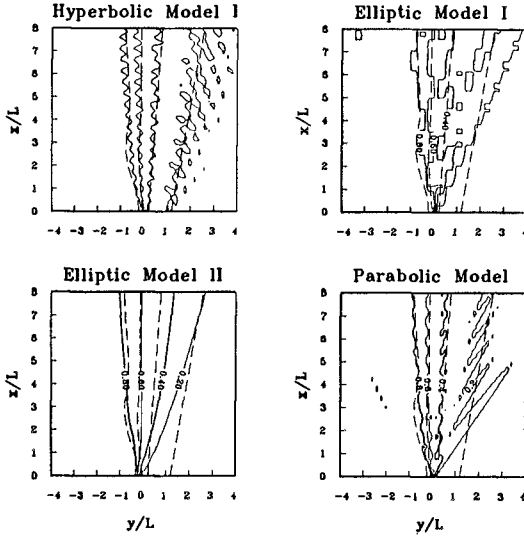

Figure 4: Comparison of wave diffraction for semi-infinite breakwater ( $0^\circ$ ) between analytic solutions (dotted line) and numerical solutions (solid contour line of 0.8, 0.6, 0.4 and 0.2 diffraction coeff. from left).

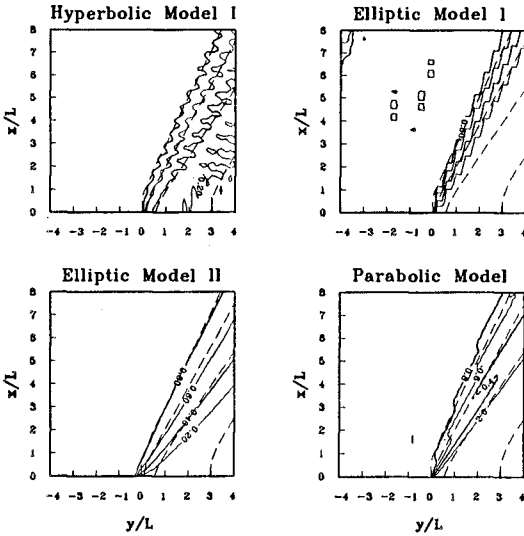

Figure 5: Comparison of wave diffraction for semi-infinite breakwater ( $30^\circ$ ).

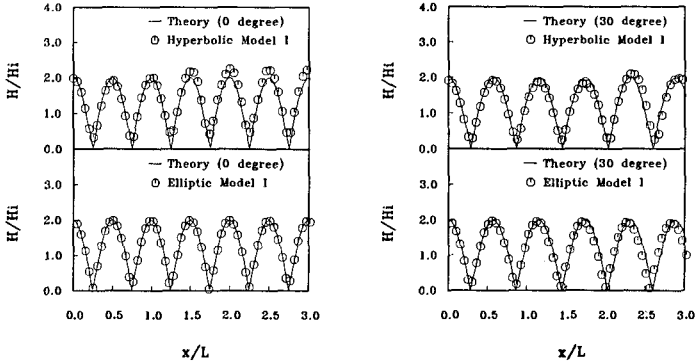

Figure 6: Wave reflection tests against wall.

4.5 Wave reflection

Wave reflection was tested for the case of waves approaching a seawall at 0° and 30° in constant deep water depth of 3 m, using the listed input conditions,

input data	NX	NY	$\Delta x(m)$	$\Delta y(m)$	$\Delta t(sec)$	$T(sec)$
HM	61	21	0.08	0.08	0.02	1.0
EM I	61	21	0.08	0.50	—	1.0

Owing to the finite grid size and time step a numerical error is also expected. Figure 6 shows that the numerical results, on the whole, agree well with theory for both 0° and 30° wave angles. The hyperbolic model tends to yield slightly larger error in wave height, whereas the elliptic model I produces slightly larger phase error.

The wave reflection against the bottom slope was also compared with the 3-dimensional numerical solution represented by Booij (1983). Both models run in this study give reasonably good agreement as shown in Fig.7.

4.6 Wave-current interaction

Wave-current interaction is compared for cases of colinear current and wave refraction due to the shearing current, both in constant deep water depth of 3 m. The analytic solution for the shearing current is given by Longuet-Higgins and Stewart (1961). The given wave conditions are  $H_i=0.1$  m at the upwave boundary and  $T=1$  sec. Waves are allowed to freely pass through the downwave boundaries. The input data are uniform with  $NX=101$ ,  $NY=21$ ,  $\Delta x=0.1$  m  $\Delta y=0.6$  m for the elliptic models and  $\Delta y=0.1$  m for the rest.  $\Delta t$ , whenever applicable, is taken as 0.01 sec.

The comparisons with analytical solutions are given in Fig.8. For the colinear case, all except hyperbolic model I performed adequately. For non-colinear case, hyperbolic model II and elliptic model II yield good results; the rest all produce varying degrees of inconsistency.

Figure 7: Wave reflection tests against bottom slope.

Figure 8: Wave-current interaction comparison.

4.7 Summary

Each model was evaluated or run on a number of bench mark cases. The final evaluations with assigned rankings are given in the following matrix:

Table 6

Case	HM I	HM II	EM I	EM II	PM
Governing equation	M	O	O	O	M
Programming ease	O	M	O	M	O
Numerical stability	M	X	X	X	O
Computational time	X	X	O	M	O
Shoaling	O	O	O	O	O
Refraction	M	O	M	O	M
Diffraction (normal)	O	O	O	O	O
Diffraction (oblique)	O	O	X	O	M
Reflection (vertical)	O	-	O	-	-
Reflection (slope)	O	-	O	-	-
Current (colinear)	M	O	O	O	O
Current (refraction)	X	O	M	O	X

O: good M: marginal X: bad -: not applicable

5 Conclusions

Five numerical wave-current interaction models were evaluated in a two-dimensional domain through mutual comparisons. The evaluation is limited in that the bench mark cases are restricted to those with either theoretical solution or accepted hydraulic model results. Within this context, the performance of each model is evaluated, and the comparisons are given in a matrix form. At this moment, there appears to be no single model that clearly outperforms the others. The selection of a model for application depends upon the intended purpose. Therefore, the present paper should serve as a useful guide line for model selection.

## CHAPTER 32

### WAVE TRANSFORMATIONS OVER A SUBMERGED BAR: EXPERIMENTS AND THEORETICAL INTERPRETATIONS

Gianfranco Liberatore<sup>1</sup> and Marco Petti<sup>2</sup>

#### Abstract

Random wave tests were performed in a flume to investigate wave transformations above a submerged bar built on a horizontal bottom.

Wave data were analysed in the frequency and time domains. In the time domain, reference was made both to short ( $f > 0.5f_p$ ) and long waves (with  $f < 0.5f_p$ ). This allowed in particular investigation of transformations of long waves passing over the bar.

Experimental results were interpreted using a second-order analytical model, able to separate first- and second-order components from given (measured) variance spectra. The analytical method proved to be conveniently applicable as long as breaking phenomena are not too intense.

#### Introduction

As is well-known, the presence of a bar in domains of relatively shallow-water severely modifies the evolution of wave trains during their propagation from deep to shallow water.

At present, knowledge of wave transformations over submerged bars is not satisfactory and theoretical models are still not able to take into account adequately phenomena such as wave breaking occurring on a bar in shallow waters. The problem, certainly interesting from both the theoretical and engineering points of view, has recently been studied in several theoretical investigations aiming at a better mathematical description of wave transformations over a bar. In this regard, recent theoretical contributions deal, for example, with inclusion of breaking effects in Boussinesq-type equations (e.g., Schäffer et al., 1991, Brocchini et al., 1991) or in mild slope type equations (Rojanakamthorn et al. 1989). A number of experimental

<sup>1</sup>Associate Professor, Institute of Maritime Structures, University of Padova, Via Ognissanti, 39 – 35129 Padova (Italy)

<sup>2</sup>Researcher, Department of Civil Engineering, University of Firenze, Via S. Marta, 3 – 50139 Firenze (Italy)

investigations has also been conducted recently to improve understanding of wave transformations over bars and to calibrate numerical models (Thorkilsen et al., 1991, Liberatore and Petti, 1991, Battjes and Beji, 1992, Beji et al., 1992, Smith and Kraus, 1992).

The aim of the present paper is first to contribute via experimental investigations to better understanding of the phenomena occurring when a bar is present and, second, to interpret spectral transformations using a non-linear (second-order) theoretical model (Petti, 1991).

### Experimental apparatus and procedure

Investigations were carried out in a flume 33 m long, 1 m wide and 1.2 m deep. A smooth 30 cm high submerged bar, with offshore slope 1:20, inshore slope 1:10 and top width of 2 m was built on the horizontal (concrete) bottom of the flume. A spending beach with slope 1:10 (covered with absorbing mattresses) was also modelled in the flume (Fig. 1). Concrete was used to built both bar and beach.

Fig.1 – *Experimental apparatus and location of wave gauges*

Waves were measured at thirteen measuring stations in the flume using eight parallel wire resistance wave gauges in two shifts. In Fig. 1, squared numbers correspond to group 1 (8 gauges, first shift) and circled numbers and letters to group 2 (second shift). Three of the measuring points (A, B and C) were common to the two shifts, enabling the repeatability of the two experiments to be checked. The gauges were set up so as to permit measurement of transformations of waves passing the bar, as well as reflections from both bar and spending beach.

Two offshore water depths of 40 and 50 cm were considered in the experiments; water depth above the bar was therefore 10 and 20 cm respectively.

For each water depth, three different random wave trains were generated. Their characteristics are shown in Tab.1.

Waves in the flume were produced by an hydraulically driven servo-controlled wave generator operated by a personal computer. A white noise filtering technique was used for wave generation. Every run lasted 1000 s. Sampling rate was 10 Hz.

Both short and long waves were analysed by filtering the signal and, considering the frequencies respectively higher and lower than  $0.5f_p$ , reconstructing the time domain signal (the basis for subsequent zero-crossing

analyses) using Inverse Fourier Transforms. This type of procedure was first proposed by Petti (1988).

Table 1 – *Characteristics of waves generated in flume.*

Test no.	$\alpha$	$f_p$ (Hz)	$H_{m_0}$ (cm)	$\gamma$	depth (cm)
1	0.0075	0.650	9.8	2.0	40
2	0.0081	0.781	7.9	3.0	40
3	0.0081	0.850	7.0	3.0	40
4	0.0075	0.650	11.6	2.0	50
5	0.0075	0.781	9.4	3.0	50
6	0.0081	0.850	8.2	3.0	50

Reflection coefficients in front of the bar and in front of the spending beach were also calculated using the method of Goda and Suzuki (1976).

For short waves, these coefficients ranged between 0.17 and 0.22 for the berm, and between 0.22 and 0.30 for the beach (lower values corresponding to shorter peak periods). For long waves, reflection coefficients were much higher, varying between 0.91 and 0.98 for the bar and between 0.62 and 0.70 for the beach.

### Results of experiments

As an example, Figs. 3a and 3b show profiles of short and long waves in the time domain obtained for gauges 1 and 6 during test 1. As the figures show, non-linearities and consequent long waves are definitely more pronounced for gauge 6, located at a shallower depth.

Fig. 3a – *Example of profiles of short waves in time domain (test 1).*

Fig. 3b – Example of profiles of long waves in time domain (test 1).

Spectral analyses generally reveal non-linear transformations of spectra on the seaside slope of the bar, with build-up of energy at low and high frequencies ( $f=2f_p$ ) due to shallow water effects. As a consequence of wave breaking processes on the bar, further transformations of spectra occur, leading to decreased energy depending on intensity of breaking. Behind the bar, rather broad, uniform spectra result.

Wave spectra computed during test 1 ( $h=40$  cm,  $f_p=0.65$  Hz,  $H_{m0}=9.8$  cm) are shown as examples in Figs. 4a and 4b.

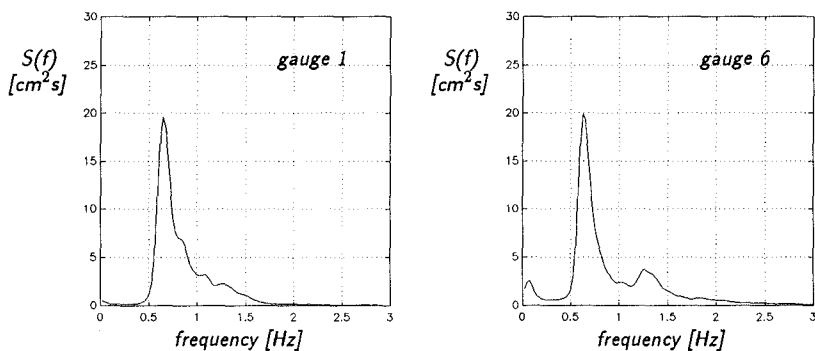

Fig.4a – Wave spectra obtained for test 1 (gauges 1 and 6).

Figs. 5 and 6 show trends for significant short wave heights  $H_s$  and for corresponding periods  $T_s$ , obtained for the two water depths of 40 and 50 cm, for all random wave trains generated during the experiments.

Figs. 5a show some increases in wave heights in the wave trains considered, due to shoaling effects, reaching a maximum on the seaside slope of the bar.

Fig.4b – Wave spectra obtained for test 1 (gauges 7 and 12)

Then decreases occur, due to breaking effects for waves passing the bar, with (nearly) constant wave heights for the three wave trains considered here.

Similar trends are observed for the greater water depth (50 cm; Fig. 6a), although in this case breaking processes are weaker and decreases in wave height are also less evident.

Fig. 5a – Significant wave heights of short waves calculated along flume for tests 1 – 3.

As regards wave periods, in the case of the 40 cm depth (Fig. 5b), after slight, rather uniform increases up to the top of the bar, decreases occur after the bar, and these are probably related to the intensity of breaking.

For the 50 cm water depth (Fig. 6b), periods are quite uniform with slight increases in the area of the bar.

Fig. 5b—Significant periods of short waves calculated along flume for tests 1–3.

Fig. 6a—Significant heights of short waves calculated along flume for tests 4–6.

As regards long waves (Figs. 7a and 7b), in the case of the 40 cm water depth, their significant wave height initially increases, reaching a maximum on the top of the bar. After that, they rapidly decrease, although their height is still higher than offshore the bar.

This effect might at first sight be ascribed to flume seiches: this, however, would not explain wave height asymmetries with respect to the bar.

Fig. 6b—Significant periods of short waves calculated along flume for tests 4–6.

Fig. 7a—Significant heights of long waves calculated along flume for tests 1–3.

Instead, in our opinion, this phenomenon may more probably be ascribed either to seiches occurring between the bar and the spending beach or to partial persistence of the long waves generated above the bar.

Similar trends are also observed for the greater water depth (50 cm), although in this case breaking processes are weaker and decreases also less evident (Fig. 7b).

The significant periods of long wave ranged between 8 and 12 s.

Fig. 7b – Significant heights of long waves calculated along flume for tests 4 – 6.

### Resumé of theoretical model

A non-linear theoretical model, able to separate first and second order components from a given non-linear (measured) spectrum, was utilised to interpret the experimental data. The model (Petti, 1991), is based on a systemic approach to sea wave behaviour and on some characteristic parameters which can be derived from the classic Stokes second-order solution. The method relies upon two fundamental assumptions: narrow-band spectrum and second order non-linearity. As a consequence of the last assumption, theoretical limits of the model should also be considered when applying the method. These may be expressed in terms of the generalised Ursell parameter or the "significant slope".

Let  $S_{\eta}(f)$  be a non-linear spectrum, as our spectrum measured at any location in the wave flume. Using the well-known Wiener-Khinchine relation (Bendat and Piersol, 1971) we can write:

$$B_{\eta}(\tau) = \int_0^{\infty} S_{\eta}(f) \cos(2\pi f\tau) df \quad (1)$$

Starting from Stokes' theory, it may be shown that the autocorrelation function  $B_{\eta}(\tau)$  of surface elevation may be written as:

$$B_{\eta}(\tau) = B_{\eta}^{(1)}(\tau) + B_{\eta}^{(2)}(\tau) \quad (2)$$

where  $B_{\eta}^{(1)}(\tau)$  and  $B_{\eta}^{(2)}(\tau)$  are respectively the first- and the second-order autocorrelation functions.

Second order contribution  $B_{\eta}^{(2)}(\tau)$  may in turn be expressed as function of first-order contribution  $B_{\eta}^{(1)}(\tau)$  as:

$$B_{\eta}^{(2)}(\tau) = 8 [f_2(k_0, h)]^2 [B_{\eta}^{(1)}(\tau)]^2 \quad (3)$$

where  $f_2(k_0, h)$  is a function of depth  $h$  and wave number  $k_0$  (relative to the peak frequency), equal to:

$$f_2(k_0, h) = \frac{k_0}{4} \left[ \frac{3}{\tanh^3(k_0 h)} - \frac{1}{\tanh(k_0 h)} \right] \tag{4}$$

Substituting (3) into (2) allows us to calculate  $B_\eta^{(1)}(\tau)$  as:

$$B_\eta^{(1)}(\tau) = \frac{-1 + \sqrt{1 + 32 [f_2(k_0, h)]^2 B_\eta(\tau)}}{16 [f_2(k_0, h)]^2} \tag{5}$$

while  $B_\eta^{(2)}(\tau)$  may then be obtained from (3).

Lastly, first- ( $S_\eta^{(1)}(f)$ ) and second- order ( $S_\eta^{(2)}(f)$ ) spectra may easily be obtained from corresponding autocorrelation functions  $B_\eta^{(1)}(\tau)$  and  $B_\eta^{(2)}(\tau)$  again using Wiener-Khintchine's relations.

Application of theoretical model: comparisons and discussion

Spectral wave transformations obtained in the laboratory were interpreted and compared with the results of above non-linear theory, by calculating first and second-order contributions for measured spectra.

As examples, measured and calculated spectra for tests 2 ( $h = 40$  cm,  $H_{m_0} = 7.9$  cm,  $T_p = 1.28$  s) and 5 ( $h = 50$  cm,  $H_{m_0} = 9.4$  cm,  $T_p = 1.28$  s) are shown in Figs. 8 and 9 for gauges 1, 6, 8 and 12. For better evidence of linear and second-order contributions, spectral densities are drawn on both linear and logarithmic scales.

Considering first the results for test 2, these show the very small contributions of second-order components for the offshore data (gauge 1).

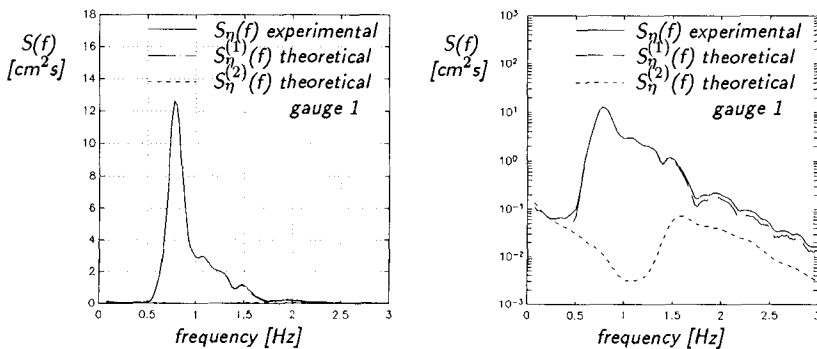

Fig. 8a – Example of wave spectra computed during test 2 (gauge 1) expressed in linear (left) and logarithmic scale (right).

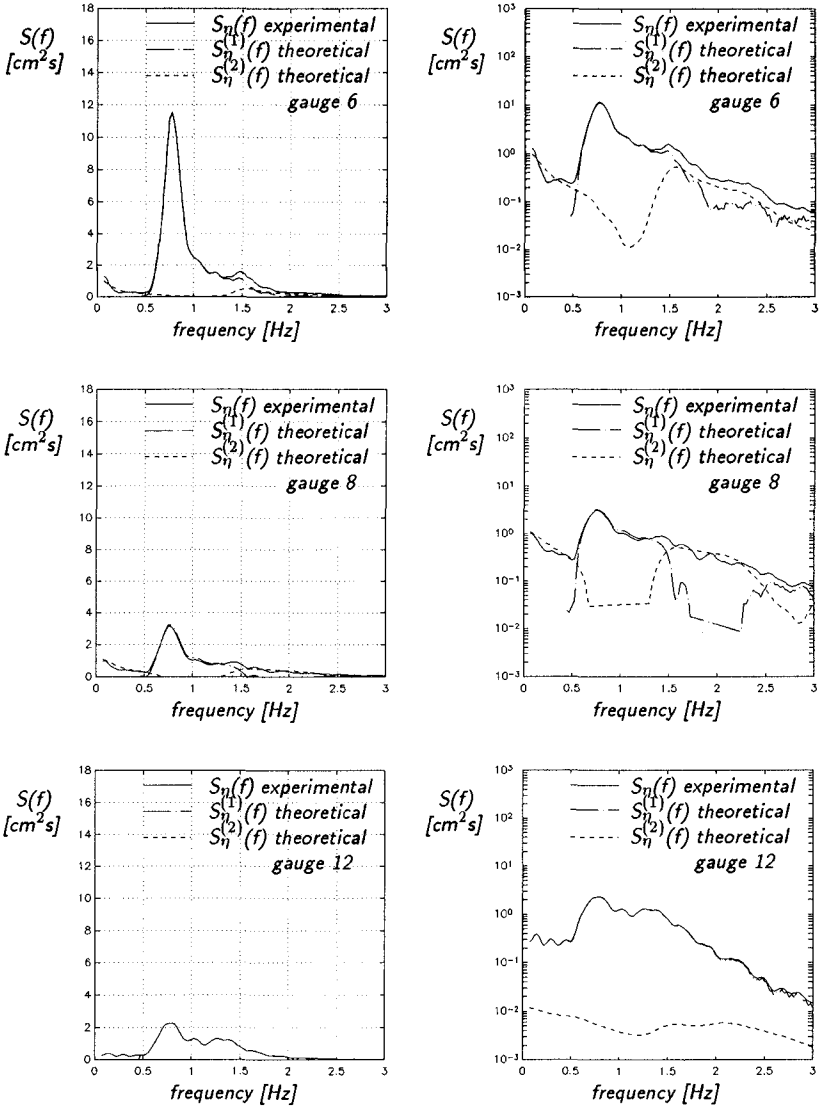

Fig. 8b – Example of wave spectra computed during test 2 (gauges 6, 8 and 12) expressed in linear (left) and logarithmic scale (right).

These become important with decreasing depths, as indicated by the results for gauge 6 (at the end of the offshore slope, near the top of the bar, just before intensive breaking occurs). In this case, second-order components at low and high frequencies are evident and may be predicted accurately by the

analytical model.

For gauge 8, the results do not appear very convincing, if only because the second-order components are in some cases greater than measured spectra. At the position of this gauge (above the top of the barrier, shoreside) intensive breaking occurs, and the measured spectrum is rather wide and therefore not suitable for analytic treatment, since this requires narrow banded spectra.

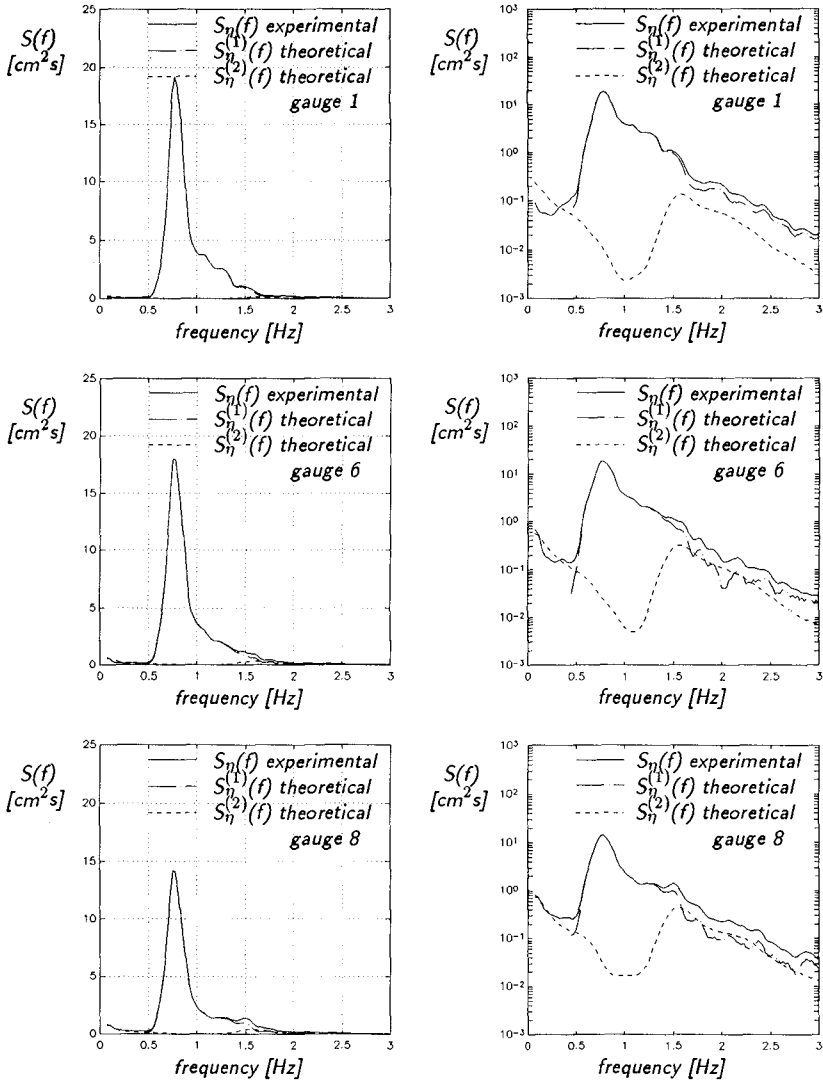

Fig. 9a – Example of wave spectra computed during test 2 (gauges 1, 6, and 8) expressed in linear (left) and logarithmic scale (right).

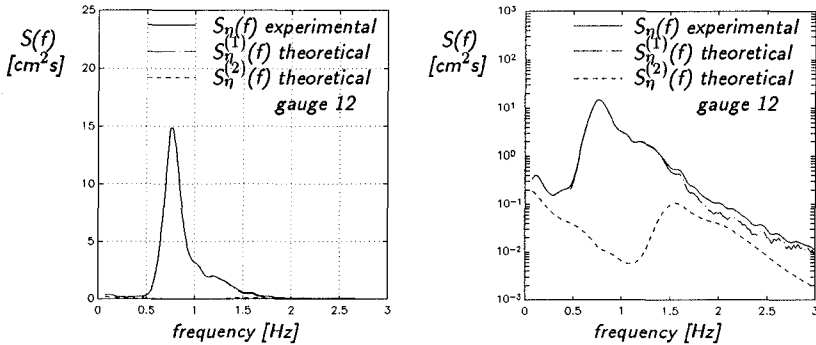

Fig. 9b – Example of wave spectra computed during test 2 (gauges 12) expressed in linear (left) and logarithmic scale (right).

Nevertheless, low frequency components may still be predicted quite well by the model.

Lastly, the spectrum measured at gauge 12 (shoreside of the bar) is quite broad and far beyond the applicability of the method; calculated second-order components are very small and not very meaningful.

For test 5 ( $h = 50$  cm,  $H_{m0} = 9.4$  cm,  $T_p = 1.28$  s) analytical results also appear satisfactory for shoreside gauges such as gauge 8. This is ascribable, in this case, to less intense breaking occurring above the bar (due to greater depths over it); measured wave spectra are still rather narrow and non-linear effects still pronounced.

In this case too, non-linearities become very small, due to greater water depths, for gauges located shoreside of the bar and therefore, again, the method cannot be properly applied.

### Summary and conclusions

Transformations of random waves over a submerged bar are investigated in this paper.

In particular, experimental results are analysed through zero-crossing analysis (including separation of short and long waves) and spectral analysis. In this regard, some features of the evolution of variance spectra above the bar were observed and the importance of non-linear effects and breaking on spectral transformations are highlighted and discussed.

Modified zero-crossing analysis allowed us to reveal some aspects of long wave behaviour over the submerged bar. A new and interesting problem observed during the experiments was the possibility of long waves resonances between the spending beach and the bar.

The influence of flume seiches on this phenomenon will be more fully investigated with new experiments to be carried in the near future using a longer flume. In these experiments, a new absorbing system recently installed on the flume will allow to investigate the influence of paddle re-reflection of waves on the observed phenomena.

A second order analytical method was applied to the data in order to

interpret non-linear transformations of spectra. As regards the procedure applied, which separates first- and second-order components for the measured spectra, the analytical method used seems conveniently applicable to describe non-linear effects, as long as breaking phenomena are not too intense.

### Acknowledgements

This work was undertaken within the framework of the MAST G6 Coastal Morphodynamics research programme. It was funded by the Commission of the European Communities, Directorate General for Science, Research and Development under contract no. 0035C.

## CHAPTER 33

### Nonlinear Transformation of Irregular Waves in Shallow Water

Per A. Madsen<sup>1</sup>  
Ole R. Sørensen<sup>1</sup>  
Hemming A. Schäffer<sup>1</sup>

#### 1. Introduction

Propagation and shoaling of irregular wave trains in shallow water is a nonlinear process, where substantial cross spectral energy transfer can take place in relatively short distances. This process involves the generation of bound sub- and super-harmonics and near-resonant triad interactions, which are defined as the energy exchange between three interacting wave modes.

In the literature it is common practice to distinguish between bound waves and resonant free triads. The theory for bound waves is based on the assumption of a one way transfer of energy to generate higher and lower harmonics which are phase locked to the primary wave train. In reality, however, a feed back of energy to the primary frequencies will occur leading to near-resonant interactions.

This phenomena has previously been treated by e.g. Freilich and Guza (1984) on the basis of the classical Boussinesq equations. It turns out, however, that the accuracy of the linear dispersion relation for higher wave numbers is of major importance for the exchange of energy even in shallow water and for this reason we recommend as governing equations a special form of the Boussinesq equations. These were derived by Madsen et

---

<sup>1</sup> Danish Hydraulic Institute, Agern Allé 5,  
DK-2970 Hørsholm, Denmark

al. (1991a) on a horizontal bottom and here we shall extend these equations to a mildly sloping bottom.

The paper will contain a Fourier analysis of the inherent linear shoaling properties, transfer functions for bound sub and super-harmonics and a discussion of two cases of triad interactions.

## **2. New Boussinesq Equations**

The applicability of various forms of the Boussinesq equations expressed in terms of e.g. the bottom velocity, the surface velocity, the depth-averaged velocity and the depth-integrated velocity was discussed by Madsen et al. (1991a). With the objective of improving the linear dispersion characteristics a new set of equations were derived in two horizontal dimensions. As the first step an improved linear dispersion relation was obtained by combining a polynomial expansion of Stokes first order theory with Pade's approximant. As the second step the classical Boussinesq equations were modified by invoking the linear long wave approximation and using the method of operator correspondence.

The equations presented in this paper represent an extension of the approach by Madsen et al. (1991a), by including first derivatives of the sea bed. The result will be a set of two-dimensional equations which incorporate excellent linear dispersion characteristics and are applicable to irregular wave propagation on a slowly varying bathymetry from deep to shallow water.

The starting point for the derivation is the classical Boussinesq equations derived by Peregrine (1967). These equations, which are valid on a variable bathymetry, are reformulated in terms of depth-integrated velocity variables, i.e. flux components, and are simplified by neglecting higher derivatives and products of derivatives of the still water depth  $h$ . First derivatives of  $h$  are considered small but are included in the formulation.

It is a classical procedure to simplify higher order terms in the Boussinesq or KdV equations by introducing the linear long wave approximations (see e.g. Mei, 1983; Madsen et al., 1991a). As an example  $P_{xxt}$  type terms can be replaced by  $S_{xxx}$  type terms by the use of this method. In shallow water it makes no difference, but in deeper water the form of the Boussinesq terms is critical for the accuracy of the linear dispersion relation. Instead of replacing  $P_{xxt}$  with  $S_{xxx}$  type terms we use a different

approach. Spatial differentiations of the linear long wave equations lead to expressions containing the terms  $P_{xxt}$ ,  $P_{xyt}$ ,  $Q_{yyt}$  and  $Q_{xyt}$ . Since these expressions are effectively zero in shallow water we add them to the original Boussinesq equations and obtain the following new set of equations:

$$S_t + P_x + Q_y = 0 \quad (2.1a)$$

$$P_t + \left(\frac{P^2}{d}\right)_x + \left(\frac{PQ}{d}\right)_y + gdS_x + \psi_1 = 0 \quad (2.1b)$$

$$Q_t + \left(\frac{Q^2}{d}\right)_y + \left(\frac{PQ}{d}\right)_x + gdS_y + \psi_2 = 0 \quad (2.1c)$$

where subscripts x, y and t denote differentiation with respect to space and time, d is the total water depth, h is the still water depth, S is the surface elevation, P and Q are the depth-integrated velocity components, and  $\psi_1$  and  $\psi_2$  are the new Boussinesq terms defined by:

$$\begin{aligned} \psi_1 = & - \left(B + \frac{1}{3}\right) h^2 (P_{xxt} + Q_{xyt}) - Bgh^3 (S_{xxx} + S_{xyy}) \\ & - hh_x \left(\frac{1}{3}P_{xt} + \frac{1}{6}Q_{yt} + 2BghS_{xx} + BghS_{yy}\right) \\ & - hh_y \left(\frac{1}{6}Q_{xt} + BghS_{xy}\right) \end{aligned} \quad (2.2a)$$

$$\begin{aligned} \psi_2 = & - \left(B + \frac{1}{3}\right) h^2 (Q_{yyt} + P_{xyt}) - Bgh^3 (S_{yyy} + S_{xxy}) \\ & - hh_y \left(\frac{1}{3}Q_{yt} + \frac{1}{6}P_{xt} + 2BghS_{yy} + BghS_{xx}\right) \\ & - hh_x \left(\frac{1}{6}P_{yt} + BghS_{xy}\right) \end{aligned} \quad (2.2b)$$

Except for the slope terms proportional to  $h_x$  and  $h_y$ , these expressions are identical to the Boussinesq terms presented by Madsen et al. (1991a). B is the linear dispersion parameter, which will be determined in the following section. Further details concerning the derivation, and a description of the numerical method used to solve them, will appear in Madsen and Sørensen (1992b).

### 3. Linear dispersion relation and shoaling properties

A Fourier analysis of the linearized one-dimensional version of the new Boussinesq equations will be made with the objective of studying the linear dispersion relation and the linear shoaling gradient embedded in the new equations.

As a starting point for the analysis, the one-dimensional wave equation corresponding to (2.1a-c) combined with (2.2a-b) is derived. By using (2.1a) linear terms containing P are eliminated and secondly (2.1a) and (2.1b) are cross-differentiated and subtracted. This leads to:

$$\mathbf{L} = \mathbf{M} + \mathbf{N}_{xx} \quad (3.1a)$$

where

$$\mathbf{L} = \left[ S_{tt} - ghS_{xx} + Bgh^3S_{xxxx} - \left( B + \frac{1}{3} \right) h^2S_{xxtt} \right] \quad (3.1b)$$

$$\mathbf{M} = \left[ gS_x + (2B + 1)hS_{xtt} - 5Bgh^2S_{xxx} \right] h_x \quad (3.1c)$$

$$\mathbf{N} = \left[ \frac{1}{2} gS^2 + \frac{P^2}{d} \right] \quad (3.1d)$$

In the following linear analysis the non-linear operator  $\mathbf{N}$  is neglected and we shall look for solutions to (3.1a) on the form

$$S(x, t) = A(x) e^{i(\omega t - \varphi(x))} \quad (3.2)$$

where  $\omega$  is the cyclic frequency,  $A$  is the local wave amplitude and  $\varphi$  is the phase function, which is related to the local wave number by

$$\varphi_x = k(x) \quad (3.3)$$

The water depth, the wave number and the wave amplitude are considered to be slowly varying functions of  $x$  and consequently products of derivatives and higher

derivatives of these quantities will be neglected in the following.

The linear dispersion relation is obtained by inserting (3.2) into (3.1) and neglecting all x-derivatives of h, k and A,

$$-\omega^2 + ghk^2 + Bgh^3k^4 - \left(B + \frac{1}{3}\right) k^2h^2\omega^2 = 0 \quad (3.4)$$

Alternatively this can be formulated as:

$$\frac{c^2}{gh} = \frac{1 + Bk^2h^2}{1 + \left(B + \frac{1}{3}\right) k^2h^2} \quad (3.5)$$

where c is the wave celerity defined by  $c = \omega/k$ .

As shown by Madsen et al. (1991a) various classical formulations of the Boussinesq equations all lead to (3.5) with different values of B: using the surface velocity as dependent variable leads to  $B = -1/3$ , the bottom velocity leads to  $B = 1/6$  and the depth-averaged or depth-integrated velocity leads to  $B = 0$ . By far the best agreement with Stokes first order theory is obtained by using the value  $B = 1/15$ , which is determined by matching (3.5) with a Taylor expansion of the Stokes first order celerity combined with Pade's expansion technique. This value was originally suggested by Witting (1984). Madsen et al (1991a) analyzed the accuracy of (3.5) for the various possible values of B and concluded that the new Boussinesq equations combined with  $B = 1/15$  provide excellent linear dispersion characteristics for values of  $h/L_0$  as large as 0.5.

Proceeding with the Fourier analysis and collecting terms to the next order in (3.1) includes the terms proportional to the first derivatives of h, k and A. The frequency  $\omega$  is eliminated by the use of (3.4) and differentiation of this equation also makes it possible to eliminate terms proportional to  $k_x/k$ . After algebraic manipulations we get the expression:

$$\frac{A_x}{A} = -\gamma \frac{h_x}{h} \quad (3.6)$$

where  $\gamma$  is the linear shoaling gradient. The expression for  $\gamma$  reads:

$$\gamma = \frac{1}{4} \left[ 1 + (4B - 1)k^2h^2 + \left(6B^2 - \frac{2}{3}B\right)k^4h^4 + \left(4B^3 + \frac{1}{3}B^2 + \frac{1}{9}B\right)k^6h^6 + \left(B^4 - \frac{1}{9}B^2\right)k^8h^8 \right] \left[ 1 + 2Bk^2h^2 + \left(B^2 + \frac{1}{3}B\right)k^4h^4 \right]^{-2} \quad (3.7)$$

The reference linear shoaling coefficient based on Stokes first order theory is derived by using the concept of conservation of energy flux. After differentiation and algebraic manipulations this leads to:

$$\gamma_{Stokes} = \frac{2kh(\sinh 2kh) + 2k^2h^2(1 - \cosh 2kh)}{(2kh + \sinh 2kh)^2} \quad (3.8)$$

A comparison between (3.7) and (3.8) as a function of  $h/L_0$  requires that (3.7) is combined with the Boussinesq dispersion relation (3.4), while (3.8) is combined with Stokes dispersion relation. The result is presented in Fig. 1 and it can be concluded that the standard Boussinesq equations with  $B = 0$  lead to major discrepancies for  $h/L_0$  larger than 0.10, while  $B = 1/15$  has a remarkable effect and results in an excellent agreement with Stokes first order theory for  $h/L_0$  as large as 0.50.

#### 4. Bound waves in shallow water

Irregular wave trains travelling in shallow water can generate and sustain a considerable amount of bound harmonics, which travel phase-locked to the primary wave train. At locations, where drastic changes of the wave heights occur e.g. due to diffraction or wave breaking, the bound waves can be released and proceed as free waves. This may cause harbour resonance, drift motion of moored vessels and surf beats. The phenomena of bound waves has been discussed in numerous papers in connection with the reproduction of regular and irregular waves in physical wave flumes (e.g. Barthel et al., 1983 and Sand and Mansard, 1986). It has been concluded that linear boundary conditions often are insufficient and should be replaced by second order boundary conditions including the effect of bound sub- and super-harmonics. This problem is important for physical waves flumes and equally relevant for numerical models solving non-linear equations.

Fig. 1 Linear shoaling gradient,  $\gamma$  defined by (3.6), (3.7) and (3.8).

In this section transfer functions for second order bound sub and super-harmonics will be presented on the basis of the new Boussinesq equations. The derivation is straight forward and is based on a perturbation solution to the wave equation given in (3.1a-d). As a start we consider the forcing due to a simple first order wave group made up of just two frequencies  $\omega_n$  and  $\omega_m$  at a constant depth. Each of the two wave components are considered to be solutions to the linearized problem  $L\{S^{(1)}\} = 0$  where  $L$  is defined by (3.1b). The next step is to look for second order solutions to  $L\{S^{(2)}\} = N_{xx}\{S^{(1)}\}$  where  $N$  is defined by (3.1d). The first order bichromatic wave train will force a second order wave train consisting of four new frequencies: one sub-harmonic and three super-harmonics. The four second order wave numbers are determined from combinations of  $k_n$  and  $k_m$ , and they do not satisfy the linear dispersion relation, which implies that these waves are bound or phase-locked to the first order wave train. For general irregular wave trains consisting of many wave components, the contributions from all pairs of frequencies inherent in the wave train can be summed up (see Sand and Mansard, 1986).

The second order transfer function derived from the new Boussinesq equations reads:

$$G_p = \frac{ghk_p^2 (\sqrt{2} + \omega_n \omega_m / (ghk_n k_m))}{(\omega_p^2 - ghk_p^2 - Bgh^3 k_p^4 + (B + 1/3) h^2 \omega_p^2 k_p^2)} \quad (4.1)$$

where  $\omega_p = p\Delta\omega$  denotes the discrete sub or super-harmonic frequency receiving energy transfer from the primary frequencies  $\omega_n = n\Delta\omega$  and  $\omega_m = m\Delta\omega$ . For sub-harmonics (4.1) should be used with  $n = m + p$  and  $k_p = k_{m+p} - k_m$ . For super-harmonics  $n = p-m$  and  $k_p = k_{p-m} + k_m$ . Further details and the complete formulation of second order boundary conditions for irregular waves can be found in Madsen and Sørensen (1992a).

Fig. 2 Transfer Functions for super-harmonics and for sub-harmonics.

- Boussinesq transfer function determined by (4.1)  $B=1/15$
- Ratio between the Boussinesq transfer and the transfer function determined from the Laplace equation.

Fig. 2 shows the transfer function for the super-harmonics  $\omega_p$  generated by the interaction between  $\omega_m$  and  $\omega_{m+p}$ , and for the sub-harmonics  $\omega_p$  generated by the interaction between  $\omega_m$  and  $\omega_{m-p}$ .  $G^+$  and  $G^-$  determined by (4.1) are shown as full lines in Fig. 2, while the ratios

between  $G$  and the transfer functions derived from the Laplace equation (Sand and Mansard, 1986) are shown as dotted lines. Generally, the Boussinesq equations tend to underestimate the super-harmonics while the sub-harmonics can be underestimated as well as overestimated. Discrepancies up to 40% are noticed in the shown truncated spectrum, but typical errors are less than 10%.

An application of the theory is presented in Fig. 3, where time series of surface elevations are generated from a JONSWAP spectrum with  $\gamma = 3.3$ . The water depth is 10 m, the significant wave height is 2.0 m and the peak period is 9.0 s. The linear wave train is generated with random phases and with energy in the interval 0.05 Hz to 0.20 Hz. The maximum frequency corresponds to  $h/L_0 = 0.25$  which is within the range of application of the new Boussinesq equations. The bound sub-harmonics cover the interval the 0.001 Hz to 0.15 Hz, while the bound super-harmonics cover the interval from 0.10 Hz to 0.40 Hz.

The consequence of neglecting the bound wave components in the input time series will be the release of spurious free wave components of the same order of magnitude. In this situation the free sub-harmonics are by far the most critical, since they can penetrate, e.g. into harbours almost without being reduced in magnitude and result in harbour resonance or at least in a major overestimation of the local wave disturbance.

## 5. Triad Interactions

The theory of bound waves assumes an equilibrium situation where the non-linear wave train propagates without changing its form. In reality and especially in shallow water a substantial cross spectral energy transfer will take place due to triad interactions, which describe the exchange of energy between three interacting wave modes (see e.g. Freilich and Guza, 1984).

The simplest example of triad interactions occur, when first order monochromatic boundary conditions are applied in shallow water. This will unintentionally generate spurious free second order waves in addition to the bound second order waves, leading to an energy exchange between the primary wave frequency and its super-harmonics. A numerical example is presented in Fig. 4a, which shows the computed surface elevation at eight equidistant times within one wave period as a function of the distance from the open boundary. The corresponding spatial variation of the amplitudes of the

first three harmonics is obtained by FFT-analysis of the computed time series and is shown in Fig. 4b.

Fig. 3 First order irregular waves and their correspondingly bound sub-harmonics.

Boussinesq Eq. with  $B = 1/15$ . Water depth = 10 m.

JONSWAP SPECTRUM with  $H_s = 2.0$  m,  $T_p = 9.0$  s,  $\gamma = 3.3$ .

As discussed in Madsen et al. (1991b) the energy transfer can be shown to depend strongly on the phase mismatch, which is defined by:

$$\delta^+ \equiv k_m + k_{p-m} - k_p \tag{5.1a}$$

$$\delta^- \equiv k_{m+p} - k_m - k_p \tag{5.1b}$$

This calls for an accurate description of the linear dispersion relation and in connection with this it should be emphasized that even when the primary wave corresponds to very shallow water in terms of  $h/L_0$ , this is not necessarily the case for the higher harmonics. Hence, by using classical types of KdV or Boussinesq equations, the estimate of the phase mismatch may be rather inaccurate.

The new Boussinesq equations with  $B = 1/15$  improve the accuracy considerably and as an example Fig. 5 shows a comparison with the measurements of Chapalain et al. (1992). The agreement between the measurements and the FFT analysis of the time domain simulations is seen to be excellent, except for the beat length of the third harmonic, which is slightly underestimated. More examples of harmonic generation forced by linear monochromatic and bichromatic boundary conditions on a constant depth can be found in Madsen and Sørensen (1992a).

The final example is a study of non-linear refraction-diffraction on a semi-circular shoal. This was studied experimentally by Whalin (1971) for wave periods of 1, 2 and 3 seconds. We shall concentrate on a discussion of the case of 1 second waves, which has not previously been treated by the use of Boussinesq equations. The value of  $h/L_0$  varies from 0.29 at the toe of the shoal to 0.096 behind the shoal. An FFT analysis of time series in each grid point along the centre line has been made and the resulting spatial evolution of first and second harmonics is compared with Whalin's experimental data in Fig. 6. A considerable scattering in the data is seen in front of the shoal but behind the shoal the agreement between the data and the new Boussinesq equations with ( $B = 1/15$ ) is acceptable. Reasonable agreement is also found between the new Boussinesq equations and the results obtained by Liu and Tsay (1984), who solved the non-linear Schrödinger equation. Finally the classical Boussinesq equations (i.e.  $B = 0$ ) are seen to fail completely by predicting an unrealistic decrease of the first harmonic, a discrepancy which can be explained by the variation of the linear shoaling gradient in Fig. 2.

In fact this example demonstrates that Fig. 2 should be taken quite seriously as a measure of the range of application of different types of Boussinesq equations. A common mistake is that the accuracy of the wave celerity is taken as the practical measure, in which case a 5% error restricts the use of the standard Boussinesq equations to approximately  $h/L_0 = 0.22$ . However, according to Fig. 2 this is clearly much too optimistic in case of a variable bathymetry and the shoaling falsification increases rapidly for  $h/L_0$  exceeding 0.10. This emphasizes the importance of using the new Boussinesq equations presented in this paper, in which case  $h/L_0$  as large as 0.5 can be considered.

## 6. Conclusion

The paper presents a new set of Boussinesq equations applicable to irregular wave propagation on a slowly varying bathymetry from deep to shallow water. It can be concluded that the new equations are capable of describing the phenomenon of harmonic generation and triad interactions with an accuracy which is significant better than what can be obtained on the basis of the classical forms of the Boussinesq equations.

## CHAPTER 35

### Hybrid Frequency-Domain KdV Equation for Random Wave Transformation

Hajime Mase<sup>1</sup>, M. ASCE, and James T. Kirby<sup>2</sup>, M. ASCE

**ABSTRACT:** This paper develops a hybrid model for random wave transformation by employing a modified spectral model of the KdV equation and a probabilistic bore-type wave breaking model, and compares the numerical predictions with experimental observations. Main results are as follows: 1) Original frequency-domain KdV equation overestimates energy densities, due to over-shoaling term by Green's law in the equation, even in a region where wave breaking is not seen; 2) Modification of the original KdV equation in order to represent shoaling for linear-dispersive component waves leads to better predictions in the non-breaking region; 3) Damping coefficients in the model equation, either estimated from measured spectral densities or the numerically predicted, are in inverse proportion to the water depth and in proportion to the square of frequency, similar to the viscous damping term of the Burgers equation; 4) The hybrid model developed here can predict transformations of random waves satisfactorily, as indicated by comparison of energy spectra, representative wave heights, periods, and crest heights.

#### INTRODUCTION

The Boussinesq equations include the effects of weak dispersion and nonlinearity under the condition of  $\mu^2 = (k_0 h_0)^2 \ll 1$ ,  $\varepsilon = a_0/h_0 \ll 1$ , and  $O(\mu^2) = O(\varepsilon)$  where  $k_0$ ,  $h_0$ ,  $a_0$  are the characteristic wave number, the water depth, and the wave amplitude (Peregrine, 1967; Madsen and Mei, 1969), and are a useful tool for predicting the transformation of shallow water waves. The Boussinesq type equations with a damping term introduced to simulate a turbulence dissipation can predict the change of monochromatic wave height both in the shoaling and the breaking regions (Karambas and Koutitas, 1992).

An efficient method to solve the Boussinesq equations is to deal with the equations in the frequency domain instead of the time domain. The resulting one-dimensional coupled mode equations considering only shoreward-propagating waves can predict the evolution of nearshore field wind waves (Freilich and Guza, 1984; Elgar and Guza, 1985), and the parabolic coupled mode equations can predict the transformation of periodic long waves over two-dimensional topography (Liu et al., 1985). An angular spectrum model of the Boussinesq equations can predict Mach reflection of cnoidal waves well (Kirby, 1990). The KdV equation is consistent with the Boussinesq equations when considering only shoreward-propagating waves. Although the Boussinesq equations and the KdV equation have only the lowest order of nonlinearity, the frequency-domain equations can estimate shoaled wave heights as well as wave

profiles fairly close to the breaking point (Vengayil and Kirby, 1986). Extension of the Boussinesq equations and the KdV equation to improve their dispersion characteristics was studied by Madsen, Murray and Sørensen (1991) and Khangaonkar and LeMehaute (1991).

This paper develops a hybrid model for random wave transformation by employing a modified frequency-domain KdV equation and a probabilistic bore-type wave breaking model. The original frequency-domain (spectral) KdV equation is modified to reproduce the shoaling and the dispersion relation for linear component waves exactly. In order to include energy dissipation due to wave breaking, a damping term is introduced into the modified spectral KdV equation. A form for the coefficient of the damping term is first deduced by inspection of measured spectral energy densities together with calculated densities by the modified spectral KdV equation, and the coefficient is then formulated by using a probabilistic model of expected energy dissipation rate based on the bore model of Thornton and Guza (1983), taking into account the experimental characteristics.

The model equation developed here can be called a hybrid model, since it employs a spectral method and a probabilistic method (individual wave analysis method). Comparisons between experimental observations and numerical predictions by the hybrid model are carried out against energy spectra, representative wave heights, periods, and crest heights.

## MODEL EQUATION

Assuming a vertically two-dimensional case, small water depth variation such as  $O(|\nabla_h h|) \leq O(\mu^2)$ , and considering only shoreward-propagating waves (neglecting reflected waves), we reduce the Boussinesq equations to the KdV equation for variable depth as expressed by

$$\zeta_t + \sqrt{gh} \zeta_x + \frac{\sqrt{gh} h_x}{4h} \zeta + \frac{3\sqrt{gh}}{2h} \zeta \zeta_x + \frac{\sqrt{gh} h^2}{6} \zeta_{xxx} = 0, \quad (1)$$

$O(\epsilon) \qquad O(\mu^2)$

where  $\zeta$  is the surface displacement,  $h$  is the water depth,  $t$  is the time, and  $x$  is the horizontal coordinate. Substituting the Fourier series representation of surface displacement with complex amplitudes,  $A_n$ ,

$$\zeta = \sum_{n=1}^{\infty} \frac{1}{2} A_n e^{i n \left( \int k_1 dx - \omega_1 t \right)} + c. c. \quad (2)$$

into Eq.(1) yields the lowest-order frequency-domain KdV equation, equivalent to the consistent shoaling model of Freilich and Guza (1984):

$$\frac{dA_n}{dx} + \frac{h_x}{4h} A_n - \frac{1}{6} i n^3 k_1^3 h^2 A_n + \frac{3 i n k_1}{8h} \left[ \sum_{l=1}^{n-1} A_l A_{n-l} + 2 \sum_{l=1}^{N-n} A_l^* A_{n+l} \right] = 0; \quad n = 1, 2, \dots, N, \quad (3)$$

where  $dA_n/dx \sim O(\epsilon)$  is assumed. The procedure followed in deriving the above equation follows that of Freilich and Guza (1984), and Liu et al. (1985). The second

term on the left hand side of Eq.(3) represents shoaling by Green's law; that is, the equation for linear waves

$$\frac{dA_n}{dx} = -\frac{h_x}{4h} A_n \quad (4)$$

is integrated to

$$\frac{A_n(x)}{A_n(0)} = \left\{ \frac{h(x)}{h(0)} \right\}^{-1/4} \quad (5)$$

This can be compared to the component form of fully dispersive linear theory, which gives

$$\frac{dA_n}{dx} = -\frac{(C_{g_n})_x}{2C_{g_n}} A_n \quad (6)$$

The integrated form is then

$$\frac{A_n(x)}{A_n(0)} = \left\{ \frac{C_{g_n}(x)}{C_{g_n}(0)} \right\}^{-1/2} \quad (7)$$

which corresponds to the linear shoaling theory. The third term on the left hand side of Eq.(3) represents the effect of dispersion. For linear component waves in uniform depth, Eq.(3) reduces to

$$\frac{dA_n}{dx} - \frac{1}{6} i n^3 k_1^3 h^2 A_n = 0 \quad (8)$$

The resultant surface displacement is described by

$$\zeta = \frac{1}{2} a_n e^{i \left\{ \left( n k_1 + \frac{1}{6} n^3 k_1^3 h^2 \right) x - n \omega_1 t \right\}} + \text{c. c.} \quad (9)$$

From Eq.(9) the phase speed is given by

$$C_n = \frac{\omega_1}{k_1} \frac{1}{1 + (n k_1 h)^2 / 6} \quad (10)$$

where  $\omega_1/k_1 = \sqrt{gh}$ . Eq.(10) is an approximation in shallow water of the dispersion relation,

$$\frac{C_n}{\sqrt{gh}} = \sqrt{\frac{\tanh k_n h}{k_n h}} \quad (11)$$

where  $k_n$  is obtained from  $(n\omega_1)^2 = gk_n \tanh k_n h$ . When we adopt the equation given by

$$\frac{dA_n}{dx} - i n k_1 \left[ \sqrt{\frac{k_n h}{\tanh k_n h}} - 1 \right] A_n = 0 \quad (12)$$

instead of Eq.(8), we can provide the exact dispersion relation.

In summary a modified version of spectral KdV equation in order to provide exact shoaling and dispersion relation of each frequency mode is obtained by changing the shoaling and the dispersion terms:

$$\begin{aligned} \frac{dA_n}{dx} + \frac{(C_{g_n})_x}{2C_{g_n}} A_n - ink_1 \left( \sqrt{\frac{k_n h}{\tanh k_n h}} - 1 \right) A_n + \frac{3ink_1}{8h} \\ \times \left[ \sum_{l=1}^{n-1} A_l A_{n-l} + 2 \sum_{l=1}^{N-n} A_l^* A_{n+l} \right] = 0; \quad n = 1, 2, \dots, N. \end{aligned} \quad (13)$$

When energy dissipation is taken into account, a damping term  $\alpha_n A_n$  should be added to the left hand side of Eq.(13), where  $\alpha_n$  is a damping coefficient to be determined theoretically or experimentally:

$$\begin{aligned} \frac{dA_n}{dx} + \frac{(C_{g_n})_x}{2C_{g_n}} A_n - ink_1 \left( \sqrt{\frac{k_n h}{\tanh k_n h}} - 1 \right) A_n + \frac{3ink_1}{8h} \\ \times \left[ \sum_{l=1}^{n-1} A_l A_{n-l} + 2 \sum_{l=1}^{N-n} A_l^* A_{n+l} \right] + \alpha_n A_n = 0; \quad n = 1, 2, \dots, N. \end{aligned} \quad (14)$$

Depending on whether  $\alpha_n$  is real, image, or complex, change of energy only, phase only, or both energy and phase, respectively, can be introduced. Here we take  $\alpha_n$  to be real.

In shallow water the model equation with damping term is transformed to

$$\left( \sum_{n=1}^N |A_n|^2 \right)_x + \frac{h_x}{2h} \left( \sum_{n=1}^N |A_n|^2 \right) + 2 \sum_{n=1}^N \alpha_n |A_n|^2 = 0, \quad (15)$$

by adding the two equations of Eq.(14) multiplied by  $A_n^*$  and the complex conjugate of Eq.(14) multiplied by  $A_n$ . By using the relation of

$$E = \frac{1}{2} \rho g \sum_{n=1}^N |A_n|^2, \quad (16)$$

Eq.(15) is rewritten as in a form of an energy flux equation:

$$\left( E \sqrt{gh} \right)_x = - \rho g \sqrt{gh} \left( \sum_{n=1}^N \alpha_n |A_n|^2 \right). \quad (17)$$

It is confirmed from Eq.(17) that the  $\alpha_n$  is a kind of energy damping coefficient.

## EXPERIMENT ON RANDOM WAVE TRANSFORMATION

Random waves used here were simulated to have the Pierson-Moskowitz spectrum with  $f_p = 0.6$  Hz and  $f_p = 1.0$  Hz ( $f_p$ : the peak frequency), referred as Case 1 and Case 2, respectively. Dominated wave breaking type seen in Case 1 was plunging, while in Case 2 spilling breakers were dominated. Figure 1 shows a sketch of experimental setup. Water surface variation were measured by capacitance-type wave gauges (WG.1~WG.12) at water depths of 47 cm, 35 cm, 30 cm, 25 cm, 20 cm, 17.5 cm, 15 cm, 12.5 cm, 10 cm, 7.5 cm, 5.0 cm and 2.5 cm over a 1/20 plane beach. The data were recorded by a digital data recorder at the sampling interval of 0.025 see for about 30 min duration for Case 1 and 20 min for Case 2.

Fig. 1 Experimental Setup.

Figure 2 shows the change of measured energy spectra of Case 1 and Case 2. The data of water surface variations at each wave gauge were split into ten segments of 1024 points with the time interval of 0.1 sec. The energy spectrum of each segment was summed up and averaged. The ensemble averaged spectrum was smoothed by averaging three points. The degree of freedom is 60, and the resolution frequency is 0.03 Hz. The figures show the decay of energies around the initially peak frequency, the shift of peak frequency to the lower frequency, and the increase of energies in lower and higher frequency regions with decrease in the water depth. At the shallowest water of 2.5 cm (WG.12), the energy level of low frequency modes becomes almost the same as that around the initially peak frequency.

Fig. 2 Change of Measured Energy Spectra.

The calculated spectral energy densities by the original spectral KdV equation (Eq.(4)), the modified spectral KdV model without damping term (Eq.(14)), and the linear shoaling theory were compared with the measured energy densities, as shown in Fig.3. The 300 complex Fourier amplitudes at WG.1 ( $h = 47$  cm) were used as input data. The energy spectra were calculated for ten segments and were averaged as in the case of experimental data. The original KdV model overestimates the energy densities at WG.7 where wave breaking is very infrequent. The prediction by the modified KdV model agrees well with the observation at WG.7, but does not at WG.10 where energy dissipation due to wave breaking is important. The result means that since the Green's law is applied to all spectral components by the original KdV model, the overestimation occurs, and that the modified KdV model provides a better prediction outside the surf zone, but results in overestimation in the surf zone, due to the lack of a wave damping

term. The predictions by the linear shoaling theory differ from the observations in spectral shape.

Fig. 3 Comparison between Calculated Results by the Frequency-Domain KdV Model, Modified KdV Model and Linear Shoaling Theory.

**DAMPING COEFFICIENT**

For constant water depth, the following equation for spectral densities is obtained from Eq.(15) multiplied by  $N\Delta t/2$ :

$$\sum_{n=1}^N \{ (S_n)_x + 2 \alpha_n S_n \} = 0 \tag{18}$$

When  $\alpha_n$  is nearly constant for short distance, the solution of Eq.(18) is

$$S_n(\Delta x) = S_n(0) e^{-2\alpha_n \Delta x} \tag{19}$$

and  $\alpha_n$  is expressed by

$$\alpha_n = - \ln \{ S_n(\Delta x) / S_n(0) \} / (2\Delta x) \tag{20}$$

The Taylor expansion of the above equation is

$$\alpha_n = [ 1 - \{ S_n(\Delta x) / S_n(0) \} ] / (2\Delta x) \tag{21}$$

However,  $\alpha_n$  estimated by Eq.(20) or Eq.(21), using the measured spectral energy densities, contains the effects of shoaling and nonlinear wave interaction. Some revision to remove such effects is required. Here the numerical results are utilized. Since the difference between the calculated spectral density at  $\Delta x$  downstream,  $S_n(\Delta x)_{Cal.}$ , and the measured density at a reference point,  $S_n(0)_{Meas.}$ , may be considered as the effects of shoaling and nonlinear interaction, the measured spectral density at  $\Delta x$  downstream,  $S_n(\Delta x)_{Meas.}$ , is modified as

$$S_n'(\Delta x) = S_n(\Delta x)_{Meas.} - \{ S_n(\Delta x)_{Cal.} - S_n(0)_{Meas.} \} \tag{22}$$

Since  $S_n'(\Delta x)$  takes negative value sometimes and the form of Eq.(20) is inconvenient, Eq.(21) is used as

$$\alpha_n = \left[ 1 - \left\{ S_n'(\Delta x) / S_n(0) \right\}_{Meas.} \right] / (2\Delta x) . \tag{23}$$

Another way is to obtain the  $\alpha_n$  so as to coincide  $S_n(\Delta x)_{Cal.}$  with  $S_n(\Delta x)_{Meas.}$  described by the following equation:

$$\alpha_n = - \ln \left\{ S_n(\Delta x)_{Meas.} / S_n(\Delta x)_{Cal.} \right\} / (2\Delta x) . \tag{24}$$

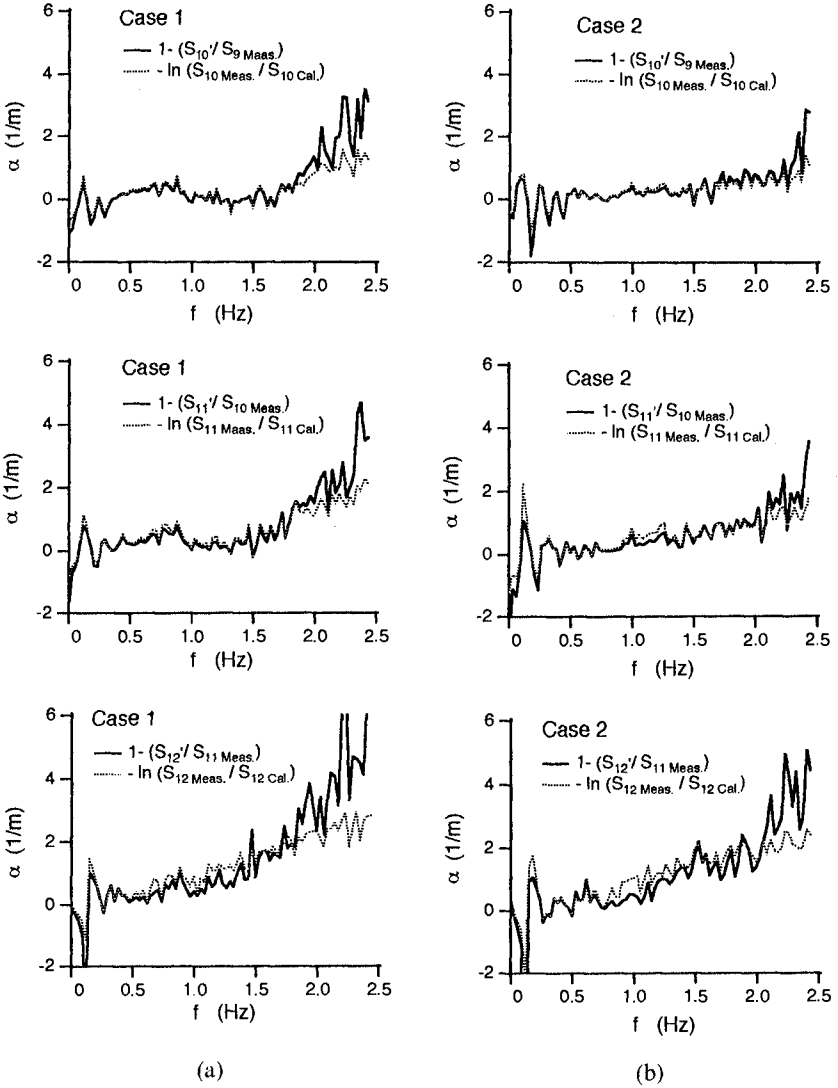

Fig. 4 Estimated Damping Coefficient.

Figure 4 shows the estimated  $\alpha_n$  using the data of consecutive wave gauges of WG.9 and WG.10, WG.10 and WG.11, WG.11 and WG.12, separated by 50 cm each other, in which the solid line is the result using Eq.(23) and the dotted line is by Eq.(24). The solid line and the dotted line are almost the same in a region of  $f < 2.0$  Hz. The  $\alpha_n$  at a given frequency becomes large with decrease in the water depth and appears to be proportional to  $f^2$  with a small constant value. The tendency is similar to that of the viscous damping term of the Burgers equation (given by  $-\nu \zeta_{xx}$  where  $\nu$  is the positive coefficient). The Fourier representation for  $-\nu \zeta_{xx}$ , using Eq.(2), results in  $\nu(nk_1)^2 A_n$ , which is rewritten as  $\nu(n\omega_1)^2/(gh) \cdot A_n$  using the relation of  $(nk_1)^2 = (n\omega_1)^2/(gh)$ ; that is,  $\alpha_n = \omega_n^2/(gh)$ . Because of the denominator  $gh$ , the  $\alpha_n$  becomes large with decrease in the water depth, and is proportional to the frequency squared. These results are used below to guide the choice of the distribution of damping on a frequency-by-frequency basis.

Thornton and Guza (1983) formulated the expected value of energy dissipation rate,  $\langle \epsilon_b \rangle$ , based on the probabilistic method (or individual wave analysis method), by using the Rayleigh distribution for wave height distribution, the specific weight function to represent the wave height distribution of broken waves, and an energy dissipation model of bore for each broken wave. The energy flux equation in shallow water is described by

$$\left( E\sqrt{gh} \right)_x = - \langle \epsilon_b \rangle, \tag{25}$$

$$\langle \epsilon_b \rangle = \frac{3\sqrt{\pi}}{16} \rho g B^3 \bar{f} \frac{H_{rms}^5}{\gamma^2 h^3} \left[ 1 - \frac{1}{\left\{ 1 + (H_{rms}/\gamma h)^2 \right\}^{5/2}} \right], \tag{26}$$

where  $B$  is a breaking coefficient,  $\bar{f}$  is the characteristic frequency,  $H_{rms}$  is the r.m.s. wave height,  $\gamma$  is the parameter to relate the  $H_{rms}$  with the water depth. Here we choose the parameter values to be

$$B = 1, \quad \gamma = 0.6, \quad \bar{f} = f_p, \quad H_{rms} = 2 \sqrt{\sum_n |A_n|^2}. \tag{27}$$

The right hand sides of Eqs.(17) and (25) should be equal to each other:

$$\begin{aligned} \sum_{n=1}^N \alpha_n |A_n|^2 &= \frac{3\sqrt{\pi}}{16\sqrt{gh}} B^3 \bar{f} \frac{\left( 2 \sqrt{\sum_n |A_n|^2} \right)^5}{\gamma^2 h^3} \\ &\times \left[ 1 - \frac{1}{\left[ 1 + \left\{ \left( 2 \sqrt{\sum_n |A_n|^2} \right) / \gamma h \right\}^2 \right]^{5/2}} \right] \equiv \beta(x) \sum_{n=1}^N |A_n|^2. \end{aligned} \tag{28}$$

Following Kirby et al. (1992),  $\alpha_n$  was determined to represent the experimental tendency as follows:

$$\alpha_n = \alpha_0 + (f_n / \bar{f})^2 \alpha_1 \tag{29}$$

$$\alpha_0 = F \cdot \beta, \quad \alpha_1 = (\beta - \alpha_0) \frac{\bar{f}^2 \sum_n |A_n|^2}{\sum_n f_n^2 |A_n|^2}. \tag{30}$$

Fig. 5 Comparison between Measured Spectra and Calculated Ones by Hybrid Model Equation.

The first constant term of Eq.(29) represents uniform energy decay over all frequency components, and the second term is to express the  $f^2$  dependence. Here we chose as  $F = 0.5$ . Eq.(14) using  $\alpha_n$  determined by Eqs.(29) and (30) is the hybrid model equation used hereafter. The resulting model is integrated shoreward from the initial gauge position without any subsequent reference to use of measured data.

### COMPARISON BETWEEN EXPERIMENTAL OBSERVATIONS AND HYBRID MODEL PREDICTIONS

Figure 5 shows the comparisons of the measured spectra with the calculated ones by the hybrid model equation. Input data was given at WG.1 ( $h = 47$  cm). For Case 1, although there are slight differences in the region of  $f > 1.0$  Hz at WG.11 and  $f < 1.0$  Hz at WG.12, both results agree fairly well. The measured and calculated spectra of Case 2 also show good agreement. Predictions estimate the increase of energies in high and low frequency regions.

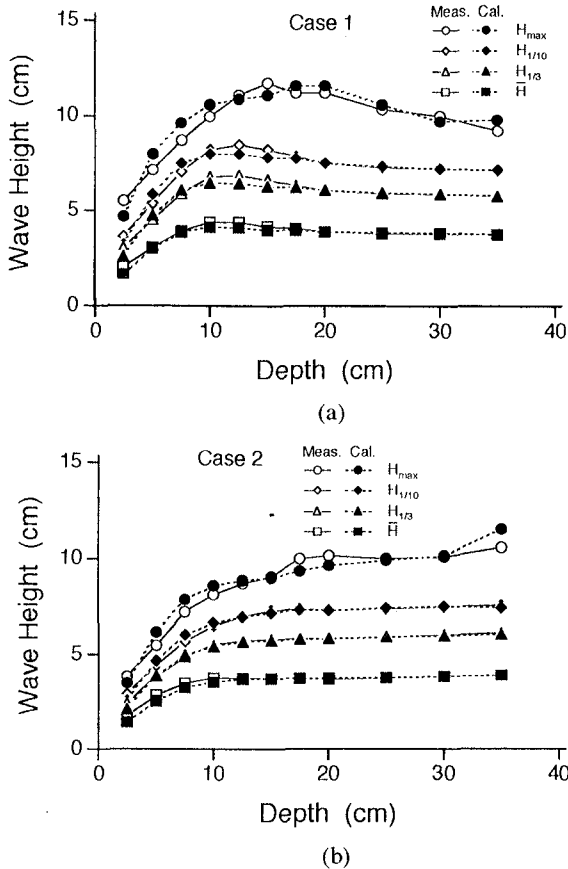

Fig. 6 Comparison between Measured and Calculate Representative Wave Heights.

Using the inverse FFT on the calculated  $A_n$ , we can obtain water surface variations from which wave characteristics such as wave heights, periods, crest heights, and so on, can be calculated. In the following comparisons, measured wave characteristics were calculated from the consecutive low-pass filtered (4.0 Hz) water surface variations with  $\Delta t = 0.025$  sec. Figure 6 shows the comparisons of the measured representative wave heights with the calculated ones for Case 1 and Case 2. It can be seen from the figures that the agreement between measured and calculated wave heights is good.

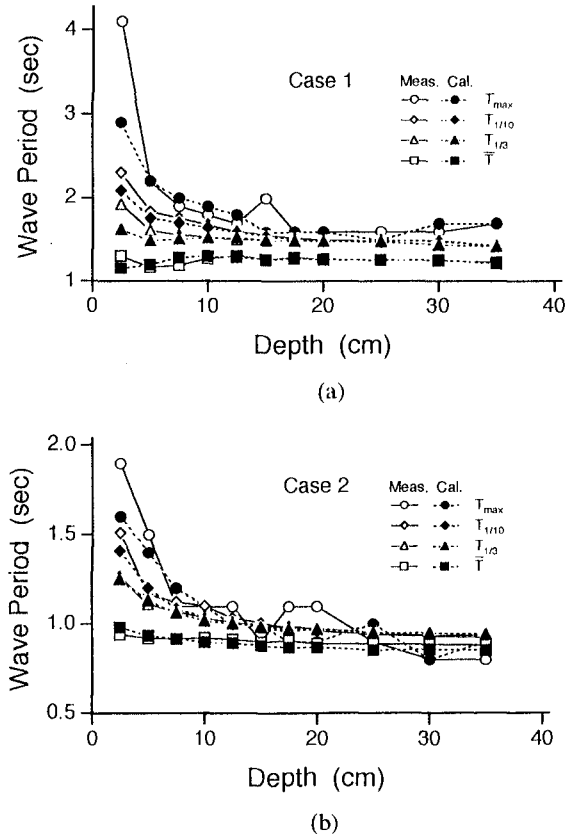

Fig. 7 Comparison between Measured and Calculated Representative Wave Periods.

Figure 7 shows the change of representative wave periods. Existing models based on the individual wave analysis model assume that the wave period is constant, or cannot deal with the change of wave period. Increase of energies of low frequency modes and decrease of energies around the initially peak frequency, according to Fig. 2, make the zero-upcrossing periods long compared to the incident wave periods. The present

hybrid model can estimate such change of wave periods, although a little differences can be seen at the shallowest water.

The wave crest height is an important factor for the design of the height of seawalls, platforms, and so on. Figure 8 shows the comparisons between the measured representative crest heights and the calculated ones. Although the predictions are a little smaller than the observations, satisfactorily good agreement is obtained. The representative normalized crest heights (each crest height was normalized by the wave height) are shown in Fig.9, which shows a little different tendency of change between the observations and the predictions. The values themselves agree fairly well.

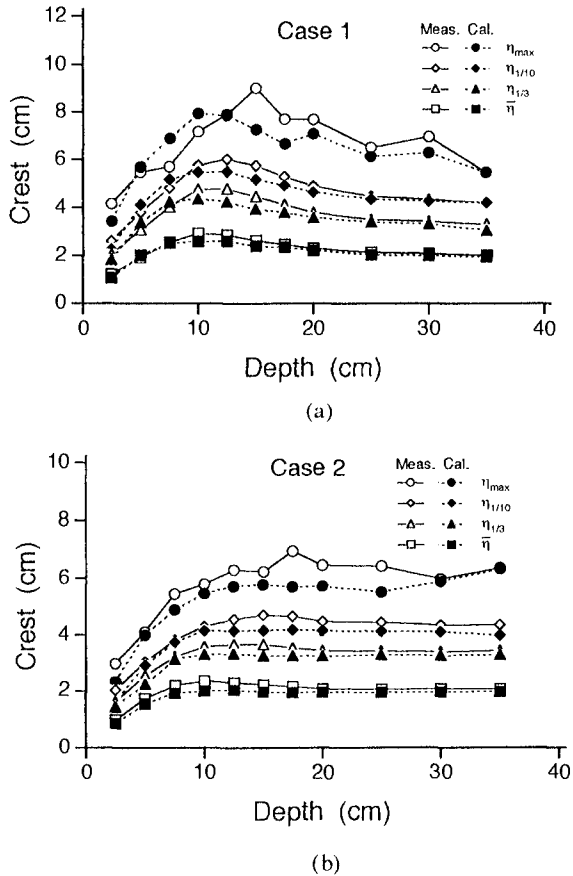

Fig. 8 Comparison between Measured and Calculated Representative Wave Crest Heights.

Fig. 9 Representative Normalized Wave Crest Heights.

## CONCLUSIONS

This paper proposed a hybrid model for random wave transformation, and compared the numerical predictions with the experimental observations. In the hybrid model a spectral model and a probabilistic model were employed: the former is the modified frequency-domain (spectral) KdV model to provide the shoaling and the dispersion relation for linear component waves with a damping term; the latter is a probabilistic model of energy dissipation due to wave breaking to formulate the coefficient of the damping term in the modified spectral KdV model.

The numerical predictions of energy spectra agreed well the experimental observations concerning the decay of energies around the initially peak frequency, the shift of peak frequency to the lower frequency, and the increase of energies in lower and higher frequency regions with decrease in the water depth. In addition to the energy spectra, the agreement between the predictions and the observation was satisfactorily

good against the representative wave heights, wave periods, wave crest heights. Thus, it was confirmed that the hybrid model developed here was useful as a vertically two-dimensional random waves over a uniform slope. The hybrid model should be further examined on the applicability to other situations such as multiple peak waves over a bar type topography.

## CHAPTER 36

### BREAKING OF IRREGULAR WAVES ON A SLOPE\*

M. MIZUGUCHI<sup>1</sup>

#### ABSTRACT

Breaking condition of irregular waves on a slope is studied through a series of laboratory experiment of bichromatic waves. First, breaking condition of individual waves defined by zero-down crossing method is compared with breaking condition of regular waves. An empirical formula is proposed to take into account of the influence of both the depth and width of the following trough. Then it is shown that the breaking condition of regular waves can be applied successfully when the individual waves are properly defined by paying attention to the nature of the wave crests. Finally these results obtained from the laboratory experiment are tested against the field data with reasonable success.

#### 1. INTRODUCTION

Several studies have been already reported on the breaking of irregular waves on slopes. Goda (1973), Battjes and Janssen (1978), and Thornton and Guza(1983) dealt with probabilistic ( and somewhat heuristic ) methods to be incorporated into the transformation model of wave height distribution in the nearshore zone. Sugawara and Yamamoto (1978), Mizuguchi and Matsuda (1980), and Mase et al.(1986) constructed an irregular wave transformation model, in which wave breaking condition of individual waves are assumed to be the same as that of monochromatic waves.

---

\*) Part of this paper was published in Proc. of 35th Japanese Conf. on Coastal Eng. in Japanese( Mizuguchi et al., 1988)

<sup>1</sup>Professor, Dept. Civil Eng., Chuo Univ., Kasuga, Bunkyo-ku, Tokyo, JAPAN 112

There also have been presented some papers, which directly and experimentally investigated breaking conditions of individual waves in irregular wave trains either in laboratory or in the field (Iwagaki et al.;1977, Isobe et al.;1980, Hotta et al.;1984, Kimura and Seyama;1986, and Mizuguchi et al.;1987). One can summarize these papers as follows.

- 1) Local wave breaking condition of individual waves ( normally defined by zero-down crossing method ) shows considerably larger data scatter than that of monochromatic waves.
- 2) In average, individual waves in irregular wave trains tend to break more easily, that is, to break with smaller wave height compared with regular waves.
- 3) Adjacent waves, in particular, the depth of the following trough for the waves defined by zero-down crossing method, have some influence on its breaking.

In this paper, first, we look for a possible explanation for the cause of the data scatter as well as the tendency that irregular waves break more easily, taking into account of the influence of the neighbouring waves. In due course, we test the applicability of regular wave breaking criterion to irregular waves, and propose a way to relate the breaking criterions of irregular waves and regular waves. For that purpose, we conducted a series of laboratory experiment, using bichromatic waves, which essentially show a characteristic feature of the irregular waves that the neighbouring waves are not the same as is so for regular waves. An advantage to employ the bichromatic waves is that it is easy to measure the breaking waves by wave gauges, as they have limited number of fixed breaking points. Finally, we apply our results obtained from the laboratory experiments to the field data and discuss the improvement accomplished and problems remained.

## 2. LABORATORY EXPERIMENT

Experiment was carried out in a wave flume of 30 cm wide, 20 m long and 45 cm in height with glass side walls. Beach of 1/20 slope with painted plate was installed in one end. Wave maker in the other end was of an absorbing type. Water depth was 35.5 cm in the constant depth area.

Wave generating signal  $e$  was chosen as follows.

$$e = a \cos(2\pi t) + qa \cos(\pi t + \epsilon) \quad (1)$$

Here  $a$  is the amplitude of the primary waves of period 1 s. Various combinations of bichromatic waves were produced in the wave breaking area by varying the phase difference

Fig. 1 Typical wave profile in time of two-wave train at one of breaking points. Various quantities to possibly influence the breaking condition are evaluated.

$\epsilon$  and the wave amplitude ratio  $q$ . This signal generates two-component waves also in terms of the time series, since the secondary wave has the half frequency of the primary waves. Hereafter we call this wave train as two-wave train. The amplitude  $a$  of the primary wave was set to be around 3 or 6 cm in the uniform depth area. The amplitude ratio  $q$  was varied as 0.1, 0.2, 0.3, and 0.5. Typical surface profile at a breaking point is shown in Fig. 1. Total of 160 runs of two-wave train experiment were conducted. In addition, 36 runs of regular wave experiment, which can be considered to be of the cases  $q=0$ , were also carried out in order to check the validity as well as the values of the experimental constants of the following Goda's breaking criterion (Goda; 1973).

$$H/d = A(L_0/d)[1 - \exp\{-Bd(1 + K\tan^s\beta)\}] + C \quad (2)$$

where  $H$ ,  $d$ , and  $L_0$  denote wave height, water depth, and deep-water wave length respectively.  $\tan\beta$  is the beach slope.  $A$ ,  $B$ ,  $K$ ,  $s$  and  $C$  are experimental constants and the originally proposed values are 0.17, 1.5, 15, 4/3 and 0 in its order. However, Eq.(2) with the original values of constants gives slightly larger breaking wave height as shown in Fig.2, as was also pointed out by Sugawara and Yamamoto(1978).  $A=0.158$ , with original values for other constants, is used in this paper, since it gives the better fitted curve to our regular wave experiment.

In the experiment, first, video-camera was used to determine the breaking points. Then capacitance-type wave gauges were placed at those breaking points ( normally two for two-wave trains ) to measure the surface profiles. The breaking points were defined visually as the position where significant white foams were observed. If not obvious, then the point of maximum wave height was searched by moving the

Fig. 2 Local breaking condition of regular waves on a uniform slope. Solid lines denote the experimental formula by Goda(1973) with specified values of A.

wave gauges in the cross-shore direction. The data was recorded on a digital tape recorder with sampling frequency of 50 Hz for the cases of  $a \approx 3$  cm and 100 Hz for both cases of  $a \approx 6$  cm and of regular waves. Data processing as well as signal making were done on a personal computer (Sord M343 SXII).

### 3. ANALYSIS OF LABORATORY DATA

The obtained data show small fluctuation of period 30 s, which is roughly the period of the first harmonics of the wave flume. The quantities defined for individual waves were averaged over 30 cycles of the primary wave. Positions of wave breaking also fluctuated within the horizontal distance of about 5 cm. This value gives rough estimate for the experimental error.

Zero-down crossing method was employed to define the individual waves, since this method takes the rise from the trough to the crest as the wave height as shown in Fig.1. This height is more appropriate for investigating the wave breaking condition than the fall height from the crest to the trough taken by the zero-up crossing method. As shown in Fig.1, various quantities associated with the defined wave, or more precisely with the shape of the troughs of both sides of the concerned crest, were also calculated in

Fig. 3 Breaking condition of two-wave train waves. Goda's experimental formula for regular waves, Eq.(2), is denoted by a solid line.

order to study the influence of the adjacent waves, For the breaking depth, the still water depth at each location is employed. In this stage, a data-base of 196 cases of local wave breaking conditions is obtained.

### 3.1 Breaking Conditions of Waves Defined by Zero-Down Crossing Method and Regular Waves

Fig. 3 shows the local wave breaking condition in which  $(H/d)_B$  is plotted against  $(d/L_0)_B$ . Subscripts B indicates those evaluated at the breaking point. The distribution of the data is very similar to the case of irregular waves and the data scatter is much larger than that in Fig. 2 for regular waves. For irregular wave results in laboratory experiment, see Fig. 2 in Kimura and Seyama (1986).

Fig. 4 shows direct comparison of measured relative wave height,  $(H/d)_B$ , against that,  $(H/d)_R$ , given by Eq.(2). This figure shows that the waves break with wide range of relative wave height, 0.45-0.95, in spite of the expectation from the regular wave formula that they break with narrow range of relative wave height, 0.6-0.85. This may suggest that there are some other hidden parameters to control the breaking of irregular waves and also that the large data scatter in Fig. 3 can be reduced by playing with the definition of the water depth.

Fig. 4 Direct comparison of breaking wave condition for two-wave train waves with Goda formula.

Kimura and Seyama (1986) succeeded to reduce the data scatter by introducing a modified water depth  $d_m$ , that is the depth below the median level of wave crest and trough. However, the reduction may be largely due to the resulting nonlinear scaling in the vertical axis, i.e.  $H/d_m$ . Moreover, it is difficult to find physical meaning of  $d_m$  for the wave breaking.

Here, first, we assume that the large data scatter is brought in as a result of neglecting the difference of the adjacent waves. We plotted the ratio of measured relative wave height,  $(H/d)_E$ , to the relative height given by Eq.(2),  $(H/d)_R$ , against various parameters defined from the quantities shown in Fig.1. Then the ratio shows clear dependency on the following parameters,  $HU/H$  ( where  $HU = H - HT + HT_1$  ) and  $TU/T$  ( where  $TU = T - TT + TT_1$  ).  $HU$  and  $TU$  are, respectively, the wave height and period, defined by the zero-up crossing method for the concerned wave crest. This is very conceivable when one thinks of the fact that it is the wave crest that breaks. In Fig. 5, the ratio of  $(H/d)_E/(H/d)_R$  is plotted against  $HU/H$  with  $TU/T$  as a parameter. The data, as a whole, show monotonical increase, implying the tendency that the larger the  $HU/H$  is, i.e., the deeper the following trough is, the higher the breaking wave height is, as was pointed out by Isobe et al.(1980). However, once the length of the following wave trough is taken into account, the data show monotonical decrease, indicating that the waves which are followed by relatively

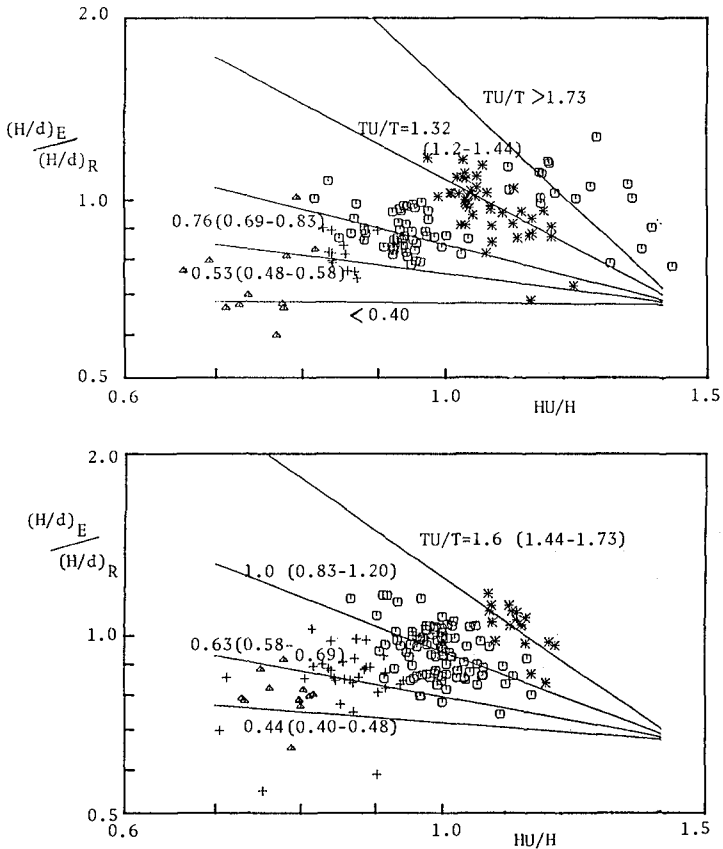

Fig. 5 Effect of the shape of the following trough on in individual wave breaking in two-wave trains. Upper and lower diagrams are for different values of the parameter  $TU/T$ .

deeper and shorter trough do break easily or with smaller wave height. In other words, the following deep trough, which is nearer to the wave crest, makes the crest break easily. This is reasonable as the situation means that the wave is sharp-crested and the actual water depth for the crest is shallow. The least square error method was applied to deduce the best-fitted curves, which are plotted with solid lines in Fig.5. They are expressed by the following equation.

$$\frac{(H/d)_E}{(H/d)_R} = 0.58(HU/H)^{-TU/T} \exp\{0.48(TU/T)\} \quad (3)$$

Fig. 6 Comparison of breaking conditions for two-wave trains after modification.

Equation (3) gives value of 0.94 for the ratio when  $TU/T=1$  and  $HU/H=1$ , although unit value may be expected as the conditions correspond to the regular waves. The irregular shape of the individual waves may be responsible for the easy breaking, although there is a possibility that the difference is within the experimental error. The data in Fig. 5 still show large scatter. In order to reduce the scatter, other parameters like  $TM_1$  to directly describe the shape of the trough could be better to be used. However we chose  $HU$  and  $TU$  to introduce the empirical formula, as they are the traditional quantities defined by zero-up crossing method.

Figure 6 shows comparison of measured relative wave height with that given by Eq.(2) with modification after Eq.(3). The improvement is obvious as the average tendency follows that of regular waves. The correlation coefficient in Fig. 6 is 0.68 and much larger than the value of 0.15 for Fig. 4. It may be possible to further reduce the data scatter by introducing another parameter to describe the irregular shape of the waves. However that sort of approach may not be productive.

### 3.2 Breaking Condition of Individual Wave Crest

In the preceding section a modification of regular wave breaking formula for the individual waves defined by zero-down crossing method was attempted. The results

Fig. 7 Properties of an individual wave crest in bichromatic waves.

Fig. 8 Breaking condition of individual wave crests in two-wave train waves.

indicates that the properties of the wave crest are important to control the breaking. Now we look into the breaking condition of a wave crest in comparison with regular wave breaking. Here we define an individual waves by trough-to-trough method as shown in Fig. 7. For this individual waves, the height,  $H_*$ , is defined as the vertical distance between wave crest and the line drawn from the preceding trough to the following trough. Local water depth  $d_*$  is calculated by applying first order cnoidal wave theory ( Isobe;1985 ) as  $d_* = d_t + (\text{mean elevation of cnoidal waves over trough level})$ , with  $H_*$ , trough-to-trough period,  $T_*$ , and trough depth  $d_t$  given.

Fig. 9 Bottom topography of field observation site

Fig. 10 Comparison of breaking condition of field waves defined by zero-down crossing method and regular waves.

Figure 8 shows local wave breaking condition for the individual wave crests. In contrast to Fig. 2, similarity with regular wave breaking is remarkable. There is still seen large data scatter, some of which may be of experimental error but most of which may be due to an artifice to approximate an individual wave by a regular wave. It is noted that the differences of wave period  $T$ , from the period  $T$  defined by zero-down crossing method are large and contribute quite significantly to move the data points in Fig. 7. In Fig. 7, average values of breaking height-depth ratio as well as their standard deviation could be evaluated for a given relative depth, as was done

Fig. 11 Comparison of breaking condition of field waves after the modification.

by Kimura and Seyama(1986) for waves defined by zero-down crossing method with their modified depth  $d_m$ , yielding experimental formulae for the breaking condition, though not tried here.

#### 4. BREAKING CONDITION OF FIELD WAVES

16 mm camera movies, which shot the target poles in the nearshore zone were used to take out the waves, which are just breaking at the location. This film was already analyzed and the results for the zero-down crossing waves were reported by Mizuguchi et al.(1987). Here we re-analyze the film in the same way as we did for the laboratory data and calculated the quantities shown in Fig. 1. Fig. 9 shows the cross-shore bottom topography of the site. The data at position D is used. The mean water depth was 2.79 m. Numbers of just breaking waves at position D were 47 out of 1118 waves defined during the observation.

In Fig. 10, relative wave heights at the breaking point for field waves are compared with regular wave formula. For  $\tan\beta$ , value of  $1/25$  is used. Figure 10 is very similar to Fig. 4, showing that waves break with wide range of,  $H/d$ , values, although Eq.(2) gives narrow range of the values.

Figure 11 shows comparison of relative wave heights for field waves,  $(H/d)_F$ , with those of the breaking formula

Fig. 12 Comparison of breaking condition of individual waves defined by trough-to-trough method for field waves.

modified with Eq.(3),  $(H/d)_{RM}$ . Figure 12 shows comparison of breaking condition of the wave crests,  $(H_*/d_*)_F$ , for field waves and regular waves. Both diagram show a linear trend though large data scatters are still observed. There is no tendency in Fig. 12 that the field values are smaller than those given by regular wave formula, in contrast to the results in Fig. 8. The linear trends proves that the present modifications are in the right direction to establish the wave breaking condition of the individual waves in the field waves. The data scatter may result from various complexities observed in the field, such as three dimensional feature of field waves and non-uniform bottom slope, in addition to the factors possible in laboratory data. Recently, Sato et al.(1990) looked into the effect of long period waves on the irregular wave breaking. Interaction between long period waves and wind waves may be partially responsible for the remaining data scatter.

## 5. CONCLUSIONS

We can conclude that the individual waves in an irregular wave train do, in average, break in a similar condition to that of the regular waves. However, conventional zero crossing methods may not be suitable to defining the breaking waves, for thus defined waves need the systematic modification as given by Eq.(3). Regular wave breaking condition can be applied reasonably well to

the waves defined by the trough-to-trough method.

One can also conclude that the average breaking height-depth ratio of two-wave train is slightly smaller (about 5 % ) than that of regular waves, although this tendency is not clear in field waves, and that some data scatter is inevitable when the regular wave formula is used for the individual waves. The irregular shape of the individual waves may be responsible for both of them.

Here only local wave breaking criterion is studied. It is necessary to develop a shoaling model for irregular waves as well as for two-wave trains, which is valid upto breaking point, in order to be able to predict both the breaking depth and wave height.

#### ACKNOWLEDGEMENTS

I would like to thank T. Watanabe, Y. Takemura, M. Itoh and T. Mori for their great help in carrying out this research. This research was financially supported by Grant-in-Aid of Ministry of Education and Culture, Japan.

## CHAPTER 37

### Oscillating Water Column Modelling

Iain G. Morrison <sup>1</sup> and Clive A. Greated<sup>2</sup>

#### Abstract

The development of a mathematical model to calculate the response of a simple oscillating water column wave energy device (OWC) to a known wave climate is described. The power available from the device is calculated and this is compared with results from model tests in a wave flume.

Particle Image Velocimetry (PIV) has been used to map the flow of water within the chamber of the device and vorticity maps have been calculated. The estimation of energy loss in vortices due to viscous dissipation is discussed in detail and is shown to account for as much as 8% of the total energy of an incident wave.

#### Introduction

The oscillating water column wave energy converter (OWC) is now a well established means of extracting useful energy from water waves both simply and cost effectively. It consists of a chamber with two orifices. One is open to the sea below the low water level and the other is typically at the top of the chamber and connects to a turbine. A water column is formed in the chamber and oscillates due to the force of the incident waves. This in turn forces air through the turbine thus generating electricity. Several devices are now in operation worldwide but these are single prototype units working at only a fraction of their true potential either due to turbine restrictions or to large scale dissipation of energy within the chamber itself.

<sup>2</sup>Director, Fluid Dynamics Unit, Physics Department, The University of Edinburgh, Edinburgh, EH9 3JZ, U.K.

This paper attempts to develop a mathematical model to predict the power available from a simple design of OWC and to use Particle Image Velocimetry (PIV) to study the characteristics of water flow in the chamber of a model of the same OWC. Analysis of the highly detailed velocity maps produced with PIV allows regions of energy dissipation to be identified and the magnitudes of these energy losses to be estimated.

The OWC under study here is a simplified  $\frac{1}{36}$ th scale model of the prototype designed by Whittaker[4] and now operational on the island of Islay off the west coast of Scotland. This working example utilises a self rectifying axisymmetric Wells turbine[3] for the conversion to electrical energy.

### The OWC model

The scale model measures approximately  $0.5\text{m} \times 0.5\text{m} \times 0.4\text{m}$  - the dimensions chosen to coincide with those of models built and tested at Queen's University, Belfast. The water depth shallows from a maximum of  $0.75\text{m}$  'offshore' to  $0.12\text{m}$  at the mouth of the OWC, the variation occurring steadily along a beach of slope 1:12 (figure 1).

Figure 1: OWC model at top of 1:12 beach

### Mathematical modelling

It is important that an OWC and its turbine are capable of extracting the maximum amount of energy from the waves incident upon the chamber. In order to achieve this the natural frequency of the chamber must be chosen to be

close to that of the prevailing wave climate. Therefore it is useful to be able to predict theoretically the resonant frequency of an OWC chamber and the air pressure variations within it since it is these pressures which provide the force to drive the turbine. Linear wave theory is used as a first approximation here to model the typically low amplitude waves produced in the wave flume experiments.

It is assumed that the air column compresses adiabatically and the variation of the mass of this column due to air movement through the orifice is considered. It is further assumed that the air travels through the orifice with a velocity proportional to the excess pressure in the chamber. This yields a differential equation giving the rate of change of air pressure within the OWC:

$$\frac{dp}{dt} = \frac{\gamma p}{d - y} \left[ \frac{dy}{dt} - \frac{\kappa}{\rho_0 A} \left( \frac{p_0}{p} \right)^{\frac{1}{\gamma}} (p - p_0) \right] \quad (1)$$

where  $p$  is the air pressure in the chamber,  $y$  is the height of the water surface in the chamber above mean water level (MWL),  $\gamma$  is the ratio of the specific heat of air at constant pressure to that at constant volume,  $d$  is the length of the air column at MWL,  $p_0$  is atmospheric pressure,  $\kappa$  is a constant relating to the size of the orifice,  $\rho_0$  is the density of air at atmospheric pressure, and  $A$  is the cross sectional area of the air column.

Consideration of both the static and dynamic pressure under an incident wave and the upward force this exerts on the water column leads to the second differential equation :

$$\frac{d^2 y}{dt^2} = \frac{1}{\rho_w(L + y - d)} \left[ \rho_w g \left( a \sin \omega t - y - \frac{a \sinh k(h - b) \sin \omega t}{k(b - h) \cosh kh} + \frac{g a^2 k \sinh 2k(h - b)}{8 \omega^2 (b - h) \cosh^2 kh} \right) + p_0 - p \right] \quad (2)$$

where  $L$  is the chamber height,  $\rho_w$  is the density of water,  $h$  is the mean water depth at the OWC,  $b$  is the distance below mean water level of the lip of the front wall,  $a$  is the amplitude,  $k$  is the wavenumber and  $\omega$  is the angular frequency of the incident wave.

Equations (1) and (2) are insoluble analytically. They are solved numerically using a fourth order Runge-Kutta algorithm with a small time step. The program

which does this starts with deep water waves of known frequency and amplitude and calculates their amplitude and wavenumber in the shallower water at the mouth of the OWC before calculating the wave pressures at that point. This allows more reliable duplication of wave flume experiments where the amplitude and wavenumber of waves produced is only known accurately at their point of origin in deep water.

From calculated values of water elevation and chamber air pressure the instantaneous power is given approximately by :

$$P = A \frac{dy}{dt} (p_0 - p) \quad (3)$$

### The PIV system

PIV is a full field velocity measurement technique consisting of two distinct stages. First the displacement of small, neutrally buoyant, seeding particles in the flow is recorded on a photographic negative using a high quality medium format camera. Then the negative is analysed using the Young's fringe method to produce a detailed map of regularly spaced flow velocity vectors with a typical maximum error of the order of 5% of the maximum velocity magnitude.

The seeding particle displacements are recorded by illuminating the flow several times on a single frame with intense laser light. In the experiments carried out in Edinburgh the beam from a 15W continuous wavelength argon ion laser is scanned at high speed into the centre of the tank via a spinning mirror and a parabolic mirror which produce a 'sheet' of light illuminating a region about 1m wide.

One of the drawbacks of a PIV system is that although particle spacings on the film can be accurately determined the sense of direction of flow cannot. There is a 180° ambiguity in the direction of flow vectors which was overcome by the development of a rotating mirror image shifting system. This consists of a high quality front silvered mirror placed in a vertical plane and rotating on a turntable about a vertical axis through its centre. The turntable rotates at a constant known speed. The PIV pictures are then taken with the flow reflected in the mirror. The rotation effectively superimposes a known horizontal velocity on the flow. This is chosen to be large enough such that the sense of all the resulting velocity vectors can be inferred at the time of analysis. Finally the superimposed shift velocity is subtracted to give the true flow vectors.

The technique of PIV is discussed in greater detail by Gray & Greated[1] and

by Greated et al[2].

### Wave flume experiments

All wave flume experiments were carried out in a flume purpose built for PIV applications. The flume is 9.75m long, 0.4m wide and has a depth of 0.75m at mean water level. The walls and base of the tank are constructed from glass to allow unobstructed optical access from the base and sides of the tank. Waves are produced by a computer controlled hinged paddle with the capability to simultaneously produce waves and absorb reflections to minimise any seiche effects in the flume.

An OWC model was built entirely from perspex to allow access for the laser sheet from below and for photography from the side. The model was fitted with a high precision differential air pressure transducer. A resistance type wave gauge was fitted inside the chamber of the model and three further gauges were placed at different water depths on the sloping beach to measure the amplitudes of incoming and reflected waves. All five channels of data collection were sampled at a rate of 80Hz.

Building a scaled down Wells turbine for the model would not only be impractical but would also be unlikely to replicate the linear damping effect of a real turbine on the oscillation of the water column. Instead the square orifice of the model was closely packed with many small diameter tubes to reduce the Reynolds number of the airflow so that the flow would be laminar and thus proportional to the difference between chamber pressure and atmospheric pressure.

Wave gauge and air pressure records were taken for various amplitudes and frequencies of sinewaves and for nine different sizes of orifice ranging from a closed orifice to a maximum opening of 39mm  $\times$  39mm.

### Results

PIV was used to produce velocity vector maps of the flow within the OWC for various frequencies and amplitudes of forcing waves and several different orifice sizes. Each map contains about 2500 vectors with a resolution of about 5mm.

At frequencies below about 0.8Hz a strong vortex forms just within the lip of the front vertical wall of the model when water rushes in to the chamber. Figure 2 shows the flow of water into the OWC chamber just after the crest of a 0.6Hz, 15mm amplitude wave is incident. A vortex then forms as the water level rises in the chamber as shown in figure 3 and this is shed as the level drops again.

Figure 2: PIV vector map,  $f=0.6\text{Hz}$ , wave amplitude=15mm

Figure 3: PIV vector map,  $f=0.6\text{Hz}$ , wave amplitude=15mm

Figure 4 shows the comparison of typical pressure and chamber water elevation results from theoretical and wave flume experiments. It can be seen that the theoretical results correctly predict the amplitude of oscillation of water in the column but underestimate the pressure variations. This may be due to the difficulty of determining the effective mass of water involved in the oscillations of the water column. However a more likely explanation is that the small diameter tubes placed in the orifice of the OWC model failed to lower the Reynolds number sufficiently to ensure laminar flow through them.

As a result of the underestimated pressure variations the theoretical model also underestimates the mean instantaneous power available from the device. The theoretical results in figure 5 suggest that the natural frequency of the OWC is about  $0.55\text{Hz}$  with an orifice of  $25\times 25\text{mm}$  whereas the experimental results suggest a lower value of less than  $0.5\text{Hz}$ . Unfortunately it was not possible to produce lower frequency sinusoidal waves in the flume. The experimental results in figure 6 show an optimum orifice size of about  $24\times 24\text{mm}$  whereas the the-

Figure 4: Air pressure and water elevation results,  $f=0.5\text{Hz}$ , wave amplitude=10mm, orifice=10x10mm

oretical results suggest an optimum size of  $22 \times 22\text{mm}$  at a frequency of  $0.5\text{Hz}$ . These dimensions compare remarkably well despite the large discrepancy in peak air pressures between the two sets of results.

### Vortex energies

Figure 3 shows a strong vortex within the chamber of the OWC. Much of the kinetic energy within the vortex is lost due to viscous dissipation. Therefore it is useful to attempt to calculate, from PIV vector maps, the kinetic energy contained in such a vortex.

For calculation of kinetic energies from PIV vector maps to be possible it is necessary to assume that the flow in the OWC is completely two dimensional i.e. in the plane of the PIV photographs. Although there is some movement through this plane it serves as good first approximation in this case.

Figure 5: Calculated instantaneous power, orifice=25x25mm, wave amplitude=10mm

Each vector in the PIV velocity map is taken to lie at the centre of a cuboid of fluid with dimensions  $d_x \times d_y \times w$  where  $d_x$  and  $d_y$  are, respectively, the horizontal and vertical spacings of vectors and  $w$  is the width of the OWC model. The cuboid is assumed to have a translational velocity equal to that of the vector at it's centre and an angular velocity equal to half the magnitude of the calculated vorticity at that point. This allows the translational and rotational energies to be calculated and combined yielding a total kinetic energy  $E$  given by :

$$E = \frac{1}{2} \rho_w d_x d_y w (v_x^2 + v_y^2) + \frac{1}{96} \rho_w w d_x d_y \left( \frac{\partial v_y}{\partial x} - \frac{\partial v_x}{\partial y} \right)^2 \quad (4)$$

where  $v_x$  and  $v_y$  are the horizontal and vertical velocities respectively and  $\rho_w$  is the water density. These values can be summed to give the total kinetic energy within the frame of the PIV picture or the total kinetic energy of a vortex subject to the difficulty of determining it's size. This can be compared with the calculated energy of the wave transmitted by the wavemaker in order to estimate the proportion of wave energy dissipated by these vortices.

In figure 3 the kinetic energy of the water in the OWC chamber is calculated to be 0.21J with about 0.16J being contained within the vortex. This corresponds to about 8 % of the original wave energy. However it clearly accounts for a much

Figure 6: Calculated instantaneous power,  $f=0.5\text{Hz}$ , wave amplitude=10mm

higher proportion of the wave energy actually reaching the device since energy is dissipated as the wave travels from deep to shallow water. It should be noted that these energy calculations from PIV plots take no account of potential energy due to variations in water level.

### Conclusions

An attempt has been made to develop a theoretical model of an oscillating water column wave energy converter. It has been shown that although the model does not satisfactorily predict the pressure variations in the chamber it is able to approximate the optimum orifice size and the optimum frequency of power extraction. PIV vector maps of the flow into the chamber of the OWC have been used to calculate the energy trapped within a large vortex. This has been shown to account for more than 8% of the wave energy incident on the device.

These PIV experiments should enable future OWC wave energy converters to be designed with a more quantitative approach to reducing hydrodynamic losses within the device.

## CHAPTER 38

### NEW APPROACH FOR ESTIMATING THE SEVEREST SEA STATE FROM STATISTICAL DATA

Michel K. Ochi\*

#### Abstract

This paper discusses a feature of the generalized gamma distribution which is particularly appropriate for statistical analysis of long-term significant wave height data. The agreement between the cumulative distributions of the data and the generalized gamma distribution is shown to be satisfactory. Methods to estimate the probable extreme sea state (significant wave height) expected in a specified time period as well as the extreme sea state for design consideration of marine systems are presented.

#### Introduction

Probabilistic estimation of the extreme sea state expected in 50 or 100 years provides information vital for the design of offshore and nearshore structures as well as for the stochastic analysis of various coastal processes such as wave-induced sediment transport.

Sea severity as evaluated from wave height measurements depends to a great extent on the geographical location where the data are obtained, since the crucial factors for sea severity are the frequency of occurrence of storms, water depth and fetch length. In addition, sea severity depends on the growth and decay stage of a storm even though wind speed is the same. Thus, there is no scientific basis for selecting a specific probability distribution function to represent the statistical distribution of sea state (significant wave height). Because of this, various probability distribution functions have been proposed which appear to best fit particular sets of observed data. These include (a) log-normal distribution [Ochi 1978a], (b) modified

---

\* Professor, Coastal & Oceanographic Engineering Department  
336 Weil Hall, University of Florida, Gainesville,  
Florida, 32611, U.S.A.

log-normal distribution [Fang and Hogben 1982], (c) three-parameter Weibull distribution [Burrows and Salih 1986] [Mathisen and Bitner-Gregersen 1990], (d) combined exponential and power of significant wave height [Ochi and Whalen 1980] and (e) modified exponential distribution [Thompson and Harris 1972], etc.

It is highly desirable that a more rational probability distribution be developed so that sea severity evaluated from data obtained anywhere in the world can be reasonably represented and analyzed by a specific distribution thereby permitting a direct comparison of data, including extreme values. To achieve this goal, this paper introduces a probability distribution called the generalized gamma distribution, and discusses a feature of the distribution which is particularly appropriate for analysis of long-term significant wave height data.

#### Statistical Trend of Long-Term Significant Wave Height Data

Prior to introducing a probability distribution to represent long-term significant wave height data, it may be well to examine the general trend of the statistical distribution. For this, significant wave height data obtained at various geographical locations as well as various water depths are analyzed in the present study.

Figures 1(a) through 1(g) show the cumulative distribution functions of significant wave height plotted on log-normal probability paper. These data were obtained at locations: (a) Norwegian coast [Mathisen and Bitner-Gregersen 1990], (b) North Sea [Bouws 1978], (c) North Pacific off Japan [Tomita 1988], (d) North Pacific off Canada [National Data Buoy Center 1990], (e) Atlantic Ocean off Georgia [National Data Buoy Center 1990], (f) Florida East Coast (shallow water area) [Coastal Data Network 1990] and (g) Gulf of Mexico (shallow water area) [Work 1992], respectively. Included also in these figures is a straight line which represents the cumulative distribution function by fitting the following log-normal probability distribution:

$$f(x) = \frac{1}{\sqrt{2\pi}\sigma x} \exp\left\{-\frac{1}{2}\left(\frac{\ln x - \mu}{\sigma}\right)^2\right\}, \quad 0 \leq x < \infty \quad (1)$$

As can be seen in Figure 1, the cumulative distributions of all significant wave height data show a consistent trend irrespective of geographical location and water depth. That is, at least 90 to 95 percent of each set of data is well represented by the log-normal probability distribution; however, the data diverge from the log-normal distribution for large significant wave heights which are extremely critical for estimating extreme values. The divergence is always consistent in such a way that the cumulative distribution function of the data converges to unity faster than that of the log-normal distribution. This implies that the log-normal distribution will overestimate the extreme significant wave height by a substantial amount.

Figure 1(a): Long-term significant wave height data obtained off Norwegian coast plotted on log-normal probability paper (Data from Methisen & Bitner-Gregersen 1990)

Figure 1(b): Long-term significant wave height data obtained in the North Sea plotted on log-normal probability paper (Data from Bouws 1978)

Figure 1(c): Long-term significant wave height data obtained in the North Pacific Ocean off Japan plotted on log-normal probability paper (Data from Tomita 1988)

Figure 1(d): Long-term significant wave height data obtained in the North Pacific Ocean off Canada plotted on log-normal probability paper (data from Nat.Data Buoy Center 1990)

Figure 1(e): Long-term significant wave height data obtained in the Atlantic Ocean off Georgia plotted on log-normal probability paper (Data from Nat.Data Buoy Center 1990)

Figure 1(f): Long-term significant wave height data obtained off Florida East Coast plotted on log-normal probability paper (Data from Coastal Data Network 1990)

Figure 1(g): Long-term significant wave height data obtained in the Gulf of Mexico plotted on log-normal probability paper (Data from Work 1992)

Figure 2: Comparison between the standardized cumulative distributions of (a) log-normal and (b) generalized gamma distribution for  $\sigma = 0.20$  and for various  $m$ -values

We may conclude from the results shown in Figure 1 that the statistical characteristics of long-term significant wave height can best be represented by a probability distribution whose cumulative distribution is by and large close to that of the log-normal distribution but converges to unity much faster than the log-normal distribution at higher values, say over 0.95.

### Generalized Gamma Probability Distribution

An extensive search was made to find an appropriate probability distribution which represents the cumulative distribution of significant wave height data. For this, various probability distribution functions were standardized so that a comparison of distributions could be made under the uniform condition of zero-mean and unit variance. Here, standardization was achieved through a change of random variables by subtracting the mean and dividing by the standard deviation of the original random variable. Let us define the standardized random variable as  $Z$  and its probability density function  $f(z)$ . The standardized log-normal distribution is given by

$$f(z) = \frac{1}{\sqrt{2\pi}\sigma} \frac{\sqrt{\alpha^2-1}}{\sqrt{\alpha^2-1}z+1} \exp \left\{ -\frac{\left( \ln \left\{ \alpha \left( \sqrt{\alpha^2-1}z+1 \right) \right\} \right)^2}{2\sigma^2} \right\}, \quad (2)$$

where  $-1/\sqrt{\alpha^2-1} \leq z < \infty$ ,  $\alpha = \exp\{\alpha^2/2\}$ .

Note that the standardized log-normal distribution has only one parameter  $\sigma$ , and its lower bound is a function of  $\sigma$ .

It was found that the following generalized gamma distribution (in the standardized form) appears to satisfy the conditions required for analysis of significant wave height data discussed in the previous section:

$$f(z) = \frac{c\sqrt{q}}{\Gamma(m)} \left( \sqrt{q}z+p \right)^{cm-1} \exp \left\{ -\left( \sqrt{q}z+p \right)^c \right\}, \quad (3)$$

where  $-p/\sqrt{q} \leq z < \infty$ ,  $p = \Gamma\left(m + \frac{1}{c}\right) / \Gamma(m)$ ,

$$q = \left[ \Gamma\left(m + \frac{2}{c}\right)\Gamma(m) - \left\{ \Gamma\left(m + \frac{1}{c}\right) \right\}^2 \right] / \left\{ \Gamma(m) \right\}^2.$$

Figure 3: Comparison between the standardized cumulative distributions of (a) Norwegian data, (b) log-normal and (c) generalized gamma distribution for  $\sigma = 0.528$  and for various  $m$ -values

In order to elaborate on the above statement, let us compare the two standardized probability distributions given in Eqs. (2) and (3) for an arbitrarily chosen value  $\sigma = 0.20$  of the log-normal distribution and  $m = 1, 4$  and  $8$  of the generalized gamma distribution. Since the lower bounds of these two probability density functions are equal, we have a functional relationship between Eqs. (2) and (3). That is,

$$\exp\{\sigma^2\} = \Gamma\left(m + \frac{2}{c}\right) \Gamma(m) / \left\{ \Gamma\left(m + \frac{1}{c}\right) \right\}^2 \quad (4)$$

Hence, from Eq. (4), we can evaluate  $c = 5.70, 2.50$  and  $1.76$  for each  $m$ -value with  $\sigma = 0.20$ . A comparison of cumulative distribution functions of the log-normal and generalized gamma distributions (in standardized form) is shown in Figure 2. As can be seen in the figure, cumulative distributions are nearly equal up to  $0.90$ , but depending on the  $m$  and  $c$ -values in the generalized gamma distribution, the difference can become substantially large for cumulative distribution is greater than  $0.90$ .

For further confirmation of this feature, another comparison is shown in Figure 3 for  $\sigma = 0.528$  of the log-normal distribution evaluated from data obtained off Norwegian coast shown in Figure 1(a), and  $m = 1, 2$  and  $4$  of the generalized gamma distribution. Included in the figure is the cumulative distribution of the Norwegian data which is also standardized by using the mean and variance evaluated from the data. It can be seen in the figure that the values of significant wave height (standardized) for a specified cumulative distribution show little difference for the two probability distributions and they both agree well with data in the range of cumulative distribution up to  $0.95$ . However, the difference becomes substantially large for cumulative distribution greater than  $0.95$ . The cumulative distribution of the data is very close to the generalized gamma distribution with  $m = 8$  in this case.

This feature of the generalized gamma distribution shown in Figures 2 and 3 is considered to make its use advantageous in statistical analysis of significant wave height data. With this background, let us compare the cumulative distribution functions of measured data with the generalized gamma distribution (non-standardized) whose probability density function  $f(x)$  and cumulative distribution function  $F(x)$  are given as follows:

$$f(x) = \frac{c}{\Gamma(m)} \lambda^{cm} x^{cm-1} \exp\{-(\lambda x)^c\}, \quad 0 \leq x < \infty. \quad (5)$$

$$F(x) = \Gamma\left\{m, (\lambda x)^c\right\} / \Gamma(m), \quad (6)$$

where the numerator is the incomplete gamma function.

Figures 4(a) through 4(g) show comparisons of cumulative distributions of data with the generalized gamma distribution. Data in each figure correspond to those shown in Figures 1(a) and 1(g), respectively. Included also in each figure are the values of the three parameters of the distribution evaluated from the data. Methods to estimate the parameter values will be discussed in the next section. As can be seen in Figure 4, the long-term significant wave height data can be well represented by the generalized gamma distribution.

#### Estimation of Parameters of Generalized Gamma Distribution

Methods to estimate the three parameters involved in the generalized gamma distribution are discussed by Stacy and Mihram [Stacy and Mihram 1965]. They present a procedure based on two different approaches; one being the maximum likelihood method, the other the moment method. In both methods, the logarithm of the variables (significant wave height for the present problem) is used. In particular, the second method considers the following sample mean, variance and skewness:

$$\begin{aligned} \bar{u} &= \frac{1}{n} \sum_{i=1}^n u_i, \quad \text{where } u_i = \ln x_i \\ s_u^2 &= \frac{1}{n-1} \sum_{i=1}^n (u_i - \bar{u})^2 \\ g_u &= \frac{n}{(n-1)(n-2)} \frac{1}{s_u^3} \sum_{i=1}^n (u_i - \bar{u})^3 \end{aligned} \quad (7)$$

By equating Eq.(7) to the theoretical mean, variance and skewness (in logarithmic form), respectively, we may estimate the three

parameters. For example, the parameter  $m$  can be estimated from the following equation:

$$-|g_u| = \frac{\frac{d^3}{dm^3} \ln \Gamma(m)}{\left\{ \frac{d^2}{dm^2} \ln \Gamma(m) \right\}^{3/2}} \quad (8)$$

Although the Stacy and Mihram method is mathematically correct, some difficulty is often encountered in practice in solving Eq.(8) for certain set of data. It should be noted that in estimating the statistical properties of long-term significant wave height, the sample size of data is usually extremely large, on the order of several thousand. If this is the case, we may simply estimate the parameter values by equating the sample moments to theoretical moments. Here, the  $j$ -th moment of the generalized gamma distribution is given by

$$E[x^j] = \frac{1}{\lambda^j} \frac{\Gamma\left(m + \frac{j}{c}\right)}{\Gamma(m)} \quad (9)$$

Since the generalized gamma distribution has three unknown parameters  $m$ ,  $c$  and  $\lambda$ , we may consider a set of equations consisting of either the first three moments or the 2nd, 3rd and 4th moments; the latter places more emphasis on the higher order moments. It is found through statistical analysis of many data that the solution of a set of three moments consisting of the 2nd, 3rd and 4th moments yields the generalized gamma distribution which well represents the cumulative distribution of the observed data. The parameter values of the generalized gamma distributions given in each example in Figure 4 are all determined by this procedure. That is, from a set of three equations for  $j = 2, 3$  and  $4$  of Eq.(9), we can derive the following two equations by eliminating the parameter  $\lambda$ .

$$\frac{\{\Gamma(m)\}^{1/2} \Gamma\left(m + \frac{3}{c}\right)}{\left\{\Gamma\left(m + \frac{2}{c}\right)\right\}^{3/2}} = \frac{E[x^3]}{\{E[x^2]\}^{3/2}} \quad (10)$$

$$\frac{\Gamma(m) \Gamma\left(m + \frac{4}{c}\right)}{\left\{\Gamma\left(m + \frac{2}{c}\right)\right\}^2} = \frac{E[x^4]}{\{E[x^2]\}^2}$$

The parameters  $m$  and  $c$  are determined from the above equations.

### Estimation of Extreme Sea State

Estimation of the extreme sea state (significance wave height) expected to occur in a specified time period (50 years, for example) based on the generalized gamma distribution is discussed in this section.

#### (a) Probable Extreme Sea State

The probable extreme sea state refers to that most likely to occur in a specified time period which is the modal value of the probability density function of extreme values. It is essentially the value of the significant wave height which satisfies the equation of return period being equal to the number of significant wave heights in a specified time. In order to avoid possible confusion, the extreme value in  $N$ -observations is denoted by  $Y_N$ -value which satisfies the following equation:

$$\ln \left\{ 1 / \left[ 1 - \Gamma \left\{ m, (\lambda y_N)^c \right\} / \Gamma(m) \right] \right\} = \ln N \quad (11)$$

where  $N$  = number of significant wave heights expected in a specified time period.

Another approach for evaluating the probable extreme sea state is through application of Cramér's asymptotic extreme value statistics. This method was used for evaluating the extreme value of the generalized gamma distribution and therefrom the following equation to estimate the probable extreme values was derived [Ochi 1978b]:

$$\frac{1}{\Gamma(m)} u_N^{m-1} e^{-u_N} = \frac{1}{N} \left\{ 1 - \frac{1}{u_N} \left( m - \frac{1}{c} \right) \right\}, \quad (12)$$

where  $u_N = (\lambda y_N)^c$ .

The left-side of Eq.(12) is the gamma probability distribution, and hence solution of the equation with respect to  $u_N$  can easily be obtained for a given  $m$ ,  $c$  and  $\lambda$ . The asymptotic probable extreme value  $y_N$  can be evaluated from the extreme value of  $u_N$ . It is noted that the asymptotic probable extreme value thus obtained is very close to the value obtained as the solution of Eq.(11) when  $N$  is large.

#### (b) Extreme Sea State for Design Consideration

The probable extreme sea state discussed in the previous section is the modal value of the probability density function of  $y_N$ . However, the probability that the extreme value exceeds the probable extreme value is theoretically  $1 - e^{-1} = 0.632$ . Since this probability is very large, the probable extreme value should not be used for design of marine systems. For the design of marine systems, it

is necessary to consider an extreme value for which the probability of exceedance is a very small specified value,  $\alpha$ , called the risk parameter. It can be evaluated from the cumulative distribution function given in Eq.(6) as

$$F(x) = \frac{\Gamma\{m, (\lambda x)^c\}}{\Gamma(m)} = (1-\alpha)^{1/N} \quad (13)$$

Although Eq.(13) yields the exact solution numerically, we can derive the following equation for large  $N$  and small  $\alpha$ :

$$1 - \frac{\Gamma\{m, (\lambda x)^c\}}{\Gamma(m)} = 1 - (1-\alpha)^{1/N} \sim \frac{\alpha}{N} \quad (14)$$

Eq.(14) yields an equation in a form similar to that given in Eq.(11); and hence, the design extreme value with risk parameter,  $\alpha$ , can be obtained by finding the  $y_N$ -value which satisfies the following equation:

$$\ln \left\{ 1 / \left[ 1 - \Gamma\{m, (\lambda y_N)^c\} / \Gamma(m) \right] \right\} = \ln(N/\alpha), \quad (15)$$

where  $\alpha$  = risk parameter; namely, the probability that the extreme value exceeds the design extreme value.

The design extreme value can also be obtained as the solution of the following equation which has a form similar to that given in Eq.(12):

$$\frac{1}{\Gamma(m)} u_n^{m-1} e^{-u_n} = \frac{\alpha}{N} \left\{ 1 - \frac{1}{u_n} \left( m - \frac{1}{c} \right) \right\} \quad (16)$$

As an example of the estimation of extreme sea states, Figure 5 shows the probable and design severest sea states as a function of time using the Norwegian data shown in Figure 4(a). The estimations are made by Eqs. (12) and (16). As can be seen, the magnitude of the probable as well as that of the design extreme sea state with risk parameter  $\alpha = 0.01$  do not increase significantly with increase in time. However, the design extreme sea state with the risk parameter  $\alpha = 0.01$  is substantially larger (approximately 40 percent) than the probable extreme sea state in this example. The severest sea state observed in 7 years at this location agrees well with the estimated probable extreme sea state for this period.

### Conclusions

Results of statistical analysis of long-term significant wave height data obtained at various geographical locations and at various water depths show a consistent trend. That is, at least 90 to 95 percent of the cumulative distribution of each set of data is well represented by the log-normal probability distribution; however, the data diverge from the log-normal distribution for large significant wave heights. The divergence is consistent in such a way that the cumulative distribution of the data converges to unity faster than that of the log-normal distribution.

From comparisons of many probability distributions in standardized form, it is found that the generalized gamma distribution satisfies the condition that its cumulative distribution is by and large close to that of the log-normal distribution but it converges to unity much faster than the log-normal distribution at higher cumulative distribution values, say over 0.95. Comparisons of cumulative distribution functions of data and the generalized gamma distribution show satisfactory agreement. Methods for estimating the probable extreme sea state expected in a specified time as well as the extreme sea state for design consideration of marine systems are presented.

## CHAPTER 39

### Modeling the Transformation of Nonlinear Waves Passing over a Submerged Dike

Takumi Ohyama <sup>1</sup> and Kazuo Nadaoka <sup>2</sup>

#### Abstract

The decomposition phenomenon of a nonlinear wave train passing over a submerged dike has been investigated by a previously developed numerical model. The model, based on the time-dependent boundary element method, employs an effective nonreflective open boundary treatment and can be applied to arbitrary nonlinear wave processes. The results for regular wave incidence indicate that the higher harmonics generated during passage over the dike are transformed into prominent free waves in the trailing side of the dike, revealing the essential mechanism of the observed decomposition phenomenon. The computed wave profiles at various locations agree favorably with experimental observations. The transformation of multicomponent random waves has also been investigated. The results show that a substantial amount of wave energy is transferred into higher frequency components. The power spectrum of the transmitted wave is found to be significantly influenced by the phase differences among the incident components as well as by the incident wave spectrum itself.

#### 1. Introduction

The decomposition phenomenon of waves passing over a submerged dike is directly related to the variation of wave spectrum and therefore of great importance for predictions of coastal wave fields and beach profile formation (Hulsbergen, 1974). This phenomenon is believed to be governed by both the nonlinearity and the dispersivity of wave fields.

The methods of numerical approaches to this phenomenon may be classified into the following groups. The first approach is based on shallow-water wave

---

<sup>1</sup>Institute of Technology, Shimizu Corporation, Etchujima 3-4-17, Koto-ku, Tokyo 135, JAPAN

<sup>2</sup>Department of Civil Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152, JAPAN

theories, such as Boussinesq's theory. However, because this approach relies on assumptions of both weak nonlinearity and weak dispersivity of wave fields it may not be valid especially for prediction in the trailing side of the dike, where higher harmonics may arise as deep-water waves. In fact, its applications have been restricted to the case of solitary wave evolution (Seabra-Santos et al., 1987). The incidence of periodic wave trains is taken into account in the second approach, which is based on the second-order Stokes' wave theory (Massel, 1984). However, because of the limitation of this wave theory, its application is restricted to the case of a deeply submerged dike in a weakly nonlinear wave field. Thus, the applications of these two approaches have been limited with respect to incident wave conditions and the submergence of the dike. In addition, these approaches cannot directly treat the evolution of random waves composed of multiple-frequency components.

By contrast, the time-dependent boundary element method may apply to a wave field of more general conditions, including an arbitrary nonlinear wave field, since the free-surface boundary condition can be fully incorporated without approximations. The lack of efficient open boundary treatments, however, has made it impossible to deal with the incidence of continuous wave trains and, therefore, in many cases solitary waves have been imposed instead (Cooker et al., 1990). Recently, the authors (Ohyama and Nadaoka, 1991) have successfully developed an idealized "numerical wave tank" model based on the boundary element method. This numerical model employs an effective nonreflective open boundary treatment so that it can be applied to arbitrary wave fields including nonlinear random waves. The present study investigates the decomposition of periodic and random wave trains passing over a rectangular submerged dike by using the previously developed numerical model.

## 2. Numerical Wave Tank Model

Numerical analyses have been performed by using a two-dimensional numerical wave tank model previously developed by the authors (Ohyama and Nadaoka, 1991). At both ends of the computational domain, numerical wave-absorption filters are installed as shown in Fig. 1. The filter is composed of a sponge layer to absorb the incoming shorter waves energy by frictional damping and a Sommerfeld-type radiation boundary at the lee side of the layer to transmit the outgoing longer waves. This numerical wave tank model additionally incorporates a nonreflective wave generator which combines a vertically distributed wave-making source ( $S_S$ ), introduced by Brorsen and Larsen (1987).

A decay term proportional to the velocity magnitude is added to the equation of motion in the sponge layers. Based on the potential theory, the dynamic

Figure 1. Numerical wave tank model used for the analyses.

condition on the free surface is consequently derived as

$$\frac{\partial \phi}{\partial t} + \frac{1}{2}(\nabla \phi)^2 + g\eta + \mu\phi - \int_{x_1}^x \frac{\partial \mu}{\partial x} \phi \Big|_{on S_F} dx = 0 \quad (on S_F), \quad (1)$$

in which  $\phi(x, z, t)$  is the velocity potential,  $\eta$  is the surface elevation from the mean water level, and  $\mu$  is the damping factor. The factor,  $\mu$ , is distributed linearly in the layers as shown in Fig. 1 in order to relieve the wave reflection at the leading side of the layers. Based on the results of the earlier study (Ohyama and Nadaoka, 1991), the maximum value of the damping factor in the sponge layers,  $\mu_{max}$ , is given as  $\mu_{max} \sqrt{h_D/g} = 0.25$  in the subsequent computations.

Since the governing equation for the velocity potential in the fluid domain  $\Omega$  is expressed by a Poisson equation, an integral equation is introduced by applying the second form of Green's theorem. All the boundary conditions except the dynamic condition on  $S_F$ , Eq. (1), are substituted into the integral equation. Another integral equation is derived by applying the method of weighted residuals to Eq. (1). These equations, which involve  $\phi$  (on  $S_F$ ,  $S_V$ ,  $S_2$  and  $S_4$ ) and  $\partial \phi / \partial t$ ,  $\eta$  and  $\partial \eta / \partial t$  (on  $S_F$ ) as unknown variables, are discretized spatially and solved simultaneously for successive time steps.

The nodal points on the free surface,  $S_F$ , are considered to move in a vertical direction with the time step advance. The unknown variables,  $\phi$ ,  $\partial \phi / \partial t$ ,  $\eta$  and  $\partial \eta / \partial t$ , can be rewritten by using  $\Delta \phi$  and  $\Delta \eta$ , which are the increments of  $\phi$  and  $\eta$ , respectively, during the time increment  $\Delta t$ . In this time-stepping procedure, nonlinear terms, which correspond to the spatial displacement of the nodal point on  $S_F$ , are taken into account for better accuracy (Ohyama, 1990). The linear algebraic equations to be solved for  $\Delta \phi$  (on  $S_F$ ,  $S_V$ ,  $S_2$  and  $S_4$ ) and  $\Delta \eta$  (on  $S_F$ ) are consequently obtained. The earlier paper (Ohyama and Nadaoka, 1991) provides a detailed description of the numerical procedure.

In the subsequent computations, the time increment,  $\Delta t$ , and the horizontal projection of distance between the surface nodes,  $\Delta x$ , are given to be 1/32 of

(a) Wave profile both in time and space.

(b) Wave height distribution.

Figure 2. Evolution of periodic wave for  $D/h_D = 5.25$ ,  $h_S/h_D = 0.4$ ,  $\sigma^2 h_D/g = 0.8$ ,  $H_0/h_D = 0.1$ .

incident wave period (or of significant wave period for the case of random waves) and 1/40 to 1/20 of incident wave length (or of significant wave length for the case of random waves), respectively. The initial condition for each case is the still-water condition, i.e.,  $\phi = \eta = 0$ , and numerical results 10 periods after the “cold” start are used for discussion.

### 3. Decomposition Phenomenon of Periodic Waves

Figure 2(a) shows a numerical example of the wave profile around the dike both in time and space, in which  $\sigma$  and  $H_0$  represent the angular frequency and the height of the incident waves. The conspicuous decomposition into the shorter waves occurs immediately after passage over the submerged dike, and the transmitted waves propagate as nonconservative waves composed of multiple-frequency components. The corresponding wave height distribution is indicated in Fig. 2(b), together with the linear solution for transmitted wave height (Ijima and Sasaki, 1971). Preliminary studies found that the linear theory accurately

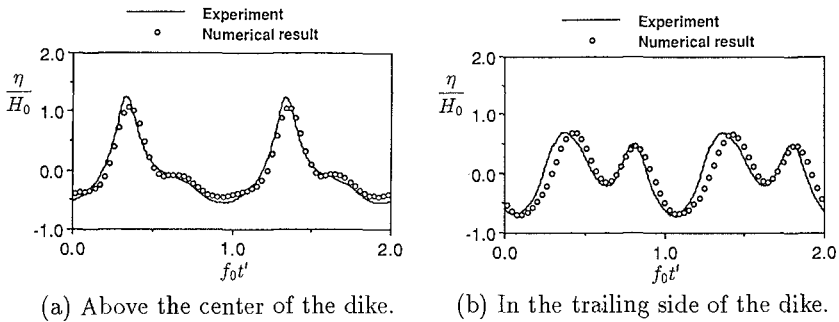

Figure 3. Comparison of computed wave profiles with experimental observations for  $\sigma^2 h_D/g = 0.97$ ,  $h_S/h_D = 0.3$ ,  $H_0/h_D = 0.1$ ,  $D/h_D = 4.0$ .

predicted reflected and transmitted wave energies, even when a conspicuous decomposition of wave trains occurs. As shown in Fig. 2(b), however, the predicted wave height in the trailing side of the dike is markedly greater than the corresponding linear solution, and varies in space since the transmitted waves propagate as nonconservative waves.

The wave evolution during passage through the dike, therefore, produces significant phenomena such as the transfer of a large amount of energy to higher frequency components along with the augmentation of wave height.

#### 4. Experimental Verification

Physical model experiments have been conducted to verify the present numerical method. The experimental wave tank is 17m long and 0.4m wide; the water depth,  $h_D$ , and the incident wave height,  $H_0$ , were set at 25cm and 2.5cm, respectively ( $H_0/h_D = 0.1$ ). The model of the submerged rectangular dike has a width of 100cm ( $D/h_D = 4.0$ ) and a height of 17.5cm ( $h_S/h_D = 0.3$ ). The wave profiles were measured at three locations: one over the center of the dike, and the others 125cm apart from the center of the dike on both sides.

Comparisons of wave profiles at a point over the center of the dike and at a point in the trailing side are given in Figs. 3(a) and 3(b), respectively, in which  $f_0$  represents the incident wave frequency ( $= \sigma/2\pi$ ). The computed wave profiles are found to agree favorably with the corresponding experimental observations, indicating the reliability of the present numerical model.

Figure 4. Wave profile both in time and space around stepped bottom for  $h_S/h_D = 0.4$ ,  $\sigma^2 h_D/g = 0.8$ ,  $H_0/h_D = 0.1$ .

### 5. Mechanism of the Decomposition Phenomenon

Figure 4 shows the computed wave profile for the case of a stepped bottom with  $h_S/h_D = 0.4$ . The incident wave conditions are identical to those of the previous case of the submerged dike (Fig. 2[a]). Figure 4 illustrates that a secondary wave appears at the trailing side of the primary wave as the wave crest propagates onto the step. It then gradually parts from the main crest and is overtaken by the following wave. These basic features of the wave deformation are similar to those of solitary wave disintegration over a stepped bottom (Madsen and Mei, 1969). As indicated in Fig. 2(a), by contrast, wave decomposition during passage over the dike occurs drastically, suggesting that its mechanism is quite different from that of the solitary-wave disintegration over the stepped bottom. Therefore, the wave field in the trailing side of the dike is compared with that over the stepped bottom in order to investigate the mechanism of wave decomposition.

The spatial evolutions of the lowest three harmonic amplitudes,  $|\eta_n|$  ( $n = 1, 2, 3$ ), are indicated in Figs. 5(a) and 5(b), in which  $|(\eta_0)_1|$  is the first harmonic amplitude of the incident wave. As shown in these figures, the second harmonic amplitude,  $|\eta_2|$ , is spatially modulated over the step, but is preserved in the trailing side of the dike. This modulation phenomenon over the step is explained by *nonlinear resonant interaction* based on the phase mismatch between the free and bound waves in the second harmonic (Mei and Ünlüata, 1972; Bryant, 1973).

Furthermore, in order to investigate the characteristics of the wave number (or celerity), spectral analyses in the wave number/frequency space have been performed for both the wave field over the stepped bottom ( $6.0 \leq x/h_D \leq 25.0$ ) and that in the trailing side of the dike ( $12.5 \leq x/h_D \leq 25.0$ ). The results are

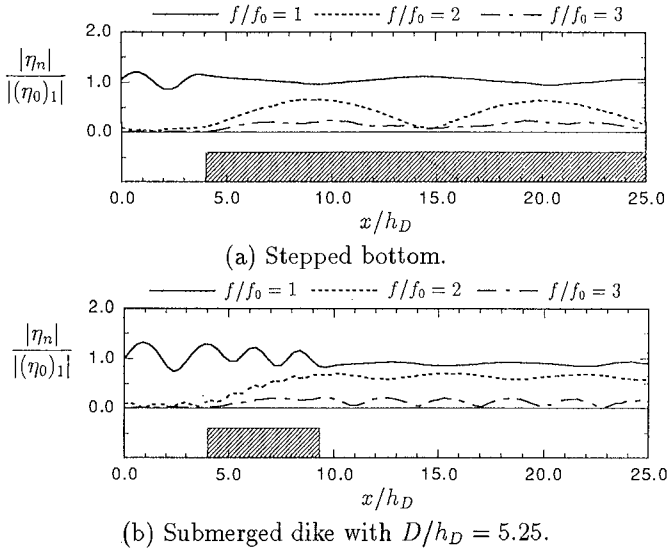

Figure 5. Distribution of each harmonic amplitude for  $h_S/h_D = 0.4$ ,  $\sigma^2 h_D/g = 0.8$ ,  $H_0/h_D = 0.1$ .

indicated in Figs. 6(a) and 6(b), respectively, in which  $k$  is the wave number and  $h$  is the water depth ( $h = h_S$  for the stepped bottom and  $h = h_D$  for the submerged dike). In the ordinates, the power spectrum for each component,  $p'_n$ , is divided by the maximum value of the spectrum in the first harmonic ( $p'_1$ )<sub>max</sub>. In each  $f/f_0 - kh$  plain, a curved line (**F**) represents the linear dispersion relation ( $k \tanh kh = 4\pi^2 f^2/g$ ), and a straight line (**B**) is drawn from the origin of direction to a point at which the spectrum for the first harmonic ( $f/f_0 = 1$ ) is at a maximum. The wave components on line (**F**) and those on line (**B**) correspond to the free waves and the bound waves, respectively. A larger difference in the celerity between the free and bound waves is found in the trailing side of the dike compared to the case of the stepped bottom. A comparison of the wave number spectra in the second harmonic is indicated in Fig. 7. In the shallow-water region over the stepped bottom, the amount of energy in the bound wave component is larger than that in the free wave component; whereas in the case of the submerged dike almost all the energy of the second harmonic exists as the free wave component.

The results of the spectral analyses yield the following description on the decomposition phenomenon: In the shallow-water region, both the free and bound waves in the higher harmonics result from wave nonlinearity. However, wave

(a) Shallow-water region over the stepped bottom.

(b) Deep-water region in the trailing side of the dike with  $D/h_D = 5.25$ .

Figure 6. Comparison of wave number-frequency spectrum for  $h_S/h_D = 0.4$ ,  $H_0/h_D = 0.1$ ,  $\sigma^2 h_D/g = 0.8$ .

Figure 7. Comparison of wave number spectrum in second harmonic for  $h_S/h_D = 0.4$ ,  $H_0/h_D = 0.1$ ,  $\sigma^2 h_D/g = 0.8$ .

disintegration in this region emerges rather gradually because of the small difference between the celerities of the free and bound waves. When these waves propagate into the deep-water region where wave nonlinearity is so weak that the bound waves can no longer exist, a large amount of energy is transferred abruptly to the free waves in the higher harmonics. Since the celerities are significantly different among the primary wave and these free waves in the deep-water region, the wave disintegration phenomenon is conspicuous compared to the case of the stepped bottom.

## 6. Variation in Decomposition Phenomenon According to Dike Width

As shown in Fig. 5(a), the second harmonic amplitude fluctuates spatially over the shallow-water region. Assuming the weak nonlinearity of a wave field, the beat length of  $|\eta_2|$ ,  $\lambda_2$ , can be expressed in the following form (Massel, 1983):

$$\lambda_2 = 2\pi/(k_2 - 2k_1), \quad (2)$$

where  $k_1$  and  $k_2$  represent the wave numbers of the free waves in the first and second harmonics, respectively. The beat length of  $|\eta_2|$  in Fig. 5(a) agrees favorably with the value calculated from Eq. (2).

According to the aforementioned mechanism of wave decomposition, it is expected that the amount of energy transferred into the free wave components varies appreciably with the dike width, and that the dike width relative to the beat length of  $|\eta_n|$ ,  $D/\lambda_n$ , is a definitive parameter, as suggested by Mei and Ünlüata (1972). The first numerical example indicated in Figs. 2(a) and 2(b) corresponds to the case of  $D/\lambda_2 = 0.5$  ( $\lambda_2/h_D = 10.5$ ), while Figs. 8(a) and 8(b) show the numerical results for  $D/\lambda_2 = 1.0$ , in which the dike width is twice as

(a) Wave profile both in time and space.

(b) Distribution of each harmonic amplitude.

Figure 8. Wave deformation around submerged dike for  $D/h_D = 10.5$ ,  $h_S/h_D = 0.4$ ,  $\sigma^2 h_D/g = 0.8$ ,  $H_0/h_D = 0.1$ .

large as in the first example. In this case of  $D/\lambda_2 = 1.0$ , the transmitted wave profile is almost sinusoidal and a negligible amount of energy is transferred to the higher frequency components during passage over the dike, although nonlinear effects such as steepened wave crests can be seen over the dike. Comparison of Fig. 8(b) with Fig. 5(a) reveals that the distribution of  $|\eta_2|$  over the dike is similar to that over the corresponding stepped bottom.

The variations in  $|\eta_2|$  and  $|\eta_3|$  of the transmitted waves, with  $D/\lambda_2$ , are indicated in Figs. 9(a) and 9(b) for the cases of  $h_S/h_D = 0.4$  and  $0.3$ , respectively. In the ordinates, the higher harmonic amplitudes are normalized with the first harmonic amplitude. Since  $|\eta_2|$  and  $|\eta_3|$  are slightly modulated even in the trailing side of the dike, spatially averaged values over each beat length are plotted in these figures. The results for  $h_S/h_D = 0.4$  (Fig. 9[a]) show that the maximum value of  $|\eta_2|$  appears at  $D/\lambda_2 = 0.5$  and the minimum value at  $D/\lambda_2 = 1.0$ , substantiating that the modulation of  $|\eta_2|$  over the dike is similar to that over the stepped bottom and its value at the trailing edge is preserved in the transmitted wave. In the case of  $h_S/h_D = 0.3$  (Fig. 9[b]), on the other

(a)  $h_S/h_D = 0.4$ .(b)  $h_S/h_D = 0.3$ .

Figure 9. Variation in  $|\eta_n|$  of transmitted waves with  $D/\lambda_2$  for  $\sigma^2 h_D/g = 0.8$ ,  $H_0/h_D = 0.1$ .

hand, the value of  $D/\lambda_2$ , where  $|\eta_2|$  attains its maximum, is smaller than 0.5. This may be because the wave nonlinearity over the dike is so strong that the use of  $\lambda_2$  obtained from Eq. (2) is no longer adequate. Furthermore, in this condition, since the beat length of  $|\eta_3|$  over the step is nearly one-half of  $\lambda_2$ ,  $|\eta_3|$  becomes the minimum at the location where  $|\eta_2|$  is at the maximum, and the peaks of  $|\eta_3|$  appear on both sides.

These results lead to the following conclusions: As inferred by Mei and Ünlüata (1972), each harmonic amplitude in the transmitted waves becomes remarkably larger when  $D/\lambda_n$  is nearly 0.5. When the water depth over the dike is very shallow, however, the stronger nonlinearity yields a shorter beat length of  $|\eta_2|$  than predicted from the weakly nonlinear solution.

## 7. Spectral Transformation of Random Waves

Lastly, this study investigates spectral transformation of random wave trains. The nonlinearity of the incident random waves considered here is so weak that they are expressed as a sum of multiple-frequency components:

$$\eta_{in} = \sum_n a_n \sin(k_n x - 2\pi f_n t + \varepsilon_n), \quad (3)$$

in which  $\eta_{in}$  is the surface elevation of the incident wave train, and  $a_n$ ,  $k_n$ ,  $f_n$  and  $\varepsilon_n$  represent the amplitude, the wave number, the frequency and the phase lag of each component, respectively.

Figures 10(a) - 10(c) show the power spectrum of simulated random incident waves (10[a]), and their modifications through the transmission over a submerged dike with  $D/h_D = 4.0$  and  $h_S/h_D = 0.3$  (10[b] and 10[c]). The incident wave train considered here is composed of 96 wave components and the amplitudes of each component have been prescribed according to the spectrum of Bretschneider-Mitsuyasu (Mitsuyasu, 1970) with  $T_{1/3}\sqrt{g/h_D} = 8.0$ ,  $H_{1/3}/h_D = 0.07$ , in which  $T_{1/3}$  and  $H_{1/3}$  are the significant wave period and height, respectively. The power spectra of the water surface fluctuation were calculated from 4096 wave data at a point  $7h_D$  away from the center of the dike. The power spectrum of the incident waves was obtained from the computation for a flat-bed condition in which the dike does not exist.

In the transmitted wave spectra, several noticeable peaks arise in higher frequency components, indicating that a substantial amount of wave energy is transferred into the higher frequency components. This is of great importance because the augmentation of the wave energy for high frequency makes the significant wave period appreciably shorter. In addition, these spectral peaks are not located as the higher harmonics of the peak frequency of the incident wave spectrum.

Figures 10(b) and 10(c) show the transmitted wave spectra for the incident waves with the same power spectrum (Fig. 10[a]), but with a different series of pseudo-random numbers for the specification of the phase lags among the wave components. The significant difference in the peak frequencies of the wave spectrum between these two cases indicates the importance of the phase difference among the wave components for the transformation of the random wave train.

## 8. Conclusions

The previously developed numerical model has been applied to the analyses of wave decomposition during passage over a submerged dike. The computed wave profiles at various locations agree favorably with experimental observations.

(a) Incident wave composed of 96 components.

(b) Transmitted wave (CASE 1).

(c) Transmitted wave (CASE 2).

Figure 10. Power spectra of random waves for  $T_{1/3}\sqrt{g/h_D} = 8.0$ ,  
 $H_{1/3}/h_D = 0.07$ ,  $D/h_D = 4.0$ ,  $h_S/h_D = 0.3$ .

The higher harmonics generated over the dike are found to be transformed into prominent free waves in the trailing side of the dike, demonstrating the essential mechanism of the observed decomposition phenomenon. Further computations show that the occurrence of decomposition and its degree depend significantly on dike width. The results for random waves indicate that a substantial amount of wave energy is transferred into higher frequency components. Furthermore, the power spectrum of the transmitted wave is significantly influenced by the phase spectrum of the incident random waves.

## CHAPTER 40

### Probabilistic Calculation Model of Directional Random Waves

Wi-Gwang Pae<sup>1)</sup>, Hajime Mase<sup>2)</sup>, M. ASCE  
and Tetsuo Sakai<sup>3)</sup>, M. ASCE

**ABSTRACT:** A probabilistic calculation model is developed, for the simplicity of inclusion of wave breaking and energy dissipation, to predict the transformation of directionally-spreading random waves by using parabolic refraction-diffraction equations. The numerical predictions are compared with the experimental observations of random wave transformation over an elliptic shoal by Vincent and Briggs (1989); the predictions agree well with the observations under the non-breaking condition, however, the agreement is poor under the wave breaking condition.

#### INTRODUCTION

Estimation of refraction and diffraction, shoaling and wave breaking deformation over complicated bathymetry is an important problem in coastal engineering. Although random sea state is usually approximated by a monochromatic wave equivalent to the significant wave, there are some differences between the actual sea state and the results of monochromatic representation.

There are mainly two methods to deal with transformations of random waves: that is, spectral and individual wave analysis methods. Here we employ the individual wave analysis method for the simplicity of inclusion of wave breaking and energy dissipation. Incident wave heights and incident angles of individual waves are given from probabilistic density functions of wave heights and angles, and periods are given depending on their wave heights. Model wave equations used here are two different parabolic refraction-diffraction equations depending on incident angles. The numerical predictions are compared with the experimental observations of wave transformations of directionally-spreading random waves over an elliptic shoal carried out by Vincent and Briggs (1989).

**NUMERICAL MODEL FOR DIRECTIONAL RANDOM WAVES**

**Input Wave Heights**

One-parameter Weibull distribution was adopted as an input wave height distribution (Mase and Kobayashi, 1991).

$$p(x) = \frac{m}{2\phi} h_{1/3}^m x^{m-1} \exp \left\{ -\frac{1}{2\phi} (h_{1/3} x)^m \right\}, \tag{1}$$

$$h_{1/3} = \frac{3m}{2\phi} \int_{(2\phi \ln 3)^{1/m}}^{\infty} h^m \exp \left( -\frac{h^m}{2\phi} \right) dh, \tag{2}$$

$$\phi = \frac{1}{2} \left[ \Gamma \left( \frac{m+1}{m} \right) \right]^{-m}, \tag{3}$$

where  $x$  is the wave height normalized by the significant wave height,  $H_0$ ,  $\Gamma$  is the Gamma function, and  $m$  is the shape factor related to the wave groupiness factor,  $GF$ , as described by

$$m = 3.44 - 1.99 GF, \tag{4}$$

according to Mase (1989) and Mase et al. (1990). Therefore, the effect of wave grouping is indirectly taken into account in the wave transformation model through Eq.(4).

From the Weibull distribution, representative individual wave heights were defined by dividing  $x$ , ranging from 0 to 2, into  $N$  ( $=20$ ) segments,  $x_i$  ( $i = 1, \dots, N$ ), and the corresponding occurrence probabilities,  $p_i$  ( $i = 1, \dots, N$ ) were calculated. A dimensional wave height is given by  $x_i * H_0$ .

**Input Wave Periods**

Considering that higher waves have longer periods and referring observed joint distributions of wave heights and periods (Goda, 1978), we set wave periods as

$$\left. \begin{aligned} T_i &= 0.6 T_0; & 0 < H_i \leq 0.5H_0, \\ T_i &= T_0; & 0.5H_0 < H_i \leq 1.5H_0, \\ T_i &= 1.2 T_0; & 1.5H_0 < H_i, \end{aligned} \right\} \tag{5}$$

in a simple manner, where  $T_0$  is the significant wave period.

An alternative way to give input wave heights and periods is to use a joint probability density function of wave heights and periods; however, this method results in more number of waves in the calculation of wave transformation than the present method, since several wave periods are defined for a given wave height.

### Input Incident Wave Angles

Here directional spreading of individual waves was considered as in the case of spectral method (Panchang et al., 1990). Directional distributions of individual waves were assumed to be described by the following function:

$$G(\theta) = G_0 \cos^{2S} \left\{ (\theta - \theta_0) / 2 \right\}, \quad (6)$$

where  $\theta_0$  is the principal (mean) direction against the  $x$  axis,  $S$  is the parameter representing the degree of directional concentration,  $G_0$  is the constant to make the integration of Eq.(6) unity. Eq.(6) was originally proposed for spectral components (Mitsuyasu et al., 1975); which was treated as a probability density function of incident angles here.

Assuming that the directional distribution of individual waves is narrow compared to that of spectral components, and since parabolic refraction-diffraction equations are employed as model wave equations, we limit the maximum absolute value of  $\theta$  to  $60^\circ$ . The representative incident wave angles,  $\theta_j$  ( $j=1, \dots, M$ ), were given by every  $10^\circ$  in the range between  $-60^\circ$  and  $60^\circ$ , and the corresponding occurrence probabilities,  $q_j$  ( $j=1, \dots, M$ ), were determined from Eq.(6).

The directional spreading function used by Vincent and Briggs (1989) was

$$G(\theta) = \frac{1}{2\pi} + \frac{1}{\pi} \sum_{j=1}^J \exp \left\{ -\frac{(j\sigma)^2}{2} \right\} \cos j(\theta - \theta_0). \quad (7)$$

Fig. 1 Comparison of directional spreading functions.

If  $S$  in Eq.(6) is assigned to 400, 65, or 10, the directional distribution by Eq.(6) corresponds to that by Eq.(7) with  $\sigma = 0^\circ, 10^\circ$  or  $30^\circ$ , used as the experimental conditions of uni-directional, narrow-, or broad-banded directional spreading by Vincent and Briggs (1989). Figure 1 shows the comparison of the two directional distributions by Eqs.(6) and (7). It is seen from the figure that both almost agree.

**Model Wave Equation**

Transformations of all  $N^*M$  individual waves of wave heights  $H_i$ , wave periods  $T_i$ , and incident angles  $\theta_j$ , with the occurrence probabilities  $p_i^*q_j$ , were calculated by parabolic refraction-diffraction equations. The calculated results were superposed according to their occurrence probabilities. For waves with large incident angle  $|\theta_j| \geq 5^\circ$ , the minimax approximation model of Kirby (1986) was used:

$$\begin{aligned}
 A_x + i(\bar{k}-a_0k)A + \frac{C_{gx}}{2C_g}A + \frac{i}{\omega C_g} \left( a_1 - b_1 \frac{\bar{k}}{k} \right) (CC_g A_y)_y - \frac{b_1}{\omega k C_g} (CC_g A_y)_{yx} \\
 + \frac{b_1}{\omega} \left( \frac{k_x}{k^2 C_g} + \frac{C_{gx}}{2k C_g^2} \right) (CC_g A_y)_y - \left( a_1 - b_1 \frac{\bar{k}}{k} \right) \frac{W}{C_g} A \\
 + i b_1 \left( \frac{k_x}{k C} + \frac{C_{gx}}{2k C_g^2} \right) WA - \frac{i b_1}{k C_g^2} W_x A - \frac{i b_1}{k C_g^2} W A_x = 0 \quad , \quad (8)
 \end{aligned}$$

where  $A$  is the complex amplitude,  $\bar{k}$  is the wave number averaged over the  $y$  direction,  $k$  is the local wave number,  $C_g$  is the group velocity,  $\omega$  is the angular frequency,  $W$  is the damping coefficient described later, and  $a_0, a_1, b_1$  are the coefficients taken to be 0.9947, -0.8900, -0.4516. It is noted that the derivative of  $W$  was included in Eq.(8) compared to the original minimax model of Kirby (1986).

For waves with small incident angle  $|\theta_j| < 5^\circ$ , the following parabolic equation with an energy dissipation term was used:

$$A_x - i(K - \bar{k}_0)A + \frac{(K C C_g)_x}{2K C C_g} A - \frac{i}{2K C C_g} (C C_g A_y)_y = 0 \quad , \quad (9)$$

$$K^2 = k^2 + i \frac{kW}{C_g} \quad , \quad (10)$$

where  $\bar{k}_0$  is the wave number at the incident boundary averaged over the  $y$  direction. Eq.(9) is obtained from the mild slope equation with a damping term (Booij, 1981) by using the splitting matrix method (Radder, 1979; Dalrymple et al., 1984).

Incipient of wave breaking was estimated by a simple equation,

$$H_b/h_b = 0.85 (0.7 + 5 \tan \beta) \quad , \quad (11)$$

where  $H_b$  and  $h_b$  are the wave height and depth at the breaking point,  $\tan\beta$  is the bottom slope.

The damping coefficient in Eqs.(8) and (10) was formulated by a bore model (Battjes, 1986) as follows:

$$W = \frac{2B}{\gamma^3} \frac{1}{T} \left(\frac{H}{h}\right)^4, \tag{12}$$

$$\gamma = 0.7 + 5 \tan\beta, \tag{13}$$

$$B = \begin{cases} 11-10 h/h_b, & 0.6 \leq h/h_b \leq 1.0 \\ 5, & h/h_b \leq 0.6 \end{cases} \tag{14}$$

Eq.(14) was used to represent the measured wave height change of monochromatic waves more accurate (Mase and Iwagaki, 1982). In the calculation, a treatment of the lateral boundary condition followed Yamamoto (1987).

**COMPARISON BETWEEN NUMERICAL PREDICTIONS AND EXPERIMENTAL OBSERVATIONS**

Experiments of random wave transformations over a shoal were carried out by Vincent and Briggs (1989). Figure 2 illustrates the experimental layout of an elliptical shoal and measurement locations, but

**Fig. 2 Experimental layout.**

the coordinates are rewritten so that the center of the shoal is located at  $(x, y) = (6\text{m}, 9\text{m})$ , for the convenience in the numerical calculations. The TMA spectrum was used as a target spectrum. Spectral peakedness was changed by two; that is, broad-banded and narrow-banded frequency spectra. In the present model, an energy spectrum was not given as input data, but given by a wave height distribution. As general, a narrow-banded spectral wave trains lead to the Rayleigh distribution of wave heights.

(a)

(b)

**Fig. 3 Spatial wave height distribution for narrow-banded directional spreading waves of Case N1 and N2.**

Figure 3 shows the comparison of measured and calculated wave heights along the measuring line #4 (figure (a)), and in a horizontal region (figure (b)), for the case of narrow-banded directional spreading waves with two different spectral peakedness of Case N1 and Case N2 in the paper of Vincent and Briggs (1989). Since the experimental results of N1 and N2 were almost the same, the experimental results were averaged and shown in Fig.3. In the calculation, the Rayleigh distribution ( $m = 2$  in Eq.(1)) was given as the input wave height distribution. Comparing wave heights along the measuring line #4, we see a fairly good agreement between both results, but the calculated wave heights around  $y = 9\text{m}$  are a little larger than the measured ones. One of the reasons of the discrepancy may be attributed to unsatisfactory smoothing due to inadequate number of division in both wave periods and incident angles in the calculation.

Figure 4 shows the comparison of wave heights along the measuring line #4 for the case of uni-directional random waves under the condition of non-breaking. In this figure, not only the significant wave height but also the one-hundredth maximum, the one-tenth maximum and the mean wave heights are plotted. Easiness to calculate such wave heights is one of the advantages of the present calculation method compared to spectral calculation methods. Experimental results of U3 and U4 were averaged in the figure. We can see a good agreement in this condition.

Fig. 4 Comparison of measured and calculated wave heights along the measuring line #4 for uni-directional random waves.

Figure 5 is the result of narrow-banded directional spreading waves of Case N3 and Case N4. Numerical predictions agree well with the observations.

Figure 6 shows the comparison for the case of broad-banded directional spreading random waves. The spatial wave height distribution along the measuring line #4 is very flat due to wide directional spreading. Averaged measured wave heights and calculated ones agree well. The

**Fig. 5 Comparison of measured and calculated wave heights along the measuring line #4 for narrow-banded directional spreading random waves.**

**Fig. 6 Comparison of measured and calculated wave heights along the measuring line #4 for broad-banded directional spreading random waves.**

difference between the calculated one-hundredth and the mean wave heights around  $y = 9$  m is larger than that in both sides; that is, the wave height distribution around  $y = 9$  m becomes wider than that in both sides.

Figure 7 shows the effect of the shape factor of the Weibull distribution on the calculated wave heights along the measuring line #4. There is little difference in the significant wave heights, but we can see the difference for higher waves such as the one-hundredth maximum wave height. As the shape factor  $m$  becomes small, that is, the incident wave height distribution becomes wider, the one-hundredth maximum wave height becomes large especially around  $y = 9$  m.

**Fig. 7 Effect of incident wave height distribution on calculated wave heights along measuring line #4.**

**Fig. 8 Comparison of measured and calculated wave heights under the wave breaking condition.**

Figure 8 shows a result of the cases that wave breaking occurred over the shoal. The measured spatial wave height distributions along the measuring line #4 are different from the calculated ones. The observations become minimum around  $y = 9$  m, but the predictions are maximum. Even if the incipient condition of wave breaking was modified to make waves break at deeper water, by multiplying 0.5 to the original incipient condition, the shape of calculated spatial wave height distribution is unchanged, only resulting in smaller values (shown by broken line).

The following point should be noted. Experiments of uni-directional random wave transformations over a shoal were carried out by Lie and Tørum (1991). Even in the case that severe wave breaking occurred on the shoal, a concave wave height distribution along a transverse section, that is, being minimum of wave heights at the center of a transverse section cannot be seen, judging from contour maps of wave heights. The difference between the measured and the calculated wave heights under the wave breaking condition, and the difference between the measured results by different researchers may be attributed to the complexity of the breaking point and energy dissipation process over an arbitrary varying bathymetry.

## CONCLUSIONS

This study developed a probabilistic model to calculate transformations of directionally-spreading random waves, by using an incident wave height distribution, an incident angle distribution, and parabolic refraction-diffraction equations, for the simplicity of inclusion of wave breaking and energy dissipation. Other advantages of the present model were as follows: 1) the present model could estimate any representative wave heights including the significant wave height; and 2) could evaluate the effect of wave grouping through the relationship between the incident wave height distribution and groupiness factor. The experimental results of random wave transformations over an elliptic shoal by Vincent and Briggs (1989) agreed well with the predictions by the present numerical model in the case of non-breaking condition. In the case that wave breaking occurred on a shoal, the predictions were not in agreement with the observations. The shape of measured wave height distribution in a transverse section was concave, however, the calculated wave height distribution was convex. Therefore, one of the advantages of the present model, that is, the simplicity of inclusion of wave breaking process was not examined yet. The present model should be checked for other experimental observations over a shoal, since some of the observations showed a different pattern of wave height distribution.

## CHAPTER 41

### DIRECTIONAL WAVE MEASUREMENTS IN RIO DE JANEIRO COAST

C.E.Parente<sup>1</sup>, C.P Hansen<sup>2</sup>, R.M. Sampaio<sup>3</sup>,  
J.M. Lima<sup>4</sup>, J.L.B. Carvalho<sup>1</sup>

#### ABSTRACT

This paper presents the experience and results with a slope array of wavestaffs specially designed and built for directional wave measurements from an offshore platform off the Rio de Janeiro coast. We discuss the main features of the system, limitations and noise sources. A promising adaptive technique is introduced.

#### 1. INTRODUCTION

Having one of the biggest coastlines of the world, Brazil still lacks long term wave data, either in offshore areas or in the coast. In the last decade most of the oil production in the country is coming from offshore, and fields as deep as 1500 meters will be exploited in the incoming years. In this way, information on directional wave, wind and current, for the design of new huge structures to face such challenge, is mandatory. Besides that, an emerging consciousness in relation to the occupation, protection and management of coastal areas is also putting a big demand in environmental data.

Three directional wave measurement projects are going on in the Rio de Janeiro State coast (positions are shown in fig.1).

- A) A Directional Waverider buoy in front of Guanabara Bay (Rio de Janeiro city);

This instrument is being used in a joint project conducted by the Federal University of Rio de Janeiro and the Brazilian Navy Hydrographic Office (DHN), owner of the equipment (Melo et al, 1991). The main purpose is to characterise the wave climate along the famous Ipanema-Leblon beach that have been under severe erosion in the last years.

- B) A directional buoy built by CONSUB, a Brazilian company, for PETROBRAS, moored in 1500 meters of water.

This buoy sends via Imarsat satellite, meteorological and oceanographic data including directional wave data.

- C) An array of resistive wavestaffs mounted as a slope array in an offshore platform in waters 100 meters deep;

This paper describes the experience and results with this slope array.

Fig.1 Rio de Janeiro coast with the locations of the directional measurements.

## 2. DIRECTIONAL MEASUREMENTS FROM AN OFFSHORE PLATFORM WITH A SLOPE ARRAY

The objective of this project is to simultaneously measure wave, current and wind in order to determine long term resultant forces in an offshore platform.

Directional wave measurements are made with arrays of resistive wavestaffs suspended from the platform.

Following the idea of Ford et al (1968), we built a slope array of resistive wavestaffs to be suspended from an offshore platform in the Campos basin. One array consists of four wavestaffs made with 0.25 mm stainless steel wire spirally wound around a 1.25 mm synthetic cable. The staffs are suspended from the platform, fixed in a light frame forming a square of 1.12 m each side. This configuration has shown several advantages in terms of handling, maintenance of vertical position and relative horizontal position among the staffs.

Due to safety reasons (protection against fishing boats) the array is mounted inside the platform; as we discuss later, this can be a source of noise.

The staffs are excited with CW signals in order to extend the life of the wires. All the signals are conditioned and processed in a central station producing surface elevation and two orthogonal surface slopes. We followed the processing techniques of Borgman (1982) and Kuik et al (1987) to get the one point spectrum, main direction and spread about the main direction. We can also calculate the wave number and compare with the value given by the linear theory.

Preliminary results have shown good agreement with visual observation (sea and swell) and measured data (wind and current).

The main characteristics of the slope array are:

**Requirements:** low drag and small weight in order to be easily placed by hand in the support base and keep good vertical position. In the beginning we have tried just single wires (very low drag), but the sensitivity was not enough for lower frequencies.

**Number of staffs:** 4 - mounted in a square of 1.12 m side.

**Sensor spacing:** 1.12 m. The spacing is a compromise between adequate sensitivity for slope measurements and spatial aliasing in high frequencies.

**Staff:** resistive. A stainless steel wire .25 mm in diameter is spirally wound in a 1.25 mm polypropylene wire.

**Resistance:** 135 ohms/meter.

**Weight:** Each staff has a 5 kg weight.

**Linearity:** 1.7 per cent.

**Length:** 12 meters.

**Excitation:** pulsed CW.

**Detection:** synchronous (sample/hold).

**Signal conditioning:** all the conditioning circuits are analog, the A/D conversion being done in the computer.

### 3. DATA ANALYSIS IN SITU

All the data (wave, current and wind) is transferred to a PC type computer and processed in real time; it is also send to Rio via satellite.

The software perform the following operations:

- data acquisition;
- data quality tests;
- time domain analysis;
- frequency domain analysis;
- directional wave analysis.

Raw data and calculated parameters are also send to shore via satellite.

We use the classical Fourier and the Borgman and Kuik techniques mentioned above to calculate the directional spectral parameters (main direction and spread); they are summarized below.

Elevation and slopes for a monochromatic wave ( $f, \theta$ ) are given by:

$$\eta = \alpha \cos(kx \cos \theta + ky \sin \theta - \omega t + \varepsilon) \quad (1)$$

$$\eta_x = -\alpha k \cos \theta \sin(kx \cos \theta + ky \sin \theta - \omega t + \varepsilon) \quad (2)$$

$$\eta_y = -\alpha k \sin \theta \sin(kx \cos \theta + ky \sin \theta - \omega t + \varepsilon) \quad (3)$$

Taking the origin at (0,0) and  $\epsilon=0$ ;

$$\eta = \alpha \cos \omega t \tag{4}$$

$$\eta_x = -\alpha k \cos \theta \sin \omega t$$

$$\eta_y = -\alpha k \sin \theta \sin \omega t \tag{6}$$

Now we Fourier transform and take cross spectra:

$$\eta \qquad \qquad \eta_x \qquad \qquad \eta_y \tag{7}$$

$$\alpha \cos \omega t \qquad -\alpha k \cos \theta \sin \omega t \qquad -\alpha k \sin \theta \sin \omega t \tag{8}$$

$$\begin{matrix} \downarrow & & \downarrow & & \downarrow \\ \cos \omega t & \sin \omega t & \cos \omega t & \sin \omega t & \cos \omega t & \sin \omega t \end{matrix} \tag{9}$$

$$\begin{matrix} \downarrow & & \downarrow & & \downarrow \\ \alpha & & -\alpha k \cos \theta & & -\alpha k \sin \theta \end{matrix} \tag{10}$$

$$\begin{matrix} \text{-----} & & \downarrow & & \downarrow & & \text{-----} \\ & & \alpha^2 k \cos \theta = a_1 & & \alpha^2 k \sin \theta = b_1 \end{matrix} \tag{11}$$

$$\text{main direction} \Rightarrow \theta = \text{atan}(b_1/a_1) \tag{12}$$

Kuik et al (1988) suggest that the energy distribution around the main direction,  $D(\theta)$ , can be associated to a probability distribution, the standard deviation representing the spread of energy.

$$\sigma = \sqrt{2(1 - m_1)} \ ; \ m_1 = \sqrt{a_1^2 + b_1^2} \tag{13}$$

Some data quality control are made comparing the measured wavenumber ( $k_m$ ) with the wavenumber given by linear theory ( $k_l$ ). For the same monochromatic case, taking the spectrum:

$$G_\eta = \alpha^2; G_{\eta_x} = \alpha^2 k^2 \cos^2 \theta; G_{\eta_y} = \alpha^2 k^2 \sin^2 \theta \quad (14)$$

and summing:

$$k_m = \sqrt{\frac{G_{\eta_x} + G_{\eta_y}}{G_\eta}} \quad (15)$$

We can see below an example from a fetch limited NE sea, typical of the Campos area. In fig. 2 the spectrum, in fig.3 main direction, in fig 4 spread and in fig. 5 comparison of wavenumbers.

Fig.2 Spectrum of a NE sea

Fig.3 Main direction

Fig.4 Spread

#### 4. DATA ANALYSIS ASHORE

Fig.6 shows the evolution of the spectrum for the peak frequency along the record, advancing one value of the series each time. We can notice regions of high and low values suggesting that possibly at a given moment the energy in the main direction is low but could be measurable at other directions.

Fig.6 Spectrum (peak frequency) changing with time

We may consider that these ups and downs along the record are due not only to the fact that different frequencies, close together, combine in a constructive or destructive way but also to other factors, identified as noise, non-linearities, non-stationarity, inaccuracies, etc...

- limited number of sensors;
- non-linearities of staffs and circuitry;
- non verticality of staffs;
- influence of platform structure;
- non-stationarity of the wave field;
- finite sensor spacing and aliasing;

All this factors tend to contribute to the non-stationarity of the process along the recording time.

We can recall some basic principles of spectral analysis, quoting Gardner (1988):

The fundamental reason for interest in a statistical (e.g. time averaged) spectrum of some given data is a belief that interesting aspects of the phenomenon being investigated have spectral influences on the data that are masked by uninteresting (for the (purpose at hand) random effects and an additional belief (or, at least, hope) that these spectral influences can be revealed by averaging out the random effects. This second belief (or hope) should be based on the knowledge (or, at least, suspicion) that the spectral influences of the interesting aspects of the phenomenon are time-invariant, so that the corresponding invariant spectral features (such as peaks or valleys) will

**be revealed rather than destroyed by time averaging.**

The random combination or action of all the mentioned factors could destroy some features of the process rather than enhance if we average along the entire record, as mentioned by Gardner.

We could possibly select some recording periods where a given frequency band or directional sector is showing a better signal quality, wave grouping or other special feature. This is a kind of adaptive technique that we are trying now and we show here some results.

A possible criterium would consider how close are the wavenumber values (measured and from linear theory); another, perhaps, wave grouping. Using the first one, for each selected series (close values of  $k_l$  and  $k_m$ ) we collect spectrum and main direction. The result is a possible representation of the directional spectrum. If we sum, for each frequency, all the contributions in direction we approach the one point spectrum, whose area should agree with the mean square value of the process.

The technique could be resumed as follows:

1) For each sensor take series of  $m$  point at time, and calculate spectrum, main direction,  $k_m$  and spread. ( $m$  is typically 64, 128 or 256).

2) Take the average of all 4 sub-arrays (it is worth while to have some redundancy).

3) Select the series where  $ABS(k_m - k_l) < s \times k_l$ ;

$s$  between 0.05 and 0.2, for example.

4) Accumulate the spectrum value in the corresponding direction box.

We can see below some results. In Fig.7 we can see a 3D plot of the evolution of the spectrum value and main direction for the peak frequency along a given recording period. During this time we have enhancement of the spectrum value for different direction inside a given sector, changing in a well behaved way.

Fig. 7 Spectrum value and mean direction for the peak frequency changing along the time.

In fig. 8 a construction of  $D(\theta)$  for the peak frequency taking the contributions of all sub-arrays.

Fig.8  $D(\theta)$  for the peak frequency, using the contributions of all sub-arrays. Vertical axis is spectral density and horizontal axis is direction in degrees.

In fig. 9 we see a 3D plot of "directional spectrum" (frontal view). We have in the same graph two plots of the one-point spectrum. One is calculated using the entire record with 4 d.f. (dashed line); the other one is calculated summing the contributions of direction "boxes" for each frequency (continuous line).

Fig. 9 3D plot of directional spectrum (frontal view). Vertical axis is direction and horizontal axis is frequency (axis z is spectral density). In the same graph one point spectrum.

In fig. 10 a 3D plot of the same data (side view). Vertical axis is frequency and horizontal axis is direction; z axis is spectral density.

Fig. 10 3D plot of directional spectrum (side view). Horizontal axis is direction; vertical axis is frequency; z axis is spectral density.

## 5. CONCLUSIONS

The results are showing very good consistency compared with measured wind values and visual observations from the platform. As we would expect the resolution is relatively poor for low frequencies. We are about to use two arrays 30 m apart in an attempt to solve this problem.

The resistive wave staff have been used for many years and is a very cheap and reliable way to get wave data from an ocean fixed structure. Usually it is not very easy as one could expect to make oceanographic measurements from an offshore platform, mainly if it depends on divers, big cranks and special locations, just to mention a few problems. In this way, a small and light array suspended from the spider deck of a platform (the deck closest to the sea level) provided that the resolution is adequate for low frequencies, can be very useful not only as source of log term data but also for the day to day operation of the platform.

Work in progress is toward better resolution in low frequencies, simulations with artificial seas, combination of two or three arrays and the search for adaptive techniques.

## ACKNOWLEDGEMENTS

The slope array project is being supported by the Brazilian oil company, PETROBRAS.

## CHAPTER 42

# ON THE ATTENUATION OF WAVES PROPAGATING WITH A CURRENT

Michio Sato\*

### Abstract

In this paper, the mechanisms which dissipate the energy of waves propagating on a current are considered. It is shown that the surface slope of an actual uniform current plays an important part for the variation of wave height attenuation rates with the intensity of the current. The surface slope enhances the attenuation of waves propagating on an opposing current and weakens it for a following current. It is also shown that, as the wave attenuation rate increases in stronger opposing currents, it affects the change in height of waves on a gradually varying opposing current to such an extent that we can not ignore the effect.

## 1 INTRODUCTION

When waves propagate on an opposing uniform current, the rate of wave height attenuation increases with the current velocity. Iwasaki and Sato (1972; hereafter referred to as IS) attempted to explain the increase of the wave height attenuation through the dissipation of wave energy due to the work done by internal and boundary shear stresses.

On the other hand, it has been pointed out that, when waves propagate on a following current, the wave attenuation rate decreases as the strength of the superimposed following current increases. Kemp and Simons (1983) and Simons et al. (1988) provided experimental results which showed the reduction of wave height attenuation rates on following currents.

The objective of this paper is to provide a theoretical explanation for the reduction of the wave attenuation rates on following currents together with the increase of ones on opposing currents.

## 2 WAVE HEIGHT CHANGE ON A UNIFORM CURRENT

Problems on coexisting system of waves and currents have been treated frequently in an unrealistic situation of horizontal bed and uniform depth. However, when the bottom is horizontal, the depth of a flow changes in the flow direction and a uniform flow is not possible in real fluid.

Before going to the main subject, we consider the role of the mean surface slope in somewhat intuitive fashion through a thought experiment.

When waves propagate on still water of constant depth with a horizontal bottom, the wave energy fluxes and the wave heights at the sections I and II in figure 1(a) are equal unless the wave energy dissipates due to viscosity. Then, we consider the situation like (b) in figure 1 where waves go uphill assuming no wave energy dissipation due to viscosity. If waves propagate without change in height, there must be mass transports of the same intensity through the sections I and II. However, the potential energy of the mass transported through the section I is greater than the one transported through the section II by the quantity of the mass times the gravitational acceleration times the difference of mean surface elevations, and there are no energy sources which supply the potential energy other than wave energy. Therefore, the constant wave energy flux does not hold and wave height is expected to decrease as the waves propagate.

In the situation like (c) in figure 1, we can deduce that the wave height will increase as the waves propagate. This thought experiment suggests that the effect of surface slope be taken into consideration for the discussion of wave height change on a uniform current.

**WAVE ENERGY BALANCE** Now, we consider a two dimensional situation in which waves propagate on a current with uniform depth. The mean surface has the same inclination as the bottom slope. Choosing space coordinates  $x$  and  $y$  to be along and perpendicular to the mean water surface respectively (figure 2), equations of motion and continuity are

$$\frac{\partial u}{\partial t} + (U + u) \frac{\partial u}{\partial x} + v \frac{\partial (U + u)}{\partial y} = g \sin \theta - \frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{1}{\rho} \frac{\partial \tau}{\partial y} \quad (1)$$

$$\frac{\partial v}{\partial t} + (U + u) \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = -g \cos \theta - \frac{1}{\rho} \frac{\partial p}{\partial y} \quad (2)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (3)$$

In IS, the term  $g \sin \theta$  in equation (1) was omitted on the assumption that the gradient of  $\tau_c$ , which was a part of  $\tau$  due to pure current, in  $y$  direction was compensated with this term when flow was uniform without waves. However, the mean surface slope of wave-current co-existing system differs from the surface slope of

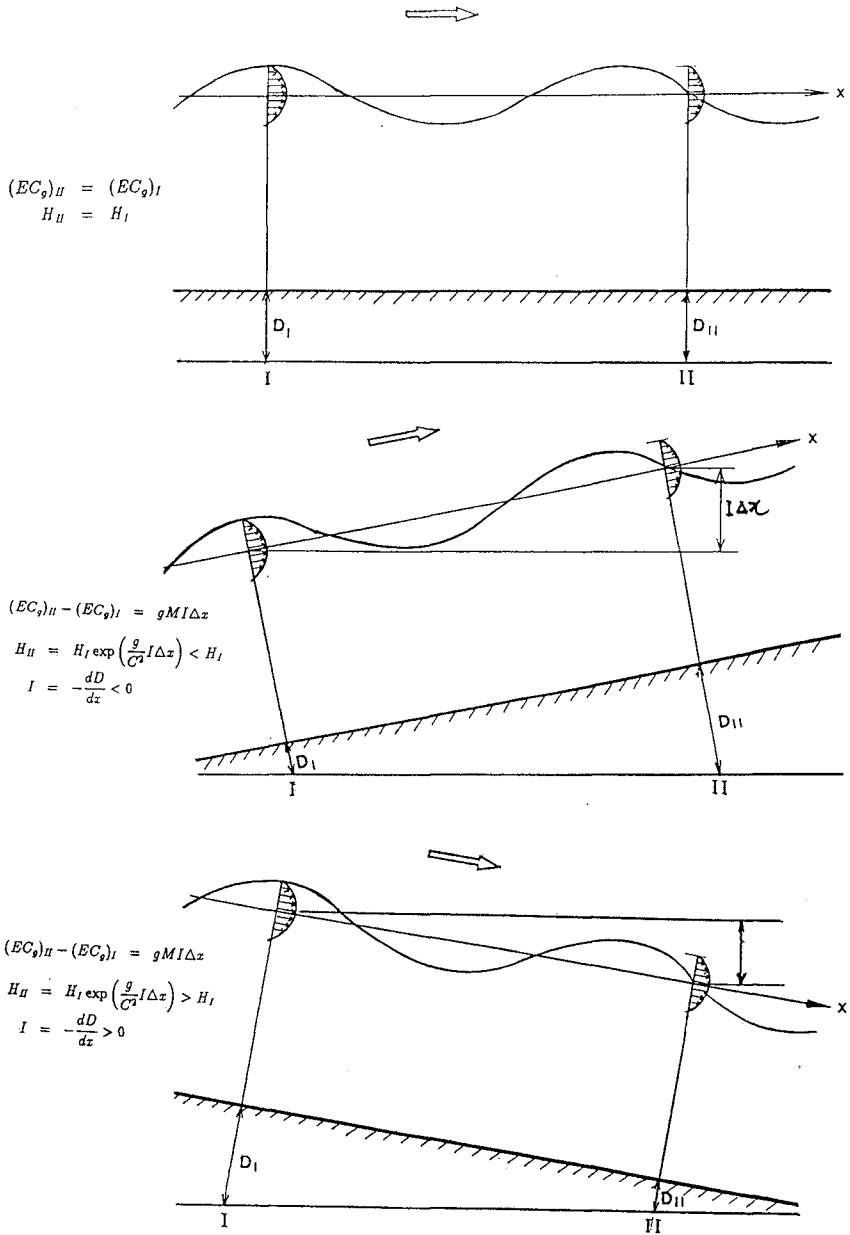

Figure 1: Energy balance of waves propagating over a still water with inclined surface

Figure 2: Definition sketch

pure current and this has been confirmed experimentally by Asano et al.(1986). The boundary conditions at the free surface  $y = h + \eta$  and at the bottom  $y = 0$  are

$$v = \frac{\partial \eta}{\partial x} + (U + u) \frac{\partial \eta}{\partial x} \quad \text{at } y = h + \eta \quad (4)$$

$$p = 0 \quad \text{at } y = h + \eta \quad (5)$$

$$v = 0 \quad \text{at } y = 0 \quad (6)$$

where  $u$  and  $v$  are the velocity components of wave motion in  $x$  and  $y$  direction,  $U$  is the current velocity and assumed to be a function of  $y$ ;  $\rho, p, g, \tau$  and  $\eta$  are density, pressure, gravitational acceleration, Reynolds stress and surface elevation.

Integrating the sum of equation (1) multiplied by  $\rho u$  and equation (2) multiplied by  $\rho v$  over the depth with respect to  $y$ , and making use of equations (3) to (6) together with the Leibnitz's rule, an equation for the balance of wave energy is obtained as follows after averaging over a wave period.

$$\begin{aligned} & \frac{\partial}{\partial t} \left[ \overline{\int_0^{h+\eta} \frac{\rho}{2} (u^2 + v^2) dy} + \frac{1}{2} \overline{\rho g \eta^2 \cos \theta} \right] \\ & + \frac{\partial}{\partial x} \left[ \overline{\int_0^{h+\eta} \left\{ \frac{\rho}{2} (u^2 + v^2) + p + \rho g (y - h) \cos \theta \right\} u dy} \right. \\ & \quad \left. + \overline{\int_0^{h+\eta} \frac{\rho}{2} (u^2 + v^2) U dy} + \frac{1}{2} \overline{\rho g \cos \theta \eta^2 U_{h+\eta}} \right] \\ & = \frac{1}{2} \overline{\rho g \cos \theta \eta^2 \frac{\partial U_{h+\eta}}{\partial x}} + \overline{\int_0^{h+\eta} u \frac{\partial \tau}{\partial y} dy} + \overline{\int_0^{h+\eta} (-\rho uv) \frac{dU}{dy} dy} \\ & \quad + \overline{\rho g \sin \theta \int_0^{h+\eta} u dy} \end{aligned} \quad (7)$$

Assuming that the slope is small enough for the following approximation to be valid

$$\cos \theta \approx 1 \quad \text{and} \quad \sin \theta \approx \tan \theta = I$$

and confining ourselves to the second order approximation of wave motion in the following discussion for the sake of simplicity, the wave energy balance equation becomes as follows

$$\frac{\partial E}{\partial t} + \frac{\partial F}{\partial x} = \int_0^h u \frac{\partial \tau}{\partial y} dy + \int_0^h (-\rho \bar{u} \bar{v}) \frac{dU}{dy} dy + \rho g I \int_0^{h+\eta} u dy \tag{8}$$

where E is the wave energy density and F is the wave energy flux given by

$$E = \int_0^h \frac{\rho}{2} (\overline{u^2 + v^2}) dy + \frac{1}{2} \rho g \bar{\eta}^2 \tag{9}$$

$$F = \int_0^h \bar{p} u dy + \int_0^h \frac{\rho}{2} (\overline{u^2 + v^2}) U dy + \frac{1}{2} \rho g \bar{\eta}^2 U_h \tag{10}$$

There appear three sources of wave energy in the righthand side of equation (8).

The first term gives energy dissipation due to viscosity. The second term shows the possibility of energy transfer between waves and a current through the mechanism similar to the energy transfer through the work done by Reynolds stress against flow strain in turbulent flow. This term vanishes for inviscid wave motion because of the phase difference of  $\pi/2$  between  $u$  and  $v$ . However, the existence of bottom wave boundary layer is expected, this term should be examined.

The last term stems from the existence of the inclination of surface on an actual uniform flow. As was mentioned previously, waves must do work against the gravity in order to maintain the mass transport over the inclined surface.

**WAVE HEIGHT CHANGE** Putting each terms of the righthand of the equation (8) as follows

$$\int_0^h u \frac{\partial \tau}{\partial y} dy = -2\alpha_1 F \tag{11}$$

$$\int_0^h (-\rho \bar{u} \bar{v}) \frac{dU}{dy} dy = -2\alpha_2 F \tag{12}$$

$$\rho g I \int_0^{h+\eta} u dy = -2\alpha_3 F \tag{13}$$

For monochromatic waves,  $\partial/\partial t = 0$  and equation (8) reduces to

$$\frac{d}{dx} F = -2(\alpha_1 + \alpha_2 + \alpha_3) F$$

Integrating this with respect to  $x$

$$\frac{F}{F_0} = \exp\{-2(\alpha_1 + \alpha_2 + \alpha_3)x\}$$

where the subscript  $_0$  denotes the quantities at  $x = 0$ , and the wave energy flux  $F$  is expressed using wave height  $H$  and wave energy transfer velocity  $C_g$ <sup>1</sup> as

$$F = EC_g = \frac{1}{8}\rho g H^2 C_g \quad (14)$$

For the uniform current under consideration,  $C_g = C_{g0}$ . Therefore, the change in height of the waves on a uniform current is given by

$$\frac{H}{H_0} = \exp\{-(\alpha_1 + \alpha_2 + \alpha_3)x\} = \exp(-\alpha x) \quad (15)$$

In order to obtain the attenuation coefficients  $\alpha$ , expressions relevant to the quantities on waves and currents must be given. In the following analysis, expressions in IS were used. They were derived on the assumption that the mean velocity profile was logarithmic for smooth bed and the prevailing part of eddy viscosity was due to the current and the contribution of waves to the eddy viscosity was small.

Examples of calculated results of the wave height attenuation rates are shown in figure 3. These results show that  $\alpha_1$ , defined by equation (11) and discussed in IS is positive and makes the base of the wave attenuation;  $\alpha_2$ , which is the part due to the Reynold's stress like stress induced by the wave orbital velocity components  $u$  and  $v$ , is small for a following current compared to the others, but this enhances the wave attenuation for a strong opposing current;  $\alpha_3$ , which is related to the slope of the mean water surface, is negative for a following current and positive for an opposing current and the absolute value increase with the current velocity.

Hence, the wave attenuation rate  $\alpha$  decreases with the velocity of the following current, and this seems to give a possible physical explanation for the experimental results of Simons et al. (1988).

When the velocity of a following current is small,  $\alpha_3$  is smaller than  $\alpha_1$  and the resultant  $\alpha$  gives wave attenuation. For a certain velocity of the following current,  $\alpha_1$  and  $\alpha_3$  cancel out and waves are expected to propagate without changing the height. And when the velocity exceeds the critical one,  $\alpha_3$  overcomes  $\alpha_1$ . In such situation as this, the resultant attenuation rate  $\alpha$  becomes negative and gives waves the growth in height.

On the other hand,  $\alpha_1, \alpha_2$  and  $\alpha_3$  all enhance the attenuation of wave height on opposing currents.

<sup>1</sup>To be exact,  $E$  is not necessarily equal to  $(1/8)\rho g H^2$  and wave energy transport velocity also does not necessarily coincide with group velocity defined by  $d\sigma/dk$  ( $k$ : wave number,  $\sigma$ : radian frequency) except the case in which the vertical velocity distribution is uniform. But the differences for the logarithmic flow are small.

Figure 3: Calculated results of wave attenuation rate

The comparison between the calculated results and some experimental data is shown in figure 4. The agreement of the calculation with the experimental data is improved compared to IS. The experiment were conducted only for opposing currents since the experimental facilities were not available for following currents.

### 3 WAVES ON NON-UNIFORM CURRENTS

Next, the case in which both of water depth and velocity change along the direction of a current is considered (figure 5). In this case we choose space coordinates  $x$  and  $y$  along and perpendicular to a horizontal plane taken near the mean surface, respectively. Then, the basic equations and the boundary conditions are given by

$$\frac{\partial u}{\partial t} + (U + u) \frac{\partial (U + u)}{\partial x} + (V + v) \frac{\partial (U + u)}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \frac{1}{\rho} \left( \frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} \right) \quad (16)$$

$$\frac{\partial v}{\partial t} + (U + u) \frac{\partial (V + v)}{\partial x} + (V + v) \frac{\partial (V + v)}{\partial y} = -g - \frac{1}{\rho} \frac{\partial p}{\partial y} + \frac{1}{\rho} \left( \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma_y}{\partial y} \right) \quad (17)$$

$$\frac{\partial (U + u)}{\partial x} + \frac{\partial (V + v)}{\partial y} = 0 \quad (18)$$

$$V + v = \frac{\partial \eta}{\partial t} + (U + u) \frac{\partial \eta}{\partial x} \quad \text{at } y = \eta \quad (19)$$

$$p = 0 \quad \text{at } y = \eta \quad (20)$$

$$V + v = -(U + u) \frac{dh}{dx} \quad \text{at } y = -h \quad (21)$$

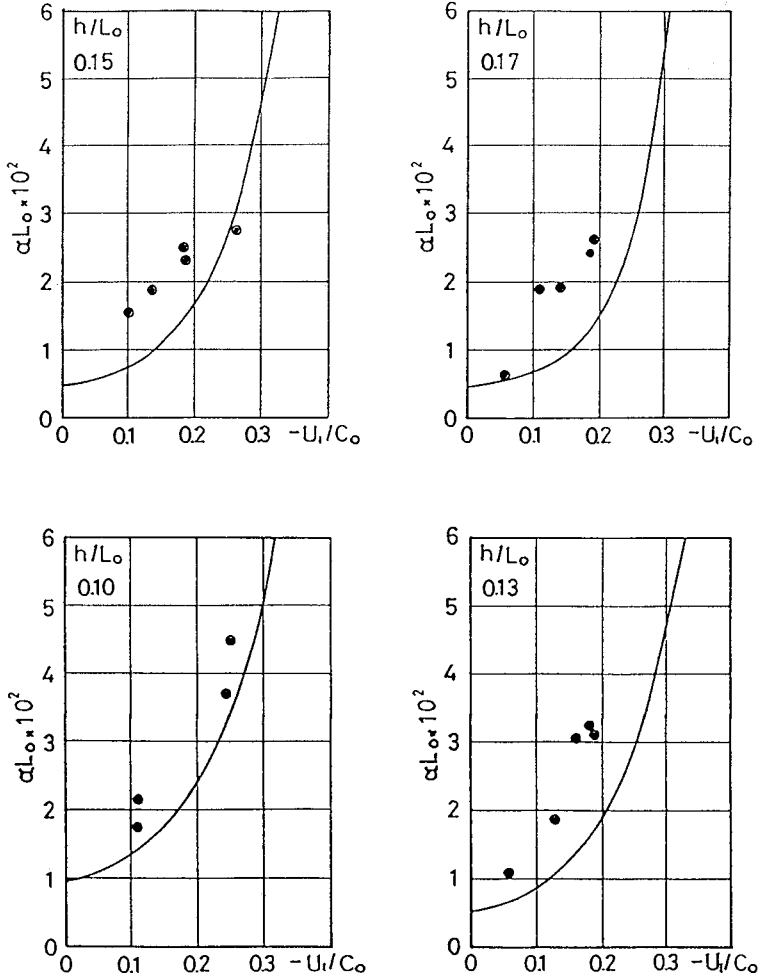

Figure 4: Comparison with experimental results for opposing currents

Figure 5: Definition sketch

where  $V$  is the vertical velocity component of the current and  $\sigma_x, \sigma_y, \tau_{xy}, \tau_{yx}$  denote stress component due to turbulence.

**WAVE ENERGY BALANCE** Based on these equations, we obtain an equation for wave energy balance in the same way as the case of uniform currents as

$$\begin{aligned}
 & \frac{\partial}{\partial t} \left[ \overline{\int_{-h}^{\eta} \frac{\rho}{2} (u^2 + v^2) dy} + \frac{1}{2} \overline{\rho g (\eta - \bar{\eta})^2} \right] \\
 & + \frac{\partial}{\partial x} \left[ \overline{\int_{-h}^{\eta} \left\{ \frac{\rho}{2} (u^2 + v^2) + p + \rho g (y - \bar{\eta}) \right\} u dy} \right. \\
 & \quad \left. + \overline{\int_0^{h+\eta} \frac{\rho}{2} (u^2 + v^2) U dy} + \frac{1}{2} \overline{\rho g (\eta - \bar{\eta})^2 U_{h+\eta}} \right] \\
 & = \frac{1}{2} \overline{\rho g (\eta - \bar{\eta})^2 \frac{\partial U_{h+\eta}}{\partial x}} - \overline{\int_{-h}^{\eta} \rho (U + u) u \frac{\partial U}{\partial x} dy} - \overline{\int_{-h}^{\eta} \rho (U + u) v \frac{\partial V}{\partial x} dy} \\
 & - \overline{\int_{-h}^{\eta} \rho (V + v) u \frac{\partial U}{\partial y} dy} - \overline{\int_{-h}^{\eta} \rho (V + v) v \frac{\partial V}{\partial y} dy} + \overline{\rho g (\eta - \bar{\eta}) \left[ V - U \frac{\partial \bar{\eta}}{\partial x} \right]_{\eta}} \\
 & + \overline{\int_{-h}^{\eta} u \left( \frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} \right) dy} + \overline{\int_{-h}^{\eta} v \left( \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma_y}{\partial y} \right) dy} - \overline{\rho g \frac{\partial \bar{\eta}}{\partial x} \int_{-h}^{\eta} u dy} \quad (22)
 \end{aligned}$$

where  $\bar{\eta}$  denotes mean water level.

In the righthand side of this equation, lots of sources of wave energy appear and rather complicated. For the sake of simplicity, we assume gradually varying flow. Then,  $(\partial U / \partial x)^2$  and  $V^2$  are small, and we may put  $-\rho v^2 = p - \rho g (\bar{\eta} - y)$ . Besides, we assume that  $(\partial \tau_{yx} / \partial y) \gg (\partial \sigma_x / \partial x), (\partial \sigma_y / \partial y), (\partial \tau_{xy} / \partial x)$  and  $(\partial U / \partial y) \gg (\partial V / \partial x)$ .

To the second order approximation, equation (22) reduces to

$$\frac{\partial E}{\partial t} + \frac{\partial F}{\partial x} = - \left[ \int_{-h}^{\eta} (\rho u^2 + p) \frac{\partial U}{\partial x} dy - \int_{-h}^{\bar{\eta}} p_0 \frac{\partial U}{\partial x} dy \right] + \int_0^h u \frac{\partial \tau}{\partial y} dy + \int_0^h (-\rho \bar{u} \bar{v}) \frac{dU}{dy} dy - \rho g \int_0^{h+\eta} u dy \frac{d}{dx} \left( \bar{\eta} + \frac{U^2}{2g} \right) \quad (23)$$

where E and F have been given by equations (9) and (10).

When  $U$  is independent on  $y$ , the part in the bracket of equation (23) becomes as follows

$$[\dots] = \left[ \int_{-h}^{\eta} (\rho u^2 + p) dy - \int_{-h}^{\bar{\eta}} p_0 dy \right] \frac{dU}{dx} = S_x \frac{dU}{dx} \quad (24)$$

where  $S_x$  is the radiation stress introduced by Longuet-Higgins and Stewart (1960). Therefore, the bracket can be considered to correspond to the radiation stress term in the case where current velocity varies not only horizontally but also vertically.

The last term of the righthand side corresponds to the one in equation (7). When we consider the head loss of the mean flow, we should take this term into consideration.

**WAVE HEIGHT CHANGE** Considering monochromatic waves and defining  $\alpha^*$  and  $\alpha$  as

$$-2\alpha^* F = \left[ \int_{-h}^{\eta} (\rho u^2 + p) \frac{\partial U}{\partial x} dy - \int_{-h}^{\bar{\eta}} p_0 \frac{\partial U}{\partial x} dy \right] \quad (25)$$

$$-2\alpha F = \int_0^h u \frac{\partial \tau}{\partial y} dy + \int_0^h (-\rho \bar{u} \bar{v}) \frac{dU}{dy} dy - \rho g \int_0^{h+\eta} u dy \frac{d}{dx} \left( \bar{\eta} + \frac{U^2}{2g} \right) \quad (26)$$

Equation (23) reduces to

$$\frac{d}{dx} F = 2\alpha^* F - 2\alpha F \quad (27)$$

Integrating this from  $x = 0$  to  $x$  with respect to  $x$

$$\frac{F}{F_0} = \frac{C_{g0}}{C_g} \exp \left( 2 \int_0^x \alpha^* dx \right) \exp \left( -2 \int_0^x \alpha dx \right) \quad (28)$$

Thus, wave height change is given by

$$\frac{H}{H_0} = \left( \frac{C_{g0}}{C_g} \right)^{1/2} \exp \left( \int_0^x \alpha^* dx \right) \exp \left( - \int_0^x \alpha dx \right) \quad (29)$$

We could calculate the change of wave height on non-uniform currents using this equation. However, it is rather complicated and laborious job to carry out the calculation.

When wave motion and currents are inviscid and vertical velocity distribution of the current is independent on  $y$ , equation (29) reduces to

$$\frac{H}{H_0} = \left( \frac{C_{g_{u_0}}}{C_{g_u}} \right)^{1/2} \exp \left( \int_0^x \alpha_u^* dx \right) \tag{30}$$

where subscript  $u$  denotes the expressions for waves on vertically uniform currents. So, equation(30) corrected by the factor  $\exp(-\int_0^x \alpha dx)$  was used in the following calculation.

The integrals in equation(30) were approximated using trapezoidal approximation for equally divides intervals of  $\Delta x$ . Then

$$\frac{H_n}{H_0} = \prod_{i=0}^{n-1} \frac{H_{i+1}}{H_i} = \prod_{i=0}^{n-1} \left( \frac{C_{g_{u_i}}}{C_{g_{u_{i+1}}}} \right)^{\frac{1}{2}} \exp \left\{ \frac{1}{2} (\alpha_i^* + \alpha_{i+1}^*) \Delta x \right\} \exp \left\{ \frac{1}{2} (\alpha_i + \alpha_{i+1}) \Delta x \right\} \tag{31}$$

Prior to the calculation of wave height, the depth and the velocity of the current and  $dU/dx$  were calculated at points  $i$  and  $i + 1$  by a conventional calculation method for a non-uniform current. Then, the wave height at each  $i$  was calculated.

Figure 6 is an example of calculated results for opposing currents. In this figure, subscript  $0$  denotes the quantities at  $x = 0$ .

As the bottom slope becomes smaller, the factor  $\exp(-\int_0^x \alpha dx)$  weaken the amplification effects due to the shoaling effect and the energy transfer through  $S_x (dU/dy)$  for the waves traveling over an opposing current. Figure 7 shows the comparison between experimental results and calculated ones. These results show that the dissipative effect of the factor  $\exp(-\int_0^x \alpha dx)$  plays an important role for the wave height change on a gradually varying opposing current.

Figure 6: A model calculation results

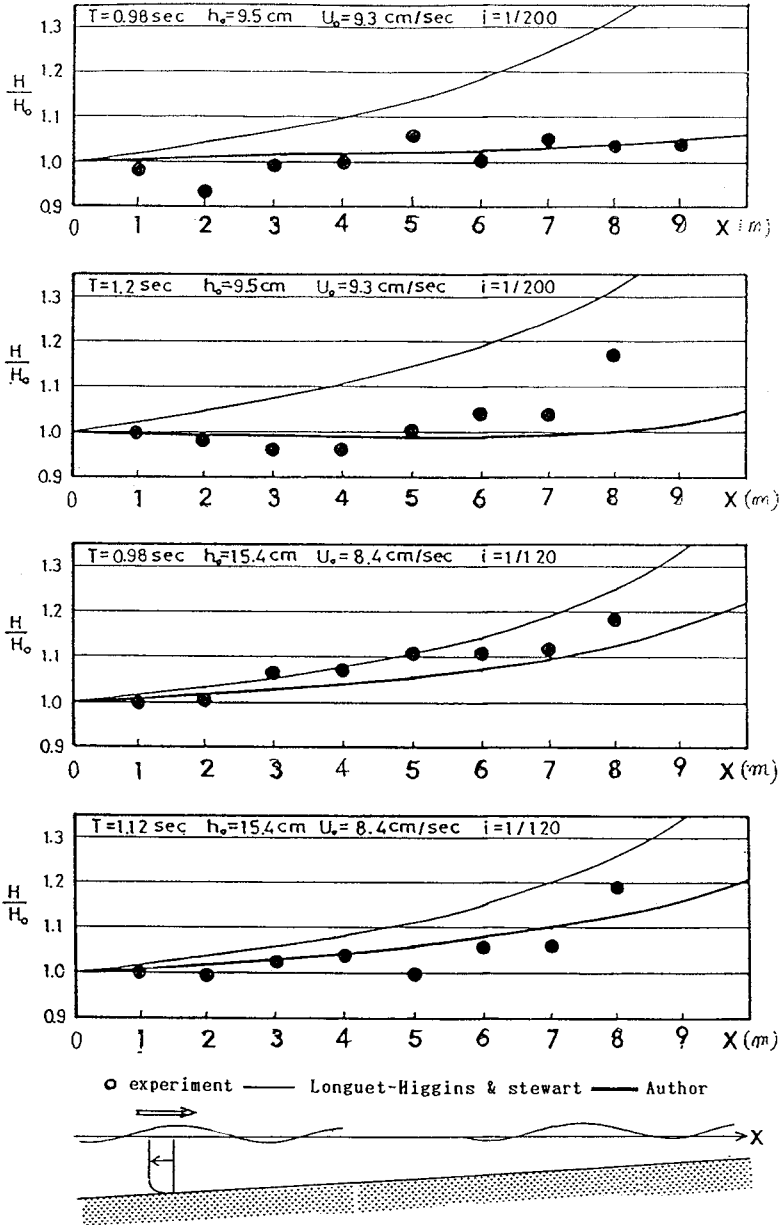

Figure 7: Comparison between measurements and calculated results

## 4 CONCLUSION

Waves propagating on a uniform current attenuate their height due to the effects of 1) viscosity, 2) Reynolds stress like wave stress induced by the orbital velocity in bottom wave boundary layer and 3) the existence of the inclination of the mean surface.

The effect of 1) makes the base of the wave attenuation rate. The effect of 2) is small for a following current, but this enhances the wave attenuation for a strong opposing current. And the effect of 3) gives positive attenuation rate for an opposing current and negative attenuation rate for a following current.

The combined effect of them increases the wave attenuation rate for an opposing current. But it decreases the attenuation rate as the velocity of a following current increases, and this seems to give a possible physical explanation for the experimental results of Simon et al. (1988).

As the wave attenuation rate increases with the velocity of an opposing current, it affects the change in height of waves on a gradually varying opposing current to such an extent that we can not ignore the effect.

## CHAPTER 43

### A Two-Dimensional Surf Zone Model Based on the Boussinesq Equations

H. A. Schäffer<sup>1</sup>, R. Deigaard<sup>2</sup> and P. Madsen<sup>1</sup>

#### Abstract

A simple approach to wave breaking using the concept of surface rollers is introduced in a two-dimensional Boussinesq model. A surface roller represents a passive bulk of water riding on the front of a breaking wave and the vertical redistribution of momentum associated with the formation and change of surface rollers leads to additional terms in the Boussinesq equations. A simple geometrical method is used for the determination of the shape and location of these rollers at each time step in the simulation. This automatically results in a time-varying break point position in the case of irregular waves. Furthermore, breaking may well cease for example when waves reach a trough inshore of a bar.

Comparison between one-dimensional simulations and experiments shows good agreement for the variation of wave height and mean water surface as well as surface elevation time series throughout the surf zone for both regular and irregular waves. Simulations in two horizontal dimensions are still at the initial stage. A sample simulation is shown.

#### Introduction

The modelling of wave conditions in the surf zone is an important basis for the description of wave-driven currents and sediment transport.

Previously, waves breaking on a beach have been modelled by the non-linear shallow water equations. These predict that the front face of the wave will gradually become steeper until it is vertical. In such a model, the front of a break-

---

<sup>1</sup> Danish Hydraulic Institute, Agern Allé 5, 2970 Hørsholm, Denmark

<sup>2</sup> DTH, ISVA, DK-2800 Lyngby, Denmark

ing wave may then be represented by a jump condition in which mass and momentum are conserved. Thus only the integrated energy dissipation over the wave front is represented.

The details of the turbulent front of a bore were studied by Madsen (1981) and Madsen and Svendsen (1983) and Svendsen and Madsen (1984) using a two-layer model, and it was found that the energy dissipation can be represented in a depth-integrated model by taking the non-uniform velocity distribution into account in the momentum equation.

The main restrictions for the use of the non-linear shallow water equations are that they can only be used for very shallow water, and that they cannot describe a wave of constant form propagating over an even bottom. One consequence of this is that the offshore boundary must be very close to the surf zone and in some cases even within the surf zone. Another consequence is that once a wave has started breaking, it will continue to do so even if it enters deeper water, eg in a trough inshore of a bar. Due to these restrictions, it is of interest to develop a model for the surf zone based on the Boussinesq equations which has a wider range of applicability than the non-linear shallow water equations.

Boussinesq models for the surf zone have been developed by Abbott et al (1983), Karambas and Koutitas (1989, 1992) and Karambas et al (1990) using a depth-integrated one-or-two-equation turbulence model. Deigaard (1989) introduced the concept of surface rollers in Boussinesq modelling and estimated the surface roller geometry using ideas of Engelund (1981). The roller was taken to be a lump of water moving with the speed of wave propagation as in the models of Svendsen (1984, 1984a). The present work is an extension and modification of the model by Deigaard (1989).

## The Flow Description

The flow velocity in the surface roller is very large compared to the orbital motion, as the water in the roller travels with the wave celerity,  $c$ . Thus, the velocity distribution is very uneven in the presence of rollers. The breaking/broken waves are represented by including the effect of the surface rollers in the equations expressing the conservation of mass and momentum. The contribution from the rollers is determined by considering the momentum flux of the velocity profile shown in Figure 1. First, the one-dimensional case is considered. The orbital velocity,  $U_o$ , is taken to be uniformly distributed over the vertical, and the surface roller with a thickness  $\delta$  has the velocity  $c$ . The instantaneous water depth is  $h$ , the still water depth is  $D$ , and the water surface elevation is  $\eta$ .

The instantaneous depth-integrated flux in the  $x$ -direction  $p$  is then

$$p = \int_{-D}^{\eta} u \, dz = U_o (h - \delta) + c \delta = U_o h + (c - U_o) \delta \quad (1)$$

and the depth-integrated momentum flux,  $F_m$ , is

$$\begin{aligned} F_m &= \int_{-D}^{\eta} \rho u^2 dz = \rho U_o^2 (h-\delta) + \rho c^2 \delta \\ &= \rho U_o^2 h + \rho (c^2 - U_o^2) \delta \end{aligned} \quad (2)$$

Figure 1. Cross-section and assumed velocity profile components of a breaking wave with a surface roller.

If no roller is present ( $\delta=0$ ), the momentum flux of the uniformly-distributed orbital velocity is given by

$$F_{m0} = \rho \frac{p^2}{h} \quad (3)$$

Retaining this expression for the momentum flux, even when rollers are present, a correction term must be included. This term (divided by  $\rho$ ) takes the form

$$\begin{aligned} R &= \frac{1}{\rho} (F_m - F_{m0}) \\ &= U_o^2 h + (c^2 - U_o^2) \delta - \frac{1}{h} (U_o h + (c - U_o) \delta)^2 \\ &= \delta (c - U_o)^2 \left( 1 - \frac{\delta}{h} \right) \end{aligned} \quad (4)$$

or with  $U_o$  determined from (1):

$$R = \delta \left( \frac{ch-p}{h-\delta} \right)^2 \left( 1 - \frac{\delta}{h} \right) = \delta \frac{\left( c - \frac{p}{h} \right)^2}{1 - \frac{\delta}{h}} \quad (5)$$

This contribution to the momentum flux from the rollers is then - together with  $F_{mo}$  - included in the full Boussinesq equation for conservation of momentum:

$$\frac{\partial p}{\partial t} + \frac{\partial}{\partial x} \left( \frac{p^2}{h} \right) + \frac{\partial R}{\partial x} + gh \frac{\partial \eta}{\partial x} + \frac{D^3}{6} \frac{\partial^3}{\partial x^2 \partial t} \left( \frac{p}{D} \right) - \frac{D^2}{2} \frac{\partial^3 p}{\partial x^2 \partial t} = 0 \quad (6)$$

The continuity equation is not affected by the presence of rollers:

$$\frac{\partial \eta}{\partial t} + \frac{\partial p}{\partial x} = 0 \quad (7)$$

When the flow equations are solved with the surface rollers at the wave fronts, the additional, third term in the momentum equation will cause an energy loss, which represents the energy dissipation in spilling breakers and broken waves.

The extension of this analysis to two dimensions is simple, and the three correction terms  $R_{xx}$ ,  $R_{xy}$  and  $R_{yy}$  are given by the expressions:

$$\frac{1}{\rho} F_{mxx} = \int_{-D}^{\eta} u^2 dz = \frac{p^2}{h} + \delta \frac{\left( c_x - \frac{p}{h} \right)^2}{1 - \frac{\delta}{h}} = \frac{p^2}{h} + R_{xx} \quad (8)$$

$$\frac{1}{\rho} F_{mxy} = \int_{-D}^{\eta} uv dz = \frac{pq}{h} + \delta \frac{\left( c_x - \frac{p}{h} \right) \left( c_y - \frac{q}{h} \right)}{1 - \frac{\delta}{h}} = \frac{pq}{h} + R_{xy} \quad (9)$$

$$\frac{1}{\rho} F_{myy} = \int_{-D}^{\eta} v^2 dz = \frac{q^2}{h} + \delta \frac{\left( c_y - \frac{q}{h} \right)^2}{1 - \frac{\delta}{h}} = \frac{q^2}{h} + R_{yy} \quad (10)$$

where  $c_x$  and  $c_y$  are the x- and y-components of the wave celerity vector, and  $q$  is the depth-integrated flux in the y-direction.  $\partial R_{xx}/\partial x + \partial R_{xy}/\partial y$  is then included in the equation for x-momentum and  $\partial R_{yy}/\partial y + \partial R_{xy}/\partial x$  is included in the equation for y-momentum. The equation for mass conservation is unchanged:

$$\frac{\partial \eta}{\partial t} + \frac{\partial p}{\partial x} + \frac{\partial q}{\partial y} = 0 \quad (11)$$

## Geometrical Determination of Surface Rollers

The consequence of the presence of surface rollers has now been established and it remains to determine their variation in space and time,  $\delta(x,y,t)$ . There is no appropriate theory available for this purpose, and we adapt the heuristic geometrical approach of Deigaard (1989) with some modifications.

As a shoaling wave approaches a shoreline, the local steepness of the front increases, the wave becomes unstable, and breaking initiates. Assuming that the local gradient of the front of a non-breaking wave has a maximum  $\tan\varphi$ , we simply take the wave to be breaking when this gradient is exceeded. Furthermore, we assume that the water above the tangent of slope  $\tan\varphi$ , to the water surface belongs to the roller as shown in Figure 2. This also implies that breaking ceases if the maximum of the local slope becomes less than  $\tan\varphi$ .

Figure 2. *a: Geometrical detection of surface roller (cross-section A-A in Figure 3), b: The same roller with  $f_{\delta} = 1.5$  applied.*

Engelund (1981) found that  $\varphi = 10^{\circ}$  was appropriate for weak hydraulic jumps, and using the bore/hydraulic jump analogy, we use this value in the inner surf zone. However, waves over a constant depth can be stable for much larger local slopes from which it is clear that  $\varphi = 10^{\circ}$  is inadequate near the break point. For this reason,  $\varphi$  is chosen to vary in time while being constant in space within each surface roller.

Breaking is initiated using  $\varphi = \varphi_B$ , which then gradually changes to the smaller terminal value  $\varphi = \varphi_0$ . Since breakers often transform rather quickly to the bore-like stage, an exponential transition of  $\tan\varphi$  is chosen: where  $t^*$  is the halftime for  $(\tan\varphi - \tan\varphi_0)$ . Thus, the roller is determined by the three parameters,  $\tan\varphi_B$ ,  $\tan\varphi_0$ , and  $t^*$ .

Furthermore, we introduce a roller shape parameter,  $f_{\delta}$ , to partially com-

$$\tan\varphi = \tan\varphi_0 + (\tan\varphi_B - \tan\varphi_0) \exp \left[ - \ln 2 \frac{t-t_B}{t^*} \right] \quad (12)$$

pensate for the primitive way of separating the surface roller from the rest of the flow. After the geometrical determination of the roller at each time step,  $\delta$  is simply multiplied by  $f_b$  before the influence of the roller is computed. Note that this has no direct influence on the roller determination.

In the 2D case, the toe of the roller becomes a curve (segment) instead of a single point, see Figure 3, and the cut-off line is a surface defined by the roller-toe curve and a set of generating lines. These generating lines are determined by the instantaneous local cut-off angle,  $\varphi$ , and the local direction of the maximum slope of the free surface.

Figure 3. Plane view of a 2D surface roller. The cross vertical section A-A is shown in Figure 2.

The roller shape parameters,  $f_b$ , is maintained without difficulty. As in the 1D case,  $\varphi$  ( $\tan \varphi$  to be exact) is chosen to vary as given by (12). In the 2D case, however,  $\varphi$  is not constant in space within each surface roller (as in the 1D case), but only along a roller-toe orthogonal (see Figure 3), ie a lateral variation of  $\varphi$  within each roller is possible. This is because the age of different sections of the surface roller may vary: from the time of initial breaking, each roller section is traced along the roller-toe orthogonal and this provides a way of determining the age of each roller section. This age is then used for the determination of the local value of  $\varphi$ .

The detection procedure outlined above automatically allows for very different situations within the same surface roller. For example, for oblique incident waves on a beach, the bore-like stage in the inner surf zone is modelled using  $\varphi = \varphi_0$  simultaneously with initial breaking ( $\varphi \approx \varphi_B$ ) occurring in the seaward end of the roller.

## Numerical Results and Comparison with Measurements

In all numerical simulations shown below, three of the four parameters governing the instantaneous determination of the surface roller were kept constant using  $\varphi_0 = 10^\circ$ ,  $t^*/T_{(\varphi)} = 0.1$  where  $T_{(\varphi)}$  is the (peak) period, and  $f_b = 1.5$ . Furthermore,  $\varphi_\beta = 20^\circ$  was used in all tests but one, for which it was necessary to reduce the value to  $\varphi_\beta = 18^\circ$  in order to match the measured break point. At the seaward boundary, the depth-integrated velocity was specified, and at the shoreward boundary, the remaining waves were absorbed by a numerical sponge layer (Larsen and Dancy, 1983). The celerity was modelled by  $1.3\sqrt{gD}$  throughout.

Figure 4a shows the surface elevation at  $t = 24$  s including the rollers for a regular wave of  $T = 4$  s climbing a plane slope of 1:40. This computation was made with a time step of 0.1 s and a grid size of 0.4 m, using 37 CPU seconds on an IBM 4381 P12. The figure gives a first impression of the capability of the model to reproduce the wave decay and the development of asymmetric wave profiles resembling bores. Figure 4b shows the results when no surface-roller term is applied.

Figure 4. Instantaneous surface elevation of regular waves on a plane sloping beach. a: with surface rollers, b: without surface rollers.

In Figure 5, comparison of wave height,  $H$ , and mean water surface, MWS, with measurements from DHI (Thorkildsen et al, 1991) is shown. The beach profile has a bar with a depth of 0.10 m and the waves are regular with  $T = 1.6$  s and  $H_o = 0.12$  m (wave height at seaward boundary where the depth is 0.54 m).

Figure 5. Comparison of wave height and mean water surface with DHI measurements for regular waves breaking over a bar (Thorkildsen et al, 1991).

Both the wave height and MWS compare very well with measurements. An interesting feature is that both measurements and numerical results exhibit the well-known 'delay' of the change of sign for the MWS-gradient relative to the breakpoint. This indicates that the model reproduces the effect of a rapid transformation of potential energy to kinetic energy and the change in the wave profile taking place in the initial breaking process. In Figure 6, surface elevation time series for another profile with a bar are compared with measurements from Hansen and Svendsen (1986). At the two locations shown, the depth was 70% and 42% of the breaker depth, respectively. The latter location is on the top of the bar where breaking has almost ceased, and the wave height is seen to be somewhat overestimated.

Figure 6. Comparison of surface elevation time series with measurements by Hansen and Svendsen, 1986.

We now turn to irregular waves bearing in mind that this only requires a change in the seaward boundary condition for the simulation and that no additional assumptions are needed regarding eg the variation of the break point position. Figures 7, 8 and 9 show results for incoming waves given by a JONSWAP spectrum with random phase assignment and a peak enhancement factor of 3.3. The incoming significant wave height is 0.14 m and the peak period is 1.8 s. The profile is the same as for the results shown in Figure 5 (Thorkildsen et al, 1991).

Figure 7 shows an instantaneous surface elevation and Figure 8 gives spatial variation of the RMS of the surface elevation as well as the MWS. Both quantities compare well with measurements, except for a general vertical shift between calculated and measured MWS-values. This, however, is explained by loss of water in the numerical sponge layer due to setup, and the problem is expected to disappear when a run-up condition is incorporated. Figure 9 shows time series of surface elevation at gauges nos 5 and 9 (indicated in Figure 8). The agreement is surprisingly good considering that the physical and numerical shoreline absorption are bound to be a little bit different.

Figure 7. Instantaneous surface elevation of irregular waves breaking over a bar.

Figure 8. Comparison of RMS of surface elevation and mean water surface for irregular waves breaking over a bar with DHI measurements (Thorkildsen et al, 1991).

Figure 9. Comparison of time series of surface elevation for positions nos 5 and 9 in Figure 8.

Figure 10 shows a close-up of the instantaneous surface roller thickness and surface elevation for a two-dimensional simulation of a regular wave ( $H_o = 0.15$  m,  $T = 2$  s) breaking over a focusing shoal. The topography, known as the Whalin shoal, is given in Figure 11 where the close-up area is indicated by the square. The effects of breaking (Figure 10) have resulted in a decay of wave height in the central part of the wave. Without breaking, this part of the wave would have been the highest.

*Figure 10. Two-dimensional simulation of a wave breaking over a focusing shoal. a: surface roller, b: surface elevation.*

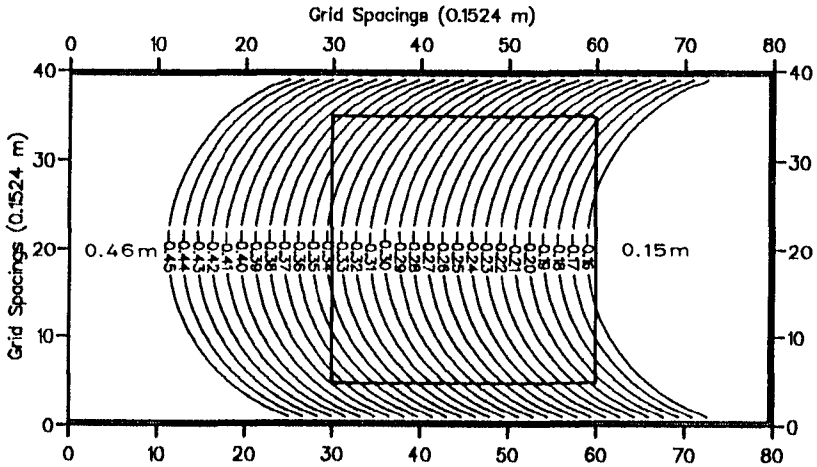

Figure 11. *Focusing shoal (Whalin topography).*

## Conclusion

Effects of wave breaking have been successfully incorporated in a Boussinesq model using the concept of surface rollers. Comparison with experiments shows that the model is capable of reproducing the variation of wave height and mean water surface for regular as well as irregular waves breaking in shallow water. Even details of surface elevation time series in the inner surf zone are reproduced quite well. The model has the potential to simulate irregular short-crested waves over a varying topography under surf conditions including phenomena like nearshore calculation and infragravity waves.

## CHAPTER 44

### FIELD VERIFICATION OF NUMERICAL MODELS FOR CALCULATION OF NEARSHORE WAVE FIELD

Takuzo Shimizu <sup>1</sup>, Akiyuki Ukai <sup>1</sup> and Masahiko Isobe <sup>2</sup>

#### ABSTRACT

Field applicabilities of both the parabolic equation model and the energy flux equation model are verified through comparisons with field data. The results show that the parabolic equation model has fairly good accuracy for estimating the wave height distribution of the actual wave field over a complex bottom topography, but the transformation of directional wave spectra cannot be reproduced satisfactorily in the surf zone. It is also found that the energy flux equation model is applicable for practical use although its basic equation has a shortcoming of not taking into account the diffraction in a strict sense.

#### INTRODUCTION

In recent years, a numerical predictive model of three-dimensional beach topography change has been developed and applied to many practical problems in Japan. A few attempts have been made to demonstrate the practical applicability of the model through comparisons of the numerical predictions with the actual topographical changes around a harbor (e.g. Shimizu et al. 1990). In order to properly predict the beach evolution due to construction of a coastal structure, it is first of all important to evaluate the wave field with good accuracy. In a numerical model for estimating the wave field in the nearshore region, wave transformation such as shoaling, refraction, diffraction and wave breaking should be taken into account. Moreover, treatment of random waves is important for the field application. In this study, two calculation models are examined; namely,

---

<sup>2</sup>Professor, Dept. of Civil Eng., Univ. of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan.

the wave energy flux equation model as described with the directional wave spectrum proposed by Karlsson(1969) and the parabolic-type equation model derived from the mild slope equation by using the wave ray-front coordinates proposed by Isobe(1987). We try to verify the field applicability of these two models quantitatively, through comparisons with the field measurement data. We shall also investigate the effects of the calculation results of the wave field on those of the wave-induced nearshore current field.

## FIELD INVESTIGATION

The field verification of the models has not been thoroughly discussed owing to difficulties of obtaining field data on nearshore waves and currents under severe wave conditions. The field observation was, therefore, carried out around the Tomioka Fishery Harbor, facing directly the Pacific Ocean, Fukushima Prefecture, Japan. The Tomioka Fishery Harbor is under construction and has been troubled with harbor shoaling since the construction started in 1986.

Fig. 1 shows the bottom topography of the investigation site and the locations of observation points. The calculation area is the same as shown in this figure and is about 2.5 km long in the alongshore direction and about 1.5 km long in the cross-shore direction. The calculated wave rays by Snell's law are also shown in this figure. The wave rays are calculated for the mean wave condition of storm waves which attacked during the observation. The significant wave period is 8.6 seconds and the direction of the crestline is 6 degree oblique to the shoreline. The bottom contours are complex and there exist some rocky shoals. In the southeast of the harbor entrance, the bottom contours extend offshoreward like a tongue and the wave rays converge and intersect with each other around this shoal.

At six points in the nearshore region with the water depth of about 5 m, waves and nearshore currents were measured by using a combination of an ultrasonic wave gauge and an electro-magnetic current meter with a pressure sensor. The incident wave conditions were also measured at Point 0 with the water depth of 12 m. Synchronized measurements of the water surface elevation and the two components of horizontal water particle velocities were conducted. The measuring instruments have the self-recording system and had been placed on the seabed during the observation. 10-minutes measurements with the sampling time of 0.5 seconds were recorded on the magnetic cassette tape every 2 hours for approximately one month.

The data obtained by an ultrasonic wave gauge during the storm waves beyond approximately 2 m are not normal because of intrusion of air bubbles due to wave breaking. The pressure fluctuations obtained by a pressure sensor are, therefore, converted into the water surface motion on the basis of the small amplitude wave theory. First, the pressure fluctuation profile is decomposed into a finite number of Fourier series components with the aid of the Fast Fourier Transform algorithm. The Fourier coefficients of the pressure fluctuations are converted into those of the water surface fluctuations on the basis of the linear wave theory. The wave profile is, then, reconstructed with these converted Fourier coefficients

Fig. 1. Bottom topography of investigation site.

of water surface motion in the frequency range from 0.03 to 0.3 Hz. Moreover, the wave profiles estimated by using the pressure data are compared with those observed directly by the ultrasonic wave gauge during the relatively calm period when the simultaneous records of both data were obtained successfully.

The field observation was carried out over a period of approximately one month from September to November in 1990. During the observation, fortunately, storm waves greater than 3 m in significant wave height attacked twice. Our interests are focussed on the data obtained at Point 4 where the increase in wave height is a result of refraction and diffraction effects due to bottom topography, and at Point 5 where diffraction behind the breakwater occurs.

### CALCULATION METHOD

#### Energy Flux Equation Model (EFEM)

The wave energy flux equation model as described with the directional wave spectrum proposed by Karlsson(1969) has been widely used for refraction of random waves. In this study, the model with an additional term of energy dissipation is employed.

$$\frac{\partial}{\partial x}(Dv_x) + \frac{\partial}{\partial y}(Dv_y) + \frac{\partial}{\partial \theta}(Dv_\theta) = -f_D D \tag{1}$$

$$v_x = c_g \cos \theta, \quad v_y = c_g \sin \theta, \quad v_\theta = \left(\frac{c}{c_g}\right) \left(\frac{\partial c}{\partial x} \sin \theta - \frac{\partial c}{\partial y} \cos \theta\right) \tag{2}$$

where  $D(f, \theta)$  is the directional wave spectrum,  $c_g$  the group velocity,  $c$  the wave celerity and  $f_D$  the energy dissipation coefficient.

In this model, random waves are treated directly as the directional wave spectrum. Therefore, this model has an advantage of the computational time being relatively short in a wide region such as the actual field. On the other hand, this equation has a shortcoming of not taking the diffraction into account in a strict sense. But, this model gives an approximate estimation of diffracted wave height for practical applications, because diffraction of random waves can be explained mainly by the directional spreading.

### Parabolic Equation Model (PEM)

Many numerical models for calculation of the wave field under combined refraction and diffraction above a complex bottom topography have been developed on the basis of the mild slope equation. Approximate parabolic-type equations are often adopted because much computational time can be saved owing to the forward stepping scheme.

Isobe(1987) developed a parabolic equation model for the random waves transformation due to refraction, diffraction and wave breaking. Irregular waves are described as a superposition of component regular waves with different frequencies and directions. In order to improve the accuracy of calculating the wave transformation for a wide range of propagation directions of component waves, a curvilinear coordinate system is introduced and the parabolic equation is derived by taking into account the difference between directions of wave propagation and a pre-chosen coordinate. This coordinate consists of wave rays and fronts for modified bottom topography in which wave rays do not intersect with each other. In this model, the curvilinear coordinates are defined from the peak wave frequency and peak direction of the directional spectrum. In a shadow region, additional wave rays are radiated from the tip of the breakwater.

The following parabolic-type approximate equation was derived in the curvilinear coordinate system.

$$\frac{1}{Gh_\xi} \frac{1}{h_\eta} \frac{\partial}{\partial \eta} \left( G \frac{h_\xi}{h_\eta} \frac{\partial \phi}{\partial \eta} \right) + 2ik_\xi \frac{1}{h_\xi} \frac{\partial \phi}{\partial \xi} + \left\{ \frac{i}{Gh_\eta} \frac{1}{h_\xi} \frac{\partial(k_\xi Gh_\eta)}{\partial \xi} + (k^2 + k_\xi^2) + i \frac{\omega}{G} f_D \right\} \phi = 0 \quad (3)$$

where  $\phi$  is the complex amplitude of water surface fluctuation,  $G = cc_g$ ,  $\omega$  the angular frequency,  $k$  the wave number,  $k_\xi$  the  $\xi$ -direction component of the wave number vector, and  $h_\xi$  and  $h_\eta$  the  $\xi$ - and  $\eta$ -direction scale factors of the curvilinear coordinates, respectively.

### Energy Dissipation Model

As for the energy dissipation term due to wave breaking, the model proposed by Isobe(1987) is employed in both models. This energy dissipation model is divided into two phases. The first phase is the determination of breaking point

and the second is the evaluation of energy dissipation coefficient. The breaker index of an individual wave is expressed by the ratio of water particle velocity to wave celerity as follows.

$$\begin{aligned} \gamma'_b &\equiv (\dot{u}/c)_b \\ &= 0.53 - 0.3 \exp \left\{ -3\sqrt{d_b/L_0} \right\} + 5 \tan^{3/2} \beta \exp \left\{ -45 \left( \sqrt{d_b/L_0} - 0.1 \right)^2 \right\} \end{aligned} \quad (4)$$

where  $\gamma'_b$  is the criterion for regular waves,  $u$  the amplitude of horizontal water particle velocity at still water level,  $d$  the water depth,  $L_0$  the deepwater wavelength,  $\tan \beta$  the bottom slope, and the subscript  $b$  denotes quantities at the breaking point.

The ratio at the breaking point for individual waves of an irregular wave train was temporally taken as 0.8 times that for regular waves in the original paper. In this study, through comparisons with field measurement data, the coefficient is assumed to be 0.7. The breaker index for random waves,  $\gamma_b$ , is indicated as follows.

$$\gamma_b = 0.7\gamma'_b \quad (5)$$

The energy dissipation coefficient of irregular waves is given as the product of the probability of breaking waves and the energy dissipation coefficient of regular waves.

$$f_D = P_B f'_D \quad (6)$$

where  $f_D$  is the energy dissipation coefficient of irregular waves,  $P_B$  the probability of breaking waves, and  $f'_D$  the energy dissipation coefficient of regular waves.

$$f'_D = -\frac{5}{2} \sqrt{\frac{g}{d}} \sqrt{\frac{\gamma - \gamma_r}{\gamma_s - \gamma_r}} f_d(kd) \tan \beta \quad (7)$$

$$f_d(kd) = \sqrt{\frac{\tanh kd}{kd}} \frac{1}{2} (1 + s_2) \left\{ 1 - \frac{5(1 - s_2)(1 + s_2) + 2s_2(s_2 \cosh 2kd - 1)}{5(1 + s_2)^2} \right\} \quad (8)$$

$$s_2 = 2kd / \sinh 2kd \quad (9)$$

$$\gamma_s = 0.4 \times (0.57 + 5.3 \tan \beta) \quad (10)$$

$$\gamma_r = 0.135 \quad (11)$$

where  $\gamma_s$  and  $\gamma_r$  give the maximum values of  $\gamma$  on a uniform slope and in the wave recovery zone respectively. Eq.(7) to (9) are evaluated by using the significant wave as a representative wave.

On the assumption of the Rayleigh distribution, the probability of breaking waves is expressed as follows.

$$P_B = \left\{ 1 + 2.004 \left( \frac{\gamma_b}{\tilde{\gamma}_{1/3}} \right)^2 \right\} \exp \left[ -2.004 \left( \frac{\gamma_b}{\tilde{\gamma}_{1/3}} \right)^2 \right] \quad (12)$$

where  $\tilde{\gamma}_{1/3}$  is the value of  $\gamma$  without breaking dissipation corresponding to the significant wave. Both the energy equation model and the parabolic equation model are based on the small amplitude wave theory. However, the effect of wave nonlinearity cannot be neglected in the shallow water. Here, the nonlinearity effect is treated by multiplying a correction factor to the wave height. For non-breaking waves, the first-order cnoidal wave theory is used (Isobe, 1985) and for breaking waves, the correction factor is taken to be 1.25 on the basis of experimental results.

## COMPARISON OF WAVE HEIGHT AND DIRECTION

The parabolic equation method and the energy flux equation method were applied to reproduction of the observed wave field. In order to compare the calculations with the measurements, the measurement data obtained at Point 0 are classified into three cases in accordance with the wave height level. The wave direction is limited to the predominant direction, E. The numerical calculations are conducted for the mean significant waves of these three classifications, using the Bretschneider-Mitsuyasu frequency spectrum and the Mitsuyasu-type directional spreading function. The directional spreading parameter  $S_{max}$  is set to be 25, because the observed values at Point 0 were about 20 to 30 during the observation. The numbers of frequency and directional intervals with equal spacing are 10 and 15 respectively for calculation by the parabolic equation model, and 10 and 45 for that by the energy equation model.

Fig. 2(a) and (b) show the calculated wave fields for regular waves and for irregular waves by the parabolic equation model. The incident significant wave height is 2.9 m, the significant wave period is 8.5 s and the wave direction is E. As seen in Fig. 2(a) for regular waves, the extraordinary spatial variations in wave height are calculated owing to refraction over the complicated bottom topography. The calculation for random waves, on the other hand, show rather smooth wave height distribution because of presence of various directional and frequency components. Fig. 2(c) is the calculation result by the energy flux equation model. The spatial variation in wave height is even smoother than that of the parabolic equation model. Judging from these results, treatment of random waves is seemed to be inevitable for field application.

Fig. 3 shows the relationship between the incident wave height at Point 0 and that at the representative observation point in the nearshore region. The scattered plots are the measurements and the symbols are the calculations. At Point 3 near the harbor entrance, the significant wave height is almost the same as the incident wave height under relatively calm waves and becomes a little smaller owing to the wave breaking when the incident wave height is beyond 2 m. At Point 4 around the rocky shoal, the wave height increases owing to refraction over the shoal compared with the incident wave height, and the effect of wave breaking appear when the incident wave height becomes greater than 2 m. Although the conventional refraction analysis of regular waves gives the crossing of wave rays, both of the computed results by the parabolic equation model and by the energy flux equation model show good agreements with the measurements. As it was

Fig. 2. Calculated wave fields.  
 (  $H_{1/3}=2.9\text{m}$ ,  $T_{1/3}=8.5\text{s}$ , E )

expected at Point 5, in the sheltering area behind the breakwater, the results calculated by the energy flux equation model underestimate the measurements. On the other hand, the calculated results by the parabolic equation model show fairly good agreements with the measurements.

Fig. 4 shows the comparisons between the measured and the calculated significant wave heights including data at Point 1 and 2. The calculations of the parabolic equation model agree with the measurements much better than those of the energy flux equation model.

Fig. 5 shows the comparisons between the measured and the calculated principal directions. The calculations of both the parabolic equation model and the energy flux equation model for irregular waves agree fairly well with the measurements.

## COMPARISON OF DIRECTIONAL WAVE SPECTRUM

### Measured Directional Wave Spectra

The directional wave spectra were estimated by the Maximum Entropy Method (MEP ; Kobune and Hashimoto, 1986). The Maximum Entropy Method has an

Fig. 3. Relationship between incident wave height at Point 0 and that at representative observation point.

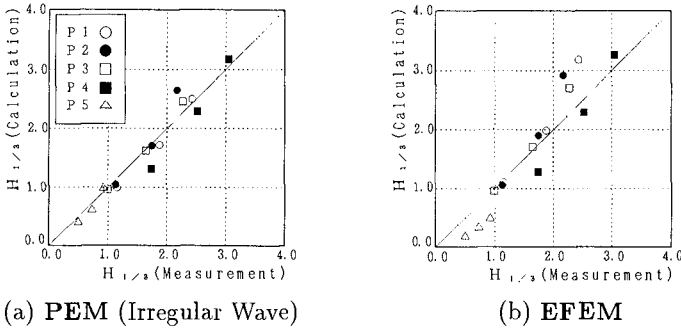

Fig. 4. Comparisons between the measured and the calculated significant wave heights.

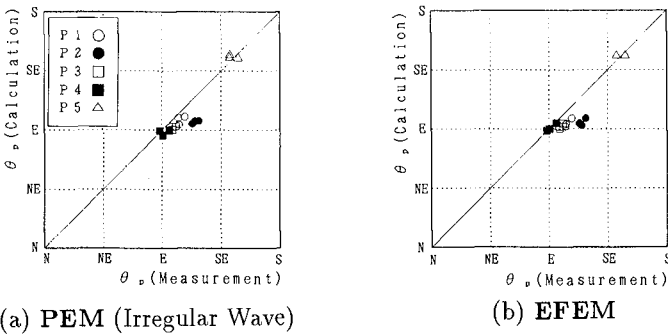

Fig. 5. Comparisons between the measured and the calculated principal directions.

extremely high resolution for a three sensor array. In this study, the pressure fluctuation measured by a pressure sensor and the two components of the horizontal water particle velocities measured by an electromagnetic current meter are used for estimating the directional wave spectrum. The directional spreading parameter  $S$  of the Mitsuyasu-type directional distribution function can be estimated as a function of frequency as follows (e.g. Isobe, 1988).

$$S(f) = \left( \frac{1}{\gamma(f)^2} - \frac{1}{2} \right) + \left( \frac{1}{\gamma(f)^4} - \frac{3}{4} \right)^{1/2} \quad (13)$$

The frequency-dependent longcrestedness parameter,  $S(f)$ , can be evaluated by eq.(14) and (15) and using the estimated directional spectrum.

$$\gamma(f) = \left\{ \frac{M_{20} + M_{02} - \sqrt{(M_{20} - M_{02})^2 + 4M_{11}^2}}{M_{20} + M_{02} + \sqrt{(M_{20} - M_{02})^2 + 4M_{11}^2}} \right\}^{1/2} \quad (14)$$

$$M_{pq}(f) = \int_{\theta_p - \frac{\pi}{2}}^{\theta_p + \frac{\pi}{2}} D(f, \theta) k^{p+q} \cos^p \theta \sin^q \theta d\theta \quad (15)$$

where  $\theta_p$  is the angle at the spectral peak.

Fig. 6(a) shows the observed frequency spectra and frequency-dependent directional spreading parameters under non-breaking wave condition with an incident significant wave height of 0.92 m and its period of 6.95 s, and (b) shows those under breaking wave condition with corresponding values of 3.21 m and 7.6 s. The frequency spectra observed at Point 3 and 4 in the nearshore region, have higher energy densities in both low and high frequency regions than those observed at Point 0. This tendency is remarkable under the severer wave condition as shown in Fig. 6(b). The high frequency fluctuations are due to wave breaking and the long-period motions are due to surf beats. Under the relatively calm condition, as shown in Fig. 6(a), the peakedness of directional wave spectrum increases owing to refraction at Point 3 near the harbor entrance compared with that at Point 0. On the contrary, as can be seen from Fig. 6(b), under the severe wave condition the peakedness does not increase. At Point 4 around the shoal, the peakedness does not increase owing to the intersection of wave rays under both conditions.

Fig. 7 shows the observed relations between the incident significant wave height and two ratios at the two points; one is the ratio of the significant wave height to the incident wave height and the other is the ratio of the directional spreading parameter of the peak frequency to that of the incident waves. Under the non-breaking condition where the significant wave height is below 2 m, at Point 3 near the harbor entrance as indicated schematically by the dash line, the peakedness of the directional distribution function increases owing to refraction compared with that of the incident wave. This can be usually seen in an area where the seabed topography has straight and parallel depth contours. At Point 4 around the shoal as illustrated by the solid line, the directional spreading parameter does not increase and is nearly equal to that of the incident wave, although

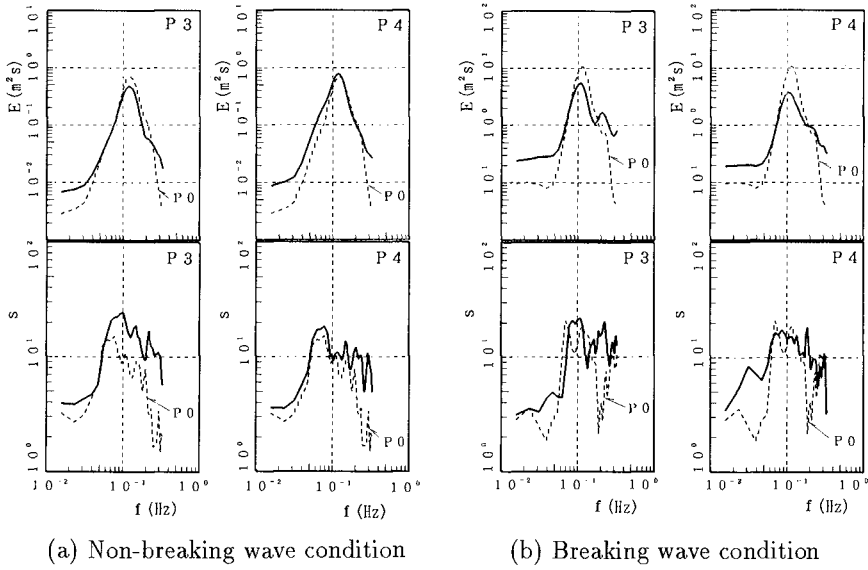

Fig. 6. Observed frequency spectra and frequency-dependent directional spreading parameters.

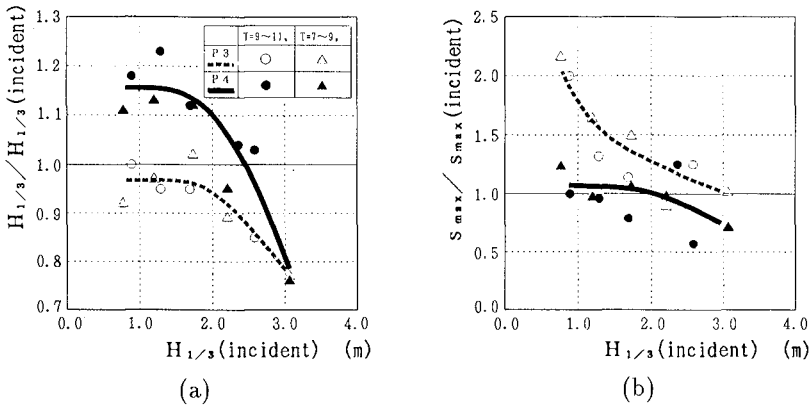

Fig. 7. Observed relations between incident significant wave height and two ratios; (a) the ratio of the significant wave height to the incident wave height and (b) the ratio of the directional spreading parameter of the peak frequency to that of the incident waves.

the wave height increases owing to refraction. In fact, because of the intersection of wave rays, the diffraction effect due to bottom topography occurs. Under the stormy wave conditions where the significant wave height is beyond 2 m, the directional spreading parameter at Point 3 decreases and is approximately equal to that at Point 4 around the shoal. This is supposed to be caused by wave breaking.

### Comparison between Calculations and Measurements

Fig. 8 shows comparisons between the measured and the calculated directional distribution functions which are integrated with respect to frequency. The calculations are conducted for the severest wave condition during the observation. The significant wave height is 3.5 m and the significant wave period 8.5 s. Under this condition, the observation points in the nearshore region were included in the surf zone. At Point 3 near the entrance of the harbor, both the results of the parabolic equation model and the energy flux equation model give larger peakedness than the measurements. At Point 4 behind the shoal, it is reproduced qualitatively that the calculated directional distribution functions have a smaller peakedness than those at Point 3. But the results of the energy flux equation model show better agreement with the measurements than that of the parabolic equation model. At Point 5 behind the breakwater, according to the results by the parabolic equation model, an extremely sharp directional distribution function is calculated of which the spectral peak direction is on a line from the tip of the breakwater to the observation point. The measured peakedness is, on the other hand, considerably dull and is close to the one calculated by the energy equation model. Although in the energy flux equation model diffraction cannot be taken into account, but the directional spreading is considered and there exists also a numerical diffusion especially in calculating the directional convection.

Fig. 9 shows the comparisons between the measured and the calculated frequency-dependent directional spreading parameter of the Mitsuyasu-type directional distribution function. Around the peak frequency of 0.12 Hz, the same tendencies are seen as shown in Fig. 8. It is a cynical result that the measured directional spectrum transformation in the nearshore region is reproduced seemingly better by the energy flux equation model, although the parabolic equation has theoretically good accuracy for calculating combined refraction and diffraction over a complicated bottom topography and behind a breakwater. There are some reasons for disagreement between the calculations by the parabolic equation and the field measurements in the surf zone. The first reason is that the parabolic equation model is based on the linear wave theory, but the actual waves are nonlinear in the surf zone. The second reason is that the energy dissipation model used in this study is a model for estimating the total energy transformation due to wave breaking and that the energy dissipation coefficient is assumed to be constant irrelevantly to the direction. Namely, it is assumed that the directional spectral shape does not change after wave breaking, which seems to be unrealistic. The other reason is that the method for estimating the directional wave spectrum is

$$G(\theta) = \int_0^\infty G'(f, \theta) df, D(f, \theta) = S(f) G'(f, \theta)$$

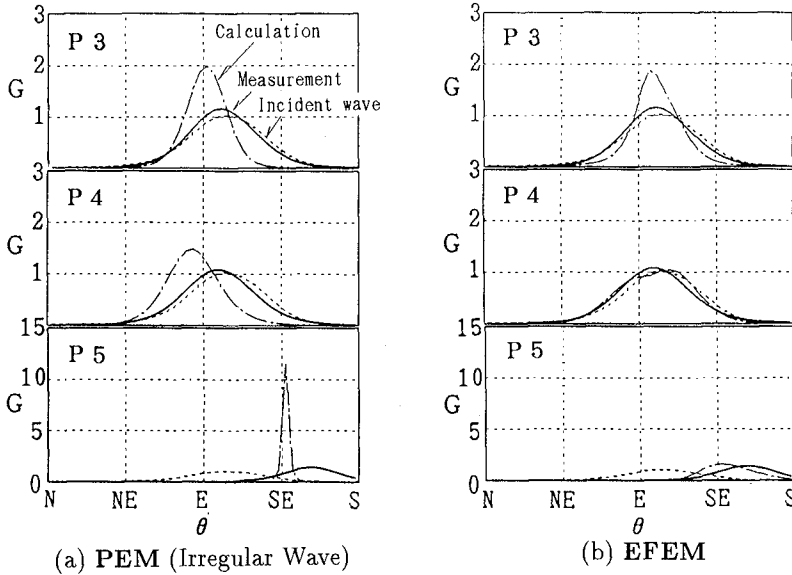

Fig. 8. Comparisons between the measured and the calculated directional distribution functions.

Fig. 9. Comparisons between the measured and the calculated frequency-dependent directional spreading parameters.

also based on the linear wave theory, and therefore, it does not have high resolution for data measured in the surf zone. Thus, there remains rooms for improving the estimation method of the directional spectrum by taking into account non-linearity of the actual sea state in the surf zone.

## INFLUENCES ON NEARSHORE CURRENT FIELD

Finally, we attempt to investigate the effects of the calculation results of the wave field on those of the wave-induced nearshore current field. Fig. 10 shows the results of the nearshore current calculations. The measured velocity vectors are also illustrated, but in a different scale from the calculated vectors. Fig. 10(a) and (b) show the results for regular waves and for random waves by the parabolic equation model and (c) shows the results by the energy flux equation model. In computing the nearshore current field of random waves, the radiation stress is evaluated as for a regular wave with the equivalent wave energy and the principal direction which are estimated from the calculated directional wave spectrum. The group velocity and the wave celerity are estimated by using the significant wave period.

The result for regular waves gives an extremely large spatial variation and a strong shoreward current is calculated around the shoal in accordance with the spatial variation in wave height. On the other hand, the calculations by both

(a) PEM (Regular Wave)

(b) PEM (Irregular Wave)

(c) EFEM

Fig. 10. Calculated current fields.

models for random waves show relatively smooth current fields. The observed dominant current pattern is reproduced satisfactorily. Thus, the current field calculation results are not so sensitive to the difference in the wave field calculation results if random waves are treated in the wave calculation model.

## CONCLUDING REMARKS

The parabolic equation model and the energy flux equation model are applied to the calculation of the actual wave field over a complicated bottom topography and their field applicabilities are investigated through comparisons with the field data. As a result, it is found that both the parabolic equation model and the energy flux equation model are applicable for practical use and that the former has extremely good accuracy for estimating the wave energy transformation over a shoal, where the increase in wave height due to refraction and the diffraction effect due to bottom topography occur, as well as behind a breakwater. The transformation of directional wave spectra due to refraction and diffraction in the surf zone can be reproduced qualitatively by the parabolic equation model, but the observed directional spectra show smaller peakedness of the directional spreading function than the calculated ones. The observed spectra can be estimated better by the energy flux equation model. This is, however, a seeming agreement due to numerical diffusion. In order to properly estimate the transformation of directional wave spectra, it is necessary to accumulate further field data in the surf zone with good accuracy. It is also needed to develop a wave transformation model in which wave nonlinearity can be taken into account.

## CHAPTER 45

### Bottom Shear Stresses in the Boundary Layers under Waves and Currents crossing at Right Angles

Richard R.Simons<sup>1</sup>  
Tony J.Grass<sup>2</sup>  
Mehrdad Mansour-Tehrani<sup>3</sup>

#### Abstract

This paper describes a two year experimental research programme investigating the influence of non-linear wave-current interactions on wave and current characteristics. The tests focus on the mean and oscillatory velocity components and shear stresses within the bottom boundary layer over a rough bed for cases where waves propagate at right angles to the line of the current flow. Bed shear stresses have been measured directly by means of a novel shear plate device. The aim of the research is to generate a reliable data set for use by modellers.

Results show that currents experience a significant change both in mean bed shear stress and apparent bed roughness when waves are superimposed. However, the oscillatory, wave-induced, bottom shear stress has been shown to be insensitive to the addition of an orthogonal current.

#### Introduction

Recent years have seen the development of many mathematical models for predicting the boundary layer characteristics of combined wave-current flows and hence sediment transport along and across the coastline. However, the proliferation of models has not been matched

by the availability of experimental results against which they can be validated, particularly at large scale and where waves propagate orthogonally or at arbitrary angles to the current.

Published field data which include combined wave-current conditions generally lack sufficient control over the main parameters to provide a reliable basis for model calibration. Laboratory experiments on wave-current interaction have most often considered only the case of colinear waves and current (for example, Bakker and van Doorn (1978); Brevik and Aas (1980); Kemp and Simons (1982), (1983); Simons et al. (1988)). This situation matches that found in estuaries and in some offshore regions, but contrasts with the condition frequently occurring along many coastlines where waves propagate directly on-shore, over a longshore current. Only Bijker (1967), and more recently Visser (1986), Arnskov et al. (1991), and Sleath (1990), have considered this more complex, but extremely important, orthogonal case. Bijker's tests were restricted to measurements of shear stress deduced from observations of water surface slope in an orthogonal wave-current field, and his instrumentation was unable to determine velocity profiles above the bed. Arnskov's tests were restricted to flows over a smooth boundary and are thus hard to extrapolate to real coastal engineering situations where the bed is invariably rough, and frequently rippled. Sleath's tests were performed over a variety of rough boundaries, and he simulated waves crossing a current at right angles by oscillating a section of roughened bed across the line of a unidirectional current flowing along a laboratory flume.

Another shortcoming of earlier data has been that shear stresses have had to be implied, from nearbed velocity profiles, water surface slopes, or wave attenuation, rather than from direct measurement. It is the aim of this paper to fill a gap in existing data by providing direct measurements of bottom stress and velocity field under laboratory conditions for a range of combined waves and currents crossing orthogonally.

### Wave Basin

The experiments were performed in a wave basin approximately 20 m square, designed for a water depth of 1.5 m but with a raised central test area, 9 m by 6 m, over which the still water depth was just 700 mm. This plateau area was installed specially for these tests, and was coated with a fixed layer of sand (nominal diameter of 2 mm) to produce a uniform rough boundary.

Ten ram-type wave generators were mounted along one

wall of the basin, the other three walls supporting permeable beach units 2.5 m long at a slope of  $15^\circ$ . Each ram could be operated under independent control to generate waves with periods between 1 s and 3 s, and with heights up to 300 mm.

Currents were introduced through a set of gate valves under the beaches in one of the side walls, flow being removed through a corresponding set of openings in the other side. The current strength was controlled by adjusting the speed of a pump which circulated water through a 2-compartment channel round the perimeter of the basin. For the tests described here, three current conditions were investigated: zero mean flow (wave alone), 125 mm/s, and 200 mm/s.

### Shear Plate Device

A vital element in the programme was the ability to make direct measurements of shear stress applied to the bed by the wave-current flow above. Very few attempts have been made to design such a device in the past, mainly because of the high sensitivity required to resolve the small forces involved, and the difficulty of reducing the wave-induced pressure gradient effect on the vertical faces of the structural elements. The most important results reported from such a device are those of Reidel & Kamphuis (1973), who measured friction factors for a rough boundary under a wide range of wave conditions in a two-dimensional laboratory flume. Oebius (1982) has also developed an instrument intended for deployment in the field under mobile bed conditions, while Arnskov et al. (1991) have used a hot film technique to measure shear stresses on a smooth bed.

The main criteria to be satisfied by the shear plate device during the present project were that it should be capable of measuring a 2-dimensional horizontal force vector varying rapidly in magnitude and direction, have sufficient sensitivity to resolve the relatively small shear stresses induced by the mean current, have the range to follow large wave-induced oscillatory stresses, have a surface area small enough relative to the length of a wave in the basin that spatial averaging would not significantly reduce the recorded peak oscillatory stress, have a sufficiently high natural frequency relative to the "forcing" wave frequency that inertial phase lag and resonant vibrations would be negligible, remain co-planar with the surrounding bed during test conditions, and tolerate the presence of sediment and debris in the water.

The design adopted consisted of a 0.9 mm thick, circular disc (250 mm diameter), supported on four tubular

columns, mounted flush with the surrounding bed, and deflecting sideways in a sway motion under the action of any lateral force. A clearance of under 0.5 mm was allowed between the circumference of the plate and the adjoining bed, imposing a physical constraint on the maximum possible deflection of the plate, and thus also on the measurable force for any given structural stiffness.

The horizontal displacement of the plate was measured by two eddy current transducers mounted orthogonally under the bed and positioned to monitor the movement of a small target block attached to the centre of the plate. These devices had a sensitivity of just over 0.1 microns, and operated with a working clearance of 1 mm.

Because of the finite length of the waves under test, there was a horizontal pressure gradient across the bed of the basin which exerted a significant force on the edge of the active shear plate. Although the plate was made as thin as possible to minimize the effect, pressure on the edge still contributed a significant proportion to the total force observed. The correction procedure adopted for these tests involved deducing the pressure gradient from direct measurements of orbital velocity (and hence acceleration) just above the oscillatory boundary layer. The edge force was calculated by dividing the plate into 1000 sectors, determining the radial force on each at discrete phases through the wave cycle, resolving this force into the direction of wave propagation, and integrating round the circumference.

To check whether the pressure correction was adequate, and to determine whether the shear plate was capable of measuring shear stresses to sufficient accuracy under oscillatory flow conditions, a set of preliminary tests was carried out in a wave flume. These tests were performed over a smooth bed, using a smooth active plate, for a range of wave periods between 1.0s and 1.35s. The smooth bed provided conditions for which there is a reliable theoretical solution for amplitude and phase of the bottom shear stress - calculated from the orbital velocity just outside the viscous-dominated oscillatory boundary layer.

The measured force was corrected for edge pressure, and the resulting shear stress plotted out with the theoretical shear stress and the orbital velocity through the wave cycle (**fig.1**). Bearing in mind that the edge pressure effect corrected for was generally far greater than the shear stress sought, there was remarkably good agreement between theory and experiment, with errors between 1% and 15%. This was felt to be satisfactory, as the shear stresses induced at the rough boundary in the main test programme were almost an order of magnitude

Fig.1 Pressure correction test for waves alone over a smooth bed: measured shear stress plotted with theoretical curve through a wave cycle.

greater than those at the smooth bed.

### Velocity Measurements

To determine the velocity field in the complex three-dimensional flow, measurements were made using an ultrasonic flow meter which yielded three velocity components simultaneously. The transmitters on this instrument "pinged" at 100Hz, giving a response time of 1/30s and a resolution of 1mm/s in a range up to 1 m/s. However, while it was ideal for determining the instantaneous velocity vector in the upper flow, its size (with a measuring volume 15 mm in diameter) meant that it was unable to provide detailed information within the relatively thin wave boundary layer.

Velocities close to the bed were measured with a fibre-optic laser anemometer supported by a vertical traversing device on the overhead gantry. The measuring volume was some distance away from the optical fibre probe, and thus provided a relatively non-intrusive means of determining velocities. Tests using the LDV had to be carried out twice in order to obtain all 3 velocity components. The main set of tests had the optical fibre

head set up pointing vertically downwards at the bed to measure the two horizontal components of velocity. Tests were then repeated with the optics pointing into the current, close to horizontal, so as to measure horizontal and vertical components of wave-induced velocity.

### Other Instrumentation

Wave characteristics were monitored by 16 resistance-type wave probes mounted in a rectangular grid pattern (spacing 0.5m by 0.66m) from an overhead gantry over the test area. Data from all the instruments (water surface, shear plate, anemometers) were recorded synchronously through a 32-channel data logger directly onto computer disc, together with a signal from the wave generators.

### Results

27 different wave/current conditions were tested from combinations of four wave periods [1.1s, 1.5s, 2.0s, 2.5s.], wave heights in the range 80 mm to 190 mm, and 700.

Table 1: General test parameters: water depth = 700mm.

Mean velocity profiles of the two currents on their own took a form typical of most turbulent boundary layers, following a logarithmic curve through the near-bed region (within 100mm of the bed), with velocities continuing to increase but more gradually above this level up to the water surface. However, when waves were superimposed, running orthogonally to the direction of flow, there was a significant reduction in mean velocity in the upper flow, matched in most cases by an increase in the lower half of the flow (**fig.2**). This effect was most pronounced for the waves with longest periods (1.5s, 2.0s, 2.5s) and greatest heights, whereas the 1.1s period waves showed little change in general profile shape.

When plotted out on log-linear axes, the profiles revealed that the apparent bed roughness  $z_A$  was increased, in some cases by more than a factor of 20 times its value for current alone. The mean bed shear stress was also increased by the addition of wave action (**Table 2**).

Table 2: Wave-current tests: mean flow parameters

As the shear plate was set up during these tests to measure the large oscillatory shear stresses induced by the wave action, relatively small mean stresses caused by the mean current were difficult to determine precisely. Nevertheless, the values obtained from the combined wave-current tests, when substituted into the "Law of the Wall", suggest that the von Karman constant  $\kappa$  lies between 0.30 and 0.50 - a wide range, but probably acceptable in view of the experimental difficulties involved in measuring both

the mean velocities and the shear stress.

Table 1 listed the basic characteristics of the waves used for each test run. All the waves lay in the "intermediate" zone, although the 1.1s period waves were close to "deep water" conditions, and the 2.5s periods approached "shallow water" status. It should be noted that the reflexion coefficients were found to be very high in many of the tests - an inevitable consequence of using waves with a length far greater than that of the absorbing beaches round the perimeter of the basin.

The most interesting tests as far as the main objective of the research was concerned were those inducing significant shear stresses at the bed of the basin. These tended to coincide with tests involving waves with the longer wave periods and lengths, and hence also with high reflexions. However, this was not considered to be a serious problem, as the majority of wave-current theories are based on the interaction of a plane oscillatory flow with a current - and a standing wave pattern induces just such a plane oscillatory flow at the bed (albeit a spatially varied one).

Data analysis included a correction to the oscillatory shear stress measurements to account for the effect of wave-induced pressure gradients at the bed of the basin. Its effect is relatively greater for the short period waves. Sleath (1991) has pointed out that an equivalent force also acts on each sand grain at the bed, and this has been taken into account in the present work.

Results from the tests with wave alone (**fig.3**), and those with waves and currents combined (i.e. **fig.4**), both showed that the oscillatory shear stress, after correction, always peaked approximately  $30^\circ$  before the orbital velocity. Another important observation was that the maximum shear stress was relatively unaffected by the superposition of a turbulent current - either strong or weak (see **Table 3**). This contrasted with the significant effect the addition of waves had on the properties of the currents.

### Discussion

Considering first the changes caused to the mean current profiles by the superposition of waves, the additional resistance experienced in the upper flow is something that has been reported in earlier papers on wave-current interaction (Kemp & Simons, 1982; Bakker & van Doorn, 1978). However, it is an effect not included in any of the present generation of mathematical models purporting to describe the wave-current process. The most likely

Table 3: Oscillatory boundary layer parameters.

explanation is that additional Reynolds stresses are set up by the wave-induced orbital velocities, and these may be interacting with the mean current.

The increase in apparent bed roughness implied from the log-linear velocity profiles was qualitatively as predicted by all wave-current models, and, when compared with the predictions of Sleath (1991), there was good agreement in many cases. However, some of the values were found to be considerably lower than predicted by the theory, the greatest discrepancies occurring for waves with the shortest wave periods and the lowest amplitude Reynolds numbers.

Again, the increase in mean shear stress observed when waves were added to the current was as predicted by theory, and similar to that observed by Sleath (1990) in experiments on flow over an oscillating plate. It is also very much in line with that found by other researchers for a wide variety of test conditions including both field and laboratory tests.

Fig.5 Variation of wave friction factor with relative bed orbital amplitude for different wave-current combinations.

Turning now to the effect the addition of currents has on the wave characteristics, the most important finding of the work is that the maximum oscillatory bed shear stress appears to remain virtually unaltered, irrespective of the strength of the superimposed current. This is demonstrated in **fig. 5**, where friction factors calculated from the maximum shear stresses under waves with and without currents are plotted out against relative orbital excursion at the bed,  $a/k$ . The tendency for observed friction factors to move above the theoretical predictions as  $a/k$  decreases may be due to some uncertainty about the velocity measurements by which they have been normalized. The effect may also relate to lower Reynolds numbers lying in the transitional rough regime where the Nikuradse roughness may vary from that determined in the tests on current alone.

The authors are presently analysing field data from a site off the south coast of Australia where conditions generally meet the criterion that waves propagate orthogonally across a coastal current (Black et al. (1992)). When available, those results will complement the present laboratory data.

### Conclusions

Currents experience a significant change both in mean bed shear stress and apparent bed roughness when waves are superimposed and propagate orthogonally across it. However, under the present test conditions, the oscillatory, wave-induced, bottom shear stress is insensitive to the addition of an orthogonal current.

## CHAPTER 46

### The Effect of Sheared Currents on Wave Kinematics and Surface Parameters

D.J.Skyner<sup>1</sup> & W.J.Easson<sup>2</sup>

#### ABSTRACT

Steep, steady non-linear waves have been generated onto strongly sheared currents. Quantitative, full-field velocity measurements have been made for a number of wave/current combinations using the method of Particle Image Velocimetry (PIV). For one of the combinations, the measured kinematics are compared to the estimate obtained by adding the stretched current profile to the predictions from irrotational theory. The steadiness of the conditions is assessed by calculating the vorticity distribution for different cycles in the wavetrain. Finally, the measured wavelengths for a range of wave frequencies are used to estimate the effective current.

#### INTRODUCTION

Knowledge of representative wave kinematics is crucial in the understanding of coastal processes and the design of offshore structures. Often, waves ride on top of steady currents, generated by the tides or the wind, and it is important that the combination of the kinematics in these cases can be understood and predicted.

High-order methods have been used for some time to predict the properties of steep waves, in the absence of current, and have been extensively verified by laboratory studies. On a uniform current the combined wave-current kinematics can be calculated by changing reference frame to one moving with the current and using a high-order model, after Doppler shifting the wave frequency. Several authors have recently tackled the problem of steep waves on currents of an arbitrary profile [Dalrymple and Heideman, 1989, Chaplin, 1990] and have implemented numerical models, but experimental studies are still rare.

Swan [1990] produced moderate amplitude waves on strongly sheared currents and addressed some of the difficulties posed by Dalrymple and Heideman in

their cautionary note on tank testing. Other notable experiments include those of Thomas [1990], where good agreement was obtained between laboratory measurements and numerical predictions for weakly sheared currents, and Kemp and Simons [1983] whose study concentrated on the effects near the bed.

There is a severe experimental difficulty encountered when measuring currents with non-uniform profiles near the surface, in the presence of waves. Whichever end of the flume the currents are injected from, the wave action will ultimately disturb the formation of the upper part of the profile. One solution to this problem is to make the measurements of the combined kinematics during the short time window once the waves are established, but before the current formation is affected and reflected waves return. However, even with this approach the steadiness of the conditions must still be questioned.

## EXPERIMENTAL CONDITIONS

Experiments were performed in a purpose built wave flume, depth .75m, capable of producing forward or reverse currents with various profiles. The experimental arrangement is shown in figure 1.

Figure 1: Wave flume used for the kinematic measurements

The main current profile required for the experimental programme was one which was strongly sheared in the direction of wave propagation. The current was generated by introducing a flow opposed to the waves along the bottom half of the flume. In the subsequent analysis, the bulk value of the current was altered to yield the desired profile in the chosen reference frame, and the wave frequency modified with the appropriate Doppler shift. If the frequency in a given frame is  $f_1$ , then the frequency measured in a second frame, moving with velocity  $u$  compared to the first, is given by

$$f_2 = f_1 - \frac{u}{\lambda} \quad (1)$$

The most strongly sheared current profile used in the tests is shown in figure 2, along with the rms turbulence level. The profile has an approximately linear form,

Figure 2: Current profile, sheared in the direction of wave propagation, used in the experiments

velocity gradient  $0.427\text{s}^{-1}$ , in the top half of the water depth and was shifted to a frame of reference moving at  $-0.3\text{ms}^{-1}$  when analysing the combined kinematics. The form of the current near the bed should be disregarded when assessing the profile, as the wave action in this region is small.

## EXPERIMENTAL MEASUREMENTS

In the experimental test sequence, steep waves were run onto the current and kinematic measurements made once the waves were steady and before reflections came back. In addition, estimates of the wavelength were obtained from wavelength records at different positions in the tank and from the photographs of the flow.

The combined kinematics were measured by the method of Particle Image Velocimetry (PIV), in which small seeding particles are multiply exposed by a pulsed light sheet in the flow and their images recorded onto film. From the separations of the images in each part of the film the local velocity at that location can be deduced, and hence the complete flow field established. Further details of the use of the technique in this and other hydrodynamic studies are described in Greated et al [1992].

A typical flow field measured in the study is shown in figure 3 as a vector

Figure 3: Internal kinematics of a wave on a sheared current measured with PIV

plot. Measurements were achieved up to the surface, and the measurement error was typically less than 2% of the maximum velocity, depending on the velocity gradients present. The missing data in the central part of the wave corresponds to a region of near-zero velocity in the flow, where the crest kinematics of the wave and the opposing current produce an instantaneous stagnation point. This results in overlapping particle images on the PIV photograph, whose separations cannot be resolved. Measurements could be made in this region by using an image shifting technique [Bruce,1992].

For the strongly sheared current, six wave conditions, were studied in detail. These wave cases covered a range of steepnesses ( $H/\lambda$ ) from .054 to .098, and a range of water depth to wavelength ratio ( $h/\lambda$ ) from .27 to .57. Results for these wave cases and other current profiles have been reported by the authors [Skyner,1992,1993]. The results presented here are for the central wave case on the strongly sheared current ( $H/\lambda=.0729, h/\lambda=.412$ ).

Figure 4: Horizontal velocity profiles under the crest, for a wave on a strongly sheared current. -●- experimental data, with scatter, - - - undisturbed current, — — irrotational numerical model, ——— prediction from numerical model and stretched current profile

## MEASURED KINEMATICS

The experimentally measured horizontal velocity profiles under the crest for the central wave condition, in the presence of the strongly sheared current is plotted in figure 4, along with numerical predictions. The graph contains the undisturbed current profile, the velocity profile under the crest for the combined flow, a numerically generated profile for an irrotational wave with the same height and wavelength, and the numerical data combined with the stretched current profile. The irrotational numerical data was generated by a program based on the Fourier approximation method of Riencker and Fenton [1981]

The method used for obtaining the combined kinematics was that recommended by the UK Department of Energy [1990], when a complete wave/current model is not available. The current value at a given height above the bed is moved to a new location by multiplying the distance from the bed by the factor  $(1 + C_N/h)$ , where  $C_N$  is the crest elevation, obtained numerically, and  $h$  the water depth. The recommendation is that no attempt be made to conserve the total mass flux of the current when stretching.

For wave case being considered, a composite vector map was constructed from flow records at different phases, in order to obtain information over a complete wavelength. From this data the average horizontal velocity component was obtained at various levels, and the results are plotted in figure 5. A significant reduction in the average shear is apparent, greater than that which would be

expected if the assumed current stretching applied over the whole wave, when the shear would decrease in the crest but increase in the trough, leading to an average value only slightly less than the undisturbed current value.

Figure 5: Mean horizontal velocities for medium steepness waves on a strongly sheared current.

### Derived Vorticity

Calculating vorticity from the experimentally measured flow fields is a profitable exercise because it separates the irrotational part of the motion, associated with the wave, from the rotational part, associated with the sheared current. It is possible to extract vorticity from the data obtained with PIV, because the velocity field is known over two spatial dimensions. The vorticity component perpendicular to the measurement plane is

$$\Omega_y = \frac{\partial u_z}{\partial x} - \frac{\partial u_x}{\partial z} \quad (2)$$

A reasonable estimate for the local vorticity can be obtained by numerically differentiating the velocity data, which is available on a regular grid. In order to reduce the effect of turbulence and reveal the underlying trends, the velocity fields obtained from a number of repeats of each wave phase were averaged before calculating the vorticity.

Figure 6 contains a shaded contour plot of vorticity, obtained from the repeats of the flow field illustrated in figure 3. Light areas corresponds to negative vor-

ticity (forward shear), and dark areas to positive vorticity. The blank area in the centre of the wave is due to missing data, no attempt been made to interpolate.

Figure 6: Vorticity contours for the average of 6 repeats of a medium amplitude wave on the strongly sheared current, *first* wave crest. Contour line interval:  $0.5s^{-1}$

Comparison with the undisturbed current profile shown in figure 2 reveals that the vorticity field has the expected features. The bed boundary layer is present as strip of high positive vorticity, and there is a major transition from positive to negative vorticity at around  $z = -0.4m$ . Apart from the small pockets of turbulence, the vorticity in the upper part of the wave is fairly constant with an average value between  $-0.3s^{-1}$  and  $-0.4s^{-1}$ .

The available time window for the kinematic measurements of the wave case

being considered corresponded to four wave periods. This portion of the wave elevation timeseries is shown in figure 9 as a continuous trace. The kinematic measurements presented here are for the first wave crest in this “steady portion” of the wavetrain at  $t = 12.4s$ . PIV measurements were also made for the third and fifth crests in this portion.

Figure 7: Vorticity contours for the average of 6 repeats of a medium amplitude wave on the strongly sheared current, *third* wave crest. Contour line interval:  $0.5s^{-1}$

Figure 7 contains the vorticity levels found in the third crest of the steady portion of the wave train. While the vorticity distribution is similar to the earlier cycle of the wave in the middle and lower parts, sizable areas of positive vorticity have appeared near the surface.

In figure 8 the areas of positive vorticity near the surface have increased still further compared to the previous cycles of the wave. The position of the crest is also noticeable retarded compared to its expected position in the middle of the plot.

Figure 8: Vorticity contours for the average of 6 repeats of a medium amplitude wave on the strongly sheared current, *fifth* wave crest. Contour line interval:  $0.5s^{-1}$

Figure 9 also shows the average vorticity estimated for the top half of the wave (above  $z = -0.4m$ ). These values were calculated for each available wave crest by averaging the vorticity data, shown in figures 6 to 8, with no attempt being made to interpolate missing values. A clear trend is apparent, with the average vorticity moving away with time from the undisturbed current value towards zero.

This is equivalent to a decrease in the shear of the underlying current.

Figure 9: Average vorticity value obtained for different crests in the wavetrain, along with the wave elevation timeseries where the continuous trace represents the "steady" portion of the wave

## Wavelength

The measured wavelengths for the cases selected for the kinematic measurements were found to correspond, within experimental error, to those predicted from irrotational theory, given the wave height and wave frequency, after Doppler shifting the frequency to a frame moving with the surface current. From a sequence of tests, sweeping through a range of frequencies of small amplitude waves, the effective current was calculated from the measured wavelength using Doppler theory. The uniform current with the equivalent effect on the wavelength is plotted against wave frequency in figure 10. The values of the surface current and the current at half the depth are also shown.

## DISCUSSION

The estimate for the kinematics made by adding the stretched current to irrotational predictions assumed that the underlying current was not effected by the wave action, other than by being stretched according to the phase of the wave. However, calculation of the vorticity for different cycles in the "steady" portion

Figure 10: Equivalent uniform current velocity deduced using Doppler theory from measured wavelength on sheared current

of the wave train indicates that the rotational part of the fluid motion is changing with time. This may be due to the presence of turbulence influencing the wave/current interaction. However, the presented results should be viewed with some caution, as although care was taken in the experiments when establishing the wave train that the leading wave did not break, it is possible that interactions occurring at the front of the wave group may have been advected back to the measurement zone, effecting the later wave cycles.

## CONCLUSIONS

For the conditions considered, the kinematics in the crest were found to be well predicted by combining the results of an irrotational, high-order numerical model with the stretched current profile. In addition, it was found that the wavelength was accurately predicted using irrotational theory, after Doppler shifting the wave frequency to the frame of reference of the surface current. However, there was strong evidence that the conditions were not steady, particularly the change in the vorticity field between the cycles in the wave train.

## ACKNOWLEDGMENT

The authors would like to thank G. Klopman, of Delft Hydraulics for allowing the use of his numerical model in this study, and the UK Department of Energy who funded the majority of the work.

## CHAPTER 47

### LABORATORY STUDY OF WAVE TRANSFORMATION ON BARRED BEACH PROFILES

Ernest R. Smith<sup>1</sup> and Nicholas C. Kraus<sup>2</sup>

**ABSTRACT:** In previously reported laboratory experiments, the authors found that incident waves with the same characteristics in deep water break differently on barred and plane-sloping beaches. For example, waves of greater steepness that plunge on plane beaches tend to collapse on barred beaches, and plunge distance on barred profiles is about half that on a plane sloping beach for a given wave steepness. In the present study, wave height transformation, reflection, and runup of monochromatic and random waves are investigated for barred and plane beach profiles in a wave tank, with deep-water wave steepness varied from 0.0085 to 0.09. For monochromatic and random waves, wave-height to water-depth ratios are higher for waves breaking on bars, whereas just seaward of breaking these ratios are lower than on a plane beach. For plane and barred beaches, the ratios unite in the inner surf zone, and the magnitude and shape of wave spectra are the same at fixed points outside and inside the surf zone, except just shoreward of the break point, where the spectrum on a barred profile has the same shape but contains less energy. Despite differences in breaker-related quantities on barred and plane beach profiles, runup, reflection, and wave height transformation in the surf zone on barred profiles are mainly controlled by the plane beach slope on which the bar or reef is located, with only minor influence by a bar, even for extremely-shaped obstacles such as reefs.

#### INTRODUCTION AND BACKGROUND

Most laboratory studies on wave transformation, runup, and reflection have been conducted on plane sloping beaches. In the field, however, linear bars are common, and waves will transform differently over barred profiles as compared to plane beaches. To elucidate these differences, the authors conducted an extensive laboratory study to examine breaking and broken wave properties on barred and terraced profiles, and the results were compared to those obtained for plane slopes. Results determined from video records were

presented in Smith and Kraus (1991) and in a report (Smith and Kraus 1990) that covers the experiment procedure and results. The present paper focuses on selected results determined from the digital wave gage data, and some analyses from the project report are extended.

As motivation, we consider breaker type and plunge distance on barred and plane slopes (Smith and Kraus 1991). Galvin (1968) expressed breaker type transition values in terms of beach slope  $m$ , wave height  $H$ , and wave period  $T$ . Battjes (1974) re-expressed the transition values in terms of the surf similarity parameter,  $\xi_o = m(H_o/L_o)^{1/2}$ , in which  $H_o$  and  $L_o$  are wave height and wavelength in deep water, respectively. Smith and Kraus observed different transition values of breaker type on single-bar profiles than determined by Battjes for plane slopes. Transition values between breaker types on barred profiles and plane slopes are shown as a function of  $\xi_o$  in Fig. 1. Transition values are lower for barred profiles, which means some waves that would spill on a plane slope plunge if a bar is present, and some plunging waves on plane slopes collapse on a barred profile.

Plunge distance  $X_p$  of breaking waves differs on plane and barred beaches (Smith and Kraus 1991). Fig. 2 plots plunge distance normalized by breaker height  $H_b$ , and the visually fit solid line for barred profiles as a function of  $\xi_o$ . The dashed line represents the predictive equation for plane slopes determined by Smith and Kraus. Plunge distance was 60 to 70 percent shorter over bars than over plane slopes. Differences in breaker height and depth, and splash distance between plane slopes and barred profiles were also found. On the basis of these findings, in the present work, the digital data of water surface elevation are examined to investigate wave transformation, runup, and reflection on barred and terraced (shelf) profiles, and the results are compared to those for plane sloping beaches.

## PROCEDURE

Data collection was conducted in a 45.70-m-long, 0.46-m-wide, and 0.91-m-high glass walled tank (Fig. 3). The tank contained a 1 on 30 smooth concrete-capped slope, which was separated from the wave generator by a 21-m-long horizontal section. Monochromatic and random waves were produced by an electronically controlled hydraulic system that drove a piston-type wave board. Water surface elevation was recorded at eight double-wire resistance-type gages. Gage 1 was located 9.1 m from the wave generator, Gages 2 and 3 were placed seaward of the bar and positioned to measure wave reflection according to the method of Goda and Suzuki (1976), Gage 4 was placed at the incipient break point, and Gages 5 through 8 were distributed through the surf zone. The water surface elevation was analyzed to obtain statistical wave heights and periods, and spectra.

Deep-water wave steepness  $H_o/L_o$  in part controls breaking wave characteristics. Therefore, it was desirable to generate waves with a wide range of steepnesses. A fixed water level (0.38 m) was maintained in all tests and allowed generation of relatively high waves while minimizing the effect of surface tension. Five design monochromatic wave conditions were selected ( $H_o/L_o = 0.09, 0.07, 0.05, 0.03, 0.0088$ ) through consideration of a diagram given by Galvin (1970, his Fig. 8) for delineating domains where periodic waves, single and multiple solitons, and breaking waves exist to obtain periodic breaking waves without contamination by soliton generation. Three random wave conditions were also developed from an input JONSWAP spectrum for spectral peak periods  $T_p$  of 1.0, 1.5, and 1.75 sec, with significant wave heights  $H_s$  of 11.3, 14.3, and 13.7 cm, respectively, in the horizontal section of the tank.

Fig. 1. Breaker type classification for plane and barred slopes (Smith & Kraus 1991)

Fig. 2. Plunge distance on plane and barred slopes (Smith & Kraus 1991)

Submerged solid triangular-shaped objects were installed on the 1-on-30 slope to represent natural barred profiles, terraced profiles, and artificial reefs. The geometry of the objects was selected based on large wave tank studies and field measurements of bars (Larson and Kraus 1989). Seaward bar angles  $\beta_1$  varied from 5 to 40 deg, and shoreward angles  $\beta_2$  ranged from 0 deg (terrace) to 40 deg. The steeper seaward angles were included to observe breaking waves on shapes that approximate those of submerged breakwaters or reefs. The size and placement of the bars were determined based on findings of Larson and Kraus.

Bars used in the study were constructed of marine plywood, with the seaward and shoreward faces connected with strap hinges. For longer bars, legs were attached under the structure to minimize flexing of the faces due to wave action. Openings created at the crest by the seaward and shoreward faces and the sides of the bar against the tank wall were sealed to maintain a flush surface and minimize leakage. Steel plates were installed under the bar to prevent it from floating or moving when subjected to wave action.

Wave data were collected for 2 min at 50 Hz for monochromatic-wave tests, but only 15 successive waves were analyzed. The analyzed portion of the record began after waves reflected off the concrete slope and ended before reflected waves from the board had returned to the bar. This procedure eliminated contamination of the data by waves reflected off the board, yet simulated the natural reflection of waves by the beach and bar or reef. Random waves were recorded at 20 Hz and analyzed for 500 waves. Because the wave height and period varied, a long record was required to obtain a statistically strong confidence interval for the wave spectrum. Reflection and re-reflection between the beach and the wave board could not be avoided in the random-wave tests.

In summary, 108 tests were performed with regular waves, of which five tests were with a plane slope, and 12 tests were performed with random waves, of which three tests were with a plane slope. Table 1 summarizes the design test conditions. The table shows nominal values for design which were approximated in actual tests.

## RESULTS

### Wave Reflection

Miche (1951) developed a theoretical relation for the reflection coefficient  $K_r$  for smooth plane slopes. He assumed the reflected portion of wave energy corresponded to a critical deep-water wave steepness  $(H_o/L_o)_{cr} = (2\beta/\pi)(\sin^2\beta/\pi)$  in which  $\beta$  is the slope angle. Miche defined the quantity  $(H_o/L_o)_{cr}$  as the wave steepness to obtain complete reflection, and wave energy that exceeded this value was assumed to be dissipated. Wave reflection was expressed as  $K_r = (H_o/L_o)_{cr}/(H_o/L_o)$  if  $H_o/L_o > (H_o/L_o)_{cr}$ , and  $K_r = 1$  if  $H_o/L_o < (H_o/L_o)_{cr}$ . Miche stated that actual reflection coefficient values would be lower than theoretical values because of viscosity and roughness, and recommended a multiplicative factor of 0.8 to calculate reflection coefficients for smooth, plane slopes.

Battjes (1974) re-expressed the equation of Miche (1951) to obtain  $K_r$  as a function of the surf similarity parameter:

$$K_r = 0.1\xi_o^2 \quad (1)$$

Reflection coefficients calculated from wave data at Gages 2 and 3 are shown as a function of  $\xi_o$ , using  $\beta_1$  as input, in Fig. 4. Also shown are the predicted values of Miche and Battjes, using the reduction coefficient of 0.8. The data are scattered and show overlapping

of values for different seaward bar angles. Values obtained by the Miche equation produce a steep curve that approaches a perfectly reflected wave for bar and wave conditions if  $\xi_o \approx 1$ . The Battjes equation underpredicts the measured  $K_r$  at low values of  $\xi_o$  (including the plane slope data), and overpredicts  $K_r$  at higher  $\xi_o$  values. In general, the data show near constant reflection, whereas the Miche and Battjes equations give increasing values of  $K_r$  with increasing  $\xi_o$ . Measured  $K_r$  were also compared to the Miche and Battjes predictions using the 1/30 plane slope to calculate  $\xi_o$ , but both equations gave significantly lower values. Neither the equation of Miche nor that of Battjes estimates  $K_r$  well for barred profiles over the range of  $\xi_o$  values. These equations were developed for plane slopes and, as Fig. 5 illustrates, are not valid if the bottom topography is irregular.

Seelig and Ahrens (1981) developed an equation to determine  $K_r$  for plane smooth slopes, plane beaches, and breakwaters, as

$$K_r = \frac{\alpha}{1 + \frac{\chi}{\xi_o^2}} \quad (2)$$

in which  $\alpha$  and  $\chi$  are empirical coefficients, and equal to 1.0 and 6.2, respectively, for plane smooth slopes. The recommended values of Seelig and Ahrens were used in Eq. 2 to compare to the measured plane-slope  $K_r$  values, but the equation greatly underpredicted the measured values. However, for our data, Eq. 2 gave good predictions if values of  $\alpha$  and  $\chi$  were 0.22 and 0.02, respectively.

Reflection coefficients for barred profiles were grouped according to shoreward angle and plotted as a function of  $\xi_o$ , calculated using  $\tan\beta_1$  in place of  $m$  as the bottom slope. Linear regression was performed on the  $\alpha$  and  $\chi$  values that best fit the data for each group as a function of  $\tan\beta_1$ . The resulting equations for determining the empirical coefficients for use in Eq. 2 for barred profiles are  $\alpha = 0.19 + 0.07\tan\beta_1$  and  $\chi = 0.23 + 0.19\tan\beta_1$ . The correlation coefficients  $r^2$  of the regression analysis were 0.99 and 0.95 for  $\alpha$  and  $\chi$ , respectively. Fig. 5 shows predictions of Eq. 2 as a function of  $\xi_o$  using calculated  $\alpha$  and  $\chi$  values for the shoreward angles used in the study. Reflection coefficients differ by 5 percent for higher values of  $\xi_o$ , but are identical for lower values. Because reflection coefficients were found to be nearly constant, it is concluded that reflection on barred beaches is mainly dependent on the primary slope of the beach and the wave steepness, and only weakly dependent on seaward and shoreward bar angles.

### Wave Runup

Hunt (1959) gave an expression for wave runup  $R$  as a function of slope, wave height, and wave period, which was re-expressed by Battjes (1974) as a function of the surf similarity parameter, as

$$\frac{R}{H_o} = 1.0\xi_o \quad (3)$$

Fig. 4. Measured reflection coefficient vs. surf-similarity parameter

Fig. 5. Empirical curves for reflection coefficients for a 1/30 plane slope with a bar

in which the empirical coefficient value of 1.0 was determined from Hunt's results to be valid for plane, smooth slopes. (Runup is defined as the combination of a superelevated mean water level, called setup, and a time-dependent oscillation called swash.) Hunt recommended smaller values depending on slope roughness. Measured values of runup normalized by deep-water wave height display no dependence on surf similarity parameter if  $\xi_o$  was calculated using  $\tan\beta$ , as the primary angle. Runup normalized by wave height was plotted versus the surf similarity parameter using the 1/30 slope as the primary angle to determine  $\xi_o$  (Fig. 6). The data show increasing  $R/H_o$  with  $\xi_o$ . The line shown in Fig. 6 represents the average value of  $(R/H_o)/\xi_o$ , which was 0.76, and is approximately the value (0.78) given by Hunt for a 1.0-mm grain size slope. The discrepancy between Eq. 3 and measured values may be attributed in part to the slope used in the present study not being as smooth as the slope used by Hunt, but this hypothesis could not be confirmed.

Ahrens (1981) developed the following equation for average wave runup for random waves,

$$\frac{R}{H_{s_o}} = 0.84\xi_o \quad (4)$$

in which  $H_{s_o}$  is the significant deep-water wave height. Average runup for random waves and the calculated values by Eq. 4 were plotted as a function of  $\xi_o$ , calculated using  $\beta_1$ . Predictions by Eq. 4 estimate runup well for the plane-slope cases, but underpredict runup for cases with bars. Runup for barred profiles nearly equals that for plane slopes and is independent of  $\xi_o$ . However, Eq. 4 gives better results if the plane slope is used to calculate  $\xi_o$  (Fig. 7).

Holman and Sallenger (1985) analyzed field data of runup for a mildly barred beach. Although there was wide scatter in the data, they concluded that runup depended on  $\xi_o$ . However, the choice of slope with which to calculate  $\xi_o$  was unclear. The foreshore slope appeared to be appropriate for data taken at high tide and mid-tide, whereas the bar slope appeared to "have at least some influence" on setup at low tide. It is not evident if the bar was a major cause of wave breaking in their low-tide measurements. The present tests indicate that a bar has a very weak influence, if any, on runup if waves break on the bar. In agreement with Holman and Sallenger, the foreshore, or wide-area slope, appears to be the best quantity to use in correlating runup with  $\xi_o$ ; however, only one slope (1/30) was used in the present study, so this conclusion can only be tentative.

### Breaking Waves

Figures 8 and 9 show average wave height  $\bar{H}$  (monochromatic waves) and root-mean-square (rms) wave height  $H_{rms}$  (random waves), respectively, normalized by local still-water depth  $h$  as a function of distance from the shoreline at the still-water level. Wave decay for identical wave conditions is shown in each figure for plane (solid line) and irregular profiles (dashed lines). The tests conducted with bars show a significant increase of  $\bar{H}/h$  and  $H_{rms}/h$  over the bar. The increase results from shallower water at the bar and higher waves by (nonlinear) shoaling over the bar. Wave height to water depth decreases directly shoreward of the bar because the water is deeper, and a majority of the waves broke on the bar. The ratio increases as water depth decreases in the surf zone for all tests, including tests on the plane slope. The figures indicate that wave height does not decay uniformly through

Fig. 6. Runup on barred and plane slopes (monochromatic waves)

Fig. 7. Runup on barred and plane slopes (random waves)

Fig. 8. Wave height on plane slope & two barred slopes,  $H_{so}/L_p = 0.09$  (mono. waves)

Fig. 9. Wave height on plane slope & two barred slopes,  $H_{so}/L_p = 0.078$  (random waves)

the surf zone for either barred profiles or plane-sloping beaches. Figs. 8 and 9 show that the wave height to water depth ratio is the same in the inner surf zone for barred profiles and plane slopes, despite appreciable differences near breaking. Although the ratio is identical in the inner surf zone, visual observations showed that for most tests broken waves on plane slopes remained as bores through the surf zone, whereas most broken waves on the barred profile reformed.

Maximum wave height  $H_{max}$ , significant wave height, and rms wave height were calculated from the time series of the random wave trains and were plotted versus distance from the still-water shoreline in Figs. 10 and 11. The deviation between  $H_{max}$ ,  $H_s$ , and  $H_{rms}$  decreased as the waves entered shallower water, indicating the waves become constant in height in the inner surf zone. This behavior has also been shown in other random wave studies, such as Thompson and Vincent (1984) for a plane-slope laboratory beach, and by Ebersole and Hughes (1987) for a barred profile in the field, and by Battjes and Beji (1992) for an irregular-bottom laboratory beach.

### Transformation of Wave Spectra

Wave spectra showed surprisingly little variation at fixed points along the profile for plane and barred slopes. Fig. 12 shows spectra for selected gages in two tests with the same gage locations and deep-water waves (random waves,  $H_s = 14.3$  cm,  $T_p = 1.5$  sec). The spectra were averaged over 16 frequency bands. Gage 2 was located in the shoaling zone seaward of significant breaking, Gage 4 was located in a region of significant breaking (on top of the bar in the case of the barred profile), Gage 6 was located shoreward of the bar in the outer surf zone, and Gage 8 was at the most shoreward measurement point in the inner surf zone where many waves had reformed. Two spectra are plotted for each gage, one for the barred slope and the other for the plane slope; these spectra are difficult to distinguish, having the same magnitude and shape, except for Gage 6, located directly shoreward of significant breaking. At Gage 6, energy in the vicinity of the peak frequency for the barred profile is greatly reduced, as is the energy of the low-frequency seiching mode. This result was pointed out in a different way in Figs. 8 and 9, as a decrease in rms wave height. (Note, in Fig. 12, the energy density is given in units of  $\text{ft}^2/\text{Hz}$ , where  $1 \text{ ft} = 0.3048 \text{ m}$ .)

### CONCLUSIONS

For monochromatic and random waves, wave-height to water-depth ratios were higher for waves breaking on bars than on plane slopes because of increased wave height and reduced water depth. Directly shoreward of breaking, the ratio for barred profiles was less than the plane slope. Wave-height to water-depth ratios increased in the surf zone for cases with and without bars and were identical in the inner surf zone. Although the wave height and spectra were approximately equal in the inner surf zone for both barred and plane beaches, broken waves on the plane slope tended to remain as bores through the surf zone, whereas most broken waves on barred profiles reformed. Maximum, significant, and root-mean-square wave heights of random waves became constant in height in the inner surf zone. Similarly, for the same deep-water wave condition, the energy content and shape of wave spectra were preserved from deep water to the inner surf zone, except in a region directly shoreward of the break point, where the spectra on barred profiles contained less energy than that on a plane slope.

Fig. 10. Statistical wave heights on a plane slope,  $(H_s/L_p)_o = 0.044$  (random waves)

Fig. 11. Statistical wave heights on a barred slope,  $(H_s/L_p)_o = 0.044$  (random waves)

Reflection coefficients were found to be nearly constant across all tests. Reflection was controlled mainly by the plane bottom slope, and only weak variations in  $K_r$  were attributable to the seaward and shoreward bar angles. Barred profiles, including extreme bars or reefs, did not alter runup, which was controlled by the plane slope. For monochromatic waves, the measurements followed the runup equation of Hunt (1959) for beaches with 1.0-mm sand grain size. An equation of Ahrens (1981) well predicted average runup for random waves on barred profiles, with the bottom slope in the equation given by the plane slope. In summary, despite differences between breaker-related quantities on barred profiles and plane slopes, wave runup, reflection, and transformation in the inner surf zone on barred profiles were controlled by the plane bottom slope, with only minor influence by the bar, even for extreme (unnatural) bars.

## CHAPTER 48

### ESTIMATION OF IRREGULAR WAVE KINEMATICS FROM A MEASURED RECORD

Rodney J. Sobey<sup>1</sup>

#### Abstract

This review of rational predictive methodologies for irregular wave kinematics confirms the crucial importance of the complete nonlinear free surface boundary conditions. Four methods, the global design wave method, the global linear superposition method, the local Wheeler stretching method and the local Fourier approximation method, have been compared for a very large measured wave from hurricane Camille. Free surface boundary condition errors are comparable to the wave height for the design wave and Wheeler stretching methods. They are sharply reduced by the local Fourier approximation method, though not eliminated. Linear superposition fails completely in the crest-trough region.

#### Introduction

The success that has been achieved in the theoretical prediction of regular wave kinematics is not immediately transferable to the prediction of surface and near-surface kinematics in irregular waves. Significant predictive difficulties have been encountered, especially near the crest.

In many situations, analysis is based on measured or simulated water surface time histories at a fixed location. Spatial measurements of the sea state are most rare and the vast majority of measured field and laboratory records are discrete water surface  $\eta(t)$  records from wave staffs or accelerometer buoys at a fixed location. The balance of the wave kinematics (velocities, accelerations and pressures) at the fixed location needs to be estimated from the known  $\eta(t)$  trace. A closely related problem arises in statistical simulation of a random sea state from the linear Gaussian random wave model. Considerable success is achieved in the prediction of the space and time varying water surface. Unfortunately, this

---

<sup>1</sup>Professor of Civil Engineering, Environmental Resources Engineering Group, University of California, Berkeley, CA 94720, USA

success does not carry through to the near-surface kinematics, where spurious predictions result from the increasing dominance of the higher frequency (but much smaller magnitude) spectral components.

Consideration here will be restricted to a subset of this problem where there is no  $y$  variation and the direction of both the wave motion and any coexisting Eulerian current coincides locally with the  $x$  axis.

Considerable attention has been given to this problem as water velocities, accelerations and dynamic pressures all reach their maximum magnitudes at the water surface. Unfortunately, predictive methodologies are most vulnerable at the water surface, as a direct consequence of approximations in the imposition of the nonlinear free surface boundary conditions. Any methodology for the prediction of irregular wave kinematics that is both rational and viable must give appropriate attention to the free surface boundary conditions.

Global and local methodologies are distinguished. Local methods do not compromise fidelity in the representation of the free surface boundary conditions in the global interest. Global methods, which closely follow regular wave theory, are less attractive for irregular wave kinematics. This paper will compare the predictive capabilities of two common global methods (the design wave approach and linear superposition), a common local method (Wheeler stretching) and the local Fourier approximation method. As interest in irregular wave kinematics inevitably centers on big waves, the comparison will be based on a measured wave segment from Hurricane Camille, Gulf of Mexico, 1969. The selected segment has the highest crest height in the sequence and is among the biggest waves ever recorded.

## BACKGROUND IN REGULAR WAVE THEORY

Common approaches to the prediction of irregular wave kinematics closely follow the pattern adopted in classical regular progressive wave theory. The discussion is simplified by recalling the basis of the classical theory.

Attention will be directed to the unsteady formulation of regular wave theory. With the velocity potential function  $\phi(x, z, t)$  as the dependent variable, the field equation is the Laplace equation

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial z^2} = 0 \quad (1)$$

where the velocity components  $(u, w)$  in the fixed frame are  $(\partial\phi/\partial x, \partial\phi/\partial z)$ .

This field equation is subject to the following boundary conditions:

(i) Bottom boundary condition (BBC), representing no flow through the horizontal bed, is

$$w = 0 \quad \text{at } z = -h \quad (2)$$

where  $-h$  is the elevation of the bed.

(ii) Kinematic free surface boundary condition (KFSBC), representing no flow through the free surface, is

$$w = \frac{\partial \eta}{\partial t} + u \frac{\partial \eta}{\partial x} \quad \text{at } z = \eta(x, t) \quad (3)$$

where  $\eta(x, t)$  is the free surface.

(iii) Dynamic free surface boundary condition (DFSBC), representing constant atmospheric pressure on the free surface, is

$$\frac{\partial \phi}{\partial t} + \frac{1}{2}(u^2 + w^2) + g\eta = \bar{B} \quad \text{at } z = \eta(x, t) \quad (4)$$

where  $g$  is the gravitational acceleration and  $\bar{B}$  is the Bernoulli constant.

(iv) Periodic lateral boundary conditions (PLBC), imposing wave periodicity in space and time, are

$$\phi(x, z, t) = \phi(x + 2\pi/k, z, t) = \phi(x, z, t + 2\pi/\omega) \quad (5)$$

where  $k$  is the wave number and  $\omega$  is the wave frequency.

(v) Wave maintains a stable profile shape (or permanent form), requiring the wave profile to be symmetric in both  $x$  and  $t$  about the crest.

Because of conditions (iv) and (v), progressive waves of permanent form are steady in a frame of reference moving at the phase speed  $C = \omega/k$ . The space and time variations of the water surface must follow

$$\frac{d\eta}{dt} = \frac{\partial \eta}{\partial t} + C \frac{\partial \eta}{\partial x} = 0 \quad (6)$$

### Predictive Capability of Regular Wave Theory

Established regular wave theories (Stokes, Cnoidal, Fourier approximation) generally take advantage of the relative simplicity of the steady formulation where the independent variables are reduced to  $x - Ct$  and  $z$ . Basis function predictors of the dependent variable (typically the stream function) identically satisfy both the field equation and the bottom boundary condition, together with the permanent form constraint and the periodic lateral boundary conditions. Compatibility conditions designate the wave height and the co-flowing current.

The essential detail of the solution however is determined largely by the free surface boundary conditions, which must be satisfied along the complete water surface. The complexity of the gravity wave problem is manifested through these free surface boundary conditions, which introduce nonlinearity to the problem and are applicable at a free surface that is itself part of the solution. Different orders of the same wave theory are distinguished by the level of approximation to the free surface boundary conditions, higher orders providing enhanced fidelity.

A conflict is immediately identified between the predictive capabilities of regular wave theory and the nature of the solution field. Wave theory consistently predicts that peak magnitudes and response extremes in velocities, accelerations and dynamic pressures are located along the free surface. Unfortunately, this region of peak interest in the kinematics and dynamics exactly coincides with the

region of maximum uncertainty in the wave theory predictions.

Appropriate measures of theoretical error may be formulated from the free surface boundary conditions at the water surface. The kinematic and dynamic free surface boundary condition errors are respectively

$$K(x, t) = w(x, \eta, t) - \frac{d\eta}{dt} \quad (7)$$

and

$$D(x, t) = \frac{\partial \phi}{\partial t}(x, \eta, t) + \frac{1}{2}[u^2(x, \eta, t) + w^2(x, \eta, t)] + g\eta - \bar{B} \quad (8)$$

In application, these will be represented in length units, as  $K/\omega$  and  $D/g$  respectively, for direct comparison with the local water surface elevation.

For waves of even moderate height, the free surface boundary condition errors associated with the lowest order theory are significant. Predictive difficulties for near-surface kinematics must be expected from adoption of linear wave theory. They are indeed experienced. Nevertheless, there remains a reluctance to reject the simplicity and familiarity of the linear theory, and several measures have been proposed to mitigate the near-surface failings.

Higher order theories by definition do a much better job in satisfying the free surface boundary conditions. They have little theoretical difficulties in the prediction of near-surface kinematics in steady waves, though they may often impose a considerable computational burden. Irregular waves are not steady, but it is clear that fidelity in representing the free surface boundary conditions must have a crucial role in any rational predictive methodology for irregular wave kinematics.

Several unfavorable comparisons of regular wave theory and laboratory measurements have received considerable attention. The evidence however is not conclusive and closer scrutiny (Sobey 1989b) suggests that the predictive potential of regular wave theory remains sound. Errors both in measurement and in application of theory can be substantial and more than sufficient to negate any hasty conclusions.

The influence of current in particular is often not given the attention it deserves. This involves the specification of the appropriate definition (Stokes' first or second) of phase speed and the associated current. The differences are potentially significant and compounded by the fact that many published wave theories have automatically assumed Stokes' first definition of phase speed (and often also zero current) in the problem formulation. Current is assumed to be depth-uniform and any vertical structure is ignored<sup>2</sup>. The adoption of a higher order wave theory may not be realistic where due attention has not been given

---

<sup>2</sup>A Stokes theory with a linear velocity profile (i.e. constant vorticity) by Kishida and Sobey (1988) has suggested that vorticity has only a very minor influence. After subtracting out the current profile, the residual "wave" kinematics are little different from those that would have been predicted for a uniform current with the same depth-averaged magnitude. The generality of this observation is presently uncertain.

to the influence of tidal or other ocean currents on the wave kinematics. Alternatively, if the current is not known, higher order precision cannot and should not be expected.

Steady wave theory provides predictions of kinematics in long-crested regular progressive waves. Despite some unfortunate misinterpretation in the literature, steady wave theory does do a credible job where the waves correspond with the assumptions of the theory. The waves must be reasonably long-crested and steady, and the adopted wave theory must be consistent with the field or laboratory conditions. While the basis of wave theory is indeed sound, irregular waves clearly violate the permanent form and periodicity assumptions of the classical steady wave problem. Accordingly, there can be no strong expectation that regular wave theory will predict more than an outline of the kinematics in irregular waves.

### **Generalization to Irregular Waves**

The spatial and temporal complexity of irregular waves would initially appear to have little in common with the conspicuous order of regular wave theory. Nonetheless, much of the problem formulation remains appropriate. Irregular waves are by nature unsteady, so that an unsteady formulation is pertinent. The field equation (Eq. 1), the bottom boundary condition (Eq. 2) and both free surface boundary conditions (Eqs. 3 and 4) continue to be applicable; these make up the bulk of the mathematical physics. Neither the periodic lateral boundary conditions, nor symmetry about the crest in  $x$  and  $t$  are appropriate for irregular waves. Further, application of the KFSBC is inconsistent with the present reliance on measured water surface records at a fixed location, as spatial gradients  $\partial\eta/\partial x$  are not available from the measured record.

The crucial aspects of the mathematical physics of the regular wave problem are the nonlinear free surface boundary conditions. The close relationship between regular and irregular wave theory guarantees that the free surface boundary conditions will remain a crucial aspect of irregular wave theories.

### **GLOBAL APPROXIMATIONS**

Methodologies that seek to represent a complete irregular wave, from crest to following crest, from trough to following trough or from zero-crossing to following zero-crossing, are categorized as global. Among global methods, only the design wave and linear superposition methods will be considered here. Fourier-style methods (Dean 1965, Lambros 1981) and numerical field solutions (Forristall 1985) have also been proposed.

### **Design Wave**

An obvious candidate is to couple a trough to trough or zero-crossing identification of a wave height and a wave period for an individual wave record with an appropriate steady wave theory prediction for the same height, period, water depth and current. In principle, this is the essence of the design wave approach. As the dominant length and time scales are essentially correct, there

is an intuitive expectation that ensuing predictions of crest kinematics have the correct order of magnitude. There can be no expectation however that the predictive capability will consistently exceed order-of-magnitude precision. The associated regular wave theory will predict the water surface profile of the design wave. Regular and irregular wave profiles are unlikely to correspond, so that the free surface boundary conditions will not be satisfied on the actual water surface.

The nature of the design wave approximation is illustrated in Fig. 1, which is based on a measured water surface record from Hurricane Camille in the Gulf of Mexico in 1969. The record sequence is amongst the biggest waves ever recorded. The water depth is 340 ft (103.6 m). In selecting design waves from a measured record, trough to trough identification is often preferred because of its focus on the crest. The height and period are 72.1 ft (22.0 m) and 13.8 s respectively, so that this is a deep water wave. The solid line shows the steady wave theory (Fourier) prediction of horizontal velocity along the predicted water surface, located such that the crest time corresponds with the measured record. Also shown are the KFSBC and DFSBC errors along the measured water surface. These errors are of comparable order to the wave height. The design wave approach will certainly provide order of magnitude estimates of irregular wave kinematics, but consistently better predictions cannot be expected.

### Superposition of Linear Waves

A familiar alternative is the superposition of numerous freely-propagating Airy waves, whose amplitudes, frequencies and phases are determined from a discrete Fourier transform of the irregular water surface profile. Consistent kinematics are available from Airy wave theory.

As a direct consequence of the linear superposition approximation, the Fourier transforms all involve relatively simple transformations on the Fourier transform of the irregular water surface profile. The transfer functions (e.g.  $\omega CS(kz, kh)$  for horizontal velocity, where  $CS(kz, kh) = \cosh k(h+z)/\sinh kh$ ) are frequency, depth, (wave number,) and elevation dependent, where each of the component Airy waves separately satisfies the linear dispersion relationship. A

**Figure 1.** Design wave approximation to a measured deep water wave from hurricane Camille. Profile comparisons. horizontal velocity and free surface boundary condition errors along measured water surface.

discrete inverse Fourier transform will predict the time history of the field variable.

Using the FFT algorithm, the numerical procedure is tidy and efficient, but linear superposition does introduce some explicit assumptions regarding the nature of the irregular sea state and its spatial and temporal evolution. The adoption of Airy theory to characterize the separate components assumes that the irregular sea state is composed entirely of free modes, each component being a freely propagating Airy wave that separately satisfies the linear dispersion relationship. There are no bound modes and the FFT algorithm imposes a periodicity in time equal to the duration of the measured record.

In addition, considerable difficulties are encountered at elevations above the MWL, which is the strict upper bound of the Airy solution domain. The hyperbolic function quotients (CS, SS and CC) become exceptionally large for the high frequency (and high wave number) components. Where the record segment is a single irregular wave, the frequency resolution is  $\omega_0 = 2\pi/T$ , where  $T$  is the duration of the record and the approximate period. The frequency of the  $n$ th component is  $\omega_n = n\omega_0$  and the relative depth  $\omega_n^2 h/g = n^2 \omega_0^2 h/g$  rapidly increases with  $n$ . For  $\omega_n^2 h/g > 2.5$ , the CS( $k_n z, k_n h$ ), SS( $k_n z, k_n h$ ) and CC( $k_n z, k_n h$ ) hyperbolic function quotients approach  $\exp(k_n z)$  or  $\exp(n^2 \omega_0^2 z/g)$ . For large positive  $z$  in the crest region, these functions enormously magnify the influence of the high frequency components in the Fourier transform or variance spectrum. Kinematic predictions in the crest region become exceptionally large and clearly incorrect. They generally overflow the high number capacity of digital computer software, even in double precision. Any positive value of  $z$  is of course outside the strict Airy solution domain, and crest elevations are well above even the water surface of the smaller magnitude higher frequency components.

As these high frequency components generally contribute little to the total variance of the water surface record, low pass filtering of the Fourier transform is a potentially pragmatic response to this difficulty. An application to the Camille record segment is shown in Fig. 2. The fundamental frequency is  $\omega_0 = 2\pi/13.8 \text{ s}^{-1}$  or  $f_0 = 0.072 \text{ Hz}$  and the record Nyquist frequency is 2.0 Hz. Part (a) shows the measured water surface record together with the horizontal velocity prediction and the KFSBC and DFSBC errors at the measured water surface for a frequency cutoff at 0.1 Hz. This includes only a single frequency component  $\omega_0$ . It is effectively a design wave approximation using Airy theory, and the free surface boundary condition errors are broadly comparable to Fig. 1. Part (b) shows the same traces for a 0.15 Hz cutoff. This includes only two frequencies  $\omega_0$  and  $2\omega_0$ , yet predictive problems at the crest are already apparent. The predicted peak horizontal velocity has risen from 14.8 ft/s (4.5 m/s) to 59.6 ft/s (18.2 m/s) and the KFSBC error oscillates off scale. Including also  $3\omega_0$  increases the predicted peak horizontal velocity still further to 114.6 ft/s (34.9 m/s).

Clearly, Airy wave superposition, even with an arbitrarily determined cutoff frequency, has no credibility in estimating kinematics in the crest region (Forristall 1985). For elevations below the MWL, linear superposition may continue to provide credible predictions of the wave kinematics.

**LOCAL APPROXIMATIONS**

Methodologies that seek only to represent the local behavior of an irregular wave are categorized as local. Given that significant problems such as crest kinematics are strongly related to local errors in the free surface boundary conditions, there is evident attraction in such an approach. These methodologies compromise applicability in a global sense in an effort to achieve fidelity in a local sense. Note that this contrasts with the general approach of steady wave theory where local fidelity (especially near the wave crest) is perhaps sacrificed in the global interest.

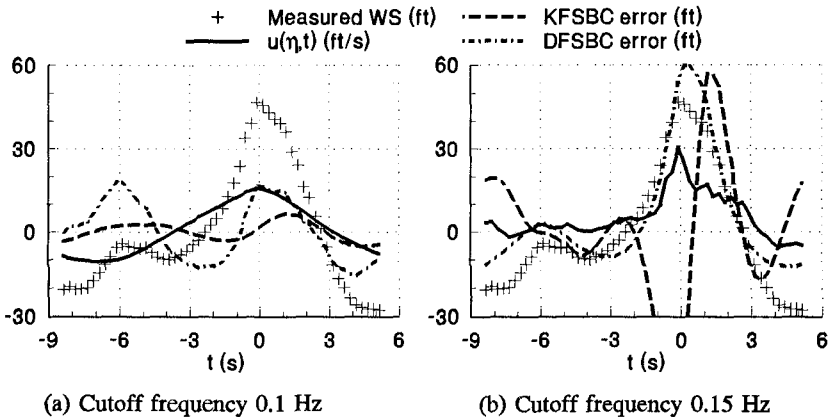

**Stretching Approximations**

One form of local approximation, the so-called 'stretching' method of Wheeler (1969), has found considerable favor as a pragmatic approach to the prediction of irregular wave kinematics. Recognizing that the failure of Airy superposition was contributed by extrapolation of the hyperbolic function quotients beyond the upper bound of the Airy solution domain, Wheeler introduced an empirical transformation on the local elevation such that it never exceeds the MWL. The horizontal velocity was predicted as

$$u(x, z, t) = \sum_j \omega_n \frac{\cosh \alpha k_n h}{\sinh k_n h} \eta_n(x, t) \tag{9}$$

where  $\alpha(x, z, t) = (h + z)/(h + \eta)$ , the transformation depending on the local water surface elevation  $\eta(x, t)$ . Though not defined by Wheeler, consistent definitions for the balance of the kinematics follow directly from the linear superposition approximations.

The stretching transformation shifts the instantaneous water surface to the MWL and avoids the spurious predictions of crest kinematics from direct linear

**Figure 2.** Linear superposition approximation to a measured deep water wave from hurricane Camille. Horizontal velocity and free surface boundary condition errors along measured water surface.

superposition. It also remains a linear superposition approximation and a linear spectral description of the kinematics. As such, it preserves access to the familiar methodologies of (linear) time series analysis in the time and frequency domains that are common practice in applications such as the dynamic structural analysis of offshore platforms.

Significant problems nonetheless remain. As a result of the stretching transformation, mass and momentum are no longer conserved by the predictive equations for the kinematics. The nature of the residual problems however remains best illustrated in the context of the free surface boundary conditions. The relocation of the local water surface to the MWL does sharply reduce errors in the free surface boundary conditions, as Airy theory imposes the free surface boundary conditions at the MWL. But the Airy theory does not impose the full free surface boundary conditions, and the omitted nonlinear terms are especially influential in the crucial crest region for the moderate to extreme waves that are common in design.

Smaller magnitude high frequency components in the Fourier transform remain troublesome and Wheeler (1969), for example, adopted a low pass cutoff frequency of 0.3 Hz. An application of the stretching methodology to the Camille record segment is shown in Fig. 3, which shows the measured water surface together with the predicted horizontal velocity, KFSBC and DFSBC traces at the measured water surface; frequencies above 0.3 Hz were excluded from the Fourier transforms. The 0.3 Hz cutoff includes the fundamental frequency  $\omega_0 = 2\pi/T$ , where  $T$  is the duration of the record segment (and the approximate period), together with the first three harmonics  $2\omega_0$ ,  $3\omega_0$  and  $4\omega_0$ . With direct linear superposition (as shown in Fig. 2), the horizontal velocity predictions in the crest region would be extremely large and well off scale, because of the influence the  $3\omega_0$  and  $4\omega_0$  frequencies on the hyperbolic function quotients in the crest region. The stretching approximation constrains these spurious contributions and

**Figure 3** Stretching approximation to a measured deep water wave from hurricane Camille. Horizontal velocity and free surface boundary condition errors along measured WS. Cutoff frequency 0.3 Hz.

provides a prediction of horizontal velocity at the water surface that is similar in magnitude to the design wave approximation in Fig. 1. Whether or not it is a superior approximation is unclear, as both have free surface boundary condition errors of significant magnitude.

The stretching approximation focuses on satisfying the linearized free surface boundary conditions at the measured water surface. This is done exactly for the KFSBC and approximately<sup>3</sup> for the DFSBC. But the nonlinear terms become significant, especially the KFSBC term  $u\partial\eta/\partial x$  in the crest region. Fig. 3 shows this error to be comparable in magnitude to the wave height.

### Local Airy Approximations

Airy wave theory has also been used with locally defined rather than globally defined parameters. Airy theory predicts that the water surface profile is

$$\eta(x,t) = a \cos(kx - \omega t + \theta) \quad (10)$$

where  $\theta$  is the phase. At a fixed location, the local parameters are the amplitude  $a$ , the frequency  $\omega$  and the net phase  $kx + \theta$ .

Nielsen (1986, 1989) localized the definition of amplitude, frequency and phase to a moving window of three consecutive water surface observations  $\eta_-$ ,  $\eta_0$  and  $\eta_+$ , spaced in time by  $\Delta t$ . Together with Eq. 10, these are sufficient to uniquely define the local amplitude, frequency and phase, as

$$\omega = \frac{1}{\Delta t} \cos^{-1}\left(\frac{\eta_+ + \eta_-}{2\eta_0}\right), \quad kx + \theta = \tan^{-1}\left(\frac{\eta_+ - \eta_-}{2\eta_0 \sin \omega \Delta t}\right), \quad a = \frac{\eta_0}{\cos(kx + \theta)} \quad (11)$$

respectively. The simplicity of this approach is immediately appealing, especially as it accommodates the irregularity by varying the local wave parameters and retains the familiarity and computational simplicity of the Airy wave theory. Unfortunately, Airy theory remains inadequate in the prediction of crest kinematics. Even with the addition of vertical coordinate stretching, it excludes the nonlinear terms in the free surface boundary conditions, especially the  $u\partial\eta/\partial x$  term, which are not small in the crest region of moderate and extreme waves.

In addition, Eqs. 11 fail frequently along the water surface on application to strongly irregular waves.  $(\eta_+ + \eta_-)/2$  is approximately  $\eta_0$ , so that the argument of the inverse cosine function in the predictive equation for the local frequency is approximately one. Arguments less than one are always encountered for an exactly linear profile. For a nonlinear wave of approximately permanent form, arguments in excess of one are computed in the neighborhood of the profile MWL crossings. A local frequency cannot be estimated; neither can the local phase and amplitude be estimated, as they depend on the frequency estimate. More significantly perhaps, similar problems are encountered at inflection points and around local minima and maxima in the crest and trough regions, such as are observed in the Camille trace.

---

<sup>3</sup>But exactly at the smoothed (i.e. after low pass frequency filtering) location of the water surface.

### Local Fourier Approximation

As outlined previously, a rational approximation to irregular waves should satisfy the field equation (Eq. 1), the bottom boundary condition (Eq. 2) and the complete form of both free surface boundary conditions (Eqs. 3 and 4); the permanent form and spatial and temporal periodicity constraints are not appropriate. Maximum advantage, at least from a theoretical viewpoint, can be made of a local approximation that does not compromise on these requirements, especially on the free surface boundary conditions along the actual water surface. However, measurements of  $\eta(t)$  at a fixed  $x$  location provide no information on  $\partial\eta/\partial x$ . Some compromise is necessary in representing this term, but it should not be allowed to dominate the solution methodology.

A local Fourier approximation (Sobey 1992) provides a pragmatic and rational response to these constraints. As a local approximation method, it enhances fidelity in representation of the crucial free surface boundary conditions and minimizes the influence of the necessary spatial evolution assumption. Further, it is a generalization of the widely successful (but global) Fourier approximation method for regular waves, which has almost universal applicability for both deep and shallow water waves and for coflowing uniform currents. The methodology is extended to complete irregular water surface profiles by means of a moving window of duration  $\tau$ , which is small in comparison with the local zero-crossing period.

The basis of the method is the representation of the velocity potential function within each window as

$$\phi(x, z, t) = U_E x + \sum_{j=1}^J A_j \frac{\cosh jk(h+z)}{\cosh jkh} \sin j(kx - \omega t) \quad (12)$$

This representation is familiar from global Fourier wave theory (e.g. Sobey 1989a), where  $U_E$  is the spatially-uniform Eulerian current,  $h$  is the water depth,  $A_j$  are the Fourier coefficients,  $k$  is the wave number,  $\omega$  is the wave frequency and  $(x, z)$  is the spatial position in the fixed frame. The current and the water depth define the local propagation medium and must be specified. In Fourier wave theory,  $\omega$ ,  $k$  and the  $A_j$ , together with the Bernoulli constant  $B$ , are a defining set of parameters that have unique values. In the local Fourier approximation method, the defining set of parameters is no longer constant but varies from window to window.

Within each window, the Eq. 12 basis functions exactly satisfy both the field equation throughout the fluid domain and the bottom boundary condition, whatever the numerical values of the defining set of parameters. The defining set of parameters is determined within each window to best satisfy the free surface boundary conditions at the measured elevations of the free surface within the window. In addition, the Bernoulli constant in the DFSBC is not a free parameter, being related to the other solution parameters through an exact integral relationship. In a global approximation, this constraint is implicit in imposition of the DFSBC along the entire water surface from crest to trough.

For each window solution, the given information is the local water depth

$h$  and the local coflowing uniform Eulerian current  $U_E$ , together with a set of water surface elevations  $\eta_i$ , where the  $i = 1, 2, \dots, J$  are distributed over the local window of duration  $\tau$ .

The temporal and spatial gradients of the water surface in the KFSBC equations remain to be specified. Temporal gradients can be estimated from the water surface time history. Cubic spline interpolation among the measured water surface nodes conveniently provides consistent and smoothly varying estimates of both  $\eta$  and  $\partial\eta/\partial t$ . The spatial gradient  $\partial\eta/\partial x$  is estimated from a locally steady assumption, which imposes Eq. 6 in each local window and relates the spatial and temporal gradients as

$$\frac{\partial\eta}{\partial x} = -\frac{1}{C} \frac{\partial\eta}{\partial t} \quad (14)$$

where  $C = \omega/k$  in the local window. The steady profile assumption is not imposed beyond the local window and does not dominate the solution methodology, as it does for example in the global Fourier-style methodologies.

This equation set is nonlinear and implicit. The primitive unknowns in the local window are  $\omega$ ,  $k$ ,  $kx$  and the  $A_j$ , of which there are  $J$ . There are two independent equations potentially available at each of the  $\eta$  observations within the local window, of which  $M$  are selected for the numerical solution. The problem is uniquely defined for  $M = 3 + J$  and overspecified for  $M > 3 + J$ . In recognition of the certain existence of error bands about the measured water surface elevations, some overspecification is advantageous. Though significantly complicated by the error bands, numerical solution considerations are similar to those encountered in the Fourier steady wave theory; they are discussed in detail by Sobey (1992).

From a strictly numerical viewpoint, the only constraint on the choice of order  $J$  and the local window width  $\tau$  is the  $M \geq 3 + J$  requirement. There is a clear expectation however that an appropriate choice of these parameters will be dependent on the physical nature of the water surface time history together with the local resolution of the measured record. With cubic spline interpolation of the water surface record, the time location of individual windows is independent of the order and the window width. Nonetheless, adequate resolution must be provided to capture the temporal variation in the near-surface kinematics.

An application of this methodology to the Camille record segment is shown in Fig. 4. The free surface boundary condition errors are substantially reduced, especially in the crest region where interest is often centered. Overall, errors are small with respect to the wave height, but residual errors persist at profile zero-crossings and around local minima and maxima in the trough region.

### Local Polynomial Approximation

Fenton (1986) introduced a local polynomial approximation for the interpretation of submerged pressure records. With some changes to reflect the different context, the local polynomial methodology can be extended to irregular water surface records.

**Figure 4** Local Fourier approximation to a measured wave from hurricane Camille. Horizontal velocity and free surface boundary condition errors along measured water surface.  $J=1$ ,  $\tau=0.1$  s.

The wave field is assumed to be locally steady with local phase speed  $C$ , such that variations with  $x$  and  $t$  in the fixed frame can be combined in a locally steady frame as  $X = x - Ct$ , as in steady wave theory. The local solution is represented by a truncated polynomial series for the complex potential function

$$\Phi(X, z) + i\Psi(X, z) = \sum_{j=0}^M \frac{A_j}{j+1} [X + i(h+z)]^{j+1} \quad (15)$$

where the  $a_j$  polynomial coefficients are real. These basis functions satisfy the field equation and bottom boundary condition exactly. The polynomial coefficients would be determined numerically to best fit the kinematic and dynamic free surface boundary conditions at the known water surface nodes  $\eta_i$ , where the  $i = 1, 2, \dots, I$  are distributed over the local window of duration  $\tau$ .

The specific equations defining the window solutions closely parallel those for the local Fourier approximation. As  $\omega$  and  $k$  are involved in the local approximation, the local phase speed  $C$  is an explicit unknown. Given an estimate of the mean fluid speed in the locally steady frame, such as  $\Psi(0, 0)/h$  (Fenton 1986), the phase speed is estimated from a local dispersion relationship.

A polynomial variation in the vertical is a feature of the steady Cnoidal wave theory, and it would be expected that this approximation would be most appropriate in shallow water. It may be less satisfactory for deep water waves, where the vertical variation tends to exponential and local Fourier approximation may be more suitable. The local polynomial and Fourier approximations appear complementary.

## CONCLUSIONS

Even in regular wave theory, errors are centered on the free surface boundary

conditions. For irregular wave kinematics, a rational predictive capability should give particular attention to the complete nonlinear kinematic and dynamic free surface boundary conditions. Four approaches to irregular wave kinematics, the global design wave method, global linear superposition, local Wheeler stretching and the local Fourier approximation method, have been compared for a very large measured wave from hurricane Camille. Free surface boundary condition errors are comparable to the wave height for the design wave and Wheeler stretching methods. They are sharply reduced by the local Fourier approximation method, though not eliminated. Linear superposition fails completely in the estimation of surface and near-surface kinematics.

## CHAPTER 49

### ON SPECTRAL INSTABILITIES AND DEVELOPMENT OF NON-LINEARITIES IN PROPAGATING DEEP-WATER WAVE TRAINS

C.T. Stansberg <sup>1</sup>

#### Abstract

Modulation instabilities in surface waves on deep water are investigated. Experimental wave elevation records from laboratory tests are analysed, based on simultaneous records at different distances from the wavemaker. Initially monochromatic and bi-chromatic wave trains are seen to gradually change with the propagation, by splitting up into smaller groups. After further propagation, large individual waves, and wave breaking, may occur. Results from tests with irregular (random) waves indicate that the skewness of the record, which is mainly a measure of 2nd order nonlinearities, is closely connected to the wave steepness during the whole propagation, more or less independently of other wave processes going on. The non-linear wave group formation, however, which is related to higher-order instabilities, show a development during the propagation. This may lead to frequency down-shift of the wave energy, combined with energy dissipation and wave breaking.

#### 1. INTRODUCTION

Initially monochromatic wave trains (or more correctly: periodic Stokes waves) are unstable (Benjamin & Feir 1967). After a certain propagation distance, slow modulations will occur and grow with further propagation. This non-linear phenomenon, also known as side-band instabilities in the frequency domain, depends further on the wave steepness and is therefore coupled to the initial 2nd order (Stokes) non-linear component of the waves. The modulation itself, however, is a

-----  
<sup>1</sup>Principal Research Engineer, Norwegian Marine Technology Research Institute A/S (MARINTEK), P.O.Box 4125 Valentinslyst, N-7002 Trondheim, Norway

higher-order non-linear effect, and may be described by a 3rd order theory through the non-linear Schrödinger equation (Zakharov 1968). A 4th order correction is necessary in order to account for an asymmetric behaviour of the 2 sidebands (Dysthe 1979), resulting in a net frequency downshift of the wave energy, which is an important practical consequence of this phenomenon.

Such modulational instabilities will also occur in irregular (random) wave trains, although a complete theoretical description then may become rather complex. Tulin & Li (1991) have proposed a theoretical model where these effects are coupled to the development of large and breaking waves in wave groups, even in moderate sea states. Similar results have been shown by Cointe & Boudet (1991). These ideas may, together with experimental studies, lead to interesting contributions in the general problem of modelling random wave trains, and in particular problems like the prediction of the extreme wave of a given sea state.

The main purpose of the present work is to show some observations from laboratory tests with irregular waves, and thus provide experimental documentation of the nature of such higher-order non-linearities. The interpretation of the results will basically be done by spectral and statistical analysis of the measured wave elevation. Prior to the presentation of these results, however, results from an experimental verification of these modulational instabilities in monochromatic and bichromatic wave trains is given, as a first step to understand the problem.

## **2. INSTABILITES DEVELOPING IN MONOCHROMATIC AND BICHROMATIC WAVE TRAINS**

Results from laboratory tests with initially monochromatic & bichromatic waves are shown in the following. The monochromatic test was performed in MARINTEKs Ocean Basin, measuring 50mx80m, with the waves generated in the longitudinal direction. The bichromatic test was performed in MARINTEKs long towing tank, measuring 10mx270m. Wave elevation measurements were simultaneously made at a number of distances from the wavemaker, on the central longitudinal axis of the basin/tank. The water depth in the Ocean Basin tests was 2.8m, while for the long tank test it was 5.0m. These depths correspond to deep water for the tests considered. All input to the wavemakers were generated as linear wave signals.

The measured time series samples in fig. 1 as well as fig. 3 illustrate how the wave trains gradually develop from more or less undisturbed linear wave signals into wave trains breaking up into smaller groups with relatively large extreme waves.

Wave breaking was also observed at the largest distances from the wavemaker. The power spectra in figs. 2 & 4 show how the energy is spread out from the initial frequencies into neighbouring side bands. Some loss of energy is also observed.

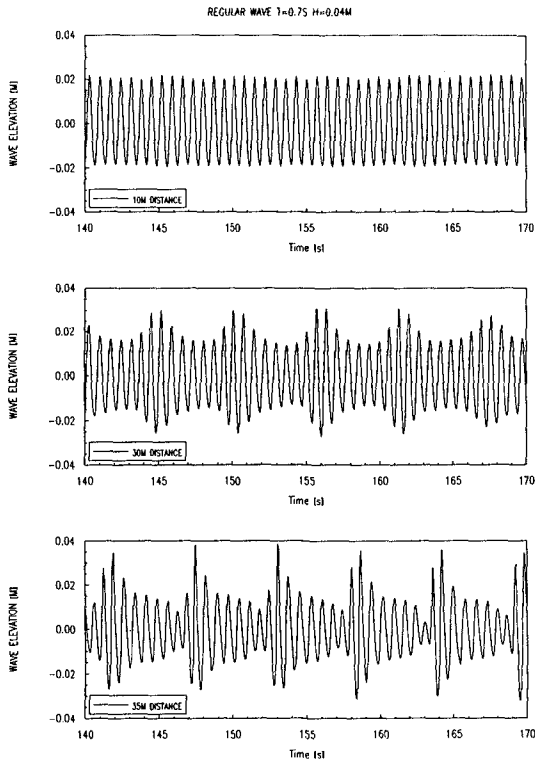

Figure 1. Time series samples of an initial monochromatic wave train, measured simultaneously at 3 locations.

Figure 2. Power spectra of the wave records in figure 1.

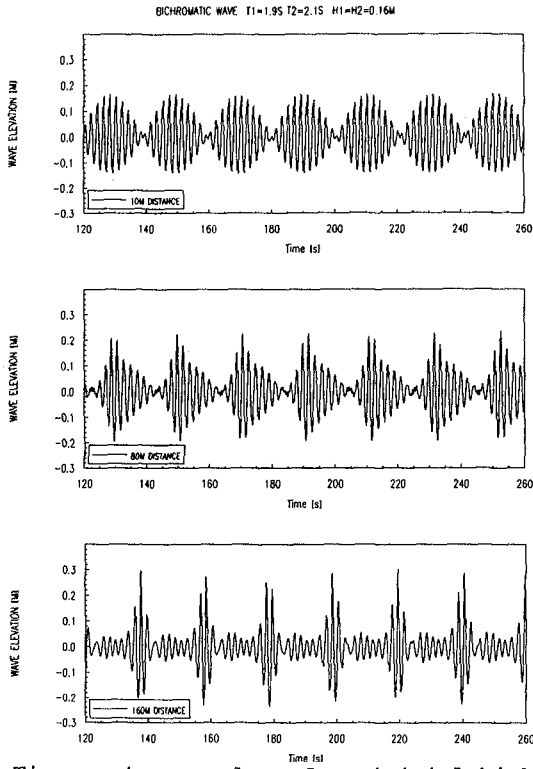

Figure 3. Time series samples of an initial bichromatic wave train, measured simultaneously at 3 locations.

Figure 4. Power spectra of the wave records in figure 3.

### 3. SPECTRAL AND STATISTICAL PROPERTIES OF IRREGULAR WAVE TRAINS.

The influence from wave steepness and propagation length on the characteristics of longcrested irregular wave trains is experimentally investigated in the following. Measured records from laboratory tests in MARINTEKs Ocean Basin (size & depth: see Chapter 2) are used. The irregular input signal to the wavemaker was synthesized as a linear superposition of harmonic components by use of inverse Fast Fourier Transform with 4096 components. JONSWAP spectra with a peak enhancement factor, Gamma, equal to 3.0 were generated. A more detailed description of the irregular wave generation procedure is given in Stansberg (1990). Wave elevation measurements were made simultaneously at a number of distances from the wavemaker, in the same manner as described in Chapter 2. The total duration of each record was 20 minutes. In the analysis, we shall distinguish between the measurements made close to the wavemaker (only some wavelengths), and those made further away.

#### 3.1 Observations at short distances (< 10 wavelengths).

Fig. 5 shows selected time series samples from 2 tests with spectral peak period  $T_p=1.8s$ , both measured at 35m distance (i.e. 7 wavelengths) from the wavemaker. The selected time windows include the largest waves of the records. The 2 tests were run with the same input signal apart from a scaling factor of 2. The main difference observed is, apart from the scaling, the asymmetric and peaked shape of the extreme crests in the highest sea state. This is also reflected in the values obtained for the statistical skewness, based on the 3rd order statistical moment of the wave elevation record:

$$\text{skewness} = (1/N\sigma^3) \cdot \sum_{i=1}^N (x_i - \bar{x})^3 \quad (1)$$

(expected to be zero for a Gaussian process)

Here  $\bar{x}$  = mean value,  $\sigma$  = standard deviation, N = no. of samples.

It is seen that for the high sea state, the skewness value is twice the value for the low sea state. We may interpret this result as a direct result of steepness-induced 2nd order (Stokes) processes in the waves (Marthinsen & Winterstein 1992, Stansberg 1993). On the other hand, the values for the kurtosis, which is based on the 4th order statistical moment of the record:

$$\text{kurtosis} = (1/N\sigma^4) \cdot \sum_{i=1}^N (x_i - \bar{x})^4 - 3 \quad (2)$$

(expected to be zero for a Gaussian process)

is relatively low in both cases. The kurtosis is a measure of group formation, i.e. of enhanced modulation, in the signal. Thus an increased steepness of the waves does not seem to induce any increase in higher-order instabilities at this distance.

Figure 5. Time series samples from 2 irregular wave tests with  $T_p=1.8$ s. Significant wave heights  $H_{m0}$ : 0.095m and 0.19m. Both measured at 35m.

The influence from the wave steepness on the statistical skewness and kurtosis is also reflected in fig. 6, where results from several test runs are presented.

The power spectra in fig.7 show that a small part of the wave energy has dissipated at high frequencies for the steepest wave condition. No significant changes have taken place, however, in the frequency distribution of the energy.

Figure 6. Measured skewness vers. wave steepness (Lp=wavelength of spectral peak frequency).

Figure 7. Power spectra of the waves in figure 5 (based on full 20 minutes records).

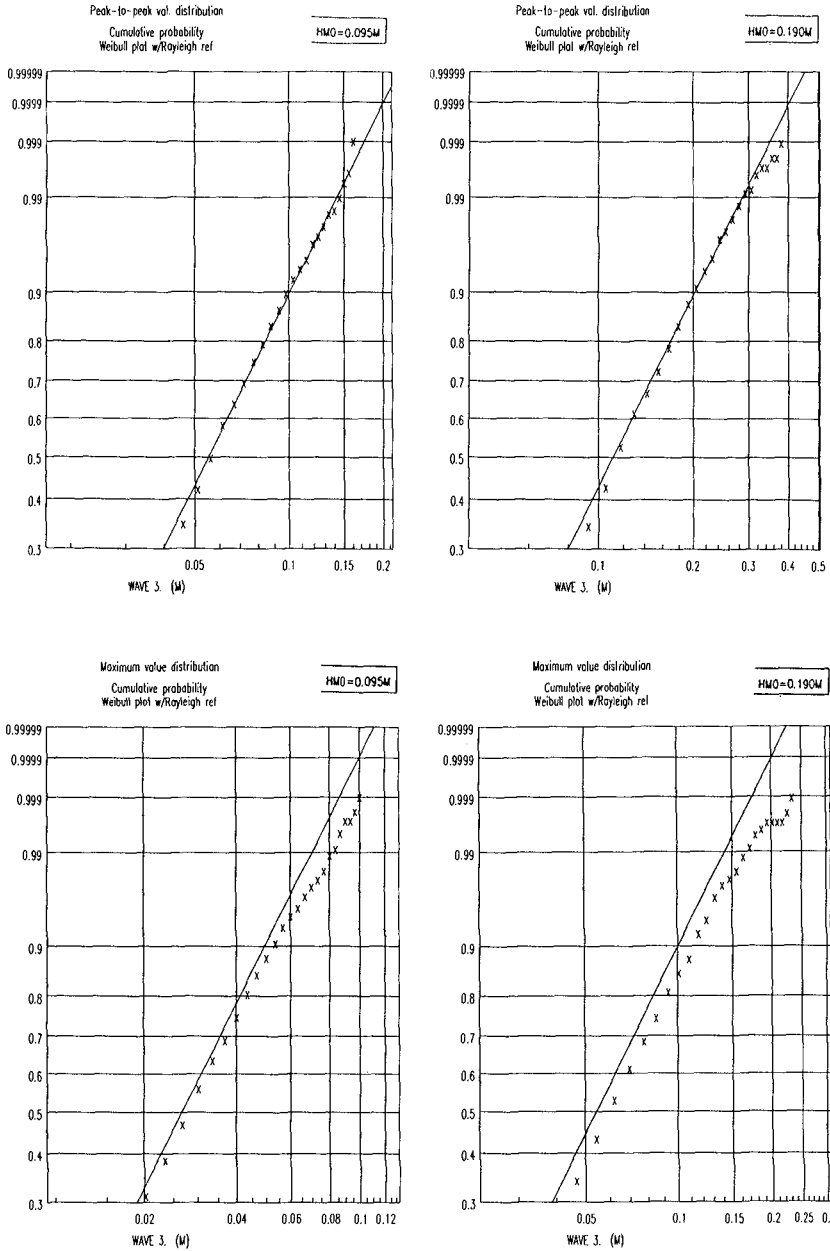

Figure 8. Cumulative distributions of wave and crest heights of the wave records in figs. 5 and 7.

The statistical distribution of wave and crest heights from the tests shown in figs. 5 & 7, are presented in fig. 8. In both wave conditions, the peak-to-peak wave heights seem to follow the commonly used Rayleigh model reasonably well, while the highest crests somewhat exceed the Rayleigh estimates. The latter observation is also discussed and reported in Stansberg (1991,1993), and is connected with 2nd order non-linearities commented on above.

### 3.2. Observations at a longer distance (>10 wavelengths).

The influence from the wave propagation on steep irregular waves is illustrated in fig. 9, where time series samples from a test with  $T_p=1.0s$  is shown. Wave elevation records measured simultaneously at 10m & 35 m distance (i.e. at 7 & 20 wavelengths, respectively) are shown. The selected samples include the largest waves of the records. The first location corresponds to the case discussed in section 3.1, while propagation-dependent effects may be observed in the latter. The shown samples illustrate how a wavetrain with steep, large waves may develop into a wavetrain

Figure 9. Time series samples recorded at 2 locations, for steep irregular wave with  $T_p=1s$ ,  $H_{m0}=0.1m$ .

with high group formation and a few particularly high waves. A similarity between the recorded extreme wave group and the unstable groups in Chapter 2 is observed. The increase in wave group formation may also be identified through the kurtosis value, which increases from 0.2 to 0.7 as the wave propagates. This development is additional to the 2nd order skewness effect seen in the previous section, and may probably be connected with the higher-order modulational instabilities demonstrated in Chapter 2. It is interesting to note that the skewness value is the same at both locations.

From the spectral plots in fig. 10, a net energy transfer from high to lower frequencies is observed. In addition, a 10% wave energy loss occurs due to dissipation by wave breaking and other processes.

Figure 10. Power spectra of the wave in figure 9 (based on full 20 minutes record).

The influence from the propagation distance on the statistical wave parameters is shown in fig. 11, where results from several tests with different wave periods and wave heights are included. The propagating distance is normalized as  $D/L_p$ , where  $D$  is the distance from the wavemaker, and  $L_p$  is the "peak wavelength of the spectrum":

$$L_p = (g/2\pi) \cdot T_p^2 \quad (3)$$

It is seen that up to a certain point, the kurtosis (i. e. the non-linear wave group formation) increases with  $D/L_p$ . Then energy dissipation occurs by breaking etc., and the wave steepness decreases. A connected decrease in the kurtosis is then also observed at a far distance. The skewness, assumed to be related to 2nd order effects, seems to be given by the steepness (as in fig.6), regardless of the other higher-order wave processes.

Figure 11. Measured statistical parameters vers. normalized propagation distance.

The statistical distribution functions of the full 20-minutes records illustrated in fig.9, are shown in fig. 12. As expected, the record closest to the wavemaker shows similar properties to the records in section 3.1, and may probably be described by 2nd order effects. At the far location, however, the increased modulation is observed through larger deviations from the Rayleigh estimates for large wave heights as well as large crest heights. This is connected with the high kurtosis value discussed above.

#### 4. DISCUSSION WITH CONCLUSIONS.

The tests with initially monochromatic and bichromatic waves verify the expected effects: After a certain propagation length ( $> 10$  wavelengths), the wave trains get unstable, and with further propagation they gradually form smaller groups. This may lead to groups with some asymmetric and pronounced individual waves. Wave breaking may also occur, even in wave trains with initially moderate steepness. The

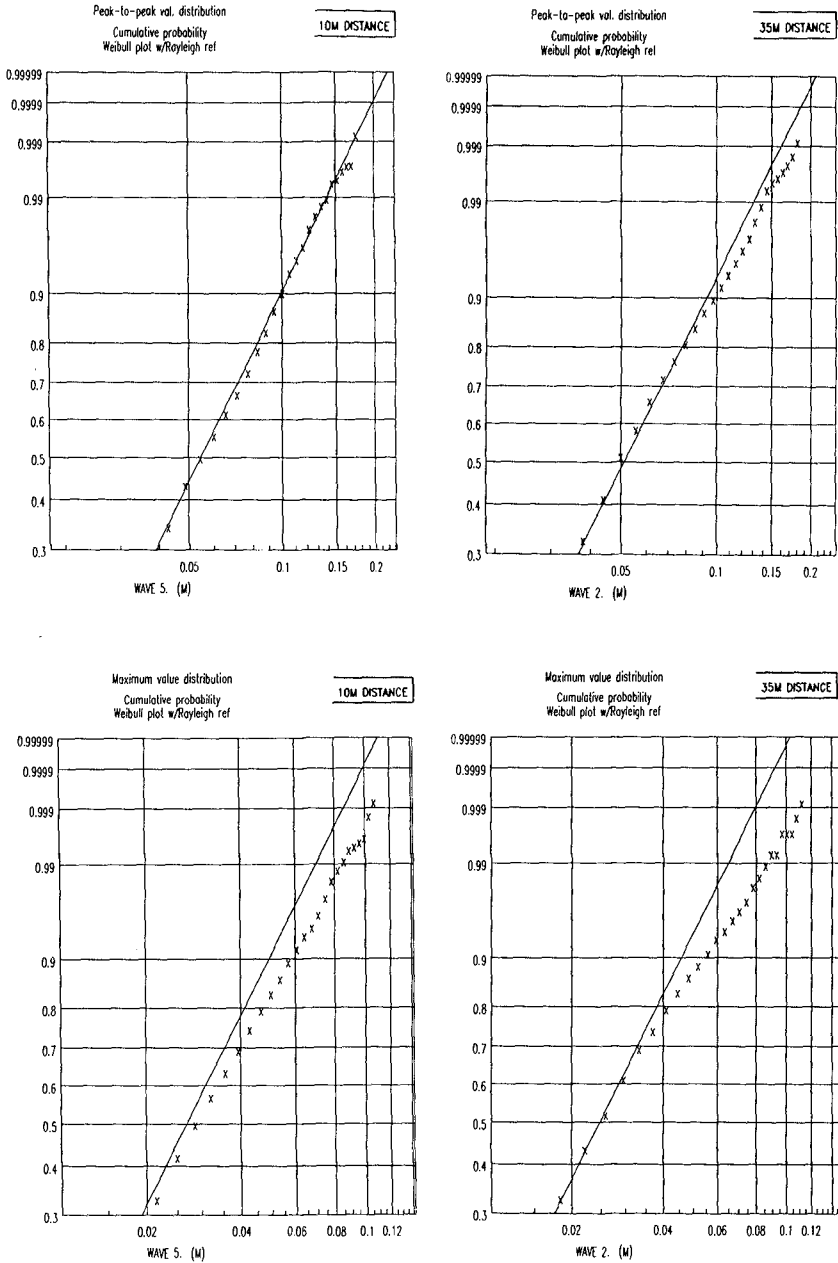

Figure 12. Cumulative distributions of wave 2 and crest heights of the wave records in figs. 9 and 10.

instabilities are connected with a continuous formation of side bands in the wave spectrum, i.e. the wave energy spreads out to lower as well as to higher frequencies. The net effect, as observed from a number of different tests (also including tests that are not shown in figs. 3 & 4), seems to be an energy transfer to lower frequencies, although the high-frequency side-bands seem to decrease rather slowly with the propagation. This confirms the results of Dysthe (1979) and others. Energy dissipation also occurs.

From the irregular wave tests it is observed that the statistical skewness of the records, interpreted as a consequence of 2nd order (Stokes) non-linearities, occurs already at a few wavelengths from the wavemaker. With further propagation, the skewness is still determined mainly by the steepness of the sea state. On the other hand, the statistical kurtosis, interpreted as a consequence of higher-order modulational instabilities, grows gradually with the propagation until the instabilities lead to energy dissipation (wave breaking and other processes) in the same manner as observed for monochromatic and bichromatic waves. The growth of the instabilities also seem to depend on the wave steepness, as expected. After the dissipation, however, the results seem to indicate that the wave train "reorganizes" to a more stable process with lower energy, lower skewness and lower kurtosis values.

For practical purposes, we may interpret the above results in the way that for proper future modelling of random wave fields, one should probably include at least 2nd order non-linearities, if the occurrence of large waves is an essential matter. Whether the higher-order instability effects should also be considered, is more uncertain, since the rise and decrease of such effects may possibly occur more as local events rather than permanent, homogenous properties. This is, however, a field where more studies are needed.

## CHAPTER 50

### INTERACTION of NONLINEAR WAVE and CURRENT

S. Supharatid<sup>1</sup>, H. Tanaka<sup>2</sup>, and N. Shuto<sup>3</sup>

#### Abstract

A nonlinear wave-current model is developed to obtain the velocity and shear stress. The model employing an "empirical velocity deviation" which introduces the modification of the time-mean velocity caused by waves is proposed. With an application of a time-invariant linear eddy viscosity and making use of the truncated Fourier series, a boundary value problem is formulated and is solved numerically. Comparisons among many cases of measured and predicted results show reasonable agreements.

#### 1 Introduction

Knowledge on the combined wave and current in the boundary layer flows has been investigated theoretically and experimentally by many researchers. However, the modifications of the fundamental characteristics of the waves and current resulted from their interactions have been rarely mentioned.

At present, there are some numerical models which incorporate currents into their formulations. Dalrymple(1974) proposed a numerical perturbation while Teles da Silva and Peregrine(1988) used a boundary integral method to simulate the flow fields under waves with a linear shear current. Kishida and Sobey(1988) modified the Stokes theory to include the effect of a linear shear current. These wave-current model are still needed to be verified with experimental data or field measurements.

Recently, Tanaka(1989) extended his one-layer model to account for the nonlinear wave by a modifying Dean's stream function.(Dean, 1965) This model, however, does not succeed to predict the time-mean velocity near the water surface.

2 Assoc. Prof., Asian Institute of Technology, Bangkok, Thailand.

3 Prof., Disaster Control Research Center, Faculty of Engineering, Tohoku Univ., Sendai, Japan.

The present work was made by the incorporation of a modified current profile instead of the conventional log-current profile. The usual boundary value problem, with the application of the eddy viscosity approach and Fourier wave theory, is formulated in term of the stream function. The predicted velocity and bottom shear stress are compared with author's experimental data.

## 2 Boundary value problem

Prior to the formulation, the following assumptions should be made.

- 1) Waves propagate without change in form.
- 2) Wave height is known.
- 3) Current is uniform in the flow direction.
- 4) Flow is incompressible and fully turbulent.

Consider a two-dimensional periodic wave train propagating on a steady uniform current over a horizontal bottom(see Fig. 1). Equation of continuity is

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad (1)$$

where  $(u, w)$  are  $(\partial\psi/\partial z, -\partial\psi/\partial x)$  for the stream function

The boundary conditions to be satisfied in a moving reference frame with the wave celerity,  $c$  are as follows:

Non-slip condition at the bottom,

$$\frac{\partial \psi}{\partial z} = 0, \quad z = z_0 \quad (2)$$

No flow through the bottom,

$$\psi(x, z) = 0, \quad z = z_0 \quad (3)$$

No flow through the water surface(KFSBC),

$$\psi(x, z) = Q, \quad z = \eta(x) \quad (4)$$

Dynamic free surface boundary condition(DFSBC),

$$\frac{1}{2} \left( \frac{\partial \psi}{\partial x} \right)^2 + \frac{1}{2} \left( \frac{\partial \psi}{\partial z} \right)^2 + gz = R, \quad z = \eta(x) \quad (5)$$

Periodic lateral boundary condition with respect to wave length,  $L$

$$\psi(x+L, z) = \psi(x, z) \quad (6)$$

The mass conservation requires the invariant mean water level, on taking the x-co-ordinate with the origin at the wave crest,

$$\int_0^{L/2} \eta dx = D \quad (7)$$

The wave height, H is assumed known and is defined as the vertical difference between wave crest and wave trough.

$$\eta(0) - \eta(L/2) = H \quad (8)$$

where  $\eta$  = water surface elevation measured from the bottom  
 Q, R = constants  
 D = water depth  
 $z_0$  = bottom roughness height  
 H, L = wave height and wave length.

### 3 Stream function formulation

The stream function for a combined wave-current motion is expressed as

$$\psi = \psi_c + \psi_{WIR} + \psi_{WR} \quad (9)$$

where  $\psi_c$ ,  $\psi_{WIR}$ , and  $\psi_{WR}$  correspond to the stream functions for a steady current, irrotation(WIR) and rotation(WR) waves respectively.

#### 3.1 Stream function for a steady current

The stream function for a steady current,  $\psi_c$  is obtained from the normal momentum equation with the use of a time-invariant linear eddy viscosity,  $\tau_c / \rho = \kappa u_{*c} z \partial u_c / \partial z$ . However, with the introduction of an experimentally determined "velocity deviation,  $\Delta u_{cd}$ " as the water surface boundary condition, the final solution can be written in term of the time-mean velocity,  $u_c$  as

$$u_c = \frac{u_{*c} |u_{*c}|}{\kappa u_{*c}} \ln \frac{z}{z_0} \pm \Delta u_{cd} \frac{z - z_0}{D - z_0} \quad (10)$$

where  $u_{*c}$  = friction velocity for the steady current  
 $u_{*wc}$  = friction velocity for the combined flow  
 $\kappa = 0.41$ .

Symbols + and - are for waves with the following and opposing currents, respectively. Here,  $\Delta u_{c \pm}$  (see Fig. 2) is expressed empirically in term of the relative strength of waves to current,  $U_0/U_c$  by

$$\frac{\Delta u_{c \pm}}{|U_c|} = - \frac{1}{5} \frac{U_0}{U_c} \tag{11}$$

where  $U_0$  is the velocity amplitude at the bottom of the wave-induced motion (linear theory).  $U_c$  is the depth-averaged current velocity, symbol  $||$  means the absolute value.

It is clearly seen from Eq. (10) that the neglect of the second term on the right hand side reduces to a familiar log-current profile similar to that of the steady current alone.

3.2 Stream function for waves

Equations (12) and (13) represent the stream function for irrotational and rotational waves, respectively. For  $j = 1$ , they reduce to the fundamental forms of the first-order solution obtained by Fenton (1980) and Grant & Madsen (1979).

$$\psi_{WIR} = B_0(z-z_0) + \sum_{j=1}^n \frac{B_j \sinh(jk(z-z_0)) \cos(jkx)}{\cosh(jkD)} \tag{12}$$

$$\psi_{WR} = \frac{K_0 k}{\omega} \sum_{j=1}^n \frac{B_j}{R_{j0} \cosh(jkD)} F_j \tag{13}$$

where  $B_0, B_1, \dots, B_n =$  unknown constants

$$K_0 = \kappa u_{\infty c}, k = \text{Wave number}, \omega = \text{Angular frequency of wave}$$

$$R_{j0} = 2( \text{Ker}^2 \xi_{j0} + \text{Kei}^2 \xi_{j0} ) \quad \xi_{j0} = 2(j\omega z_0 / K_0)^{1/2}$$

$$\xi_j = 2(j\omega z / K_0)^{1/2}$$

$$F_j = \xi_j ( \text{Ker}' \xi_j \text{Kei} \xi_{j0} - \text{Kei}' \xi_j \text{Ker} \xi_{j0} ) \cos(jkx)$$

$$- \xi_j ( \text{Ker}' \xi_j \text{Ker} \xi_{j0} + \text{Kei}' \xi_j \text{Kei} \xi_{j0} ) \sin(jkx)$$

$$+ \xi_{j0} ( \text{Kei}' \xi_{j0} \text{Ker} \xi_j - \text{Ker}' \xi_{j0} \text{Kei} \xi_j ) \cos(jkx)$$

$$+ \xi_{j0} ( \text{Kei}' \xi_{j0} \text{Kei} \xi_j + \text{Ker}' \xi_{j0} \text{Ker} \xi_j ) \sin(jkx) .$$

$\text{Kei}, \text{Ker} =$  Kelvin functions of zero order.

Subscript "j" denotes the order of the finite Fourier expansions. Subscript "o" denotes values evaluated at the bottom except  $B_0$  which is one of unknown constants,  $B_j$ . Symbol " ' " means the 1st derivative of  $\text{Ker}$  and  $\text{Kei}$  with respect to  $\xi$ .

#### 4 Solution method

It is convenient to make variables dimensionless with respect to the mean water depth,  $D$ , and gravitational acceleration,  $g$  as shown Table 1.

The stream functions introduced above satisfy the equation of continuity, non-slip condition at the bottom, no vertical velocity at the bottom, and the periodicity with the wave length,  $L$ . Therefore, equations to be solved are kinematic and dynamic conditions at the free surface Eqs. (4) and (5), invariant condition for the mean water level Eq. (7), and the wave height Eq. (8).

Strictly speaking, the dynamic boundary condition at the free surface (Eq. (5)) is only applicable for an inviscid flow but not to the present case. This is because the flow under consideration inevitably yields the energy dissipation caused by viscous and turbulent motions. However, most of the energy dissipation occurs within the very thin region near the bottom, and outside this region the flow nearly behaves like an inviscid flow, making Eq. (5) applicable to the present case.

Now, we have  $(2n+4)$  equations for  $(2n+7)$  unknowns ( $u, w, c, B_0, k, Q, R, \eta_j (j=0, n)$ , and  $B_j (j=0, n)$ ). Therefore, three more equations are introduced as follows.

The value of  $u^*w_c$  has to be solved by iteration on an assumption of constant stress layer approximation near the bottom, i.e.

$$\tau_{wc} = \rho u^*w_c = \rho K_0 z_0 \left. \frac{\partial^2 \psi}{\partial z^2} \right|_{z=z_0} \quad (14)$$

where  $\tau_{wc}$  = maximum bottom shear stress for the combined flow.

The first definition of wave celerity,  $c$  is related to the time-mean velocity,  $\bar{u}$  and the Eulerian velocity,  $U_E$  as

$$U_E = c + \bar{u} \quad (15)$$

where

$$\bar{u} = \frac{1}{L} \int_0^L \frac{\partial \psi}{\partial z} dx = B_0 + \partial \psi_0 / \partial z \quad (16)$$

The  $z$ -dependent terms in Eq. (15) with Eq. (16) inserted should be balanced with each other. This yields

$$c = -B_0 \quad (17)$$

Now, the problem formulation provides  $(2n+7)$  non-linear equations for  $(2n+7)$  unknowns. The solutions are obtained by using the Newton-Raphson method. The solution flowchart is shown in Fig. 3

## 5 Results.

### 5.1 Time-mean velocity over a rough bed

The computed results are compared with the measurements conducted by authors in term of the time-mean velocity in Fig. 4. Modifications caused by waves are dependent on the flow direction, i.e. decrease and increase of the time-mean velocity near the free surface for waves with following and opposing currents. Introducing the "velocity deviation",  $\Delta u_0$  results in relatively good agreement above a height of about 100 mm.

In fact, discrepancies below this height may be caused by violent generation and transportation of vortices excited by triangular roughnesses on the bottom. With the use of the Nikuradse roughness to represent the bottom, the present model does not allow to predict such a 3-D phenomenon.

### 5.2 Ensemble-averaged velocity over a rough bed

Profiles of the ensemble-averaged velocity at phases of acceleration and deceleration are shown in Fig. 5(a)(following flow) and 5(b)(opposing flow). Agreements are reasonably well except in the vicinity of the bottom and the overshooting zone. However, the height of overshooting is well predicted. This near bottom phenomena, in fact, suggests that any model employing the closure assumption of a time-invariant eddy viscosity will suffer the same effect.

To improve the solution near the overshooting zone, it is necessary to adopt more realistic models such as the  $K-\epsilon$  model (Supharatid et. al., 1992). This certainly requires a considerably time-consuming computation.

### 5.3 Bottom shear stress over a smooth bed

The bottom shear stress for a smooth bed was measured directly using a hot-film sensor. Comparisons with the present theory are made in Fig. 6 for both waves with following and opposing currents. In the figure, two thin lines denote values of  $\langle \tau_b \rangle + \sigma_\tau$  and  $\langle \tau_b \rangle - \sigma_\tau$  of the measured data where  $\sigma_\tau$  is the standard deviation.

Throughout the wave cycle, the model generally gives satisfactory agreement, except for the results near the phase of wave trough in the case of waves with the opposing current. The distinct phase advance of the bottom shear stress is observed and predicted rather well by the model.

## 6 Conclusions

A model for nonlinear wave interacting with the steady current is developed to obtain the velocity as well as the shear stress. The effect of waves on the current is introduced in term of the "velocity deviation". The time-mean velocity, as a result, is given by a summation of logarithmic and linear profiles.

Good agreements are generally found between the predicted results and measured data. Velocity profiles are predicted rather well except in the vicinity of the "overshooting zone" where a time-invariant eddy viscosity assumed by the model is not applicable. Time histories of the bottom shear stress are also predicted reasonably well.

## CHAPTER 51

### A stream function solution for waves on a strongly sheared current.

Christopher Swan<sup>1</sup>

#### Abstract.

A perturbation analysis is presented in which a series of small amplitude progressive gravity waves interact with a strongly sheared current. The solution, which is extended to a second order of wave steepness, shows that if the time averaged vorticity distribution varies with depth the wave motion becomes rotational. An additional wave component, expressed in terms of the first harmonic, is identified at a second order of wave steepness. This does not arise within an irrotational solution and is quite distinct from the Doppler shift associated with the surface current. Explicit solutions are given for the dispersion equation and the wave induced kinematics. These are found to be very different from the existing irrotational solutions, and suggest that the non-linear wave-current interaction terms can become very important if the current profile is strongly sheared in the vicinity of the water surface. In such cases the underlying velocity field should not be predicted by an irrotational solution based upon an "equivalent" uniform current.

#### 1. Introduction.

The combination of waves and currents is an important feature of most marine environments. The present paper considers the fluid flow resulting from such an interaction once it has achieved a state of equilibrium. It will not consider the initial generation of waves on a strongly sheared current; nor will it consider the propagation of waves onto a strongly sheared current. The initial transfer of energy between the various components of the flow field,

<sup>1</sup> Lecturer, Department of Civil Engineering, Imperial College, London. SW7 2BU, UK.

and the resulting change in the wave height, forms part of a transient problem which has already been considered by a number of authors. These include Longuet-Higgins and Stewart (1960, 1961), Bretherton and Garrett (1968), and Brink-Kjær and Jonsson (1975). A full discussion of these matters is given in the review articles by Peregrine (1976) and Jonsson (1990).

It is well known that the equilibrium conditions associated with the interaction of waves and currents are strongly dependent upon the vertical distribution of the current velocity. In many practical cases it may be assumed that the current profile is approximately uniform with depth. Important examples of this type of behaviour are the large scale ocean currents, and the majority of tidal flows. Under these conditions, the wave motion remains irrotational and, in effect, the only interaction occurs within the associated dispersion equation. At a second order of wave steepness the dispersion equation for waves propagating on a uniform current ( $U=U_0$ ) is given by:-

$$c = \frac{\sigma}{k} - \left[ \frac{g}{k} \tanh(kh) \right]^{1/2} + U_0 \quad (1)$$

where  $c$  is the wave celerity,  $h$  is the water depth and  $g$  is the gravitational constant. The wave number ( $k$ ) and the wave frequency ( $\sigma$ ) are defined in the usual way so that  $k=2\pi/\lambda$  and  $\sigma=2\pi/T$ , where  $\lambda$  is the wave length and  $T$  is the wave period. This solution is often referred to as a "Doppler shifted solution" since it describes the wave form propagating on the surface current.

A second example which has been widely considered is that of waves on a linear shear current, or one in which the current velocity varies linearly with depth. Tsao (1959) considered this case and showed that the wave motion, or the oscillatory component of the flow field, will remain irrotational provided the vorticity is constant throughout the water depth. In this case the stream function ( $\psi$ ) can no longer be expressed in the form of a solution to Laplace's equation as would be the case in a classical Stokes' expansion (1847). The governing equation is thus expressed in the form of a Poisson equation:-

$$\nabla^2 \psi = \Omega_0 \quad (2)$$

where  $\Omega_0$  is the constant vorticity or the gradient of the linear shear current. Although the oscillatory motion remains irrotational, it is different from that which would be predicted in the absence of a current. If the current is assumed to be of a similar magnitude to the first order wave motion, an additional oscillatory term arises at a second order of wave steepness ( $O(a^2k^2)$ ). Kishida and Sobey (1988) identified this term as:-

$$\psi_{wc} = 2az\Omega_0 \frac{\sinh(kh+kz)}{\sinh(kh)} \cos(kx - \sigma t) \quad (3)$$

where  $a$  is the wave amplitude (or half the wave height,  $H$ ) and  $(x, z)$  are the Cartesian co-ordinates described below.

In many practical cases neither the current velocity or the vorticity distribution are uniform. For example, in the absence of significant vertical mixing, a wind driven current decays exponentially with depth. This creates a strongly sheared current with a concentration of vorticity near the water surface. To describe an interaction of this type has hitherto required a complex numerical model similar to that proposed by Chaplin (1989). The present paper will consider this case and presents a new analytical solution which is simple to use, and which provides a first approximation to the non-linear wave-current interaction which arises in the presence of a strongly sheared current profile.

## 2. Theory.

The new solution will take the form of a perturbation expansion in which a series of two-dimensional monochromatic waves, propagating in water of constant depth, interact with a strongly sheared current. To simplify the non-linear boundary conditions which must be applied at the water surface, the analysis will be conducted within an orthogonal curvi-linear co-ordinate system.

The Cartesian co-ordinates shown on figure 1a translate with the phase velocity ( $c$ ) to provide a steady ( $d/dt=0$ ) frame of reference. These axes are mapped onto the curvi-linear co-ordinates shown on figure 1b. To achieve this a sequence of transformations must be applied so that at each order of the perturbation (see below)  $\eta=0$  defines the free surface and  $\eta=-h$  the position of the impermeable bottom boundary. At a first order of approximation these transformations are similar to those applied by Benjamin (1959). The general form of the transformations are given by:-

$$\eta - z - \sum_{n=1}^N A_n \frac{\sinh(nkh+nk\eta)}{\sinh(nkh)} \cos(nk\xi) - B_n \tag{4}$$

$$\xi - x - \sum_{n=1}^N A_n \frac{\cosh(nkh+nk\eta)}{\sinh(nkh)} \sin(nk\xi)$$

where the subscript defines the order of the terms, and the unknown constants ( $A_n, B_n$ ), are dependent upon the water surface elevation ( $\zeta$ ). Since this cannot be known a priori an iterative approach is adopted in which an initial estimate of the surface profile is made, the co-ordinates are transformed, and a solution obtained as indicated below. This solution is then used in conjunction with the boundary conditions to define, where necessary, an appropriate modification of the surface elevation. In this way a unique solution can be identified which satisfies both the governing equation and the boundary conditions.

Figure 1. Co-ordinate arrangements.

To achieve this iterative approach the irrotational solution proposed by Stokes (1847) was used to provide an initial estimate of the surface elevation. If  $\zeta$  is measured relative to the still water level ( $z=0$ ), then the required second order expression is given by:-

$$\zeta = a \cos(\Phi) + a^2 k \cosh(kh) \frac{[2\sinh^2(kh) + 3]}{4\sinh^3(kh)} \cos(2\Phi) - \frac{a^2 k}{2\sinh(2kh)} \tag{5}$$

where  $\Phi$  is the phase angle ( $kx - \sigma t$ ). It is important to note that the surface elevation alone is being adopted as an initial estimate. No assumptions are made about the nature of the associated dispersion equation, and the flow is not assumed to be irrotational.

The transformations given above (4) are orthogonal, and the Jacobian  $J$  is defined by:

$$J = \frac{\alpha(\xi, \eta)}{\partial(x, z)} \quad (6)$$

Within the  $(\xi, \eta)$  co-ordinates the two dimensional vorticity equation for flow in an inviscid fluid is given by:

$$\frac{\alpha(\psi, \sqrt{\nabla^2 \psi})}{\partial(\xi, \eta)} = 0 \quad (7)$$

where the stream function ( $\psi$ ) is defined so that the total velocity components in the  $\xi$  and  $\eta$  directions are:-

$$(U+u)_\xi = J^{1/2} \frac{\partial \psi}{\partial \eta}, \quad u_\eta = -J^{1/2} \frac{\partial \psi}{\partial \xi} \quad (8)$$

In accordance with the arguments originally outlined by Stokes (1847) an exact solution of a two dimensional wave train does not exist. Consequently, a perturbation expansion must be employed in which the stream function ( $\psi$ ), the surface elevation ( $\zeta$ ), and the Jacobian ( $J$ ), are expressed in terms of a small expansion parameter ( $\epsilon$ ):

$$\begin{aligned} \psi &= \psi_0 + \epsilon \psi_1 + \epsilon^2 \psi_2 + \epsilon^3 \psi_3 + \epsilon^4 \psi_4 + \dots \\ \zeta &= \zeta_0 + \epsilon \zeta_1 + \epsilon^2 \zeta_2 + \epsilon^3 \zeta_3 + \epsilon^4 \zeta_4 + \dots \\ J &= J_0 + \epsilon J_1 + \epsilon^2 J_2 + \epsilon^3 J_3 + \epsilon^4 J_4 + \dots \end{aligned} \quad (9)$$

where the subscript again denotes the order of the term involved. In the present solution the wave steepness ( $ak$ ) is adopted as an appropriate expansion parameter, and the co-ordinate arrangement shown on figure 1b defines the following "zero order" terms:

$$\psi_0 = -c\eta, \quad J_0 = 1, \quad \zeta_0 = 0 \quad (10)$$

Substituting (9) and (10) into the governing vorticity equation and collecting powers of  $\epsilon$  gives the required expressions of the vorticity equation at successive steps in the perturbation:

$$c \frac{\partial}{\partial \xi} (\nabla^2 \psi_1) = 0$$

(11)

$$c \frac{\partial}{\partial \xi} (\nabla^2 \psi_2) = \frac{\partial (\nabla^2 \psi_1, \psi_1)}{\partial (\xi, \eta)} - c \frac{\partial}{\partial \xi} (J_1 \nabla^2 \psi_1)$$

Before discussing the boundary conditions we must define the characteristics of the current profile. Firstly, it should be noted that if the magnitude of the current velocity is close to the phase velocity (c), the vorticity equations (11) are indeterminate. Fortunately, this situation seldom arises within either a coastal or an ocean environment. Current velocities are typically much smaller than the phase velocity, and are generally more closely related to the magnitude of the first order wave motion ( $U=0.(ak)$ ). This assumption is adopted within the present formulation.

Figure 2. A strongly sheared current profile.

To ensure that an appropriate range of current profiles can be incorporated within the present solution, a polynomial representation is adopted to describe a current profile within the region  $0 \leq \eta \leq -mh$  where  $m$  is a constant within the range  $(0 \leq m \leq 1)$ . Hence:

$$U = (P + 2Q\eta + 3R\eta^2 + 4S\eta^3) \delta_s(\eta + mh) \tag{12}$$

Where  $\delta_s(\eta+mh)$  is the heavyside step function defined by:

$$\begin{aligned} \delta_s(\eta+mh) &= 1 & \text{if } (\eta+mh) \geq 0 \\ \delta_s(\eta+mh) &= 0 & \text{if } (\eta+mh) < 0 \end{aligned} \quad (13)$$

Figure 2 compares the current profile defined in (12) with a wind driven profile based on the lamina flow solution proposed by Lamb (1932).

The vorticity equations (11) must be solved within the confines of the following boundary conditions:

(a) If the bottom boundary is assumed to be both horizontal and impermeable, the vertical velocity at the bed must be zero:

$$-J^{1/2} \frac{\partial \psi}{\partial \xi} = 0 \quad \text{on } \eta = -h \quad (14)$$

(b) Since the water surface is a streamline the kinematic condition requires the velocity normal to the surface to be zero:

$$-J^{1/2} \frac{\partial \psi}{\partial \xi} = 0 \quad \text{on } \eta = 0 \quad (15)$$

(c) The dynamic free surface boundary condition further requires the pressure ( $p$ ) acting on the water surface to be constant. In general orthogonal co-ordinates the equations of motion are given by:-

$$\frac{\partial \underline{u}}{\partial t} + \frac{1}{2} \nabla(\underline{u}^2) - \underline{u} \times \omega = -\frac{1}{\rho} \nabla(p) + F \quad (16)$$

where the under-bar denotes a vector quantity,  $\omega$  is the vorticity distribution, and  $F$  is a body force. Taking the first component of (16) and applying the kinematic condition (15) gives the required dynamic condition:

$$\frac{\partial p}{\partial \xi} = F_\xi J^{1/2} - \frac{1}{2} \frac{\partial J}{\partial \xi} \left[ \frac{\partial \psi}{\partial \eta} \right]^2 - J \frac{\partial \psi}{\partial \eta} \frac{\partial^2 \psi}{\partial \eta \partial \xi} = 0 \quad \text{on } \eta = 0 \quad (17)$$

where  $F_{\xi}$  is the resolved component of the body force per unit mass in the  $\xi$  direction. If  $g$  is the gravitational constant, and  $\theta$  is the angle separating the  $z$  and  $\eta$  directions (figure 1), we obtain:

$$F_{\xi} = -g \sin(\theta) \tag{18}$$

(d) Finally the fluid motion must be continuous throughout the entire water depth. In the case of ( $m < 1$ ) the flow may be divided into two distinct regions which are characterised by the presence ( $0 \geq \eta \geq -mh$ ), or absence ( $-mh \geq \eta \geq -h$ ), of the current profile. If the governing equation (7) is to be consistent across this interface ( $\eta = -mh$ ) the time averaged vorticity must be zero at the lower edge of the current profile:

$$\lim_{(\eta \rightarrow -mh)}(\omega) = 0 \tag{19}$$

Furthermore, the value of the stream function and the velocity components must also be continuous across this region. If  $(\eta \rightarrow -mh)$  represents the limit taken in the negative  $\eta$  direction (from above) and  $(\eta \leftarrow -mh)$  represents the limit taken in the positive  $\eta$  direction (from below) the final boundary conditions are given by:

$$\begin{aligned} \lim_{(\eta \leftarrow -mh)}(\psi) &= \lim_{(\eta \rightarrow -mh)}(\psi) \\ \lim_{(\eta \leftarrow -mh)}\left(j^{1/2} \frac{\partial \psi}{\partial \eta}\right) &= \lim_{(\eta \rightarrow -mh)}\left(j^{1/2} \frac{\partial \psi}{\partial \eta}\right) \\ \lim_{(\eta \leftarrow -mh)}\left(-j^{1/2} \frac{\partial \psi}{\partial \xi}\right) &= \lim_{(\eta \rightarrow -mh)}\left(-j^{1/2} \frac{\partial \psi}{\partial \xi}\right) \end{aligned} \tag{20}$$

### 3. Results and discussion.

The perturbation analysis is extended to a second order of wave steepness. Since the current velocity is assumed to be of order  $ak$ , the solution will provide a first approximation to the wave-current interaction. The resulting stream function is given by:

$$\psi_0 = -c\eta$$

$$\psi_1 = (Q\eta^2 + R\eta^3 + S\eta^4) \delta_s(\eta + mh) - P\eta \delta_s(-\eta - mh)$$

$$\psi_2 = a(2Q\eta + 3R\eta^2 + 4S\eta^3 + \frac{6S\eta}{k^2} + F_a) \frac{\sinh k(h+\eta)}{\sinh kh} \cos(k\xi) \delta_s(\eta + mh) \quad (21)$$

$$+ a(-\frac{3R\eta}{k} - \frac{6S\eta^2}{k} + F_b) \frac{\cosh k(h+\eta)}{\sinh kh} \cos(k\xi) \delta_s(\eta + mh)$$

$$+ aF_c \sinh k(h+\eta) \cos(k\xi) \delta_s(-\eta - mh)$$

Where the heavyside function ( $\delta_s$ ) is defined in (13) and the terms  $F_a$ ,  $F_b$ , and  $F_c$  are constants for a given wave-current interaction (figure 3).

Figure 3. The constant coefficients ( $F_a$ ,  $F_b$ ,  $F_c$ ).  
(Defined for a cubic shear current).

The three terms within this series solution can be identified in the following way. The zero order term ( $\psi_0$ ), which arises due to the translation of the co-ordinate axes, may be used in conjunction with the Jacobian ( $J$ ) to define the irrotational velocity components within a classical Stokes expansion. The first order term ( $\psi_1$ ) provides a description of the current profile in a steady frame of reference, and the second order term ( $\psi_2$ ) defines the additional terms associated with the wave-current interaction.

To complete the required solution a dispersion equation describing the combined wave-current motion is required. At a second order of wave steepness the phase velocity measured relative to a stationary observer is given by:-

$$c = \frac{\sigma}{k} - \left( \frac{g \tanh(kh)}{k} \right)^{\frac{1}{2}} + P - \frac{Q \tanh(kh)}{k} + \frac{3R}{2k^2} - \frac{3S \tanh(kh)}{k^3} + \frac{F_a}{2 \cosh^2(kh)} \tag{22}$$

where P, Q, R and S are the constants used to define the current profile (12). Assessing these terms at the water surface ( $\eta=0$ ) we obtain:

$$P = (U)_{\eta=0} \quad , \quad Q = \frac{1}{2!} \left( \frac{dU}{d\eta} \right)_{\eta=0} \tag{23}$$

$$R = \frac{1}{3!} \left( \frac{d^2U}{d\eta^2} \right)_{\eta=0} \quad , \quad S = \frac{1}{4!} \left( \frac{d^3U}{d\eta^3} \right)_{\eta=0}$$

The effect of the surface vorticity ( $\omega_s$ ) is considered in figure 4. Convention dictates that a vorticity distribution is positive if it causes an anti-clockwise rotation of the fluid particles ( $\omega = -dU/d\eta$ ). Unfortunately, this definition results in a positively sheared current ( $dU/d\eta > 0$ ) having negative vorticity. To avoid confusion the horizontal abscissa on figure 4 is expressed in terms of ( $-\omega_s$ ) so that an increase in the positive x-direction indicates an increase in the positive shear.

Figure 4 considers a number of realistic current profiles in which a "favourable" current ( $U_s > 0$ ) has positive shear ( $-\omega_s > 0$ ) and an "adverse" current ( $U_s < 0$ ) has negative shear ( $-\omega_s < 0$ ). In all cases the vorticity distribution acts to reduce the effect of the Doppler shift associated with the surface current ( $U_s$ ). For example, if a series of waves propagate onto a "favourable" current the individual waves will be "stretched" thereby producing a reduction in the wave number. If however, the current profile is sheared ( $dU/d\eta > 0$ ) then the apparent change in the wave number is much reduced. Indeed, figure 4 indicates that a highly sheared current profile can entirely negate the wave length changes associated with the Doppler shift.

Figure 4. The wave number ( $k$ ).

This reduction in the apparent Doppler shift has led some authors to suggest that the interaction with a strongly sheared current can be described by an "equivalent" uniform current ( $U(\eta)=U_a$ ). Hedges and Lee (1992) define this "equivalent" uniform current as that which produces the same wave number ( $k$ ) as the actual depth varying current for a particular wave period, wave height, and water depth. This approach is considered in figures 5a-5b which respectively concern the interaction with a positively sheared "favourable" current and a negatively sheared "adverse" current. In each case the first figure provides a description of the current profile ( $U$ ), and the second figure describes the oscillatory velocity occurring beneath the wave crest ( $u$ ). Four different solutions of the wave induced velocity are presented: the first is a waves only solution which neglects the effect of the current profile; the second assumes that the surface current exists uniformly with depth ( $U(\eta)=U_a$ ); the third is based on the present solution for waves on a strongly sheared current, and the fourth is based on an "equivalent" uniform current.

Figures 5a and 5b show that the wave kinematics resulting from the interaction with a strongly sheared current are dependent upon two separate effects. The first corresponds to a change in the dispersive characteristics of the wave form given in equation (22), and the second is associated with the rotational wave components identified in equation (21). The dispersive characteristics are found to be dependent upon the magnitude of the surface current and

the time averaged vorticity distribution. In consequence the actual wave number falls between the values predicted by the waves only solution and the uniform current solution which is based upon the magnitude of the surface current ( $U_s$ ).

Figure 5a. Interaction with a "favourable" current. ( $T=5s$ ,  $h=10m$ ,  $H=2m$ ).

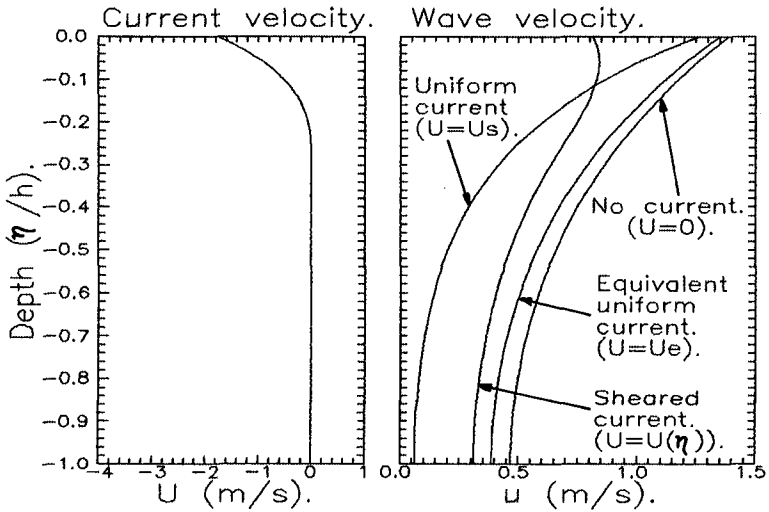

Figure 5b. Interaction with an "adverse" current. ( $T=5s$ ,  $h=10m$ ,  $H=2m$ ).

The "equivalent" uniform current will, by definition, correctly model the dispersive characteristics of the combined wave-current motion. However, this alone is not sufficient to describe the wave induced flow field in the presence of a strongly sheared current. Figures 5a and 5b clearly indicate that the wave kinematics are directly dependent upon the vorticity distribution. In the upper region of the flow field ( $0 \geq \eta \geq -mh$ ), where the current profile exists, figure 5a shows that a positively sheared "favourable" current produces a significant increase in the amplitude of the oscillatory velocity occurring near the water surface. In figure 5b a negatively sheared "adverse" current reduces the oscillatory velocity in this region. These changes are associated with the rotational wave component identified in equation (21). They are not related to the effective Doppler shift, and cannot therefore be predicted by an irrotational solution based on an "equivalent" uniform current.

It is interesting to note that even in the lower layers of the flow field ( $-mh \geq \eta \geq -h$ ) where no current profile exists, and consequently the flow must be irrotational, the solution based upon an "equivalent" uniform current again provides a poor representation of the wave kinematics. This arises because of the continuity conditions (20) which must be applied at the lower edge of the current profile ( $\eta = -mh$ ). This suggests that a wave-current interaction involving a non-uniform vorticity distribution will effect the entire wave field, even if, as in the present case, the vorticity profile is contained within a relatively narrow layer near the water surface.

#### 4. Conclusions.

An analytical solution has been presented to describe a series of two dimensional progressive gravity waves propagating on a strongly sheared current. The solution has been extended to a second order of wave steepness and shows that the wave motion becomes rotational if the vorticity distribution varies with depth.

The dispersion equation describing the combined wave-current motion is found to contain additional first order terms which are related to the vorticity distribution. These terms have a significant effect upon the predicted wave number, and in the case of a realistic current profile lead to a reduction in the apparent Doppler shift.

The oscillatory velocities associated with the wave motion are also shown to be very different from the existing irrotational solutions. In addition to the wave number effects discussed above, a favourable current with positive

shear produces a significant increase in the amplitude of the oscillatory motion, while an adverse current with negative shear reduces the amplitude of the oscillatory motion. These changes are associated with a rotational wave component which arises at a second order of wave steepness. This additional component is directly related to the vorticity distribution and does not therefore arise within a classical Stokes' expansion. As a result, the wave motion generated in the presence of a strongly sheared current cannot be predicted by an irrotational solution, even if this includes the effect of an "equivalent" uniform current.

## CHAPTER 52

### WAVE, TURBULENT AND MEAN MOMENTUM FLUXES ACROSS THE BREAKING WAVE TRANSITION REGION IN THE SURF ZONE

R. J. Thieke<sup>1</sup>, A.M. A.S.C.E.

#### ABSTRACT

This paper presents an application to the transition region of an integral momentum conservation model incorporating a Reynolds type decomposition for both wave and turbulent fluctuations. With simple parameterizations the model provides both a rough predictive capability for the limiting wave reduction across the transition zone and also an alternative means of examining the partitioning of flow momentum across the region.

#### INTRODUCTION

Historically, the quantitative prediction of many surf zone processes has suffered from a lack of sufficient understanding of the detailed hydrodynamics of the wave transformation, wave-induced circulation and turbulent velocity fluctuations across the nearshore zone. The processes of wave shoaling, wave breaking, subsequent wave decay in the surf zone, wave setup and wave induced cross-shore mean circulation occur simultaneously and are intimately interdependent. Their complexity has typically resulted in each process being studied in piecemeal fashion. While important advances have been made, there are notable regions where a thorough understanding is still lacking, particularly the transition region following breaking. The physical processes in the transition (or "outer") region play an important role in the establishment of the flow characteristics of the surf zone, however the dynamics of the region are not well understood quantitatively or qualitatively.

The transition region begins at the breakpoint and extends shoreward, and it is characterized by a rapid decrease in wave height with almost no change in the setup of the mean water level (Svendsen, 1984). The end of the transition region (hereafter referred to as the transition point) is best defined by the point where the setup begins to increase, which is typically accompanied by a decrease in the rate of wave height decay. The entire region represents a relatively rapid reorganization of the wave motion.

The following analysis presents the application of an integral momentum rapidly varied flow analysis to the transition region. A Reynolds type decomposition for both wave and turbulent fluctuations is incorporated. In view of the lack of detailed experimental data within this region, the simplest possible parameterizations of the mean flow and wave properties are adopted. Nevertheless the model provides both a rough predictive capability for the limiting wave reduction across the transition zone and also an alternative means of examining the partitioning of flow momentum across the region.

## BACKGROUND

### Wave Height Decay and Rapidly Varied Flow

The rapid nature of change in the transition region render it largely unsuitable for a gradually varied flow analysis or a similarity approach. An example is provided by the energy flux conservation models for wave height decay in the surf zone. Such models solve the depth integrated energy and momentum conservation equations, and differ largely only in the chosen description of the breaking wave energy dissipation. Svendsen (1984) found very poor agreement with laboratory data when wave height decay computations were initiated at the breakpoint; agreement was substantially improved by starting the decay computations after the transition region following breaking, beyond which point surf zone waves are largely self-similar. Dally et al. (1985), found that a similar improvement in prediction could be achieved for certain of their comparisons with laboratory data by initiating decay computations after the transition region.

These observations suggest a simple analogy to jet flows: The transition region serves as the "zone of flow establishment" for the surf zone, while the inner surf zone is the "zone of established flow," in which similarity approaches have met with considerable success. The dynamics of these two regions appear quite dissimilar and warrant independent treatment.

### Transition Region "Paradox"

Another significant feature of the transition region is the "paradox" observed by Basco and Yamashita (1986) and Svendsen (1984). This paradox is evidenced by the simplified momentum balance in the x (onshore) direction:

$$\frac{dS_{xx}}{dx} + \rho g(h + \bar{\eta}) \frac{d\bar{\eta}}{dx} = 0 \quad (1)$$

where:  $S_{xx}$  = "radiation stress"  
 $\rho$  = mass density  
 $g$  = gravitational acceleration  
 $h$  = depth to still water level  
 $\bar{\eta}$  = mean water level setup

The paradox arises since  $S_{xx}$  ("the radiation stress") is known to be a function of wave height and hence is decreasing rapidly across the transition region. The first term in Equation 1 would appear to be finite and negative. Measurements indicate that the setup is constant, so the second term is approximately zero; the equality is not satisfied.

### Return Flow Modelling

Spatially varying wave height and setup fields have been used as input to a variety of return flow (or "undertow") models which solve for the distribution of the mean flow in the lower portion of the water column (for example Stive and Wind, 1986; Svendsen and Hansen, 1988). Such models follow the qualitative arguments of Dyhr-Nielsen and Sorensen (1970), wherein the return flow is driven by the vertical imbalance between the gradients of radiation stress and setup that is imbedded (but not explicit) in the depth integrated Equation 1. The models typically employ an eddy viscosity parameterization and differ in the description of the wave parameters (particularly the shoreward mass flux in the crest portion of the wave) and the boundary conditions. The mass flux in the crest region is observed to be substantially greater than that of a nonbreaking wave of equivalent height (Nadaoka and Kondoh, 1982) and is dynamically quite significant; the overall magnitude of the local return flow is largely determined by the value of the shoreward mass flux above the trough (which is entered as a "boundary condition"). Svendsen and Hansen (1988) particularly note that this feature of the flow is rather poorly understood.

The nature of the transition region paradox and the importance of this region to both wave height and return flow modelling and indeed to all surf zone processes suggests that additional analysis of this region is warranted. It should be noted that although these effects are sharply evident for the case of monochromatic waves, the "smearing" of the breakpoint in the random wave case tends to mask the importance of the transition region. However Nairn, et al. (1990) found that the inclusion of the lag effect of the transition region was crucial to the accurate modelling of both regular and random wave cases.

## INTEGRAL MOMENTUM CONSERVATION EQUATIONS

In the present context, emphasis is placed on the three hydrodynamic mechanisms which are locally crucial to the various surf zone processes of interest, namely, 1) the (generally nonlinear) wave orbital velocity, 2) the mean flow (often

wave induced), and 3) the residual turbulent velocity fluctuations. Throughout the breaking process and wave decay in the surf zone, the motion consists of complicated interactions between these three mechanisms, and the total available flow momentum is partitioned and exchanged between them. Consequently this analysis will include each of these component motions in a Reynolds type representation of the instantaneous velocity:

$$u = \bar{u} + u'' + u' \quad (2)$$

where the overbar indicates an average over the wave period (mean flow), and the double and single primes refer to the wave and turbulent fluctuations, respectively. This decomposition can be applied to the fundamental variables in the shorenormal (x) momentum conservation equation. Time averaging the resulting equation over a wave period and depth integrating produces the following integral equation:

$$\frac{d}{dx} \int_{-h}^{\eta_e} \rho \bar{u}^2 dz = -\rho g (h + \bar{\eta}) \frac{d\bar{\eta}}{dx} - \frac{d}{dx} \int_{-h}^{\eta_e} (s_{xx}'' + s_{xx}') dz - \tau_b \quad (3)$$

with the apparent stresses now retaining their depth variation and defined as:

$$\begin{aligned} s_{xx}'' &= \text{depth varying wave "radiation stress"} \\ s_{xx}' &= \text{depth varying turbulent "apparent stress"} \end{aligned}$$

The integral on the right hand side of Equation 3 is essentially equivalent to the conventional radiation stress  $S_{xx}$ , however in this instance it includes contributions from both wave and turbulent velocity fluctuations. The momentum flux associated with the mean flow is separated from the "radiation stress" and is represented by the integral on the left hand side of Equation 3.

By neglecting the bed shear stress  $\tau_b$ , Equation 3 can be used to reevaluate the transition region paradox. The paradox appears to stem partially from the conventional linear wave description of radiation stress in which the mean flow and turbulent fluctuations are neglected. Basco and Yamashita (1986) indicate that the paradox merely reflects the redistribution between the velocity and pressure parts of the radiation stress. The above decomposition explicitly including the mean flow further indicates that a reduction in wave height (and hence  $s_{xx}''$ ) in the absence of a setup gradient must be balanced by an increased mean flow and/or an increase in the turbulence intensity. The measurements of Nadaoka and Kondoh (1982) confirm that both the mean mass flux and turbulence intensity increase across the transition region. The success of the "surface roller" parameterization within the inner surf zone (Svendsen, 1984) also substantiates the requirement of an increase in mean flow.

The crucial objective in this region is thus to quantify the relative magnitudes of wave, mean flow and turbulent momentum fluxes from the point of incipient breaking to the end of the transition region. This breaking process sets up the entire flow in the inner surf zone, within which the previously mentioned gradually varied flow and similarity approaches may be more suitably employed.

### SIMPLE RAPIDLY VARIED FLOW MODEL

Further examination of the partitioning of flow momentum is accomplished by the development of a rapidly varied flow analysis of the transition region in direct analogy to the techniques used successfully for hydraulic jumps and bores in channel flows. Because the gradient of setup is zero, Equation 3 can be reduced to a momentum equality across a "shock" which can be considered short enough to neglect bottom friction:

$$\left[ \int_{-h}^{\eta_c} \rho \bar{u}^2 dz + \int_{-h}^{\eta_c} (s_{xx}'' + s_{xx}') dz \right]_b = \left[ \int_{-h}^{\eta_c} \rho \bar{u}^2 dz + \int_{-h}^{\eta_c} (s_{xx}'' + s_{xx}') dz \right]_t \quad (4)$$

The subscript b denotes the breakpoint and the subscript t denotes the transition point. To employ this relationship, a successful parameterization of the quantities in square brackets is necessary.

As a first approximation, the turbulent contributions to Equation 4 are neglected. For simplicity, linear wave theory is used to evaluate the radiation stress and mean flow. A two layer model dividing the flow at the wave trough level is adopted, following Thieke and Sobey (1990). However in this case the simplest possible "block-type" mean velocity profile is considered with the mean velocity considered uniform within each layer and estimated from linear theory for the upper layer (subscript 1) and the lower layer (subscript 2) respectively by:

$$\bar{u}_1 = \frac{ga^2k}{2\sigma H} = \frac{gHk}{8\sigma} \quad (5)$$

$$\bar{u}_2 = -\frac{ga^2k}{2\sigma h_r} = -\frac{gH^2k}{8\sigma h_r} \quad (6)$$

Where:

$h_r$  = water depth below wave trough level

$k$  = wave number

$\sigma$  = angular wave frequency

$a$  = wave amplitude

$H$  = wave height

Linear theory alone cannot capture the increased mass flux of surf zone waves, and guidance is accordingly sought from experimental evidence. The laboratory measurements of Nadaoka and Kondoh (1982) indicate that the mass flux in a surf zone wave is 2-3 times that of a linear wave of equal height. To accommodate this a constant mass flux correction  $Q$  is applied to the velocity profile at the transition point. The value  $Q = 2.5$  was selected to reflect the observations. It is recognized that the wave part of the radiation stress as predicted by linear theory is not a completely accurate representation, however the aerated flow in the surf zone has so far prevented any guidance from experimental evidence in this instance.

Substituting the aforementioned parameterizations into Equation 4 yields:

$$\begin{aligned} & \left[ \frac{\rho g^2 k^2}{64 \sigma^2} \left( H^3 + \frac{H^4}{h_r} \right) + \frac{\rho g H^2}{8} \left( 2n - \frac{1}{2} \right) \right]_b \\ & = \left[ Q^2 \frac{\rho g^2 k^2}{64 \sigma^2} \left( H^3 + \frac{H^4}{h_r} \right) + \frac{\rho g H^2}{8} \left( 2n - \frac{1}{2} \right) \right]_t \end{aligned} \quad (7)$$

Given the conditions at the breakpoint as known, substituting the appropriate parameters on the right-hand side of Equation 7 gives a single equation for the wave height at the transition point,  $H_t$ . An initial estimate of one-half the breaking height ( $H_t = 0.5 H_b$ ) is used together with a Newton-Raphson convergence procedure to solve for  $H_t$ .

## COMPARISON TO MEASURED DATA

The model was tested against the laboratory wave data of Hansen and Svendsen (1979). Measured conditions at the breakpoint are input to the model on the left hand side of Equation 7. The measured wave height at the transition point was obtained by determining the wave height corresponding to the sharp increase in the gradient of the setup of the mean water level. The controlling parameters for the various test conditions are given in Table 1.

The model results are shown graphically in Figure 1, which compares (in dimensionless fashion) the predicted wave height at the transition point with the corresponding measured values as a function of the breaking wave height.

Note that the predicted curve (which assumes all lost wave momentum is transmitted to the mean flow), provides an effective upper limit to the transition point wave height, and also explains a large portion of the observed behavior. This is shown schematically in Figure 2, where the departure of the predicted wave height from the best fit line through the measured data can be viewed as an approximate representation of the fraction of the wave momentum converted into turbulent momentum flux. The model indicates that the majority of the wave height reduction in the transition region is associated with the generation of the enhanced mean flow, with a smaller contribution toward the turbulent momentum flux.

Test No.	T (s)	$H_o$ (mm)	$H_b$ (mm)	$x_b$ (m)	$h_b$ (mm)	$\bar{\eta}_b$ (mm)

## REFINEMENT OF PARAMETERIZATIONS

### Higher Order Wave Theories

Accurate modelling of the transition region requires an adequate representation of the initial conditions, that is, the kinematics of incipient breaking waves. Such waves are highly nonlinear and are typically strongly asymmetric with time due to the effect of the sloping bottom. While the use of a steady wave theory (assuming a flat bottom) is strictly not consistent with these conditions, in the absence of any other practical analytical or hybrid numerical-analytical method such a theory can (if appropriately chosen) provide some predictive capability. Given the highly nonlinear nature of near-breaking waves and the obvious inappropriateness of linear wave theory for this region, it is natural to turn to a higher order wave representation.

Figure 1: Dimensionless comparison of measured and predicted wave heights  $H_i$  at the transition point in terms of the breaking wave height  $H_b$ .

Figure 2: Schematic representation of the transition point partitioning of the increased mean flow and turbulent momentum flux resulting from wave height reduction.

Figures 3a and 3b compare velocity amplitudes measured in the laboratory for waves approaching breaking using a laser doppler anemometer (LDA) (Thieke, 1992), with those predicted by Stokes, Cnoidal and Fourier wave theories of varying order (following Sobey et al. 1987). In each case the velocities are measured at a point just seaward of the breakpoint. Figure 3a (for a relatively short wave) shows that the Fourier theory (to eighteenth order) predicts the positive velocity amplitude tolerably well and the negative amplitude slightly less so. The Stokes wave solutions are not at all useful; the higher order solution shows a clearly recurved profile. Figure 3b (for a somewhat longer wave) again shows that the Fourier wave theory predicts the velocity amplitudes quite well, while a Cnoidal II prediction is quite disparate from the measurements. Higher order Cnoidal predictions diverge quite rapidly under waves of this height ( $H/h$  greater than 0.5); Stokes wave solutions at this point were entirely divergent. The performance of the Fourier wave theory in each of these instances suggests that it should yield reasonable predictions of integral properties (mass flux, momentum flux) of waves approaching the breakpoint.

Although some difficulty is encountered in obtaining Fourier wave solutions at the maximum wave heights attained by waves breaking on a slope (which prevents the ready inclusion of such a parameterization in the model), it is generally possible to obtain informative solutions for all but the most extreme near breaking (albeit assumed steady) wave heights.

### **Evolution of Wave, Turbulent and Mean Momentum Fluxes**

The aforementioned predictions from Fourier wave theory, together with existing laboratory measurements in the surf zone, can be used to clarify the relative contributions of the wave, turbulent and mean motions to the total momentum flux as well as the spatial variation of these contributions. Figure 4 shows comparisons of Fourier wave predictions of Eulerian mean velocity with the laboratory LDA mean velocity measurements of Nadaoka and Kondoh (1982) for waves over a plane sloping beach. The example shown is for Case 1, a spilling breaker (wave period  $T = 1.32$  s) on a 1 on 20 slope. Comparisons are shown for three locations. Station P7 ( $h = 0.347$  m) is located just seaward of the breakpoint, while station P4 ( $h = 0.207$  m) is just inshore of the end of the transition region and station P2 ( $h = 0.107$  m) is well within the inner surf zone. The wave heights (scaled from trough and crest elevations) were 0.197 m (P7), 0.161 m (P4), and 0.065 m (P2), respectively. The setup was taken as zero since it was not measured in the experiments. The Fourier prediction of mean velocity in the near breaking wave is quite reasonable, despite the asymmetry and unsteadiness inherent in such a wave. However two observations are significant in the surf zone. The first is that the actual mean flow (as suggested earlier) grows to be much greater than that in a nonbreaking wave of similar height, leading to severe underprediction by the wave theory. Secondly, there are substantial mean vertical velocities present in the surf zone which do not exist outside the breakpoint. Note that these are essential for the maintenance of mass conservation in two dimensions due to the divergence of the horizontal velocity. They cannot be directly predicted by the wave theory.

Figure 3: Comparison of LDA measured horizontal velocity amplitudes ( $\bullet$ ) with wave theory predictions ( $-$ ).

Figure 4: Profiles of predicted Eulerian mean velocities and comparison with data of Nadaoka and Kondoh (1982), Case 1.

Figure 5: Profiles of predicted wave apparent stress and measured turbulent Reynolds stress from data of Nadaoka and Kondoh (1982), Case 1.

Similar comparisons are made for predictions of wave (double primed) momentum fluxes and laboratory (LDA) measurements of turbulent (single primed) momentum fluxes across the surf zone in Figure 5. It is seen that the turbulent intensities are essentially zero outside the breakpoint, but are "produced" through the transition region and then exhibit decay in the inner surf zone as the shoreline is approached. It is noteworthy that the wave momentum fluxes in the below trough region are approximately an order of magnitude greater than their turbulent counterparts. Although these measurements cannot cover the turbulent aerated crest region due to extensive air entrainment and LDA signal dropout, they indicate that over a large portion of the water column the dominant feature of the momentum balance is still the wave orbital motion, although it is clear that the mean flow has also taken on greater importance than it does outside the surf zone.

Flow Component	Depth Integrated Momentum Flux ( in N/m )	
	Station P7	Station P4
$\int_{-h}^{\eta_c} s_{xx}'' dz$	33.0	17.6
$\int_{-h}^{\eta_c} \rho \bar{u}^2 dz$	3.2	10.1
$\int_{-h}^{\eta_{tx}} \rho \overline{u^2} dz$	≈ 0	0.3
$\int_{-h}^{\eta_{tx}} \rho \overline{w^2} dz$	≈ 0	0.2

Table 1: Partitioning of total depth integrated momentum flux among wave, mean flow and turbulent components for the experimental test Case 1 (T = 1.32 sec) of Nadaoka and Kondoh (1982). (Mean flow and turbulent components inferred from measured data; wave apparent stress computed from Fourier wave theory)

Figures 4 and 5 together show the global trends of development of surf zone mean and turbulent momentum fluxes, with a limited predictive capability provided by Fourier wave theory. These results can be used to quantitatively analyze the partitioning of total momentum flux between the wave, mean flow and turbulence components across the transition region. For this purpose, locations P7 and P4 of

the previous Nadaoka and Kondoh example were again considered. The results of this exercise are given in Table 2. In this instance the wave radiation stress is evaluated from Fourier wave theory, while the turbulent apparent stresses are evaluated from the laboratory measurements and are limited to the below trough region. The depth integrated mean momentum flux is found by integrating the below trough measurements and inferring the remaining contribution through mass conservation constraints.

The wave radiation stress is clearly decreasing across the transition region, however it is in a large part balanced by an accompanying increase in the mean momentum flux. The below trough turbulent stresses are of little consequence. Complete closure is not possible due to the lack of information regarding the turbulent apparent stresses in the crest to trough region (a potentially larger contribution) and the neglect of bed shear. Nevertheless the measurements indicate that a substantial portion of the wave height reduction across the region is tied to an increase in mean flow momentum.

## CONCLUSIONS

A simple rapidly varied flow model of the breaking wave transition region provides insight into the mechanics of the region and a certain predictive capability, despite the relatively crude parameterizations employed. The model results support the arguments of Svendsen (1984) and Basco and Yamashita (1986) that only part other wave height reduction in the transition region is the result of energy dissipation (i.e. turbulence production). More specifically, the following conclusions may be drawn:

- a) A large portion of the wave height reduction across the transition region results from momentum being transferred to the mean flow, with a somewhat smaller reduction resulting from actual energy dissipation.
- b) Linear wave theory (with empirical adjustments) and the assumption of all momentum transfer to the mean flow provides a reasonable upper limit for the wave height at the transition point, despite the crude nature of the assumptions.
- c) The separation of the "velocity part" of the radiation stress permits the identification of the distribution of the total momentum flux to the wave, turbulent and mean flow contributions.
- d) Below the wave trough level the turbulence contributes minimally to the total balance of momentum (above the trough however the contribution is potentially larger and not well documented).
- e) The model described is not truly predictive but rather informative (i.e. the length of the transition region is not determined since the region is effectively compressed into a "shock"). Practical empirical measures for including the finite width of the

transition region in surf zone modelling are presented by Nairn, et al. (1990).

f) Detailed measurements of the wave, mean flow and turbulence characteristics in the trough-to-crest region are crucial to a complete understanding of the dynamics of the transition region.

## CHAPTER 53

### EFFECTS OF THE GULF STREAM ON WIND WAVES IN SWADE

Hendrik L. Tolman \*

#### ABSTRACT

Preliminary results of a numerical study of wave-current interactions in SWADE for 20 Oct. 1990 to 31 Oct. 1990 are presented. The results are obtained with the wave model WAVEWATCH, which incorporates both wave-current interactions and a full description of the dynamics wave growth and decay. It is shown that wave-current interactions are expected to be sufficiently strong to be observed in mean wave parameters, but that significant effects of interactions occur close to the Gulf Stream only. Furthermore, wave growth and decay are strongly influenced by the currents. Thus, modelling of wave-current interactions on the scales considered requires a comprehensive assessment of both (conservative) wave-current interactions and of the dynamics of wave growth and decay.

#### 1 Introduction

Effects of the Gulf Stream on wind waves are assessed in the light of the Surface Wave Dynamics Experiment (SWADE, Weller et al. 1991). This experiment took place during the winter 1990-1991 on the continental shelf at the East coast of the United States, north of Cape Hatteras. Due to the vicinity of the Gulf Stream (the Gulf Stream actually intruded into the measurement array in early March 1991), wave-current interactions are potentially important in analyzing experimental data. Furthermore, the SWADE data provides a unique opportunity to verify wave-current interaction models due to the above intrusion.

The wave-current interaction studies within SWADE consist of two parts. First, a mainly numerical assessment of wave-current interactions is made for the first Intensive Observation Period (IOP) of October 20 through 31 1990. The objective is to estimate effects of a realistic Gulf Stream on ocean wind waves using a full third-generation ocean wave model to provide a synthesis of all the idealized wave-current interaction studies performed so far. Such a study is the logical extension of Holthuijsen and Tolman (1990, 1991; henceforth denoted as HT). Secondly, an intercomparison of observations and model hindcasts will be made for part of the third IOP (March 3 through 5, 1991). The objective is to assess and verify present insights in wave-current interactions. In the present paper, preliminary results for the first part of the SWADE wave-current interaction studies will be presented.

## 2 Models

A cascade of nested models with increasing spatial resolution has been used, consisting of an Atlantic basin model ( $1^\circ \times 1^\circ$  longitude-latitude resolution), a regional model ( $1/4^\circ \times 1/4^\circ$ ) and the so-called SWADE model ( $1/12^\circ \times 1/12^\circ$ ) (see Weller et al. 1991, Fig. 11 and present Fig. 1). The Atlantic basin model is primarily used to provide boundary conditions for the regional model, and does not include currents. Because winds and waves outside the regional model proved irrelevant for the period considered, the Atlantic basin will not be considered in the following discussions. Gulf Stream surface currents for the regional and SWADE models (see Fig. 1) are obtained from feature models and the operational surface temperature analysis of NOAA/NMC. Wind fields for both models consist of high resolution SWADE wind analyses.

The results presented in this paper are obtained with the latest version of the model WAVEWATCH (Tolman 1991, 1992, 1993). In this model, the evolution of the action density spectrum  $N(\omega, \theta, \phi, \lambda, t)$  is calculated, where  $\omega$  is the absolute wave frequency (as observed in a fixed frame of reference),  $\theta$  is the wave direction,  $\phi$  is the latitude,  $\lambda$  is the longitude and  $t$  is the time. The action density spectrum  $N$  is directly related to the energy or variance density spectrum  $F(\omega, \theta, \phi, \lambda, t)$ ,  $N = F/\sigma$  (for brevity of notation dropping the dependence of  $N$  and  $F$  on  $\omega$ ,  $\theta$ ,  $\phi$ ,  $\lambda$  and  $t$ ), where  $\sigma$  is the intrinsic or relative frequency, as observed in a frame of reference moving with the mean current. The frequencies  $\sigma$  and  $\omega$ , the wavenumber vector  $\mathbf{k}$ , the depth  $d$  and the current velocity  $\mathbf{U}$  are interrelated in the combined Doppler-dispersion relation

$$\sigma = \sqrt{gk \tanh kd} = \omega - \mathbf{k} \cdot \mathbf{U} . \quad (1)$$

The balance equation for the action density spectrum  $N$  becomes (e.g., WAMDI group 1988, Tolman 1991):

$$\frac{\partial N}{\partial t} + (\cos\phi)^{-1} \frac{\partial}{\partial \phi} [c_{\phi} \cos\phi N] + \frac{\partial}{\partial \lambda} [c_{\lambda} N] + \frac{\partial}{\partial \omega} [c_{\omega} N] + \frac{\partial}{\partial \theta} [c_{\theta} N] = S, \quad (2)$$

where  $c_{\phi} = d\phi/dt$  etc. are the propagation velocities in the corresponding spaces (e.g., WAMDI group 1988, Tolman 1991), and where  $S$  denotes the net source term. The source term  $S$  consists of wind input (Janssen, 1989, 1991), nonlinear wave-wave interactions (Hasselmann and Hasselmann, 1985), energy dissipation due to whitecapping (Janssen, 1991) and energy dissipation due to bottom friction (Hasselmann et al., 1973). Thus, the present source terms are equivalent to those of cycle 4 of the WAM model (see, e.g., Mastenbroek et al., 1993). The source terms are corrected for effects of mean currents by applying them in a frame of reference moving with the mean current.

The numerics of WAVEWATCH as used in the present study incorporate a second order SHASTA propagation scheme and dynamic implicit source-term integration as described by Tolman (1992). The spectrum is discretized using 24 directions ( $\Delta\theta = 15^\circ$ ) and 33 frequencies (0.042 Hz through 0.88 Hz,  $f_{i+1} = 1.1f_i$ ). The time steps  $\Delta t$  are 450 s for the regional model and 240 s for the SWADE model.

In the final presentation of this part of the SWADE wave-current interaction studies, results of the WAM model (WAMDI Group, 1988) will also be included. These results are presently obtained by S. Hasselmann, H.C. Graber and R.E. Jenness. Note that cycle 4 of WAM (spring 1992) incorporates wave-current interactions for steady currents.

### 3 Meteorological conditions

On Oct. 20, winds in the regional model are weak with predominantly northeasterly directions, except for a fairly strong depression, which moves rapidly eastward over Nova Scotia. For the next few days, the entire region has weak northeasterly winds. On Oct. 24 a small depression develops over Cape Hatteras and starts moving in a northeasterly direction. On Oct. 25, this system is located south of Nova Scotia and on Oct. 26 it has left the regional model area. On the same day several systems develop around Cape Hatteras. These systems merge into a complex structure with strong northeasterly, northwesterly and southwesterly winds in the northwest, southwest and southeast quadrants respectively (wind speeds over 20 m/s). In the next two days this systems moves in a northeasterly direction and at Oct. 29 this

system has left the regional model. Finally, on this day a cold air outbreak occurs north of Cape Hatteras, and the associated depression moves over Nova Scotia on Oct 31.

#### 4 Results

Model calculations have been performed for the period of Oct. 15 1990 through Oct 31, 1990. The period of Oct 15 through Oct 20, 0000 UTC is used to initialize the models. For both the regional model and the SWADE model calculations have been performed with and without the Gulf Stream. Thus, effects of the Gulf Stream can be isolated by simply taking the difference between the two model runs. All weather systems described in section 3 are accompanied by a distinct wind sea system. Furthermore, all these systems generate swell traveling in northerly to easterly directions. The complicated structure on Oct 26 through 28, also radiates swell energy in southern directions.

Effects of wave-current interactions are found to vary on small space and time scales. This is illustrated in Fig. 2 with the maximum and minimum current-induced modulation of the significant wave height  $H_s$  and the mean wave length  $L$  for several models and areas.

$$H_s = 4\sqrt{E} \quad , \quad E = \iint F(\omega, \theta) d\omega d\theta \quad . \quad (3)$$

$$L = E \left( \iint 2\pi k^{-1} F(\omega, \theta) d\omega d\theta \right)^{-1} \quad . \quad (4)$$

The time scale of pronounced features in this figure is typically several hours to several days. A comparison of results for the SWADE model (solid lines) and the corresponding area in the regional model (dashed lines) shows qualitatively similar results. Due to the fairly limited resolution of the region model (a cross section of the Gulf Stream consists of no more that five grid points), the regional model shows less detail (figures not presented here) and consequently slightly different but similar extreme values for  $\Delta H_s$  and  $\Delta L$  (see Fig. 2). Consequently, one might expect the regional model to give a fairly accurate estimate of the wave-current interactions, in spite of the relatively poor resolution. Furthermore, Fig. 2 shows only limited effects of wave-current interactions in the overall quiet periods of Oct 20 through 23, Oct 25 and Oct 29. This might be expected because the wave heights in this period are generally less than 2 m. Finally, Fig. 2 shows that the largest impacts of wave-current interactions occur outside the SWADE area on Oct. 27 and 28.

To assess effects of wave-current interactions in more detail, the spatial distribution of effects of wave-current interactions will be discussed in some detail for Oct. 28, 0000 UTC. This time has been selected for the interesting interactions in the model. Note that, as discussed above, this time is not representative for the entire period considered. The discussion will concentrate on results for the regional model, because this model is expected to be sufficiently accurate to show the general features of the present Gulf Stream current field. In Fig. 3 the significant wave height  $H_s$  (obtained from a model including the Gulf Stream) and the current-induced modulation of the wave height  $\Delta H_s$  (model differences) are presented. Similarly, Fig. 4 shows the mean absolute period  $T_a$ , Fig. 5 shows the integral input source term  $S_{in,i}$  and Fig. 6 shows the integral dissipation (whitecapping) source term  $S_{ds,i}$ .

$$T_a = E \left( \iint 2\pi \omega^{-1} F(\omega, \theta) d\omega d\theta \right)^{-1} . \quad (5)$$

$$S_{in,i} = \iint S_{in}(\omega, \theta) d\omega d\theta . \quad (6)$$

$$S_{ds,i} = \iint |S_{ds}(\omega, \theta)| d\omega d\theta . \quad (7)$$

Figures 3 through 6 show that the space scales of current-induced modulations of the wave field are governed by the corresponding scales of the current and wind fields. Furthermore, such modulations are mostly confined to the immediate vicinity of the Gulf Stream and modulations can be large enough to be observed in the overall model results (i.e., without differencing models, figure panels a). However, it is nearly impossible to pinpoint the exact location of the Gulf Stream from such mean wave parameters only.

In the wave height and period fields presented in Figs. 3 and 4, several features can be observed.

First, swell trapping occurs south of Cape Hatteras. The trapped swell is identified by the significant increase of the wave height and the absolute period, which are closely confined to the Gulf Stream. The trapped swell was generated in the coastal area between Cape Hatteras and Cape Cod in the previous 36 hours. Note that the trapped swell is accompanied by a "shadow zone" just south of the Gulf Stream, as would be expected from straightforward energy conservation. Note furthermore the occurrence of two focal points of long wave energy on the coast south of Cape Hatteras (see Fig. 4). This current-induced modulation of swell energy around the Gulf Stream, and the location the Gulf Stream near the coast

suggest that swell penetration at coast south of Cape Hatteras can be influenced significantly by Gulf Stream (unlike coastal waves in most other areas).

Secondly, the combined wind-wave and swell field east of  $68^{\circ}\text{W}$  shows a complicated impact of the currents. Note the apparent reflection of wave energy south of the meander at  $39^{\circ}\text{N}$ ,  $56^{\circ}$ - $60^{\circ}\text{W}$  (Fig. 4). Given the predominant wave direction, such a reflection was expected from the results of HT for a straight section Gulf Stream. Furthermore, the meander at  $42^{\circ}\text{N}$ ,  $58^{\circ}\text{W}$  shows an impact similar to that of a ring for swell as shown by many authors.

Finally, several small and fairly weak rings in the area between the above two areas all show a the typical signature of a ring for swell fields, although the impact is typically small. Note that the rings identify the locally dominant swell direction.

As discussed by HT indirect effects of currents on the dynamics of wave growth and decay are expected to be important on the scale of the Gulf Stream. For a separate ring, such effects are easily isolated, due to the closed-system nature of the ring. For a meandering Gulf Stream, effects of modified growth dynamics can occur simultaneously with reflection and trapping of waves. Thus an assessment of current-induced modulations of wave-growth dynamics requires a detailed analysis of individual spectra. In the present paper, only the potential of such effects will be established by assessing the integral source terms  $S_{\text{in},i}$  (Fig. 5) and  $S_{\text{ds},j}$  (Fig. 6). These figures show current-induced modulations of  $S_{\text{in},i}$  and  $S_{\text{ds},j}$  of 20% to 50%, which agrees well with the results of HT for a ring. Considering the importance of current-induced modulations of the dynamics of wave growth in the latter case, a similar importance is expected here. The Gulf Stream, however, does show differences compared to the corresponding idealized cases of HT. The current-induced modulations of the input source term (Fig. 5) are centered on the currents (as in HT). This might be explained from the fact that the input winds (relative to the current) and local (conservative) interactions show similar modulations. The dissipation, however, changes both in and outside the Gulf Stream. In particular in the above mentioned reflection zone ( $39^{\circ}\text{N}$ ,  $56^{\circ}$ - $60^{\circ}\text{W}$ ) increased dissipation occurs at the edge of the Gulf Stream rather than at the center (in contrast to the results of HT).

One final remark should be made on the results of Figs. 3 through 6. The impacts of wave-current interactions as presented in these figures appear to occur mainly when the winds are decreasing, in other words, when the relative importance of wave growth decreases. This suggests that the dynamics of wave growth and decay dominate wave-current interactions in active growth conditions, which is another indication for the importance of incorporating the dynamics of wave growth and decay when considering wave-current interactions at the present scales.

## 5 Preliminary conclusions

The above preliminary results for numerical simulation of wind waves on the Gulf Stream lead to the following preliminary conclusions.

- Wave-current interactions induced by the Gulf Stream are sufficiently strong to be identified in wave height and mean period, but do not necessarily pinpoint the exact location of the Gulf Stream.
- Space (and time) scales of effects of wave-current interactions are relatively small and are governed by the corresponding scales of the wind field and the Gulf Stream.
- Effects of wave-current interactions are mainly confined to Gulf Stream and its direct surroundings, in particular for regions with active wave generation. Effects away from the Gulf stream are usually related to swell propagation and generally of moderate magnitude.
- The model indicates that trapping of swell can occur in realistic conditions. South of Cape Hatteras this might significantly influence swell penetration at the coast.
- In active generation conditions an interplay between conservative wave-current interactions and the dynamics of wave growth and decay occurs. Such an interplay is neglected in virtually all other wave-current interaction studies.
- The spatial resolution of regional model appears to be sufficient to assess wave-current interaction features of the Gulf Stream. The SWADE model, however, is expected to be significantly more accurate due to the better resolution.

## 6 Outlook

As stated in the introduction, this paper presents preliminary results of SWADE wave-current interaction studies. For the first part of the SWADE wave-current interaction study, the following work is in progress.

- The interplay between dynamics and kinematics are analyzed in more detail both by intercomparing spectra and by analyzing evolution of the net effect of wave-current interactions in space and time.
- Effects of different physical and numerical approaches are assessed by intercomparing results of the models WAVEWATCH and WAM.
- An assessment of effects of wave-current interactions with regard to remote sensing is being considered.

*Acknowledgements.* The author acknowledges with pleasure that H.C. Graber supplied the bottom grids for the present study. V.J. Cardone supplied the wind fields and S.M. Glenn and J.H. Clark supplied current data. The interaction with the SWADE group, in particular H.C. Graber, R.E. Jenssen, D.G. Duffy and S. and K. Hasselmann and the help of L. Rumburg in preparing the figures was greatly appreciated. Computer time was provided under the Air-Sea Interaction Studies grant, RTOP 461-31, funded by NASA Headquarters. This work was done while the author held a National Research Council - NASA Research Associateship.

## CHAPTER 54

### AN IMPROVED ARRANGEMENT FOR THE PROGRESSIVE WAVE ABSORBER

S. W. TWU\* and C. C. LIU\*\*

#### Abstract

The progressive wave absorber discussed here in this paper contains several porous plates with different porosity. Four arrangements of progressive wave absorbers were compared in wave absorption. The results indicate that of the four arrangements examined, Arrangement 4 is the most effective at absorbing waves, for a relative water depth ranging from 0.05 to 0.5. The results also show that an eight-plate wave absorber is more effective than a six-plate wave absorber. When waves are well within the relative water depth ranging from 0.05 to 0.5, reducing the  $G$  value of the rear plates further may provide even greater wave absorption efficiency .

#### I. INTRODUCTION

Wave reflection by such structures as wharves, breakwaters, or boundaries in a wave basin is of concern to many investigators, due to the many problems reflected waves can create. Le Me' haute (1972) first presented the concept of a progressive wave absorber, in which the porosity decreases toward the rear of the wave absorber. He developed a theory on progressive wave absorption and conducted model tests on a wave absorber constructed of aluminum shavings, which became more compact in the direction of propagation of the incident waves. Relatively low reflection coefficients were measured and experimental results qualitatively demonstrated the validity of his theoretical development.

Jamieson & Mansard(1987) conducted experimental studies on a progressive wave absorber constructed of multiple rows of perforated vertical metal sheets, with a progressive decrease in porosity toward the rear of the wave absorber. Their metal sheets were aligned normal to the direction of the incident wave propagation. They concluded that the upright wave absorber can be designed to provide low reflection coefficients (less than 5%) over a wide range of wave heights, wave periods, and water depths.

Twu & Lin(1991)developed a theory on a progressive wave absorber constructed of multiple rows of vertical porous plates, which were similar in structure to those of Jamiesons'. They conducted model tests to verify their theoretical solution and noted that the model test results agree fairly well with the theoretical solution. In their study,a dimensionless porous effect parameter,  $G = \rho\omega b/\mu K_0$  (Chwang and Dong,1984),was used to represent the porosity of the porous plates, in which  $\mu$  is the dynamic viscosity of the fluid,  $b$  is a material constant of the porous plate, having the dimension of length,  $K_0$  is the wave number,  $\omega$  is the circular frequency and  $\rho$  is the fluid density. Twu & Lin concluded that the progressive wave absorber should function better if the difference in  $G$  value between adjoining porous plates is larger for the front plates than for the rear plates. In Twu & Lin's study, the difference in  $G$  values between adjoining porous plates were progressively decreased, but the rate of decrease was arbitrarily selected. The goal of this paper is to determine exactly what decreased rate of  $G$  value should be adopted so that the progressive wave absorber will function more effectively, and if fewer porous plates can be installed without adversely affecting the wave absorption efficiency.

## II. CALCULATION PROCEDURE AND RESULTS

The progressive wave absorber used by Twu & Lin(1991) contained several porous plates, as shown in Figure 1. They assumed that the flow velocity passing through each porous plate obeys Darcy's Law. Defining the reflection coefficient,  $C_r$ , as the amplitude ratio of the reflected wave to the incident wave, they developed the following equations ( Twu & Lin 1991):

$$C_r = (A^2 + B^2)^{1/2} \quad (1)$$

in which

$$A = Re(M_1) \quad (2)$$

$$B = Im(M_1) \tag{3}$$

$$M_s = \frac{M_{s+1}(2G_s - 1) + \exp(-i2K_0L_{s-1})}{(2G_s + 1) - M_{s+1} \exp(i2K_0L_{s-1})} \quad s = 1, 2, 3, \dots (n-1) \tag{4}$$

$$M_n = \frac{F_1 + iF_2}{F_3 + iF_4} \tag{5}$$

where n is the number of porous plates used in the wave absorber.

$$\begin{aligned} F_1 &= (G_n - 1) \sin K_0 r_n \cos K_0 L_{n-1} + G_n \cos K_0 r_n \sin K_0 L_{n-1} \\ F_2 &= G_n \cos K_0 r_n \sin K_0 L_{n-1} - (G_n - 1) \sin K_0 r_n \sin K_0 L_{n-1} \\ F_3 &= -(G_n + 1) \sin K_0 r_n \cos K_0 L_{n-1} - G_n \cos K_0 r_n \sin K_0 L_{n-1} \\ F_4 &= G_n - \cos K_0 r_n \cos K_0 L_{n-1} - (G_n + 1) \sin K_0 r_n \sin K_0 L_{n-1} \\ G_s &= \frac{b_s \omega \rho}{\mu K_0} \quad (s = 1, 2, 3, \dots n) \end{aligned}$$

$G_s$  is a dimensionless porous-effect parameter of the plate "s".  $L_n$ ,  $L_{n-1}$  and  $r_n$  are indicated in Figure 1. According to Twu and Lin (1991), wave reflection by a progressive wave absorber is closely related to the spacing between the adjacent porous plates, as well as to the progression of  $G$  value of these plates. In this investigation a distance of 0.88 times the water depth has been adopted as the spacing between adjacent plates, as suggested by Twu and Lin. Four methods of reducing the  $G$  value along the direction of incident wave propagation are compared for both six-plate and eight-plate wave absorber. The  $G$  values of the first and

Fig.1 Schematic diagram of a progressive wave absorber

last plates are fixed at 16 and 1, respectively, for the first part of the study. The  $G$  values of the first and last plates were varied in the second part of the study.

The four arrangements of six-plate wave absorbers analyzed in this study were determined as follows:

1. The  $G$  values of the plates were evenly distributed, to obtain values of 16, 13,10,7,4 and 1, for plates 1 through 6, respectively.
2. The  $G$  value of each succeeding plate was reduced by the formula “16 exp (-x)”, with x ranging from 0 to 2.7726, yielding  $G$  values of 16, 9.19, 5.28, 3.03,1.74,and 1.
3. The  $G$  value of each succeeding plate was reduced by the formula “16/x”, with x ranging from 1 to 16, yielding  $G$  values of 16, 4, 2.28,1.6,1.23, and 1.
4. The  $G$  value of each succeeding plate was reduced by the formula “16/x<sup>2</sup>”, with x ranging from 1 to 4, yielding  $G$  values of 16, 6.25, 3.31, 2.04, 1.38 and 1.

The  $G$  values for each arrangement are summarized in Table 1.

Table 1.  $G$  Values for Six-Plate Wave Absorber

Arrangement number	Method of $G$ reduction	$G$					
		Plate number					
		1	2	3	4	5	6
1	linear	16	13	10	7	4	1
2	$16 \exp(-x_1)$	16	9.19	5.28	3.03	1.74	1
3	$16/x_2$	16	4	2.28	1.6	1.23	1
4	$16/(x_3)^2$	16	6.25	3.31	2.04	1.38	1

$x_1$  ranges from 0 to 2.7726

$x_2$  ranges from 1 to 16

$x_3$  ranges from 1 to 4

The reflection coefficient of these progressive wave absorbers were calculated over a relative water depth ranging from 0.05 to 0.5. The results are shown in Figures 2 through 5. The figures indicate that the reflection coefficient is higher for the first wave absorber (Figure 2) than for the last three. This verifies the conclusion reached by Twu and Lin, that the progressive wave absorber would function better if the difference in  $G$  values between adjacent porous plates is

larger in the front part than in the rear part of the wave absorber. These figures also indicate that Arrangement (4), shown in Figure 5, is most effective in wave absorption among these four arrangements.

Fig.2 Wave reflection coefficient for the Arrangement (1) of six-plate wave absorber

Fig.3 Wave reflection coefficient for the Arrangement (2) of six-plate wave absorber

Fig.4 Wave reflection coefficient for the Arrangement (3) of six-plate wave absorber

Fig.5 Wave reflection coefficient for the Arrangement (4) of six-plate wave absorber

The  $G$  values for each arrangement of the eight-plate wave absorber were determined by applying the same formulas used to determine the  $G$  values for the six-plate wave absorber.

The  $G$  values for each arrangement are presented in Table 2, and the results are plotted on Figures 6 through 9. These figures indicate that the wave reflection coefficient follows a similar trend for both six-plate and eight-plate wave absorbers,

and that Arrangement 4 again yields the most effective wave absorption over the considered range. This wave absorber maintains a wave reflection coefficient of less than .04 over the relative water depth ranging from 0.11 to 0.46, which satisfies the requirement for a wave basin wave absorber.

Table 2.  $G$  values of an Eight-Plate Wave Absorber

Arrangement number	Method of $G$ reduction	$G$							
		Plate number							
		1	2	3	4	5	6	7	8
1	linear	16	13.86	11.71	9.57	7.43	5.29	3.14	1.0
2	$16 \exp(-x_1)$	16	10.77	7.25	4.88	3.28	2.21	1.49	1.0
3	$16/x_2$	16	5.10	3.02	2.15	1.67	1.37	1.15	1.0
4	$16/(x_3)^2$	16	7.84	4.64	3.06	2.17	1.62	1.25	1.0

$x_1$  ranges from 0 to 2.7726

$x_2$  ranges from 1 to 16

$x_3$  ranges from 1 to 4

Fig.6 Wave reflection coefficient for the Arrangement (1) of eight-plate wave absorber

The next step was to analyze the effect on the reflection coefficient of varying the  $G$  value of the first and last plate. The best arrangement in the previous analysis, Arrangement 4, was selected for an eight-plate wave absorber. For the first case, the  $G$  value of the first plate was changed from 16 to 14 and from 16 to 20, while holding the  $G$  value of the last plate constant. The  $G$  values of the plates

Fig.7 Wave reflection coefficient for the Arrangement (2) of eight-plate wave absorber

Fig.8 Wave reflection coefficient for the Arrangement (3) of eight-plate wave absorber

Fig.9 Wave reflection coefficient for the Arrangement (4) of eight-plate wave absorber

in between were determined from the formula  $G_1/x^2$  where  $G_1$  is the  $G$  value of the first plate. The results are plotted on Figures 10 and 11. A comparison of Figures 10 and 11 with Figure 9 indicates a slight increase in the reflection coefficient when the  $G$  values of all but last plate is either increased or decreased.

Fig.10 Wave reflection coefficient for the Arrangement (4) of eight-plate wave absorber with  $G$  value reduced for the front plates

Fig.11 Wave reflection coefficient for the Arrangement (4) of eight-plate wave absorber with  $G$  value increased for the front plates

For the second case, the  $G$  value of the first plate is held at 16 and the  $G$  value of last plate changed to 0.5 and 2.0. The  $G$  values of the plates in between are modified relative to the  $G$  value of the last plate following the formula  $G_1/x^2$ . The results are plotted on Figures 12 and 13. A comparison of Figure 12 with Figure

Fig.12 Wave reflection coefficient for the Arrangement (4) of eight-plate wave absorber with  $G$  value reduced for the rear plates

Fig.13 Wave reflection coefficient for the Arrangement (4) of eight-plate wave absorber with  $G$  value increased for the rear plates

9 indicates that, when the  $G$  value of the last plate is equal to 0.5 the reflection coefficient is lower for  $h/\lambda$  values between approximately 0.15 and 0.42, but higher for other  $h/\lambda$  values. Changing the  $G$  value of the last plate to 2.0 resulted in a larger reflection coefficient for most values of  $h/\lambda$ , as shown on Figure 13.

This comparison indicates that the reflection coefficient is more sensitive to the  $G$  values of the rear plates than the front plates of the progressive wave absorber. If waves which contain only a small range of wave lengths require damping, such as for  $0.15 < h/\lambda < 0.42$ , the  $G$  values of plates in the rear part of the wave absorber can be reduced.

### III. CONCLUSIONS

The wave absorption efficiency of a six-plate and eight-plate wave absorber was investigated mathematically to determine the most effective distribution of  $G$  values. The results indicate that of the four arrangements examined, Arrangement 4 is the most effective at absorbing waves, for a relative water depth ranging from 0.05 to 0.5. The results also show that an eight-plate wave absorber is more effective than a six-plate wave absorber. When waves are well within the relative water depth ranging from 0.05 to 0.5, reducing the  $G$  values of the rear plates further may provide even greater wave absorption efficiency.

## CHAPTER 55

### Interrelation of Cnoidal Wave Theories

by Masataka Yamaguchi<sup>1</sup>

#### Abstract

The aim of this paper is to analytically clarify the interrelation among all of the existing cnoidal wave theories of the third order approximation. The result is that the Chappellear theory expressed with two expansion parameters is found to include the other theories. This means that they are able to be derived from the Chappellear theory by changing expansion parameters in the expressions of wave characteristics and integral properties and identifying the definition for wave celerity to be used in the theory. The expressions for the trajectory of a water particle, mass transport velocity and integral properties of waves are newly derived using these theories, and the wave characteristics and integral properties are examined based on the numerical computation and comparison with the experiments. As a result, use of the theory expressed with a single expansion parameter is recommended from a practical viewpoint. The figures describing a limiting range of wave parameters for the application of the above-mentioned theory are also provided by comparing wave characteristics and integral properties of the theory with those of Fenton's Fourier approximation wave theory.

#### 1. Introduction

Higher order solutions of cnoidal waves have been derived by Laitone(1960, 1965; the second order approximation, the second definition for wave celerity), Chappellear(1962; the third order approximation, the first definition), Fenton(1979; the ninth order approximation, the first definition), Tsuchiya & Yasuda(1985; the third

Bunkyocho 3, Matsuyama 790, Ehime Pref., Japan

order approximation, the third definition) and Isobe (1988; the third order approximation, the second definition). These solutions are different from each other in the definitions used for the derivation of wave celerity and the expansion parameters for the expression of wave characteristics.

Yamaguchi & Tsuchiya (1974) mathematically proved that the Laitone theory can be derived from the Chappelear theory within the second order approximation when the expressions of wave characteristics in the Chappelear theory are rewritten with the parameter in the Laitone theory under the condition that the same definition is applied for the derivation of wave celerity in each theory.

Now there are at least 4 kinds of third order cnoidal wave theories derived with different expansion parameters and definitions for wave celerity.

The aim of this paper is to mathematically clarify the interrelation among these third order solutions and to examine the wave characteristics and integral properties, and limiting conditions for practical application based on numerical computation and the comparison with experiments.

## 2. Theoretical Considerations

### (1) Definitions for wave celerity

Usually, either of the first and second definitions proposed by Stokes has been used for the determination of wave celerity, although Fenton(1990) recommends use of the term "approximation" in place of the term "definition". The first and second definitions for wave celerity are given respectively as

$$\overline{u^I} = 0 \quad \text{or} \quad c^I = \overline{\tilde{u}} \quad (1)$$

$$\int_{-D}^{\eta} \overline{u^{II}} dz = 0 \quad \text{or} \quad c^{II} = \int_{-D}^{\eta} \overline{\rho \tilde{u}} dz / \rho D \quad (2)$$

where  $c$  is the wave celerity,  $u$  the horizontal water particle velocity in a fixed frame of reference,  $\tilde{u}$  the horizontal water particle velocity in a moving frame of reference,  $D$  the water depth,  $\eta$  the surface displacement,  $z$  the ordinate taken vertically upward on the still water level, ' $\overline{\quad}$ ' the time-mean, and superscripts 'I' and 'II' indicate the first and second definitions respectively. The first definition means that time-averaged horizontal water particle velocity at a level under the trough in a frame of reference moving with a constant speed vanishes, and the second definition means that time-mean of depth-

integrated momentum in a frame of reference moving with a constant speed vanishes.

Tsuchiya & Yasuda have defined the wave celerity as gradient of the characteristics in  $x$ - $t$  space. In this case, the Bernoulli constant in wave field of the steady state  $C$  is equivalent to that in the coordinate system moving with wave celerity in still water.

$$C = gD + (c^{III})^2/2 \tag{3}$$

where  $g$  is the acceleration of gravity. This is tentatively termed the third definition for wave celerity, in which case superscript 'III' is used as the indication.

(2) The Chappellear theory

Chappellear derived a cnoidal wave theory with two expansion parameters  $L_0$  and  $L_3$ . The Bernoulli constant and horizontal water particle velocity in a moving frame of reference, wave celerity and horizontal water particle velocity in a fixed frame of reference based on the first definition are expressed respectively as

$$C = \{3/2 + L_0(1+x^2) + 3L_3 + (9/10)L_0^2(2+3x^2+2x^4) + 6L_0L_3(1+x^2) + (3/2)L_3^2 + (3/35)L_0^3(45+97x^2+97x^4+45x^6) + 9L_0^2L_3(2+3x^2+2x^4) + 15L_0L_3^2(1+x^2)\}gD \tag{4}$$

$$\begin{aligned} \bar{u}/\sqrt{gD} = & 1 + L_3 + L_0x^2\text{sn}^2\gamma\chi + \{L_0^2(1+x^2) + 5L_0L_3\}x^2\text{sn}^2\gamma\chi \\ & + L_0^2x^4\text{sn}^4\gamma\chi - (y/D)^2(3/4)L_0^2\{x^2 - 2(1+x^2)x^2\text{sn}^2\gamma\chi + 3x^4\text{sn}^4\gamma\chi\} \\ & + \{(1/5)L_0^3(7+19x^2+7x^4) + 9L_0^2L_3(1+x^2) + 10L_0L_3^2\}x^2\text{sn}^2\gamma\chi \\ & + \{(9/5)L_0^3(1+x^2) + 9L_0^2L_3\}x^4\text{sn}^4\gamma\chi + (6/5)L_0^3x^6\text{sn}^6\gamma\chi \\ & - (1/4)(y/D)^2\{3L_0^3x^2(1+x^2) + 15L_0^2L_3x^2 + 6\{L_0^3(-1+x^2-x^4) \\ & - 5L_0^2L_3(1+x^2)\}x^2\text{sn}^2\gamma\chi + 15\{-L_0^3(1+x^2) + 3L_0^2L_3\}x^4\text{sn}^4\gamma\chi \\ & + 30L_0^3x^6\text{sn}^6\gamma\chi\} + (3/16)(y/D)^4L_0^3\{-x^2(1+x^2) \\ & + (2+13x^2+2x^4)x^2\text{sn}^2\gamma\chi - 15(1+x^2)x^4\text{sn}^4\gamma\chi + 15x^6\text{sn}^6\gamma\chi\} \end{aligned} \tag{5}$$

$$\begin{aligned} c'/\sqrt{gD} = & 1 + L_3 + L_0(1-e) + 5L_0L_3(1-e) + (1/3)L_0^2\{5 \\ & + 4x^2 - 5(1+x^2)e\} + 10L_0L_3^2(1-e) + (1/25)L_0^3\{81 + 146x^2 \\ & + 58x^4 - (81 + 169x^2 + 81x^4)e\} + 3L_0^2L_3\{5 + 4x^2 - 5(1+x^2)e\} \end{aligned} \tag{6}$$

$$\begin{aligned} u'/\sqrt{gD} = & L_0(1-e-x^2\text{sn}^2\phi) + 5L_0L_3(1-e-x^2\text{sn}^2\phi) \\ & + (1/3)L_0^2\{5+4x^2-5(1+x^2)e-3(1+x^2)x^2\text{sn}^2\phi-3x^4\text{sn}^4\phi\} \\ & + (y/D)^2(3/4)L_0^2\{x^2-2(1+x^2)x^2\text{sn}^2\phi+3x^4\text{sn}^4\phi\} \\ & + 10L_0L_3^2(1-e-x^2\text{sn}^2\phi) + 3L_0^2L_3\{5+4x^2-5(1+x^2)e \\ & - 3(1+x^2)x^2\text{sn}^2\phi-3x^4\text{sn}^4\phi\} + (1/25)L_0^3\{81+146x^2+58x^4 \\ & - (81+169x^2+81x^4)e-5(7+19x^2+7x^4)x^2\text{sn}^2\phi\} \end{aligned}$$

$$\begin{aligned}
& -45(1+x^2)x^4\text{sn}^4\phi - 30x^6\text{sn}^6\phi + (3/4)(y/D)^2[L_0^3\{(1+x^2)x^2 \\
& - 2(1-x^2+x^4)x^2\text{sn}^2\phi - 5(1+x^2)x^4\text{sn}^4\phi + 10x^6\text{sn}^6\phi\} \\
& + 5L_0^2L_3\{x^2 - 2(1+x^2)x^2\text{sn}^2\phi + 3x^4\text{sn}^4\phi\}] \\
& + (3/16)(y/D)^4L_0^3\{(1+x^2)x^2 - (2+13x^2+2x^4)x^2\text{sn}^2\phi \\
& + 15(1+x^2)x^4\text{sn}^4\phi - 15x^6\text{sn}^6\phi\}
\end{aligned} \tag{7}$$

where  $x$  is the argument of elliptic function,  $e=E/K$ ,  $K$  and  $E$  are the complete elliptic integrals of the first and second kinds,  $\text{sn}$ ,  $\text{cn}$  and  $\text{dn}$  the Jacobian elliptic functions,  $y=D+z$ ,  $\gamma = \sqrt{3L_0}/2D$  and  $\phi = \gamma(x-c t)$ .

The relation between two expansion parameters is written as

$$\begin{aligned}
& 2L_3 + L_0(x^2+e) + L_0^2\{(1/5)(-1+6x^2+9x^4) + 2(1+x^2)e\} \\
& + 6L_0L_3(x^2+e) + L_3^2 + L_0^3\{(1/175)(-102+223x^2+944x^4+675x^6) \\
& + (1/25)(111+214x^2+111x^4)e\} + 2L_0^2L_3\{-1+6x^2+9x^4 \\
& + 10(1+x^2)e\} + 15L_0L_3^2(x^2+e) = 0
\end{aligned} \tag{8}$$

and the relation between wave height  $H$  and expansion parameters is expressed as

$$\begin{aligned}
H/D = x^2L_0\{1+(1/4)L_0(10+7x^2) + 6L_3 + (1/40)L_0^2(251+369x^2 \\
+ 151x^4) + (5/2)L_0L_3(10+7x^2) + 15L_3^2\}
\end{aligned} \tag{9}$$

Yamaguchi et al. (1990) confirmed that the Chappellear theory is correct except for some printing errors, and newly calculated the trajectory of a water particle and integral properties such as energy flux.

### (3) Relation with the Tsuchiya & Yasuda theory

Tsuchiya & Yasuda derived a cnoidal wave theory with a single parameter  $L_0$ .

If the parameter  $L_3$  in the Chappellear theory is expanded into the power series form of  $L_0$ ,  $L_3$  is expressed as

$$\begin{aligned}
L_3 = -(1/2)(x^2+e)L_0 + (1/40)\{4-24x^2+19x^4+10(-4+7x^2)e \\
+ 55e^2\}L_0^2 - (1/2800)\{-816+3884x^2-5048x^4+1375x^6+(8316 \\
- 21616x^2+10941x^4)e + 2625(-8+9x^2)e^2+14875e^3\}L_0^3
\end{aligned} \tag{10}$$

and the relation between wave height  $H/D$  and  $L_0$  becomes

$$\begin{aligned}
H/D = x^2L_0 + (1/4)x^2(10-5x^2-12e)L_0^2 + (1/8)x^2\{55-55x^2 \\
+ 13x^4 + 74(-2+x^2)e + 96e^2\}L_0^3
\end{aligned} \tag{11}$$

Substitution of  $L_3$  relation into the wave characteristics in the Chappellear theory yields the following expressions.

$$c^{III}/\sqrt{gD} = 1 - (1/2)(-2 + x^2 + 3e)L_0 + (1/40)\{64 - 64x^2 + 19x^4 + 90(-2 + x^2)e + 135e^2\}L_0^2 - (1/2800)\{-10448 + 15672x^2 - 7974x^4 + 1375x^6 + 21(2288 - 2288x^2 + 563x^4)e + 36225(-2 + x^2)e^2 + 36225e^3\}L_0^3 \quad (12)$$

$$\begin{aligned} \alpha^{III}/\sqrt{gD} = & (1 - e - x^2 \text{sn}^2 \psi)L_0 + [(1/2)\{3 - 2x^2 - (7 - x^2)e + 4e^2 \\ & - (2 - 3x^2 - 5e)x^2 \text{sn}^2 \psi - 2x^4 \text{sn}^4 \psi\} + (3/4)(y/D)^2\{x^2 - 2(1 + x^2)x^2 \text{sn}^2 \psi \\ & + 3x^4 \text{sn}^4 \psi\}]L_0^2 + [(1/200)\{688 - 842x^2 + 209x^4 - (2838 - 1888x^2 \\ & + 63x^4)e + 75(49 - 12x^2)e^2 - 1525e^3 + 5\{-76 + 148x^2 - 71x^4 \\ & + 10(38 - 37x^2)e - 375e^2\}x^2 \text{sn}^2 \psi - 180(2 - 3x^2 - 5e)x^4 \text{sn}^4 \psi \\ & - 240x^6 \text{sn}^6 \psi\} + (3/8)(y/D)^2\{x^2(2 - 3x^2 - 5e) + 2\{-2 + 7x^2 + 3x^4 \\ & + 5(1 + x^2)e\}x^2 \text{sn}^2 \psi - 5(2 + 5x^2 + 3e)x^4 \text{sn}^4 \psi + 20x^6 \text{sn}^6 \psi\} \\ & - (3/16)(y/D)^4\{-x^2(1 + x^2) + (2 + 13x^2 + 2x^4)x^2 \text{sn}^2 \psi - 15(1 + x^2)x^4 \text{sn}^4 \psi \\ & + 15x^6 \text{sn}^6 \psi\}]L_0^3 \end{aligned} \quad (13)$$

These expressions coincide perfectly with those in the Tsuchiya & Yasuda theory. Relation between  $L_0$  and the expansion parameter in the Tsuchiya & Yasuda theory  $\lambda$  is given as

$$\lambda = x^2 L_0 \quad (14)$$

(4) Relation with the Isobe theory

Isobe gave a third order solution of cnoidal waves expressed with relative wave height  $H/D$ .

If the expansion parameters  $L_0$  and  $L_3$  in the Chappellear theory are expanded into the power series of  $H/D$ ,  $L_0$  and  $L_3$  are written as

$$L_0 = (1/x^2)(H/D) - (1/4x^4)(10 - 5x^2 - 12e)(H/D)^2 + (1/8x^6)\{3(15 - 15x^2 + 4x^4) - 46(2 - x^2)e + 48e^2\}(H/D)^3 \quad (15)$$

$$\begin{aligned} L_3 = & -(1/2x^2)(x^2 + e)(H/D) + (1/40x^4)\{2(2 + 13x^2 - 3x^4) \\ & + 5(2 - 3x^2)e - 5e^2\}(H/D)^2 + (1/2800x^6)\{-584 - 2659x^2 + 2073x^4 \\ & - 150x^6 + (-511 + 4011x^2 - 861x^4)e + 1050(1 - x^2)e^2 - 175e^3\}(H/D)^3 \end{aligned} \quad (16)$$

and if these  $L_0$  and  $L_3$  relations are used, the wave characteristics in the Chappellear theory are transformed as

$$\begin{aligned} c^{II}/\sqrt{gD} = & 1 + (1/2x^2)(2 - x^2 - 3e)(H/D) + (1/40x^4)\{2(-8 + 8x^2 \\ & - 3x^4) + 5(2 - x^2)e + 15e^2\}(H/D)^2 + (1/2800x^6)\{1558 - 2337x^2 \\ & + 1079x^4 - 150x^6 - (2653 - 2653x^2 + 203x^4)e + 350(2 - x^2)e^2 \\ & + 175e^3\}(H/D)^3 \end{aligned} \quad (17)$$

$$\begin{aligned}
u''/\sqrt{gD} = & (1/x^2)(1-e-x^2\text{sn}^2\psi)(H/D) + (1/4x^4)[-2-x^2+x^2e \\
& + 2e^2 + (6+x^2-2e)x^2\text{sn}^2\psi - 4x^4\text{sn}^4\psi + 3(y/D)^2\{x^2-2(1+x^2)x^2\text{sn}^2\psi \\
& + 3x^4\text{sn}^4\psi\}](H/D)^2 + (1/x^6) \{ (1/200)[\{153+23x^2-71x^4+(-153-97x^2 \\
& + 47x^4)e + 25(-1+2x^2)e^2+25e^3\} + 5\{-101-27x^2+19x^4+10(10+x^2)e \\
& - 15e^2\}x^2\text{sn}^2\psi + 20(32+2x^2-15e)x^4\text{sn}^4\psi - 240x^6\text{sn}^6\psi] \\
& + (3/8)(y/D)^2\{-8+2x^2+7e\}x^2 + 2\{2(4+6x^2-x^4)-7(1+x^2)e\}x^2\text{sn}^2\psi \\
& + (-40-10x^2+21e)x^4\text{sn}^4\psi + 20x^6\text{sn}^6\psi\} + (3/16)(y/D)^4\{(1+x^2)x^2 \\
& - (2+13x^2+2x^4)x^2\text{sn}^2\psi + 15(1+x^2)x^4\text{sn}^4\psi - 15x^6\text{sn}^6\psi\} (H/D)^3 \quad (18)
\end{aligned}$$

These expressions are exactly the same as the Isobe theory.

#### (5) Relation with the Fenton theory

Fenton derived a cnoidal wave theory expressed with relative wave height  $H/h_t$ , in which  $h_t$  is the water depth under the trough,

If  $L_0$  and  $L_3$  are expanded into the power series of  $H/h_t$  and  $h_t/D$  relation is taken into account,  $L_0$ ,  $L_3$  and  $h_t/D$  are expressed as a function of  $H/h_t$ .

$$\begin{aligned}
L_0 = & (1/x^2)(H/h_t) + (1/4x^4)(-6+x^2+8e)(H/h_t)^2 + (1/8x^6)\{3(3+x^2) \\
& - 8(2+x^2)e + 8e^2\}(H/h_t)^3 \quad (19)
\end{aligned}$$

$$\begin{aligned}
L_3 = & -(1/2x^2)(x^2+e)(H/h_t) + (1/40x^4)\{2(2+3x^2+7x^4)-5(2-5x^2)e \\
& + 15e^2\}(H/h_t)^2 - (1/2800x^6)\{24+279x^2+307x^4+710x^6+7(53-153x^2 \\
& + 253x^4)e - 1050(1-2x^2)e^2+875e^3\}(H/h_t)^3 \quad (20)
\end{aligned}$$

$$\begin{aligned}
h_t/D = & 1 + (1/x^2)(1-x^2-e)(H/h_t) + (1/4x^4)\{2(1-3x^2+2x^4) \\
& - (6-7x^2)e + 4e^2\}(H/h_t)^2 - (1/400x^6)\{-66+399x^2-733x^4+400x^6 \\
& + 2(233-683x^2+458x^4)e - 200(4-5x^2)e^2+400e^3\}(H/h_t)^3 \quad (21)
\end{aligned}$$

Substitution of  $L_0$ ,  $L_3$ , and  $h_t/D$  relations into the wave characteristics of the Chappellear theory yields the following expressions, which agree exactly with those in the Fenton theory again.

$$\begin{aligned}
c^1/\sqrt{gh_t} = & 1 + (1/2x^2)(1-2e)(H/h_t) + (1/120x^4)\{- (13+2x^2+3x^4) \\
& + 10(4+x^2)e\}(H/h_t)^2 + (1/16800x^6)\{-2888+5697x^2-2689x^4+780x^6 \\
& + 4(392-1442x^2+917x^4)e\}(H/h_t)^3 \quad (22)
\end{aligned}$$

$$\begin{aligned}
 \bar{u}/\sqrt{gh_i} = & 1 + (1/2x^2)(-1 + 2x^2 - 2x^2 \text{cn}^2\gamma\chi)(H/h_i) + (1/40x^4)\{3(3 - 8x^2 \\
 & + 3x^4) + 10(4 - 5x^2)x^2 \text{cn}^2\gamma\chi + 40x^4 \text{cn}^4\gamma\chi\}(H/h_i)^2 + (3/4x^2)\{1 - x^2 \\
 & + 2(-1 + 2x^2) \text{cn}^2\gamma\chi - 3x^2 \text{cn}^4\gamma\chi\}(y/h_i)^2(H/h_i)^2 + (1/1120x^6)\{-88 + 167x^2 \\
 & + 181x^4 - 200x^6 + 4(-112 + 378x^2 - 133x^4)x^2 \text{cn}^2\gamma\chi \\
 & + 16(-119 + 133x^2)x^4 \text{cn}^4\gamma\chi - 1344x^6 \text{cn}^6\gamma\chi\}(H/h_i)^3 + (3/8x^4)\{-1 + x^4 \\
 & + 2(1 - 7x^2 + 4x^4) \text{cn}^2\gamma\chi + (19 - 29x^2)x^2 \text{cn}^4\gamma\chi + 20x^4 \text{cn}^6\gamma\chi\}(y/h_i)^2(H/h_i)^3 \\
 & + (3/16x^4)\{1 - 3x^2 + 2x^4 + (-2 + 17x^2 - 17x^4) \text{cn}^2\gamma\chi \\
 & + 15(-1 + 2x^2)x^2 \text{cn}^4\gamma\chi - 15x^4 \text{cn}^6\gamma\chi\}(y/h_i)^4(H/h_i)^3
 \end{aligned}
 \tag{23}$$

(6) Summary of the considerations

In short, substitution of these series forms for  $L_0$  and  $L_3$  into the wave characteristics and integral properties by the Chappellear theories based on three definitions for wave celerity yields the same expressions as those developed by the above-mentioned researchers in all the cases investigated. This means that all of the existing third order solutions of cnoidal wave theory can be derived from the Chappellear theory by properly changing expansion parameters when the definition for wave celerity is identified in each solution. Details of the wave characteristics and integral properties calculated are given in the series papers by the authors (Yamaguchi et al. 1990, 1991 and 1992).

Fig. 1 summarizes the interrelation established among the existing cnoidal wave theories.

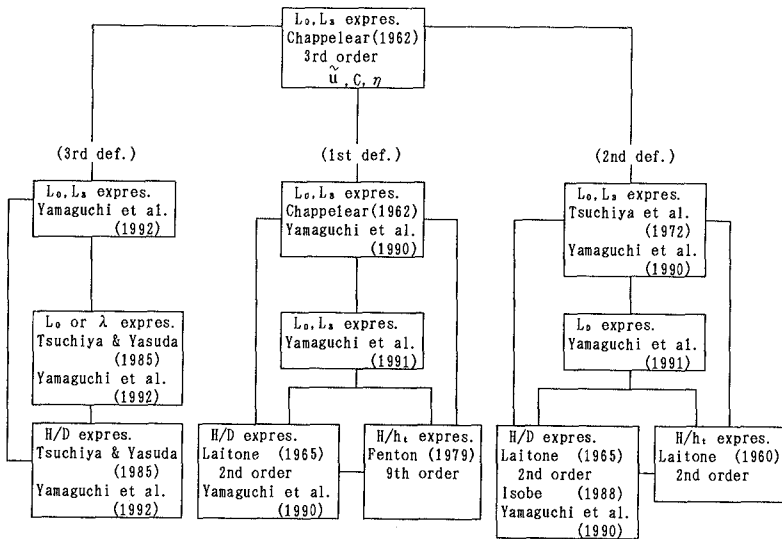

Fig. 1 Interrelation of cnoidal wave solutions.

3. Numerical Considerations

Fig.2 shows the vertical distributions of maximum horizontal water particle velocity  $u_c/\sqrt{gD}$  based on the cnoidal wave theories using the first definition with two parameters, one parameter and H/D parameter indicated by c-3-1, c-3-1M and c-3-1L respectively, in which T is the wave period. The theory with H/D parameter gives a more and more unrealistic distribution in the case of larger H/D values, and the theory with  $L_0$  parameter produces similar results to that with two parameters. But integral properties of the theory with two parameters do not show favorable behavior in the case of smaller  $T\sqrt{g/D}$ . Therefore, use of the cnoidal wave theory with  $L_0$  parameter is recommended for its practical application.

Fig. 2 Vertical distributions of maximum horizontal water particle velocity based on cnoidal wave theories with different parameters.

Examples of the comparison between computations with the experiments for wave celerity and maximum horizontal water particle velocity distribution are given in Fig. 3, which shows reasonable agreement between them. It is also

Fig. 3 Comparison between experiments and computations for wave celerity and vertical distribution of maximum horizontal water particle velocity.

seen that water particle velocity becomes larger according to the order of the theories with the second, first and third definitions.

Lagrangian velocity of a particular water particle is equal to Eulerian velocity at the position at time  $t$

$$dx/dt = u(x, z), \quad dz/dt = w(x, z), \quad x = x_0 + \xi(t), \quad z = z_0 + \zeta(t) \quad (24)$$

where  $(x_0, z_0)$  are the initial horizontal and vertical positions of a water particle, and  $(\xi, \zeta)$  the horizontal and vertical displacements of a water particle from its initial positions. Substitution of water particle velocities by cnoidal wave theory based on the first definition and use of a successive approximation method yield the trajectory of a water particle, in which case the initial conditions  $x=x_0$  and  $z=z_0$  at  $t=0$  are imposed. Horizontal and vertical displacements are written respectively as

$$\begin{aligned} x'/T\sqrt{gD} &= x_0/T\sqrt{gD} + (1/2K)\{[ea - E(\alpha)]L_0 \\ &+ [(1/6)\{2(1-x^2)[\alpha] + 2(-4+2x^2+3e)[E(\alpha)] + (4-5x^2-15e \\ &+ 6x^2\text{sn}^2\alpha)[ea - E(\alpha)]\} - (3/4)(y_0/D)^2x^2[\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha]\}L_0^2 \\ &+ [(1/600)\{20(24-41x^2+17x^4)[\alpha] + 20\{-149+169x^2-34x^4 \\ &+ 5(52-29x^2)e-135e^2\}[E(\alpha)] + \{-256-244x^2+369x^4 \\ &+ 150(-32+25x^2)e+5625e^2\}[ea - E(\alpha)] + 200(1-x^2)x^2\text{sn}^2\alpha[\alpha] \\ &+ 200(-4+2x^2+3e)x^2\text{sn}^2\alpha[E(\alpha)] + 100(10-11x^2-27e \\ &+ 6x^2\text{sn}^2\alpha)x^2\text{sn}^2\alpha[ea - E(\alpha)] + 600x^2\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha[ea - E(\alpha)]^2 \\ &- 8(1+x^2)x^2[\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha] + 24x^4[\text{sn}^3\alpha\text{cn}\alpha\text{dn}\alpha]\} \\ &+ (1/40)(y_0/D)^2\{16(2-3x^2+x^4)[\alpha] + 32(-1+x^2-x^4)[E(\alpha)] \\ &- 30x^2\{1-2(1+x^2)\text{sn}^2\alpha+3x^2\text{sn}^4\alpha\}[ea - E(\alpha)] \\ &+ 30x^4\text{sn}\alpha\text{cn}\alpha_0\text{dn}\alpha_0[\text{sn}^2\alpha] + (-44+61x^2+105e)x^2[\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha] \\ &- 60x^4\text{sn}^2\alpha_0[\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha] - 18x^4[\text{sn}^3\alpha\text{cn}\alpha\text{dn}\alpha]\} \\ &+ (3/16)(y_0/D)^4\{- (1+x^2)x^2[\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha] + 3x^4[\text{sn}^3\alpha\text{cn}\alpha\text{dn}\alpha]\}L_0^3 \end{aligned} \quad (25)$$

$$\begin{aligned} z'/T\sqrt{gD} &= z_0/T\sqrt{gD} - (3/2K\sqrt{3L_0})(y_0/D)x^2 \{ (1/2)[\text{sn}^2\alpha]L_0^2 \\ &- (1/8)\{2(-4+3x^2+7e-2x^2\text{sn}^2\alpha_0)[\text{sn}^2\alpha] - 8\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha[ea \\ &- E(\alpha)] + (y_0/D)^2\{-2(1+x^2)[\text{sn}^2\alpha] + 3x^2[\text{sn}^4\alpha]\}\}L_0^3 \\ &+ [(1/240)\{80(1-x^2)\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha[\alpha] + 80(4-2x^2 \\ &- 3e)\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha[E(\alpha)] + 40(10-11x^2-27e+6x^2\text{sn}^2\alpha \\ &+ 6x^2\text{sn}^2\alpha_0)\text{sn}\alpha\text{cn}\alpha\text{dn}\alpha[ea - E(\alpha)] + 120\{1-2(1+x^2)\text{sn}^2\alpha \\ &+ 3x^2\text{sn}^4\alpha\}[ea - E(\alpha)]^2 + \{548-704x^2+213x^4+10(-200+133x^2)e \\ &+ 1665e^2\}[\text{sn}^2\alpha] + 60x^2\text{sn}^2\alpha_0(6-5x^2-11e+2x^2\text{sn}^2\alpha_0)[\text{sn}^2\alpha] \\ &- 24x^2(1+x^2)[\text{sn}^4\alpha] + 24x^4[\text{sn}^6\alpha]\} + (1/16)(y_0/D)^2\{8(1+x^2 \end{aligned}$$

$$\begin{aligned}
& -3x^2 \text{sn}^2 \alpha \text{sn} \alpha \text{cn} \alpha \text{dn} \alpha \left[ e\alpha - E(\alpha) \right] + 2\{4 - 8x^2 - 3x^4 \\
& - 7(1 + x^2)e\} \left[ \text{sn}^2 \alpha \right] + 2x^2 \text{sn}^2 \alpha_0 (8 + 8x^2 - 3x^2 \text{sn}^2 \alpha_0) \left[ \text{sn}^2 \alpha \right] \\
& + 3x^2 (7x^2 + 7e - 6x^2 \text{sn}^2 \alpha_0) \left[ \text{sn}^4 \alpha \right] - 8x^4 \left[ \text{sn}^6 \alpha \right] \\
& + 12x^2 \text{sn} \alpha_0 \text{cn} \alpha_0 \text{dn} \alpha_0 \left[ \text{sn} \alpha \text{cn} \alpha \text{dn} \alpha \right] + (3/160)(y_0/D)^4 \{ (2 + 13x^2 \\
& + 2x^4) \left[ \text{sn}^2 \alpha \right] - 15x^2(1 + x^2) \left[ \text{sn}^4 \alpha \right] + 15x^4 \left[ \text{sn}^6 \alpha \right] \} L_0^4
\end{aligned} \quad (26)$$

where  $\square f(\alpha) = f(\alpha) - f(\alpha_0)$ ,  $\alpha = 2K(x_0 - ct)/L$

$$\alpha_0 = 2Kx_0/L, \quad y_0/D = 1 + z_0/D, \quad (27)$$

and  $E(\alpha)$  is the Jacobian E function defined as

$$E(\alpha) = \int_0^\alpha \text{dn}^2 \alpha d\alpha \quad (28)$$

Mass transport velocity is calculated as time-averaged residual displacement of a water particle, and the distributions based on the solutions using three definitions are given respectively as

$$\begin{aligned}
U_m^I/\sqrt{gD} &= (1/3)\{-1 + x^2 + 2(2 - x^2)e - 3e^2\}L_0^2 + [(1/30)\{-24 + 41x^2 \\
& - 17x^4 + (149 - 169x^2 + 34x^4)e + 5(-52 + 29x^2)e^2 + 135e^3\} \\
& + (1/3)\{-1 + x^2 + 2(2 - x^2)e - 3e^2\}x^2 \text{sn}^2 \alpha_0 \\
& + (2/5)(y_0/D)^2\{-2 + 3x^2 - x^4 + 2(1 - x^2 + x^4)e\}]L_0^3
\end{aligned} \quad (29)$$

$$\begin{aligned}
V_m^I/\sqrt{gD} &= \underline{-(1/3\sqrt{3}L_0)L_0^4(y_0/D)x^2 \text{sn} \alpha_0 \text{cn} \alpha_0 \text{dn} \alpha_0\{-1 + x^2 \\
& + 2(2 - x^2)e - 3e^2\}}
\end{aligned} \quad (30)$$

$$U_m^{II}/\sqrt{gD} = (2/15)L_0^3\{1 - 3(y_0/D)^2\}\{2 - 3x^2 + x^4 + 2(-1 + x^2 - x^4)e\} \quad (31)$$

$$V_m^{II}/\sqrt{gD} = 0 \quad (32)$$

$$\begin{aligned}
U_m^{III}/\sqrt{gD} &= (1/2)\{-1 + x^2 + 2(2 - x^2)e - 3e^2\}L_0^2 + [(1/60)\{-66 \\
& + 109x^2 - 43x^4 + (421 - 461x^2 + 86x^4)e + 5(-146 + 79x^2)e^2 + 375e^3\} \\
& + (1/3)\{-1 + x^2 + 2(2 - x^2)e - 3e^2\}x^2 \text{sn}^2 \alpha_0 \\
& + (2/5)(y_0/D)^2\{-2 + 3x^2 - x^4 + 2(1 - x^2 + x^4)e\}]L_0^3
\end{aligned} \quad (33)$$

$$\begin{aligned}
V_m^{III}/\sqrt{gD} &= \underline{-(3/2\sqrt{3}L_0)L_0^4(y_0/D)x^2 \text{sn} \alpha_0 \text{cn} \alpha_0 \text{dn} \alpha_0\{-1 + x^2 \\
& + 2(2 - x^2)e - 3e^2\}}
\end{aligned} \quad (34)$$

When the initial conditions such as  $x=x_0$  and  $z=z_0$  at  $t=0$  are used, mass transport velocities based on the third order solutions of cnoidal waves using the first and third definitions depend on the initial horizontal position of a water particle, as denoted by underline. This may be due to the deficiency of the successive approximation method as in the case of Stokes wave theory. Thus,

$x_0$  is set to zero.

Fig. 4 illustrates the trajectory of a water particle and vertical distribution of mass transport velocity based on cnoidal wave theories using three definitions. None of the theories describe closed orbits, and all of them result in mass transport velocity distribution.

Wave energy  $\hat{E}$  and energy flux  $\hat{F}$  nondimensionalized by those of the small amplitude wave theory are shown in Fig. 5. Increase of  $T\sqrt{g/D}$  and decrease of  $D/H$ , that is to say, increase of wave nonlinearity, give rise to consistent and favorable reduction of dimensionless integral properties.

Fig. 4 Trajectory of a water particle and vertical distribution of mass transport velocity.

Fig. 5 Relation between integral properties and wave parameters.

#### 4. Limiting Range for Applicability

A limiting range for the application of cnoidal wave theory with a single expansion parameter is investigated by comparing wave characteristics and integral properties of cnoidal waves with those of Fenton's Fourier approximation theory, because the Fourier approximation theory gives the almost exact solution to water wave problem on a uniform depth.

Fig. 6 shows two examples of the comparison for vertical distribution of maximum horizontal water particle velocity and dimensionless energy flux, which shows that decrease of  $D/H$  and  $T\sqrt{g/D}$  gives rise to greater discrepancy between both theoretical results.

Fig. 6 Comparison between vertical distribution of maximum horizontal water particle velocity and dimensionless energy flux by cnoidal wave theory and those by Fourier approximation theory.

Fig. 7 illustrates a limiting range of wave parameters for the application of cnoidal wave theory, in which errors for wave celerity, horizontal water particle velocity and integral properties of cnoidal wave theory are less than 0.5 %, 5 % and 5 % respectively. In the figures, notations  $u_0$ ,  $u_5$  and  $u_b$  are the maximum horizontal water particle velocities at the still water level, middle point between still water level and bottom, and bottom,  $E_k$  and  $E_p$  the kinetic and potential energies,  $S_{11}$  and  $S_{22}$  the principal components of radiation stress and  $\overline{u_b^2}$  is the time mean of squared horizontal water particle velocity at the bottom. The range for individual wave characteristics and for integral property are different from each other. But roughly speaking, a limiting range of  $H/D$  for the third order solution is around 2.

Fig. 7 Limiting range for application of the third order solution of cnoidal wave theory.

## 5. Conclusions

The main results are summarized as follows;

- 1) The interrelation among all of the existing cnoidal wave theories with the third order approximation is analytically established, in which case they can be derived from the Chappellear solution expressed with two expansion parameters by identifying the definition for wave celerity to be used in the theory and changing the expansion parameters in the expressions of wave characteristics and integral properties.
- 2) Based on the numerical computation of the wave characteristics and integral properties and the comparison with the experiments, use of the cnoidal wave theory expressed with a single parameter  $L_0$  was recommended from a practical viewpoint.
- 3) The figures describing a limiting range of wave parameters for the application of the cnoidal wave theory expressed with a single expansion parameter are provided by comparing wave characteristics and integral properties of the theory with those of the Fourier approximation theory.

## CHAPTER 56

# FREAK WAVES IN UNIDIRECTIONAL WAVE TRAINS AND THEIR PROPERTIES

Takashi YASUDA\* , Nobuhito MORI\*\* and Kazunori ITO†

### ABSTRACT

This study aims to make clear the cause and occurrence condition of two-dimensional(2-D) freak waves by solving the hydrodynamic equations of 2-D irrotational flow for nonlinear waves with various spectra corresponding to swell from wind waves and describing the long-time evolution. As a result, it is shown that the third order resonant interaction causes the 2-D freak waves of which surface profiles are very similar with those observed in nature and multiplies the occurrence probability with the decreasing of the spectral bandwidth in deep water. Conversely, the feature of the freak waves —*single and outstanding wave height*— gets prominent with the broadening of the spectral bandwidth.

### INTRODUCTION

In recent years there has been a growing interest in single extreme waves referred as freak waves. Freak waves are individual high waves having severely damaging potential and are defined as waves with larger heights than two times of significant wave heights. There is no doubt on the occurrence of freak waves in nature because many reports are presented on their damages on offshore platforms at deck level and so on. However, the cause and properties of freak waves are still not so clear, although the state of the research on freak waves is already summarized at NATO Advanced Research Workshop in 1989[Peregrine,1990] and some explanations are suggested as their possible cause.

Laboratory measurement(Stansberg,1990) showed that a freak wave can be generated in a 2-D wave flume. This is a fairly strong evidence showing that some freak waves can actually occur in a unidirectional wave train without the effects of directional contents, wave focusing and currents. However, so definite explanation has not yet been suggested for its occurrence. In the case of

a quasi-monochromatic wave, Dold & Peregrine(1986) solved the fully nonlinear hydrodynamic equations for 2-D irrotational waves by using a boundary integral method and showed that a unidirectional wave train as gentle as  $ka=0.10$  undergoes a considerable modulation in its envelope and develops into breaking due to the nonlinear modulation. Their result suggests that the modulation due to resonant interaction might generate a freak wave in the 2-D domain. However, even if freak waves in nature could be treated approximately as long crested(2-D) waves, it remains unchanged that they must be treated as random waves having considerably broad spectral bandwidth. We hence are required to answer the question whether or not the resonant interaction can actually generate such freak waves as observed in nature in the 2-D wave trains having the broad band spectra similar with those in field.

In this study, we focus our interest on 2-D freak waves and make clear their cause and occurrence condition. For that purpose, we solve the hydrodynamic equations of 2-D incompressible and inviscid fluid for the waves having various spectra from swell to wind waves and perform intensive numerical simulations describing their long-time evolution. On the basis of the simulated results, we investigate relationships between their initial conditions and the time evolution and give an answer to the question whether or not 2-D freak waves can actually occur in random wave trains with arbitrary spectra. Furthermore, we make clear their cause and occurrence condition.

## COMPUTATIONAL METHOD

2-D vertical domain is assigned to be the usual spatial coordinates( $x, z$ );the origin is located at the mean water level,  $x$  the horizontal coordinate and  $z$  the vertically upward one. Boundary conditions at the free surface of the irrotational flow are rewritten into the evolution equations with regard to the free surface profile  $\eta(x, t)$  and the surface velocity potential  $\phi^s(x, t)$  at  $z = \eta$ ;

$$\eta_t + \phi_x^s \cdot \eta_x - (1 + \eta_x \cdot \eta_x) \phi_z = 0 \quad |_{z=\eta}, \quad (1)$$

$$\phi_x^s + g\eta + \frac{1}{2} \phi_x^s \cdot \phi_x^s - \frac{1}{2} (1 + \eta_x \cdot \eta_x) \phi_z^2 = 0 \quad |_{z=\eta}, \quad (2)$$

where the subscripts denote the partial differentiations with regard to  $t$  and  $x$ ,  $\phi_z$  the vertical gradient of the velocity potential  $\phi(x, z, t)$ ,  $t$  the time and  $g$  the acceleration due to gravity.

It is very difficult to solve eqs.(1) and (2) into the so-called Zakharov equation on the wavenumber space for waves having both the nonlinearity higher than the 3rd order and the arbitrary spectral bandwidth as far as based on the ability of present computer, although it was carried out for quasi-monochromatic waves by Yuen & Lake(1982). Hence, following Dommermuth & Yue(1987), we solve eqs.(1) and (2) on the physical space. Considering the nonlinear correction to  $\phi_z$  up to the  $M$ th order in the wave field composed of J-Fourier modes, we

formulate  $\phi_z$  so as to satisfy the Laplace equation,  $\nabla^2 \phi = 0$ , and the boundary condition on the flat bottom at  $z=-h$ ,  $\phi_z=0|_{z=-h}$ ;

$$\phi_z(x, \eta, t) = \sum_{m=1}^M \sum_{k=0}^{M-m} \frac{\eta^k}{k!} \sum_{j=1}^J \phi_j^{(m)}(t) \frac{\partial^{k+1}}{\partial z^{k+1}} \psi_j(x, 0), \tag{3}$$

$$\psi_j(x, z) = \frac{\cosh[k_j(z+h)]}{\cosh(k_j h)} \exp(ik_j x), \tag{4}$$

where  $k$  denotes the wave number,  $h$  the mean water depth,  $\phi_j^{(m)}(t)$  is derived by solving the following equations in order.

$$\begin{aligned} \phi^{(1)}(x, 0, t) &= \phi^s, \\ \phi^{(m)}(x, 0, t) &= - \sum_{k=1}^{m-1} \frac{\eta^k}{k!} \frac{\partial^k}{\partial z^k} \phi^{(m-k)}(x, 0, t) \quad (m = 2, 3, \dots, M). \end{aligned} \tag{5}$$

In this method, an approximation is made on the expression of  $\phi_z$  alone and eqs.(1) and (2) are solved directly in the physical space by using the pseudo-spectral method. While the spatial derivations of  $\phi^{(m)}$ ,  $\phi^s$  and  $\eta$  are evaluated in the spectral space, the nonlinear products are calculated in the physical space. The time evolution of  $\eta$  and  $\phi^s$  is made in the physical space by integrating eqs.(1) and (2) with the fourth-order Runge-Kutta-Gill method. An optimum FFT scheme for the vector operation in a super computer is used to delete the alising error generated in the computaion of the nonlinear terms and accomplish the fast computation.

### VALIDITY OF THE COMPUTATION

The accuracy and convergence of the computational model are tested by giving the exact Stokes waves as initial waves. The first check of the accuracy is provided by examining the maximum difference of the surface wave profile  $\varepsilon_1 = |k\{\eta_n(x, t) - \eta_e(x, t)\}|_{max}$  between the numerical solution  $\eta_n$  and the exact solution  $\eta_e$  during the propagation process from  $t/T=0$  to 100. Here,  $T$  is the wave period. Further, the accuracy and convergence of the numerical solutions are tested by defining the error to the conservation law of the total energy  $E(t)$  as  $\varepsilon_2 = |1 - E(t)/E(0)|$  and examining its time evolution.

Table 1 indicates the maximum values of  $\varepsilon_1$  and  $\varepsilon_2$  for the shallow water waves with  $ka=0.17$  and  $kh=1$  and for the deep water waves with  $ka=0.2$  and  $0.3$  when the numerical computations are made under the condition of the values of  $M=3$  and  $4$  and  $J=8$  and  $16$ . Here,  $a$  is the wave amplitude. Figure 1 describes the time evolution of  $\varepsilon_2$  for each numerical solution shown in Table 1. Both the error criteria,  $\varepsilon_1$  and  $\varepsilon_2$ , indicate finite values because the values of  $M$  and  $J$  employed here are not large enough for the numerical solutions to agree completely with the exact solution. However, the values of  $\varepsilon_1$  are still considerably

small after the long time evolution of  $t/T=100$ . Further, although the values of  $\epsilon_2$  grow with oscillation, their envelopes are almost constant independly of the values of  $kh, ka, M$  and  $J$  and their amplitudes are sufficently small. We can hence expect the sufficient accuracy and convergency for the obtained numerical solutions if solving eqs.(1) and (2) by the aforementioned method.

Table 1. Accuracy of the numerical solutions for the exact Stokes waves

$ka$	$kh$	$M$	$J$	$\epsilon_1 \times 10^3$	$\epsilon_2 \times 10^3$
0.17	1	3	8	0.43	1.33
0.17	1	4	8	0.37	0.85
0.20	$\infty$	3	8	0.42	0.72
0.20	$\infty$	3	16	0.42	0.72
0.20	$\infty$	4	8	0.42	0.70
0.30	$\infty$	3	8	3.05	5.75

Figure 1. Time histories of the error criterion  $\epsilon_2$

**NUMERICAL SIMULATIONS**

Initial surface profiles  $\eta(x, 0)$  is given by

$$\eta(x, 0) = \sum_{n=1}^J \sqrt{2S(k_n)(2\pi/L_0)} \sin(k_n x + \epsilon_n) \tag{6}$$

where  $L_0$  is the total length of the simulated wave train,  $k_n$  the wave number of the  $n$ -th Fourier mode,  $\epsilon_n$  the phase constant of the Fourier mode given by a set of independent uniform random numbers uniformly distributed in the interval  $(0, 2\pi)$  radians and  $S(k_n)$  the desired wavenumber discrete spectrum into which the following Wallops continuous spectrum  $S(f)$  is transformed through the linear dispersion relation.

Figure 2. Spatial surface profiles of a simulated wave train at  $t/T_p=0, 30$  and  $60$  ( $k_p h=3.0, k_p a=0.17$ ).

$$S(f) = \alpha H_{1/3}^2 f^{(4-m)} (f/f_p)^{-4} \exp \left[ -0.25m (f/f_p)^{-4} \right], \tag{7}$$

where  $\alpha$  is a constant satisfying the relation,

$$H_{1/3} = 4.004 \left[ \int_0^\infty S(f) df \right]^{\frac{1}{2}}, \tag{8}$$

$f_p$  the spectral peak frequency,  $H_{1/3}$  the significant wave height and  $m$  the spectral bandwidth parameter. The value of  $m=5$  generally gives the spectrum of wind waves and those of  $m \geq 10$  swell spectra. Initial surface potential  $\phi^s(x, 0)$  is given here by the linear transformation of its conjugate  $\eta(x, 0)$ .

The numerical computations are made in the periodic space having the length of  $L_0 = 64L_p$  on the  $x$  coordinate; the subscript  $p$  denotes the quantity of the spectral peak mode. The values of  $M$  and  $J$  are fixed to 3 and 256, respectively. The time interval of the stepping is  $T_p/100$ . The simulations are performed with the accuracy of the energy error criterion  $\varepsilon_2$  of which value is always less than 0.05, under the initial statistics comprised of  $k_p h=1.04, 1.36, 1.72, 2.35$  and  $3.0, k_p a=0.17, m=5, 10, 15$  and  $30$ . The accuracy is accomplished without any consideration except for de-aliasing. This fact convinces us that

any breaking event does not occur during the propagation process because the breaking triggers the floating overflow error of the numerical solution.

Figure 2 shows the computed surface elevations for the waves with the initial statistics of  $k_p h = 3.0$ ,  $k_p a = 0.17$  and  $m = 15, 30$ . The free surface elevations at  $t/T_p = 20$  and 60 are considerably modulated in comparison with their initial ones and accompany single high waves characterized as freak waves because they are not part of a smooth wave group pattern and the crest heights clearly exceed those of their neighbours.

## NONLINEAR EFFECTS ON 2-D FREAK WAVES

### Surface profiles of 2-D freak waves

Figure 3 shows the temporal surface elevation of the typical freak wave observed in the North sea (Sandet *al.*, 1990). The wave profile definitely demonstrates the feature of a typical freak wave that is single —*not part of smooth wave group pattern*— and has remarkable horizontal asymmetry and the crest height clearly exceeding that of its neighbours.

Figure 4 indicates the spatial surface profiles of 2-D freak waves occurring in the simulated wave trains. The simulated wave profiles are easily found to be very similar with the observed wave profile shown in Fig.3, although there is a definite difference that the formers are spatial profiles in 2-D domain while the latter is temporal one in 3-D field. On the other hand, the wave profile of a linear freak wave shown in Fig.5 for comparison is mild and horizontally symmetric. We thereby notice that it is greatly differs from those shown in Figs.3 and 4 and very little possesses the aforementioned feature of the freak waves. This states that a linear combination of the Fourier modes cannot be probably the cause of the freak waves hitherto observed in nature even if it can generate the wave grouping containing a high wave of which height exceeds two times of  $H_{1/3}$ . On the contrary, the wave profiles shown in Fig.4 are very similar with that observed in nature (Fig.3) as mentioned. We could therefore say from the viewpoint of the similarity of both the wave profiles that freak waves can be generated by the 3rd order nonlinear interaction (resonant interaction) independently of the spectral bandwidth, that is, the 3rd order resonant interaction can be one of the causes of freak waves in nature. We should further notice that even if the occurrence of the freak waves might obey the Rayleigh distribution, which is based on the strict assumption of a narrow banded Gaussian process, the freak waves having the aforementioned feature —*single and outstanding*— never occurs from narrow banded linear wave trains.

Figure 6 describes the time evolution of the freak wave during the propagation process from its appearing to disappearing. Its appearing and disappearing times are denoted with the open arrows. The freak wave is not so unstable as it instantaneously appears and disappears, but so stable as it keeps the profile during about one period at least.

**Nonlinear effects causing freak waves**

Figure 7 shows the time histories of the ratio  $H_{max}/H_{1/3}$  of the maximum wave height  $H_{max}$  to  $H_{1/3}$  and  $GF$ (Groupiness Factor) of the spatial surface profiles of the evolving simulated waves. For comparison, the results of linear waves and the 2nd order nonlinear waves are also shown. The 2nd order nonlinear wave solution is derived by solving not eqs.(1) and (2) but the original hydrodynamic equations in which the nonlinear terms more than the 3rd order are deleted. The 3rd order resonant interaction is not therefore taken into account in the 2nd order solution. It is found that nonlinear effects of the 2nd order are almost negligible on the values of  $H_{max}/H_{1/3}$  and  $GF$ , although it is well-known that they affects on the skewness of the free surface profiles. On the other hand, nonlinear effects of the 3rd order on those values are remarkable and grow with the narrowing of the spectral bandwidth. The time evolution of  $H_{max}/H_{1/3}$  corresponds well to

that of  $GF$  in the nonlinear( $M=3$ ) wave train. We could hence say that the 3rd order resonant interaction strongly modulates the envelope of the wave train so that it multiplies the values of  $GF$  and  $H_{max}$  and further causes the freak waves.

Figure 8 shows the amplitude modulation of the peak and its side-band Fourier modes of the nonlinear waves( $M=3$ ) shown in Fig.7. The time evolution of the amplitude modulation of the side-band modes clearly corresponds to both the time histories of  $H_{max}/H_{1/3}$  and  $GF$ . It should be noticed that the value of  $H_{max}/H_{1/3}$  exceeds 2 and the individual wave with  $H_{max}$  becomes a freak wave at the time when the side-band modes become dominant to the spectral peak mode independently of the spectral bandwidth( $m=15$  and 30) and that these occur. This result demonstrates that the 2-D freak waves are generated by the side-band instability due to the resonant interaction.

(a)  $m = 15$

(b)  $m = 30$

Figure 7. Time histories of  $H_{max}/H_{1/3}$  and  $GF$  for the evolving nonlinear wave trains( $M=3$  and the 2nd order) and the linear one( $k_p h=3.0, k_p a=0.17$ ).

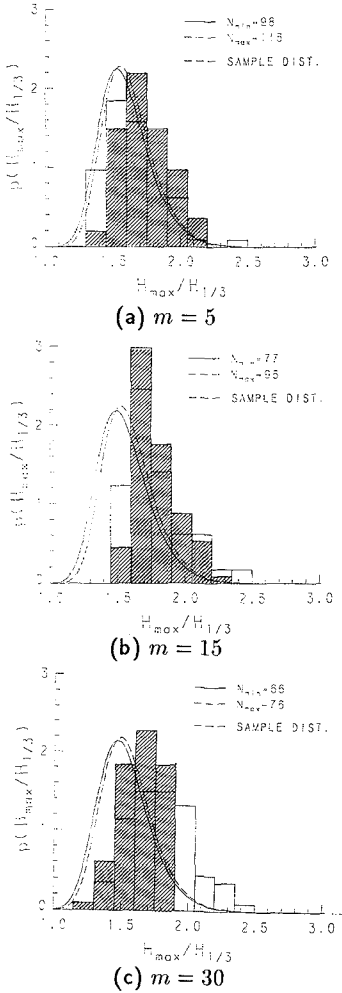

Figure 8. Time evolution of the modal energy  $S(k)$  of the spectral peak mode( $k_p$ ) and its both side-band modes( $k_p \pm k_p^2 a_{1/3}$ ) of the nonlinear waves( $M=3$ ) corresponding to the case reported in Fig.7( $k_p h=3.0, k_p a=0.17$ ).

**Nonlinear effects on the occurrence probability**

Figure 9 compares the frequency distribution of  $H_{max}/H_{1/3}$  obtained from the spatial surface profiles at every time step of  $\Delta t/T_p=1$  of the simulated waves during the propagation process from  $t/T_p=0$  to  $t/T_p=75$  with the following distribution  $p(H_{max}/H_{1/3})$  derived from the Rayleigh distribution,

$$p(x_{max}) = 2.832x_{max}\xi \exp(-\xi), \tag{9}$$

where  $x_{max}=H_{max}/H_{1/3}$ ,  $\xi=N \exp(-1.416x_{max}^2)$ .  $N_{min}$  and  $N_{max}$  in the Fig.9 denote the minimum value and the maximum one of the number of the zero-down crossing waves contained in the simulated waves during the propagation process. The frequency in the 2nd order nonlinear waves is not so influenced by the spectral bandwidth and is presumed to be almost same with that in linear waves because the 2nd order nonlinear interaction very little influences on the

**Fig.9.** Effects of the nonlinear interaction and spectral bandwidth on the frequency distribution of  $H_{max}/H_{1/3}$

On the contrary, the value of  $\mu$  in the nonlinear wave train largely exceeds that given by eq.(10) independently of the number of  $N$ . This suggests that the resonant interaction increases the occurrence probability of the 2-D freak waves 10 times ( $N=70$ ) from 5 times ( $N=500$ ) of that given by eq.(10).

wave height as mentioned above. The difference between both the frequencies (2nd and  $M=3$ ) thereby indicates the influence of the 3rd order resonant interaction on the frequency. It could hence be found from the difference that the influence of the resonant interaction is almost negligible in the case of  $m=5$  but becomes non-ignorable over the region of  $m \geq 15$ . We could thus say that the effects of the resonant interaction become pronounced and the occurrence probability of the freak waves accordingly increases as the spectral bandwidth becomes narrower.

Further, in order to investigate the influence of the number  $N$  of the zero-crossing waves on the exceedance probability  $\mu$  that the value of  $H_{max}/H_{1/3}$  is exceeds 2, that is, the occurrence probability of the 2-D freak waves, we compare the value of  $\mu$  obtained from the simulated wave train ( $M=3$ ) with that given by

$$\mu = 1 - \exp(-N/3041), \quad (10)$$

which is derived under the assumption that  $N$ -wave heights obey the Rayleigh distribution. The result is shown in Fig.10 for the waves with the number  $N$  of the zero-down crossing waves contained in the initial waves, 70, 150 and 500, respectively. The value of  $\mu$  in a linear wave train shown for comparison corresponds well to the solid line given by eq.(10) and the difference between both the results could be regarded to be within the region of statistical variation.

Figure 11 shows the relation between the frequency that the value of  $H_{max}/H_{1/3}$  of the simulated waves ( $M=3$ ) exceed 2 during their propagation process and the value of  $GF$  averaged over the propagation process,  $\langle GF \rangle$ . Symbols drawn with thick line indicate the values of the waves of which initial bandwidth parameter  $m$  equals to 30, those drawn with median line indicate the values with the initial statistics of  $m=15$  and those drawn with thin line denote the values with  $m=5$ . The mean number  $\langle N \rangle$  of the zero-down crossing waves in this case is about 80~100, so that if those wave heights obey the Rayleigh distribution, the theoretical value of  $p(H_{max}/H_{1/3} > 2)$  is about 0.026.

Figure 10. Influence of the number  $N$  of the zero-down crossing waves on the exceedance probability  $\mu(H/H_{1/3} > 2)$  [ $k_p h = 3.0, k_p a = 0.17, m = 30$ ]

Figure 11. Relation of the occurrence probability of the 2-D freak wave during the propagation process and the averaged value of  $GF$  over the process.

Table 2 Relations of the initial statistics to the frequencies(%) of  $H_{max}/H_{1/3} > 2$ ,  $\kappa > 2$  and  $\chi > 0.65$ .

m		$k_p h$		
		3.0	1.72	1.04
5	$H_{max}/H_{1/3} > 2$	6.6 (1.3)	2.6(9.2)	0.0 (0.0)
	$\kappa > 2$	23.7(14.5)	5.2(7.9)	18.4(19.7)
	$\chi > 0.65$	19.7 (1.3)	11.8(5.3)	5.2 (1.3)
		2.6 (0.0)	0.0(0.0)	0.0 (0.0)
15	$H_{max}/H_{1/3} > 2$	22.3 (5.2)	1.3(0.0)	0.0 (1.3)
	$\kappa > 2$	34.2 (0.0)	19.7(7.9)	2.6 (0.0)
	$\chi > 0.65$	14.5 (0.0)	17.1(1.3)	7.8 (0.0)
		1.3 (0.0)	0.0(0.0)	0.0 (0.0)
30	$H_{max}/H_{1/3} > 2$	23.7 (0.0)	2.6(0.0)	0.0 (0.0)
	$\kappa > 2$	19.7 (0.0)	6.6(0.0)	0.0 (0.0)
	$\chi > 0.65$	13.2 (0.0)	9.2(0.0)	7.9 (0.0)
		0.0 (0.0)	0.0(0.0)	0.0 (0.0)

Although the value of  $p(H_{max}/H_{1/3} > 2)$ , that is, the occurrence probability of the freak wave is independent of the value  $\langle GF \rangle$  in the waves with the value of  $k_p h$  less than 1.72, the occurrence probability is multiplied with the increasing of the value of  $\langle GF \rangle$  in the waves with the value of  $k_p h$  over 2.35.

Following Klinting & Sand(1987), we calculate the frequencies that the ratio  $\kappa(=H_{i+1}/H_i)$  of the wave height to its neighbour exceeds 2 and that the ratio  $\chi(=\eta_{max}/H_{max})$  of the crest height  $\eta_{max}$  to the maximum wave height  $H_{max}$  exceeds 0.65, in addition to the frequency of  $H_{max}/H_{1/3} > 2$  and show the values of these frequencies to each initial statistics in Table 2. The numerical values on the fourth line the case of  $k_p h=3.0$  within the frame corresponding to each wave indicate the frequency satisfying simultaneously these three conditions,  $H_{max}/H_{1/3} > 2$ ,  $\kappa > 2$  and  $\chi > 0.65$ . The figures in parentheses indicate the values in linear waves with the same initial statistics. The frequency of  $H_{max}/H_{1/3} > 2$  increases as the spectral bandwidth gets to narrower. On the contrary, the conditions characterizing the freak waves, that is, the frequencies of  $\kappa > 2$  and  $\chi > 0.65$  increase large as the spectral bandwidth gets to narrower. We could hence say that the 2-D freak waves incline to occur in deep water because their cause —*resonant interaction*— is strengthened to the maximum extent in deep water. Furthermore, it should be noted that although the occurrence probability itself of freak waves defined by  $H_{max}/H_{1/3} > 2$  increase with the decreasing of the spectral bandwidth, the occurrence probability of the typical freak waves possessing the feature —*single and the crest height clearly exceed those of its neighbour*— with the increasing of the spectral bandwidth and becomes maximum under the broad band spectra corresponding to wind waves.

## CONCLUSIONS

The following major conclusions may be drawn from this study

- i) The 3rd order resonant interaction causes single extreme high waves typically characterized as freak waves in unidirectional wave trains with various spectra corresponding to wind waves from swell. On the other hand, the surface profile of a linear freak wave caused by a linear combination of the Fourier modes is mild and horizontally symmetric and is very different from those observed in nature. Since the resonant interaction is thus essential to cause the 2-D freak waves, its effects on the occurrence probability of the 2-D freak waves should be taken into account.
- ii) The resonant interaction multiplies the occurrence probability of the 2-D freak waves and its effects become pronounced as the water depth gets deeper and the spectral bandwidth gets narrower. However, the feature of the surface profile characterizing freak waves —*single, remarkably horizontal asymmetric and extreme high waves*— gets prominent with the broadening of the spectral bandwidth, that is, the feature is strengthened to the maximum extent under wind wave spectra in deep water.

## CHAPTER 57

# A Method for Estimating Reflection Coefficient in Short-Crested Random Seas

Hiomune Yokoki<sup>1</sup>  
Masahiko Isobe<sup>2</sup>  
Akira Watanabe<sup>2</sup>

### Abstract

A method for estimating the reflection coefficient is developed for practical uses. In the method, a parametric expression of directional spectra is adopted and the parameters in it are estimated by the maximum likelihood method. The validity of the method is verified by applying it to simulated data. The method is also applied to field data, obtained at Oarai Port, Japan.

### 1 Introduction

The randomness of sea waves has recently become accounted for in the design of coastal and ocean structures. Directional spectra have often been used to describe multi-directional random sea waves. However, to evaluate the reflection coefficient of structures, a theory for uni-directional random waves has usually been applied with a slight modification. This is because a theory for multi-directional random waves has not yet been established for practical uses.

The purpose of this paper is to derive a method to estimate the reflection coefficient of structures for multi-directional random waves and to examine its validity by applying it to simulated and field data.

In various methods to estimate the directional spectrum, the maximum likelihood method (MLM) is the one which has a high resolution spectrum (Capon,

1969). Isobe and Kondo (1984) proposed the modified maximum likelihood method (MMLM) to estimate the directional spectrum in a combined incident and reflected waves field, taking into account the fact that there is no phase difference between the incident and reflected waves at the reflective wall. Recently for practical purposes, Isobe (1990) proposed a method to estimate the directional spectrum of a standard form in which the spectrum is expressed in terms of a few parameters. In this study, this method is modified to estimate the directional spectrum and reflection coefficient in an incident and reflected wave field.

## 2 Theory

### 2.1 Parametric expression of directional spectrum and cross-power spectrum

In a monochromatic wave field which consists of incident and reflected waves, the water surface fluctuation,  $\eta(\mathbf{x}, t)$ , at the position,  $\mathbf{x}$ , are represented by Eq. (1):

$$\eta(\mathbf{x}, t) = A(\mathbf{k}, \sigma) \{ \cos(\mathbf{k}\mathbf{x} - \sigma t + \epsilon) + r \cos(\mathbf{k}_r\mathbf{x} - \sigma t + \epsilon) \} \quad (1)$$

The definitions of the variables in the above equation are given in Table 1. We integrate Eq. (1) with respect to  $\mathbf{k}$  and  $\sigma$ , and get the expression of  $\eta(\mathbf{x}, t)$  for multi-directional random waves as Eq. (2):

$$\eta(\mathbf{x}, t) = \int_{-\infty}^{\infty} \int_{\mathbf{k}} A(d\mathbf{k}, d\sigma) \{ \exp [i(\mathbf{k}\mathbf{x} - \sigma t + \epsilon)] + r \exp [i(\mathbf{k}_r\mathbf{x} - \sigma t + \epsilon)] \} \quad (2)$$

where complex variables are introduced to represent the amplitude and phase. From Eq. (2), the directional spectrum ( wavenumber-frequency spectrum ),  $S(\mathbf{k}, \sigma)$ , is defined as Eq. (3):

$$S(\mathbf{k}, \sigma) d\mathbf{k} d\sigma = \langle A^*(d\mathbf{k}, d\sigma) A(d\mathbf{k}, d\sigma) \rangle \quad (3)$$

Figure 1: Definitions of variables

where  $\langle \rangle$  represents the ensemble average and  $A^*$  the complex conjugate of  $A$ . Then, the cross-power spectrum,  $\Phi_{mn}(\sigma)$ , can be defined by Eq. (4) (Horikawa, 1988, Isobe and Kondo, 1984):

$$\Phi_{mn}(\sigma) = \int_{\mathbf{k}} S(\mathbf{k}, \sigma) \{ \exp(i\mathbf{k}\mathbf{x}_m) + r \exp(i\mathbf{k}\mathbf{x}_{mr}) \} \times \{ \exp(-i\mathbf{k}\mathbf{x}_n) + r \exp(-i\mathbf{k}\mathbf{x}_{nr}) \} d\mathbf{k} \tag{4}$$

in which the variables are defined in Fig. 1.

In the present study, the directional spectrum,  $S(\mathbf{k}, \sigma)$ , is assumed to be expressed by using the directional spreading function proposed by Mitsuyasu *et al.* (1975). Then,  $S(\mathbf{k}, \sigma)$  is expressed by Eq. (5):

$$S(\mathbf{k}, \sigma) = P(f) \frac{2^{2s-1}}{\pi} \frac{\Gamma^2(s+1)}{\Gamma(2s+1)} \left[ \cos \frac{\theta - \theta_0}{2} \right]^{2s} \tag{5}$$

where  $P(f)$  is the frequency spectrum or the power spectrum,  $s$  the degree of directional concentration,  $\theta_0$  the peak wave direction and  $\Gamma$  the Gamma function.

We rewrite Eq. (4) by using the transformation of variables as follows. The definitions of variables are indicated in Fig. 1 as before.

$$\begin{aligned} \mathbf{k} &= (k \cos \theta, k \sin \theta) \\ \mathbf{x}_m - \mathbf{x}_n &= (R \cos \Theta, R \sin \Theta) & (= \mathbf{X}_1) \\ \mathbf{x}_{mr} - \mathbf{x}_{nr} &= (R \cos(\pi - \Theta), R \sin(\pi - \Theta)) & (= \mathbf{X}_2) \\ \mathbf{x}_{mr} - \mathbf{x}_n &= (R_r \cos \Theta_r, R_r \sin \Theta_r) & (= \mathbf{X}_3) \\ \mathbf{x}_m - \mathbf{x}_{nr} &= (R_r \cos(\pi - \Theta_r), R_r \sin(\pi - \Theta_r)) & (= \mathbf{X}_4) \end{aligned}$$

Table 2: Directional spectrum parameters

$s$	Degree of directional concentration
$\theta_0$	Peak wave direction
$r$	Reflection coefficient
$P(f)$	Frequency or power spectrum
$\varepsilon$	Ratio of the noise component to the power

Substituting Eq. (5) into Eq. (6) and using the above variables, Then we get the expression of the cross-power spectrum,  $\Phi_{mn}(\sigma)$ :

$$\Phi_{mn}(\sigma) = P(f) \frac{2^{2s-1} \Gamma^2(s+1)}{\pi \Gamma(2s+1)} \int_{\mathbf{k}} \left[ \cos \frac{\theta - \theta_0}{2} \right]^{2s} \times \left\{ \exp(i\mathbf{k}\mathbf{X}_1) + r^2 \exp(i\mathbf{k}\mathbf{X}_2) + r \exp(i\mathbf{k}\mathbf{X}_3) + r \exp(i\mathbf{k}\mathbf{X}_4) \right\} d\mathbf{k} \quad (6)$$

To rewrite Eq. (6) in a simpler form, we define a new function  $F_j$  as follows:

$$F_j(k, s, \theta_0, R_j, \Theta_j) = \frac{2^{2s-1} \Gamma^2(s+1)}{\pi \Gamma(2s+1)} \int_{-\pi}^{\pi} \exp [ikR_j \cos(\theta - \Theta_j)] \left[ \cos \frac{\theta - \theta_0}{2} \right]^{2s} d\theta \quad (7)$$

By using the above definition, Eq. (6) can be written as Eq. (8):

$$\Phi_{mn}(\sigma) = \begin{bmatrix} F_1(k, s, \theta_0, R, \Theta) \\ +r^2 F_2(k, s, \theta_0, R, \pi - \Theta) \\ +r F_3(k, s, \theta_0, R_r, \Theta_r) \\ +r F_4(k, s, \theta_0, R_r, \pi - \Theta_r) \end{bmatrix} \times P(f) \quad (8)$$

Here the noise component of the power spectrum is assumed to be  $\varepsilon P(f)$ ,  $\varepsilon$  being the ratio of the noise component to the power. Finally we get the expression of the cross-power spectrum in terms of the five parameters which are summarized in Table 2 and called the directional spectrum parameters in this paper:

$$\Phi_{mn}(\sigma) = \begin{bmatrix} F_1(k, s, \theta_0, R, \Theta) \\ +r^2 F_2(k, s, \theta_0, R, \pi - \Theta) \\ +r F_3(k, s, \theta_0, R_r, \Theta_r) \\ +r F_4(k, s, \theta_0, R_r, \pi - \Theta_r) \end{bmatrix} \times P(f) + \delta_{mn} \varepsilon P(f) \quad (9)$$

The integral on the right-hand side of Eq. (7) can be expressed by using the integral expression of the Bessel function of the first kind (*e.g.* Abramowitz and

Stegun, 1972):

$$F_j = a_0 J_0(kR_j) + 2 \sum_{n=1}^{\infty} \{(i)^n a_n J_n(kR_j) \cos n(\theta_0 - \Theta_j)\} \tag{10}$$

where  $J_n$  is the Bessel function of the first kind and  $a_n$  is defined as Eq. (11):

$$\begin{cases} a_0 = 1 \\ a_n = \left(1 - \frac{1}{s+1}\right) \times \left(1 - \frac{3}{s+2}\right) \times \dots \times \left(1 - \frac{2n-1}{s+n}\right) \end{cases} \tag{11}$$

In the present study, we use Eqs. (10) and (11) to calculate  $F_j$ .

**2.2 Definition of likelihood**

The maximum likelihood method is used to get the most probable values of the directional spectrum parameters. The likelihood,  $L$ , is defined as Isobe (1990):

$$\begin{aligned} L(A^{[j]}; \Phi) &= \{p(A^{[1]}) \times p(A^{[2]}) \times \dots \times p(A^{[J]})\}^{1/J} \\ &= \frac{1}{(2\pi \Delta f)^M |\Phi|} \exp\left(-\sum_{m=1}^M \sum_{n=1}^M \Phi_{mn}^{-1} \hat{\Phi}_{nm}\right) \end{aligned} \tag{12}$$

where  $p(A^{[j]})$  is a joint probability density function of the Fourier coefficients of the time series data,  $\Delta f$  the frequency interval, and  $|\Phi|$  the determinant of the matrix,  $\Phi_{mn}$ . The quantity  $\hat{\Phi}_{nm}$  which is represented by Eq. (13) corresponds to the periodogram with a rectangular filter and can therefore be called the power spectrum ( $n = m$ ) or the cross spectrum ( $n \neq m$ ) in the spectral analysis.

$$\hat{\Phi}_{nm} = \frac{1}{2J\Delta f} \sum_{j=1}^J \overline{A_n^{[j]}} A_m^{[j]} \tag{13}$$

where  $\overline{\phantom{x}}$  denotes the complex conjugate.

**2.3 The most probable values of the parameters**

In this Section, we show the procedure to estimate the directional spectrum parameters including the reflection coefficient by using the likelihood defined above.

The maximum likelihood method implies that the most probable values of  $\lambda_i$  are the solutions of the algebraic equation

$$\frac{\partial L}{\partial \lambda_i} = \sum_{k=1}^M \sum_{l=1}^M \frac{\partial L}{\partial \Phi_{kl}} \frac{\partial \Phi_{kl}}{\partial \lambda_i} = 0 \tag{14}$$

From Eq. (12), Eq. (15) is obtained.

$$\begin{aligned}
 \frac{\partial L}{\partial \Phi_{kl}} &= \frac{\partial}{\partial \Phi_{kl}} \left[ \frac{1}{(2\pi \Delta f)^M |\Phi|} \exp \left( - \sum_{m=1}^M \sum_{n=1}^M \Phi_{mn}^{-1} \hat{\Phi}_{nm} \right) \right] \\
 &= - \frac{1}{(2\pi \Delta f)^M |\Phi|^2} \exp \left( - \sum_{m=1}^M \sum_{n=1}^M \Phi_{mn}^{-1} \hat{\Phi}_{nm} \right) \frac{\partial |\Phi|}{\partial \Phi_{kl}} \\
 &\quad + \frac{1}{(2\pi \Delta f)^M |\Phi|} \exp \left( - \sum_{m=1}^M \sum_{n=1}^M \Phi_{mn}^{-1} \hat{\Phi}_{nm} \right) \\
 &\quad \times \left( - \sum_{m=1}^M \sum_{n=1}^M \frac{\partial \Phi_{mn}^{-1}}{\partial \Phi_{kl}} \hat{\Phi}_{nm} \right) \\
 &= -L \times \left( \frac{1}{|\Phi|} \frac{\partial |\Phi|}{\partial \Phi_{kl}} \right) + L \times \left( - \sum_{m=1}^M \sum_{n=1}^M \frac{\partial \Phi_{mn}^{-1}}{\partial \Phi_{kl}} \hat{\Phi}_{nm} \right) \tag{15}
 \end{aligned}$$

Also, the following relations are obtained from the theorem of the matrices.

$$\frac{\partial |\Phi|}{\partial \Phi_{kl}} = |\Phi| \Phi_{lk}^{-1} \tag{16}$$

$$\frac{\partial \Phi_{mn}^{-1}}{\partial \Phi_{kl}} = -\Phi_{ln}^{-1} \Phi_{mk}^{-1} \tag{17}$$

By using Eqs. (16) and (17), Eq. (15) is rewritten as follows:

$$\frac{\partial L}{\partial \Phi_{kl}} = L \times \left\{ -\Phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1} \right\} \tag{18}$$

Substituting Eq. (18) into Eq. (14) and considering that  $L \neq 0$ , we obtain:

$$\sum_{k=1}^M \sum_{l=1}^M \left\{ -\Phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1} \right\} \frac{\partial \Phi_{kl}}{\partial \lambda_i} = 0 \tag{19}$$

The directional spectrum parameters,  $\lambda_i$ , which satisfy Eq. (19) for all  $i$  ( $i = 1 \sim 5$ ) are the most probable values. Then the directional spectrum parameters, including the reflection coefficient, are estimated.

The solutions,  $\lambda_i$ , of Eq. (19) are obtained numerically by using the Newton-Raphson method. The left-hand side of Eq. (19) is first defined as a function of the directional spectrum parameters:

$$f_i(\lambda_{i'}) = \sum_{k=1}^M \sum_{l=1}^M \left\{ -\Phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1} \right\} \frac{\partial \Phi_{kl}}{\partial \lambda_i} \tag{20}$$

In the Newton-Raphson method, the value of  $\lambda_i^{(j+1)}$  at the  $(j+1)$ -th iteration of the calculation is expressed in terms of the previous values,  $\lambda_i^{(j)}$ , in the following equation:

$$\lambda_i^{(j+1)} = \lambda_i^{(j)} - \left[ \sum_{i'=1}^I \left[ \frac{\partial f_i}{\partial \lambda_{i'}} \right]^{-1} f_{i'} \right]_{\lambda_i = \lambda_i^{(j)}} \tag{21}$$

Table 3: Values of the directional spectrum parameters

$s$	14.0
$\theta_0$	3.054 radian
$r$	0.4
$P(f)$	$0.1 \text{ m}^3/\text{Hz}$
$\varepsilon$	0.1

where  $\partial f_i/\partial \lambda_{i'}$  is expressed by Eq. (22):

$$\begin{aligned} \frac{\partial f_i}{\partial \lambda_{i'}} &= \sum_{k=1}^M \sum_{l=1}^M \left\{ -\Phi_{lk}^{-1} + \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1} \right\} \frac{\partial^2 \Phi_{kl}}{\partial \lambda_{i'} \partial \lambda_i} \\ &- \sum_{k'=1}^M \sum_{l'=1}^M \sum_{k=1}^M \sum_{l=1}^M \frac{\partial \Phi_{k'l'}}{\partial \lambda_{i'}} \frac{\partial \Phi_{kl}}{\partial \lambda_i} \\ &\times \left[ -\Phi_{l'k}^{-1} \Phi_{lk'}^{-1} + \left\{ \begin{array}{l} \Phi_{lk'}^{-1} \sum_{m=1}^M \sum_{n=1}^M \Phi_{l'n}^{-1} \hat{\Phi}_{nm} \Phi_{mk}^{-1} \\ + \Phi_{l'k}^{-1} \sum_{m=1}^M \sum_{n=1}^M \Phi_{ln}^{-1} \hat{\Phi}_{nm} \Phi_{mk'}^{-1} \end{array} \right\} \right] \end{aligned} \tag{22}$$

### 3 Application

#### 3.1 Application to simulated data

To verify the validity of the present method, we first created a set of  $\Phi_{mn}(\sigma)$  by Eqs. (9) and (10) for directional spectrum parameters given in Table 3. Then, the directional spectrum parameters,  $\lambda_i$ , were estimated by the present method.

However, since a converged solution of Eq. (19) could not be obtained for any set of initial values used, solutions were determined for various fixed values of  $r$  and  $\varepsilon$ .

Table 4 shows the results of the computations. It is seen that the likelihood,  $L$ , is maximum when  $\varepsilon = 0.1$ ,  $r = 0.4$ ,  $s = 13.3$  and  $\theta_0 = 3.1$ , which agrees closely with the given values. Hence, the directional spectrum parameters were estimated adequately by the present method.

#### 3.2 Application to field data

From November 7 to December 2, 1990, a field experiment was conducted at Oarai port in Ibaraki prefecture, Japan (Fig. 2). Four measuring points are arranged normal to the offshore breakwater as sketched in Fig. 3. An ultrasonic-

type wave gauge was installed on the sea bed of each measuring point. The four wave gauges were synchronized by a cable.

The sampling interval is 0.5 s and 2,046 time series data (about 17 min) were recorded every two hours. Because the wave gauge at the measuring point No. 1 did not work, the time series data at the three measuring points No. 2 to 4 were obtained and used.

The results of the spectral analysis are shown in Figs. 4 and 5. Time series data used were obtained at 14:00 on November 8. Figure 4 shows the power spectra at the measuring points, and Fig. 5 the cross spectra, the coherence squared and phase lag between the measuring points. In addition, the wave statistics at each measuring point are shown in Table 5.

Figures 4 and 5 indicate that both the power and cross spectra are maximum

Figure 5: Cross spectra, coherence squared, phase

at the frequency of 0.1 Hz. Therefore, we calculated the directional spectrum parameters at this frequency.

The most probable values of the directional spectrum parameters as well as the likelihood are shown in Table 6. The parameters are estimated as  $\varepsilon \simeq 0.05$ ,  $r \simeq 0.4$ ,  $s \simeq 36$ ,  $\theta_0 \simeq 3.14$  rad. Since concrete blocks are installed in front of the breakwater, the reflection coefficient obtained is considered to be a reasonable value.

## 4 Conclusion

Based on the parametric expression of the directional spectrum, a method is proposed to estimate the directional spectrum parameters which include the reflection coefficient.

The validity of the method was confirmed by applying it to simulated data. The method was also applied to the data obtained by a field measurement at Oarai port. The result of estimation is considered to be reasonable.

## CHAPTER 58

### Estimating Incident and Reflected Wave Fields Using an Arbitrary Number of Wave Gauges

J.A. Zelt<sup>†</sup> A.M. ASCE and James E. Skjelbreia<sup>†</sup> A.M. ASCE

#### 1 Abstract

A method based on linear wave theory is presented to decompose one-dimensional wave fields into left and right-travelling components using an arbitrary number of wave gauges. Results are presented to show that an increased accuracy is possible if more than three wave gauges are used. The technique uses a least squares scheme with variable weights. Results will also be presented that indicate a further improvement in accuracy is possible by an appropriate choice of the weighting coefficients.

#### 2 Decomposition Theory

The decomposition of general one-dimensional wave fields into component waves travelling in opposite directions is of fundamental importance in many experimental studies. Breakwater evaluation involves estimating reflection coefficients as a function of wave frequency, and the efficiency of wave-energy extraction devices can be quantified similarly. Reflection coefficients of shorelines are also important quantities since many beach processes are driven by the energy extracted from incident waves through wave breaking. For some studies it is sufficient to obtain the spectra of the incident and reflected waves, but the complete space/time description of these waves can also be important, especially in resonance studies.

Suppose that a one-dimensional wave field is observed by recording the surface elevation  $\eta_p(t)$  at a series of locations  $\{x_p\}$ ,  $p = 1, 2, \dots, P$ , as shown in Fig. 1. Using standard Fourier analysis techniques, the elevation can be expressed as

$$\eta_p(t) = \sum_{j=-N/2}^{N/2} A_{j,p} e^{i\omega_j t}, \quad (1)$$

where  $\omega_j = 2\pi j/T$ ,  $T$  is the length of the time series, and  $N$  is large enough to resolve adequately the frequencies of interest. The time  $t$  will be discrete for a

Figure 1. Measuring incident and reflected waves with  $P$  wave gauges.

sampled signal ( $t \rightarrow m\Delta t$ , for  $m = 0, 1, \dots, N - 1$ , with  $\Delta t = T/N$ ), but this will not be explicitly indicated here to simplify the notation.

Under the assumption that the waves are one-dimensional, dissipation is negligible, and that linear wave theory is valid, the wave field in Fig. 1 can be approximated by a Fourier sum of left and right travelling waves:

$$\eta(x, t) = \sum_{j=-N/2}^{N/2} a_{Lj} e^{i(k_j x + \omega_j t)} + a_{Rj} e^{i(-k_j x + \omega_j t)}, \quad (2)$$

where  $k_j = 2\pi/\lambda_j$ , and  $k_j$  is related to  $\omega_j$  through the linear dispersion relation:

$$\omega_j^2 = gk_j \tanh k_j h. \quad (3)$$

The still water depth is  $h$  and  $g$  is the acceleration of gravity. Evaluating  $\eta(x, t)$  at the location of wave gauge  $p$  yields

$$\eta(x_p, t) = \sum_{j=-N/2}^{N/2} \{a_{Lj} e^{i\phi_{j,p}} + a_{Rj} e^{-i\phi_{j,p}}\} e^{i\omega_j t}, \quad (4)$$

where  $\phi_{j,p} \equiv k_j x_p$ . The ultimate goal is to estimate the  $\{a_{Lj}\}$  and  $\{a_{Rj}\}$  as accurately as possible from the wave records  $\{\eta_p(t)\}$ . Equating the coefficients in Eqs. (1) and (4) yields the following equations:

$$A_{j,p} = a_{Lj} e^{i\phi_{j,p}} + a_{Rj} e^{-i\phi_{j,p}} \quad p = 1, 2, \dots, P \quad (5)$$

for each Fourier component  $j$ . If there are only two wave gauges, Eq. (5) can be solved exactly for  $a_{Lj}$  and  $a_{Rj}$  (Goda & Suzuki 1976). However, for  $P > 2$ , Eq. (5) is over-determined, and  $a_{Lj}$  and  $a_{Rj}$  must be estimated by an approximate technique. Mansard & Funke (1980, 1987) treated the case  $P = 3$  using a least squares approach with uniform weighting. Here, a weighted least squares approach will be described that is valid for *arbitrary*  $P$ . Instead of forcing strict equality in Eq. (5), the value of an appropriate 'merit' function will be minimized so that Eq. (5) holds *approximately* for each wave gauge  $p$ . Let

$$\epsilon_{j,p} = a_{Lj} e^{i\phi_{j,p}} + a_{Rj} e^{-i\phi_{j,p}} - A_{j,p}. \quad (6)$$

For a given choice of  $a_{Lj}$  and  $a_{Rj}$ ,  $\epsilon_{j,p}$  represents the error in matching the  $j^{\text{th}}$  Fourier coefficient  $A_{j,p}$  at wave gauge  $p$ . The merit function is chosen to be a weighted sum of the squares of the errors for each wave gauge:

$$E_j \equiv \sum_{p=1}^P W_{j,p} \epsilon_{j,p} \epsilon_{j,p}^*, \quad (7)$$

where  $W_{j,p} > 0$  is the weighting coefficient for wave gauge  $p$  at frequency  $\omega_j$ , and  $( )^*$  represents the complex conjugate of the enclosed quantity. At a given frequency specified by  $j$ , the reliability of the estimates of  $a_{Lj}$  and  $a_{Rj}$  depends on several factors, including the spacing between the wave gauges. The motivation of introducing nonuniform weighting is to make use of this information so that the errors associated with wave gauges that provide reliable estimates are weighted more than the errors associated with wave gauges that do not provide useful information for estimating  $a_{Lj}$  and  $a_{Rj}$ . The criteria for choosing the weights  $\{W_{j,p}\}$  will be discussed in §3. The minimum of Eq. (7) occurs at the point where  $E_j$  is stationary with respect to the real and imaginary parts of  $a_{Lj}$  and  $a_{Rj}$ . At this point the following relations hold

$$\begin{aligned} \sum_{p=1}^P W_{j,p} \epsilon_{j,p} e^{-i\phi_{j,p}} &= 0 \\ \sum_{p=1}^P W_{j,p} \epsilon_{j,p} e^{i\phi_{j,p}} &= 0. \end{aligned} \quad (8)$$

These are two complex equations for the two complex amplitudes  $a_{Lj}$  and  $a_{Rj}$ .

Substituting Eq. (6) into Eq. (8) yields the two equations

$$\begin{aligned} a_{Lj} S_j + a_{Rj} \sum_{p=1}^P W_{j,p} e^{-2i\phi_{j,p}} &= \sum_{p=1}^P W_{j,p} A_{j,p} e^{-i\phi_{j,p}} \\ a_{Lj} \sum_{p=1}^P W_{j,p} e^{2i\phi_{j,p}} + a_{Rj} S_j &= \sum_{p=1}^P W_{j,p} A_{j,p} e^{i\phi_{j,p}}, \end{aligned} \quad (9)$$

where  $S_j \equiv \sum_{p=1}^P W_{j,p}$ . Rather than work with the absolute phases  $\phi_{j,p}$ , it is more useful to consider phase *differences* between wave gauges. Let

$$\Delta\phi_{j,p} \equiv \phi_{j,p} - \phi_{j,1} = k_j(x_p - x_1) \quad (10)$$

denote the phase difference between wave gauges 1 and  $p$  for frequency  $\omega_j$ . Then the solution of Eq. (9) can be expressed as

$$a_{Lj} = \left[ S_j \sum_{p=1}^P W_{j,p} A_{j,p} e^{-i\Delta\phi_{j,p}} - \sum_{p=1}^P W_{j,p} A_{j,p} e^{i\Delta\phi_{j,p}} \sum_{q=1}^P W_{j,q} e^{-2i\Delta\phi_{j,q}} \right] \frac{e^{-i\phi_{j,1}}}{D} \quad (11a)$$

$$a_{Rj} = \left[ S_j \sum_{p=1}^P W_{j,p} A_{j,p} e^{i\Delta\phi_{j,p}} - \sum_{p=1}^P W_{j,p} A_{j,p} e^{-i\Delta\phi_{j,p}} \sum_{q=1}^P W_{j,q} e^{2i\Delta\phi_{j,q}} \right] \frac{e^{i\phi_{j,1}}}{D} \quad (11b)$$

where

$$D = S_j^2 - \sum_{p=1}^P W_{j,p} e^{2i\Delta\phi_{j,p}} \sum_{q=1}^P W_{j,q} e^{-2i\Delta\phi_{j,q}} \quad (12a)$$

The denominator  $D$  is a real quantity and can be simplified to

$$D = S_j^2 - \left( \sum_{p=1}^P W_{j,p} \cos 2\Delta\phi_{j,p} \right)^2 - \left( \sum_{p=1}^P W_{j,p} \sin 2\Delta\phi_{j,p} \right)^2 \quad (12b)$$

$$= 4 \sum_{p=1}^P \sum_{q < p} W_{j,p} W_{j,q} \sin^2 \Delta\phi_{j,pq} \quad (12c)$$

where

$$\Delta\phi_{j,pq} \equiv \Delta\phi_{j,p} - \Delta\phi_{j,q} = \phi_{j,p} - \phi_{j,q} = k_j(x_p - x_q) \quad (13)$$

is the phase difference between wave gauges  $p$  and  $q$  at frequency  $\omega_j$ . Equation (12b) is the most efficient form to compute  $D$  since it requires the fewest operations to evaluate; however, Eq. (12c) is more useful for showing the behaviour of the denominator. Since the weighting coefficients  $\{W_{j,p}\}$  are positive,

it is clear that the denominator can be zero at frequency  $\omega_j$  only if the wave gauges are placed such that  $\sin \Delta \phi_{j,pq} \equiv 0$  for all  $p$  and  $q$ . Clearly this is a condition to be avoided if possible, and this will be discussed further in §3.

Further manipulation of the numerators in Eq. (11) leads to the following formulae for  $a_{Lj}$  and  $a_{Rj}$

$$a_{Lj} = \sum_{p=1}^P C_{j,p}^* A_{j,p} \quad (14a)$$

$$a_{Rj} = \sum_{p=1}^P C_{j,p} A_{j,p} \quad (14b)$$

where

$$C_{j,p} = 2iW_{j,p} \frac{e^{i\phi_{j,1}}}{D} \sum_{q=1}^P W_{j,q} \sin \Delta \phi_{j,pq} e^{i\Delta \phi_{j,q}} \quad (15)$$

This form emphasizes that  $a_{Lj}$  and  $a_{Rj}$  are simply linear combinations of the  $\{A_{j,p}\}$ . For  $P = 2$  the results of Goda & Suzuki (1976) are reproduced, and for  $P = 3$  the decomposition formulae of Mansard & Funke (1980, 1987) are obtained.

### 3 Error analysis

The sensitivity of the decomposition formulae Eq. (11) or (14) to errors in measuring the Fourier coefficients  $\{A_{j,p}\}$  at a given frequency  $\omega_j$  depends on the choice of the weighting coefficients  $\{W_{j,p}\}$  as well as the spacing of the wave gauges relative to the wave length associated with  $\omega_j$ . Consequently, the weights and the wave gauge locations should be chosen appropriately to maximize the reliability of the decomposition estimates. To illustrate this, suppose that the elevation records obtained from the wave gauges can be expressed as the sum of two one-dimensional linear waves travelling in opposite directions plus a residual or error signal  $\mathcal{E}_p(t)$ :

$$\eta_p(t) = \sum_{j=-N/2}^{N/2} \left\{ A_{Lj} e^{i(k_j x_p + \omega_j t)} + A_{Rj} e^{i(-k_j x_p + \omega_j t)} \right\} + \mathcal{E}_p(t). \quad (16)$$

The residual signal  $\mathcal{E}_p(t)$  accounts for:

- 1) noise/nonlinearities in the wave gauges and data acquisition hardware.

- 2) nonlinear hydrodynamic effects (e.g. deviations from the linear dispersion relation).
- 3) two-dimensional wave motion (such as cross modes in a wave channel).
- 4) viscous effects.

With

$$\mathcal{E}_p(t) = \sum_{j=-N/2}^{N/2} \varepsilon_{j,p} e^{i\omega_j t}, \quad (17)$$

Eq. (16) can be expressed as

$$\eta_p(t) = \sum_{j=-N/2}^{N/2} \left\{ A_{Lj} e^{i\phi_{j,p}} + A_{Rj} e^{-i\phi_{j,p}} + \varepsilon_{j,p} \right\} e^{i\omega_j t}. \quad (18)$$

This is equivalent to Eq. (1) with  $A_{j,p} = A_{Lj} e^{i\phi_{j,p}} + A_{Rj} e^{-i\phi_{j,p}} + \varepsilon_{j,p}$ . Substituting this expression for  $A_{j,p}$  into the decomposition formulae Eq. (14) yields following estimates of the Fourier coefficients of the left and right travelling waves

$$a_{Lj} = A_{Lj} + \sum_{p=1}^P C_{j,p}^* \varepsilon_{j,p} \quad (19a)$$

$$a_{Rj} = A_{Rj} + \sum_{p=1}^P C_{j,p} \varepsilon_{j,p}. \quad (19b)$$

The "exact" coefficients are obtained if the residual signal is zero; otherwise, the error  $\varepsilon_{j,p}$  at wave gauge  $p$  is amplified by the coefficient  $C_{j,p}$ . The amplification of errors associated with wave gauge  $p$  can be represented by

$$\left| \frac{\partial a_{Lj}}{\partial \varepsilon_{j,p}} \right| = \left| \frac{\partial a_{Rj}}{\partial \varepsilon_{j,p}} \right| = |C_{j,p}| = \frac{2W_{j,p}}{D} \left| \sum_{q=1}^P W_{j,q} \sin \Delta\phi_{j,pq} e^{i\Delta\phi_{j,q}} \right|. \quad (20)$$

Since the residual signal will not, in general, be perfectly correlated between different wave gauges, large errors associated with different gauges will not cancel. If the residuals  $\varepsilon_{j,p}$  are uncorrelated between wave gauges, a measure of the reliability of the decomposition as a function of frequency can be estimated by summing the terms in Eq. (20) over all wave gauges. The worst case occurs when  $D = 0$ ; for  $P = 2$  (Goda & Suzuki 1976) this occurs for  $\Delta\phi_{j,12} = n\pi$ , i.e., for  $|x_2 - x_1| = n\lambda_j/2$  for any integer  $n$ . For arbitrary  $P$  this occurs if  $\sin \Delta\phi_{j,pq} = 0$  for all  $p$  and  $q$ , i.e., if  $2|x_p - x_q|/\lambda_j$  is an integer for each combination of  $p$  and

$q$ . Care should be taken when choosing the wave gauge positions to ensure that this criterion is not approached near frequencies of interest.

To choose the weighting coefficients  $\{W_{j,p}\}$  information must be available about the relative magnitudes of the residuals  $\varepsilon_{j,p}$ . If these error terms are the same for each wave gauge (at a particular frequency  $\omega_j$ ), then uniform weighting is appropriate. However, if this residual signal varies from gauge to gauge, variable weighting is appropriate. This may be the case if the primary source of the residual signal is the deviation from the linear dispersion relation due to finite amplitude effects. In this case it may be better to concentrate the weighting near one wave gauge (say gauge number 1) and reduce the weighting for distant gauges where the phase deviates from the linear prediction  $k_j(x_p - x_1)$ . This information might be obtainable from a cross-spectral analysis between the wave gauge elevation records. It might also be possible to make use of the sensitivity analysis in this section to help choose the weights. Other techniques for choosing the weights will depend on the particular sources of the errors and their statistical properties.

Preliminary results have been obtained by using an *ad hoc* scheme based on heuristic reasoning. For each frequency  $\omega_j$  being treated, a "goodness" function  $G(\Delta\phi_{j,pq})$  is defined that quantifies the desirability of the phase difference associated with the spacing between gauges  $p$  and  $q$ . Multiples of one-half the wave length are undesirable, and a large spacing relative to the wavelength is also undesirable. A function that reflects these characteristics is:

$$G(\Delta\phi_{j,pq}) = \frac{\sin^2 \Delta\phi_{j,pq}}{1 + (\Delta\phi_{j,pq}/\pi)^2}. \quad (21)$$

A large value of  $G$  indicates a better wave gauge spacing for frequency  $\omega_j$  than a smaller value of  $G$ . The weighting coefficient  $W_{j,p}$  for wave gauge  $p$  can then simply (and somewhat arbitrarily) be defined as

$$W_{j,p} = \sum_{q=1}^P G(\Delta\phi_{j,pq}). \quad (22)$$

## 4 Results

To illustrate the use of the decomposition theory presented, a simulated wave field in 2 m water depth was created consisting of 4096 points per wave gauge record with a 0.05 s time step. A Pierson-Moskowitz type spectrum was chosen with a spectral peak at 0.47 Hz (corresponding to a wavelength of 6.64 m in 2 m of water). The RMS height of the right travelling wave is 0.5 m, and the Fourier

components of the left travelling wave are exactly 10 % of the Fourier components of the right travelling wave, although with random phase shifts applied. Hence, the RMS height of the left travelling wave is 0.05 m, and the amplitude reflection coefficient is 0.1 for all frequencies. In addition, a 0.01 m RMS uncorrelated random noise signal was added on top of these two waves to simulate a wide variety of errors, noise, and other effects that cannot be simulated directly.

Eight wave gauge records were simulated at the locations  $x = 0, 0.016, 0.052, 0.130, 0.301, 0.679, 1.551$  and  $3.341$  m. These locations were chosen so that the minimum and maximum wave gauge spacings could resolve the minimum and maximum energy containing wavelengths of interest in the wave spectrum. A simple geometric telescoping factor was used to locate the intermediate gauges.

Figure 2. Energy density spectra and left/right amplitude ratios (RMS amplitudes in parentheses).

The energy spectra resulting from using only 2 wave gauges (located at  $x = 0$  m and  $x = 1.511$  m) are presented in Fig. 2. The data was partitioned into 15 segments each with 512 points with a 50% overlap. A Welch window was applied to each segment. The spectra of both the left and the right travelling simulated waves are compared with the estimated spectra obtained from the decomposition technique described here. The left/right amplitude ratio is also shown. As discussed above, it *should* be 0.1, but instead it deviates considerably from this value except near the peak of the spectrum since the wave gauge spacing was chosen to optimize the accuracy in this region. Uniform weights were used ( $W_{j,p} = 1$ ).

The results for 3 wave gauges (located at  $x = 0, 0.679$  and  $1.511$  m) and

Figure 3. Energy density spectra and left/right amplitude ratios (RMS amplitudes in parentheses).

uniform weights are presented in Fig. 3. These results are considerably better than for only 2 wave gauges since they are not susceptible to the singularity that the 2-wave gauge arrangement is.

The results for all 8 wave gauges and uniform weights are presented in Fig. 4. These results are even better than for 3 wave gauges, although the improvement is perhaps not striking as the difference between the 2 wave gauge and the 3 wave gauge case.

However, in Fig. 5 the results for using 8 wave gauges and the *variable* weight scheme of § 3 are presented. A marked improvement is seen, with the left/right amplitude ratio very flat near 0.1 as it should be. It should be mentioned that the variable weight scheme described in § 3 yields exactly the same results for 2 wave gauges as for the uniform weight case. For 3 wave gauges, only a very slight improvement is obtained by using variable weighting coefficients, and the results do not differ appreciably from those displayed in Fig. 3.

The results in the time domain of the decomposition of with 8 wave gauges and variable weights are presented in Fig. 6. Here, only a small segment of the time record is displayed, but the relative amplitudes of the left and right waves as well as the noise signal can be seen. It should be noted here that the main source of the inaccuracy of the decomposition is due to the presence of the noise added to the left and right simulated waves. However, this noise signal does not cause significantly degrade the decomposition.

Figure 5. Energy density spectra and left/right amplitude ratios (RMS amplitudes in parentheses).

Figure 6. Left and right travelling waves (RMS amplitudes in parentheses).

## 5 Conclusions

A method based on linear wave theory has been presented to decompose one-dimensional wave fields into left and right travelling components using using an arbitrary number of wave gauges. Results were presented for simulated wave gauge data to show that an increased accuracy is possible if more than three wave gauges are used, especially for broad band wave spectra. Results were also presented to indicate that a further improvement in accuracy is possible by an appropriate choice of the least squares weighting coefficients.

## LIST OF SYMBOLS

$a_{Lj}$	estimate of the $j^{\text{th}}$ Fourier coefficient of the left travelling wave.
$a_{Rj}$	estimate of the $j^{\text{th}}$ Fourier coefficient of the right travelling wave.
$A_{Lj}$	hypothetical $j^{\text{th}}$ Fourier coefficient of the left travelling wave assuming there is no noise and that linear theory holds exactly.
$A_{Rj}$	hypothetical $j^{\text{th}}$ Fourier coefficient of the right travelling wave assuming there is no noise and that linear theory holds exactly.
$A_{j,p}$	$j^{\text{th}}$ Fourier coefficient of the wave amplitude time series recorded at wave gauge $p$ .
$C_{j,p}$	weighting coefficient for expressing $a_{Lj}$ and $a_{Rj}$ as linear combinations of the $\{A_{j,p}\}$ .
$E_j$	merit function whose minimum yields the amplitudes of the left and right travelling waves, $a_{Lj}$ & $a_{Rj}$ , at frequency $j$ .
$\mathcal{E}_p(t)$	residual elevation signal at wave gauge $p$ due to noise, nonlinear, viscous, and other effects.
$g$	gravitational acceleration.
$h$	still water depth.
$i$	$\sqrt{-1}$
$k_j$	wave number of the $j^{\text{th}}$ Fourier component: $2\pi/\lambda_j$
$P$	number of wave gauges used to record the composite wave spectrum
$S_j$	sum of the least squares weighting coefficients: $\sum_{p=1}^P W_{j,p}$ .

$T$	duration of wave gauge records $\{\eta_p(t)\}$ .
$W_{j,p}$	least squares weighting coefficient for probe $p$ at frequency $\omega_j$ .
$x_p$	location of wave gauge $p$ .
$\Delta\phi_{j,p}$	phase difference between probes 1 and $p$ for frequency $\omega_j$ : $\Delta\phi_{j,p} = \phi_{j,p} - \phi_{j,1} = k_j(x_p - x_1)$ .
$\Delta\phi_{j,pq}$	phase difference between probes $p$ and $q$ for frequency $\omega_j$ : $\Delta\phi_{j,pq} = \Delta\phi_{j,p} - \Delta\phi_{j,q} = \phi_{j,p} - \phi_{j,q} = k_j(x_p - x_q)$ .
$\epsilon_{j,p}$	the error in matching the $j^{\text{th}}$ Fourier coefficient $A_{j,p}$ at wave gauge $p$ using the least squares algorithm.
$\epsilon_{j,p}$	$j^{\text{th}}$ Fourier coefficient associated with the residual elevation signal $\mathcal{E}_p(t)$ .
$\eta_p$	wave elevation recorded at location $x_p$ .
$\lambda_j$	wavelength of the $j^{\text{th}}$ Fourier component.
$\phi_{j,p}$	absolute phase of the $j^{\text{th}}$ Fourier component at the $p^{\text{th}}$ wave gauge: $k_j x_p$
$\omega_j$	frequency of the $j^{\text{th}}$ Fourier component: $2\pi j/T$

### LABORATORY TESTS ON THE INTERACTION BETWEEN NONLINEAR LONG WAVES AND SUBMERGED BREAKWATERS

Marco Petti<sup>1</sup> and Piero Ruol<sup>2</sup>

#### Abstract

This paper deals with the use of submerged detached breakwaters as beach protection, a use that today has become quite popular. This type of structure has been largely studied both theoretically and through experimental analyses in recent years, however its behaviour has not been completely understood, specially if related to the real irregular wave attacks. In particular some laboratory studies carried out by the authors have pointed out some interesting phenomena associated with the interaction between the nonlinearities of wave transformations in shallow water and submerged breakwaters.

Aiming at discerning between the phenomena related to the structure (beach and breakwater) and flume geometry, a new series of laboratory tests have been carried out in a 50 m long wave flume; these tests and the results obtained are described in this work. Besides the study of the behaviour of submerged structures related to the bounded-long-waves, some current velocities have also been measured during this research through directional micro-propeller fluid meters.

#### Introduction

Among the work aiming to protect ports and beaches the use of detached submerged breakwaters appears today of increasing interest. This is mainly related to the small environmental effects combined with the obvious aesthetic advantages of these structures and to their relatively low costs.

Even if the case of submerged structures have been given significant coverage in literature, certain aspects do not seem to have been treated in enough depth; for example only the first steps have been taken in studying the

behaviour of such structures under irregular wave attacks (Ahrens, 1989, Van der Meer, 1988, Petti and Ruol, 1991).

The difficulties connected to similar analytical or numerical studies (Kobayashi and Wurjanto, 1989) often lead to a physical analysis of the phenomena related to similar structures in measuring water level oscillations across the structure (Adams and Sonu, 1986, Hedges et al., 1985).

To explain some anomalous water level oscillations in front of the breakwater, which were measured during a similar approach (Petti and Ruol, 1991) the writers supposed that the mass transport, caused by the waves breaking on the structure, was able to create a current directed off-shore that was affecting the incoming wave characteristics.

In particular the authors found that the bounded long waves generated by the well-known non-linear modifications of the wave spectrum on a sloping bottom, problem recently solved also in analytical manner (Petti, 1991), seem to be greatly affected by the joint effect of the structure and by the current opposite to the incoming waves.

These experimental analyses were conducted in a wave flume using a submerged breakwater located on different fixed bottom configurations. These experiments were carried out in a 33 m-long wave flume reproducing a monotonously decreasing bottom profile initially and a barred profile later (Petti and Ruol, 1990, 1991).

In the present work, in order to have a better understanding of the physics of the problem, a new series of experiments carried out using the same structure but in a longer wave flume and with different bottom configuration are described. In particular during these experiments some velocity measures over the structure were also performed in order to estimate the current velocity field induced by the wave attacks in the regions close to the submerged breakwater. At present similar measures are the object of some interesting new research (Losada, 1992).

### Laboratory experiments

The series of experiments described in this paper were carried out in the wave flume of the Department of Civil Engineering which is 50 meters long, 0.8 m wide and 0.8 m deep. The analysed structure, located on a 1:50 fixed bottom slope, consisted of an impermeable submerged breakwater 14 cm high, 24 cm wide at the top and sloping 1:3.5 sea-ward and 1:1.5 shore-ward.

The wave transformations were first of all analysed considering the simple sloping beach without any structure and later considering a submerged breakwater located in a 20 cm local water depth at about 34 meters from the wave generator (Fig. 1).

Fig. 1 – Experimental apparatus and scheme of the tested structure.

The wave characteristics in the flume were determined measuring water level oscillations with eight parallel wire resistance gauges. Besides these characteristics, reflection coefficient analyses and velocity measurements were also performed.

Both with and without the structure four different wave attacks, characterised by spectra of the JONSWAP type, were reproduced. Significant wave heights, the Phillips constant  $\alpha$ , the peak frequency  $f_p$  and the peakedness factor  $\gamma$  characteristic of each experiment are summarised in Tab. 1.

Table 1 – Characteristics of generated waves.

Test n.	$\alpha$	$f_p$ (Hz)	$H_{m0}$ (cm)	$\gamma$
1	0.0180	0.650	14.1	1.0
2	0.0100	0.650	11.7	2.0
3	0.0140	0.833	9.2	3.0
4	0.0180	0.833	8.6	1.0

### Test results and discussion

In Fig. 2a and 2b an example of the results obtained through the spectral analysis for both the case with submerged structure and without it is shown.

In these figures the wave spectra measured by the gauges located along the flume are compared; it does appear that in the first case (without structure) the non-linearities of the spectra (due to the shallow waters) are not evident in the deeper waters (gauges n. 1, 2, 3), while, as expected, the build-up of low-frequency and high-frequency components is evident in the shallow waters.

Fig. 2a – Comparison between spectral densities of the case with submerged structure (dotted line) and without it (solid line), for the test n.3 and gauges n. 1 and n. 2.

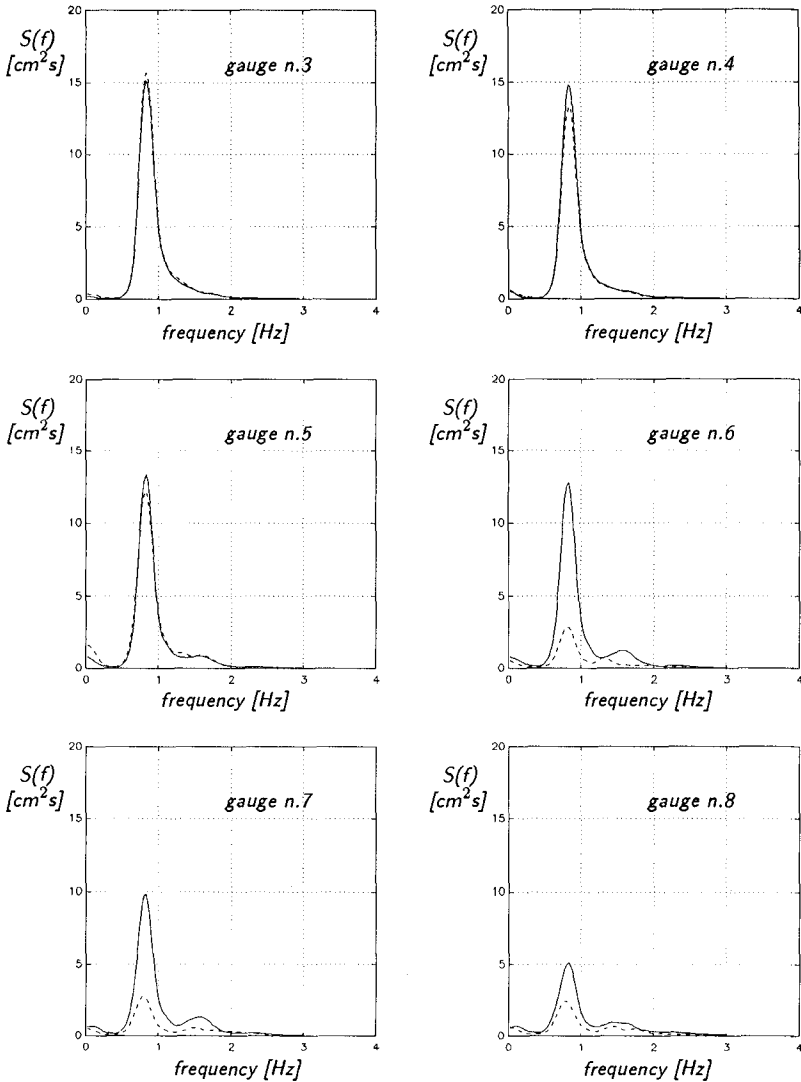

Fig. 2b – Comparison between spectral densities of the case with submerged structure (dotted line) and without it (solid line), for the test n.3 and gauges n. 3 ÷ 8.

In the second case also (with structure) the spectra referred to the deeper gauges show the absence of non linearities, while a considerable increase was found in the lower and higher frequency components just in front of the structure (gauge 5).

Of course the spectral densities decrease significantly after the impact of the breaking phenomenon located on the submerged breakwater and do not considerably change in the propagation towards the beach.

This typical non-linear phenomenon was studied in more detail dividing the long waves from the short ones: for this research the time domain records were analysed filtering the signal and considering the higher frequencies ( $f > 0.5 f_p$ ) and the lower ones ( $f < 0.5 f_p$ ) separately. An example of the results obtained through such wave data analyses referring to gauge n. 5 and lasting 60 s is shown in Fig. 3.

Fig. 3 – Example of water level oscillation data-recording (a), of the filtered signal with  $f > 0.5f_p$  (b) and with  $f < 0.5f_p$  (c) for test n. 2 and gauge n.5.

For both short and long waves previous analyses of the reflection coefficients (Goda and Suzuki, 1976) were performed in the case without the structure. These coefficients appeared to be close to 4% for short waves and 12% for long ones. The details of the results obtained by means of zero-(up)crossing analyses performed on the 4 reproduced tests are schematically drawn in Fig. 4a and 4b. In the figures significant short-wave heights  $H_s$  and periods  $T_s$  along the flume are reported.

As expected the periods perhaps appear constant along the flume, while the wave heights, as result of shoaling and breaking phenomena, decrease with decreasing water depths.

As already described, the same four tests were repeated with the submerged breakwater located on the bottom profile; the results obtained through experimental analyses are shown in Fig. 5a and 5b.

Fig. 4a – Significant wave heights for all gauges referred to short-waves zero-crossing analyses without the structure.

Fig. 4b – Significant wave periods for all gauges, referred to short-waves zero-crossing analyses without the structure.

In comparing Fig. 4a and 5a it does appear that in the off-shore region the wave heights do seem not to be greatly affected by the structure and this probably explains that, in the case analysed, the structure is not reflecting

waves significantly. Instead, wave heights following the breakwater are strongly affected by the structure itself and this is mainly related to the breaking of some waves over the structure.

Fig. 5a—Significant wave heights for all gauges referred to short-waves zero-crossing analyses with the structure.

Fig. 5b—Significant wave periods for all gauges referred to short-waves zero-crossing analyses with the structure.

As far as periods are concerned (Figs. 4b and 5b) they do not seem to be greatly influenced by the structure, except for very weak instabilities around it.

However, the most interesting phenomenon that did appear is related to

the analysis of the bounded-long-waves and in particular to the difference induced by the placing of the submerged breakwater over the bottom profile. In Fig. 6a and 6b the long-wave significant heights evaluated for all gauges during each test are drawn.

It can be observed that a considerable increase of long wave heights just in front of the structure was measured; in fact the long wave heights within the structure were evaluated to be about 40% greater than without it.

Fig. 6a – Significant wave heights for all gauges referred to long-waves zero-crossing analyses without the structure.

Fig. 6b – Significant wave heights for all gauges referred to long-waves zero-crossing analyses with the structure.

Similar results had already been found by the authors in previous experiments (Petti and Ruol, 1990, 1991) performed with the same structure but in a shorter flume and with different bottom configurations. This particular aspect lead to the thinking that the bottom configuration and the flume length affect only slightly the increasing of long wave heights in front of the structure.

As regards the length of the flume, probably some seiches were present because a non absorbing wave maker was used during the experiments. In the writers opinion, however, the results appear not to depend on them.

Firstly if the seiches were present they were very small because their reflection coefficient was small (12%). Secondly because eventual long wave oscillations should have been present in both the cases analysed: as a consequence the comparison of the results (e.g. the increase of the long wave heights) is not affected by the seiches themselves.

So as to be able to get more information about this interesting phenomenon, some velocity measurements over the structure were also performed.

A couple of water-fluid-meters (bi-directional micro-propeller) were located at 2.0 cm over the structure, one beside the other and three additional wave gauges were located in the same section in order to be able to associate the velocities with water levels (Fig. 7).

Fig. 7— Location of the micro-propellers and of the gauges over the structure.

An example of the velocity data registered during one test is reported in Fig. 8. As well as for the waves, the signal was also analysed considering the higher frequencies ( $f > 0.5f_p$ ) separately from the lower ones ( $f < 0.5f_p$ ). The results appear similar to ones referred to the wave gauge n. 5 located in front of the structure.

As regards the spectral analyses performed for velocity signals, in Fig. 9 the results relative to the four tests checked are reported.

It can be observed that while at the lower frequencies very high spectral values are present (due to nonlinear phenomena), at the higher frequencies they do not result all too evident. Moreover, while in the wave spectra calculated in front of the structure it was possible to find a frequency (about equal to  $0.5f_p$ ) dividing the low-frequency components from the high ones (Fig. 2), this was not possible for the velocity spectra.

Definitely a different behaviour of the velocity spectra compared to the wave spectra does appear: the frequency components in fact are strongly evolving towards the lower values and only weakly towards the higher values.

With regards to this, during the velocity analyses the mean values of the velocity pointing off-shore (a constant velocity distribution along the vertical was supposed) were also calculated: they were included in the range  $6 \div 14$  cm/s.

Fig. 8 – Example of velocity data-recording (a), of the filtered signal with  $f > 0.5f_p$  (b) and with  $f < 0.5f_p$  (c) for test n. 2.

Fig. 9a – Spectral analyses of the velocities measured over the structure by a micro-propeller for tests n. 1 and 2.

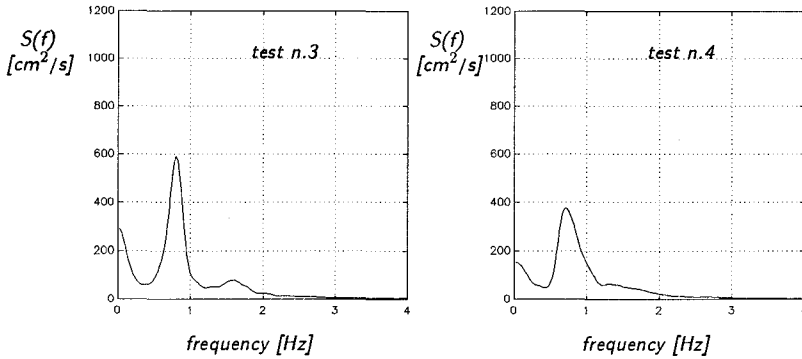

Fig. 9b – Spectral analyses of the velocities measured over the structure by a micro-propeller for tests n. 3 and 4.

In the authors' opinion these velocities, associated with the submerged breakwater presence, were able to affect the incoming bounded-long-waves; in fact the measured velocities appeared to be close to the theoretical long-wave orbital velocities (without structure) calculated, at first order, through linear theory (i.e.:  $u_{max} = 0.5H\sqrt{g/h}$ ). In conclusion, the incoming long wave really seems to be interfering with the opposite fluid discharge as if it were affected by a phenomenon similar to the interaction between waves and currents.

To corroborate this hypothesis the described mean velocity pointing offshore was related to the increase of long-wave heights due to the presence of the breakwater for each test (Fig. 10).

Fig. 10 – Increase of long wave heights in front of the structure (gauge n. 5) versus mean velocity measured over the structure.

As it does appear the greater the off-shore velocity over the breakwater the greater the increase of the long wave heights.

### Conclusive remarks

Some experimental studies carried out in a 50 m long flume on a submerged breakwater resulted in the definition of its behaviour under irregular waves attacks. In particular it was pointed out that the analysed structure was considerably affecting the bounded long wave heights: in fact the long wave heights were evaluated to be about 40% greater with the defence work rather than without it.

So as to be able to get more information about this phenomenon, some velocity measurements over the breakwater were performed: it did appear that greater the mean velocities pointing offshore (evaluated to be in the range  $6 \div 14$  cm/s), the greater the increase of the long wave heights in front of the structure.

Further experimental research with different submerged structures is asked for in order to determine analytical correlations between long wave height increases and geometrical characteristics.

## CHAPTER 60

### Field Observation of Surf Beats Outside the Surf Zone

Tsunehiro Sekimoto<sup>1</sup>, Takuzo Shimizu<sup>2</sup>, Kosuke Kondo<sup>2</sup>  
and  
Yasuhiro Kubo<sup>3</sup>

#### Abstract

Field observations of waves were conducted inside and outside a harbor in order to study the behavior of surf beats. From the observations, it is confirmed that surf beats propagate as bounded long waves at depths of 13 to 15m, whereas they behave as free waves in the harbor. It is found that the amplitude of bounded long waves become 20% of the ordinary-wave amplitude when the ordinary-waves height is 5 m.

#### 1. Introduction

Since the surf beats, which are water surface fluctuations with long periods of 1 to 5 minutes, were first observed by Munk (1949) and Tucker (1950), their characteristics have been investigated by means of field measurements and laboratory experiments by many researchers, e.g. Hotta et al. (1981), Kimura (1984), Kostence (1984), List (1988), Mansard and Barthel (1984), Ottesen-Hansen (1978), Ottesen-Hansen et al. (1980), Sand (1982), Sharma and Dean (1979), Symonds et al. (1982), Symonds and Bowen (1984). It is pointed out that surf beat plays an important role in the sediment transport in the surf zone, the slow drift oscillation of a moored vessel, the resonant edge wave growth and the harbor resonance.

<sup>2</sup>Penta-Ocean Construction Co. Ltd., 2-2-8 Koraku, Bunkyo-Ku, Tokyo 112, Japan.

<sup>3</sup>Tokyo Electric Power Co. Inc., 1-1-3 Uchisaiwaicho, Chiyoda-Ku, Tokyo 100, Japan.

Outside the surf zone, it is suggested that surf beat exists as a bounded long wave (Longuet-Higgins and Stewart, 1962). However, few field data, which show that surf beats are bounded and how much the magnitude of bounded long wave is, have been observed. Moreover the behavior of the surf beat in an actual harbor is still unclear.

The aim of this study is to explain the characteristics of surf beat in the nearshore non-breaking zone and its propagation into the harbor on the basis of the field measurement data.

In this study the term of surf beat means long period fluctuation of mean sea level with 1 to 5 minutes periods irrespective of water depth.

## 2. Field investigations

Field investigations were conducted at two sites. One site was the port of Kashiwazaki-Kariwa nuclear power plant, Niigata prefecture, Japan, which is facing the Sea of Japan. This power plant was constructed in both Kashiwazaki city and Kariwa town, so we call it shortly Kashiwazaki-Kariwa. Another site was the port of Oharai, Ibaraki Prefecture, which is located at the Pacific Ocean side of Japan. The locations of these sites are shown in Figure 1.

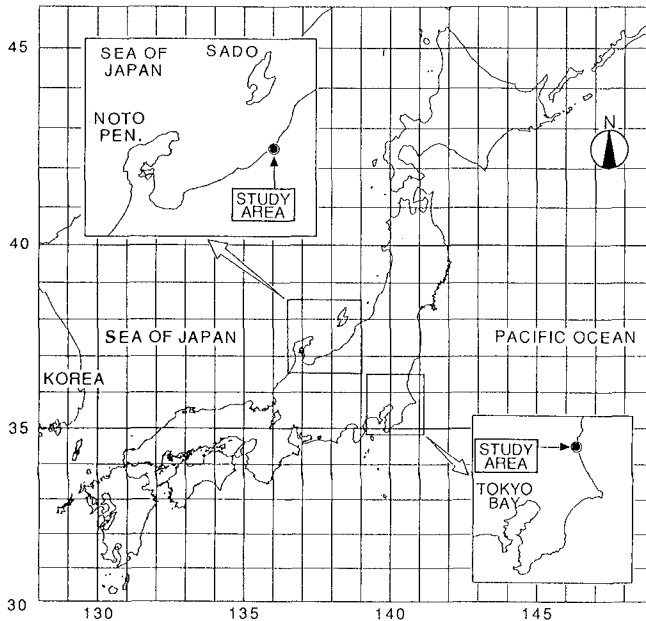

Figure 1. The location of the investigation site.

Figure 2. Location of observation points (Port of Kashiwazaki-Kariwa Nuclear Power Plant).

Figure 3. The location of observation point (Port of Oharai).

At Kashiwazaki-Kariwa site, field measurements were carried out inside and outside harbor from January through March of 1989. Figure 2 shows the port of Kashiwazaki-Kariwa nuclear power plant. The tip of main breakwater is located at 13m depth. The locations of measurement instruments are shown in this figure. At St. A and St. B the water surface elevation and two components of horizontal current velocity were measured using both ultrasonic wave gage and electromagnetic current meter. The water depths of St. A and St. B are 13.0m and 7.5m, respectively. At St. 1 through St. 10, the water surface elevation was measured by capacitance type wave gages. Since the waves higher than 2m were observed only a few times at Kashiwazaki-Kariwa during this observation, the wave data obtained in January and March of 1987 which are a part of a long term study by Tokyo Electric Power Co. Inc. were also analyzed. In this long term observation, ultrasonic wave gage is laid 1.5 km from the shore line.

At Oharai site, field observations were carried out outside the harbor, from November through December of 1990. Figure 3 is the general view of the Oharai port. The locations of measurement instruments are shown in this figure. An ultrasonic wave gage and an electromagnetic current meter with pressure gage were set at a point of 500 m away from the end of offshore breakwater.

The fluctuations of water surface level, and of pressure and two components of horizontal orbital velocities at the bottom were measured. At both sites, wave data were sampled at 0.5 second intervals and more than 300 records of time series of 20 minutes long and 150 records of 40 minutes long were obtained. The profiles of surf beat were extracted from

Figure 4. Typical wave spectrum at Kashiwazaki-Kariwa site.

those of water surface elevation and pressure by means of numerical filter. The cut off frequencies of numerical filter were 0.05 Hz for the data of Kashiwazaki-Kariwa and 0.04 Hz for the Oharai data which were determined from the results of power spectrum analysis. The extracted surf beats were used for various analyses. Typical wave spectrum at Kashiwazaki-Kariwa site is shown in figure 4. It is found that the peak frequency of ordinary-wave is about 0.1 Hz and the long wave energy is 2 orders below the peak energy of ordinary-wave.

### 3. Surf beats outside the harbor

Figure 5 shows the relationship between the significant wave height of ordinary-wave and that of surf beats at St. A. Under the condition of significant wave height higher than 1.5m, at the water depths of 13m the significant wave height of surf beats is proportional to the square of that of ordinary-waves. In this figure the calculation results estimated by unidirectional non-linear interaction theory (Ottesen-Hansen, 1978) and empirical relation proposed by Goda (1975) are also drawn.

The calculation by non-linear interaction theory is the average of 75 simulations of surf beat which are calculated from 75 simulated ordinary-waves using the procedure proposed by Sand (1982). In this calculation, the difference of the directions of ordinary-wave components is set to zero. The simulated 75 ordinary-waves were calculated from 3

Figure 5. The relationship between the wave height of surf beat and that of the ordinary-wave height (St.A).

Figure 6. The relationship between the wave height of surf beat and that of the ordinary-wave height (Stationary observation point).

types of energy spectrum and 25 sets of phase angles of component wave. The calculation results estimated by non-linear interaction theories fit the field measurements very well. Figure 6 shows the relationship between the surf beat and the ordinary-wave height of long term observation by Tokyo Electric Power Co., Inc. It is confirmed that the relationship between surf beat and ordinary-wave is the same as the relationship which was found in figure 5.

The surf beat profile was simulated on the basis of the non-linear interaction wave theory proposed by Sand (1982) by using the observed ordinary-wave profile in the condition of approximately unidirectional wave. That is the difference of the directions of ordinary-wave components is set to zero.

$$\zeta = \sum_{i=1}^{\infty} \sum_{j=1}^{\infty} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \xi_{ij}, \quad (1)$$

where

$$\xi_{ij} = a_i a_j G_{\eta \xi} \cos(\psi_i - \psi_j), \quad (2)$$

$$G_{\eta\xi} = \frac{1}{2h} \left[ \frac{G' - k_i h \cdot k_j h \cos \theta_{m_i n_j} - 16\pi^4 D_i^2 D_j^2}{4\pi^4 D_i^2 D_j^2} + 4\pi^2 (D_i^2 + D_j^2) \right], \tag{3}$$

$$G' = \left\{ (D_i - D_j) \left[ D_j (k_i^2 h - 16\pi^4 D_i^4) - D_i (k_j^2 h - 16\pi^4 D_j^4) \right] \right. \\ \left. + 2(D_i - D_j)^2 \left[ k_i h \cdot k_j h \cos \theta_{m_i n_j} + 16\pi^4 D_i^2 D_j^2 \right] \right\} / \\ \left\{ (D_i - D_j)^2 k_{ij}^- h \tanh k_{ij}^- h \right\}$$
(4)

$$\psi_i = \mathbf{k}_i \cdot \mathbf{x} - \sigma_i t + \varepsilon_i, \tag{5}$$

$$D_i = \sqrt{\frac{h}{g} \frac{\sigma_i}{2\pi}}, \tag{6}$$

$$\theta_{m_i n_j} = \theta_{m_i} - \theta_{n_j}, \tag{7}$$

$$k_{ij}^- = |\mathbf{k}_i - \mathbf{k}_j| \tag{8}$$

$$\mathbf{k}_i = (k_i \cos \theta_{m_i}, k_i \sin \theta_{m_i}), \tag{9}$$

and  $k_i$  and  $\sigma_i$  are the wave number and frequency respectively.

Figure 7 shows the directional spectra of wave which is used in surfbeat simulation. It is seen that the directional spectrum is very narrow.

Figure 7. The directional spectra of wave which is used in surfbeat simulation.

Figure 8. The comparison of the observed results with simulated surfbeat profile by non-linear interaction theory.

The comparison of observed surf beat with simulated surf beat is shown in figure 8. The observed surf beat profiles present a typical bounded long wave profile which is depressed beneath a group of high waves. The simulated profile shows good agreement with the observed one.

In order to investigate the correlation between the observed and simulated surf beat, cross-spectral analysis of these profiles was conducted. Figure 9 is the results of cross-spectral analysis. The figures are the phase function, square-root of ratio of powers, and coherence squared, respectively from top to bottom. Although the coherence squared is less

Figure 9. The results of cross-spectra (Phase function, square-root of ratio of power and coherence squared).

Figure 10. The relationship between the wave height of surf beat and the ordinary-wave height of Oharai wave data.

than unity but the phase function is nearly zero and transfer function is close to one. Considering that the coherence function is strongly affected by the fluctuation of phase difference in each component, it is concluded that the correlation is high and the observed surf beat is bounded.

Figure 10 shows the relationship between the wave height of surf

Figure 11. The variation of the ordinary-wave height and period and surfbeat wave height with the time.

Figure 12. The relationship between the wave height of surf beat and the ordinary-wave height.

beat and the ordinary-wave height of Oharai wave data. In this figure, the relationship seems not the same as previous relation. In order to study the cause of this difference, we investigate this relation in detail.

Figure 11 is the variations of the ordinary-wave height and period, and the surf beat wave height with the time. Three intervals of typical sea state were selected for analysis. The first of these is the period of rapid wave height increase and decrease. The second is the interval which large waves arrive successively. The last is the period of continuous increase of wave height. Figure 12 is the plot of the relationships between the surf beat height and the ordinary-wave height corresponding to the above three periods of typical sea state. In this figure, black symbols indicate the start and end of plot.

Figure 12(1) is in the period of rapid wave height increase and decrease. In this period when the waves increase in height, surf beats fit the nonlinear interaction theory. In the period of the decay, however, surf beat wave heights decrease with relatively higher energy level than that of the increasing time.

Figure 12(2) is in the period of arriving large wave successively. The surf beat wave heights have a relatively large energy level. So, an energy other than that of bounded long waves may also exist in surf beat in this case. Because of the shape of the port, wave energy may trap by Oharai port.

Figure 12(3) is in the period of continuous increase of wave height. This figure shows that the increase of surf beat due to nonlinear interaction is preceded by a decrease in the surf beat wave height because of the decrease in the ordinary-wave period. Therefore, it is found that in the condition that wave height increase from calm, surf beats exist as bounded long waves.

In figure 10, the black symbols show the condition that wave height

Figure 13. The comparison of the observed surfbeat with simulated surfbeat in the condition that wave height increase from calm.

increase from calm. It is seen that these fit the nonlinear interaction theory.

Figure 13 is the comparison of observed surf beat with simulated surf beat in the condition that wave height increase from calm. The simulated profile shows good agreement with the observed one. Thus it is concluded that the surf beats at the point of 13 m depth exist as bounded waves. According to both measurements and calculations, when the significant wave height of ordinary-waves is 5m, the wave height of surf beat is approximately 1m. This water surface fluctuation is not negligible to the design of maritime structures, because such a large long period fluctuation causes an increase in both hydrostatic pressure and buoyancy of the breakwater.

#### 4. Surf beats inside the harbor

Bowers (1977) investigated the long period wave behavior through theoretical and experimental study and concluded that the bounded long waves became free waves in a harbor. The surf beat behavior inside the harbor is investigated by using the field observation data. For this, wave data in Kashiwazaki-Kariwa are used. At the three points behind the breakwater, St. 2, St. 4 and St. 6, water surface elevations were measured along the direction of wave propagation. Figure 14 shows the result of cross spectral analysis between each two wave data. In figure 14, the solid curve means the phase difference which is calculated from the linear wave theory of progressive waves. From these results, it is confirmed that

Figure 14. The results of cross spectra analysis between points of behind breakwater.

surf beats in the harbor propagate as free waves.

Figure 15 shows the relationship between the significant wave height of ordinary-wave and that of surf beats at St. B. In the harbor the

Figure 15. The relationship between the wave height of surfbeat and the ordinary-wave height (St.B).

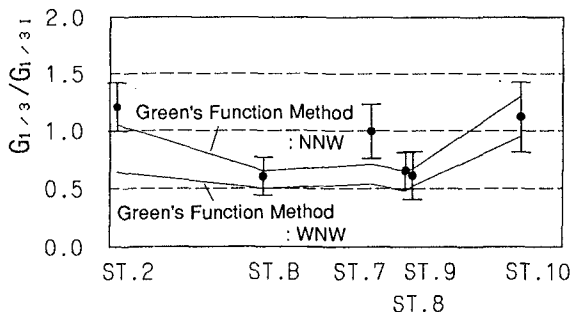

Figure 16. The comparison of the observation results with calculation results for wave height distribution inside the harbor by Green's function method.

clear relationship between the significant wave height of ordinary-wave and that of surf beats is not found because the degree of deformation of both depends on the wave direction and the wave period.

As the surf beats inside the harbor seem to be free waves, the wave height distribution of surf beat may be calculated by the method for ordinary-wave height. The wave height distribution of surf beat in the harbor was calculated, using Green's function method for ordinary-waves. The result of the comparison between the calculation and the observations is shown in figure 16. In this figure, the wave height ratio of surf beat is plotted for each observation point. Relatively good agreement was obtained between the calculation and the observation results except for St. 2 and St. 7. It is considered that the reason for these deviations are that the boundary condition of incident wave is not satisfied completely at St. 2 and the modeling of the shape of sea wall around the St. 7 is inadequate

## 5. Conclusions

Field observations of surf beat inside and outside a harbor were conducted and the characteristics of surf beat in the nearshore non-breaking zone were investigated. It was found that the surf beats exist as bounded waves outside the harbor. In the condition that wave height increase from calm, the height of surf beats may reach 20 % of ordinary-wave heights when the ordinary-wave height is 5m at the depth of 13 m. It was also confirmed that the surf beats exist as free waves inside the

harbor and the wave height distribution of surf beat inside the harbor may be calculated by the same method as that for ordinary-waves.

## CHAPTER 61

### LOW FREQUENCY WAVES IN THE SURF ZONE

Gary Watson<sup>1</sup> and D. Howell Peregrine<sup>2</sup>

#### ABSTRACT

The generation of low-frequency waves (LFW, also known as ‘infragravity waves’) within a two-dimensional surf zone is investigated numerically using a short-wave resolving model. In this simplified model, based on the nonlinear shallow-water equations, breaking waves are represented by ‘bores’, at which there are jumps in both water depth and velocity. Some idealized trains of modulated waves are then used to investigate how LFW may be generated by forcing within the surf zone, as opposed to the mechanisms of bound wave reflection and moving break point forcing. In this way, the process of LFW generation may be examined in some detail. The model is also compared with some measurements of irregular waves in a flume: good agreement is obtained.

#### INTRODUCTION

Low-frequency waves (LFW) are generated by the transfer of energy from modulated high-frequency waves (short waves) when they propagate into shallow water near the shore (Hamm et al., 1993). The energy transfer may be thought of as being brought

about by the variations in short-wave momentum flux (radiation stress) as the short waves of varying amplitude propagate over changes of water depth and break (Longuet-Higgins & Stewart, 1964). Past work on modelling LFW generation has used linear theory for the short waves and their radiation stresses. Empirical assumptions about wave amplitudes within the surf zone are used to estimate the radiation stress forces (Gallagher, 1971; Symonds et al., 1982; Nakaza & Hino, 1991; Schäffer, 1993; List, 1992; Roelvink et al., 1992).

Three particularly significant aspects of the generation process have been discussed:

(1) "Bound" LFW are generated with the short-wave groups and these grow as they propagate shorewards (Longuet-Higgins & Stewart, 1962; Agnon, 1993). The bound waves are released to propagate freely when the short waves lose their energy by breaking, or when they propagate over depth changes such as bars.

(2) Modulated short waves break in different depths. The radiation stress gradient is negative to shoreward of the break point and positive to seaward. LFW are generated as the break point moves (Symonds et al., 1982; Schäffer, 1993).

(3) Within the surf zone, the wave set-up fluctuates in response to fluctuations in incident wave amplitude. This rising and falling mass of water at the shoreline generates LFW. If the surf zone is saturated this effect is directly related to (2) but in general, modulations will penetrate into the surf zone and cause a complex time-varying radiation stress field (List, 1991).

These investigations have suffered from the disadvantage that questionable assumptions are made about the validity of linear theory for the propagation and radiation stresses of breaking waves within the surf zone. An alternative to this 'wave-averaged' approach is to use short-wave-resolving models to study the generation processes in more detail, without the need for such assumptions. Here we report studies of LFW generation using the nonlinear shallow-water equations. These are particularly appropriate in the inner surf zone, where the waves have formed into turbulent bores (Packwood, 1980) and they have been proved adequate for modelling breakers on a shallow beach (below, also Cox et al., 1992). It is in the surf zone that LFW have their largest amplitudes and the above generation mechanisms act. Other nonlinear equations such as the Boussinesq equations are only valid for non-breaking waves (although recent efforts have been made to extend their validity into the surf zone: see Schäffer et al., 1992). The shallow-water equations are thus best suited to the study of mechanism (3) above, and it is this which is discussed below.

Initially, our attention has been confined to one horizontal dimension and a

plane beach. The situation is thus simplified by the exclusion of edge waves and longshore currents. Bottom friction has been neglected, because it introduces an unnecessary empirical element into the model. Previous work has suggested that it has no qualitative effects, and that quantitative differences are mainly important in the very shallow swash zone (Packwood, 1980). Beach porosity has also been neglected for simplicity.

### MATHEMATICAL MODEL

The motion of a shallow layer of water, if the length scale of the motion is much greater than the water depth, may be described by the shallow-water equations for the conservation of mass and momentum,

$$d_t + (ud)_x = 0 \quad (1)$$

$$u_t + uu_x + g(d-h)_x = 0 \quad (2)$$

where  $u$  is the depth-averaged flow velocity,  $d$  the water depth,  $g$  the acceleration due to gravity,  $h(x)$  the undisturbed water depth and  $-h_x$  the local bottom slope (assumed small). Subscripts indicate differentiation. The surface elevation is  $\eta = d-h$ . The variables are illustrated in figure 1.

In appropriate conservation form, the equations are:

$$\frac{\partial}{\partial t} \begin{pmatrix} d \\ ud \end{pmatrix} + \frac{\partial}{\partial x} \begin{pmatrix} ud \\ u^2d + \frac{1}{2}gd^2 \end{pmatrix} = \begin{pmatrix} 0 \\ gdh_x \end{pmatrix} \quad (3)$$

Figure 1: Sketch showing variables referred to in the text.

$$\text{or, } \underline{U}_t + \underline{F}_x = \underline{S}. \tag{4}$$

$\underline{U}$  is a vector of the conserved quantities mass and momentum,  $\underline{F}$  is the flux of those quantities and  $\underline{S}$  is a source term due to the bottom slope. These nonlinear, hyperbolic partial differential equations admit the development and propagation of discontinuities which represent bores at which both mass and momentum are conserved. These fundamental conservation properties are important to ensure that the basic physics is correct. They mean that no empirical terms are required, even for wave breaking, although this does not give a detailed model. The conservation of mass and momentum at a bore may be demonstrated mathematically by integration of eq. (4) to yield the hydraulic jump relations.

A useful way in which to write eqs. (1) and (2) is in the characteristic form. This is obtained by making the substitution  $c^2 = gd$  ( $c$  is the local long-wave speed), rearranging, and expressing in terms of time derivatives along certain trajectories:

$$\frac{d}{dt}(u+2c) = gh_x \quad \text{on} \quad \frac{dx}{dt} = u+c \tag{5}$$

$$\frac{d}{dt}(u-2c) = gh_x \quad \text{on} \quad \frac{dx}{dt} = u-c. \tag{6}$$

In terms of the Riemann invariants,  $R^+ = u+2c$  and  $R^- = u-2c$ , these are

$$R^+_t + (u+c)R^+_x = gh_x \tag{7}$$

$$R^-_t + (u-c)R^-_x = gh_x. \tag{8}$$

Eqs. (5) and (6), or (7) and (8), indicate that the quantities  $R^+$  and  $R^-$  propagate along the characteristics at speeds  $u+c$  and  $u-c$  respectively, changing at a rate  $gh_x$  as they do so.  $u+c$  and  $u-c$  are equal to the local long-wave speeds of shoreward- and seaward-propagating waves respectively, advected by the local flow velocity  $u$ .  $R^+$  and  $R^-$  thus specify the shoreward- and seaward-propagating waves, respectively, a fact which is very useful in analysing results. At bores, there are jumps in  $R^+$  and  $R^-$  (Peregrine, 1974).

The boundary conditions to be satisfied are as follows. The shoreline boundary conditions are that the water depth becomes zero and its position  $x_s(t)$  moves such that it has the same velocity as the water:

$$d(x_s[t], t) = 0, \quad u(x_s[t], t) = \frac{dx_s}{dt}. \quad (9)$$

The appropriate seaward boundary conditions depend on the particular situation being studied. For wave modelling on a real beach, we need to prescribe the incident waves and yet permit outgoing waves to escape without reflection. This is done using the Riemann invariants discussed above. As long as the flow is subcritical ( $|u| < c$ ) at all times,  $R^-$  propagates into the domain at speed  $u + c$  and  $R^+$  propagates out of it at speed  $u - c$ .  $R^-$  at the seaward boundary must thus be computed from the solution just inside, using eq. (8). Incident waves are specified by prescribing  $R^+(t)$ . In supercritical conditions, both  $R^+$  and  $R^-$  would be specified if  $u > c$ , but neither need be specified if  $u < -c$ . Supercritical conditions do not occur in the cases studied here.

For wave tank experiments, the correct seaward boundary conditions must be chosen to fit the data that are available. In the case discussed below, the water depth  $d(t)$  is set equal to that measured at a wave probe, with  $R^-$  computed as before. Unfortunately this permits non-physical reflections at the seaward boundary, which must be borne in mind when interpreting the results. If the entire flume is to be modelled, the mode of generation must also be modelled correctly.

## NUMERICAL METHOD

A new numerical scheme, the weighted average flux method, was adopted for the solution of these equations. Invented primarily for aerodynamics, it is a development of currently favoured methods such as Godunov's and Roe's. Toro (1989) introduced the method for a simple advection equation and for the Euler equations of compressible gas dynamics. Toro (1992) applied it to the shallow-water equations for water of uniform depth. Watson, Peregrine & Toro (1992) adapted it for use with a moving shoreline and variable depth.

The method is 'shock-capturing', in that discontinuities (bores) are automatically treated correctly without the need for a special tracking algorithm. Bores are followed very well and for a given accuracy less discretization points are required than with most methods. It is found to be more efficient and robust than previously used methods such as the Lax-Wendroff scheme used by Hibberd &

Peregrine (1979).

The essence of the method consists of solving the initial-value Riemann problem for the shallow-water equations in each cell, with constant data in each half of the cell and a jump at the mid-point. This is done analytically using Riemann invariants and the mass and momentum conditions at bores. In this way the average mass and momentum fluxes in each cell are estimated one half-timestep in advance. A Total Variation Diminishing (TVD) adjustment is then made to the flux average in order to eliminate spurious oscillations near bores. This is done by means of upwinding, using a flux limiter to reweight the flux average (hence the name, 'Weighted Average Flux'). The TVD procedure effectively makes the scheme somewhere between first and second-order, so as to achieve a compromise between accuracy and stability. An explicit finite difference scheme is used for advancing in time. Each time step  $\Delta t_n$  must be less than the time taken for the fastest wave in the solution to propagate one grid point (the 'CFL' condition).

The shoreline boundary conditions (9) are not solved explicitly, but are approximately satisfied in the model. Any negative values of  $d$  are reset to zero and a dry-bed Riemann problem is used at the next timestep (Toro, 1990). As the depth becomes very small near the shoreline, large errors would result if the unmodified scheme were used. This is because small errors in the momentum variable  $ud$  become large errors in  $u$  when divided by a small value of  $d$ . In order to avoid such errors, an alternative approximation is used for  $u$  wherever the depth is less than a suitable small depth tolerance  $d_{tol}$ . To plot the position of the moving shoreline, another small depth  $d_s$  is chosen and the position of that depth is plotted.

The seaward boundary conditions were implemented along the lines mentioned above, using a simple finite difference approximation to eq. (8). Note that it is necessary to check whether the flow is in fact subcritical before using this scheme.

## RESULTS

Before proceeding with more complicated cases, the numerical scheme was tested against an analytic solution for non-breaking shallow-water motion on a beach (Carrier & Greenspan, 1958). The test showed good agreement, except for a small error in velocity very close to the shoreline.

### *Some Idealized Illustrations.*

Figures 2 and 3 illustrate the generation of a single low-frequency cycle by an idealized wave group. The input  $R^+(t)$  consists of fully modulated sinusoidal waves cut off after one group of ten waves. Figure 2 shows a perspective view of the surface elevation solution in space-time. All variables are dimensionless, with the beach slope scaled out of the problem. In this example, a slope of 1/30 and an offshore depth of 1 m would correspond to a wave period of 5 s and a wave height of 0.8 m. The waves steepen into bores as they travel towards the beach, decreasing in amplitude and slowing down as they do so. In the first half of the group, each successively larger wave pushes more water up the beach face. As the wave amplitude decreases in the second half of the group, this water recedes back down the beach. The inertia of the backwash of these waves pulls the shoreline water level down beneath the still water level and it finally rises rather rapidly to its initial level. This rising and falling motion, on the time-scale of the wave group, shows up clearly in the shoreline position (thick line). It generates a low-frequency wave which propagates offshore, and which can just be seen in the latter half of the plot.

In figure 3 the incident and outgoing waves are separated by means of the Riemann invariants.  $2c \pm u$  ( $-R^\pm$ ) has been plotted rather than  $u \pm 2c$  so that higher values always correspond to deeper water. These are plotted at different offshore distances after subtraction of the undisturbed value. At  $x=0.2$  the beach is normally dry, but values become defined when a wave runs up past this position.

The incident invariant shows the waves steepening and decreasing in amplitude as they approach the shore, and the raising of the mean level in the middle of the group. This corresponds to the set-up which is forced by the wave group. It also shows the modulation of the group becoming weaker as the waves saturate. The outgoing invariant shows the almost complete absence of short waves travelling away from the beach, because they have dissipated their energy and are not reflected. An asymmetric low-frequency pulse is seen to propagate away from the beach, decreasing in amplitude as it does so. Note that at  $x=0$ , positive elevation is approximately in phase with the peak of the incident group (but this is expected to depend on group length).

The incident wave group used in figure 2 is not very realistic, since such large waves are not in reality sinusoidal. Also, large-amplitude sine waves have a net mass transport associated with them because the water is deeper when the velocity is

onshore (wave crest) and shallower when it is offshore (wave trough). This transport will be an increasing function of wave height and thus will cause a LFW to be generated by the group. Although a real wave group will have a mass transport associated with it, it will not necessarily be the same as that of these sine waves, and it may be thought of as being part of the bound wave driven by the group. In this example the LFW may thus be too large: an incident wave group is normally accompanied by a bound wave of depression, whereas ours is not. The bound wave

Figure 2: Response to a single wave group. Perspective view of space-time plot of surface elevation, including shoreline motion.

Figure 3: Plots of incident and outgoing wave signals (Riemann Invariants) at various distances offshore, for the waves in figure 2.

will depend on the offshore topography, in a way which is being investigated. A theory for bound waves in moderately shallow water, where the theory of Longuet-Higgins & Stewart (1962) fails, has recently been derived by Agnon (1993).

In the mean time we look to the other extreme and present an example where there is no mass transport associated with the wave group. The wave shape is also modified to the form of a 'sawtooth', representing waves which have already broken. The mass transport in each wave is forced to be zero by choosing appropriate values of the peak and trough water depths. The results from this wave group are shown in figures 4 and 5, which are equivalent to figures 2 and 3 and have the same scales.

In these results also, a similar LF pulse is generated. Its amplitude is about half that in the previous case. The trough of the wave is deeper, indicating that the

Figure 4: As figure 2, but for a group of breaking waves with no mass transport.

Figure 5: As figure 3, but for a group of breaking waves with no mass transport.

outgoing wave, like the incident wave, carries little mass. The phase of the pulse at  $x=0$  relative to the incident wave group is also slightly different, with the peak occurring about one fifth of a cycle ( $70^\circ$ ) earlier and being more sharply defined. Note that this corresponds closely to the different shape of the incident pulse at the still-water shoreline ( $x=0$ ). In both cases, the shape of the outgoing pulse is close to the shape of the low-frequency component of the incident group at this position.

We conclude that even for a wave group where the bound wave component is small, a significant LFW will be generated if the groupiness persists inside the surf zone. Note also that in both cases, the amplitude of the LF pulse is such that the propagation velocity of the incident short waves is modified significantly. This interaction is not usually treated in wave-averaged models, nor is the substantial shoreline excursion.

Experiments are under way to verify these results for single wave groups in a wave flume. The effect on the LFW of changes in incident wave amplitude, period and group shape remains a subject for further research.

#### *Comparison with Wave Flume Experiments.*

In order to assess the relevance of the model to real waves, comparison is made with data from some wave flume experiments. The measurements are supplementary to those reported by Hansen & Svendsen (1979), and were made in the same flume. The measurements consisted of a series of depth gauges within the surf zone on a slope of 1/34.26. Data from the furthest offshore of these gauges were used to specify the waves at the seaward boundary of the model. Since velocity measurements were not available, the incident Riemann invariant  $R^+$  could not be found exactly at the boundary. Instead, the boundary condition was approximated by setting the depth equal to the measured value, and using the outgoing invariant to compute the velocity. As already noted, this is not ideal.

The result from one such run is given in figure 6. Surface elevation is plotted against time, at each offshore distance where a wave gauge was located. The first wave reaches the offshore probe at about 20s after startup from rest. The measured data are plotted with a solid line and the model result with a dashed line. The two are identical at the furthest station offshore ( $x=-2.81$  m), which was the seaward boundary for the numerical model. As the shore is approached, differences begin to appear between the two.

Except for the two gauges closest to shore, these differences are small and the

Figure 6: Comparison between measured and modelled surface elevation for irregular waves in a flume, data courtesy of J.B. Hansen and I.A. Svendsen.

agreement is very good. Propagation speeds, and changes in wave amplitude and shape, are reproduced well by the model. This is true even for the small waves at the beginning of the record. The onset of breaking is reproduced well by these equations, as was also found by Packwood (1980). At the two shallowest gauges, larger differences begin to appear. Some waves are missing altogether in the model result. This is because the waves did not reach this location in the experiment. At  $t=36\text{s}$  in the data from  $x=-0.61$ , there is a negative jump in surface elevation which was not present in the data. This results from a bore being forced to move back down the beach by the backwash from the preceding wave. The differences in this very shallow water may be due to the neglect of friction in the model. As in the above example, small changes in the position of a bore relative to a wave gauge may produce a large change in the time series at the gauge.

Despite these differences in high-frequency detail, the low-frequency component of the motion is very well reproduced in the shallow water. This manifests itself as changes in surface elevation on a timescale of about 10 seconds. This confirms that the nonlinear shallow-water equations used by the model contain all the essential components necessary for the LFW generation process to be modelled quite accurately.

## CONCLUSIONS

The nonlinear shallow-water equations have been shown to provide a good basis for the modelling of LFW generation in the surf zone. Comparison with wave flume data indicates a good reproduction of the long-wave motion everywhere, and of the short-wave properties except in very shallow water. Runs using idealized wave groups illustrate the process by which LFW are generated by forcing within the surf zone, as distinct from breakpoint forcing or bound wave reflection.

## ACKNOWLEDGEMENTS

This work was funded by the Commission of the European Communities under MAST contract 0035 as part of the G6M coastal morphodynamics program. We are grateful to E.F. Toro of Cranfield Institute of Technology for providing the constant-depth code, and for advising on its adaptation. The wave flume data were

kindly provided by J.B. Hansen and I.A. Svendsen, then at ISVA, Technical University of Denmark.

## CHAPTER 62

### Low Frequency Waves in Intermediate Water Depths E C Bowers<sup>1</sup>

#### Abstract

This paper is concerned with calculations and field measurements of low frequency or infragravity waves associated with wave grouping (frequencies in the range of 0.005 to 0.04 Hertz). These waves have periods in excess of wind generated waves and they are assuming particular importance now due to the effect they are thought to have on sediment transport in and near the surf zone. However, the impetus for the work described here originated from a need to quantify the magnitude of these waves in intermediate depths typical of harbour entrances: it being generally accepted that long period waves excite harbour resonances and moored ship movements, leading to berth downtime.

#### 1. Introduction

In intermediate water depths the infragravity waves associated with wave grouping are expected to consist largely of an incoming component bound to groups of shoreward going (primary) waves, sometimes called set-down beneath wave groups, and a free long wave component which will be referred to as surf beat in this paper. In this context surf beat includes both "leaky" modes propagating offshore and trapped, high order, edge wave modes. A full description of set-down in terms of radiation stresses associated with wave grouping was first given by Longuet-Higgins and Stewart (1964) and, in the same paper, they suggested that surf beat was the reflection of the bound long wave which became free of wave groups in the surf zone: this to account for a time lag observed by Tucker (1950) in correlations between long waves measured offshore of a beach and the envelope of the incoming waves.

Subsequently, a description was provided by Symonds et al (1982) of another mechanism for the generation of free long waves or surf beat. Called the moving breakpoint mechanism, the authors showed that gradients in radiation stresses associated with breaking waves, as the break point moves onshore and offshore at wave group periods, would generate long waves. An extension of this mechanism has been developed by Watson and Peregrine (1992). Using non-linear shallow water equations they have shown that the grouping of broken waves, that remains within the surf zone may lead to additional free long wave energy. Schaffer and Jonsson (1990) have compared results from an analytical description of long wave generation, containing the moving break point mechanism and the reflection of the bound long wave, with results of flume experiments carried out by Kostense (1984) and obtained qualitative agreement. Time domain models (List, 1992 and Roelvink 1992) and a frequency space model (van Leeuwen and Battjes 1990) containing both mechanisms of surf beat generation have also been developed and comparisons made with flume and field data.

Free long waves can also be expected to be released by incoming wave groups as they propagate over seabed irregularities (see Mei and Bennisou, 1984, for example).

-----  
<sup>1</sup>Research Department, HR Wallingford, Wallingford, Oxon. OX10 8BA, UK.

From the above discussion it can be seen that two basic long wave populations associated with wave grouping can be distinguished: the incoming bound long waves and free long waves or surf beats generated via various mechanisms. In principle, the bound long waves can be calculated from a knowledge of the primary waves. Early flume experiments verified that the amplitude of the bound long wave could be predicted in intermediate water depths using a Stokes expansion of the basic wave equations taken to second order in wave amplitude (see Bowers, 1980, for example). This suggested that surf beats could be determined in field data by calculating the bound long wave component and subtracting it from the total long wave energy. With that in mind, a method of analysis of pressure sensor data was developed to separate out the surf beat and bound long wave components in the total long wave spectrum. This analysis was applied subsequently to a number of sites around the UK coast (water depths 4m to 19m) including Port Talbot on the south coast of Wales in 1984, Dover and Shoreham on the south coast of England in 1986, Barrow-in-Furness on the west coast of England in 1988 and Sunderland on the east coast of England in 1988. The method of analysis is outlined in the next section and the results from the 5 sites discussed in a following section.

Similar analyses of field data have been carried out recently by Okihiro et al (1992) and by Herbers et al (1992).

## 2. Method of analysis

The first point to make is that calculation of the bound long wave has to take the directional spread of primary wave energy into account (Sand 1982). This is well illustrated by flat bed wave basin results obtained recently at HR Wallingford using a shallow water multi-directional wave-maker. Figure 1 shows measured long wave spectra associated with primary waves representing a significant wave height of 8m, a spectral peak period of 15s and water depth of 40m. It can be seen that even a relatively narrow rms spread of  $22.5^\circ$  in short crested primary waves will almost halve the long wave height associated with long crested uni-directional (zero spread) waves. It is also of interest to note that the long wave height is not all that sensitive to the amount of directional spread, with a broad spread corresponding to a  $\cos^2\theta$  distribution ( $32^\circ$  rms spread) resulting in only slightly smaller long waves than those measured with a primary wave spread of  $22.5^\circ$ . These results indicate that once a small degree of directional spread exists in the primary waves, it produces a considerable reduction in the height of the bound long wave component but thereafter directional spread becomes a less sensitive parameter (see Equations (17) and (18) later). Of course, surf beats due to reflections of the bound long wave from the shingle beaches on the wave basin boundaries would also have been present in these experiments but they can be expected to be a fixed percentage of the bound long wave. Thus, the relative behaviour of the total long wave spectra in Figure 1 can be considered representative of the relative behaviour of just the bound long wave spectra in the model depth equivalent of 40m.

The second point to make is that relatively long wave records are required to reduce uncertainties in long wave magnitudes. For example, there would only be 10 waves of 2 minute period in a conventional wave record 20 minutes long with the result that large variations in the long wave height would occur from record to record even with a stationary sea state. This problem can be minimised by taking a long enough record for which a full range of different wave grouping patterns has had time to occur leading to representative bound long waves. For example, Bowers (1988) has demonstrated in flume work, with compensation for set-down at the wavemaker, that in moderately long experiments the spectrum of set-down or the bound long wave component in random seas will tend to an "expected" spectrum calculated without taking into account the phases of the primary waves. In short experiments, or short wave records, these phases become important because only certain patterns of wave grouping will have occurred leading to an unrepresentative long wave spectrum. To ensure long records in the field measurements a bottom mounted pressure sensor was programmed to take 2 hour records. This was done by sampling regularly for 5 minutes every 4 hours and when the significant wave height exceeded a present threshold level, a 2 hour record was taken. This technique ensured that long records were only taken at times of relatively high primary wave activity when the associated long waves were worth measuring.

In the measurements reported here, the specially programmed pressure sensor provided information about the one dimensional primary wave spectrum, but no information

Figure 1 Wave basin long wave spectrum showing effect of short crestedness in primary waves

about directional wave properties. However, the (zero lag) correlation coefficient between the forced low frequency disturbance and the low frequency part of the square of the primary wave pressures is sensitive to the amount of directional spread in the primary waves, with narrow spreads producing higher correlations. Thus, by calculating the correlation coefficient for the total long waves from the pressure sensor data, it is possible to infer the mean directional spread in the primary waves (see Section 2.2). Armed with the one dimensional primary wave spectrum and a mean spread parameter, it is then possible to calculate the "expected" spectrum of the forced low frequency disturbance and subtract it from the measured long wave spectrum to leave the surf beat spectrum.

The bound long wave spectrum based on a second order Stokes expansion (see for example Sand 1982) really applies only to a flat seabed. If the seabed is sloping gently enough, so that the wave system has time to adjust itself to local depths, then the same calculation can be expected to apply to the real situation with the local water depth being used in the equations. While this assumption appears reasonable in most cases for the primary waves, it is less likely to apply to long waves where depth changes can be significant within a wavelength. In what follows, an allowance for seabed slope is made as a correction to the "flat bed" calculation of the bound long wave and it is found that an additional bound long wave component results which lags the main one by  $90^\circ$ . This may explain a lag in the total bound long wave component that has been reported by List (1992) in a numerical model of nearshore surf beat generation. However, for the seabed slopes and intermediate water depths applicable to the field measurements reported in this paper it is found that the additional bound long wave component remains a fraction of the "flat bed" bound long wave and, if included, alters resulting estimates of surf beat height by only a few percent.

2.1 Calculation of bound long waves

For convenience, we represent the seabed by straight parallel contours running perpendicular to the x axis of a right-handed orthogonal co-ordinate system where the x axis points offshore. The plane z = 0 is taken to be the water surface and we assume that a multi-directional sea approaches from offshore, with its mean direction parallel to the x axis. A constant seabed slope  $\alpha$  is taken so that water depth(h) is given by,

$$h = x \tan \alpha \tag{1}$$

We assume irrotational wave motion with fluid velocity  $\underline{q}$  derived from a velocity potential  $\phi$ ,

$$\underline{q} = (u, v, w) = -\nabla \phi$$

Incompressibility leads to the basic wave equation

$$\nabla^2 \phi = 0 \tag{2}$$

Solutions to (2) are sought subject to the following boundary conditions.

On the seabed z = -h, the normal velocity vanishes, i.e,

$$u \frac{dh}{dx} + w = 0 \tag{3}$$

and on the free surface z =  $\eta$  we have the kinetic condition

$$\frac{\partial \eta}{\partial t} + u \frac{\partial \eta}{\partial x} + v \frac{\partial \eta}{\partial y} - w = 0 \tag{4}$$

and Bernoulli's equation (with constant air pressure at the surface)

$$\frac{1}{2} \underline{q}^2 + g\eta - \frac{\partial \phi}{\partial t} = 0 \tag{5}$$

We solve the above equations by using a Stokes expansion, retaining linear terms in the equation in lowest order and bringing quadratic terms into next order. With in each order, flat bed solutions are obtained initially and then corrections obtained to allow for depth variations.

As the expressions for the final bound long wave spectrum are complex we consider just one component associated with two primary wave frequencies  $\omega_1$ , and  $\omega_2$  propagating at angles  $\theta_m$  and  $\theta_n$ , respectively, to the x axis,

$$\eta^{(1)} = a_{n2} \cos(\omega_2 t + \underline{k}_{n2} \underline{r} + \epsilon_{n2}) + a_{m1} \cos(\omega_1 t + \underline{k}_{m1} \underline{r} + \epsilon_{m1})$$

where

$$\begin{aligned} \underline{k}_{n2} \underline{r} &= k_2 \cos \theta_n x + k_2 \sin \theta_n y, \\ \underline{k}_{m1} \underline{r} &= k_1 \cos \theta_m x + k_1 \sin \theta_m y, \end{aligned}$$

Here,  $a_{n2}(x)$ ,  $a_{m1}(x)$  are the amplitudes of the two primary wave components and  $\epsilon_{n2}$ ,  $\epsilon_{m1}$  are their random phases, while each wave number satisfies the usual dispersion relationship in terms of the local water depth h(x),

$$\omega^2 = kg \tanh kh.$$

The depth variation can be shown to introduce an additional requirement on each primary component which expresses the conservation of wave energy during refraction over the varying seabed level,

$$\frac{d}{dx} (a^2 C_g \cos \theta) = 0$$

where  $c_g$  is the group velocity

$$c_g = \frac{\omega}{2k} \left( 1 + \frac{2kh}{\sinh 2kh} \right)$$

To next order in the Stokes expansion, the quadratic terms in (4) and (5) are expressed as products of the first order quantities and they lead to terms containing sum and difference frequencies  $\omega_2 \pm \omega_1$ . The bound long wave component has frequency  $\omega_2 - \omega_1$ , so we retain just the difference frequency component. Solutions to Laplace's equation (2) are sought for the second order potential  $\phi^{(2)}$  subject to boundary condition (3) on the seabed and the following surface condition obtained from (4) and (5),

$$\frac{\partial^2 \phi^{(2)}}{\partial t^2} + g \frac{\partial \phi^{(2)}}{\partial z} = \eta^{(1)} \left( \frac{\partial^2 w^{(1)}}{\partial t^2} \right) + g \frac{\partial w^{(1)}}{\partial z} + 2q^{(1)} \frac{\partial q^{(1)}}{\partial t} \tag{6}$$

Equation (6) shows how the surface perturbation on the right-hand side forces the bound long wave potential  $\phi^{(2)}$ . Following the pattern of solution outlined above for the primary waves, we calculate the bound long wave first of all neglecting depth variations and then consider the effect of variable depth as a perturbation on this solution. We denote the local depth solution for the bound long wave potential by  $\phi_o^{(2)}(x)$  and its correction for depth variation by  $\phi_1^{(2)}(x)$ . Thus,  $\phi_o^{(2)}(x)$  takes the form of the usual "flat bed" second order potential (see Sand, 1982 for example).

$$\phi_o^{(2)} = A_{mn} \cosh(|\underline{k}^-|(z+h)) \sin(\omega t + \underline{k}^- \cdot \underline{r} + \varepsilon) \tag{7}$$

where,

$$\begin{aligned} \varepsilon &= \varepsilon_{n2} - \varepsilon_{m1}, \\ \omega &= \omega_2 - \omega_1, \\ \underline{k}^- &= \underline{k}_{n2} - \underline{k}_{m1}, \end{aligned}$$

$$A_{mn} = \frac{1}{2} g^2 a_{n2} a_{m1} \left[ \frac{e^- + \frac{2k_1 k_2}{\omega_1 \omega_2} \omega^- (\cos(\theta_n - \theta_m) + \tanh k_1 h \tanh k_2 h)}{(\omega^-)^2 \cosh |\underline{k}^-| h - g |\underline{k}^-| \sinh |\underline{k}^-| h} \right]$$

$$e^- = \frac{k_2^2}{\omega_2 \cosh^2 k_2 h} - \frac{k_1^2}{\omega_1 \cosh^2 k_1 h}$$

To find  $\phi_1^{(2)}$  we consider solutions of (2) of the following form,

$$\phi_1^{(2)} = G_{mn}(x, z) \cos(\omega t + \underline{k}^- \cdot \underline{r} + \varepsilon) \tag{8}$$

where,

$$\begin{aligned} G_{mn} &= (B_{mn} + z E_{mn}) \sinh |\underline{k}^-|(z+h) \\ &+ (C_{mn} + z D_{mn} + z^2 F_{mn}) \cosh |\underline{k}^-|(z+h), \\ 2|\underline{k}^-| F_{mn} &= -k_x^- A_{mn} \frac{d}{dx} |\underline{k}^-| \\ |\underline{k}^-| D_{mn} &= -k_x^- A_{mn} \frac{d}{dx} |\underline{k}^-| d, \\ 2|\underline{k}^-| E_{mn} &= \frac{1}{A_{mn}} \frac{d}{dx} (k_x^- A_{mn}^2) + \frac{k_x^- h}{|\underline{k}^-|} A_{mn} \frac{d}{dx} |\underline{k}^-|, \end{aligned}$$

and,

$$k_x^- = k_2 \cos \theta_n - k_1 \cos \theta_m$$

The boundary condition (3) leads to a value for  $B_{mn}$

$$2|k^-|B_{mn} = -\frac{h}{A_{mn}} \frac{d}{dx} (k_x^- A_{mn}^2) + \frac{k_x^- h A_{mn}}{|k^-|} \frac{d}{dx} |k^-|,$$

and (6) leads to a value for  $C_{mn}$

$$C_{mn} [g|k^-| \sinh |k^-| h - (\omega^*)^2 \cosh |k^-| h] + gD_{mn} \cosh |k^-| h + gE_{mn} \sinh |k^-| h + B_{mn} [g|k^-| \sinh |k^-| h - (\omega^*)^2 \cosh |k^-| h] = H_{mn}.$$

Here,  $H_{mn}$  is the term on the right-hand side of (6) proportional to  $\cos(\omega^* t + k^- x + \epsilon)$ .

The above set of equations define the additional bound long wave component (8) due to a varying water depth. It can be seen that it has a 90° phase difference with the usual "flat bed" bound long wave (7).

The expressions derived so far relate to just a pair of primary wave components. To define the bound long wave associated with a multi-directional sea it is necessary to sum over all the pairs of wave components with amplitudes that can be defined in terms of the directional wave spectrum  $S_d$ , ie

$$a^{n2} = 2 S_d(f_2, \theta_n) df d\theta, \tag{9}$$

$$a_{m1}^2 = 2 S_d(f_1, \theta_m) df d\theta. \tag{10}$$

Finally, as measurements were made with a bottom mounted pressure sensor (with the diaphragm pointing upwards) we obtain an expression for the forced low frequency disturbance on the seabed from Bernoulli's equation,

$$\eta_s^{(2)} = \frac{1}{g} \left[ \frac{\partial \phi^{(2)}}{\partial t} - \frac{1}{2} (q^{(1)})^2 \right]_z = -h \tag{11}$$

### 2.2 Estimating directional spread

This was done using the correlation coefficient  $R_L$  (at zero lag) between the low frequency part of the square of the primary wave bed pressures, effectively the square of the seabed wave envelope, and the measured low frequency disturbance on the bed. Denoting the primary wave on the bed by  $\eta_p^{(1)}$  and the surf beat by  $\eta_b^{(2)}$  we have by definition,

$$R_L = \frac{\int (\eta_p^{(1)})^2 (\eta_s^{(2)} + \eta_b^{(2)}) dt}{(\int (\eta_p^{(1)})^4 dt)^{1/2} (\int (\eta_s^{(2)} + \eta_b^{(2)})^2 dt)^{1/2}}$$

Where  $\eta_s^{(2)}$  is defined in (11). The above quantity can be calculated from the measured pressure sensor data and examples of  $R_L$  are shown in Figure 2 for a range of lags and primary wave heights. It can be seen in all cases that a negative correlation coefficient occurs at zero lag, consistent with a set-down beneath groups of large waves. The Bernoulli pressure in (11) will contribute to this negative correlation but it is insufficient to explain the magnitude of the measured correlations. In all cases the recordings were made far enough offshore for us to assume that at zero lag surf beat is uncorrelated with both the square of the primary waves and the bound long wave so that  $R_L$  simplifies to,

$$R_L = \left( \frac{M_s}{M_L} \right)^{1/2} R_s \tag{12}$$

Figure 2 Correlation coefficients for large and small waves at Port Taibot

Where  $R_s$  is the correlation coefficient for the forced low frequency disturbance alone,

$$R_s = \frac{\int (\eta_p^{(1)})^2 \eta_s^{(2)} dt}{(\int (\eta_p^{(1)})^4 dt)^{1/2} (\int (\eta_s^{(2)})^2 dt)^{1/2}}$$

and

$$M_s = \frac{1}{T} \int_0^T (\eta_s^{(2)})^2 dt$$

In (12) the correlation coefficient  $R_L$  and the mean square of the total low frequency disturbance  $M_L$  can be obtained directly from the measurements, while the correlation coefficient ( $R_s$ ) and the mean square of the forced low frequency disturbance ( $M_s$ ) can be calculated in terms of the primary wave spectrum using (11), (7), (9) and (10). Only the "flat bed" component of the bound long wave defined in (7) is needed here because the 90° phase difference of the extra potential due to varying water depth means (8) does not contribute to the correlation coefficient at zero lag.

Clearly, both  $R_s$  and  $M_s$  are functions of the directional properties of the primary waves. We make the following assumption about the primary wave spectrum,

$$S_d(f, \theta) = \frac{1}{(\pi\theta_0)^{1/2}} \exp\left(-\frac{\theta^2}{\theta_0^2}\right) S(f) \tag{13}$$

where  $S(f)$  is the usual one dimensional wave spectrum and  $\theta_0$  defines a mean spread parameter for the primary waves. Different, and perhaps more familiar, forms for directional spread were tried in the analysis but the results were found to be insensitive to the exact form of the spreading function. The exponential form has the advantage that analytical integration is made possible (see next sub-section).

Equation (13) completes the expressions needed to define  $R_s$  and  $M_s$  in terms of the unknown  $\theta_0$ . This mean spread parameter can then be obtained making an initial guess for  $\theta_0$  and

iterating on this starting value until (12) is satisfied. Of course, even though the bound long wave quantities being used here relate to bed pressures they are expressed in terms of the spectrum  $S(f)$  of primary waves at the surface. This is obtained from the measured primary wave bed pressure spectrum by applying the square of the inverse of the (linear potential) depth attenuation factor, frequency component by frequency component. Also, in calculating the bound long wave, its "expected" value is obtained from the primary waves. This ignores the phases of the primary waves, as described above under method of analysis; a process that can be justified for long wave records.

**2.3 Calculation of the surf beat spectrum**

This spectrum is obtained by simply subtracting the calculated spectrum of the forced low frequency disturbance (11) from the measured long wave spectrum. In doing this, some estimate of the bound long wave due to a varying water depth is needed in addition to the "flat bed" bound long wave. We do this making the shallow water wave assumption,  $kh < 1$ , when evaluating expression (8). This is justified on the basis that this bound long wave component can be shown to be negligible for deep water waves. After much algebra we find its spectrum  $S_G(f)$  takes the form,

$$S_G(f) = \int S(f) S(f + f') I_G df' \tag{14}$$

where,

$$I_G = \left(\frac{h\pi}{2g}\right)^{1/2} \frac{0.0556g^5 \tan^2 \alpha}{\pi^9 h^7 \theta_0^7 f^{-4} (f + f')^4}$$

It is of interest to compare this spectrum with the spectrum  $S_F(f')$  of the "flat bed" bound wave calculated under the same shallow water wave assumption,

$$S_F(f) = \int S(f) S(f + f') I_F df \quad (15)$$

where

$$I_F = \left(\frac{h\pi}{2g}\right)^{1/2} \frac{0.2813g^2 f'}{\pi^3 h^4 \theta_0 f^2 (f + f')^2}$$

Both spectra in (14) and (15) can be evaluated and then integrated over difference frequencies  $f'$ . For typical parameters we find the ratio  $N$  of the bound long wave amplitude due to varying water depth, over the flat bed bound long wave amplitude is,

$$N = \frac{26.4 T_p^2 \tan \alpha}{h^{3/2}} \quad (16)$$

Where  $T_p$  is the spectral peak period of the primary wave spectrum and the constant has dimensions ( $m^{3/2} s^{-2}$ ). This shows immediately that effects of bed slope will only be important nearshore when the water depth is reduced. It must also be remembered that the Stokes expansions of the type being used in this paper are not valid in very shallow water when the waves become highly non-linear. This will limit the range of validity of the expressions given here. Nevertheless, it is of interest to use (15) to estimate the magnitude of the flat bed bound long wave. Defining the significant value as 4 times the standard deviation we find for a typical wave spectrum,

$$H_s (\text{bound long wave}) = 0.0413 \left(\frac{h^{1/2}}{\theta_0 T_p}\right)^{1/2} \frac{H_s^2 T_p^2}{h^2} \quad (17)$$

where  $H_s$  is the primary significant wave height and the constant has dimensions ( $m^{3/4} s^{-3/2}$ ). This compares with an equivalent expression for uni-directional primary waves,

$$H_s (\text{bound long wave}) = 0.074 \frac{H_s^2 T_p^2}{h^2} \quad (18)$$

where the constant has dimensions ( $ms^{-2}$ ). Expression (17) gives bound long waves that, typically, are half the height of those defined by (18) (see also Figure 1). Another difference between multi-directional seas and uni-directional seas is in the shape of the flat bed bound long wave spectrum. It is well known that, in theory, this spectrum has a finite value at zero frequency for uni-directional waves but (15) shows that in shallow water, the bound long wave spectrum in multi-directional waves tends to zero as the difference frequency tends to zero.

Although (17) and (18) are, in theory, limited to shallow water waves they appear, in comparisons with exact calculations, to give reasonable estimates of bound long waves even for  $kh \approx 1$ .

### 3. Field data

In applying the method of long wave analysis described in Section 2, exact calculations of the flat bed bound long waves were made using (7). The bound long wave due to varying bed level was then determined using (14). This resulted in only small corrections to the final estimate of surf beat thereby justifying the use of (a conservative) shallow water theory in deriving (14). Examples of these corrections are given for various sites in what follows.

#### 3.1 Port Talbot

In this deployment the pressure sensor was mounted about 4km from the shoreline at the seaward end of the navigation channel leading to the harbour of Port Talbot on the

south west coast of Wales. With the large tidal range at the site, depths at the sensor varied from 10m to 19m. Spectral peak periods ranged from 7s to 15s and, typically, significant wave heights were in the range of 1m to 2m but some large wave heights of 4m were measured. Such parameters indicated the main source of wave activity to be the Atlantic as shorter period waves would have been dominant if local fetches were applicable. The seabed slope in the vicinity of the wave recorder was about 1 in 600.

To illustrate the largest correction to the flat bed bound long wave due to a varying seabed level we take the record with the lowest depth. The parameters were,

$$H_s = 1.16\text{m}, T_p = 12.8\text{s}, h = 10.2\text{m}, H_s \text{ (long wave)} = 0.104$$

Exact flat bed analysis yielded,

$$H_s \text{ (bound long wave)} = 0.073\text{m with } \theta_o = 10^\circ, R_L = -0.60.$$

Here, and in what follows, the term bound long wave is taken to include the Bernoulli pressures in (11) although strictly speaking it should just refer to disturbances due to the second order potentials (7) and (8). Expression (14) leads to an additional bound long wave component with a significant height of 0.016m, ie 22% of the flat bed component. This percentage figure can also be obtained directly from (16). Thus, surf beat height is given by,

$$[(.104)^2 - (0.073)^2 - (0.016)^2]^{1/2} = 0.072\text{m}.$$

If we had neglected the additional bound long wave component our surf beat height would have been 0.074m and only a small error would have resulted. For the record with the largest water depth (18.9m) the additional bound long wave component was only 10% of the flat bed component and its neglect would have resulted in only a 0.05% error in surf beat height. Because of its small effect on estimates of surf beat it was decided to neglect the additional bound long wave component. However, it should be noted that such a component exists and, according to (16), can be expected to become more important nearer to the shore where it will tend to make the trough of total bound long wave lag behind groups of large waves: an effect also observed by List (1992).

The following table of some of the Port Talbot data gives an idea of the percentage contribution of surf beat to the total long waves measured. It can be seen that surf beat is dominant when primary waves are small but that the bound long wave component begins to dominate when primary wave heights are larger.

Table 1 Results from Port Talbot

Primary	Waves	Measured long waves	Calculated bound long waves	Surf beat
$H_s$ (m)	$T_p$ (s)	$H_s$ (m)	$H_s$ (m)	$H_s$ (m)
0.49	11.1	0.025	0.006	0.024
0.54	11.1	0.030	0.007	0.029
0.79	6.9	0.032	0.008	0.031
0.80	7.6	0.035	0.011	0.033
2.76	12.8	0.204	0.116	0.168
3.20	13.5	0.374	0.238	0.288
4.12	11.5	0.407	0.349	0.210
4.18	12.0	0.295	0.230	0.185

We know that the bound long wave component will increase with the square of wave height and period to the power 3/2 (see (17)). The above results (as well as those collected at the other sites) indicate that surf beat does not increase as rapidly with the severity of sea state. It is of interest for engineering studies to try and find an empirical relationship for the height of surf beat in terms of primary wave parameters. This was done with the powers of the following three parameters being chosen to minimise scatter in the data,

$$H_s \text{ (surf beat)} \propto H_s^\beta T_p^\alpha h^\delta$$

In the case of Port Talbot, the following relationship was found where wave height and water depth are in metres and wave period is in seconds.

$$H_s \text{ (surf beat)} = 0.0064 \frac{H_s^{1.32} T_p^{1.17}}{h^{0.34}} \quad (19)$$

Scatter in the data was judged by a normalised error parameter and it was found that this error parameter was larger when an empirical relationship of the above type was sort for the significant height of the total long wave component, i.e without first subtracting off the bound long wave energy. This result indicates that the assumptions made about the bound long wave in the method of analysis, are justified. Also, Herbers et al (1992) have provided evidence using bispectral analysis that the bound long wave spectrum in field measurements of long period disturbances, matches the bound long wave spectrum predicted by a second order Stokes expansion.

### 3.2 Shoreham Harbour

In this case, the pressure sensor was mounted about 2.5km from the shoreline, offshore of the entrance to Shoreham Harbour which lies on the south coast of England. Water depths ranged from 7m to 12m due to the tide and the wave climate consisted mainly of locally generated waves with spectral peak periods from 6s to 10s. Swell, which had propagated up the English Channel from the Atlantic was also present at times with significant heights generally under 1m and spectral peak periods of 12s to 18s.

The seabed in the vicinity of the wave recorder was very flat with a slope of about 1 in 700. The record with the largest slope induced bound long wave had the following parameters,

$$H_s = 0.6\text{m}, T_p = 15.5\text{s}, h = 8.8\text{m}, H_s \text{ (long wave)} = 0.055\text{m}.$$

The flat bed bound long wave was 0.024m which, ignoring the slope induced component, gave a surf beat of 0.0495m. Although slope induced bound long wave is 35% of the flat bed component, the inclusion of this component only reduces the surf beat estimate by 1.5% to 0.0488m. This justified neglect of the slope induced component in the other Shoreham records.

The following empirical relationship was found for the resulting surf beat heights,

$$H_s \text{ (surf beat)} = 0.0074 \frac{H_s^{0.93} T_p^{0.99}}{h^{0.06}} \quad (20)$$

### 3.3 Barrow-in-Furness

Here, the pressure sensor was deployed about 2.5km south of a sand spit, the Isle of Walney, which protects Barrow-in-Furness, on the north west coast of England. Water depths ranged from 4m to 12m due to the tide and locally generated waves occurred with significant heights of up to 2.4m and spectral peak periods of 5s to 8s. Occasional southerly swell from the Irish Sea was able to reach the recorder position with heights of under 1m and spectral peak periods of about 12s.

The seabed slope was very flat at about 1 in 600 and the record with the largest slope induced bound long wave (23% of the 0.10m flat bed component) had a surf beat height of 0.091m which was only 3% less than the surf beat height obtained ignoring the slope induced long wave. This justified neglecting the effect of the slope induced bound long wave.

The following empirical relationship was found for the resulting surf beat heights,

$$H_s \text{ (surf beat)} = 0.0024 \frac{H_s^{1.08} T_p^{1.59}}{h^{0.36}} \tag{21}$$

4. Discussion and results from other sites

Long wave recording was carried out at two other sites, Dover and Sunderland, but the separation into bound long wave and surf beat proved unsatisfactory in that scatter in the data increased after subtraction of the bound long wave. This may have been due to primary wave reflections from the vertically faced harbour breakwaters affecting the measurements. Ignoring such reflections (which could not be quantified) would tend to lead to overestimates of bound long wave energy under the assumptions made in the analysis and this in turn would under-estimate the surf beat. This problem did not arise for Port Talbot because the breakwaters were of rubble mound construction and highly absorbent of waves. At Shoreham the breakwaters were almost perpendicular to the coastline and directed reflections along and onshore rather than offshore towards the wave recorder while there was only a sandy beach at Barrow.

Averaging the powers of the primary wave parameters in (19), (20) and (21) suggests a variation,

$$H_s \text{ (surf beat)} = K \frac{H_s^{1.11} T_p^{1.25}}{h^{0.25}} \tag{22}$$

where the (dimensional) constant of proportionality K has the not dissimilar values of 0.0044, 0.0066 and 0.0041 for Port Talbot, Shoreham and Barrow, respectively. The largest scatter in surf beat heights occurred for the Barrow Data (see Figure 3).

Figure 3 Surf beats off Barrow-in-Furness

This type of result is consistent with the near linear dependence of long wave height on primary wave height found by Tucker (1950) whose measurements appear to have been dominated by surf beat rather than bound long waves. Also, the inverse quarter power of depth (which could of course be fortuitous) is not inconsistent with inverse shoaling of free long waves and high order edge wave modes (Okhiro, 1982).

We can use (22) to predict long wave heights at Shoreham and Barrow for more extreme wave conditions than those measured. [In the case of Port Talbot we already have the data in Table 1]. Limiting primary wave parameters to those where a second order Stokes expansion can be expected to remain valid we obtain the following.

**Table 2** Extreme wave predictions for Shoreham in a depth of 12.4m

Primary waves Return period	$H_s(m)$	$T_p(s)$	Significant long wave height (m)		
			$H_s$ (bound long wave)	$H_s$ (surf beat)	$H_s$ (total)
10 times/yr	3.3	7.5	0.14	0.16	0.21
1/yr	4.0	8.4	0.27	0.23	0.35
1/10 yrs	4.7	9.2	0.45	0.31	0.55

**Table 3** Extreme wave predictions for Barrow in a depth of 13.1m

Primary waves Return period	$H_s(m)$	$T_p(s)$	Significant long wave height (m)		
			$H_s$ (bound long wave)	$H_s$ (surf beat)	$H_s$ (total)
10 times/yr	2.4	7.5	0.10	0.07	0.12
1/yr	4.0	9.2	0.32	0.16	0.36
1/10 yrs	4.8	10.0	0.53	0.22	0.57

These results, together with Table 1, show that surf beat dominates the total low frequency wave energy in frequently occurring conditions while bound long waves tend to dominate in more extreme conditions. Thus, surf beat probably consisting mainly of seaward propagating free long waves and along shore propagating high order edge wave modes, has been shown to be an important component of low frequency wave energy in intermediate water depths typical of harbour entrances. This means that both the bound long waves and surf beat need to be well represented in the modelling of harbour resonance and moored ship motions.

#### Acknowledgements

The author is grateful to Mr J M A Spencer for his help in the writing of the software used for analysis of the data, and to Dr P J Hawkes and Ms C E Jelliman for their help in applying the analysis program to data from the various sites. This work was funded in part by the UK Department of the Environment (CD) and in part by the EC sponsored MAST research programme, G6 Coastal Morphodynamics.

## CHAPTER 63

### INFRAGRAVITY-FREQUENCY (0.005-0.05 HZ) MOTIONS ON THE SHELF

T. H. C. Herbers,<sup>1</sup> Steve Elgar,<sup>2</sup> R. T. Guza,<sup>1</sup> and W. C. O'Reilly<sup>1</sup>

#### ABSTRACT

Extensive field observations in depths between 8-204 m are used to investigate the sources and variability of infragravity-frequency (nominally 0.005-0.05 Hz) motions on the shelf. The predicted local forcing of 'bound' infragravity motions by difference-frequency interactions of swell and sea (Hasselmann, 1962) is verified with array measurements of sea floor pressure in 13 m depth. Observed forced infragravity energy levels agree well with theoretical predictions, but are consistently much lower than the observed total infragravity energy. Wavenumber estimates show that free waves, obeying the surface gravity wave dispersion relation, are frequently the dominant source of energy in the infragravity band. The observed directional properties and cross-shore decay of free wave energy show that refractive trapping, neglected in many current infragravity wave generation models, is of  $O(1)$  importance. Both free and forced wave energy levels generally increase with both increasing swell energy and decreasing water depth, but the observed dependencies of free and forced waves are different. The relative contributions of free and forced waves to infragravity energy on the shelf are therefore highly variable. Comparisons of observations in the same water depth at different sites suggest that free wave radiation is relatively stronger from broad, sandy beaches than from rocky, cliffed coasts.

#### 1. INTRODUCTION

Energy levels of surface elevation, velocity and pressure fluctuations at "infragravity" periods of 0.5-5 minutes, slightly longer than the 2-20 sec periods of typical wind-generated surface gravity waves, are generally weak in the deep ocean (Webb et al., 1991), but can be very energetic close to shore (surface elevation

variances  $O(10^3) \text{ cm}^2$ ; e.g., Wright et al., 1982; Guza and Thornton, 1985). Although numerous field observations have shown that infragravity and swell energy levels are highly correlated (e.g., Munk, 1949; Tucker, 1950; Holman et al., 1978; and many others), the generation mechanisms of infragravity motions on the shelf are not well understood. Nonlinear interaction of two surface waves theoretically excites a forced secondary wave with the difference frequency (e.g., Longuet-Higgins and Stewart, 1962; Hasselmann, 1962). Field observations often exhibit the phase-coupling theoretically expected between groups of swell and forced infragravity motions (e.g., Hasselmann et al., 1963; Elgar and Guza, 1985; Okihira et al., 1992; Elgar et al., 1992). However, qualitative comparisons of theoretically predicted and observed infragravity energy spectra show that forced waves may contribute significantly to infragravity energy when swell and sea are very energetic (Sand, 1982), but account for only a small fraction of the infragravity energy when swell-sea energy is low (Okihira et al., 1992).

It has long been recognized that other contributions to the infragravity band may arise from the strong nonlinearities and wave breaking processes that occur close to shore. Based on early observations by Munk (1949) and Tucker (1950), Longuet-Higgins and Stewart (1962) suggested that, as the incident swells are dissipated in very shallow water through breaking, forced secondary waves may somehow be released as free waves and radiated from the nearshore. As these long-wavelength free waves travel seaward on a sloping beach refractive trapping may occur. Alongshore wavenumber spectra of infragravity motions in the surf-zone show clear evidence of topographically trapped low-mode edge waves (Huntley et al., 1981; Oltman-Shay and Guza, 1987; and others). Observed variations in infragravity energy across the continental shelf (Webb et al., 1991; Okihira et al., 1992) suggest that infragravity motions are predominantly trapped on the shelf with relatively weak radiation to the deep ocean. Various models have been developed that describe the generation of both leaky waves (radiating out to deep water) and edge waves at infragravity frequencies through nonlinear interactions and breaking of incident surface waves (e.g., Gallagher, 1971; Bowen and Guza, 1978; Foda and Mei, 1981; Symonds et al., 1982; Schäffer and Svendsen, 1988; Schäffer et al., 1990; List, 1992; Roelvink et al., 1992; Watson and Peregrine, 1992; and others).

In this paper, preliminary results are presented of a study of free and forced infragravity motions on the shelf, based on array measurements in 13 m depth and single-point measurements in depths ranging from 8-204 m. The field data are described in section 2. In section 3, bispectral analysis is used to decompose the observed infragravity energy in free and forced wave contributions, and the forced waves are compared to predictions of second-order nonlinear theory (Hasselmann, 1962). Wavenumbers and directional properties of free waves are discussed in section 4. The dependence of infragravity motions on water depth and incident wave conditions is examined in section 5, followed by a discussion and summary in section 6. A full account of the observations will be given in Herbers et al. (1992a,b).

## 2. FIELD DATA

The variability of infragravity motions on the shelf is investigated with single point pressure measurements at a variety of locations in both the Atlantic and Pacific oceans. Nine-months of bottom pressure data (September 1990-May 1991) were collected in 8 and 13 m depths, approximately 1 and 2 km offshore of Duck, North Carolina, respectively (Elgar et al., 1992). Three-month-long bottom pressure records were collected in 30-m depth during fall/winter of 1991/92 at 16 locations along the Southern California mainland coast and at 4 locations around Santa Rosa, an island in the Southern California Bight bordered with both steep vertical cliffs and shallow reefs (O'Reilly et al., 1992). Two representative coastal sites with gently sloping sandy beaches (Ventura and Redondo) and one of the Santa Rosa rocky island stations were selected for analysis here. Measurements in deeper water were obtained during a 6-month period in the fall/winter of 1991/92 from a pressure gauge mounted 16 m below the sea surface on Harvest Platform, located at the edge of the California shelf in 204 m depth (Seymour et al., 1985). More detailed results are based on data from a large aperture (250 x 250 m) array of 24 pressure sensors deployed in 13 m depth at Duck (Herbers et al., 1992a). The sample rates of the field data vary between 0.5 and 4 Hz. The data were divided into 170 minutes long records (137 minutes where longer continuous records were not available) for analysis.

The present study is focused on low frequency motions driven by surface waves. To exclude motions driven by other sources, the infragravity band was chosen to be the range in which spectral levels are strongly correlated with swell energy, 0.004-0.05 Hz for observations in the Atlantic and 0.004-0.04 Hz for observations in the Pacific (Herbers et al., 1992b). At frequencies below 0.004 Hz, weak correlations with swell energy suggest that the observed motions may be driven by atmospheric or other processes, not surface waves (e.g., Munk et al., 1956). The upper limit of the infragravity range was conservatively chosen to exclude contributions of low frequency swell.

## 3. FORCED WAVES

A perturbation expansion in weak nonlinearity shows that the interaction between two surface gravity waves with frequencies  $f$  and  $f + \Delta f$  excites a forced secondary wave with the difference frequency  $\Delta f$  (e.g., Longuet-Higgins and Stewart, 1962; Hasselmann, 1962). Accurate predictions of forced wave energy at infragravity frequencies require accurate estimates of the surface wave frequency-directional spectrum  $E(f, \theta)$ , information unavailable in previous studies that used single-point (Hasselmann et al., 1963; Sand, 1982) or pitch-and-roll type (Okhiro et al., 1992) measurement systems. Detailed estimates of  $E(f, \theta)$  for the dominant swell and sea ( $0.06 \text{ Hz} < f < 0.24 \text{ Hz}$ ), suitable for accurate predictions of forced wave energy, were extracted from the array measurements in 13 m depth at Duck. Predictions of the forced infragravity spectrum, based on Hasselmann's (1962) theory and the  $E(f, \theta)$  estimates, were obtained for 15 data runs spanning a wide

range of conditions (Herbers et al., 1992a). In all cases, predicted forced wave energy levels are much lower than observed infragravity energy levels (Figs. 1, 2a).

Fig. 1. Second-order nonlinear theory predictions (asterisks) and bispectrum-based estimates (circles) of the forced bottom pressure spectrum at infragravity frequencies. The observed (total) bottom pressure spectrum is indicated by a solid curve. (a) 26 October 1990. (b) 19 May 1991.

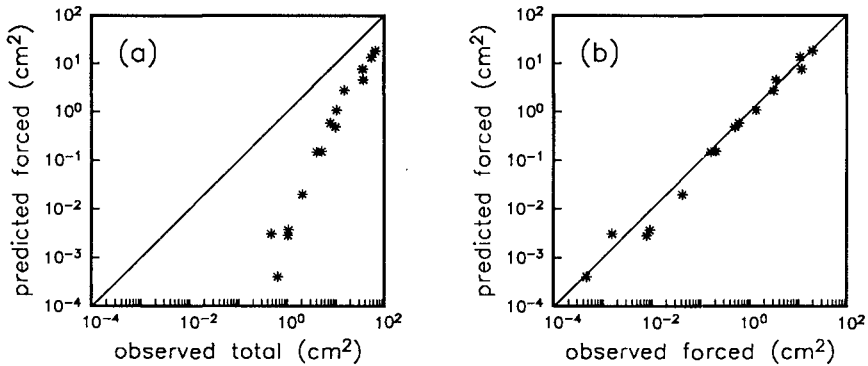

Fig. 2. (a) Predicted forced infragravity energy versus observed total infragravity energy. (b) Predicted versus observed (based on bispectral analysis) forced infragravity energy.

Bispectral analysis (frequency domain analysis of third-order statistics, Hasselmann et al., 1963) is used to estimate forced wave contributions to the infragravity band (Herbers et al., 1992a). Far from shore, free infragravity waves are statistically independent of the local swell-sea and thus do not contribute to the bispectrum. Nonzero bispectral values (i.e., nonGaussian statistics) result from phase-locking between forced waves and pairs of swell-sea components. Estimates of forced infragravity spectra, based on bispectral analysis, agree well with theoretical predictions, as illustrated in Fig. 1 (compare circles and asterisks) for two example cases with significant forced wave contributions to the infragravity band. For all 15 data runs, which span a variation of  $10^5$  in forced wave energy, (bispectrum-based) estimates and theoretical predictions of the total (integrated over the infragravity band) forced wave energy are in excellent agreement (typically within 30 %, Fig. 3b). The observed phase differences between forced waves and groups of swell are within a few degrees of the theoretical value  $180^\circ$  (Herbers et al., 1992a). Overall, the analysis shows that forced waves are accurately predicted by second-order nonlinear theory (Hasselmann, 1962), but their contribution to the infragravity band is relatively small (0.1-30 %, Fig. 2a).

#### 4. FREE WAVES

It has been suggested (e.g., Longuet-Higgins and Stewart, 1962; Symonds et al., 1982; and many others) that the surf-zone radiates seaward-travelling free waves at infragravity frequencies. The observed wavenumbers do indeed show that the remaining, not locally nonlinearly forced, infragravity energy in 13 m depth is caused by freely propagating surface gravity waves. An average wavenumber magnitude  $k_{rms}(f)$ , defined as

$$k_{rms}(f) \equiv \left[ \frac{\int_0^\infty dk \int_0^{2\pi} k d\theta k^2 E(f, k, \theta)}{\int_0^\infty dk \int_0^{2\pi} k d\theta E(f, k, \theta)} \right]^{1/2}, \quad (1)$$

with  $E(f, k, \theta)$  the frequency-(vector) wavenumber spectrum of sea floor pressure, was estimated from the 13-m depth array measurements at Duck (the technique will be described in a subsequent publication). Estimates of  $k_{rms}(f)$  are compared to the linear dispersion relation for surface gravity waves in Fig. 3 on three occasions with negligible forced wave contributions to the total infragravity energy (i.e., Fig. 2a). The observed wavenumbers in the infragravity band are in excellent agreement with the theoretical free-wave dispersion relation.

Both forced and free wave energies are expected to decrease with increasing water depth  $h$  owing to the weakening of nonlinearity and propagation effects, respectively. In shallow water forced infragravity energy is strongly amplified owing to near-resonances and approximately proportional to  $h^{-5}$  (Longuet-Higgins

and Stewart, 1962). On the other hand, the energy of leaky (radiating to deep water), free infragravity waves is approximately proportional to  $h^{-1/2}$  (e.g., Eckart, 1951; see also Elgar et al., 1992). In an earlier study, the observed ratio between total infragravity energy in 13 and 8 m depth at Duck was shown to be close to the theoretical value ( $h^{-1/2}$ ) for leaky free waves when incident swell energy levels are low, and to decrease systematically with increasing swell energy (Fig. 3 in Elgar et al., 1992). This trend was attributed to increasingly large forced wave contributions to the infragravity band with increasing swell energy. The bispectrum-based estimates of forced infragravity energy (section 3) allow for a more quantitative assessment of free wave decay with increasing depth. Free infragravity energy was estimated by subtracting the forced wave energy estimates from the total observed infragravity energy. The ratio  $R$  between free infragravity energy in 13 and 8 m depth is approximately independent of swell energy (Fig. 4), confirming that the trend observed by Elgar et al. (1992) was indeed caused by forced wave contributions. The observed  $R$  vary between 0.4 and 1, with the majority of the observations in the range 0.5-0.7, significantly lower than the theoretical value 0.8 for leaky waves. The observed low values of  $R$  indicate that a significant fraction (typically 10-50 %) of the free infragravity energy observed in 8 m depth is refractively trapped (i.e., has a turning point) between 8 and 13 m depth. According to Snell's law, free long waves travelling seaward at oblique angles greater than  $52^\circ$  in 8 m depth are trapped between 8 and 13 m depth. Hence, the observed low values of  $R$  imply that a significant fraction of free infragravity energy observed close to shore in 8 m depth is travelling at large oblique angles relative to the beach.

Fig. 3. Estimates of an average wavenumber magnitude  $k_{rms}(f)$  as a function of frequency (Eq. 1), obtained from array measurements in 13 m depth at Duck on 7 September (squares), 26 September (triangles) and 8 October (asterisks), 1990. The linear dispersion relation for surface gravity waves is indicated by a solid curve.

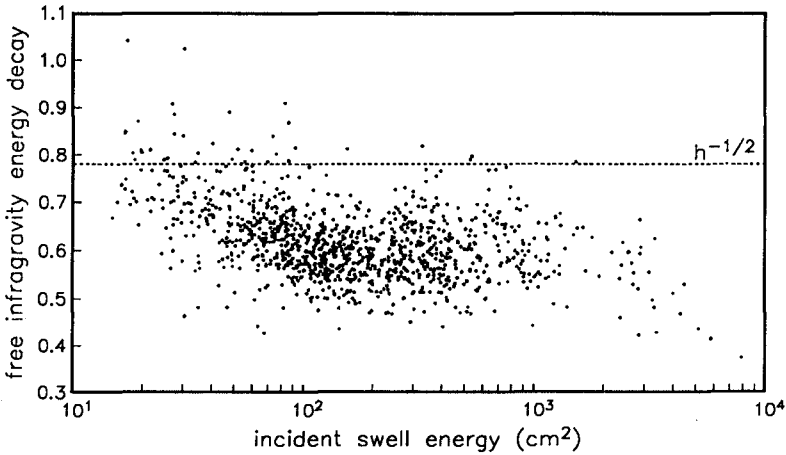

Fig. 4. Observed ratio  $R$  between free infragravity energy in 13 and 8 m depth at Duck versus incident swell energy (observed in 13 m depth). The dotted line labeled  $h^{-1/2}$  indicates the theoretical decay for leaky waves.

For swell energies larger than about  $50 \text{ cm}^2$ , the observations do not suggest a dependence of  $R$  on swell energy, but the relatively few cases with very small amplitude swell (variances  $< 50 \text{ cm}^2$ ) show weaker decay, closer to the theoretical value  $h^{-1/2}$  for leaky waves (Fig. 4). Possibly, these free infragravity motions are not generated at nearby shores but arrive from (and return to) the deep ocean. Observations by Webb et al. (1991) suggest that a small fraction of the free infragravity energy generated at coasts with energetic swell propagates off the shelf into deep water and radiates across ocean basins. These relatively weak background motions may be the dominant source of infragravity energy on the shelf when forcing by local swell is very weak.

Array measurements in 13 m depth confirm that free waves at infragravity frequencies are indeed directionally broad. Examples of estimates of directional distributions of energy at the infragravity (0.02 Hz) and swell (0.1 Hz) spectral peak frequencies, on a day with negligible forced wave contributions to the infragravity band, are shown in Fig. 5. In contrast to the directionally narrow, shoreward travelling swells, the directional distribution of infragravity energy is very broad with approximately equal amounts of energy travelling seaward and shoreward, and a maximum at  $90^\circ$ , corresponding to alongshore travelling waves. Note that although both swell and infragravity maxima correspond to waves travelling in the same upcoast direction there is significant infragravity energy travelling downcoast against the swell.

Consistent with earlier observations inside the surf-zone (e.g., Huntley et al., 1981, Oltman-Shay and Guza, 1987), the observed faster than  $h^{-1/2}$  energy decay with increasing depth and directionally very broad spectra show that refractive trapping is of  $O(1)$  importance to infragravity motions on a natural beach. The

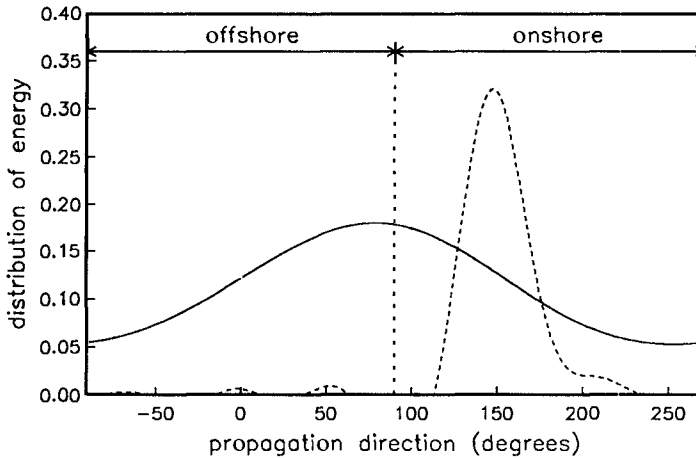

Fig. 5. Directional distributions of free infragravity energy (0.02 Hz; solid curve) and swell energy (0.1 Hz; dashed curve) observed in 13 m depth at Duck on 8 October 1990. The sector 90–270° corresponding to shoreward propagating waves, contains 98 % of the swell energy and 46 % of the infragravity energy.

assumption of uni-directional wave propagation used in current infragravity wave generation models (e.g., Symonds et al., 1982; Schäffer and Svendsen, 1988; Schäffer et al., 1990; List, 1992; Roelvink et al., 1992; Watson and Peregrine, 1992; and others) is inconsistent with the present observations.

## 5. SHELF-WIDE VARIABILITY

The mix of free and forced infragravity energy (Fig. 2a) observed on the inner North Carolina shelf (Duck) in 13 m depth is not necessarily representative of other sites, and is further investigated here using additional long-term bottom pressure measurements collected on the California shelf. Estimates of forced and free wave energy contributions to the infragravity band in 8, 30 and 204 m depth, based on bispectral analysis (section 3), are compared in Figs. 6a and 6b, respectively. Both free and forced infragravity energies are generally well correlated with swell energy (defined as the energy in the range 0.04–0.14 Hz for Pacific sites and 0.05–0.14 Hz for Atlantic sites). In all three depths forced wave energy is approximately proportional to the swell energy squared (Fig. 6a). This quadratic dependence is expected from second-order nonlinear theory because the amplitude of a forced secondary wave is proportional to the product of the amplitudes of the interacting swell components. Since the forced infragravity wave amplitude also depends on the frequencies and the difference in propagation direction of the interacting swell components, the scatter about the line with slope 2 is expected. As expected from theory, forced wave energies fall off rapidly with increasing depth. In 204 m depth

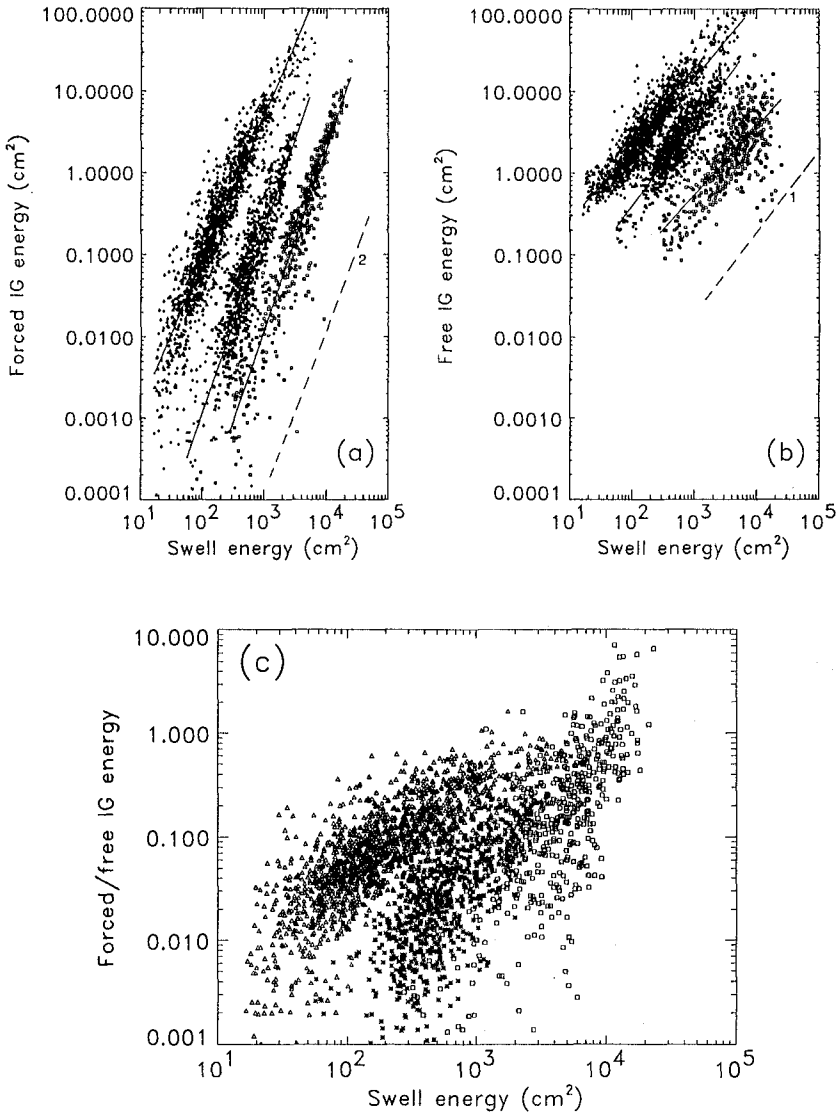

Fig. 6. Forced (a), free (b), and the ratio between forced and free (c) infragravity energies, observed in 8 m depth at Duck (triangles, upper clouds), in 30 m depth at Ventura (asterisks, middle clouds), and in 204 m depth at Harvest Platform (squares, lower clouds), are shown versus swell energy. Least-squares-fit curves to the logarithms of the observed energies are denoted by solid lines. Dashed lines labeled 1 and 2 indicate a linear and quadratic dependence, respectively.

the observed forced wave energy levels are typically smaller by a factor of  $10^2$ – $10^3$  compared to 8 m depth for comparable swell energy (Fig. 6a). The depth dependence observed for free infragravity energy (Fig. 6b) is weaker than observed for forced waves, but stronger than the  $h^{-1/2}$  dependence of leaky waves, consistent with significant refractive trapping of seaward propagating free waves.

In contrast to the strong (quadratic) dependence of forced wave energy on swell energy, in all three depths free wave energy is approximately linearly proportional to swell energy. The observed weak dependence of free infragravity energy on swell energy is not inconsistent with nonlinear generation and reflection at nearby shores, but suggests the importance of wave breaking in the generation process. If nonlinear transfer of energy from shoaling incident swell is the source of free infragravity motions, then the infragravity energy is expected to be roughly proportional to the square of the swell energy. However, the transfer of swell energy to lower frequencies may be arrested when the swell energy is dissipated through wave breaking. As larger amplitude swell break in deeper water farther from shore, the dependence of forced infragravity energy released in the surf-zone on incident swell energy is expected to be weaker than quadratic (Longuet-Higgins and Stewart, 1962). Alternative models (e.g., Symonds et al., 1982; and many others) assume that variations in set-up inside the surf-zone, rather than nonlinear interactions outside the surf-zone, drive free waves in the infragravity band. The solutions to these models (including standing waves within the surf-zone) are quite complicated, but since the driving set-up variations are linearly proportional to the incident swell amplitudes (Longuet-Higgins and Stewart, 1962), free infragravity energy generated inside the surf-zone is expected to be roughly linearly proportional to swell energy, qualitatively consistent with the present observations. A weaker than quadratic dependence of free infragravity energy on swell energy may also result from a nonlinear dependence of free wave damping (in the surf-zone or through bottom friction on the shelf) on swell energy.

The ratio of free to forced infragravity energy at the same three sites (Fig. 6c) is extremely variable, ranging from  $10^{-3}$  to 10. Owing to the different dependencies of free and forced wave energies on incident swell energy and water depth (e.g., compare Figs. 6a and 6b) the relative contribution of forced wave energy to the infragravity band generally increases with both increasing swell energy and decreasing water depth. Overall the present observations (including the sites not shown in Fig. 6, see Herbers et al., 1992b for further discussion) indicate that free waves are the dominant source of infragravity energy on the shelf (well outside the surf-zone). However, forced wave contributions are significant with energetic swell and sometimes dominate the infragravity band even in 204 m depth (e.g., the forced/free wave energy ratios  $> 1$  for swell energy  $> 10^4 \text{ cm}^2$  in Fig. 6c).

## 6. DISCUSSION AND CONCLUSIONS

Although differences in free infragravity energy levels measured in 8, 30 and 204 m depth (Fig. 6b) are qualitatively consistent with propagation (unshoaling and refractive trapping) effects, the observed energy levels may also depend on the

detailed characteristics of the nonlinear shoaling/surf-zone processes close to shore where the free waves are generated. Comparable (within roughly  $\pm$  a factor of 2) free wave energy levels observed in 30 m depth offshore of mildly sloping sandy beaches at various locations along the Southern California coast (not shown), do not indicate a strong sensitivity of the generation of free infragravity energy to the detailed, local beach morphology. However, free infragravity energy levels observed near rocky shores are much lower than observed near sandy beaches, as illustrated in Fig. 7 with comparisons of free and forced wave energy observed in 30 m depth offshore of a sandy beach at Redondo and in 30 m depth offshore of a rocky coast at Santa Rosa Island. The observed dependence of forced wave energy on swell energy is approximately the same at both sites, as expected for local nonlinear effects that depend only on the local water depth and wave conditions. However, for comparable incident swell conditions, free wave energy levels observed at Santa Rosa Island are typically an order of magnitude lower than observed at Redondo. Reflections of incident swell from steep cliffs and localized wave breaking on isolated reefs obviously affects the nonlinear shoaling and surf-zone processes at Santa Rosa Island, and may explain the observed low free infragravity energy levels. The dynamics are not understood but the observations strongly suggest that the generation and/or reflection of free infragravity motions is less efficient on rocky shores than on sandy beaches.

Fig. 7. Forced (a) and free (b) infragravity energies observed in 30 m depth, offshore of the sandy Redondo beach (asterisks, upper cloud in panel b) and offshore of the rocky Santa Rosa Island (squares, lower cloud in panel b), versus swell energy. Least-squares-fit curves to the logarithms of the observed energies are denoted by solid lines.

In summary, results of this study show that motions in the infragravity band (nominally 0.005-0.05 Hz) on the continental shelf are a mix of forced waves, phase-coupled to swell and sea, and free waves generated at nearby shores. The observed forced waves are accurately predicted by second-order nonlinear theory but the generation mechanism of free waves is not well understood. Both free and forced wave energies increase with increasing swell energy but, in contrast to the approximately quadratic dependence of forced wave energy on swell energy, the dependence of free wave energy on swell energy is approximately linear, qualitatively consistent with heuristic models of surf-zone dynamics (e.g., Longuet-Higgins and Stewart, 1962; Symonds et al., 1982; and others). Free and forced wave energies also decrease with increasing water depth owing to a weakening of local nonlinear effects and propagation effects, respectively. The observed free wave decay with increasing depth, although weak compared to the very strong forced wave decay, is much stronger than the decay theoretically predicted for leaky waves radiating to deep water. Refractive trapping of seaward travelling free waves, not included in many current infragravity wave generation models, is important on natural beaches. Very broad directional spectra at infragravity frequencies, with roughly comparable energy travelling seaward and shoreward, confirm that a large fraction of free wave energy radiating from the beach is refractively trapped on the shelf.

## CHAPTER 64

### BREAKPOINT-FORCED AND BOUND LONG WAVES IN THE NEARSHORE: A MODEL COMPARISON

JEFFREY H. LIST

*U.S. Geological Survey, 600 4th St. S., St. Petersburg, FL 33701 U.S.A.*

#### ABSTRACT

A finite-difference model is used to compare long wave amplitudes arising from two group-forced generation mechanisms in the nearshore: long waves generated at a time-varying breakpoint and the shallow-water extension of the bound long wave. Plane beach results demonstrate that the strong frequency selection in the outgoing wave predicted by the breakpoint-forcing mechanism may not be observable in field data due to this wave's relatively small size and its predicted phase relation with the bound wave. Over a bar/trough nearshore, it is shown that a strong frequency selection in shoreline amplitudes is not a unique result of the time-varying breakpoint model, but a general result of the interaction between topography and any broad-banded forcing of nearshore long waves.

#### INTRODUCTION

Recent observations have shown that long period (30-300 sec.) waves often dominate the wave energy spectrum near the shoreline, especially during storms and on dissipative beaches. Despite the evident importance of these low frequency oscillations, also known as infragravity waves, much work is needed to understand the mechanisms by which these waves are generated. This paper concerns the generation of one form of these waves—the leaky modes, normally or near-normally incident long waves whose energy is radiated seaward after shoreline reflection.

Two primary models have been proposed for the generation of leaky modes, both of which depend on forcing by incident wave groupiness. Longuet-Higgins and Stewart (1962) showed that radiation stress gradients in unbroken wave

groups force a second-order sea-surface fluctuation in the form of a phase-locked or bound long wave. Although this concept has been substantiated in both field and laboratory observations (Sand, 1982; Kostense, 1985), it is clear that bound wave theory is not applicable in very shallow water where the Ursell number is large (Longuet-Higgins and Stewart, 1964, Okihiro et al., 1992).

Symonds et al. (1982) proposed an alternate model for leaky mode generation in which incident wave groups produce a forcing region associated with the time-varying position of the breakpoint. This model predicts a characteristic frequency selection in the amplitudes of the outgoing (seaward propagating) long waves. While substantiated by one laboratory experiment (Kostense, 1985), this frequency selection has never been observed in spectra calculated from field data. With an extension to a bar/trough topography, the time-varying breakpoint model also predicts a strong frequency selection in shoreline amplitudes (Symonds and Bowen, 1984), suggesting a resonant phenomenon. However, it has remained unclear whether this apparent resonance is a direct result of the time-varying breakpoint forcing, or just a natural outcome of the interaction between a bar/trough topography and any broad-banded long wave forcing.

In this study, a numerical scheme (List, 1988b, 1992) is used to investigate the relative magnitudes of the breakpoint-forced long wave (hereafter BFLW) and bound long wave (BLW), as well as the specific predictions of the breakpoint-forcing model described above.

## MODEL FORMULATION AND RUN PARAMETERS

List (1988b,1992) constructed a finite-difference solution to the equations of cross-shore ( $x$ -directed) continuity and momentum given by

$$\frac{\partial \eta}{\partial t} + \frac{\partial(hu)}{\partial x} = 0 \quad (1)$$

$$\frac{\partial u}{\partial t} + g \frac{\partial \eta}{\partial x} = -\frac{1}{\rho h} \frac{\partial S_{xx}}{\partial x} \quad (2)$$

where  $\eta$  and  $u$  are the time-averaged (over the incident wave period) sea-surface and vertically-integrated cross-shore current respectively,  $h$  is the water depth, and  $S_{xx}$  is the radiation stress in the cross-shore direction. An incident waves model provided non-steady  $S_{xx}$  gradients in both broken and unbroken waves through the surf zone over arbitrary topography. Incident waves were modeled as the wave envelope, which progressed over the bottom topography at the shallow water phase speed, shoaling and breaking as a function of the water depth. Long waves were generated throughout the nearshore by both the time-varying breakpoint and bound wave mechanisms. Long waves were reflected from a vertical wall near the shoreline, where the depth is  $\geq$  the long wave

amplitude. This mode of shoreline reflection crudely approximates natural reflection from a sloping beach, though the position of the shoreline is shifted seaward. (Although the depth at the reflection point can be a large fraction of the long wave amplitude, the model does not permit breaking.) Following shoreline reflection, waves propagate seaward and exit from the model through a radiative boundary condition. Support for the model came from an accurate simulation of the cross-correlation signal between groups and long waves from random wave records both inside and outside a natural surf zone. Key to the present study, a means of separating the BFLW and BLW components was demonstrated in which the model is run separately with BFLW forcing only, BLW forcing only, or total combined forcing.

Here, the model is run with both a plane beach (slope  $\tan \beta = 0.025$ , Fig. 2) and the idealized bar/trough topography of Symonds and Bowen (1984) (Fig. 3). Incident waves, again parameterized as the wave envelope, enter the model at depth  $h = 15$  m, requiring a minor extension to the model described above to allow for intermediate-depth phase speeds for wave groups. Model runs are conducted at a series of discrete group frequencies defined by the beating of incident wave pairs (Table 1). Except for runs generating only the BFLW, an incoming BLW at the boundary was specified following Ottesen Hansen et al. (1981). As shown in Table 1, this gives an input BLW magnitude that is almost negligible compared to long wave amplitudes generated by the model in shallower water.

For the plane beach case, the model was run with a distance step  $\Delta x = 7.5$  m, a time step  $\Delta t = 0.5$  sec., and a shoreline reflection depth  $h_o = 0.49$  m. Plane beach results other than for the conditions reported in Table 1 are given by List (1988b). For the bar/trough case, the model was run with  $\Delta x = 5.0$  m,  $\Delta t = 0.25$  sec., and  $h_o = 0.26$  m. The different choice of parameters for the bar/trough case was related to geometric constraints; as discussed by List (1992), the choice of time step has no significant influence on the results. Other model parameters were the same as used by List (1992).

Wave amplitudes reported below were found from model-generated time series of a length of at least one group period,  $T_g$ , after an initial interval for model stabilization. For the plane beach results, amplitudes were found from the interval  $t = 200 \rightarrow 400$  sec., while for the bar/trough results amplitudes were found from  $t = 700 \rightarrow 900$  sec.; the need for a much later start time for the bar/trough case will become apparent below.

## RESULTS

*Plane Beach*

Figure 1A gives the amplitude of the long waves at the shoreline ( $h_o = 0.49$  m reflection point) for model runs in BFLW, BLW and total forcing modes for the plane beach case. Except at the lowest frequencies, the BLW is predicted to be larger than the BFLW. Interestingly, the long waves generated in total forcing mode are lower at all frequencies than the sum of the BFLW and BLW. There is also a systematic variation in the degree to which the sum of the BFLW and BLW is destructive, with the total solution being less than either the BFLW or BLW at low frequencies, while at high frequencies the total solution amplitude is nearly identical to the BLW. An investigation of the phase between the envelope,  $A(t)$ , and the BLW seaward of the surf zone as well as between the BFLW and BLW near the shoreline, shown in Fig. 2, explains this model result. As the BLW progresses into shallow water, it lags behind the group structure, with higher frequencies showing a greater departure from the deepwater  $180^\circ$  relationship with  $A(t)$ . Higher frequencies are then closer to a  $90^\circ$  relation with the BFLW in the surf zone, resulting in a less destructive interference. This lag of the BLW behind  $A(t)$  has been shown previously by Elgar and Guza (1985) and List (1992).

Figure 1B shows the amplitude of the outgoing sea-surface component,  $\eta(off)$ , found by separating the onshore ( $\eta(on)$ ) and offshore ( $\eta(off)$ ) progressive long wave components following Guza et al. (1985). Model results are again shown for runs in BFLW, BLW, and total forcing modes, with the BLW now a free long wave after shoreline reflection. The BFLW clearly shows the frequency selection predicted by Symonds et al. (1982). The amplitude of the total solution relative to the BFLW and BLW indicates a highly variable phase relation between the BFLW and BLW for these outgoing waves. However, the net result is that the total solution amplitudes do not show a distinctive structure, apart from a general increase with increasing frequency.

*Bar/Trough Nearshore*

Figure 4 gives the amplitude of the long waves at the shoreline ( $h_o = 0.26$  m reflection point) for model runs in BFLW, BLW and total forcing modes over the bar/trough profile of Symonds and Bowen (1984) (Fig. 3). While the overall trends are similar to the plane beach case (Fig. 1A), there are now marked peaks at  $f_g = 0.0172$  Hz and  $f_g = 0.0309$  Hz for all forcing modes. Except for a frequency shift in the peaks due to a shoreline reflection point with  $h_o > 0$ , the structure is almost identical to that predicted by Symonds and Bowen (1984). The most striking result in Fig. 4 is that the shallow water

bound wave is just as likely to force the distinctive set of shoreline peaks as the breakpoint-forcing mechanism.

Because the above results suggested that the forcing mode is irrelevant to the generation of the peaked amplitude spectrum, a test was conducted in which all incident wave forcing was turned off, leaving only the solution to eqns. (1) and (2) with a small input long wave of variable frequency. For Figs. 5 and 6 the model was run in this mode at a series of discrete frequencies with  $\Delta x = 5.0$  m,  $\Delta t = 0.5$  sec, and an incoming long wave at  $x = 400.0$  m ( $h = 5.2$  m, Fig. 3) with amplitude  $A = 0.01$  m for all frequencies. Shoreline amplitudes were found at a reflection point with  $h_0 = 0.1$  m. These parameters were changed from the forcing-inclusive runs to improve model efficiency; the qualitative interpretation of the results is unaffected.

With the model configured in this way, the peaked shoreline amplitude structure is reproduced once more, as shown in Fig. 5 ( $t = 700$  sec. curve). (Note that the peak frequencies are again shifted due to a different depth of shoreline reflection,  $h_0$ .) This demonstrates that the Symonds and Bowen (1984) result can be reproduced by any model that generates a white spectrum of long waves incident to a bar/trough nearshore.

Symonds and Bowen (1984) suggested that these peak frequencies satisfy a "half-wave resonance" condition, in which an antinode in  $\eta$  corresponds with the bar crest. The characteristics of this potential resonance are investigated here by examining the time development of the amplitude structure. Fig. 5 shows long wave amplitudes found from group period length intervals starting at two different times:  $t = 110$  sec., or just after input long waves have reached the shoreline, and  $t = 700$  sec. after time for model stabilization. Except at the lowest frequencies, the amplitude of the  $t = 110$  sec. curve is almost invariant with frequency, at a level of about 0.05 m. This is the expected value for the shoreline amplitude of a standing wave, given shoaling of the  $A = 0.01$  m input wave from  $h = 5.2$  m to  $h = 0.1$  m. After 700 seconds there is a strong amplitude increase at the "half-wave resonance" frequencies, supporting the concept that these frequencies represent a resonant condition.

However, two other observations complicate this otherwise straightforward interpretation of a resonant phenomenon. First, as shown in Fig. 5, the non-resonant frequencies actually decrease in amplitude over time. Although this was also seen by Symonds and Bowen (1984) in a comparison between their bar/trough and plane beach results, the reason for this model result is not known. Second, the model as formulated using eqns. (1) and (2) contains no term for frictional dissipation; "resonant" peaks should continue to grow in amplitude until model depth limits are exceeded. However, as shown in Fig. 6, this is not the case; with time, peak and valley amplitudes reach a stable value. List (1988a) predicted the same shoreline structure using leaky mode solutions over the Symonds and Bowen profile, suggesting that the peak/valley result

relates more to an uneven distribution of wave energy across the nearshore than to a true resonance.

## DISCUSSION

The prediction of a strong, apparently linear, dependence of the BLW magnitude on the group frequency, shown in Fig. 1A, may be an artifact of the model simplifications, especially the lack of an energy balance between short and long waves. Field observations do not in general support this result. More recent models (e.g. Roelvink, 1991; Roelvink et al., this volume; Watson and Peregrine, this volume) may address this problem, although these models have not yet been directly tested in this respect. Thus the model result that the total outgoing wave will not show a distinctive frequency selection, as predicted by Symonds et al. (1982), is tempered by this problem.

In fact, some laboratory data do show a frequency selection in the outgoing wave (Kostense, 1985); this same pattern is reproduced, at least qualitatively, by the model of Roelvink et al. (this volume). However, modeling of a field data set (List, 1992) suggests that the BLW can be much larger than the BFLW, at least under certain conditions. In this case the outgoing long wave will not show a strong frequency selection. Consistent with this is the lack of supporting field observations showing a strongly peaked spectrum in the long waves offshore, despite a decade of nearshore field experiments since the Symonds et al. (1982) prediction. The results presented in this paper suggest that while the breakpoint-forcing mechanism may be valid and operative, the wave generated by this means has an amplitude and phase relation to the BLW such that a frequency selection in the outgoing wave will not be strong, explaining the lack of this type of field observation.

Although the bar/trough results clearly show that any white long wave forcing can result in a distinctly-peaked elevation spectrum at the shoreline, an explanation of this result as a resonant phenomenon, as suggested by Symonds and Bowen (1984), is subject to questions concerning the mechanism for lowering the amplitudes at non-resonant frequencies and for limiting the overall response. Clearly more work is needed to understand the nature of this interaction between topography and long wave dynamics.

## CONCLUSIONS

A possible explanation for the lack of field observations showing a strong frequency selection in the seaward propagating long waves, as predicted by the Symonds et al. (1982) model, is proposed. The breakpoint-forced long wave's relatively small size and phase relation with the wave originating as a bound wave may preclude this observation.

It is also shown that a strongly peaked elevation spectrum at the shoreline in the presence of a bar/trough topography (Symonds and Bowen, 1984) is not a unique result of the time-varying breakpoint model. It is demonstrated that any white forcing of long waves incident to a bar/trough nearshore can produce this result. Accounting for this frequency selection as a resonant phenomenon will require an explanation of several unusual observations related to the time development of this peak/valley structure.

**Figure 3.** Bar/trough profile from Symonds and Bowen (1984). The profile used for model runs here (Figs. 4, 5) extends linearly to  $h = -15$  m, where wave groups enter the model over a constant depth segment as in Fig. 2.

**Figure 4.** Model-generated long wave amplitudes of  $\eta$  at the shoreline point of reflection using the bar/trough profile (Fig. 3).

**Figure 5.** Model-generated long wave amplitudes of  $\eta$  at the shoreline point of reflection using the bar/trough profile. Incident wave forcing has been turned off and long waves are input at the offshore boundary at a series of discrete frequencies, each with  $A = 0.01$  m. Long wave amplitudes were found by searching model-generated time series (obtained from independent model runs at each frequency) over an interval equal to the group period,  $T_g$ , starting at the times indicated.

**Figure 6.** Time development of three peak and two valley amplitudes shown in Fig. 5. Start time refers to the time at the beginning of the interval,  $T_g$ , for finding amplitudes from model-generated time series.

## CHAPTER 65

### The effect of waves on surges in the North Sea

C. Mastenbroek<sup>1</sup>

#### Abstract

Three effects of surface gravity waves on storm surges in the North Sea are studied with numerical models. The enhancement of the effective sea surface roughness due to growing waves causes the storm surge to build up more quickly. The maximum effect on the waterlevel along the English and Dutch coast is about 5 % of the total waterlevel elevation due to the storm. The effect of the radiation stress is opposite: it slows down the building up of the surge in the beginning of the storm. The maximum effect of the radiation stress is about 2 %. The enhancement of the bottom drag by swell in shallow water can be considerable. The lack of detailed insight in the local bottom roughness and the turbulence near the bottom defies a quantitative analysis.

## 1 Introduction

Waves influence both the generation and the decay of storm surges. In this paper three effects of waves on storm surges are discussed: the enhancement of the surface stress due to growing waves, the contribution of radiation stress and the enhancement of the bottom stress by swell in shallow water. During their generation, surface waves subtract this momentum from the atmospheric boundary layer. Some 60 to 90 % of the momentum transfer from the atmosphere to the currents goes via waves on the surface. This changes the structure of the atmospheric boundary layer. Until recently, the roughness of the sea surface was thought to be a function of the friction velocity only (Charnock, 1955).

---

<sup>1</sup>Royal Netherlands Meteorological Institute (KNMI), P.O. Box 201, 3730 AE de Bilt, the Netherlands

This leads to a drag coefficient which is roughly proportional to the windspeed. In recent years it has been shown by experiments, numerical simulations and analytical models that the sea state plays an important role in the transfer of momentum to the sea. If the waves extract a large amount of momentum from the atmosphere, which happens in the case of growing waves, the apparent roughness of the surface is enhanced. If on the other hand the phase speed of the waves is comparable to the windspeed and the waves do not grow, the roughness of the sea is relatively small. Since the growth of waves is concentrated in the first part of a storm, the generation of a storm surge will be enhanced during this period.

The second consequence of waves carrying momentum is that they are capable moving it around. In the equation for the total momentum balance, this gives rise to an additional advection term: the so-called radiation stress. At places where waves break or dissipate otherwise, this term can give rise to a wave set-up of several decimeters (Bertotti and Cavaleri, 1985) and long-shore currents (Battjes, 1974). Though this effect can be large locally, in this paper we will argue that on the scale of several tens of kilometres or larger it is of little significance. On that scale, to a very good approximation momentum goes directly from the atmosphere to the currents. This is caused by the fact that the waves carrying most of the momentum are short and dissipate quickly. Swell, which is capable of travelling a long way, carries little momentum compared to the short waves generated in the same storm.

Waves can also influence a storm surge via the bottom. If the depth of the water is comparable to the dominant wavelength, orbital wave motions reach to the bottom. This enhances the turbulent mixing near the bottom, which in its turn enhances the bottom friction felt by currents. The effect is largest in shallow regions which can be reached by swell from the open sea and where strong currents are present. In the North Sea this includes for instance the English Channel and the Bristol Channel. A few problems arise if we want to model this effect. The layer near the bottom where the orbital motions of the waves and the current interact is typically a few centimetres wide. No current measurements are available this close to the sea bed. This makes it impossible to verify theory directly. Another problem is the large variation in roughness of the seabed on the continental shelf. Compared to the errors made in the assumptions of these roughnesses the effect of the waves may be insignificant.

In the following sections the influence of waves on storm surges in the North Sea will be studied by numerical simulation. In section 2 the effect of growing waves on the storm surge elevations is discussed. The effect of the redistribution of momentum by waves is the subject of the following section. The last section focuses on the bottom roughness enhancement by long waves.

## 2 Effect of Waves on the Surface Stress

To simulate the elevations due to the tide and the storm a barotropic storm surge model of the continental shelf is used (Verboom et al, 1992). This numerical model solves the depth averaged Reynolds equation and the continuity equation with a resolution of 16 km. The waterlevels on the open boundaries, located in deep ( $> 200$  m) water, are prescribed by 10 tidal constituents. The surface stress is derived from the wind at 10 meter calculated by a regional meteorological model. In the standard version the wind is related to stress using the Charnock relation:  $z_0 u_*^2/g = \alpha$ , where  $z_0$  is the roughness length which determines the wind profile,  $u_*$  is the friction velocity,  $g$  is the gravitational acceleration and  $\alpha = 0.032$  is a constant found by tuning the model. The windprofile is assumed to be logarithmic:

$$u(z) = \frac{u_*}{\kappa} \ln\left(\frac{z}{z_0}\right), \quad (1)$$

where  $u(z)$  is the windspeed at height  $z$  and  $\kappa = 0.4$  is the von Karman constant. For given windspeed at a certain height these two equations yield  $u_*$  and  $z_0$ . The definition  $u_* = \sqrt{\tau/\rho_a}$  gives the windstress  $\tau$ .

To model the effect of waves on the momentum transfer the theory described by Janssen (1992) was used. In this theory, Janssen assumes that the momentum is transferred to the water by the turbulence and via the waves. To calculate the contribution of the waves a wave model is needed. In this research a regional implementation of the third generation WAM model was used (WAMDI, 1988). In fig. 1 an overview is given of the three models involved: the meteorological model, the wave model and the storm surge model. In the theory of Janssen, waves act to increase the effective roughness of the surface in the following way:

$$z_e = \frac{z_0}{\sqrt{1 - \tau_w/\tau}}, \quad (2)$$

where the roughness length  $z_0$  is given by the Charnock relation:  $z_0 = \tilde{\alpha} u_*^2/g$  with  $\tilde{\alpha} = 0.01$ . The windprofile is given by:

$$u(z) = \frac{u_*}{\kappa} \ln\left(\frac{z + z_e - z_0}{z_e}\right). \quad (3)$$

The total stress is now calculated in the following way. First, the wind at 10 meters  $u_{10}$  is obtained from a meteorological model. Using a wave model, the flow of momentum  $\tau_w$  to the waves is calculated with this wind. The equations (2), (3) and the Charnock relation give an implicit set of equations from which  $\tau$  (or  $u_*$ ),  $z_0$  and  $z_e$  can be obtained. Sometimes it is necessary to repeat this procedure, since the wave stress  $\tau_w$  depends on  $u_*$ . However, it converges very quickly and in practice no more than two iterations are required.

The coupled storm surge model has been compared with the standard version for several recent storm periods (Mastenbroek et al, 1992). Results from both versions have been compared with waterlevel measurements along the English

and Dutch coast. It is found that the elevations calculated with the coupled model are in good agreement with measurements. This is important because it means that the description of the flow of momentum according to Janssen is consistent with the momentum balance of the waves. A more detailed analysis reveals that the drag coefficient, defined as  $C_d = u_*^2/u_{10}^2$ , can vary a factor two depending on the sea state. Growing waves, dominant during the first part of the storm, enhance the drag considerably. This is illustrated in fig. 3. Due to this enhancement of the momentum transfer in the first part of the storm, the storm surge builds up more quickly. The maximum difference between elevations calculated with the coupled model and the reference model is about 10 cm, which is about 5 % of the total elevation due to the storm. This small difference disappears in the noise caused by measurement uncertainties and errors in the numerical model.

### 3 Transportation of Momentum by Waves

Due to the fact that propagating waves carry some momentum with them, an additional advection term arises in the balance equation for the total momentum, the so-called radiation stress term. The total momentum is the sum of the momentum of the depth averaged current and the momentum associated with waves. In terms of the wave spectrum  $F(f, \theta)$ , where  $f$  is the frequency and  $\theta$  the propagation direction, the radiation stress  $\tau_i$  in deep water is given by:

$$\tau_i = \rho g \nabla_j \int_{-\pi}^{\pi} \int_0^{\infty} \left\{ \frac{c_g}{c} \frac{k_i k_j}{k^2} + \left( \frac{c_g}{c} - \frac{1}{2} \delta_{ij} \right) \right\} F(f, \theta) df d\theta. \quad (4)$$

In the numerical experiment discussed here, the radiation stress is calculated from the wave spectrum of the regional WAM model mentioned above. It is then subtracted from the wind stress. The calculations show that the waves transport away less than 5 % of the total stress applied by the atmosphere. The rest either goes directly to the currents by means of a tangential turbulent stress or via waves that dissipate within one time interval (3 hours) between to consecutive windfields in the same gridbox where they were generated. In the case of the storm of 12/13 December 1990, dissipating waves exert a force on the water of up to 0.15 N/m<sup>2</sup> for a period as long as 12 hours on the Doggerbank. This corresponds to a windspeed of more than 10 m/s. This leads, in the case this storm, to an extra current of 3 cm/s to the South West on the Doggerbank and to an increase in the waterlevel along the English South East coast and the Dutch coast of 5 cm. During the storm of 13/14 February 1989, when the maximum winds were directed more to the East, the maximum force exerted by dissipating waves on the watercolumn occurred in the German Bight, raising the waterlevel a few centimetres along the German coast. Unfortunately these differences are small compared to the accuracy of the surge model and the measurements. The comparison of waterlevel measurements and calculations does not lead to conclusive evidence in favour or against the phenomenon discussed here.

## 4 Effect of Waves on the Bottom Stress

In most 2D storm surge models the bottom stress  $\tau_b$  is parametrised like  $\tau_b = \rho_w f_c \bar{u}^2$ , where  $\bar{u}$  is the depth averaged current. The bottom friction coefficient  $f_c \simeq 0.0025$  is constant. From recent experiments (Gross et al, 1992) it is known that waves have an important influence on this coefficient. A theoretical model of the effect of the orbital motions of waves on the turbulence near the bottom is given by Christoffersen and Jonssen (1985). For typical values for the North Sea, this theory predicts a significant variation of the bottom stress depending on the sea state. To model the effect of waves on the turbulence near the bottom, first an assumption has to be made for the turbulence in absence of waves. A convenient assumption is to parametrise the vertical exchange of horizontal momentum with an eddy viscosity  $\mu$ :

$$\tau = \rho_w \mu \frac{\partial u}{\partial z}. \quad (5)$$

The assumption that this eddy viscosity is proportional to the distance to the bottom  $\mu = \kappa u_* z$  leads to a logarithmic velocity profile  $u(z) = (u_*/\kappa) \ln(z/z_0)$ . The profile depends on an integration constant  $z_0$  which is usually associated with the roughness of the bottom. If the profile is integrated over the depth  $h$ , it can be found that the bottom friction coefficient equals:

$$f_c = \frac{\kappa^2}{(\ln(h/z_0) - 1)^2}. \quad (6)$$

Note that the assumption  $f_c = \text{constant}$  implies that the bottom roughness  $z_0$  is proportional to the water depth. The amplitude of the orbital motions at the bottom of a wave with amplitude  $a$  are  $u_w = (a\omega)/\sinh(kh)$ , where  $\omega$  is the angular frequency and  $k$  the wavenumber. This periodic motion causes an enhancement of the turbulent viscosity near the bottom in a region (the so-called *wave boundary layer*) which is typically a few centimetres wide. The apparent roughness felt by the current will be enhanced, leading to an enhancement in the bottom friction coefficient. In fig. 2 the bottom friction is given as a function of the wave height for a set of parameters which are typical for the North Sea.

In order to study the sensitivity of a storm surge model to a wave dependent bottom drag, a storm surge model (Flather, 1984) has been coupled to a wave model. If the results of this coupled model are to be compared with results from the conventional model, we have to assume that the roughness  $z_0$  is proportional to the depth. This is not based on a physical consideration, but it is implied by taking the bottom drag coefficient  $f_c$  constant in the conventional model. The calculations were performed for the storm surge which occurred 1 February 1983. Two regions on the continental shelf seem to be specifically sensitive to a wave dependent bottom drag: the English Channel and the Bristol Channel. Both of these regions are relatively shallow, have an open connection to the sea and sustain large currents. On the Doggerbank, which is shallow and experiences

large waves from the North, the drag coefficient is affected considerably. But on this location the currents are small, so the extra energy loss to the bottom due to the waves is small.

To make a quantitative analysis rather than a qualitative, several problems should be solved. First of all the modelling of the turbulence in the watercolumn in absence of waves should be made more sophisticated, specifically near the bottom. This will require a three dimensional model. Second, to test and calibrate theories such as the one discussed above, turbulence measurements near the bottom are needed. The interaction with ripples and other features on the bottom should be examined. Finally a bottom roughness map should be compiled for all relevant shallow areas.

## 5 Conclusions

- Growing wind sea enhances the wind stress in the beginning of the storm considerably. After a few hours this enhancement disappears. In the case of the North Sea, the maximum effect on the water level is about 5 % of total elevation due to the storm.
- In a growing sea, the radiation stress modifies the wind stress no more than 5 %. When swell generated in the Norwegian Sea reaches the shallow parts of the North Sea a radiation stress can be as large as  $0.15 \text{ N/m}^2$ . The maximum effect on the waterlevel along the English and Dutch coast is about 2 % of the total elevation due to the storm.
- The modification of the bottom stress by waves is important in shallow regions which can be reached by swell and which sustain large currents. Specific knowledge about the local bottom roughness and turbulence near the bottom is needed to make quantitative statements.

Fig. 3. Bottom drag coefficient  $f_c$  as a function of significant wave height for a typical North Sea case (depth is 40 m, wave period is 8 sec). The three line represent different sea bed roughnesses:  $z_0$  is 5, 3.3 and 1.7 mm from top to bottom.

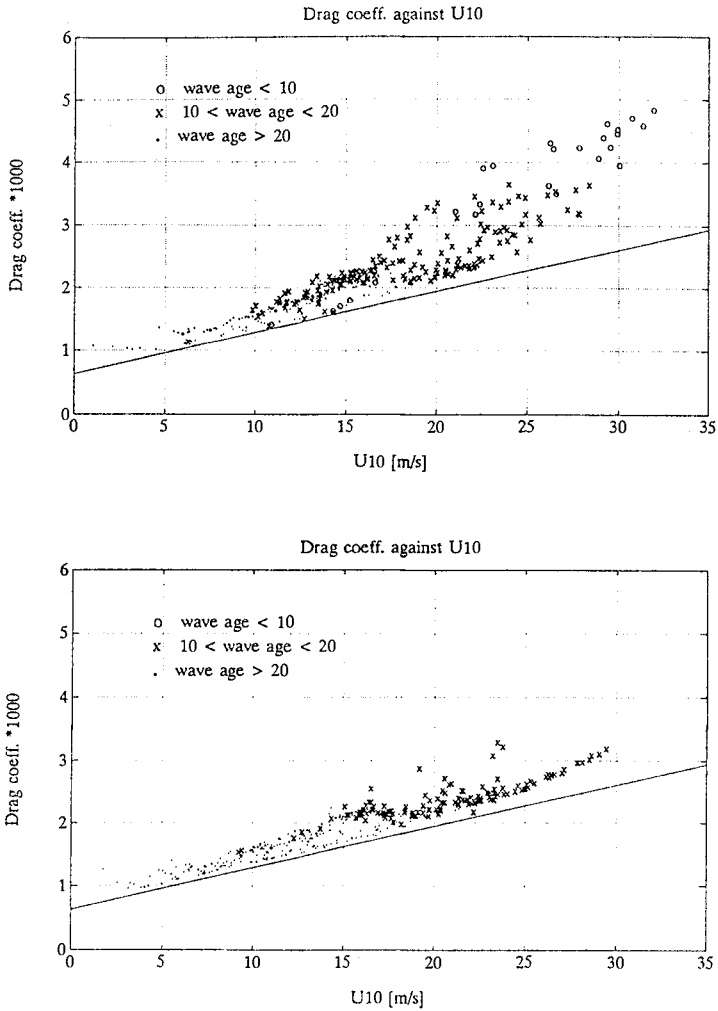

Figure 2: Scatter plots of the drag coefficient against windspeed at two different stages in the storm of 12 December 1990. Above, at the beginning of the storm, a lot of young sea is present. Below, 9 hours later, the waves are older. The wave age is defined as the phase velocity of the peak frequency divided by the friction velocity:  $c_p/u_*$ .

## CHAPTER 66

### DISTRIBUTION OF UNDERTOW AND LONG-WAVE COMPONENT VELOCITY DUE TO RANDOM WAVES

Akio Okayasu<sup>1</sup> and Hiroyuki Katayama<sup>2</sup>

#### Abstract

Laboratory measurements were performed on cross-shore velocity variations in the surf zone caused by random waves by using a laser Doppler velocimeter. Two-dimensional distributions of undertow and long-wave component velocity were obtained on a uniform slope bed and a bar-type beach. A model was presented to estimate undertow distribution due to random waves on an arbitrary beach topography.

#### 1. Introduction

In order to predict the sediment transport and the material diffusion in the surf zone, it is necessary to evaluate the velocity distribution of undertow with high accuracy. In the last decade, many detailed laboratory measurements related to the velocity distribution in the surf zone were performed under regular wave conditions [see e.g. Stive and Wind (1982), Nadaoka and Kondoh (1982) and Okayasu *et al.* (1986)]. In these researches, it was pointed out that the characteristics of waves and velocity fields change significantly around breaking or plunging points. The mass flux due to waves and vertical profiles of undertow also differ between the outer and inner region of the surf zone. On the basis of the experimental results, some theoretical and numerical models have been presented to estimate the undertow distribution by, such as, Svendsen (1984), Nadaoka and Hirose (1986), Tsuchiya *et al.* (1988) and Okayasu *et al.* (1990).

---

<sup>1</sup> Research Associate, Department of Civil Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240, Japan

<sup>2</sup> Graduate Student, Department of Civil Engineering, Yokohama National University, Hodogaya-ku, Yokohama 240, Japan

However, the actual wave field is random. Velocity measurements under random wave conditions and models based on them are needed for practical use. Sato *et al.* (1988) performed laboratory measurements of near-bottom velocity in the surf zone under random wave conditions by using a laser Doppler velocimeter (LDV). Isobe (1983) and Mckee Smith *et al.* (1992) measured nearshore velocity in the field, then investigated the vertical distribution of cross-shore steady current. However, the number of measuring points was not enough for the quantitative discussion.

In the present study, laboratory experiments were performed for random wave conditions to measure cross-shore velocity in the surf zone by using LDV. The beach topographies were a 1/20 constant slope and a bar-type beach. Then a model was investigated to estimate the undertow distribution due to random wave breaking on an arbitrary beach topography by applying a model for regular wave conditions.

In recent years, the importance of long-wave component velocity on the sediment transport have been recognized in and near the surf zone, especially in terms of the suspended sediment transport. In this study, the velocity distribution of long-wave component in the surf zone is also investigated.

## 2. Experimental arrangements

The experiments were performed in a wave flume which was 17 m long and 0.5 m wide. A random wave generator with absorption control for reflected waves was equipped at one end of the flume. Beach topographies were a 1/20 uniform slope and a bar-type beach. The bar-type beach consisted of the first 5 m of 1/20, the next 1 m of  $-1/20$  and the last 4 m of 1/20 slopes. The bottom of the slopes were smooth. The figure 1 shows the side view of the flume with the bar-type beach.

Regular and random incident waves were used for the case of uniform slope beach to investigate the difference in the velocity field. The random waves (case 1) had the Bretshneider-Mitsuyasu spectrum and the significant wave height and period were planed to be almost same values as the wave height and period of the regular waves (case 2). In cases 3 and 4, velocity was measured on a bar-type beach for two random waves which had different significant wave heights and periods. The waves broke just before the top of the bar in case 3, and they began to break offshoreward away from the bar in case 4. The still water depths in the offshore regions,  $h_i$ , were 35.0 cm in cases of the uniform slope and 32.0 cm for the bar-type. The water depth at the top of the bar was 7.0cm. The experimental conditions are listed in Table 1. In the table,  $T$  is the wave period,  $H_i$  the wave height in the offshore region. For random waves, they are noted as the values for significant waves analyzed by using the zero-down cross method.

Fig. 1 Side view of the flume (bar-type beach).

Table 1 Experimental conditions

case	beach type	$h_i$ (cm)	$T$ (s)	$H_i$ (cm)	wave condition
1	uniform	35.0	1.20	7.85	regular
2	uniform	35.0	1.26	8.28	random
3	bar-type	32.0	0.945	5.67	random
4	bar-type	32.0	1.14	7.52	random

Seven vertical measuring lines were set on the beach model in each case, which covered the whole surf zone. Along these lines, several measuring points were arranged vertically from 2 mm above the bottom to the mean water level in every 3 to 40 mm. The distance from the points to the side wall of the flume was 16 cm. The total number of the measuring points were 49 for the uniform slope beach and 53 for the bar-type beach. The  $x$ -axis and  $z$ -axis were set to be onshoreward and vertically upward, respectively. The origin of the co-ordinates was the shoreline at the still water level.

An one-component LDV (15 mW, He-Ne) was used to measure the cross-shore velocity. The data of water surface elevation above the measuring point were also taken simultaneously by using a capacitance-type wave gage. The velocity and wave profile data were sampled every 20 ms and were stored in a digital data recorder.

For regular wave condition (case 1), the ensemble mean value of velocity was obtained as the average at the same phase of waves over 100 wave period. The steady current was calculated from those ensemble mean values. In case of random wave conditions, data were recorded for 5 minute (3 minute for case 2) after 3 minute of wave generating to make the wave field steady in every measurement. When the velocity was repeatedly measured at each point, the same incident signal for random waves was used in each case.

The long-term gradual fluctuation of the output voltage from the LDV system may seriously affect the precision of the velocity measurement, especially for the steady current, because the value of steady current is usually far smaller than the amplitude of the orbital velocity by waves. Therefore, the output signal from the LDV system in the still water condition was recorded for every measuring point and was used to compensate the zero level of the recorded velocity.

### 3. Experimental results

In random wave conditions, the cross-shore velocity  $u$  and the water surface elevation  $\eta$  can be divided into 4 components in terms of frequency  $f$ . They are, steady components  $U$  and  $\bar{\eta}$ , long-wave components  $u_l$  and  $\eta_l$ , short-wave components  $u_s$  and  $\eta_s$  and turbulence components  $u_t$  and  $\eta_t$ . In the present study,  $u_l$  and  $\eta_l$  were defined as  $f < 0.3$  (Hz),  $u_s$  and  $\eta_s$  as  $0.3 \leq f < 5$  (Hz) and  $u_t$  and  $\eta_t$  as  $5 \leq f$  (Hz). They were obtained by using numerical filters.

#### 3.1 Distribution of undertow

Figure 2 shows the results of steady current distribution on the uniform slope. The distributions for regular wave condition and that of random wave condition are shown together. In the figure, "b.p." denotes the breaking point by regular waves, "b.p.<sub>.1/3</sub>" denotes the significant breaking point due to random waves. Since these breaking points were determined on the measuring lines where the wave height or the significant wave height take their maximum values, the exact points of wave breaking may be different within the neighboring measuring lines. The mean water level due to regular waves is indicated in the figure.

In case of regular waves, the vertical profiles abruptly change a little after the wave breaking ( $x = -180$  to  $-120$  in Fig. 2). On the contrary, profiles near breaking point show gradual change in their forms for the random wave condition. The reason should be because that the positions of breaking have a variation in the cross-shore direction. The change already takes place from the breaking point in the case of random waves. This means that the influence by large waves in random condition cannot be neglected on the steady current distribution, although the frequency in appearance of the large waves is small.

No significant difference in the profiles is found in the inner region where almost all waves break. Vertically averaged values of undertow in random wave condition are 10 % or 30 % smaller than those by regular waves with equivalent wave heights.

Fig. 2 Measured undertow due to regular and random waves (uniform slope).

Fig. 3 Measured undertow due to random waves (bar-type).

Figure 3 gives the undertow distributions on the bar-type beach. In the figure, the mean water level for case 4 is shown. The crest and trough levels were obtained by averaging those of 1/3 maximum waves. In these cases, waves break around the top of the bar. At the onshore side of the bar, the distribution shows the typical profiles for inner region which has strong offshore directed current near the bottom.

After the first breaking, waves recover at the trough of the bar. The undertow profiles there become similar to the profiles outside the surf zone. The near-bottom velocity is offshoreward at the top of the bar, however, it comes onshoreward again at the trough. It can be considered that the bottom boundary layer develops at the trough of the bar.

**3.2 Distribution of long-wave component velocity**

Figure 4 shows the two-dimensional distribution of long-wave component of velocity, which was extracted by using a numerical filter from the time series of measured velocity. The root-mean-square value  $u_{l,rms}$  of the low frequency component velocity  $u_l$  on the uniform slope is given in the figure.

Fig. 4 RMS Value of long-wave component velocity (uniform slope).

Fig. 5 RMS value of long-wave component velocity (bar-type).

The distribution of  $u_{l\text{rms}}$  on the bar-type beach is shown in Fig. 5. In both cases, the amplitudes of long-wave component are almost constant in vertical direction same as the distribution of the short-wave component, although the figures show maximum values around the elevation of 1 cm from the bottom. Below the level, the amplitudes considerably decrease. It should be due to the bottom boundary layer, but probably it is different from the ordinary turbulent oscillatory boundary layer because of the turbulence from the upper layer produced by wave breaking.

Figure 6 gives distribution of vertically averaged values  $u_{lm}$  of  $u_{l\text{rms}}$  on the bar-type beach. The variation of root-mean-square value  $\eta_{l\text{rms}}$  of low-frequency component of water surface elevation is shown together. Both of them take large values at the top of the bar, then decrease a little with increasing water depth in wave recovery zone, and then increase remarkably after second wave breaking. This result supports the previous researches for cross-shore variations of the long-wave components.

Fig. 6 Cross-shore variation of long-wave component velocity (bar-type).

#### 4. Undertow Model for Random Wave Condition

In random wave condition, the spatial distribution of breaking points cause gradual change of undertow profile around the break points as shown in the section 3.1. Therefore, in this case, good accuracy near the breaking points cannot be expected to undertow models developed for regular wave conditions.

In the present study, a model was investigated to estimate the undertow profile under random wave breaking by applying a model for regular waves.

In order to obtain the undertow distribution due to random waves by using a model for regular waves, it may be possible to estimate the distribution by superimposing the calculated values for every individual wave in the time series of random waves. However, it should not be practical because this way must need much computing time. Therefore, representative wave heights which were obtained by using the individual wave analysis was used in this study.

At first, individual offshore measured waves are classified into three groups which contain 1/10 of the highest, 7/30 of the next highest and 2/3 of the rest, that is the lowest waves. Then, the average wave heights  $H_1$ ,  $H_2$  and  $H_3$  for each group are calculated. The values  $H_1$ ,  $H_2$  and  $H_3$  are easily obtained by using the relations as shown below from the 1/10 maximum wave height  $H_{1/10}$ , the significant wave height  $H_{1/3}$  and the mean wave height  $\bar{H}$ .

$$H_1 = H_{1/10}$$

$$H_2 = \frac{10H_{1/3} - 3H_{1/10}}{7} = 1.429H_{1/3} - 0.429H_{1/10}$$

$$H_3 = \frac{3\bar{H} - H_{1/3}}{2} = 1.5\bar{H} - 0.5H_{1/3}$$

The each value is put into the undertow model presented by Okayasu *et al.* (1990) for regular wave conditions as the incident wave condition to evaluate the undertow distribution due to the representative waves.  $U_1$ ,  $U_2$  and  $U_3$  are calculated undertow value from  $H_1$ ,  $H_2$  and  $H_3$  with the significant wave period  $T$ . Contributions by the three representative waves were estimated by multiplying the factor of 1/10, 7/30 and 2/3 which are the frequencies of appearance of the each obtained values. Finally, the contributions are linearly superimposed and the undertow distribution due to the random waves is obtained. Figure 7 gives the flow chart of this process.

The calculated undertow distribution on the uniform slope is shown in Fig. 8 with the measured distribution. The calculated profile changes gradually around the breaking point.

Figure 9 shows the distribution on the bar-type beach. The overall agreement is good. The model can evaluate the profiles also in wave recovery zone, especially for onshore directed flow in the vicinity of the bottom. It can be said that the model is able to estimate the undertow distribution due to random waves.

Fig. 7 Flow chart of the process of undertow evaluation.

Fig. 8 Calculated and measured undertow (uniform slope).

Fig. 9 Calculated and measured undertow (bar-type).

5. Conclusions

In the present study, laboratory experiments were performed for random wave conditions to measure cross-shore velocity in the surf zone on a 1/20 constant slope and a bar-type beach. Then a model was formulated to estimate undertow distribution caused by random wave breaking on arbitrary beach topographies from the offshore wave height distributions. The vertical distribution of long-wave component velocity was also investigated.

The conclusions obtained in this study are as follows.

- 1) The vertically averaged values of undertow due to random waves are 10 to 30 % smaller than those by regular waves. The change of vertical profiles of

undertow in the cross-shore direction around the breaking point is gradual under random wave conditions.

- 2) The amplitude of long-wave component velocity can be considered almost constant in vertical direction, although the influence by the boundary layer is obvious in the vicinity of the bottom.
- 3) The distribution of undertow caused by random waves can be estimated from three representative wave heights obtained from offshore wave height distribution. The distributions for the three representative wave heights calculated by using a model for regular waves are superimposed with factors depending on the frequencies of appearance.

## CHAPTER 67

### Occurrence Distribution of Maximum Wave Height including Wave Grouping Effect

Kosuke Kondo<sup>1</sup>, Tsunehiro Sekimoto<sup>2</sup>, Takuzo Shimizu<sup>1</sup>  
and  
Sumio Imai<sup>3</sup>

#### Abstract

The effect of wave grouping on the occurrence frequency distribution of maximum wave height was investigated on the basis of field observation data. The observed maximum wave height distribution fitted the distribution derived from Weibull distribution and was closely related with not only the wave grouping but also wave non-linearity. In the case of large degrees of wave grouping and wave non-linearity, it was found that the maximum wave height was greater than that estimated by the Rayleigh distribution.

#### 1. Introduction

Since the wave grouping may influence several important issues of coastal engineering, many researchers have been studying the characteristics of wave grouping. The first treatment of wave grouping was the analysis of statistical properties of run length (Goda, 1970; Kimura, 1980; Longuet-Higgins, 1984). The characteristics of run length of field data have been also studied (Goda, 1983). Besides the statistics of run length, the square of water surface elevation has been commonly used for wave grouping analysis (Funke and Mansard, 1979). Recently the concept of the modulational instability has been used for describing the wave

grouping process (Mase and Iwagaki, 1986) and the spatial change of wave group properties due to wave group propagation has been investigated (Ukai, 1990). Also, the relationship between wave grouping and occurrence frequency distribution of wave height has been studied by Mase(1989).

According to Mase's study, it was suggested that the frequency distribution of wave height becomes wider as the degree of wave grouping is higher. This result means that the wave grouping effect has to be considered when the maximum wave height is adopted as the design wave height because the maximum wave height becomes higher, when the occurrence frequency distribution becomes wider. This will be an important problem, especially for the design of deep water structures.

In this study, we aim to investigate the relationship between wave grouping and occurrence frequency distribution of wave height on the basis of field observation data, and to study the effect of wave grouping on the occurrence frequency distribution of the maximum wave height.

## 2. Field observations

Field observations were conducted at the port of Kashiwazaki-Kariwa nuclear power plant from January through March in 1989. This power plant was constructed in both Kashiwazaki city and Kariwa town, so we call it shortly Kashiwazaki-Kariwa. Figure 1 shows the location of observation site which is located in Niigata Prefecture in Japan and faces to the Sea of Japan. Along the WNW direction from this site, there is Noto peninsula and in the direction of N there is Sado island. Therefore the incident wave direction to this site is restricted to a range from WNW-direction to N-direction. Figure 2 shows the port of Kashiwazaki-Kariwa nuclear power plant. This port has an area of about 3 km wide along the shoreline and about 1.3 km long normal to shoreline. The wave height and direction were measured at the water depth of 13m by using ultrasonic wave gage and electromagnetic current meter. The locations of observation points are shown in this figure. More than 200 time series of wave data, 20 minutes each, were recorded every two hour. During this observation, the observed maximum significant wave had height of 3.45m and period of 8.3 s. However, waves higher than 2m were observed only a few times. Therefore wave data which were obtained in January and March in 1987, as part of a long term study by Tokyo Electric Power Co. Inc. were also analyzed. In this period, waves had relatively large height and maximum significant wave height was 5.13m with period of 9.9 s. In this long term observation, ultrasonic wave gage was laid 1.5 km far from the shoreline.

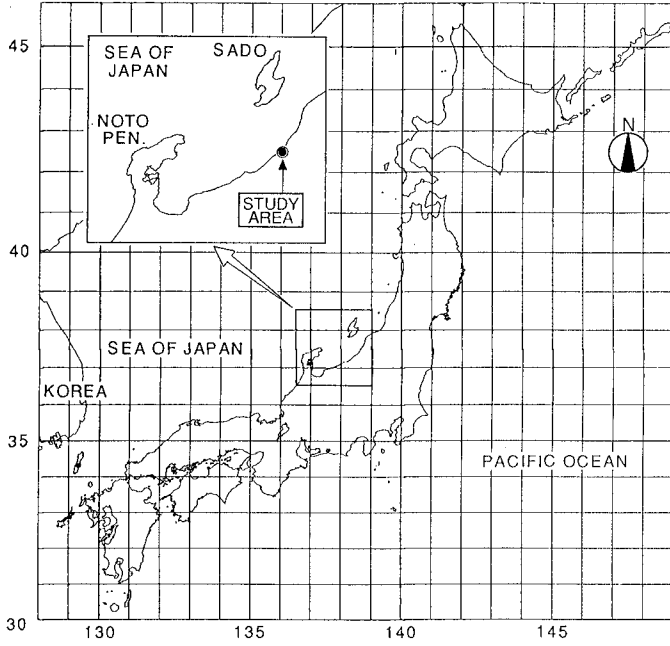

Figure 1. The location of the investigation site.

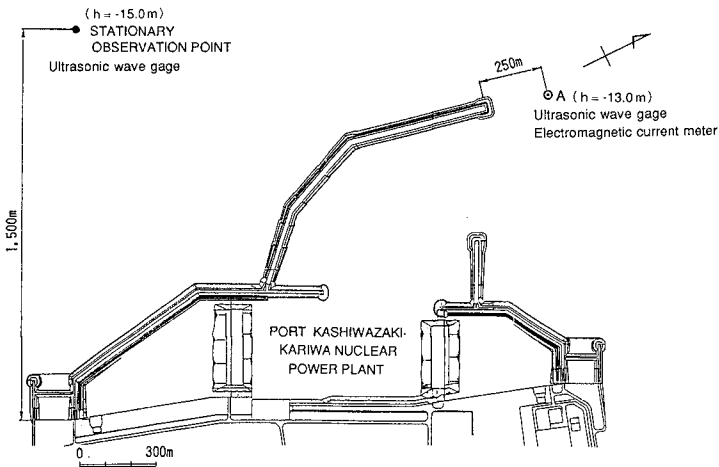

Figure 2. Location of observation points (Port of Kashiwazaki-Kariwa Nuclear Power Plant).

### 3. Wave Grouping

The wave grouping properties were discussed by using the groupiness factor,  $GF$ . The relationship between  $GF$  and the wave dispersion  $kh$ , non-linearity  $ka$ , and Ursell's parameter  $Ur$  were investigated, where  $k$  is the wave number,  $h$  the water depth and  $a$  the wave amplitude. The wave amplitude means half of significant wave height in this study.

Figure 3 shows the results of wave grouping analysis. Values of  $GF$  are plotted against the relative water depth,  $kh$ . The figures are classified for different ranges of the wave non-linearity,  $ka$ . From these figures, the so-called "shallow water effect", which is the phenomenon that  $GF$  becomes smaller as  $kh$  becomes smaller, can be confirmed. It is also confirmed that the non-linearity effect exists. In the case of large  $kh$ ,  $GF$  becomes large as  $ka$  becomes large and in the case of small  $kh$ ,  $GF$  and its scatter become smaller as  $ka$  becomes large.

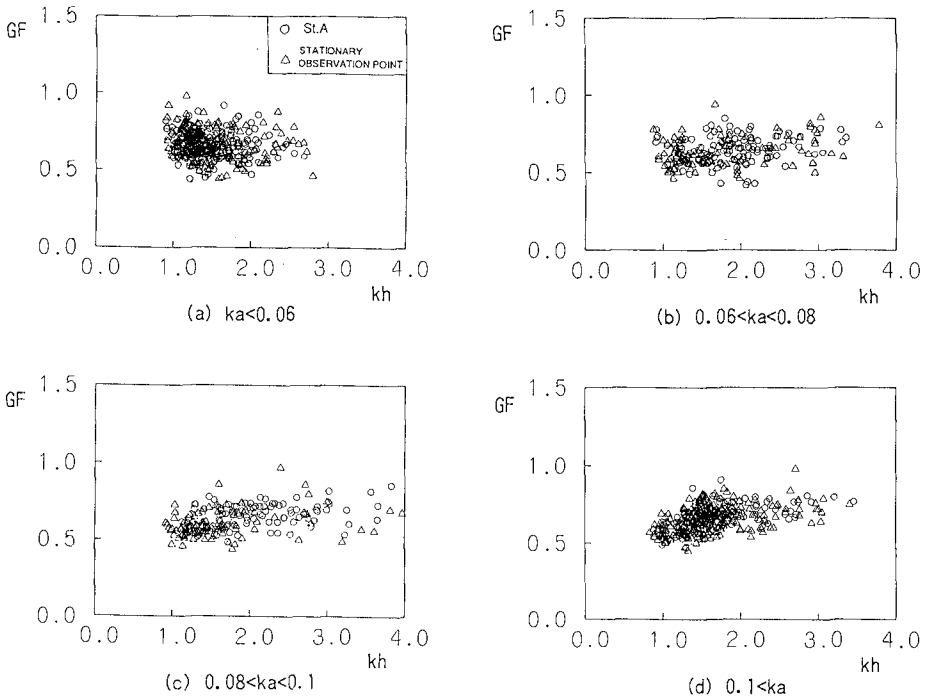

Figure 3. The relationship between relative water depth  $kh$  and groupiness factor  $GF$ .

Figure 4. The relationship between Ursell's parameter  $Ur$  and groupiness factor  $GF$ .

Next, the relationship between  $GF$  and Ursell's parameter was investigated. Values of  $GF$  are plotted against Ursell's parameter in figure 4. This figure shows that  $GF$  becomes smaller and its distribution becomes narrower as the Ursell's parameter becomes larger. From these analyses of wave grouping, it was found that non-linearity of waves affects the wave grouping.

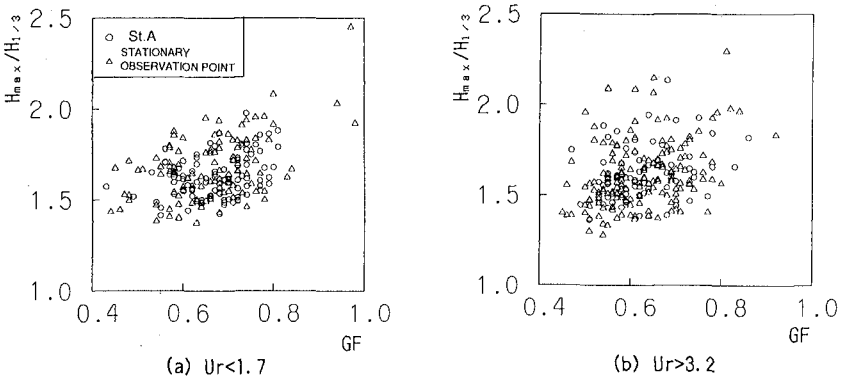

Figure 5. The relationship between groupiness factor  $GF$  and maximum wave height.

In this study, our main interest was in the occurrence distribution of maximum wave height. Therefore the relationship between maximum wave height and  $GF$  was investigated. Figure 5 shows this relationship. The ordinate is  $H_{max}/H_{1/3}$  and the abscissa is  $GF$  in this figure. It was found that weak correlation is available between  $GF$  and maximum wave height. In the case of large Ursell's parameter, distribution of maximum wave height is much broader. However, it was found that the lower limit of maximum wave height is almost the same in both, but the upper limit of maximum wave height is larger in the case of large Ursell's parameter. This results suggested that in the case of large Ursell's parameter higher maximum wave height occurs even if  $GF$  has the same value. Hence, also the occurrence frequency of maximum wave height is affected by the non-linearity of waves.

#### 4. Wave height distribution

Following the study of Mase(1989), the Weibull distribution was adopted to the observed wave heights. The Weibull distribution for ocean waves was given by Kimura(1981) and it's representation is

$$p(x) = \frac{m}{2\phi} x^{m-1} \exp\left(-\frac{x^m}{2\phi}\right) \quad (1)$$

where,  $\phi$  is the normalized factor, which is changed by a reference wave height, and  $x$  is the normalized wave height.  $\phi$  and  $x$  were expressed as follows.

$$\phi = \frac{1}{2} \left[ \Gamma\left(\frac{m+1}{m}\right) \right]^{-m} \quad (2)$$

$$x = \frac{H}{\bar{H}} \quad (3)$$

in which  $\Gamma(*)$  is the gamma function. The probability density is changed by the shape factor  $m$ . When  $m$  is small the distribution is wide and when  $m$  is large the distribution is narrow. The reference wave height employed here is the mean wave height  $\bar{H}$ .

The shape factor  $m$  of the observed waves was estimated by the maximum likelihood procedure proposed by Cohen (1960), which was also used by Mase (1989).

$$m = \frac{N_w}{\frac{1}{2\phi} \sum_{i=1}^{N_w} x_i^m \ln x_i - \sum_{i=1}^{N_w} \ln x_i} \tag{4}$$

where  $x_i$  means each wave height in a wave train normalized with the mean wave height and  $N_w$  is the number of waves.

The observed wave height distributions were shown in the form of histograms expressed in terms of probability density. Figure 6 presents an example of wave height distribution of an observed wave train. The fitted Weibull distribution is drawn as smooth curves in the figures. Figure 6(1) presents a very narrow distribution case and (4) is a very wide one. Figure

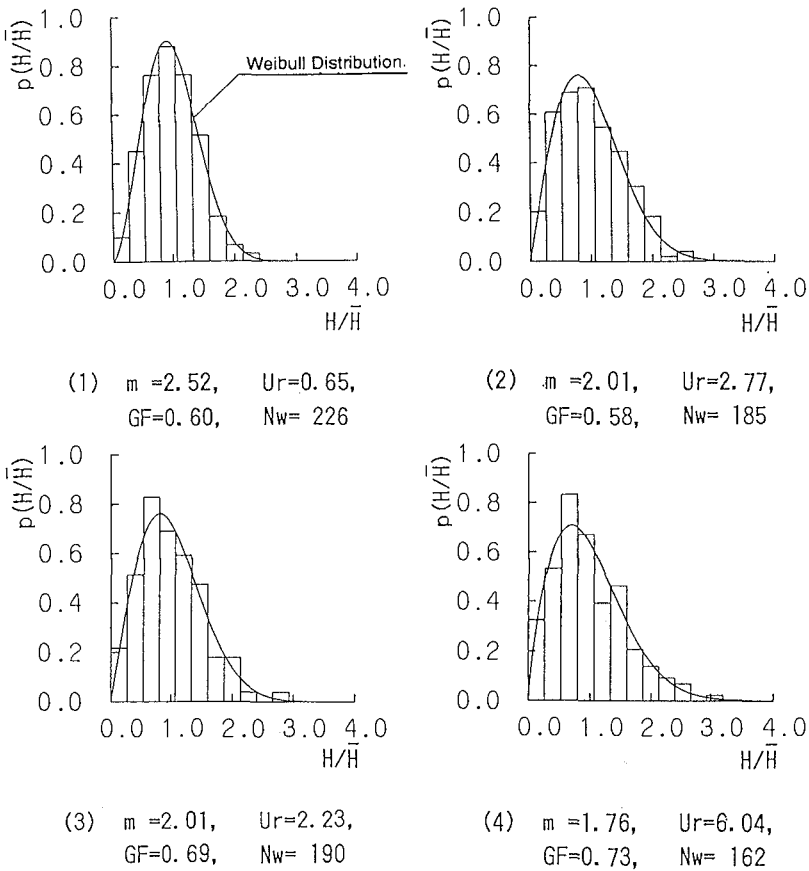

Figure 6. The occurrence distribution of wave height with Weibull distribution.

6(2) and (3) have the same shape factor. In these figures, the number of waves are 150 through 200. Considering the reliability of a small sample, the agreement between the observation results and fitted curve by means of Weibull distribution is good.

Since the application of Weibull distribution to observed wave height distribution was confirmed, the relationship between  $GF$  and shape factor  $m$  was investigated. Since  $GF$  is defined as the coefficient of variation of smoothed instantaneous wave energy history, distributions of wave height become broad as  $GF$  becomes large. Thus, it seems that a negative correlation should be available between the shape factor and  $GF$ . Mase(1989) proposed this relationship empirically.

$$m = 3.44 - 1.99GF \quad (5)$$

Figure 7(1) is the result of comparison between all observed data and the above empirical relation. It was confirmed that Mase's relationship seems to describe the mean of the observation data.

After careful analysis of the relationship between  $m$  and  $GF$ , it was found that the relationship between  $m$  and  $GF$  depends on Ursell's parameter. Figures 7(2), (3) and (4) show the case that  $Ur$  is less than unity, the case that  $Ur$  is from 1 to 3, and that  $Ur$  is greater than 3, respectively. For the same value of  $GF$ , the greater the Ursell's parameter is, the smaller  $m$  becomes. That is, in the case of larger Ursell's parameter, the occurrence frequency distributions of wave height become wider and therefore the maximum wave heights become larger, even if  $GF$  is the same. It should be mentioned that the wave height distributions become wider due to wave non-linearity.

According to these figures, even for the case of small Ursell's parameter, when  $GF$  is above 0.7 the shape factor  $m$  is less than 2.0. The Rayleigh distribution, which is often selected as the wave height distribution, has shape factor of 2. Therefore, the Rayleigh distribution underestimates the occurrence frequency distribution of higher wave heights, when  $GF$  is greater than 0.7.

## 5. Maximum wave height

Since the Weibull distribution successfully described the observed occurrence distribution, comparison was made between the occurrence distribution of maximum wave height derived from Weibull distribution and the observed one. Maximum wave height distribution on the basis of Weibull distribution can be expressed by equation (6). This equation is derived using the same manner proposed by Longuet-Higgins (1952), with the assumption of independence of each wave from others.

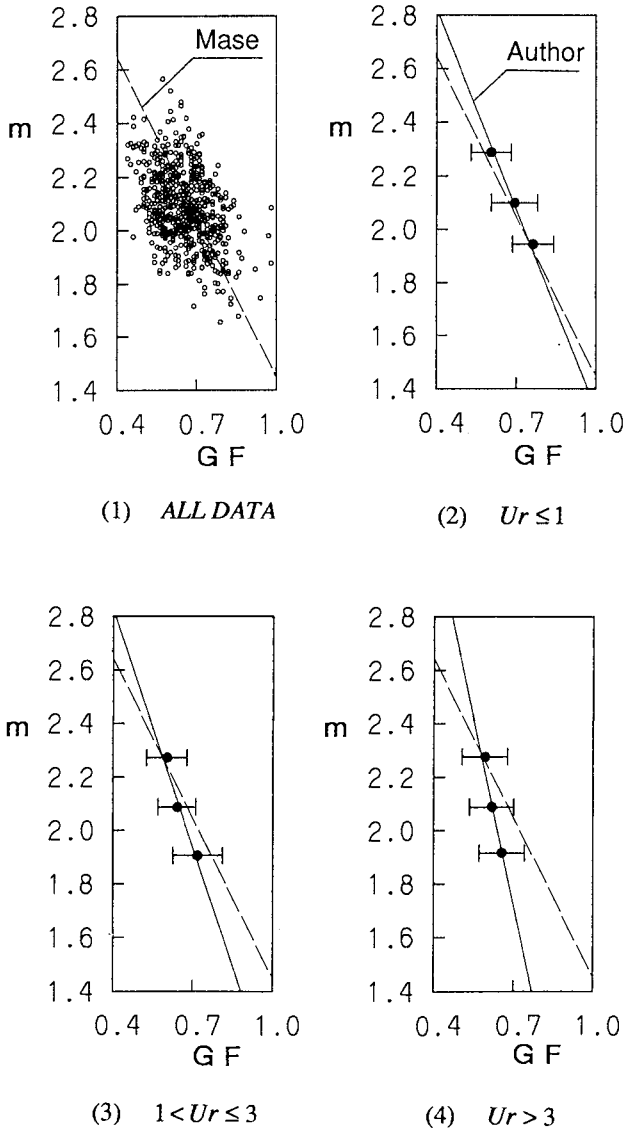

Figure 7. The relationship between groupiness factor  $GF$  and shape factor  $m$  of Weibull distribution.

$$p^*(X) = mN_w \beta (\beta X)^{m-1} \left[ 1 - \exp\{-(\beta X)^m\} \right]^{N_w-1} \exp\{-(\beta X)^m\} \quad (6)$$

$$\beta = (-\ln q)^{1/m} + \Gamma(1/m, -\ln q) / (qm) \quad (7)$$

$$X = H_{\max} / H_q \quad (8)$$

In these equations,  $\Gamma(*,*)$  is the incomplete gamma function of the second kind,  $H_q$  is a reference wave height and it is taken as the mean value of the highest  $qN_w$  waves, where  $q$  is less than or equal unity. When  $q$  is  $1/3$ ,  $H_q$  means significant wave height and  $q$  is  $1$ ,  $H_q$  means the mean wave height.

The results of the comparison between the observed maximum wave height and those predicted from Weibull distribution were described for four ranges of the shape factor. The lower part of figure 8 shows occurrence distribution of wave height with the Weibull distribution.

It was found that Weibull distribution fits these histograms very well. The upper part of the figure shows the distribution of the maximum wave height normalized by the significant wave height. In these figures, the three solid curves indicate the distribution derived from Weibull distribution with minimum, mean and maximum number of waves in the wave records. The occurrence frequency distribution of maximum wave height derived from Weibull distribution for the mean number of waves showed good agreement with histograms of the observed maximum waves except for the case of small value of the shape factor. When the shape factor is small,  $GF$  is large and the correlation between waves in a wave train is generally high. So, the agreement between the derived and observed distribution is not so good in this case.

Figure 9 shows the relationship between  $H_{\max}/H_{1/3}$  and  $m$ . The mean values of observed data are plotted by dots and their positive and negative standard deviations are described by lines. In this figure, the expected value of  $H_{\max}/H_{1/3}$  is drawn by dashed line. This expected value was calculated for 196 waves which is the mean number of waves in the observed records. Excluding the case that the shape factor is less than 2, calculation results described the observed data well. However, even in the case that the shape factor is less than two, the deviation between calculated results and observed results is small. Then, it may be concluded that the maximum wave height can be estimated by using the probability density derived from Weibull distribution. The shape factor of Weibull distribution may be estimated from  $GF$  and  $Ur$ .

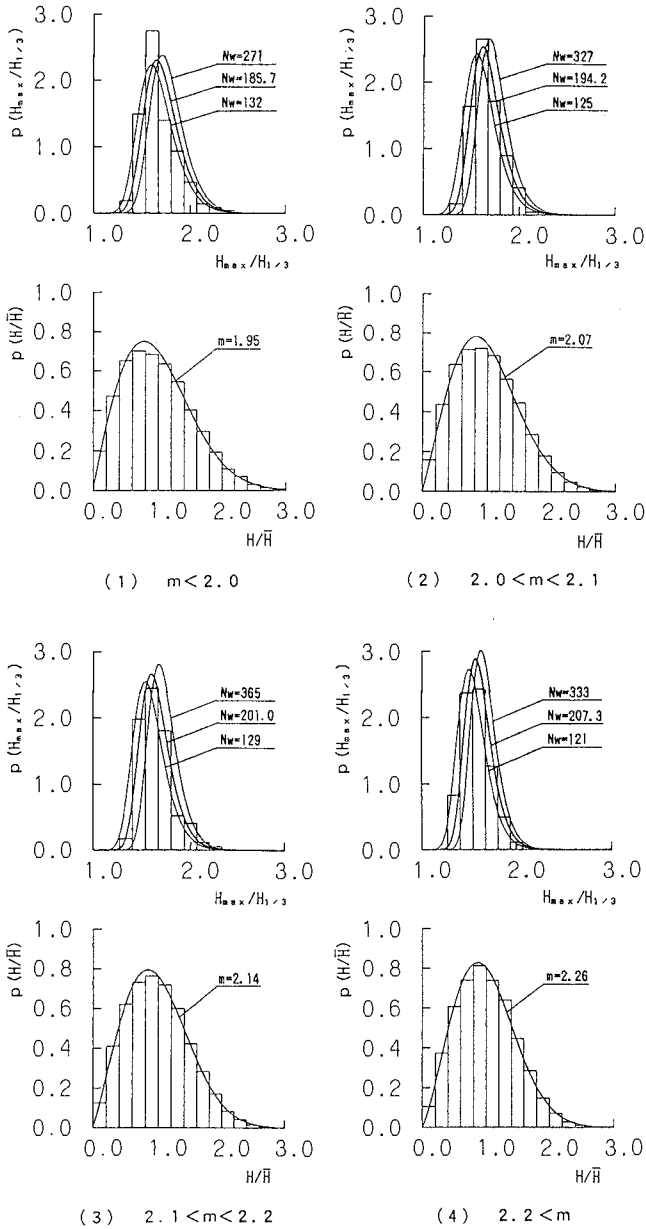

Figure 8. Comparison between the observed maximum wave heights and those predicted from Weibull distribution.

Figure 9. The relationship between shape factor  $m$  of Weibull distribution and maximum wave height.

## 6. Conclusions

The effect of wave grouping on the occurrence frequency distribution of maximum wave height was investigated through the field observations.

The conclusions of this study are summarized as follows.

- (1) Weibull distribution fits the observed wave height distribution very well.
- (2) The wave height distribution is affected by the wave groupiness.
- (3) The relationship between  $GF$  and the shape factor  $m$  of wave height distribution is affected by the Ursell's parameter.
- (4) Maximum wave height distribution derived from Weibull distribution fits the observed maximum wave height.
- (5) The maximum wave height can be estimated by the shape factor  $m$ . Then the maximum wave height is connected with the wave groupiness by using the shape factor with the Ursell's parameter.

## CHAPTER 68

### AN EXPERIMENT AT SEA ON MECHANICS OF THE WAVE GROUPS

Paolo Boccotti (°), Giuseppe Barbaro (°°), Lucio Mannino (°°°)  
Department of Fluid Mechanics and Offshore Engineering  
University of Reggio Calabria

#### Abstract

Three field experiments were executed in the Straits of Messina starting in 1990 in order to verify the closed solution for the mechanics of the highest wave groups in a random wind generated sea state (Boccotti, 1984-88-89). The paper presents the first experiment which was concerned with the first part of the theory: the wave groups in an open sea. An array of nine wave gauges and nine pressure transducers supported by vertical piles provided space-time information on waves generated over a fetch of approximately 10 Km.

#### 1 Introduction

A wave with a given very large crest-to-trough height of  $H$ , in a random sea state assumed Gaussian, is expected to belong to a well defined wave group whose average configuration in space and time is specified in terms of the autocovariance of the random wave field,

$$\psi(\underline{X}, T) = \langle \eta(\underline{x}, t) \eta(\underline{x} + \underline{X}, t + T) \rangle \quad (1.1)$$

where  $\eta(\underline{x}, t)$  is the surface displacement. Specifically, if the crest of the given very high wave occurs at  $\underline{x}_o = (x_o, y_o)$  at time  $t_o$ , the mean surface configuration of the wave group is given by

$$\eta_c(\underline{x}_o + \underline{X}, t_o + T) = \frac{H}{2} \left\{ \frac{\psi(\underline{X}, T) - \psi(\underline{X}, T - T')}{\psi(\underline{O}, 0) - \psi(\underline{O}, T')} \right\} \quad (1.2)$$

(°°) Assistant professor

(°°°) Engineer at the Department

where  $T^*$  is the abscissa of the absolute minimum of the autocovariance function, which is assumed to exist and to be the first minimum after  $T=0$ . The result (1.2), which was got by Boccotti (1984-1988-1989), assumes that  $H$  is very large compared with the mean wave height, or with  $\sigma = (\overline{\eta^2})^{1/2}$  for the wave field as a whole and, in effect, that the spectrum is narrow in the sense described by Longuet-Higgins (1984), so that  $\eta$  is a damped oscillatory function in  $\underline{X}$  and  $T$ . Superimposed on the deterministic form (1.2) is of course the "random noise" of the residual wave field whose r.m.s. surface displacement approaches  $\sigma$  as  $\underline{X}$  and  $T$  increase, but when  $H/\sigma$  is large, the variations in the actual sea surface configuration about  $\eta_c$  surrounding  $\underline{x}_o, t_o$  are small compared with  $\eta_c$  itself.

Associated with the configuration (1.2) is a distribution of velocity potential in the water, which to the lowest order in a Stokes expansion is given by

$$\phi_c(\underline{x}_o + \underline{X}, z, t_o + T) = \frac{H}{2} \left\{ \frac{\Phi(\underline{X}, z, T) - \Phi(\underline{X}, z, T - T^*)}{\Psi(\underline{O}, O) - \Psi(\underline{O}, T^*)} \right\} \quad (1.3)$$

where

$$\Phi(\underline{X}, z, T) = \langle \eta(\underline{x}, t) \phi(\underline{x} + \underline{X}, z, t + T) \rangle. \quad (1.4)$$

Note that the hypothesis that  $H/\sigma$  is large is not necessarily inconsistent with the use of the lowest order (linear) terms in the Stokes expansion, provided  $H$  remains small with respect to the wave length and the water depth. Note also that, if  $\eta$  and  $\phi$  are taken as solutions to the linear problem, then so are  $\eta_c$  and  $\phi_c$ . This can be demonstrated formally from (1.2) and (1.3).

The covariance functions in (1.2) and (1.3) can be expressed in terms of the spectra; for example

$$\Psi(\underline{X}, T) = \int_{-\pi}^{\pi} \int_0^{\infty} S(\omega, \theta) \cos(\underline{k} \cdot \underline{X} - \omega t) d\omega d\theta \quad (1.5)$$

where  $S(\omega, \theta)$  is the directional frequency spectrum and

$$\underline{k} \cdot \underline{X} = \frac{\omega^2}{g} (X \sin \theta + Y \cos \theta). \quad (1.6)$$

The substitution of (1.5) into (1.2) gives  $\eta_c$  as a function of position and time surrounding  $\underline{X} = 0, T = 0$  and leads to the sequence of configurations illustrated in Figure 1, representing a wave group moving along the  $y$ -axis, the dominant direction of the spectrum. The spectrum was taken as that used by Hasselmann et al. (1973) with the spreading direction function by Mitsuyasu et al. (1975). In deep water this has the form

$$S(\omega, \theta) = \alpha g^2 \omega^{-5} \exp \left[ -\frac{5}{4} \left( \frac{\omega_d}{\omega} \right)^4 \right] \exp \{ \ln(\gamma) \exp [ -(\omega - \omega_d)^2 / 2 S^2 \omega_d^2 ] \} \cdot \\ \cdot N(n) \left| \cos \frac{1}{2} (\theta - \theta_o) \right|^{2n}, \quad n = n_o \left( \frac{\omega}{\omega_d} \right)^5 \quad \text{if } \omega \leq \omega_d, \quad (1.7)$$

$$n = n_o \left( \frac{\omega}{\omega_d} \right)^{-2.5} \quad \text{if } \omega > \omega_d, \quad N(n) = \left[ \int_{-\pi}^{\pi} \cos^{2n} \frac{1}{2} \theta d\theta \right]^{-1}.$$

where the parameters  $\gamma, S$  and  $n_o$  are taken respectively as 3, 0.08 and 20, as Hasselmann et al. and Mitsuyasu et al. suggest ( $n_o=20$  applies

Fig.1 Quasi-determinism of the extreme wave events in a random wind generated sea state, assumed Gaussian, (Boccotti, 1989): an extremely high individual wave at a point  $x_0, y_0$  (center of the framed area), with a probability approaching 1, is produced by the transit of the wave group shown by the pictures. The water is deep, the spectrum of the sea state is that described in section 1. The time interval between two consecutive pictures is equal to one wave period  $T_d$  and the framed area is large  $3 L_d$  along x-axis and  $6 L_d$  along y-axis.

to the conditions of the experiment: fetch of 10 Km and wind speed of about 7 m/s).

The basic phenomena that occur during the course of evolution of the group are not dependent on the detailed shape of the wave spectra. First, the wave group has a development stage in which the height of the central wave grows to a maximum and the width of the wave front reduces to a minimum. Secondly, the individual waves have a propagation speed greater than the envelope. Each wave is born at the tail of the group and then dies at the head of the group, as illustrated by wave A in Figure 1. The wave with the given very large height  $H$  proves to be that at the center of the wave group at the apex of the development stage.

## 2 The field experiment

In order to test the predictions, a small scale field experiment was undertaken during May, 1990 at a location off the beach of Reggio-Calabria on the eastern coast of the Straits of Messina. Figure 2 shows the site of the experiment.

*Fig.2 The experiment was executed off the beach at Reggio-Calabria.*

An array of nine small towers was installed 20 m from the beach in the configuration shown in Figure 3. These rested on the sea bed and their bases (0.8 m squared) were ballasted by pig iron discs. The water depth ranged within 3 m at the inner row (numbered 1-7) and 4 m at the outer pair (8,9). Each tower supported an ultrasonic wave probe furnished by Delft Hydraulics Laboratory, having range 0.6-2.0 m, and a pressure transducer (full scale 0.175 bar) some 0.5 m below the water surface. The sampling rate was 10 Hz for each gauge and the data were stored in two personal computers. Since the station was equipped to receive data (wave elevation and pressure) from eight towers only, one of the nine had to be disconnected. During the experiment tower six was disconnected because its ultrasonic probe was damaged.

Fig.3 Plan view of the small towers which supported the gauges. The configuration of the towers is shown also in Figure 1 where the dominant wave length  $L_d$  is assumed to be 7.5m.

Suitable wind and wave conditions with a steady wind from the North West and the absence of southerly swells, were encountered 10 days after the array was installed. The experiment was conducted over a 12 hour period, starting at 8 AM on May 10, 1990. A total of 64 records was obtained, each of nine minutes duration and containing 280 to 360 dominant waves. The significant height ranged within 0.15 and 0.35 m and the dominant period of the spectrum ranged within 1.7 and 2.5 s, so that the water depth at the gauge locations was in effect deep.

### 3 Results of the experiment

#### 3.1 The surface displacement

The space-time covariances in equations (1.2) can be found from the measurements by cross-correlation of the time series obtained at the discrete measurement locations. The time series data of a record provide measured auto-covariances as a function  $T$  for the various gauge locations and these can be used on the right hand side of equation (1.2) to estimate the surface displacement at these locations in an extreme

wave. With  $x_0$  taken as the location of one of the gauges, the vectors  $X$  were specified by the relative locations of the other gauges.

A typical example of the result is shown in Figure 4 which was obtained from the time series data of record 30 without smoothing, with  $x_0$  taken as the location of gauge 4. Thus the figure represents the time histories of the expected surface configuration at the various gauge locations, if an extreme wave of given crest-to-trough height  $H$  is encountered at location 4. In this figure, A denotes the wave which is the highest at location 4, and B is the wave immediately before this one.

The direction of the wave can be estimated accurately since the front of wave A in the central position of the group along the traverse of locations 1-7 proves to be nearly straight. The relative phases indicate an angle of incidence of  $20^\circ$  - the front center before point 3 transits point 9, and this is consistent with the fact that in Figure 4, the wave group at point 9 is higher than at point 8.

Note that at locations 8, 9, wave B is slightly larger than A, but as it passes to the line 1-7, it decreases, passing from the center to the head of the group while the succeeding wave A grows because it replaces B at the group center. Note also that, in the course from location 9 to location 4, the period of wave B increases as it passes from the center to the head of the group, while the period of wave A decreases as it reaches its maximum height.

Similar calculations have been performed for all the records and the results are consistent with those described above. Specifically, there is an increase in period of the decreasing wave B, a decrease in the growing wave A and a local minimum period coupled to the maximum wave height.

Also Figure 5 shows the time histories of the expected surface waves at the various gauge locations, if an extreme wave of given crest-to-trough height  $H$  is encountered at location 4. In this case the auto-covariances in eq(1.2) were calculated from the theoretical spectrum (1.7), with the same dominant period and direction of record 30 ( $T_d = 2.17$  s,  $\theta_0 = 20^\circ$ ). We see that the result from the theoretical spectrum (Figure 5) is very close to that from the time series data (Figure 4): all the basic features described earlier are still evident.

### 3.2 The fluctuating pressure head at the transducer depth

The variations in pressure at a fixed depth are given by  $-\rho \partial \phi / \partial t$  or  $\rho g \zeta$  where  $\zeta$  is the fluctuating "pressure head" at this depth, so that the derivative of eq(1.3) with respect to  $T$  provides the following relation for the expected fluctuating pressure head at a fixed depth  $z$  below an extreme wave

Fig.4 This picture was obtained from equation (1.2), using the time series data of the surface elevation of record 30, without smoothing. It shows the time histories of the expected surface waves at the locations of the gauges, if a wave with a very large height  $H$  is recorded at location 4. The first number over each wave denotes the crest-to-trough height, and the second number denotes the wave period; the wave height is scaled to given height  $H$  and the wave period is scaled to dominant wave period  $T_d$ .

Fig.5 This picture was obtained from equation (1.2), with the auto-covariances calculated from the spectrum (1.7). Like Fig.4, it shows the time histories of the expected surface waves at the locations of the gauges, if a wave with a very large height H is recorded at location 4.

$$\zeta_c(\underline{x}_o + \underline{X}, z, t_o + T) = \frac{H}{2} \left\{ \frac{\Pi(\underline{X}, z, T) - \Pi(\underline{X}, z, T - T^*)}{\psi(0, 0) - \psi(0, T^*)} \right\} \quad (3.1)$$

where  $\Pi$  is the covariance of the surface displacement and the fluctuating pressure head, of the whole record

$$\Pi(\underline{X}, z, T) = \langle \eta(\underline{x}, t) \zeta(\underline{x} + \underline{X}, z, t + T) \rangle. \quad (3.2)$$

The time histories of the expected pressure head waves at the transducer depth at the various gauge locations, if a surface wave of given very large height  $H$  is encountered at location 4, were calculated by means of eq(3.1) from the time series data of the measured pressure and surface elevation of record 30. The results are shown in Figure 6. The overall similarity between this and Figure 4 gives confidence in the consistency of the measurements.

Note that the enhancement of wave A during its course from location 9 to location 4 is somewhat smaller at the transducer depth (Figure 6), than at the surface (Figure 4), and this is consistent with the reduction in period during this interval. Also, the abatement of the height of wave B from point 9 to point 4 is somewhat smaller at the transducer depth (Figure 6) than at the surface (Figure 4), which again is consistent with the increase in period between these two points. Finally, the wave direction estimated from the pressure head wave of Figure 6 is the same as that estimated from the surface measurements - the difference is smaller than  $1^\circ$ .

#### 4 Conclusive remarks

The comparison between the extreme wave groups and the predictions in terms of the measured space-time autocovariance, which was the goal of the experiment, is shown in the paper by Boccotti et al. (1992), which also gives a wider overall description of the experiment.

The experiment of May, 1990 revealed that it was possible to work off the beach of Reggio Calabria nearly like in a wave tank, because of the wave characteristics (pure wind waves with typical sizes of the laboratory tanks), of the very small tide excursion and the clearness of the water. That was because we decided to attempt some more complex experiments.

On May, 1991 a reflecting wall of 12x2.2 m was assembled on 1.6 m of water depth and thirty wave gauges were placed before the wall. The experiment essentially aimed to verify the theory of Boccotti (1988-89) as regards the nonhomogeneous wave fields. In particular, the theory shows that a very high wave at a wall forms because a well defined wave group like that of Figure 1, at the apex of the development stage, impacts the wall and is reflected mirrorwise. Also the significant wave height before the wall was analyzed through measurements at growing distances from the wall, like in the laboratory experiment of Hirakuchi et al. (1992). A preliminary illustration of the results was given by Boccotti (1992).

Finally, a third experiment dealing with the inertia loads on a big offshore platform has just been completed. The 1:50 scale model of a gravity platform was assembled in 2.5 m of water depth and two sets

Fig.6 This picture was obtained from equation (3.1), using the time series data of the measured transducer pressure and surface elevation of record 30, without smoothing. It shows the time histories of the expected pressure head variations at transducer depths, if a wave with a very large height  $H$  is recorded at the surface at location 4. The wave heights are scaled to  $H(\zeta^2/\eta^2)^{1/2}$ . The periods are scaled to the dominant period of the surface waves.

of wave gauges and pressure transducers were placed at the platform and far from it, in order to compare the wave forces on the column and on an ideal mass of water with the same shape and volume.

## CHAPTER 69

### Wave Group Modulations in Cross-shore Breaking Patterns

T. C. Lippmann<sup>1</sup> and R. A. Holman<sup>2</sup>

#### ABSTRACT

The principal aim of this work is to quantify the long period (group) time scales associated with incident wave breaking in the surf zone. A video based sampling technique is employed to distinguish those waves which are breaking from those which are not. The technique relies on the gray tone contrast between higher luminance of turbulent generated bubbles and foam associated with wave breaking, and the darker, unbroken surrounding water. Video image intensity time series,  $I(x,y,t)$ , are sampled across the width of the surf zone at 10 m increments, from just outside the shore break to the far offshore region of the wave breaking. Outside the point of minimum depth (at the bar crest), the width of the surf zone fluctuates over several hundred meters. In this region, low frequency oscillations in  $I$ , phase coupled to the crest of breaking incident waves, are associated with wave groups. Cross-shore phase relationships indicate a shoreward progressive group structure up to the crest of the bar. Landward of the bar crest in the trough, low frequencies in  $I$  are uncoupled from group modulations seaward of the bar. Video data also show that wave breaking does not cease immediately as waves propagate past the bar crest, but continues well into the deeper water of the trough.

#### INTRODUCTION

Modulations in wave height of incident sea and swell produce variations in the position of break points in the surf zone. These modulations are on the order of wave groups, with much longer periods than typical gravity waves. In the past two decades, considerable effort has been focused on understanding the importance of wave groupiness inside the surf zone.

---

<sup>1</sup>Department of Oceanography, Naval Postgraduate School, Monterey, CA 93943

<sup>2</sup>College of Oceanic and Atmospheric Sciences, Oregon State University, Corvallis, OR 97331-5503.

Previous estimates of breaking wave distributions in the surf zone were determined by visually identifying breaking waves in the time series of sea surface elevation on site during the collection of the data (Thornton and Guza, 1983; Whitford and Thornton, 1988). Breaking waves were defined as "when white water was observed passing the sled mast" (Whitford and Thornton, 1988). This method works well, although with tremendous logistical effort.

In this study, video-based data are presented which quantify the temporal evolution of breaking wave patterns on wave group time scales in a cross-shore transect across the width of the surf zone. In our methods, essentially the same determination of breaking waves is utilized but with a higher level of quantification, synchronous ground coverage over large spatial areas, and reduced logistical difficulty. The premise of the technique is based on contrast between the relatively low luminance of non-breaking water and the higher luminance of actively breaking waves and bores. An example snap shot of wave breaking is shown in Figure 1. The high intensity of the foam and bubbles created from active wave breaking contrasts with the darker non-breaking water. Local maxima in image intensity associated with the turbulent water motion of the breaker or roller is phase locked to a region near the crest of the wave (Figure 2).

Our principal aim is to quantify the time scales associated with modulations in incident wave breaking,  $\eta_b$ . We hypothesize that time series of image intensity,  $I(x,y,t)$ , can be used as a means to quantify the time (and space) scales of  $\eta_b(x,y,t)$  at given locations throughout the surf zone. Thus we assume

$$I(x,y,t) \propto \eta_b(x,y,t) \quad (1)$$

where  $x$  and  $y$  are the cross-shore and alongshore Cartesian coordinates, respectively. For this work we are only interested in the phase relationship and coherence in (1), not the absolute magnitude of  $I$ . This relationship has been shown to work well for estimating the phase speed and wave angle of breaking waves (Lippmann and Holman, 1991). An example time series of both  $I$  and  $\eta_b$  from the same position in the surf zone is shown in Figure 2 (taken from Lippmann and Holman, 1991). The passage of breaking waves is clearly identified in the video data. There are also waves which are not identified in  $I$ , indicating that not all the waves are breaking.

Quantification of images is accomplished using a real time image processing system. Video frames are digitized by the image processor into an array of 512 x 480 picture elements (pixels). Individual pixels store the value of light intensity (luminance) in gray shades from 0 (black) to 255 (white). Images are digitally enhanced to stretch the contrast in the image prior to analysis.

Fig. 1. Example photographic snap shot of wave breaking in the surf zone from October 13, 1990 at ~0900 EST. Breaking waves and bores are identified by the sharp contrast between breaking and non breaking waves.

Fig. 2. Example co-located sea surface elevation (converted from pressure data; top) and video image intensity (bottom) mean-corrected time series from October 12, 1990 (from Lippmann and Holman, 1991).

Image locations of interest (for example the location of a fixed surf zone instrument) are determined using known photogrammetric transformation equations assuming the vertical coordinate to be the still water level (Lippmann and Holman, 1989). Time series at each location are then collected by sampling the corresponding pixel intensity at 6 Hz for the entire run (tape) length of ~2 hours. Resolution in image pixels is typically much less than 1 m in the cross-shore direction, and from ~0.5-2.5 m in the longshore direction.

A brief description of the field site and ancillary measurements used in the study is presented next. Analysis of wave breaking time series are then presented as a function of cross-shore distance. Results are then briefly discussed in terms of surf zone forcing models and cross-shore distributions in wave breaking patterns.

## FIELD METHODS

The data were collected as part of the DELILAH experiment in October of 1990, held at the Army Corps of Engineers Field Research Facility (FRF) on the Outer Banks of North Carolina near the village of Duck. A general description of the experiment and beach conditions at the FRF is given by Birkemeier, *et al.* (1991). The imaged area ranges from the dune crest to ~400 m offshore and begins ~180 m north of the FRF pier and extends alongshore ~350 m. The cameras were mounted on top of a 44 m high tower in weatherproof housings and hard wired to the FRF building for recording. Video time series were sampled along a cross-shore transect, from just outside the shore break ( $x = 135$  m) to the far reaches of the surf zone ( $x = 505$  m) with a spacing of 10 m.

Data are presented from October 13 at ~0645 EST, coinciding with swell generated by Hurricane Lily. Low tide (-0.21 m NGVD) occurred at ~0900 EST. A photographic snap shot from this day is shown in Figure 1. The offshore incident waves during this period were long crested and energetic, with  $H_s \approx 2.23$  m in 8 m depth. Directional spectra from an alongshore array of pressure gages in 8 m depth (Long and Olman-Shay, 1991) shows a very narrow banded swell at the peak frequency,  $f_p \approx 0.083$  Hz, approaching from an incident angle  $\alpha_o \approx 24^\circ$  CW from normal to the beach. The nearshore bathymetry consisted of a prominent linear bar ~100 m offshore (Birkemeier, pers. comm.). Cross-shore profiles at the position of the cross-shore transect from October 12, 13, and 14 are shown in Figures 3 and 5. For reference, the position of the shoreline is at  $x \approx 120$  m and the approximate bar crest is at  $x \approx 220$  m.

## RESULTS

The one-dimensional pattern of wave breaking is shown graphically by plotting together time series of  $I$  sampled along a cross-shore transect spanning the width of the surf zone. Figure 3 shows 38  $I$  time series, each of 120 minute duration, stacked vertically with offshore distance increasing toward the top of the figure. Intensity values are normalized to  $\pm 3$  standard deviations about the mean in each respective time series. Also shown on the right hand side is the approximate beach profile.

Seaward of the bar crest wave breaking distributions clearly show the arrival of wave groups, with breaking being more infrequent in the outer surf zone. The groupy modulations are destroyed by breaking in shallower depths. At the bar crest, nearly all of the waves are breaking. Interestingly, bores do not cease breaking immediately landward of the point of minimum depth over the bar, but continue to break well into the deeper water of the trough.

Example auto power spectra (with  $\sim 54$  degrees of freedom) of  $I$  are shown in the upper panels of Figure 4 for locations  $x = 188$  (in the landward slope of the bar) and  $x = 505$  m (in the outer surf zone). Both spectra show a prominent narrow peak at  $f \approx 0.08$  Hz, corresponding to the peak incident frequency ( $f_p \approx 0.083$  Hz). There is also considerable low frequency variance, as has been observed in previous video time series (Lippmann and Holman, 1991). This low frequency energy occurs at all locations sampled in the surf zone (not shown).

### *Low Frequency Modulations in Wave Breaking*

If modulations in the breaking wave field are associated with wave groups, with periods long compared to peak incident periods, then we expect low frequency energy in  $I$  to be coupled with incident frequencies. Coupling between frequencies in the power spectrum of any given time series are detected with the third order spectrum, the bispectrum (*e.g.*, Kim and Powers, 1979; Elgar and Guza, 1985a). The bispectrum is a measure of lowest order triad interactions between a pair of primary frequencies ( $f_1, f_2$ ) and a secondary frequency,  $f_3$

$$f_1 \pm f_2 = f_3 \quad (2)$$

Sum interactions in (2) generate harmonics which are phase-locked to the primary, and thus are not free and travel at the phase speed of the primary (Elgar and Guza, 1985b). Difference frequencies are associated with coupling between two signals of nearly the same frequency, and a secondary low frequency signal. In strongly amplitude modulated time series, lower frequency signals are phase-coupled to the primary frequencies, as in rectified signals commonly found in electrical engineering applications.

Fig. 3. Time series (120 minute records) of  $I$  sampled along a cross-shore transect at 10 m intervals, from just beyond the shore break to the outer surf zone. The vertical axis is nondimensional image intensity (mean corrected) scaled to  $\pm 3$  standard deviations. Time series are stacked vertically with offshore distance increasing toward the top. The beach profile along the transect is shown at the right.

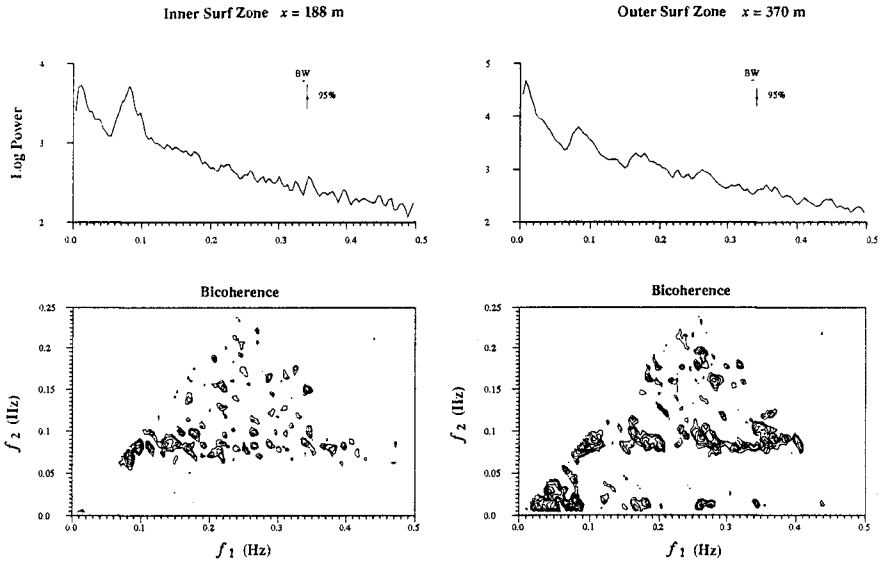

Fig. 4. Example power spectra (upper panels) and bicoherence (lower panels) for  $I$  sampled on the landward slope of the bar (left panels) and in the far offshore region of the surf zone (right panels). Bicoherences greater than the 95% significance level for 56 d.o.f. ( $b = 0.33$ ) are plotted in bi-frequency space with  $f_1$  along the horizontal axis and  $f_2$  along the vertical axis.

Bicoherence ( $b$ , normalized bispectrum) estimates from  $I$  sampled in the trough of the bar ( $x = 188$  m) and in the outer region of the surf zone ( $x = 370$  m) are shown in the lower panels of Figure 4. Only contours of bicoherence which are greater than the 95% significance level ( $b_{crit} = 0.33$ ) are plotted (at 0.5 increments). Due to its symmetry properties, only the unique portion of the bispectrum is shown (see Kim and Powers, 1979). Figure 4 shows strong coupling between the primary frequency (0.08 Hz) and the higher harmonics in both regions of the surf zone, arising from the sharp (non sinusoidal) peaks in the time series records. Strongest coupling occurs at the self-self interaction ( $f_p, f_p$ ),  $b \approx 0.61$  and  $b \approx 0.68$ , and the interaction between the primary and first harmonic ( $f_p, 2f_p$ ),  $b \approx 0.51$  and  $b \approx 0.55$ , for the inner and outer surf zone data, respectively.

There is a distinct lack of coupling between incident ( $f \geq f_p$ ) and lower frequencies ( $f \ll f_p$ ) in the trough of the bar, suggesting that  $I$  variance at infragravity frequencies in the trough is derived from free signals not directly associated with incident wave breaking. However, seaward of the bar crest, widespread bicoherence at low  $f$  reveals strong coupling to  $f_p$ . Highest coupling ( $b = 0.62$ ) occurs at  $(f_1, f_2) \approx (0.082, 0.015)$ . Low frequency spectral energy in  $I$  in this region is coupled to modulations in incident wave breaking patterns throughout the surf zone seaward of the bar.

#### *Phase Propagation of Breaking Wave Groups*

Wave group modulations also appear coherent across the surf zone up to the region near the bar crest (Figure 3). The phase propagation of the groups can be quantified using frequency domain (complex) empirical orthogonal functions (CEOF). In CEOF analysis, eigenvectors of the cross-spectral matrix are computed at each frequency (Wallace and Dickinson, 1972). Thus the data are decomposed into orthogonal factors representing the amplitudes and phases at each frequency as a function of cross-shore distance.

The first CEOF from the peak incident frequency ( $f_p \approx 0.082$  Hz), and also from the low frequency peak ( $f \approx 0.015$  Hz) observed in the power spectra (Figure 4) are shown in Figure 5. Only the first factor is shown since it contains the greatest proportion of the variance (63.7% at  $f_p$  and 45.9% at low  $f$ ), and because orthogonality constraints in the decomposition of the data make interpretation of higher modes unclear. CEOF phases are relative to cross-shore position (the absolute value of individual phase estimates is arbitrary), and amplitudes are normalized by the spectral power within each frequency band. Also shown are estimated (relative) phase relationships for phase speeds,  $C_p$ , predicted by shallow water (Solitary) wave theory

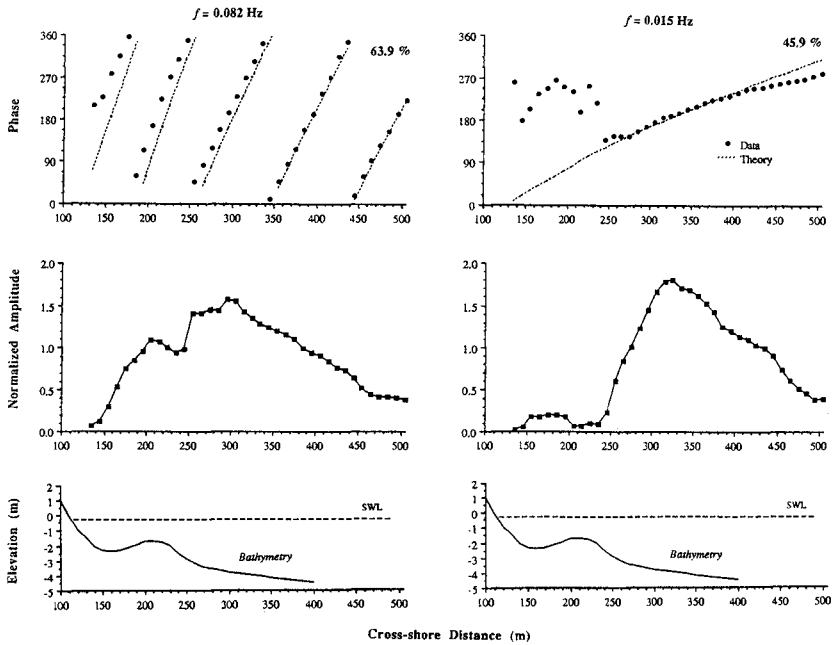

Fig. 5. Frequency domain empirical orthogonal functions (CEOF) from  $I$  at the peak frequency ( $f_p = 0.082$  Hz; left panel) and also the low frequency peak in the power spectra ( $f = 0.015$  Hz; right panel), plotted as a function of cross-shore distance. Phases are shown in the upper panels and normalized amplitudes in the middle panels. The approximate (smoothed) beach profile (from October 14) is shown in the lower panels for comparison. Predicted relative phase relationships (equation 4) are indicated with the dashed lines in the phase plots.

$$C_p = \sqrt{g(h + H_{\text{rms}})} \quad (3)$$

where  $H_{\text{rms}}$  is the root mean square wave height.  $H_{\text{rms}}$  across the surf zone was estimated using the random wave dissipation model of Thornton and Guza (1983), shown previously to well predict the energy decay of incident wave energy in the surf zone. The predicted phases,  $\phi(x)$ , in Figure 5 were computed by

$$\phi(x) \approx \frac{2\pi f \Delta x}{\bar{C}_p} \quad (4)$$

where  $\bar{C}_p$  is the mean phase speed of the peak incident waves over the distance  $\Delta x = 10$  m.

For  $f_p$ , predicted and observed phases are matched at the most seaward location to allow comparison across the surf zone. The first CEOF shows a clear negative phase ramp, indicating shoreward progressive (breaking) incident waves are coherent all the way through the surf zone. The data are reasonably predicted by (4), although near the bar crest and in the trough the theory systematically over predicts the observations (*i.e.*, steeper phase ramps), consistent with previous comparisons with video derived data (Lippmann and Holman, 1991).

At the low frequency peak ( $f \approx 0.015$  Hz), the cross-shore phase structure in the first CEOF also has a linear trend, but only seaward of the bar crest. In this region theoretical group phase speeds are in excellent agreement with the data (although deviates slightly in the far reaches of the surf zone,  $x > \sim 425$  m). Predicted phase relationships (4) are best fit to the data in the region of (approximately) constant celerity, between  $x \approx 255$ -425 m. The average phase speed between  $x = 255$ -425 m,  $\bar{C}_p \approx 7.3$  m/s, is very nearly the same as predicted by Solitary theory,  $\bar{C}_p \approx 7.5$  m/s. The phase relationships are consistent with a shoreward propagating group modulation in the breaking incident wave field traveling at the group velocity of the incident waves. Furthermore, the very small CEOF amplitudes over the bar crest indicate that low frequencies observed in this region are uncoupled to wave groups seaward of the bar, a consequence of widespread breaking over the bar destroying the group structure in the breaking wave field.

## DISCUSSION

In the surf zone, break point amplitudes are often taken as a linear proportion of the depth

$$H_b = \gamma h_b \quad (5)$$

where  $H_b$  is the height (twice the amplitude) of the breaking wave,  $h_b$  is the water depth at the break point, and  $\gamma$  is a constant of  $O(1)$  (e.g., Thornton and Guza, 1982). For a plane sloping bottom,  $h_b = x_b \tan \beta$ , breaking wave amplitudes can be expressed in terms of break point positions. Models based on forcing due to modulations in break point amplitudes can be distinguished by the behavior of  $\gamma$ . In one type (i.e., Foda and Mei, 1981; Schaffer and Svendsen, 1988), break point positions are assumed constant, and the group modulations are allowed to progress to the shoreline. Thus,  $\gamma$  in (5) is a temporal function of the amplitude modulation, in which  $\gamma$  is larger for the bigger waves. In the second type (i.e., Symonds, *et al.*, 1982),  $\gamma$  is assumed constant, and break point position is the parameter that fluctuates.

Our data indicates that the initial break points vary over large distances, ranging from far ( $> 400$  m) offshore for the largest waves to near the bar ( $\sim 100$  m offshore) for the smallest waves. Moreover, the group structure is substantially reduced by wave breaking in the inner surf zone, thus restricting group modulations to seaward of the bar. Thus constant  $\gamma$  more accurately describes the data, and is consistent with energy saturation in shallow depths (verified previously with field data; Thornton and Guza, 1982; Sallenger and Holman, 1985).

#### *Wave Breaking in the Trough*

Some recent models predicting longshore current profiles,  $V(x)$ , have been based on the ensemble distribution of incident wave dissipation,  $\langle \varepsilon_b(x) \rangle$  (e.g., Thornton and Guza, 1986; Whitford and Thornton, 1988). Incident wave breaking is assumed to decrease shoreward of the bar crest due to increasing depths in the trough. Thus model predictions over barred profiles suggest that longshore currents are strongest on the seaward flank of the bar where maximum incident wave dissipation occurs. However, recent observations of  $V(x)$  at Duck suggests that the maximum current often occurs in the trough, in direct conflict with the dissipation models (Whitford and Thornton, 1988; Howd, *et al.*, 1992).

The decay of wave height across a barred profile is well predicted by the model of Thornton and Guza (1983). However, the model assumes implicitly that no time lag exists between the production of turbulent kinetic energy by wave breaking and actual energy dissipation (a point made previously by Roelvink and Stive, 1989; Nairn, *et al.*, 1991). Our observations of wave breaking across the width of the surf zone (Figure 3) indicate that, although the initiation of breaking is confined to depths seaward of the bar, wave breaking does not cease immediately shoreward of the crest, but continues into the trough. The widespread presence of wave "rollers" and bores past the bar crest suggests that advecting turbulence away from the region of highest production over the bar, can be a viable mechanism for transporting momentum into the trough where often the maximum longshore current is observed.

## CONCLUSIONS

A video based technique is presented which accurately quantifies temporal modulations in wave breaking across the width of the surf zone. The technique is based on the gray tone (intensity) contrast between the lighter foam and bubbles created by actively breaking waves and bores, and the darker, surrounding non-breaking water. Thus video records of the surf zone contain visible-band time histories of wave breaking patterns. Quantification is accomplished with an image processing system, in which images are digitized at discrete pixels corresponding to defined field coordinates.

Data are presented from a very narrow banded ( $f_p \approx 0.083$  Hz), unidirectional day ( $\alpha_0 \approx 24^\circ$  CW) during the DELILAH experiment. In addition to energetic incident frequencies associated with the actively breaking incident waves, considerable low frequency variance was observed in all video time series, from the outer portions of the surf zone to the trough of the bar. In the outer surf zone wave breaking at incident frequencies is coupled to low frequency energy, indicating that fluctuations in break point patterns are associated with long period modulations in incident wave amplitudes. Group modulations propagate landward at the phase speed of the incident waves, consistent with simple shoaling expectations.

Finally, we observe the group structure in the wave field to be greatly reduced by breaking in the inner surf zone. All initiation of breaking occurs seaward of the crest, with generally larger waves breaking further offshore and a higher percentage of breaking waves in progressively shallower depths. This suggests that surf zone forcing models which assume a depth dependence on breaking amplitude are more in keeping with the data (*e.g.*, Symonds, *et al.*, 1982). Furthermore, breaking does not cease at the point of minimum depth at the crest, and in fact breaking is widespread in the trough of the bar. This suggests that lateral mixing of momentum across the surf zone, due to the advection of turbulence at the wave front (*e.g.*, Svendsen, 1984, Roelvink and Stive, 1989; Nairn, *et al.*, 1991, and others), could be an important mechanism for modeling longshore currents.

## ACKNOWLEDGEMENTS

This work was supported by the Office of Naval Research, Coastal Sciences program under grant number N00014-90-J1118. Additional funding for DELILAH was provided by CERC. Chuck Long computed the frequency-direction spectra. Ed Thornton provided the surf zone instrumentation for DELILAH. Appreciation is given to the hard working staff of the FRF who provided unparalleled support during the experiment. We wish to thank in particular Bill Birkemeier, Kent Hathaway, Todd Walton, and Todd Holland for aiding in the collection of the video data. The late Paul O'Neill was chief engineer for the OSU group, and without his efforts this

work would not have been possible. Over the past few years, Paul was instrumental in the development of all aspects of our video techniques and image analysis. He was a contemporary scientist, creative engineer, and a good friend.

## CHAPTER 70

# PROBABILISTIC STRUCTURE OF RANDOM WAVE GROUPS

Ke Yu \*

### Abstract

This paper deals with the statistical properties of wave groups in a stationary ergodic normal process. For a narrowband Gaussian process, a method based on Kimura's theory is developed to estimate the characteristics of wave groups directly from the wave spectrum. For a non-narrowband Gaussian process with an arbitrary bandwidth, a new model is established to predict the formation of the wave groups by means of zero-upcrossing method. Thus the probabilistic structure of the wave groups in a Gaussian process with an arbitrary bandwidth can be determined. Using this model, the mean run length of the wave groups above any amplitude and the probability distribution of run length at any level can be obtained. On the other hand, a representative wave period of the wave group is suggested to describe the time intervals between two successive maxima. The computational data shows that the bandwidth parameter has a significant effect on the statistical properties of wave groups.

## 1 Introduction

A wave group can be conveniently defined as several successive waves which exceed a given amplitude level. The waves in the group have similar wave height and wave period. Wave groupiness is an important feature of stochastic wave processes. It has been proven that wave groups have significant effects on many ocean engineering problems, such as the resonance of offshore structures and the overtopping above coastal structures. Because of the importance of the groupiness phenomenon in naval, ocean and communication engineering, extensive studies have been made on this property of stochastic waves in the past twenty years, for example, Kimura (1980) and Funke *et al.* (1979). Using the Markov chain concept in expressing the relationship between two maximum points, Kimura (1980) derived the probability distributions about the runs of high waves, the runs of low waves, and the runs of resonant wave periods respectively. Funke *et al.* (1979) developed a different method, SIWEH, to describe a wave process. A parameter GF was defined to express the groupiness degree in a random wave process. Though SIWEH may have the advantages in describing non-Gaussian processes, the author appreciates Kimura's theory

more for the wave group problem because it provides the information about the probabilistic structure of wave groups which is of concern by engineers and researchers.

However, there are some weaknesses in Kimura's theory. One is the adoption of the narrowband assumption. It is observed that most wave processes in the sea environment have spectrum bandwidth parameter values varying from 0.5 to 0.9, hence the application of Kimura's theory in this case may overestimate the correlation among successive maximum points. The other (Battjes *et al.*, 1984) is the inconvenience in deriving the statistical characteristics of wave groups. It is also worth mentioning that in previous studies, the wave period corresponding to a high wave run is neglected whereas the importance of this parameter is evident.

Therefore, the present study emphasizes the problem in assuming that the process is a stationary ergodic Gaussian process with an arbitrary bandwidth and that the maximum series is subject to the Markov chain condition. The author expects to derive the probabilistic structure of wave groups which include the probability distribution of wave runs above any given amplitude level and to provide some description about the representative wave amplitude and wave period at any given amplitude level.

## 2 Formation of the Probabilistic Structure of Wave Groups

### 2.1 Wave run and its probability distribution

Following Kimura (1980), we can consider a stationary ergodic Gaussian process  $x_1(t)$  with a zero mean and another random process  $x_2(t)$  which is essentially identical to  $x_1(t)$  but has a time shift  $\lambda$  prior to  $x_1(t)$ , i.e.,

$$x_2(t) = x_1(t + \lambda). \quad (1)$$

Assuming the successive maxima of  $x_1(t)$  and  $x_2(t)$  are subject to the Markov chain condition, the maxima of  $x_1(t)$  and  $x_2(t)$  are written as:  $A_1 = \{x_1(t), |x_1(t) \geq 0, \dot{x}_1 = 0, \ddot{x}_1 < 0\}$ ,  $A_2 = \{x_2(t), |x_2(t) \geq 0, \dot{x}_2 = 0, \ddot{x}_2 < 0\}$ . If the time interval  $\lambda$  is defined as the expected wave period between two successive maxima, the joint probability density function of two maxima  $f(A_1, A_2)$  becomes the probability density function of two successive maxima. The probability density function of  $A_1$  (or  $A_2$ ) is defined as  $f(A_1)$  and can be derived from  $f(A_1, A_2)$ .

Two states of wave height are defined. One state is  $S_0 = \{A_i, |A_i < A_L, i = 1, 2\}$ , the second is  $S_1 = \{A_i, |A_i \geq A_L, i = 1, 2\}$ . Hence, all the maxima of  $x_1(t)$  and  $x_2(t)$  can be classified into these two states according to their amplitude values and the given amplitude level  $A_L$ . The two states combined form a state space  $\Omega = \{S_0, S_1\}$ .

For this two state Markov chain, the one-step transition probability matrix is given by

$$P^{[1]} = P = \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix}, \quad (2)$$

where

$$P_{11} = Prob\{A_2 \in S_0, |A_1 \in S_0\} = \frac{\int_0^{A_L} \int_0^{A_L} f(A_1, A_2) dA_1 dA_2}{\int_0^{A_L} f(A_1) dA_1}, \tag{3}$$

$$P_{12} = Prob\{A_2 \in S_1, |A_1 \in S_0\} = \frac{\int_{A_L}^{\infty} \int_0^{A_L} f(A_1, A_2) dA_1 dA_2}{\int_0^{A_L} f(A_1) dA_1}, \tag{4}$$

$$P_{21} = Prob\{A_2 \in S_0, |A_1 \in S_1\} = \frac{\int_0^{A_L} \int_{A_L}^{\infty} f(A_1, A_2) dA_1 dA_2}{\int_{A_L}^{\infty} f(A_1) dA_1}, \tag{5}$$

$$P_{22} = Prob\{A_2 \in S_1, |A_1 \in S_1\} = \frac{\int_{A_L}^{\infty} \int_{A_L}^{\infty} f(A_1, A_2) dA_1 dA_2}{\int_{A_L}^{\infty} f(A_1) dA_1}. \tag{6}$$

Because of the homogeneous feature and the Markov property of maximum point process, the N-step transition probability matrix can be easily obtained as follows

$$P^{[N]} = P^N. \tag{7}$$

The N-step transition probability matrix describes the probabilities of N-step transition through all possible paths. Now we consider a wave run which has a run length L. The transition path of this run must be the pattern as shown in the following figure .

The initial state probability distribution is taken as  $P_0 = [0 \quad 1]$ . The row matrix  $P_0$  means that the wave run starts when a wave exceeds the amplitude level  $A_L$  initially. The run ends when the Lth wave exceeds  $A_L$  at last.

The probability matrix after L-step transition can be expressed as

$$P_L = P_0 P^L = [0 \quad 1] \begin{bmatrix} P_{11} & P_{12} \\ P_{21} & P_{22} \end{bmatrix}^L. \tag{8}$$

From the above equation, the cumulative probability of a wave run which follows the mentioned pattern can be found as below

$$P(L) = P_{22}^{L-1} (1 - P_{22}), \tag{9}$$

where L is the length of the run . The mean run length of wave groups above some amplitude level can also be derived from equation (9) as follows

$$\bar{L} = \frac{1}{(1 - P_{22})}. \tag{10}$$

By a similar method, the probability distribution of a run of low waves and the distribution of the total wave run can be obtained. For conciseness, these results are not included in this paper.

## 2.2 Representative amplitude and period of wave groups

When an amplitude level is given the wave groups are defined. The global statistical properties of wave groups can be determined by using the method described above. However, in order to describe a wave group in detail, a wave amplitude  $A^*$  and a wave period  $T^*$  can be defined to represent the wave run.

$A^*$  could be defined as the expected amplitude value above the level  $A_L$

$$A^* = \frac{\int_{A_L}^{\infty} A_1 f(A_1) dA_1}{\int_{A_L}^{\infty} f(A_1) dA_1} \quad (11)$$

and  $T^*$  could be defined as the expected wave period under the condition of  $A = A^*$

$$T^* = \int_0^{\infty} T f(T, |A^*) dT, \quad (12)$$

where  $f(T, |A^*)$  can be derived from the joint probability density function of wave amplitude and wave period.

In addition to  $A^*$  and  $T^*$ , the characteristic extreme value of the maxima in a wave group with run length  $L$  can be calculated based on extreme value theory. For example, the probability density function of extreme values in a wave group can be expressed as

$$g(\xi) = L \{ f(\xi) [1 - P(\xi)]^{L-1} \} \quad (13)$$

and the required characteristic values of extreme value distribution can be evaluated from equation (13).

## 3 Wave Groups in a Narrowband Gaussian Process

### 3.1 The joint probability density function of two maxima

Suppose a narrowband Gaussian process  $x(t)$  has a zero mean and a spectrum  $S_X(\omega)$ . It is a well known fact that  $x(t)$  can be written as (Ochi, 1982)

$$x(t) = X_C(t) \cos(\omega_0 t) - X_S(t) \sin(\omega_0 t), \quad (14)$$

in which  $X_C$  and  $X_S$  are two orthogonal components which vary slowly with time and  $\omega_0$  is the central frequency. It can be proven that  $X_C$  and  $X_S$  are also the Gaussian processes which have the exact same mean and variance with  $x(t)$ . The auto-spectrum and co-spectrum of  $X_C$  and  $X_S$  can be expressed in terms of  $S_X(\omega)$  as

$$S_{X_C}(\omega) = S_{X_S}(\omega) = S_X(\omega - \omega_0) + S_X(\omega + \omega_0), \quad (15)$$

$$S_{X_C X_S}(\omega) = -S_{X_S X_C}(\omega) = i [S_X(\omega - \omega_0) - S_X(\omega + \omega_0)]. \quad (16)$$

An inverse Fourier transfer is applied to get the auto-correlation or correlation functions of  $X_C$  and  $X_S$  as follows

$$\begin{aligned} R_{X_C}(\lambda) &= R_{X_S}(\lambda) = \int_{-\infty}^{\infty} S_{X_C}(\omega) \exp\{i\omega\lambda\} d\omega \\ &= 2 \int_0^{\infty} S_X(\omega) \cos[(\omega - \omega_0)\lambda] d\omega, \end{aligned} \quad (17)$$

$$R_{X_C X_S}(\lambda) = -R_{X_S X_C}(\lambda) = \int_{-\infty}^{\infty} S_{X_C X_S}(\omega) \exp\{i\omega\lambda\} d\omega \quad (18)$$

$$= 2 \int_0^{\infty} S_X(\omega) \sin[(\omega - \omega_0)\lambda] d\omega,$$

where  $\omega_0 = \omega_p$  (peak frequency) and  $\lambda$  is defined as the expected period between two successive maxima estimated by following equation

$$\lambda = 2\pi \sqrt{\frac{m_0}{m_2}}, \quad (19)$$

where

$$m_i = \int_{-\infty}^{\infty} \omega^i S_X(\omega) d\omega, \quad i = 0, 2.$$

Alternatively, equations (17) and (18) can be expressed in terms of the one-side spectrum  $S(\omega)$

$$R_{X_C}(\lambda) = R_{X_S}(\lambda) = \int_0^{\infty} S(\omega) \cos[(\omega - \omega_0)\lambda] d\omega, \quad (20)$$

$$R_{X_C X_S}(\lambda) = -R_{X_S X_C}(\lambda) = \int_0^{\infty} S(\omega) \sin[(\omega - \omega_0)\lambda] d\omega, \quad (21)$$

where  $S(\omega) = 2S_X(\omega)$ .

If the spectrum is symmetric about  $\omega_0$ , then  $R_{X_C X_S}(\lambda) = R_{X_S X_C}(\lambda) = 0$ . It can be inferred (Middleton, 1960) that the two dimensional amplitude probability density function is given by

$$f(A_1, A_2) = \frac{A_1 A_2}{B} I_0 \left\{ \frac{\sqrt{R_{X_C}^2 + R_{X_C X_S}^2}}{B} A_1 A_2 \right\} \exp \left\{ -\frac{m_0(A_1^2 + A_2^2)}{2B} \right\}, \quad (22)$$

where  $B = m_0^2 - [R_{X_C}^2 + R_{X_C X_S}^2]$  and  $I_0(x)$  is the zeroth order Bessel function of the first kind.

After introducing two non-dimensional amplitudes,  $\xi$  and  $\eta$ , defined as

$$\xi = \frac{A_1}{\sqrt{m_0}}, \quad \eta = \frac{A_2}{\sqrt{m_0}}, \quad (23)$$

equation (22) can be rewritten as

$$f(\xi, \eta) = \frac{\xi \eta}{1 - \rho^2} I_0 \left\{ \frac{\rho \xi \eta}{1 - \rho^2} \right\} \exp \left\{ -\frac{\xi^2 + \eta^2}{2(1 - \rho^2)} \right\}. \quad (24)$$

The correlation coefficient  $\rho$  can be determined by the following formula

$$\rho = \frac{\sqrt{R_{X_C}^2(\lambda) + R_{X_C X_S}^2(\lambda)}}{m_0}. \quad (25)$$

The one dimensional amplitude probability density function can be derived from equation (22) as

$$f(A_1) = \frac{A_1}{m_0} \exp \left\{ -\frac{A_1^2}{2m_0} \right\} \quad (26)$$

and the dimensionless form of  $f(A_1)$  is

$$f(\xi) = \xi \exp \left\{ -\frac{\xi^2}{2} \right\}. \quad (27)$$

### 3.2 Representative amplitude and period of wave groups in a narrowband Gaussian process

Applying the maximum distribution into equation (11), the representative amplitude of a wave group above any given level  $\xi_L$  can be obtained as

$$\xi^* = \xi_L + \sqrt{2\pi} \exp\{\xi_L^2/2\} [1 - \Phi(\xi_L)], \quad (28)$$

where

$$\Phi(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x \exp \left\{ -\frac{u^2}{2} \right\} du.$$

As for the representative wave period, the joint probability distribution of wave amplitude and period suggested by Longuet-Higgins (1975) is used to get the probability distribution of wave period under the condition of  $\xi = \xi^*$

$$f(\xi, \tau) = \frac{1}{1 - \Phi(-\xi/\nu)} \frac{1}{\sqrt{2\pi}} \xi^2 \exp \left\{ -\frac{\xi^2(1 + \tau^2)}{2} \right\}, \quad (29)$$

$$0 \leq \xi < \infty, \quad -\frac{1}{\nu} < \tau < \infty$$

where

$$\xi = \frac{A}{\sqrt{m_0}}, \quad \tau = \frac{T - \bar{T}}{\nu T}, \quad \nu = \sqrt{\frac{m_0 m_2}{m_1^2} - 1}, \quad \bar{T} = 2\pi \sqrt{\frac{m_0}{m_2}}.$$

$\Phi(x)$  is the error function and  $\nu$  is another bandwidth parameter which is determined by the spectral moments.

The conditional probability density function of the wave period is

$$f(\tau, |\xi^*) = \frac{f(\xi, \eta)}{f(\xi)} = \frac{1}{1 - \Phi(-\xi^*/\nu)} \frac{1}{\sqrt{2\pi}} \xi^* \exp \left\{ -\frac{1}{2} (\xi^* \tau)^2 \right\} \quad (30)$$

and the representative wave period can be calculated by equation (12)

$$\tau^* = \frac{1}{\sqrt{2\pi} \xi^* [1 - \Phi(-\xi^*/\nu)]} \exp \left\{ -\frac{1}{2} (\xi^* \tau)^2 \right\}. \quad (31)$$

Applying the two dimensional density function of two maxima presented by equation (22) and one dimensional density function expressed by equation (26) into equation (6), the probability  $P_{22}$  under the condition of a given amplitude level  $\xi^*$  can be determined. The  $P_{22}$  value can also be used to determine the probability distribution of wave runs which are above the level  $\xi_L$ . Equations (28) and (31) give the analytic expressions of representative wave amplitude and wave period of wave runs above a given amplitude level.

## 4 Wave Groups in a Non-narrowband Gaussian Process

### 4.1 The two dimensional maximum distribution

Given a stationary Gaussian process  $x_1(t)$  with a zero mean and an arbitrary spectral bandwidth and another process  $x_2(t)$  defined in equation (1), the time shift  $\lambda$  can be determined by the bandwidth parameter  $\epsilon$  and the moments of the spectrum

$$\lambda = 4\pi \frac{\sqrt{1 - \epsilon^2}}{1 + \sqrt{1 - \epsilon^2}} \sqrt{\frac{m_0}{m_2}}, \tag{32}$$

$$\epsilon = \sqrt{1 - \frac{m_2^2}{m_0 m_4}}. \tag{33}$$

It can be proven that the two processes  $x_1(t)$  and  $x_2(t)$  and their derivatives  $\dot{x}_1(t)$ ,  $\ddot{x}_1(t)$ ,  $\dot{x}_2(t)$ ,  $\ddot{x}_2(t)$  are subject to a six dimensional normal distribution ( Ochi, 1979). Their joint probability density function can be written as

$$f(X) = \frac{1}{(2\pi)^3 |\Sigma|^{1/2}} \exp \left\{ -\frac{1}{2} X \Sigma^{-1} X^T \right\}, \tag{34}$$

in which the row matrix X is

$$X = [ x_1(t) \quad \dot{x}_1(t) \quad \ddot{x}_1(t) \quad x_2(t) \quad \dot{x}_2(t) \quad \ddot{x}_2(t) ].$$

The covariance matrix can be expressed in terms of the spectral density function

$$\Sigma = \begin{bmatrix} m_0 & 0 & -m_2 & m_{0C} & -m_{1S} & -m_{2C} \\ 0 & m_2 & 0 & m_{1S} & m_{2C} & -m_{2S} \\ -m_2 & 0 & m_4 & -m_{2C} & m_{3S} & m_{4C} \\ m_{0C} & m_{1S} & -m_{2C} & m_0 & 0 & -m_2 \\ -m_{1S} & m_{2C} & m_{3S} & 0 & m_2 & 0 \\ -m_{2C} & -m_{2S} & m_{4C} & -m_2 & 0 & m_4 \end{bmatrix},$$

where

$$m_i = \int_0^\infty \omega^i S(\omega) d\omega \quad , \quad i = 0, 2, 4,$$

$$m_{iC} = \int_0^\infty \omega^i S(\omega) \cos(\omega\lambda) d\omega \quad , \quad i = 0, 2, 4,$$

$$m_{iS} = \int_0^\infty \omega^i S(\omega) \sin(\omega\lambda) d\omega \quad , \quad i = 1, 2, 3.$$

As mentioned before, the positive maxima of  $x_1(t)$  and  $x_2(t)$  must satisfy the conditions,  $x_i(t) \geq 0$ ,  $\dot{x}_i = 0$ ,  $\ddot{x}_i < 0$ ,  $i = 1, 2$ . The expected number of maxima

which are above the respective amplitude levels  $A_1$  and  $A_2$  per unit time can be evaluated by the following equation

$$\bar{N}_{A_1, A_2} = \int_{A_1}^{\infty} \int_{A_2}^{\infty} \int_{-\infty}^0 \int_{-\infty}^0 |\dot{x}_1| |\dot{x}_2| f(x_1, 0, \ddot{x}_1, x_2, 0, \ddot{x}_2) dx_1 dx_2 d\ddot{x}_1 d\ddot{x}_2. \quad (35)$$

Letting  $A_1 = A_2 = 0$  in equation (35), equation (35) can be rewritten as

$$\bar{N}_{0,0} = \int_0^{\infty} \int_0^{\infty} \int_{-\infty}^0 \int_{-\infty}^0 |\dot{x}_1| |\dot{x}_2| f(x_1, 0, \ddot{x}_1, x_2, 0, \ddot{x}_2) dx_1 dx_2 d\ddot{x}_1 d\ddot{x}_2 \quad (36)$$

and it can be used to estimate the expected number of maxima in  $x_1(t)$  and  $x_2(t)$  per unit time. The probability that the maxima in  $x_1(t)$  and  $x_2(t)$  exceed respective amplitude level  $A_1$  and  $A_2$  can be considered approximately as the ratio of these two expected numbers. Hence the joint probability density function of two maxima can be derived from the ratio  $\bar{N}_{A_1, A_2} / \bar{N}_{0,0}$

$$\begin{aligned} f(A_1, A_2) &= \frac{\partial^2}{\partial A_1 \partial A_2} \left( 1 - \frac{\bar{N}_{A_1, A_2}}{\bar{N}_{0,0}} \right) \\ &= \frac{\int_{-\infty}^0 \int_{-\infty}^0 |\dot{x}_1| |\dot{x}_2| f(A_1, 0, \ddot{x}_1, A_2, 0, \ddot{x}_2) d\ddot{x}_1 d\ddot{x}_2}{\int_0^{\infty} \int_0^{\infty} \int_{-\infty}^0 \int_{-\infty}^0 |\dot{x}_1| |\dot{x}_2| f(x_1, 0, \ddot{x}_1, x_2, 0, \ddot{x}_2) dx_1 dx_2 d\ddot{x}_1 d\ddot{x}_2}. \end{aligned} \quad (37)$$

Now, define two new Gaussian processes which are derived from  $x_1(t)$  and  $x_2(t)$

$$x'_1(t) = \frac{1}{\sqrt{m_0}} x_1(t) \quad , \quad x'_2(t) = \frac{1}{\sqrt{m_0}} x_2(t) \quad (38)$$

and two dimensionless maxima as before

$$\xi = \frac{A_1}{\sqrt{m_0}} \quad , \quad \eta = \frac{A_2}{\sqrt{m_0}}.$$

The two dimensional distribution of two dimensionless maxima  $\xi$  and  $\eta$  can be obtained simply by replacing  $x'_1, x'_2, \dot{x}'_1, \dot{x}'_2, \xi$  and  $\eta$  for the proper terms in equation (34) and (37). Note the covariance matrix  $\Sigma$  becomes  $\Sigma'$  and satisfies the following relation

$$\Sigma' = \frac{1}{m_0} \Sigma. \quad (39)$$

The probability density function of the maxima in process  $x_1(t)$  has the form

$$\begin{aligned} f(A_1) &= \frac{2/\sqrt{m_0}}{1 + \sqrt{1 - \epsilon^2}} \left[ \frac{\epsilon}{\sqrt{2\pi}} \exp \left\{ -\frac{1}{2\epsilon^2} \left( \frac{A_1}{\sqrt{m_0}} \right)^2 \right\} + \sqrt{1 - \epsilon^2} \left( \frac{A_1}{\sqrt{m_0}} \right) \right. \\ &\quad \left. \times \exp \left\{ -\frac{1}{2} \left( \frac{A_1}{\sqrt{m_0}} \right)^2 \right\} \left\{ 1 - \Phi \left( -\frac{\sqrt{1 - \epsilon^2}}{\epsilon} \frac{A_1}{\sqrt{m_0}} \right) \right\} \right], \quad (40) \\ &\quad 0 \leq A_1 < \infty \end{aligned}$$

and the non-dimensional form of equation (40) is as follows

$$\begin{aligned} f(\xi) &= \frac{2}{1 + \sqrt{1 - \epsilon^2}} \left[ \frac{\epsilon}{\sqrt{2\pi}} \exp \left\{ -\frac{\xi^2}{2\epsilon^2} \right\} + \sqrt{1 - \epsilon^2} \xi \right. \\ &\quad \left. \times \exp \left\{ -\frac{\xi^2}{2} \right\} \left\{ 1 - \Phi \left( -\frac{\sqrt{1 - \epsilon^2}}{\epsilon} \xi \right) \right\} \right]. \quad (41) \end{aligned}$$

## 4.2 The representative amplitude and period of wave groups in a non-narrowband Gaussian process

The representative dimensionless amplitude  $\xi^*$  can be estimated by equations (41) and (11).

For a non-narrowband Gaussian process, the joint probability density function of the maxima and the time intervals between two successive maxima can be used to calculate the representative wave period (Arhan *et al.*, 1976)

$$f(\xi, \tau) = \frac{2}{\sqrt{2\pi}} \frac{\alpha^3}{\epsilon(1-\epsilon^2)} \frac{\xi^2}{\tau^5} \exp \left\{ -\frac{\xi^2}{2\epsilon^2\tau^4} [(\tau^2 - \alpha^2)^2 + \alpha^4\beta^2] \right\}, \quad (42)$$

in which  $\xi = A_1/\sqrt{m_0}$ ,  $\tau = T/\lambda$ ,  $\alpha = 0.5(1 + \sqrt{1 - \epsilon^2})$ ,  $\beta = \epsilon/\sqrt{1 - \epsilon^2}$ .

The conditional probability density function of  $\tau$  can be expressed as

$$f(\tau, |\xi) = \frac{f(\xi, \tau)}{\int_0^\infty f(\xi, \tau) d\tau} \quad (43)$$

and the representative wave period  $\tau^*$  can be written as

$$\tau^* = \int_0^\infty \tau f(\tau, |\xi^*) d\tau. \quad (44)$$

Note that  $\tau^*$  is not a wave period according to the exact definition of a wave period by means of zero-upcrossing. It is just a time interval between two successive maxima. However, when the wave amplitude is large enough,  $\tau^*$  can be considered as a good approximation of wave period.

## 5 Computational Results and Discussions

In order to find the effect of the spectral bandwidth on the probability structure of wave groups, different  $\epsilon$  values should be applied in this computation. But the common wave spectra used in analysis and experiment, such as the JONSWAP spectrum and the Bretschneider spectrum, only have limited range of  $\epsilon$  values. Hence some typical wave records used in Ochi's study are used here again. The  $\epsilon$  values of these spectra vary from 0.46 to 0.8. A JONSWAP spectrum with  $\alpha = 0.05$ ,  $f_p = 0.1 Hz$ ,  $\gamma = 7.0$  and  $\epsilon = 0.685$  is applied to the computation. Table 1 displays the features of the spectra which include the bandwidth parameter  $\epsilon$  and the correlation coefficient  $\rho$  calculated by equations (33) and (25).

Table 1. Wave records and wave spectrum used in the computation

wave spectrum	spectral bandwidth parameter $\epsilon$	correlation coefficient $\rho$	peak frequency $\omega(2\pi * Hz)$
WS1	0.468	0.458	0.875
WS2	0.594	0.299	0.563
WS3	0.685	0.676	0.626
WS4	0.806	0.267	0.413

It is clear that the numerical integration in equation (37) is the major work in this computation. Here,  $2.401 \times 10^7$  discretizing points are used in calculating the quadruple integration in order to guarantee accuracy.

Figure 1 shows the relationship of  $P_{22}$  and  $\xi_L$ . For each spectrum, two  $\epsilon - \xi_L$  curves based on the non-narrowband and the narrowband theory respectively, are presented to compare the difference between two theories. It can be seen that the narrowband theory will give larger a  $P_{22}$  value when  $\epsilon$  is increased for fixed  $\xi_L$ . In this case it seems only the value of  $\epsilon$  will determine the  $P_{22} - \xi_L$  relation under the non-narrowband assumption. When  $\epsilon = 0.46$ , the two theories give almost the same results for small amplitude levels. For the wave spectra which have very small  $\epsilon$  values, the strong singularity of the co-variance matrix makes its determinant value approach zero and leads the elements in the inverse matrix  $\Sigma^{-1}$  to infinity. It will induce the non-existence of the joint probability density function expressed by equation (37). In this situation, the narrowband assumption could be applied to simplify the problem. We can also infer that when the value of  $\epsilon$  approaches zero, it is the correlation coefficient  $\rho$ , not the bandwidth parameter  $\epsilon$ , that will determine the  $P_{22} - \xi_L$  relation if  $\epsilon$  is very small. This estimation can be demonstrated by the one dimensional analytic distribution of wave amplitude in a non-narrowbanded Gaussian process which has a small bandwidth. From equation (41) it can be seen that the wave amplitude distribution with  $\epsilon$  value in the region  $0 < \epsilon < 0.5$  is almost the same with the Rayleigh distribution expressed by equation (27).

From equation (30) it can be seen that only the correlation coefficient  $\rho$  affects the joint distribution and finally determines the probability distribution of wave runs if the amplitude level remains constant. Employing equations (22) and (26) into equation (6), the probability distribution of wave runs can be obtained from equation (9). Figure 2 displays the relationship between the probability of wave run and its run-length with different  $\rho$  values.

Figure 2 also shows two probability distribution of wave groups based on narrowband theory and non-narrowband theory respectively. In the figure, the amplitude level  $\xi_L = 1.245$  represents the mean amplitude in a standard narrowbanded normal process. In figure 3, the level  $\xi_L = 2.005$  is just the significant amplitude in a narrowbanded normal process. By applying the two  $P_{22}$  values corresponding to a given amplitude level into equation (9), two probability distributions of the high wave runs above the amplitude level can be easily determined.

Applying equations (42) and (43) into equations (11) and (12), the dimensionless representative wave amplitude and wave period in a non-narrowband Gaussian process can be determined. Figure 4 displays the relation between the representative wave amplitude and the representative period with different  $\epsilon$  values. The curve noted as  $\epsilon = 0$  represents the  $\xi^* - \xi_L$  relation expressed by equation(28). Figure 5 shows the relationship of  $\tau^*$  and  $\xi$  with different  $\epsilon$  values. Within the narrowband theory, the representative wave period  $\tau^*$  calculated by equation (31) is zero when  $\xi^*$  takes its minimum value of 1.245. In other words, the expected wave period is considered to be the representative wave period in this case.

It is worthy to mention here that the present analysis and computation is in fact the extension of Kimura's theory to a more general case. We know from the previous analysis that two parameters, the bandwidth parameter,  $\epsilon$ , and the correlation coef-

ficient,  $\rho$ , decide the statistical properties of wave groups. For an ideal narrowband Gaussian process, the effect of the bandwidth parameter on wave groups reduces to zero and only the correlation coefficient determines the properties. For a non-narrowband Gaussian process with a large  $\epsilon$  value, the computational data shows the opposite result. The bandwidth parameter plays a major role in determining the probabilistic features of the wave groups. But for a small  $\epsilon$  value we do not know which parameter is more important. We expect to see that as  $\epsilon$  increases, the bandwidth parameter will gradually replace the correlation coefficient and dominate the statistical properties of wave groups. To see these effects more clearly, further numerical analysis is necessary with variance on the two parameters. For example, wave spectra having the same  $\epsilon$  value but different  $\rho$  values or having the same  $\rho$  value but different  $\epsilon$  values.

Another tricky problem arising in this study is the validity of the present theory when it is applied to a random process which tends to be white noise, i.e., the bandwidth parameter and the correlation coefficient approach to one and zero respectively. In this case the assumption that the successive maxima in the process subject to the Markov chain condition becomes questionable, since the successive maxima tend to be independent variables. To determine how far we can go with this model, more wave records and field data are necessary. It is definitely interesting and promising work to analyze and compare the experimental and field data about the random wave groups with the existing models. This will lead to a deeper understanding to the groupiness phenomenon in the real sea environment.

## 6 Conclusions

The following conclusions can be made from the above analysis:

1. When a stationary Gaussian process has a small bandwidth parameter, i.e.,  $\epsilon < 0.5$ , the narrowband assumption can be applied and the statistical properties of wave groups derived from the narrowband theory can be considered as a good approximation.
2. If the spectrum of a stationary Gaussian process is not assumed narrowbanded, i.e.,  $\epsilon \geq 0.5$ , the application of the narrowband assumption will overestimate the correlation between two successive maxima.
3. For a narrowband Gaussian process the correlation coefficient  $\rho$  will determine the statistical properties of wave groups. For a non-narrowband Gaussian process with large  $\epsilon$  value, it seems that the spectral bandwidth parameter will finally determine the probabilistic structure of wave groups.
4. Based on the formulas presented in this paper, the probabilistic structure of wave groups in a stationary ergodic Gaussian random process can be obtained directly from its wave spectrum.

## Acknowledgments

The author thanks Mr. Weidon Su for his meaningful insight which helped to start this work. In addition, the author expresses his appreciation to Dr. Jian Ye and Mr. Bingcan Din for their assistance in the numerical computation which was beneficial

to the development of this paper. The author also thanks Mr. Michael Poff and Mr. Daniel Cox who read this paper carefully and made many suggestions. Finally, the author's deep appreciation goes to Prof. Ib A. Svendsen, the head of Civil Engineering Department at University of Delaware, and Prof. Robert A. Dalrymple, the director of Center for Applied Coastal Research at University of Delaware, who provided a considerable financial aid for this trip. Their encouragement and support made this representation possible.

## CHAPTER 71

### Statistics of wave group parameters

Gerbrant Ph. van Vledder <sup>1</sup>

#### Abstract

The statistical properties of four spectral shape parameters ( $Q_p$ ,  $Q_e$ ,  $\kappa$  and  $\nu$ ) and the correlation coefficient between succeeding wave heights ( $\rho_{HH}$ ) are investigated using field data and numerically simulated data. The effects of spectral smoothing, integration range and duration of the data record on estimates of these parameters are discussed. The relation between spectral shape and wave grouping is discussed in relation to Kimura's theory for group length statistics. A group length distribution independent method for computing this mean group length is introduced. Further, a comparison is made between time and frequency domain estimates of the correlation coefficient between successive wave heights. Observed discrepancies between them are analyzed and an improved method for the spectral computation of this coefficient is suggested.

#### 1 Introduction

The statistical analysis of random wave groups has received much attention in the last years. These studies can be divided into analyses in terms of individual wave heights or in terms of wave envelopes. This paper concentrates on wave group analysis in terms of individual waves, where a wave group is defined as a sequence of waves all succeed a certain height. The most successful model for the statistical description of group lengths has been given by Kimura (1980). Principal parameter in this model is the correlation between successive wave heights. Various parameters have been developed to relate wave group length statistics to the spectral shape, e.g. the well known peakedness parameter  $Q_p$ , introduced by Goda

---

(1970), or the  $\kappa$  parameter, used by Battjes and Van Vledder (1984). This  $\kappa$  parameter links the spectral width via the correlation coefficient  $\rho_{HH}$  between successive wave heights to group length statistics. Other measures for the spectral width are the parameter  $\nu$ , introduced by Longuet-Higgins (1975), or  $Q_e$ , introduced by Medina and Hudspeth (1987).

Most of these parameters lack a theoretical basis linking wave group statistics and spectral width. Only the  $\kappa$  parameter has such a basis, although it underestimates group lengths. Medina and Hudspeth (1990) have theoretically analyzed the relation between the spectral shape parameters  $Q_p$ ,  $Q_e$ ,  $\kappa$  and the correlation coefficient between successive wave heights  $\rho_{HH}$ . They used a three-axes representation to show that these parameters are interrelated. They argue, that because of this interrelationship, only one of these parameters is required in order to evaluate wave groupiness. Although they note the possible effect of statistical variability on the estimates of these parameters, they do not pursue the consequences of this variability on the interrelationship between these parameters.

The purpose of this paper is to analyze the statistical properties of four spectral shape parameters ( $Q_p$ ,  $Q_e$ ,  $\nu$  and  $\kappa$ ) and their usefulness in relation to wave grouping. Also, the effects of spectral smoothing, sensitivity to integration range and duration of the underlying wave record on estimates of these parameters are investigated. Finally, assumptions in the spectral computation of this coefficient are reviewed and improved where possible.

## 2 Wave group analysis in terms of individual waves

In this paper wave groups are defined in terms of individual zero-up crossing waves. A wave group is defined as a sequence of succeeding waves with heights that all exceed a preset threshold level (e.g. the mean wave height). The length of the wave group is equal to the number of waves in a group. The mean group length in a wave record is considered as the measure for the amount of wave grouping.

Models for the probability distribution of group lengths have been given by Goda (1970) and Kimura (1980). The model of Goda underestimates group lengths since it neglects the correlation between succeeding wave heights. As was shown by Rye (1974) and others, consecutive wave heights are positively correlated. This correlation is quantified by means of the coefficient of linear correlation:

$$\rho_{HH,t} = \frac{1}{\sigma_H^2} \frac{1}{N-1} \sum_{i=1}^{N-1} (H_i - H_m)(H_{i+1} - H_m) \quad (2.1)$$

in which  $\sigma_H$  is the standard deviation and  $H_m$  the mean wave height and  $N$  the number of waves in a record. The subscript  $t$  refers to time domain.

These correlations are considered in the model of Kimura (1980), in which it is assumed that succeeding wave heights form a Markov-chain. To compute the probability of a sequence of high waves with a certain length, Kimura used the conditional probability  $p_{22}$  that a wave height exceeds the threshold level,  $H_c$ , given that the previous wave also exceeds  $H_c$ :

$$p_{22} = \text{Prob} \{ H_{i+1} > H_c \mid H_i > H_c \} \tag{2.2}$$

The group length distribution function is:

$$P_1(j) = (1 - p_{22}) p_{22}^{j-1} \tag{2.3}$$

The mean group length can be computed as:

$$\bar{j}_1 = E\{j\} = \sum_{j=1}^{\infty} j P_1(j) = \frac{1}{1 - p_{22}} \tag{2.4}$$

and the standard deviation of group length can be computed as:

$$\sigma_1(j) = \{ E\{j^2\} - E\{j\}^2 \}^{1/2} = \frac{\sqrt{p_{22}}}{1 - p_{22}} \tag{2.5}$$

The probability  $p_{22}$  is computed from the joint probability density function  $p(H_1, H_2)$  of succeeding wave heights:

$$p_{22} = \int_{H_c}^{\infty} \int_{H_c}^{\infty} p(H_1, H_2) dH_1 dH_2 \mid \int_{H_c}^{\infty} \int_0^{\infty} p(H_1, H_2) dH_1 dH_2 \tag{2.6}$$

where  $p(H_1, H_2)$  is the bi-variate Rayleigh distribution:

$$p(H_1, H_2) = \frac{\pi^2}{4} \frac{H_1 H_2}{H_m^4 (1 - \kappa^2)} \exp \left( -\frac{\pi}{4} \frac{H_1^2 + H_2^2}{H_m^2 (1 - \kappa^2)} \right) I_0 \left( \frac{\pi}{2} \frac{\kappa}{(1 - \kappa^2)} \frac{H_1 H_2}{H_m^2} \right) \tag{2.7}$$

In Eq. (2.7)  $\kappa$  is a correlation parameter,  $H_m$  the mean wave height, and  $I_0$  the modified Bessel function of zeroth order. The relation between the correlation parameter  $\kappa$  and the coefficient of linear correlation is given by:

$$\rho_{HH} = \frac{E(\kappa) - \frac{1}{2}(1 - \kappa^2)K(\kappa) - \pi/4}{1 - \pi/4} \tag{2.8}$$

in which  $K$  and  $E$  are the complete elliptic integrals of the first and second kind, respectively. An accurate approximation of Eq. (2.8) has been given by Battjes (1974):

$$\rho_{HH} \approx \frac{\pi}{16 - 4\pi} \left( \kappa^2 + \frac{\kappa^4}{16} + \frac{\kappa^6}{64} \right) \tag{2.9}$$

The truncation error involved in approximation (2.9) is less than 0.1% for  $0 \leq \kappa < 0.7$  and less than 1% for  $0.7 \leq \kappa < 0.95$ .

The model of Kimura has been verified against field measurements by Goda (1983), Battjes and Van Vledder (1984), and others. The present study also supports Kimura's model for predicting the mean group length. To that end, numerically simulated data have been used, see section 7, Fig. 1, panel a).

### 3 The mean group length

The standard method of deriving the mean group length  $\bar{j}_1$  is via Eq. (2.4) on the basis of the theoretical group length distribution (2.3). The mean group length, however, is independent of this group length distribution (Van Vledder, 1983).

Consider a wave record with  $N_w$  waves of which  $N_h$  waves are higher than the threshold level  $H_c$ . Further, the wave record contains  $N_g$  groups of high waves. The mean group length  $\bar{j}_1$  can then be computed as:

$$\bar{j}_1 = \frac{N_g}{N_h} \tag{3.1}$$

The end of each wave group can be identified as a sequence of a high wave followed by a low wave. Consequently, the number of wave groups is given by:

$$N_g = N_w \times \text{Prob}\{H_i > H_c \wedge H_{i+1} \leq H_c\} \tag{3.2}$$

The number of high waves in the wave record is given by

$$N_h = N_w \times \text{Prob}\{H_i > H_c\} \tag{3.3}$$

Thus, the mean group length  $\bar{j}_1$  can be computed as:

$$\left. \begin{aligned} \bar{j}_1 &= \frac{\text{Prob}\{H_i > H_c\}}{\text{Prob}\{H_i > H_c \wedge H_{i+1} \leq H_c\}} \\ &= \frac{1}{1 - \text{Prob}\{H_{i+1} > H_c \mid H_i > H_c\}} \end{aligned} \right\} \tag{3.4}$$

which by virtue of Eq. (2.2) is equal to expression (2.4). This result implies that the mean group length  $\bar{j}_1$  is directly related to the correlation coefficient between successive wave heights  $\rho_{HH,t}$ , through the Eqs. (2.6), (2.7) and (2.8). It also implies that the mean group length does not depend on correlations between non-successive wave heights.

## 4 Spectral shape parameters

It is well known that the spectral width is related to the amount of wave grouping. Sea states with narrow spectra show a higher amount of wave grouping than those with broad spectra (Rye, 1974, and others). Below, four spectral width parameters ( $Q_p$ ,  $Q_e$ ,  $\nu$  and  $\kappa$ ) are described that have been suggested in relation to wave grouping. The  $Q_p$  parameter has been introduced by Goda (1970) as a measure for the peakedness of the wave spectrum. It is defined as:

$$Q_p = \frac{2}{m_0^2} \int_0^{\infty} f S(f)^2 df \quad (4.1)$$

in which  $S(f)$  the frequency spectrum and  $m_0$  its zeroth moment. The  $Q_p$  parameter is frequently used by many authors in relation to the amount of wave grouping of wind waves. Recently, Medina and Hudspeth (1987) proposed the spectral peakedness parameter  $Q_e$ , similar to Goda's peakedness parameter, it is defined as:

$$Q_e = \frac{2m_1}{m_0^3} \int_0^{\infty} S(f)^2 df \quad (4.2)$$

with  $m_0$  and  $m_1$  the zeroth and first spectral moment of  $S(f)$ , respectively. Another spectral width parameter was introduced by Longuet-Higgins (1975),

$$\nu = (m_0 m_2 / m_1^2 - 1)^{\frac{1}{2}} \quad (4.3)$$

and applied by Longuet-Higgins (1984) and Chandler and Masson (1992) to wave group statistics.

Above three parameters have been proposed on intuitive grounds rather than on theoretical ones. A fundamental approach to relate the spectral shape with the amount of wave grouping is based on Rice's (1944) theoretical results on envelope statistics. Rice (1944) has derived the joint probability of two values  $R_1$  and  $R_2$  of the wave envelope  $R(t)$  for a narrow-banded Gaussian process, separated by a time lag  $\tau$ . This distribution is the bi-variate Rayleigh distribution, given by Eq. (2.7), but with the parameters  $H_1$ ,  $H_2$  and  $H_m$  replaced by  $R_1$ ,  $R_2$  and  $R_m$ , respectively. This bi-variate Rayleigh distribution contains a correlation parameter that depends on the lag  $\tau$  and the spectral shape. The definition for this parameter has been rewritten by Battjes (1974) as:

$$\kappa^2(\tau) m_0^2 = \left[ \int_0^{\infty} S(f) \cos(2\pi f\tau) df \right]^2 + \left[ \int_0^{\infty} S(f) \sin(2\pi f\tau) df \right]^2 \quad (4.4)$$

For narrow spectra, Rice's result can be used to derive the joint distribution of two consecutive wave heights  $H_1$  and  $H_2$  by substituting  $H_1 = 2R_1$  and  $H_2 = 2R_2$ , and using

$\tau = T_m$ , where  $T_m$  is the mean wave period that can be computed from the wave spectrum (Arhan and Ezraty, 1978):

$$T_m = T_{m02} = \sqrt{m_0/m_2}. \quad (4.5)$$

Using relation (2.8) a frequency domain estimate of the correlation coefficient between successive wave heights can be obtained. Such an estimate is denoted by  $\rho_{HH,f}(\tau)$ .

## 5 Wave data and analysis

Field data were collected in the North Sea using a Waverider buoy in swell and wave growth situations. These data consist of 33 wave records and include some JONSWAP data as well as data from the severe storm of January 3, 1978 (Bouws, 1979). The wave records consist of time series of surface elevation (sampling rate 2 Hz) with a duration of approximately 20 minutes.

The random Fourier coefficient method (Tucker et al., 1984) was applied to generate relatively long time series of sea surface elevation. In this method, the sea surface  $\eta(t)$  consists of  $N$  values sampled at discrete times  $t_m$  with intervals  $\Delta t$ :

$$\eta(t_m) = \sum_{n=0}^{N/2} \{ a_n \cos(2\pi f_n t_m) + b_n \sin(2\pi f_n t_m) \} \quad (5.1)$$

in which  $f_n = n/(N\Delta t)$  and where the random Fourier coefficients,  $a_n$  and  $b_n$ , each are independent variables taken from a normal distribution with zero mean and variance  $S(f_n)\Delta f$  with  $S(f)$  the frequency spectrum. An inverse Fourier transform of the set of coefficients  $a_n$  and  $b_n$  then leads to the desired time series.

A total of 161 time series were generated, each with a time step of 0.5 s and a duration of 2 hours and 16 minutes. A JONSWAP spectrum was used to compute the random Fourier coefficients. The peak enhancement factor  $\gamma$  varied from 1.0 to 20 with a step of 0.125, and the peak period was 5.0 s. Typically, each wave record contained 2000 individual waves.

## 6 Sampling properties

It is well known that raw (unsmoothed) estimates of the spectral density  $S(f)$ , based on a single record, have a relatively large sampling variability. This is generally reduced by applying some smoothing at the expense of resolution. The four spectral parameters, considered here, all depend on integrals over the entire spectrum and therefore have a relatively small sampling variability (random error), regardless of the degree of smoothing. The same is true for the bias in the estimates of  $\nu$  and  $\kappa$ , because  $S(f)$  appears linearly in the integrals. For  $\kappa$  this is also because the cosine and sine terms in (4.4) vary slowly

compared to the unsmoothed estimate of  $S(f)$ . The parameters  $Q_p$  and  $Q_e$ , however, are proportional to an integral of the square of  $S(f)$ . Therefore, sampling variability in  $S(f)$  causes a positive bias in estimates of  $Q_p$  and  $Q_e$ .

As shown by Elgar et al. (1984), the expected value of  $Q_p$  is given by

$$E\{Q_p\} = Q_p(1 + 1/n) \quad (6.1)$$

in which  $n$  is the effective number of frequency bands. A similar analysis has been performed for the  $Q_e$  parameter, with similar result. The parameters  $\kappa$  and  $\nu$  are not affected by any smoothing of the spectrum, because they depend linearly on  $S(f)$ . For smoothly varying spectra (such as analytically expressed spectra),  $Q_p$  and  $Q_e$  are measures of peakedness in the sense of concentration of energy near a single frequency (which is the conventional interpretation), but for estimated spectra it is just as much a measure of all local peaks and thus of spectral roughness due to sampling variability. Therefore, the parameters  $Q_p$  and  $Q_e$  are no suitable spectral width parameters, and not even useful in relation to wave grouping (Van Vledder and Battjes, 1992).

The sampling properties of above parameters are given in Table 1, based on the analysis of a typical North Sea wind wave record.

$n$	$Q_p$	$Q_e$	$\kappa$	$\nu$
1	6.23	7.17	0.622	0.346
3	4.02	4.59	0.620	0.347
5	3.50	3.97	0.624	0.346
7	3.57	4.04	0.620	0.344
9	3.33	3.82	0.609	0.351

Table 1 Computed values of  $Q_p$ ,  $Q_e$ ,  $\kappa$  and  $\nu$  as a function of the number  $n$  of raw frequency bands used in the spectral smoothing.

The results confirm that estimates of the parameters  $\nu$  and  $\kappa$  are practically free of bias, whereas estimates of the parameters  $Q_p$  and  $Q_e$  are strongly biased. The results for the latter two parameters are nearly proportional to  $(1 + 1/n)$ , which is in agreement with the theoretical result of Elgar et al. (1984). The dependence of estimates of  $Q_p$  and  $Q_e$  on the amount of smoothing makes them unsuited as measure for spectral width, especially when the amount of smoothing is not known.

## 7 Effect of time series duration

Nelson (1987) and Medina and Hudspeth (1990) argue that long data records are required in order to reduce the variability in the estimates of wave group parameters to an acceptable level, since the standard deviation of group lengths is of the same order as their mean. Nelson (1987) recommends to use data records of at least 2 hours duration. Since such long data records are difficult to collect, time series of sufficient duration were generated numerically.

The effect of record duration on the variability of group length statistics was analyzed by using 153 simulated time series of 2 hours and 16 min duration, and by using 153 short time series with a duration of approximately 20 minutes. The results are shown in Fig. 1. Shown are the mean group lengths  $\bar{j}_1$  as a function of  $\rho_{HH,t}$ , together with the relation according to Kimura's theory.

Fig. 1 Observed mean group lengths  $\bar{j}_1$  as a function of the correlation between successive wave heights  $\rho_{HH,t}$ . Triangles (field data), crosses (simulated data), solid line (relation 2.8). Panel a), simulated time series of 2 hour and 16 minutes duration, panel b) simulated time series of 18 minute duration.

These results show that long time series of surface elevation reduce the variability in estimates of the mean group length and correlation coefficient to an acceptable level (i.e. the data points cluster around the theoretical line). The results shown in panel b), are both based on time series of approximately 20 minute duration. As can be seen, the variability around the theoretical line is of the same order, both for field data and simulated data.

## 8 Effect of varying upper integration limit

The effect of changing the upper integration limit on the estimates of above four spectral parameters is shown in Fig. 2. Based on a simulated JONSWAP spectrum, the dimensionless upper integration limit  $f_{up}/f_p$  was varied over the range 1 to 4.

Fig. 2: Variation in the estimates of  $Q_p$ ,  $Q_e$ ,  $\kappa$  and  $\nu$  as a function of the dimensionless upper integration limit  $f_{up}/f_p$ .

The results indicate that for  $f_{up}/f_p > 2$  the  $\kappa$  parameter is converged to a limiting value, whereas for  $f_{up}/f_p > 3$  the  $Q_p$  and  $Q_e$  are converged to their final value. The  $\nu$  parameter, however, is still increasing for  $f_{up}/f_p = 4$ . These results indicate that the  $\kappa$  is least sensitive to the choice of the upper integration limit.

## 9 Spectral computation of correlation coefficient

As noted by Battjes and Van Vledder (1984), IAHR (1992), Chandler and Masson (1992), the spectrally computed coefficient of correlation between successive wave heights  $\rho_{HH,f}(T_{m0.2})$  is consistently smaller than its time domain estimate  $\rho_{HH,t}$ . This is illustrated in Fig. 3. Possible reasons for this underestimation have been considered by Stam (1988),

who identified 3 assumptions used in the derivation of the joint distribution of succeeding wave heights:

- 1 The underlying stochastic process is Gaussian,
- 2 the frequency spectrum is narrow, and
- 3 the joint distribution of two values of the amplitude envelope  $R(t)$  and  $R(t + \tau)$  is translated into the joint distribution of succeeding wave heights by defining succeeding wave heights as twice the values of  $R(t)$  and  $R(t + T_{m02})$ , respectively.

The first, Gaussian, assumption implies that the sea surface can be considered as a linear sum of mutually independent harmonic components. Possible non-linearities would increase the difference between the time and frequency domain estimates of the correlation coefficient. A possible effect of non-linearities has been investigated by Stam (1988) by analyzing wave flume experiments with different values of the ratio of water depth  $d$  over the deep water wave length  $L_0$ . These investigations indicate that non-linearities have a negligible effect. Thus, the linear assumption is not inconsistent with Stam's experiments. The linear assumption is also supported in the literature (e.g. Elgar et al., 1984; Chandler and Masson, 1992).

The second assumption is related to the existence of a well defined envelope. As argued by Battjes (1974), the assumption of a narrow spectrum is not necessary for the validity of the bi-variate Rayleigh distribution. The validity of this distribution was verified by computing the  $\kappa$  parameter directly in the time domain and comparing it with  $\rho_{HH,t}$ . As noted by Battjes (1974),  $\kappa^2$  is equal to the coefficient of linear correlation between squared succeeding wave heights:

$$\kappa_{HH,t}^2 = \frac{\frac{1}{N-1} \sum_{i=1}^{N-1} (H_i^2 - \bar{H}^2)(H_{i+1}^2 - \bar{H}^2)}{\frac{1}{N} \sum_{i=1}^N (H_i^2 - \bar{H}^2)^2} \tag{9.1}$$

The relation between  $\rho_{HH,t}$  and  $\kappa_{HH,t}$  is illustrated in Fig. 4, together with the theoretical relation (2.8). The agreement is good, which supports the validity of the bi-variate Rayleigh distribution.

The third assumption, a wave height is twice the amplitude at the time of a wave crest, is only valid for narrow spectra. For broader spectra, the use of wave envelope can underestimate, as well as over-estimate computed wave heights. This will affect the correlation between succeeding wave heights in case wave heights are based on wave amplitude values. Following Stam (1988), this was inspected by computing the correlation between succeeding wave crests (or maximum amplitudes). To that end the correlation coefficient between succeeding wave crests (or maximum amplitudes)  $\rho_{AA,t}$  was computed:

$$\rho_{AA,t} = \frac{\frac{1}{N-1} \sum_{i=1}^{N-1} (A_i - \bar{A})(A_{i+1} - \bar{A})}{\frac{1}{N} \sum_{i=1}^N (A_i - \bar{A})^2} \tag{9.2}$$

in which  $\bar{A}$  is the mean crest elevation. Estimates of this correlation coefficient have been compared with time domain estimates of the  $\kappa$  parameter, defined similarly as  $\kappa_{HH,t}$ , but now in terms of wave amplitudes:

$$\kappa_{AA,t}^2 = \frac{\frac{1}{N-1} \sum_{i=1}^{N-1} (A_i^2 - \bar{A}^2)(A_{i+1}^2 - \bar{A}^2)}{\frac{1}{N} \sum_{i=1}^N (A_i^2 - \bar{A}^2)^2} \tag{9.3}$$

Inspection of the relation between  $\rho_{AA,t}$  and  $\kappa_{AA,t}$  (not shown here) gives an even better agreement with theory (Eq. 2.8) than between  $\kappa_{HH,t}$  and  $\rho_{HH,t}$ . These results suggest that the bi-variate Rayleigh distribution is better suited to describe the joint distribution of succeeding wave amplitudes than of succeeding wave heights. Based on this notion, the relation between  $\rho_f(T_{m02})$  and  $\kappa_{AA,t}$  was investigated. The result thereof is shown in Fig. 5.

Fig. 3: Relation between  $\kappa_{HH,t}$  and  $\rho_{HH,t}$ . Crosses (simulation data), triangles (field data).

Fig. 4 Relation between  $\kappa_{AA,t}$  and  $\rho_f(T_{m02})$ , Crosses (simulation data), triangles (field data),

solid line (relation 2.8).

Fig. 4 shows good agreement between  $\kappa_{HH,t}$  and  $\rho_{HH,t}$  according to theory. The agreement between  $\kappa_{AA,t}$  and  $\kappa_f(T_{m02})$  is rather good which implies that theory of envelope statistics is applicable to wave heights, but not to wave heights. The difference between  $\kappa_{HH,t}$  and

$\kappa_f(T_{m02})$  can be attributed to the transformation of amplitudes to wave heights by a factor 2.

The assumption that the wave height is twice the value of the amplitude envelope at the time of a wave crest was considered by Tayfun (1990). An improved estimate of the wave height is to define a wave height as the sum of two values of the wave envelope separated by a time lag of half a wave period  $T$ :

$$H = A(t) + A\left(t + \frac{1}{2} T\right) \tag{9.4}$$

Substitution of Eqs. (9.4) into the definition of the correlation coefficient gives (Van Leeuwen, 1988):

$$\hat{\rho}_{HH} = \frac{\text{cov}\left(A(t_i) + A(t_i + \frac{1}{2}T), A(t_i + T) + A(t_i + \frac{3}{2}T)\right)}{\sigma\left(A(t_i) + A(t_i + \frac{1}{2}T)\right)\sigma\left(A(t_i + T) + A(t_i + \frac{3}{2}T)\right)} \tag{9.5}$$

Elaboration of Eq. (9.5) leads to:

$$\hat{\rho}_{HH,t} = \frac{\rho_{HH,f}\left(\frac{1}{2}T\right) + 2\rho_{HH,f}(T) + \rho_{HH,f}\left(\frac{3}{2}T\right)}{2 + 2\rho_{HH,f}\left(\frac{1}{2}T\right)} \tag{9.6}$$

In addition, the effect of finite bandwidth on the mean zero-crossing wave period is considered. Such a correction was given by Tayfun (1990):

$$\hat{T} = T_{m02}\left(1 - \frac{1}{2}v^2\right) \tag{9.7}$$

with  $v$  the spectral width parameter proposed by Longuet-Higgins (1975). Replacing the wave period  $T$  in Eq. (9.6) by the corrected expression of Eq. (9.7) gives:

$$\hat{\rho}_{HH,t} = \frac{\rho_{HH,f}\left(\frac{1}{2}\hat{T}\right) + 2\rho_{HH,f}(\hat{T}) + \rho_{HH,f}\left(\frac{3}{2}\hat{T}\right)}{2 + 2\rho_{HH,f}\left(\frac{1}{2}\hat{T}\right)} \tag{9.8}$$

The results of the improved method of computing the correlation coefficient between successive wave heights from the spectrum are shown in Fig. 6.

The effect of these corrections is to remove almost all of the bias in the spectral computation of the correlation coefficient between succeeding wave heights.

Fig. 5 Relation between  $\kappa_{AA,t}$  and  $\rho_f(T_{m02})$  Fig. 6: Relation between  $\rho_{HH,t}$  and  $\hat{\rho}_f$

## 10 Conclusions

- the mean group length is independent of the group length distribution.
- statistical variability distorts the inter-relationship between the parameters  $Q_p$ ,  $Q_e$ ,  $\kappa$  and  $\rho_{HH,t}$ , as proposed by Medina and Hudspeth (1990).
- the  $Q_p$ ,  $Q_e$  and  $\nu$  parameters are not suited as spectral group parameters.
- the  $\kappa$  parameter is a good parameter to relate wave grouping with the spectral shape.
- the  $Q_p$  and  $Q_e$  parameter are not suited as measures for the spectral width.
- long data records are necessary to decrease the variability in group length statistics to an acceptable level.
- the  $\kappa$  parameter is not sensitive to spectral smoothing, and least sensitive to the choice of the upper integration limit.
- the improved method of computing the spectral correlation coefficient removes practically all bias with respect to previous computations. This improved method enhance the applicability of the  $\kappa$  parameter in relation to wave grouping.

## CHAPTER 72

### VERIFICATION OF A ONE-DIMENSIONAL SURFBEAT MODEL AGAINST LABORATORY DATA

J.A. Roelvink, H.A.H. Petit and J.K. Kostense

DELFT HYDRAULICS, P.O. Box 152, 8300 AD Emmeloord

#### ABSTRACT

A mathematical model is presented which describes cross-shore low-frequency motions generated by shoaling and breaking of wave-groups on a beach. The numerical scheme is tested against known analytical solutions for standing waves on a plane beach. Model results are compared with laboratory experiments (Kostense, 1984) which refer to bichromatic carrier waves incident on a plane beach. It is shown that, apart from a good representation of the trends found in the experimental study, for realistic values of the breaking and friction coefficients the computational results also quantitatively agree surprisingly well with the experiments.

#### INTRODUCTION

Low-frequency motions on the time-scale of wave groups can have significant effects on cross-shore morphology, both in the inner nearshore region, where sometimes they even dominate over motions at wind-wave frequencies, and elsewhere in the nearshore region, through their interaction with the wave groups. Their effect on cross-shore morphology has been shown to be of the same order of magnitude as other mechanisms, such as return flow and wave asymmetry (Roelvink and Stive, 1989).

Several aspects of long-wave generation inside and outside the surf zone have been addressed in literature (e.g. Longuet-Higgins and Stewart, 1962; Symonds et al, 1982; Abdelrahman and Thornton, 1987; Schaeffer and Jonsson, 1990; List, 1992). The models presented in these references are strongly schematized in either the hydrodynamic equations or the bottom geometry and are not meant to be predictive models for arbitrary waves on an arbitrary profile. Some first attempts towards this were presented in Roelvink (1991), Symonds and Black (1991) and Sato (1991).

The purpose of the model presented here is to predict the cross-shore structure of the incident wave groups, the long waves generated inside and outside the surfzone, and their combined effect on sediment transport, for random waves incident perpendicular to a uniform beach of arbitrary profile. The model is

time-dependent on the time-scale of wave groups; the basic formulations have been described in Roelvink (1991).

In the paper we will discuss the model formulations; the numerical scheme will be outlined and tested against analytical solutions of parts of the problem. The model is then compared with experiments with bichromatic waves on a plane beach and the sensitivity of the model for the dissipation coefficients is investigated.

## MODEL FORMULATIONS

The model solves simultaneously a set of three short-wave averaged balance equations, viz. for momentum, continuity and wave energy. Closure relations which relate i.e. radiation stress to wave energy are derived from linear theory. Wave breaking is incorporated by means of an empirical formulation, which relates the dissipation rate to the local wave energy and the water depth.

The balance equations are: the momentum equation for the long waves,

$$\frac{\partial}{\partial t} Q_t + \frac{\partial}{\partial x} \left[ \frac{(Q_t - Q_w)^2}{h} + \frac{S_{xx}}{\rho} + \frac{1}{2}gh^2 \right] = gh \frac{\partial d}{\partial x} + \tau_b \quad (1)$$

the continuity equation for the long waves,

$$\frac{\partial}{\partial t} h + \frac{\partial}{\partial x} Q_t = 0 \quad (2)$$

and the wave action equation, reduced to a wave energy balance equation:

$$\frac{\partial}{\partial t} E + \frac{\partial}{\partial x} EC_g = -D \quad (3)$$

Here,  $h$  is the water depth,  $Q_t$  is the total flux,  $Q_w$  is the wave-induced flux,  $S_{xx}$  is the radiation stress,  $\rho$  is the density of the water,  $g$  is the acceleration of gravity,  $d$  is the still water depth,  $\tau_b$  is the bottom shear stress,  $E$  is the short wave energy and  $C_g$  is the group velocity of the short waves.

Additional equations are required to close the system of equations; very common ones are used here:

$$\tau_b = \frac{1}{2}\rho f_w \left| \frac{Q_t}{h} \right| \left| \frac{Q_t}{h} \right| \quad (4)$$

where  $f_w$  is a friction coefficient;

$$S_{xx} = \left[ 2 \frac{C_g}{C} - \frac{1}{2} \right] E \quad (5)$$

$$Q_w = \frac{E}{\rho C} \quad (6)$$

$$C = \frac{\omega}{k} \quad (7)$$

$$C_g = \frac{\partial \omega}{\partial k} = \frac{g}{2\omega} \left( \tanh(kh) + kh [1 - \tanh^2(kh)] \right) \quad (8)$$

Here,  $\omega$  is a representative angular frequency of the short waves and  $k$  is a representative wave number.

The short wave energy dissipation is modelled according to Roelvink (1992) as:

$$D = 2\alpha f E \left[ 1 - \exp \left[ - \left[ \frac{\sqrt{8E/\rho g}}{\gamma h} \right]^n \right] \right] \quad (9)$$

where  $f$  is a representative short wave frequency and  $\alpha$ ,  $\gamma$  and  $n$  are coefficients, with optimum values for random waves of 1.0, 0.55 and 10, respectively.

With the help of these additional equations, equations (1) through (3) are solved simultaneously for a given profile and boundary conditions for  $E$ ,  $Q_t$  and  $h$  at the seaward boundary.

#### NUMERICAL SCHEME

The differential equations are solved by a finite difference, second-order Richtmyer scheme on a nonequidistant moving grid of which the landward boundary moves up and down with the waterline. This is achieved by applying a transformation to the equations as described below.

The set of equations we want to transform can in Cartesian coordinates be described as:

$$\frac{\partial v}{\partial t} + \frac{\partial f(v)}{\partial x} = o(v) \frac{\partial p}{\partial x} + q(v) \quad (10)$$

where the functions  $f$  and  $q$  need not be linear in their arguments.

We now use a transformation to general time dependent coordinates of the following form:

$$\tau = t \quad (11)$$

$$\xi = \frac{\int_0^x W(\zeta) d\zeta}{\int_0^{x_0} W(\zeta) d\zeta} \quad (12)$$

This transformation transforms the interval in the  $x$ -domain:  $[0, X_r(t)]$  which depends on the time coordinate  $t$ , to the fixed interval  $[0, 1]$  in the  $\xi$  domain. The transformation to the  $\tau$  domain is trivial.

In order that the inverse transformation functions  $x(\tau, \xi)$  and  $t(\tau)$  exist the function  $W$  has to be chosen such that it does not change sign in the interval  $[0, X_r(t)]$ .

The function  $X_r(t)$  is the solution of an ordinary differential equation:

$$\frac{dX_r(t)}{dt} = S(v(t, X_r(t))) = u(t, X_r(t)) \quad (13)$$

In the new coordinate system the set of differential equations becomes:

$$\frac{\partial}{\partial \tau} (T_1(\tau, \xi) \hat{v}(\tau, \xi)) + \frac{\partial}{\partial \xi} (T_2(\tau, \xi) \hat{v}(\tau, \xi) + f(v(\tau, \xi))) = T_1(\tau, \xi) (o(\hat{v}(\tau, \xi)) \hat{p}_x(\tau, \xi) + q(\hat{v}(\tau, \xi))) \quad (14)$$

$$\frac{dX_r(\tau)}{d\tau} = \hat{u}(\tau, 1) \quad (15)$$

where,

$$T_1(\tau, \xi) = \frac{\int_0^{x(\tau, \xi)} W(\zeta) d\zeta}{W(x(\tau, \xi))}, \quad T_2(\tau, \xi) = - \frac{\xi W(X_r(\tau))}{W(x(\tau, \xi))} \frac{dX_r(\tau)}{d\tau}$$

$$\hat{v}(\tau, \xi) = v(\tau, x(\tau, \xi)) \text{ and } \hat{p}_x(\tau, \xi) = \frac{dp}{dx}(x(\tau, \xi)).$$

In the appendix a derivation of equation (14) is given.

Equation (14) can be written as:

$$\frac{\partial V}{\partial \tau} + \frac{\partial F(V, \tau, \xi)}{\partial \xi} = R(V, \tau, \xi), \quad (16)$$

so it has exactly the same structure as Eq.(10).

The discretization used to solve the set of differential equations (14) in the  $(\tau, \xi)$  domain is done on an equidistant grid:

$$\xi_i = \frac{i}{N} \text{ for } i=0(1)N.$$

The time steps are constant as well:  $\tau_j = j\Delta\tau$  and therefore  $t_j = j\Delta\tau$ .

In the physical domain  $(t, x)$  this introduces a non-equidistant grid with grid points  $x_i^j$  which satisfy the equation:

$$\xi_i = \frac{i}{N} = \frac{\int_0^{x_i^j} W(\zeta) d\zeta}{\int_0^{x(\tau_j)} W(\zeta) d\zeta} \quad \text{for } i=0(1)N \quad (17)$$

The weight function  $W$  can be chosen in such a way that near to regions where the physics becomes more interesting a grid refinement can be realized.

The scheme we use is Richtmeyer's predictor corrector scheme; the discretization of Eq.(16) now becomes:

Predictor:

$$V_{i+1/2}^{j+1/2} = \frac{1}{2}(V_{i+1}^j + V_i^j) - \frac{\Delta\tau}{2\Delta\xi}(F_{i+1}^j - F_i^j) + \frac{\Delta\tau}{4}(R_{i+1}^j + R_i^j) \tag{18}$$

where  $F_{i+1}^j = F(V_{i+1}^j, \tau_j, \xi_{i+1})$  ,  $R_{i+1}^j = R(V_{i+1}^j, \tau_j, \xi_{i+1})$  ,

$F_{i+1/2}^{j+1/2} = F(V_{i+1/2}^{j+1/2}, \tau_{j+1/2}, \xi_{i+1/2})$  and  $R_{i+1/2}^{j+1/2} = R(V_{i+1/2}^{j+1/2}, \tau_{j+1/2}, \xi_{i+1/2})$

$$X_r^{j+1/2} = X_r^j + \frac{\Delta\tau}{48}(34 \hat{u}(\tau_j, 1) - 14 \hat{u}(\tau_{j-1}, 1) + 4 \hat{u}(\tau_{j-2}, 1)) \tag{19}$$

$$x_{i+1/2}^{j+1/2} \text{ is solved from } \xi_{i+1/2} = \frac{i+1/2}{N} = \frac{\int_0^{x_{i+1/2}^{j+1/2}} W(\zeta) d\zeta}{\int_0^{X_r^{j+1/2}} W(\zeta) d\zeta} \text{ for } i=0(1)N-1.$$

Corrector:

$$V_i^{j+1} = V_i^j - \frac{\Delta\tau}{\Delta\xi}(F_{i+1/2}^{j+1/2} - F_{i-1/2}^{j+1/2}) + \frac{\Delta\tau}{2}(R_{i+1/2}^{j+1/2} + R_{i-1/2}^{j+1/2}) \tag{20}$$

$$X_r^{j+1} = X_r^j + \frac{\Delta\tau}{12}(23 \hat{u}(\tau_j, 1) - 16 \hat{u}(\tau_{j-1}, 1) + 5 \hat{u}(\tau_{j-2}, 1)) \tag{21}$$

$$x_i^{j+1} \text{ is solved from: } \xi_i = \frac{i}{N} = \frac{\int_0^{x_i^{j+1}} W(\zeta) d\zeta}{\int_0^{X_r^{j+1}} W(\zeta) d\zeta} \text{ , for } i=0(1)N.$$

The schemes that are used to solve Eq.(15) are (19) and (21), these are both third order Adams-Bashforth methods.

The linear stability condition for the Richtmeyer scheme is

$$\frac{\lambda\Delta\tau}{\Delta\xi} \leq 1 \tag{22}$$

where  $\lambda$  is the largest eigenvalue of  $\partial F/\partial V$  in absolute sense.

The largest eigenvalue of  $\partial f/\partial v$  in equation (10) can be approximated by  $u + \sqrt{gh}$  .

Since  $T_1$  and  $T_2$  are both scalar functions, the largest eigenvalue in the transformed problem (14) becomes:

$$\lambda = \frac{T_2}{T_1} + \frac{\hat{u} + \sqrt{gh}}{T_1}$$

Stability condition (22) can now be written as:

$$W(x(\tau, \xi)) \hat{u}(\tau, \xi) - \xi W(X_r(\tau)) \frac{dX_r}{d\tau} + W(x(\tau, \xi)) \sqrt{g \hat{h}(\tau, \xi)} \leq \frac{\Delta \xi}{\Delta \tau} \int_0^{X_r(\tau)} W(\zeta) d\zeta \quad (23)$$

The condition we use to replace Eq.(23) is:

$$W(x(\tau, \xi)) \sqrt{g(\hat{h}(0, \xi) + \epsilon)} \leq \frac{\Delta \xi}{\Delta \tau} \int_0^{X_r(\tau)} W(\zeta) d\zeta \quad (24)$$

here  $\hat{h}(0, \xi)$  is the still water depth and  $\epsilon$  is a small positive number. A convenient weight function now becomes:

$$W(x) = \frac{1}{\sqrt{g(h(0, x) + \epsilon)}}$$

With this choice the CFL stability condition (23) can now be replaced by:

$$\Delta \tau \leq \Delta \xi \int_0^{X_r(\tau)} \frac{1}{\sqrt{g(h(0, x) + \epsilon)}} dx \quad (25)$$

By replacing  $X_r(\tau)$  in Eq.(25) by a lower boundary of  $X_r(\tau)$  we found a constant value for  $\Delta \tau$ .

The scheme is compared with analytical solutions of standing long waves on a plane beach as given by Carrier and Greenspan (1957); an example is given in Figure 1. Very small deviations occur at the shoreline, which disappear with increasing number of grid points.

## MODEL RESULTS AND SENSITIVITY ANALYSIS

Model results are compared with laboratory experiments by Kostense (1984), which refer to wave channel tests of bichromatic waves on a plane beach. The experiments were carried out with active wave absorption and second order wave generation, enabling undisturbed, stable and accurate measurements. They cover a range of primary frequencies, group frequencies, amplitudes and modulation rates and are therefore well suited to verify the predictive ability of the model. The primary waves in these tests were made up of two frequencies generated in a water depth of 0.50 m and broke on a plane cemented beach of a 1:20 slope after travelling over a horizontal stretch. In Table 1 below, the ranges of frequency and amplitude of the primary waves are given. In series A, B and E, the effect of varying the difference frequency is studied for fixed primary wave amplitudes; in series C and D the effect of varying the primary wave amplitude is shown for a fixed difference frequency. Series A through D were carried out with weakly modulated waves; series E with strongly modulated primary waves.

For a given set of primary waves, the input boundary conditions for the numerical model are defined by:

$$E = \rho g \left[ \frac{1}{2}(\hat{\eta}_1^2 + \hat{\eta}_2^2) + \hat{\eta}_1 \hat{\eta}_2 \cos(\Delta \omega t) \right] \quad (26)$$

**Figure 1.** Comparison of numerical (thin lines) and analytical (thick lines) solution of standing long wave on a plane sloping beach; dimensionless elevation (top) and velocity (bottom).

Series	$\hat{\eta}_1$ (m)	$\frac{\hat{\eta}_2}{\hat{\eta}_1}$ (m)	$\omega_1$ (rad/s)	$\Delta\omega$ (rad/s)
A	0.055	0.2	3.1	0.3-0.9
B	0.055	0.2	4.1	0.3-0.9
C	0.035-0.080	0.2	4.1	0.77
D	0.030-0.055	0.2	3.1	0.61
E	0.035	0.8	4.3	0.3-0.9

**Table 1.** Ranges of primary wave parameters in Kostense experiment.

The accompanying bound long wave, which is also generated in the experiment, is given by Longuet-Higgins and Stewart (1964):

$$h - \bar{h} = - \frac{1}{\rho} \left[ \left( 2 \frac{C_g}{C} - 0.5 \right) / (gh - C_g^2) \right] \hat{\eta}_1 \hat{\eta}_2 \cos(\Delta\omega t) \tag{27}$$

$$Q_t = - \frac{C_g}{\rho} \left[ \left( 2 \frac{C_g}{C} - 0.5 \right) / (gh - C_g^2) \right] \hat{\eta}_1 \hat{\eta}_2 \cos(\Delta \omega t) \quad (28)$$

In order to prevent re-reflection of long waves at the seaward boundary, a weakly reflective boundary condition is used as described in Roelvink (1991).

The procedure to hindcast these the experiments is as follows. For a given set of primary waves, the model is run until a periodic solution is reached. The surface elevation time series are then split into three components, viz. the incoming bound wave, the reflected free wave and an incoming free wave. Incoming free waves are negligible since they are not generated and since the weakly reflective boundary condition allows waves reflected from the beach to propagate out of the model. The amplitudes of the incoming bound wave and the reflected free wave are determined by harmonic analysis. Per series A through E, approximately twenty such runs are carried out to cover the range of the free parameter for each series.

The numerical model contains empirical coefficients in the description of the dissipation of short waves by wave breaking, and of the dissipation of long waves by bottom friction. For random waves, a standard set of values for the wave breaking coefficients can be applied, as is shown in Roelvink (1992). A key factor here is the coefficient  $\gamma$ , which is proportional to the average breaking wave height over water depth ratio, and is set at 0.55 for random waves. For bichromatic waves, this ratio should be significantly higher; a reasonable estimate appears to be 0.75. Because of the uncertainty in this value, computations are performed for  $\gamma$ -values of 0.55, 0.75 and 0.90.

Since there is no accurate description of the bottom friction under combined short and long waves, the simplest possible formulation as in eq. (4) is applied. Computations are performed for three values of  $f_w$ : 0.00, 0.02 and 0.05. The variations in  $f_w$  are applied for a fixed  $\gamma$ -value of 0.75; the variations in  $\gamma$  for a fixed  $f_w$ -value of 0.02.

The results for series A through E are shown in Figures 2 through 6, respectively. In all cases, the bound long wave amplitude is predicted accurately; it does not depend on either of the coefficients. The increase in the bound wave amplitude for increasing difference frequency is due to the slight decrease in the mean of the primary frequencies. As expected, the bound wave amplitude increases quadratically with increasing primary wave amplitude.

The amplitudes of the reflected free waves show interesting interference patterns which are represented quite well by the model. Schaffer and Jonsson (1990) already concluded based on a comparison between their model and these data, that frictional effects must be important. Especially for the higher group frequencies this appears to be the case. A reasonable value for the friction factor of 0.02 appears to give acceptable quantitative agreement for all series.

Figure 2. Measured and computed amplitudes of free reflected and bound long wave elevation against difference frequency  $\Delta\omega$ ; series A.

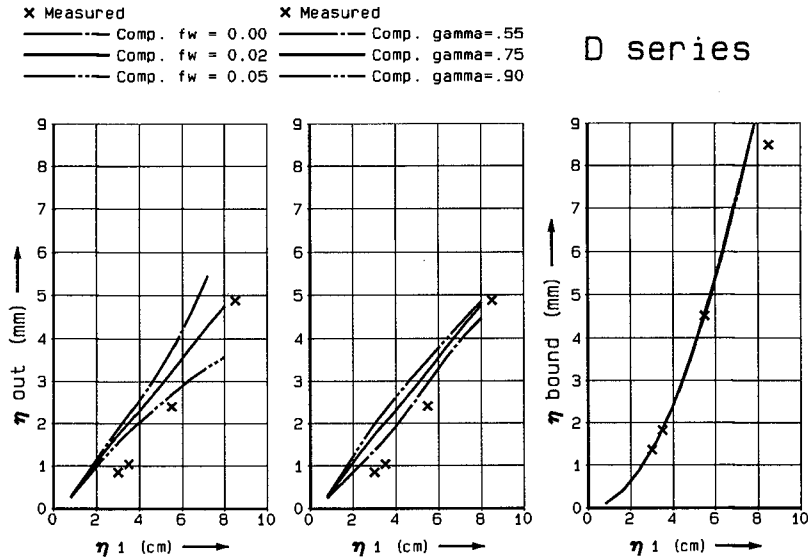

Figure 3. Measured and computed amplitudes of free reflected and bound long wave elevation against difference frequency  $\Delta\omega$ ; series B.

**Figure 4.** Measured and computed amplitudes of free reflected and bound long wave elevation against primary wave amplitude  $\hat{\eta}_1$ ; series C.

**Figure 5.** Measured and computed amplitudes of free reflected and bound long wave elevation against primary wave amplitude  $\hat{\eta}_1$ ; series D.

**Figure 6.** Measured and computed amplitudes of free reflected and bound long wave elevation against difference frequency  $\Delta\omega$ ; series E.

The model results are not extremely sensitive to variations in the breaker parameter  $\gamma$ . A reasonable value of 0.75 for these bichromatic waves gives acceptable results for all series.

The prediction of the reflected free wave amplitude for highly modulated waves in series E is quite accurate; no previous model results on this case have been presented in literature.

A disadvantage of this numerical model is, that it is not possible to separate different mechanisms of long wave generation, viz. the reflection of bound long waves, the break point mechanism or the shoreline set-up mechanism. Probably all of these mechanisms are important at times; the results indicate that no serious errors in the representation of any mechanism have been made.

**CONCLUSION**

The numerical model SURFBEAT appears to contain the necessary physics to predict long wave generation in the nearshore zone. Since it can be run with arbitrary boundary conditions over an arbitrary profile, it can be used to model realistic situations where cross-shore processes are dominant.

## ACKNOWLEDGEMENT

The work presented in this paper has been undertaken as part of the MaST G6 Coastal Morphodynamic Research Programme. It was funded partly by the Commission of the European Communities, Directorate General for Science, Research and Development under MaST Contract no. 0035-C and partly by the Tidal Waters Division of the Netherlands' Rijkswaterstaat, under the Coastal Genesis (Kustgenese) Programme.

APPENDIX

The transformation equations (11) and (12) are of the form:

$$\tau = t \tag{A1}$$

$$\xi = \xi(t, x) \tag{A2}$$

We can directly see that

$$\frac{\partial \tau}{\partial t} = 1$$

$$\frac{\partial \tau}{\partial x} = 0$$

The property  $\frac{\partial \tau}{\partial t} \frac{\partial \xi}{\partial x} - \frac{\partial \tau}{\partial x} \frac{\partial \xi}{\partial t} = \frac{\partial \xi}{\partial x} \neq 0$  implies that  $x(\tau, \xi)$  and  $t(\tau, \xi) (\equiv \tau)$  exist.

Obviously the inverse transformation has the property:

$$\frac{\partial t}{\partial \tau} = 1$$

$$\frac{\partial t}{\partial \xi} = 0$$

Since  $\frac{\partial t}{\partial \xi} = 0$  we find:

$$1 = \frac{\partial \xi}{\partial \xi} = \frac{\partial \xi}{\partial x} \frac{\partial x}{\partial \xi} + \frac{\partial \xi}{\partial t} \frac{\partial t}{\partial \xi} = \frac{\partial \xi}{\partial x} \frac{\partial x}{\partial \xi}, \text{ resulting in:}$$

$$\frac{\partial \xi}{\partial x} = \left(\frac{\partial x}{\partial \xi}\right)^{-1} \tag{A3}$$

Since  $\frac{\partial \tau}{\partial t} = 1$  and  $x$  and  $t$  are independent we have:

$$0 = \frac{\partial x}{\partial t} = \frac{\partial x}{\partial \xi} \frac{\partial \xi}{\partial t} + \frac{\partial x}{\partial \tau} \frac{\partial \tau}{\partial t} = \frac{\partial x}{\partial \xi} \frac{\partial \xi}{\partial t} + \frac{\partial x}{\partial \tau}, \text{ resulting in:}$$

$$\frac{\partial \xi}{\partial t} = -\frac{\partial x}{\partial \tau} \left(\frac{\partial x}{\partial \xi}\right)^{-1} \tag{A4}$$

The differential equation:

$$\frac{\partial v}{\partial t} + \frac{\partial f}{\partial x} = r,$$

which is one of the components of Eq.(1) to (3), can now directly be written as:

$$\frac{\partial \hat{v}}{\partial \xi} \frac{\partial \xi}{\partial t} + \frac{\partial \hat{v}}{\partial \tau} \frac{\partial \tau}{\partial t} + \frac{\partial \hat{f}}{\partial \xi} \frac{\partial \xi}{\partial x} + \frac{\partial \hat{f}}{\partial \tau} \frac{\partial \tau}{\partial x} = \hat{r},$$

where  $\hat{v}(\tau, \xi) = v(\tau, x(\tau, \xi))$  and  $\hat{f} = f(\hat{v}(\tau, \xi))$ .

With the use of Eqs.(A1),(A2),(A3) and (A4) this becomes:

$$-\frac{\partial x}{\partial \tau} \left( \frac{\partial x}{\partial \xi} \right)^{-1} \frac{\partial \hat{v}}{\partial \xi} + \frac{\partial \hat{v}}{\partial \tau} + \left( \frac{\partial x}{\partial \xi} \right)^{-1} \frac{\partial \hat{f}}{\partial \xi} = \hat{f}.$$

Multiplication with  $\frac{\partial x}{\partial \xi}$  yields:

$$-\frac{\partial x}{\partial \tau} \frac{\partial \hat{v}}{\partial \xi} + \frac{\partial x}{\partial \xi} \frac{\partial \hat{v}}{\partial \tau} + \frac{\partial \hat{f}}{\partial \xi} = \frac{\partial x}{\partial \xi} \hat{f},$$

which can be written as:

$$\frac{\partial}{\partial \tau} \left( \frac{\partial x}{\partial \xi} \hat{v} \right) + \frac{\partial}{\partial \xi} \left( -\frac{\partial x}{\partial \tau} \hat{v} + \hat{f} \right) = \frac{\partial x}{\partial \xi} \hat{f} \quad (\text{A5})$$

With the use of the expressions:

$$\frac{\partial \xi}{\partial t} = - \frac{\int_0^x W(\zeta) d\zeta}{x_{,0}} W(X_r(t)) \frac{dX_r}{dt}$$

$$\left( \int_0^x W(\zeta) d\zeta \right)^2$$

$$\frac{\partial \xi}{\partial x} = \frac{W(x)}{x_{,0} \int_0^x W(\zeta) d\zeta}$$

and the relations (A3) and (A4), equation (14) emerges from (A5)

## CHAPTER 73

### INCIDENT WAVE GROUPS AND LONG WAVES IN THE NEARSHORE ZONE

Y Foote<sup>\*</sup>, D Huntley<sup>\*</sup>, M Davidson<sup>\*</sup>, P Russell<sup>\*</sup>, J Hardisty<sup>†</sup> and A Cramp<sup>‡</sup>

#### ABSTRACT

Variations of the wave groupiness, cross-correlation between the incident wave envelope and long wave motion, and skewness of the near-bed velocity were measured on a macrotidal beach at Spurn Head, UK, as part of an experiment by the B-BAND (British Beach And Nearshore Dynamics) programme.

Wave groupiness persisted throughout the surf zone, and did not decay immediately at the breakpoint as is often assumed. The cross-correlation between the incident and long wavefields varied systematically across the nearshore, with negative values outside the surf zone and positive values near the shoreline. Offshore of the breakpoint, the skewness of the cross-shore current was dominated by three contributions - (i) the skewness of the incident waves, (ii) the interaction between the incident wave energy and the mean flow and (iii) the correlation between the incident and long waves. Onshore of the breakpoint, contributions (i) and (ii) remained important, along with the interaction between the long wave energy and the mean flow. The relative importance of these contributions to the skewness was unaffected by the incident wave characteristics.

#### 1. INTRODUCTION

Incident waves travelling towards the shoreline are known to have a groupy structure, with an alternating sequence of high waves and low waves. Longuet-Higgins and Stewart (1962, 1964), Larsen (1982) and Shi and Larsen (1984) proposed that associated with this incident wave 'groupiness' are gradients in the radiation stress generating a forced long wave (of infra-gravity frequency) where a depression of mean sea-level is correlated with groups of high waves and a rise in mean sea-level corresponds with groups of low waves. The radiation stress is proportional to the square of the amplitude of the incident waves.

<sup>‡</sup> University of Wales, Cardiff, CF1 3YE, UK

Shi and Larsen (1984) suggested that the passage of a wave group and bound long wave over an erodible bed causes the re-suspension of sediments under high waves, which in conjunction with a negative long wave flow will result in net reverse sediment transport. Hanes (1988) observed the suspension of sand at both the incident wave frequency and at frequencies corresponding to wave groups. Whilst few studies have examined the variations in wave groupiness across the surf zone, where waves are radically transformed by the breaking process, it is generally understood that groupiness of ocean waves is an important characteristic of the climatology of waves both within and beyond the surf zone. Incident wave groupiness contributes significantly to the nearshore wave field. This is demonstrated through use of groupiness as a driving mechanism in models of long wave generation both in the offshore and nearshore zones, through its relationship with nearshore sediment transport and through its effect on coastal and marine structures (List, 1991).

This paper describes observations of incident wave groups and long waves from the large data set collected during the B-BAND (British Beach and Nearshore Dynamics) field experiment at Spurn Head, UK (Russell *et al*, 1991) in order to estimate the variation of wave groupiness across the nearshore zone over a range of wave and tidal conditions on a macrotidal beach and to investigate the theory that the long wave motion is forced outside the surf zone and that the short incident waves are modulated inside the surf zone.

In addition, this study describes the second stage of data analysis which involves the examination of cross-shore current data and certain velocity moments which are expected to determine sediment transport. Relatively recent studies (e.g. Bailard, 1981) of the processes which operate in the nearshore zone and the mechanisms which drive sediment transport, have shown the important role of velocity moments. Several field measurements of the velocity field on beaches have displayed features not explicitly present in many of the existing sediment transport models (Doering and Bowen, 1985). The examination of velocity moments, which are essentially current velocity components to some power, enables a more detailed understanding of the wave motion climatology and is vital to determining the processes which must be included in models of wave-driven coastal change.

Early models for nearshore sediment transport employed bulk empirical formulae based upon the general properties of the incident waves. Existing transport models are generally extensions to these theories, developed originally for the uni-directional conditions of aeolian or fluvial transport (Bagnold, 1963; Einstein, 1972; Yalin, 1972) and such models examine either bedload or suspended load transport. A more significant contribution to cross-shore sediment transport modelling has been provided, however, by those modellers who relate net sediment transport to the small deviations from symmetry which occur in the on-offshore fluid velocity field (Bowen, 1980; Bailard, 1981; Guza and Thornton, 1985; Roelvink and Stive, 1989). Theories such those by Bowen and Bailard generate a number of current velocity moments, but as yet the relative magnitudes of these moments is poorly known for field conditions. Guza and Thornton (1985) indicated that the

moment contributing most to the cross-shore suspended transport, for their particular wave and beach slope conditions, is the skewness. The present work examines the importance of several cross-shore velocity moments derived from the skewness (including mean, low-frequency and high-frequency components) within the nearshore zone, over a range of wave and tidal conditions.

## 2. FIELD SITE AND DATA COLLECTION

Field measurements were made at Spurn Head, Humberside, UK, during 16th to 25th April 1991 by the B-BAND (British Beach and Nearshore Dynamics) group. Ten tidal cycles of data in total were collected. This extensive data-set was collected on the eastern, seaward face of Spurn Head, a sand spit approximately 5km in length, which is located between the mouth of the Humber Estuary and the North Sea (Figure 1).

The beach at Spurn Head generally comprises a mobile shallow sand lens in conjunction with some superficial deposits of gravel which cover the underlying layers of boulder clay. The mean grain size of the predominant sand at the Spurn Head field site is 0.35mm. The beach profile at the field site (Figure 2) displays the characteristics of this East Coast beach, with a narrow sandy inter tidal terrace and a steep upper beach face and berm, backed by an extensive area of vegetated dune.

Gradients vary across the beach profile from 0.0230 over the inter tidal terrace, comprising well sorted sands and the underlying local glacial deposits, to a value of 0.0975 for the steeper high tide beach face which comprises fine to medium gravel (Figure 2). This range of beach slopes results in a morphodynamic regime which can alternate between dissipative at low water and reflective at high-water, but which can generally be considered to be intermediate (Wright and Short, 1984).

Wave conditions during the measurement period covered a wide range, from calm to the 2-year return period storm (with breaking wave heights in excess of 3m). The wave climate included not only the irregular and short period local wave motions, but also regular swell with pronounced groupiness characteristics. The tidal variation at Spurn Head is macrotidal and characterised by tidal currents which flood in a south-westerly direction parallel to the shoreline and ebb in a north-easterly direction.

Data logging occurred over 10 tidal cycles from 8 sensor rigs which extended to approximately 120m offshore. The four central A-Rigs (Figure 3), each comprising 3 electro-magnetic current meters spaced at heights of 0.10, 0.25 and 0.63m above the bed, 3 optical back-scatter sensors positioned at 0.04, 0.10 and 0.25m above the bed, plus one pressure sensor; formed the most detailed and comprehensive component of the instrumentation deployed (see Russell *et al.*, 1991).

## 3. DATA ANALYSIS

Data analysis in this study examines two complete tidal cycles, Tides 184PM and 234PM, in addition to Tide 164PM a partial tidal cycle. The data discussed here comes from a point source (Rig A2). Tide 164PM, comprising

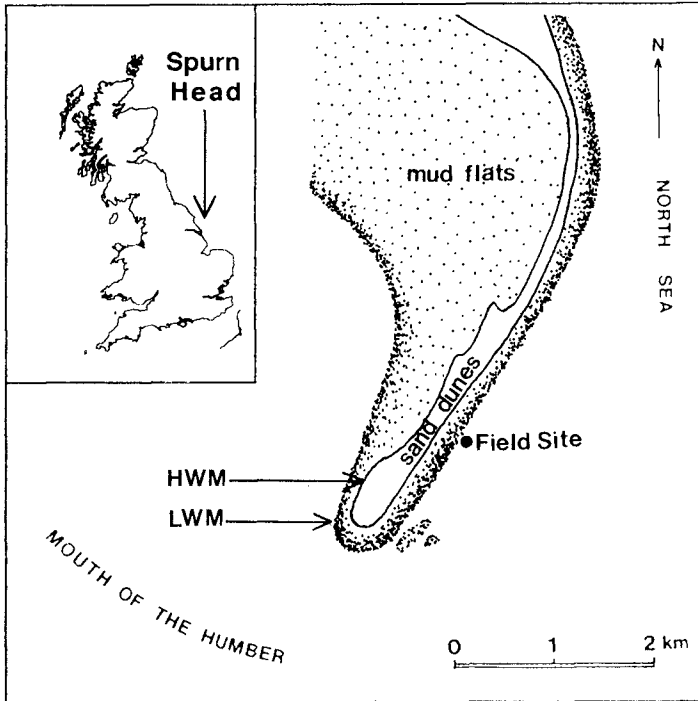

Figure 1. The location of the field experiment at Spurn Head

Figure 2. Beach Profile at Spurn Head Field Site, 18 April, 1991.

Figure 3. Field set-up used at Spurn Head, April 1991.

4 runs with each run containing 17 minutes or 1024 seconds of data, was logged on April 16th 1991 during a violent storm event with a very strong wind, a maximum  $H_s$  value of 1.6m and swell waves of up to 3m breaking height. (The significant wave height,  $H_s$ , is defined as  $4\sigma$  where  $\sigma^2$  is the total variance of the sea surface elevation data (Guza and Thornton, 1982)). Tide 184PM covers moderate swell and choppy conditions, maximum  $H_s$  of 1.1m, with a moderate wind, whilst Tide 234PM displays calmer conditions with smaller swell and chop waves and a maximum  $H_s$  value of approximately 0.8m.

### (i) ESTIMATION OF WAVE GROUPINESS AND CROSS-CORRELATION ANALYSIS

Following the selection of the three tides (Tides 164PM, 184PM and 234PM) all pressure data runs are examined for spikes, glitches or any other incongruous values, which have to be removed prior to analysis. The trend of the pressure sensor data is removed and the record is additionally 'demeaned'; such procedures help to exclude the possibility of any distorting effects upon the data by creating a quasi-stationary time series. The pressure signal is then converted to an approximate sea surface elevation record using a correction factor for the depth attenuation effect of the pressure transducer (e.g. Skovgaard *et al.*, 1974). Separation of the corrected data into both high- and low-passed components is achieved through use of a Kaiser-Reed (1977) digital filter. Spectral analysis of the pressure sensor time series indicates the presence of a trough near 0.05Hz between the incident wave peak and low frequency and sub-harmonic motion peaks and therefore, a cut-off value of 0.05Hz is applied to the separate low- and high-frequencies. The procedure for determining the incident wave groupiness involves the demeaning and squaring of the high-pass component of the surface elevation data, followed by application of the same filter used previously to produce high- and low-frequency wave height time series. The groupiness factor is then the square root of the root-mean-square of the wave envelope time series (Huntley and Kim, 1984).

The incident wave envelope time series is, therefore, used as the basis for estimating the groupiness factor. This has been determined for the three selected tides and plotted against depth (Figure 4) and significant wave height (Figure 5). Despite the examination of three very different tidal cycles the data exhibit a definite relationship whereby, outside the breakpoint, groupiness does not vary significantly (Figure 4), whilst shorewards from the breakpoint groupiness does not drop to zero but actually continues through the surf zone, decreasing to near zero only at the shoreline. Determination of the breakpoint position is achieved through examination of the current velocity mean and variance data (Davidson *et al*, 1992). As might be expected if wave heights obey a Rayleigh distribution, there is a linear relationship between wave height and the groupiness factor; Figure 5 suggests that this relationship persists to the shoreline. Thus whilst many numerical and laboratory models assume that groupiness decreases to zero at the breakpoint, the data analysed in this study based upon field results reveal a persistence of groupiness through the surf zone.

Figure 4. Variations in groupiness with depth across the nearshore zone.

Figure 5. Variations in groupiness with wave height across the nearshore zone.

Cross-correlation coefficients between the incident wave envelope and the low-frequency motion are calculated for all data runs of three selected tidal cycles. The cross-correlation function,  $C_R$ , describes the degree of linear agreement between two data sets in the time domain thus :

$$C_R = \frac{\sum (x_i - \bar{x})(y_{i+k} - \bar{y})}{\sqrt{\sum (x_i - \bar{x})^2 \sum (y_i - \bar{y})^2}} \quad (1)$$

where  $\bar{\psi}$  and  $\psi_n$  are the mean and  $n$ th value of the  $\psi$  time series respectively, and  $\psi$  represents  $x$  or  $y$ .

Figure 6a illustrates the cross-correlation function between the incident wave envelope time series and the low-frequency motion time series for a high tide data run of Tide 234PM, whilst Figure 6b illustrates the equivalent cross-correlation function for a low tide data run, also from Tide 234PM. It is interesting to note in Figures 6a and 6b that for the large water depth of the high tide example, a large negative correlation value is obtained at zero time lag and for the shallower state of the low tide example, there is a considerable positive value. Values of the cross-correlation coefficient at zero time lag for all data runs are plotted in Figure 7 against depth. There appears to be a definite trend in the data. The positive cross-correlation values within the surf zone could be explained by the modulation of short wave breaker heights through the depth variations induced by long waves (Roelvink and Stive, 1989), although it is not known whether this depth-modulation is induced by the forced waves or the free waves. The negative correlation coefficient values outside the surf zone reflect the forcing of the long wave motion by the radiation stress of the incoming wave groups. Consequently, in agreement with other field data (Abdelrahman and Thornton, 1987) and laboratory data (Roelvink and Stive, 1989; Roelvink, 1991), there does appear to be significant direct coupling between the high- and low-frequency motions. The correlation near zero which occurs just inside the breakpoint may be explained by the occurrence of a standing long wave nodal point or by the competing effects of forced and free long wave energies. The fact that data from all three tides show the same trends, within the scatter, in both the cross-correlation and the groupiness suggests that both factors are independent of the offshore wave climate.

## (ii) VELOCITY MOMENT ANALYSIS

The process of examining velocity moments and attempting to establish the moments which contribute most significantly to nearshore sediment transport (Guza and Thornton, 1985), is adapted in this study for electro-magnetic cross-shore current velocity data (bottom sensor of Rig A2) from the B-BAND Spurn Head field experiment. The present study is concerned with cross-shore sediment transport and therefore only the cross-shore velocity ( $u$ ) is used. The cross-shore current velocity is assumed to comprise a mean flow ( $\bar{u}$ ), a high frequency wave component ( $u_s$ ) and a low frequency wave component ( $u_L$ ) thus:

$$u = (\bar{u} + u_s + u_L) \quad (2)$$

**Figure 6(a). Cross-correlation between wave envelope and low frequency motion near high tide**

**Figure 6(b). Cross-correlation between wave envelope and long wave motion near low tide.**

Figure 7. Correlation coefficient between wave envelope and long wave motion across the nearshore zone.

Figure 8(a). Tide 164PM skewness outside the surf zone.

When expanded in terms of these three components, the normalised cross-shore velocity skewness, defined as  $(u^3)/(u^2)^{3/2}$  consists of ten distinct terms since :

$$\overline{u^3} = (\overline{u + u_s + u_L})^3 \quad (3)$$

$$= \overline{u^3} + \overline{u_s^3} + \overline{u_L^3} + 3\overline{uu_s^2} + 3\overline{uu_L^2} + 6\overline{uu_su_L} + 3\overline{u_L^2u_s} + 3\overline{u_s^2u_L} + 3\overline{u^2u_s} + 3\overline{u^2u_L} \quad (4)$$

(Each of the above ten terms are normalised by dividing through by  $(u^2)^{3/2}$ ). These ten skewness terms describe various mechanisms which operate within the nearshore system as follows:

$\overline{u^3}$  = Term 1, mean flow cubed

$\overline{u_s^3}$  = Term 2, skewness of the short wave velocity component

$\overline{u_L^3}$  = Term 3, skewness of the long wave velocity component

$3\overline{uu_s^2}$  = Term 4, short waves mobilise sediment which then moves with the mean flow \*

$3\overline{uu_L^2}$  = Term 5, as Term 4, but with long waves mobilising sediment \*

$6\overline{uu_su_L}$  = Term 6

$3\overline{u_L^2u_s}$  = Term 7 } correlations between short and long wave components

$3\overline{u_s^2u_L}$  = Term 8 }

$3\overline{u^2u_s}$  = Term 9

$3\overline{u^2u_L}$  = Term 10

} will be near zero and will not be significant parameters

\*cf Inman and Bagnold (1963)

The three tidal cycles selected (Tides 164PM, 184PM and 234PM) for the groupiness analysis are also used for moment analysis. All current velocity data runs are examined for spikes or glitches which have to be removed before the moment analysis, in addition to the trend and mean prior to filtering. Each of the above ten terms is calculated for all three tidal cycles and averaged into measurements made seaward of the surf zone and measurements obtained within the surf zone.

The schematic representations of the ten terms outside and inside the breakpoint for the three tides examined can be seen in Figures 8 and 9 and indicate that particular velocity moment terms dominate through the nearshore zone. For all three tidal cycles, with varying characteristics, the following velocity moments appear to prevail :

Tide 164PM (Fig. 8a)	Seaward of the Surf Zone	Terms 2, 4 and 8 dominate
Tide 184PM (Fig. 8b)	Seaward of the Surf Zone	Terms 2, 4 and 8 dominate
Tide 234PM (Fig. 8c)	Seaward of the Surf Zone	Terms 2, 4 and 8 dominate

Figure 8(b). Tide 184PM skewness outside the surf zone.

Figure 8(c). Tide 234PM skewness outside the surf zone.

Figure 9(a). Tide 184PM skewness inside the surf zone.

Figure 9(b). Tide 234PM skewness inside the surf zone.

Tide 164PM	Within the Surf Zone	No data collected*
Tide 184PM (Fig. 9a)	Within the Surf Zone	Terms 2, 4 and 5 dominate
Tide 234PM (Fig. 9b)	Within the Surf Zone	Terms 2, 4 and 5 dominate

\* Storm too violent so data logging stopped.

Seaward of the surf zone, the terms which dominate are, therefore, Term 2 (the skewness of the short wave velocity), Term 4 (the Inman/Bagnold-type term where short waves mobilise the sediment which is then moved by a mean flow) and Term 8 (the term describing the correlation between the short incident wave groups and the long wave motion). Inside the breakpoint, those terms which appear to dominate the very nearshore wave field are Terms 2 and 4 (described previously) and Term 5 (the Inman/Bagnold-type term which represents the mobilisation of sediment by long waves and the subsequent movement by a mean flow). The similarity of these terms for each of the tides, not only in direction but also in percentage contribution to the total skewness implies a remarkable degree of consistency, independent of incident wave conditions. It is also interesting to note the variation of Term 8 through the nearshore system since this reflects the earlier wave groupiness analysis; Term 8 describes the correlation between the incident wave envelope and the long wave motion and its behaviour supports the cross-correlation work which shows a large negative value occurs outside the breakpoint in the deeper water and a trend towards zero and then positive values as the shoreline is approached (Figure 8).

#### 4. CONCLUSIONS

The following conclusions can be drawn :

- (i) Outside the surf zone the cross-correlation between the long wave motion and the wave envelope has a constant negative value and is relatively insensitive to depth. At the breakpoint the correlation decreases towards zero, whilst within the inner surf zone positive correlation values occur. The interaction between long waves and short waves varies systematically through the surf zone.
- (ii) Wave groupiness does not decay immediately at the breakpoint. Instead there is a persistence of the groupiness through the surf zone. It is suggested that this might have important implications for modelling sediment response.
- (iii) The terms dominating skewness inside the surf zone are : the skewness of the incident waves, the correlation between the incident wave energy and a mean flow, and the correlation between the long wave energy and a mean flow.
- (iv) Outside the surf zone, the terms for the skewness of the short incident waves and the correlation between incident waves and a mean flow are dominant, in addition to the correlation between the wave envelope and the long wave motion.
- (v) It would appear that the relative importance of these skewness terms is almost insensitive to the incident wave conditions measured on this beach.

The authors would like to thank Mr. P. Sims and Dr. T. O'Hare at the University of Plymouth, for their useful suggestions and help with this work.

## CHAPTER 74

# GENERATION OF INFRAGRAVITY WAVES IN BREAKING PROCESS OF WAVE GROUPS

Satoshi NAKAMURA<sup>1</sup> and Kazumasa KATOH<sup>1</sup>

### Abstract

To understand the cross-shore distribution of the wave groups and the infragravity waves in a storm, field observations have been carried out at the Hazaki Oceanographical Research Facility. The relationship between the wave groups and the infragravity waves is examined. The infragravity waves are generated in the wave breaking process of the wave groups. The observed heights of infragravity waves in the surf zone agree well with the predicted one by modified Symonds' model, in which a time delay of small wave breaking due to propagation is taken into consideration.

### 1 Introduction

Infragravity waves have been considered to be the main cause of abrupt beach erosion in a storm. For example, Katoh *et al.*(1990,1992) reported the field evidences of foreshore erosion due to the infragravity waves in the storms. Then, to predict the extent of abrupt beach erosions and to develop the effective countermeasures for them, it is important to estimate the magnitude of infragravity waves in a storm.

Although sea waves may look random, inspection of wave records indicates that high waves fall into groups rather than appear individually. This is called a wave groups. Concerning to the generation mechanism of infragravity waves, Symonds *et al.*(1982) showed the attractive theory by taking the wave groups into account. Nearly 10 years, however, have passed in a situation that their theory has not been verified with the field data.

The first purpose of this study is to carry out the simultaneous observation of the cross-shore changes of the wave groups and the infragravity waves in the storm, in order to understand their actual conditions. The secondary one is to modify the theory under certain circumstances for developing the more precise predictive model of infragravity waves in the surf zone.

2 Field observations

2.1 Study site and method of observations

The site of field observations is a entirely natural sandy beach, being exposed to the full wave energy of the Pacific Ocean. On this beach, Port and Harbour Research Institute constructed the Hazaki Oceanographical Research Facility(HORF) for carrying out field observations in the surf zone under storm conditions(see Photo.1). A sediment research pier is 427 meters long.

Photo. 1 Hazaki Oceanographical Research Facility(HORF).

Figure 1 shows the sea bottom profile and the locations where wave gages were set. Seven wave gages are permanently installed on the side of pier deck at the locations from No.1 to No.7 along the research pier. They emit supersonic waves downward and receive the supersonic waves reflected by the sea surface. At each location, wave profiles were measured continuously with a sampling time of 0.5 second. The data were sent to the laboratory at the base of research pier, where

Figure 1 Beach profile and locations of measurement.

the signals were digitalized by a mini-computer and recorded on MT.

The other three wave gages at the locations from No.8 to No.10 were temporarily set on the sea bottom during storm, which were on the extension line of the pier. The water depths at these observation points were 9 meters, 14 meters and 24 meters respectively. At each location, waves were measured during 2 hours of every 6 hours with a sampling time of 0.5 second. The data were stored in a data cassette or an IC memory.

## 2.2 Wave conditions

The field observations were repeatedly carried out in the two different types of storm. Figure 2 shows the changes of offshore significant wave heights and periods, during the first observation from the 25th February to the 1st March in 1989. The maximum peak of wave height was 3.7 meters on the 26th February,

Figure 2 Changes of significant wave height and period in the first observation.

when the atmospheric depression passed through near the site. Figure 3 shows wave heights and periods during the second observation from the 5th to the 9th October in 1989. The maximum wave height was 4.6 meters on the 8th October, when the typhoon passed near the site.

Twenty-nine sets of ten wave records obtained during these two storms have been analyzed in this study. Figure 4 shows the cross-shore distribution of the spectral energy densities in two hours, when the significant wave height was 3.7

Figure 3 Changes of significant wave height and period in the second observation.

Figure 4 Cross-shore distribution of spectral energy densities.

meters in the offshore. The spectral energy density at the location of No.10 has two peaks. The first largest peak is at 0.1 Hz in frequency and second one is at 0.01 Hz. In addition, there is the minimum spectral density at the frequency of 0.04 Hz. The energy densities higher than 0.04 Hz in frequency are due to the incident wind waves, while those lower than 0.04 Hz are considered to be due to the infragravity waves. The former decreases due to the wave breaking with propagation to the shoreline in the surf zone, while the latter increases in the onshore direction. The height,  $H_L$ , and period,  $T_L$ , of infragravity waves have been estimated by calculating the 0th-order and 2nd-order moments of the spectral energy density in the frequency band from 0 to 0.04 Hz as follows;

$$H_L = 4 \int_0^{0.04} S(f)df, \tag{1}$$

$$T_L = \frac{\sqrt{\int_0^{0.04} S(f)df}}{\sqrt{\int_0^{0.04} f^2 S(f)df}}. \tag{2}$$

### 3 Data analysis on wave groups

#### 3.1 Analysis of wave groups

A new method has been introduced for analyzing the wave groups, which can be applied to irregular waves trains both in the offshore and in the surf zone. The new method of analysis is explained in Figure 5, by using the wave profile data measured in the surf zone. First of all, the low frequency components less than

Figure 5 Method of wave groups analysis.

0.04Hz have been removed by using a numerical filter. The upper in Figure 5 is a high-pass-filtered wave profile. There are many small waves which are due to wave breaking and the non-linearity of waves. If individual waves are defined by the usual zero-crossing method, a wave number is greater in the surf zone than in the offshore. For removing small waves, a certain narrow band is established around the mean water level as shown in the middle of Figure 5. The small waves, whose wave height are less than the width of band, are neglected. The width of band has been determined so as to have the same wave number as that in the offshore.

After that, a natural cubic spline curve is fitted on each train of wave crests and wave troughs respectively. As the vertical width between the upper and the lower envelop curves corresponds to the wave height, the continuous wave height,  $\rho(t)$ , can be calculated as shown in the lower.

Based on this results, a mean wave height,  $\bar{\rho}$ , and a mean deviation around the mean wave height,  $\rho_{rms}$ , can be easily calculated by the following equations.

$$\bar{\rho} = \frac{1}{T_n} \int_0^{T_n} \rho(t) dt, \tag{3}$$

$$\rho_{rms} = \sqrt{\frac{1}{T_n} \int_0^{T_n} (\rho(t) - \bar{\rho})^2 dt}, \tag{4}$$

where  $T_n$  is total length of wave record.

If we adopt the Rayleigh distribution as the distribution of wave heights, the probability density function of  $\rho(t)$  is written as

$$p(x) = \frac{\pi}{2} x \exp\left(-\frac{\pi}{4} x^2\right) : x = \rho/\bar{\rho}. \tag{5}$$

By utilizing Eq.(5) and conducting a numerical integration, Eq.(4) can be rewritten as

$$\rho_{rms} = \bar{\rho} \sqrt{\int_0^{\infty} (1-x)^2 p(x) dx} = 0.52\bar{\rho}. \tag{6}$$

There is a well-known relation between  $H_{1/3}$  and  $\bar{H}$  (Goda, 1985), that is

$$H_{1/3} = 1.60\bar{H} (= 1.60\bar{\rho}). \tag{7}$$

By substituting Eq.(7) into Eq.(6),

$$\rho_{rms} \doteq \frac{1}{3}H_{1/3}. \tag{8}$$

Figure 6 shows the comparison of  $\rho_{rms}$  with  $H_{1/3}$  in the offshore. The data are plotted close to the dashed line which is the theoretical relation of Eq.(8).

Figure 6 Comparison of  $\rho_{rms}$  with  $H_{1/3}$ .

A repetition period of wave groups is defined as an elapsed time from the time that wave height is excess of a threshold value to the time of its re-excess, that is to say, in the same manner as what is called a zero-crossing method. The individual repetition period of the wave groups and its mean value are denoted by  $T_R$  and  $\bar{T}_R$ , respectively, hereinafter. Several calculations of the mean repetition period,  $\bar{T}_R$ , have been done by changing the threshold value. Comparing the calculated mean repetition period in the offshore with the observed period of infragravity waves in the surf zone, it has been confirmed that the former agrees approximately with the latter when a highest one-tenth wave,  $H_{1/10}$ , is used as the threshold height. Figure 7 shows the histogram of the repetition periods of wave groups at the offshore in one record length of 2 hours when the significant wind wave height was 3.7 meters. The repetition periods of 60 wave groups are distributed in a wide range. Although there is no predominant peak of frequency in the distribution, the mean repetition period of  $\bar{T}_R$  is used as the representative value for convenience. Figure 8 shows a comparison of the mean repetition period of the wave groups with the significant wave period at the point of No.10. By means of the least square method, the increasing tendency of  $T_R$  can be expressed as

$$\bar{T}_R = 9.24T_{1/3}. \tag{9}$$

Figure 7 Histogram of repetition period.

Figure 8 Comparison of significant wave period with mean repetition period.

**3.2 Relationship between wave groups and infragravity waves**

Figure 9 shows the cross-shore distribution of the mean repetition period of wave groups,  $\bar{T}_R$ , and the height of the infragravity waves,  $H_L$ , when the significant wave height was 3.7 meters. The mean repetition period of the wave groups decreased rapidly near the point of No.8, where the height of the infragravity waves increased. According to our visual observation, the incident wind waves broke in the area between the points of No.7 and 8. On the other hand, when the significant wave height was 1.8 meters in the offshore, which is not shown here,

Figure 9 Distribution of  $\bar{T}_R$  and  $H_L$  in the storm.

the mean repetition period of the wave groups was not long in the offshore, and the height of infragravity wave increased slightly, being still small in the surf zone. Then, it is inferred from these evidence that infragravity waves are generated in the wave breaking process when the mean repetition period of wave groups is long.

#### 4 Modification of Symonds' model

##### 4.1 Applicability of Symonds' model

Symonds *et al.*(1982) showed that the time variation of the break point, which occurs when the incident waves are of varying amplitude, can generate waves at the group period and may be a significant source of infragravity wave energy. They used the non-dimensional, depth-integrated and linearized shallow water equations, that is,

$$\chi \frac{\partial U}{\partial t} + \frac{\partial \zeta}{\partial x} = -F(x, t), \tag{10}$$

$$\frac{\partial \zeta}{\partial t} + \frac{\partial(xU)}{\partial x} = 0, \tag{11}$$

$$\chi = \frac{\sigma^2 X}{g \tan \beta}, \quad \sigma = \frac{2\pi}{T_R}, \quad x = \frac{x'}{X}, \quad t = t'\sigma$$

where  $x'$  is a distance with the origin at the shoreline,  $\zeta$  is the sea surface,  $U$  is the depth-integrated velocity,  $a$  is the incident wave amplitude,  $X$  is the mean position of the break point,  $\tan \beta$  is the beach slope and  $g$  is the gravitational acceleration.

Figure 10 Schematic representation of Symonds' model.

To solve these equations, it is necessary to determine an analytic form for the forcing term on the right-hand side of Eq.(10). The value of the forcing term

depends on the position of the breakpoint,  $x_b(t)$ ,

$$F(x, t) = \frac{1}{2x} \frac{\partial(a^2)}{\partial x} = \begin{cases} 1 & x < x_b(t) \\ 0 & x > x_b(t) \end{cases} \tag{12}$$

The duration of the pulse of Eq.(12) is a function of  $x$ . For  $x$  located from  $x_1$  to  $x_2$ , the forcing term,  $F$ , defined by Eq.(12) tend to a series of pulses. For  $x$  located from 0 to  $x_1$ , it is unity for all time. Otherwise, it is zero for all time.

In the analytical treatment, after considering the result of pre-calculation in two cases of  $\chi$  from 1 to 5, Symonds *et al.* neglected the travel time,  $t_b$ . Then, by assuming that the break point varies sinusoidally with time as shown with the dotted line in Figure 10, they derived the analytical solution of the infragravity waves. By using the Symonds' model, the heights of infragravity waves in the surf zone had been calculated with the field data. In this calculation, we made some assumptions as follows:

a) Although there is the wide distribution of repetition periods as shown in Figure 7, the amplitude of incident waves varies sinusoidally with the observed mean repetition period of wave groups, that is,

$$\rho(t) = \bar{\rho} + \sqrt{2}\rho_{rms} \cos\left(\frac{2\pi}{T_R}t\right). \tag{13}$$

b) The slope of the bottom profile is constant, being  $\tan\beta = 1/140$  which is a mean slope around wave breaking points in the storms.

c) The wave breaking point is determined as the appearance point of the peak value of significant waves, employing the Goda's breaker indices(Goda,1985).

Figure 11 shows the comparison of the predicted height of infragravity waves with the observed one, where the dotted line indicates the relation of coincidence between them. The height of infragravity waves is defined as the mean value of the heights at the observation points in the surf zone. The predicted heights are about four times as large as observed ones. The large difference between them has

Figure 11 Comparison of observed infragravity wave height with predicted one (by the Symonds' model).

been considered to be caused by neglecting the travel time of small waves, because the conditions of their primary consideration  $\chi=25-100$  are far from our condition in the field observation. In the case of our condition, the trace of the break point has been extremely distorted sinusoidal curve, that is sawlike or overhanded, as shown with a solid line in Figure 10, even if the incident wave amplitude at the outside edge of the surf zone varies sinusoidally.

### 4.2 Modification of the Symonds' model

By taking the travel time into consideration, the Symonds' model must be modified. The position of the break point is given by

$$x_b = 1 + \Delta a \cos(t - t_b), \tag{14}$$

where  $\Delta a$  is a half width of dimension-less break point varying,  $t_b$  is the travel time required for a wave to propagate from  $x_2$  to  $x_b$ (see Figure 10), which is written as

$$t_b = 2\sqrt{\chi}(\sqrt{x_2} - \sqrt{x_b}), \tag{15}$$

according to the shallow wave theory. The forcing term,  $F$ , can be expressed as a Fourier series as follows;

$$F(x, t) = \frac{1}{2x} \frac{\partial(a^2)}{\partial x} = 2 \sum_{n=0}^{\infty} \{a_n(x) \cos nt + b_0(x) \sin nt\}, \tag{16}$$

$$a_0(x) = \frac{1}{4\pi} \int_{t_1(x)}^{t_2(x)} 1 dt, \quad b_n(x) = 0, \tag{17}$$

$$a_n(x) = \frac{1}{2\pi} \int_{t_1(x)}^{t_2(x)} \cos ntdt, \tag{18}$$

$$b_n(x) = \frac{1}{2\pi} \int_{t_1(x)}^{t_2(x)} \sin ntdt. \tag{19}$$

where  $t_1(x)$  and  $t_2(x)$  can be expressed with  $t_b$  defined by eq.(15) as follows:

$$t_1(x) = -\tau + t_b, \quad t_2(x) = \tau + t_b, \quad \tau = \arccos\left(\frac{x-1}{\Delta a}\right). \tag{20}$$

By substituting  $t_1(x)$  and  $t_2(x)$  into Eqs.(17),(18) and (19), we have

$$a_0(x) = \frac{\tau}{\pi}, \tag{21}$$

$$a_n(x) = \frac{\sin n\tau}{n\pi} \cos nt_b, \tag{22}$$

$$b_n(x) = \frac{\sin n\tau}{n\pi} \sin nt_b. \tag{23}$$

For the large value of  $\chi$ , the travel time becomes long, being  $t_b > \tau$ . In this case, the trace of breaking point is overhanded, then  $t_1(x)$  is given as

$$t_1(x) \doteq 0, \quad (24)$$

in place of Eq.(20). Under this condition, we also have  $a_0, a_n, b_n$  in the same way.

By combining Eqs.(10) and (11), the  $\zeta_0$  equation for  $n = 0$ , which is mean set-up, is simply given by

$$\zeta_0 = \begin{cases} -\frac{1}{\pi}\{(x-1)\tau - \sqrt{\Delta a^2 - (x-1)^2}\} & (x_1 < x < x_2) \\ \Delta a + (x_1 - x) & (0 < x < x_1) \end{cases}. \quad (25)$$

The  $\zeta_n$  equations for  $n > 1$  is of the following form

$$\chi \frac{\partial^2 \zeta_n}{\partial t^2} - x \frac{\partial \zeta_n}{\partial x} - \frac{\partial^2 \zeta_n}{\partial x^2} = \begin{cases} \frac{\partial(2F_n x)}{\partial x} & (x_1 < x < x_2) \\ 0 & \text{otherwise} \end{cases}, \quad (26)$$

where

$$F_n = a_n(x) \cos nt + b_n(x) \sin nt. \quad (27)$$

If we put

$$\zeta_n = \frac{V_n(x)}{x^{1/2}} \exp(int), \quad (28)$$

and by substituting Eq.(28) into Eq.(26), we have

$$\exp(int) \left[ \frac{\partial^2 V_n}{\partial x^2} + V_n \left( \frac{1}{4x^2} + \frac{\chi n^2}{x} \right) \right] = \begin{cases} -\frac{1}{x^{1/2}} \frac{\partial(F_n x)}{\partial x} & (x_1 < x < x_2) \\ 0 & \text{otherwise} \end{cases}. \quad (29)$$

The homogeneous solution of Eq.(29) is given by

$$V_n = P_n x^{1/2} Z_0(Q_n x^{1/2}), \quad (30)$$

where  $Z_0$  is the zero-th order Bessel function,  $J_0$ , or Neumann function,  $Y_0$ ,  $Q_n^2 = 4n^2\chi$ .

Outside the forcing region,  $0 < x < x_1$  and  $x_2 < x$ , the total solution is of the following form

$$\begin{aligned} \zeta_n &= \zeta_{nh}, \\ \zeta_{nh} &= \{A_n J_0(Q_n x^{1/2}) + B_n Y_0(Q_n x^{1/2})\} \cos nt \\ &\quad + \{C_n J_0(Q_n x^{1/2}) + D_n Y_0(Q_n x^{1/2})\} \sin nt, \end{aligned} \quad (31)$$

where  $A_n, B_n, C_n$  and  $D_n$  are the constants. In the forcing region,  $x_1 < x < x_2$ , the total solution is given by summing to following particular solution and eq.(31);

$$\begin{aligned} \zeta_n &= \zeta_{nh} + \zeta_{np}, \\ \zeta_{np} &= \{A_{np} J_0(Q_n x^{1/2}) + B_{np} Y_0(Q_n x^{1/2})\} \cos nt \\ &\quad + \{C_{np} J_0(Q_n x^{1/2}) + D_{np} Y_0(Q_n x^{1/2})\} \sin nt, \end{aligned} \quad (32)$$

$$\begin{aligned}
 A_{np} &= -\pi[2a_n(x)xY_0(Q_n x^{1/2})]_{x_1}^x - \pi \int_{x_1}^x a_n(x)Q_n Y_1(Q_n x^{1/2})dx, \\
 B_{np} &= \pi[2a_n(x)xJ_0(Q_n x^{1/2})]_{x_1}^x + \pi \int_{x_1}^x a_n(x)Q_n J_1(Q_n x^{1/2})dx, \\
 C_{np} &= -\pi[2b_n(x)xY_0(Q_n x^{1/2})]_{x_1}^x - \pi \int_{x_1}^x b_n(x)Q_n Y_1(Q_n x^{1/2})dx, \\
 D_{np} &= \pi[2b_n(x)xJ_0(Q_n x^{1/2})]_{x_1}^x + \pi \int_{x_1}^x b_n(x)Q_n J_1(Q_n x^{1/2})dx,
 \end{aligned}$$

where  $J_m$  is the m-th order Bessel function and  $Y_m$  is the m-th order Neumann function.

The constants are determined by setting the following conditions

- at  $x = 0$  with  $\partial\zeta_n/\partial x = 0$ ,
- at  $x = x_1$  and  $x = x_2$  with  $\zeta_n$  and  $\partial\zeta_n/\partial x$  continuous,
- at  $x = \infty$  with  $\zeta_n$  outgoing progressive.

After all, the  $\zeta$  solution is given by

$$\zeta = \sum_{n=0}^{\infty} \zeta_n. \tag{33}$$

Figure 12 shows the normalized amplitude at the shore line, which is calculated by the modified Symonds' model, as function of  $\chi$ . In this figure, the results calculated by the original model are also shown with dotted lines. For  $\chi$  smaller than 4, the modified model and the original model give the same results, while for  $\chi$  greater than 4, the results predicted by the modified model is smaller than that of the original model. In the case of  $n = 1$ , the amplitude at the shoreline increases with  $\chi$  up to  $\chi = 15$ , where the trace of break point begins to be overhanded, and it is decreases from here on.

Figure 12 Normalized amplitude as a function of  $\chi$ .

### 5 Verification of modified model with the field data

In the case of our field observation, as the value of  $\chi$  is in range from 25 to 100, it is better to use the modified Symonds' model for estimating the height of infragravity waves in the surf zone. In the calculation, the assumptions described in the former section are employed, and the summation in Eq.(33) is conducted up to  $n = 3$ . Figure 13 shows the comparison of the observed infragravity wave heights in the surf zone with those predicted by the modified Symonds' model. Also in this case, the height of infragravity wave is the mean value of the heights

Figure 13 Comparison of observed infragravity wave height with predicted one (by the modified Symonds' model).

at the observation points in the surf zone. The data are plotted close to a dotted line, on which the observed height coincide with the predicted ones.

Next, let's do another verification of the modified Symonds' model. At the Port of Kashima located near the HORF, the waves and the currents are being permanently observed during 20 minutes of every two hours at the depth of about 24 meters. By utilizing these data, the value of  $\rho_{rms}$  and  $\bar{T}_R$  were estimated by Eqs.(8) and (9) respectively, and the heights of infragravity waves in the surf zone have been predicted by the modified Symonds' model. In the HORF, the heights of infragravity wave have been measured at the point from No.1 to 7 throughout the year.

Figure 14 shows the comparison of the predicted heights of infragravity waves with the observed ones in the HORF during one year of 1989, where the comparisons are made for the data obtained at 12 o'clock of every day. There is a close agreement between them.

Figure 14 Comparison of predicted infragravity wave height by using the data of significant wave with observed one.

## 6 Conclusions

The main conclusions obtained in this study are as follows:

- a) The period of wave groups, which is long in a deep sea during the storm, decreases in the process of wave breaking, and the infragravity waves become large in the surf zone.
- b) The Symonds' theory has been modified by taking the effect of wave propagation into account. By means of this theory, the height of infragravity waves in the surf zone are estimated accurately with the representative value of wave groups,  $\rho_{rms}$  and  $\bar{T}_R$ .
- c) Even if the data of significant waves are only available, the heights of infragravity waves could be estimated by using the theoretical and the empirical relationships between the significant waves and the wave groups.

## CHAPTER 75

### MONITORING MOUND BREAKWATERS. THE CASE OF SINES

F. ABECASIS<sup>1</sup> and C. PITA<sup>2</sup>

#### ABSTRACT

The aim of monitoring mound breakwaters is presented. Available techniques and Sines breakwaters monitoring program are described.

#### INTRODUCTION

It is normal that damage occur in mound breakwaters. However, in order to avoid the inoperationality of the structures or too expensive repairs, it is essential that these damages do not overpass certain thresholds. It is therefore necessary to carry out systematic monitoring of these structures; this will allow not only the opportune correction of any deficiency but also the diagnosis of the origin of this deficiency in order to its future correction. And it must not be forgotten that the monitoring is too a valuable source of knowledge for future designs of this kind of structures.

So, in the authors' opinion, the main scope of monitoring a breakwater is to foresee and to plan maintenance works; and it is important to take into account that any repair works of a breakwater are slow and only possible with relatively calm weather. This is why maintenance works must be planned without delay after the first signs of degradation and must be carried out in the next suitable opportunity.

As a matter of fact, the possible observation of a mound breakwater is the observation of its enveloping layers, namely of the position and integrity of the outer blocks. It is not difficult to observe in such a way the part of a breakwater above the sea level; this is not the

---

1 - Partner, HIDROTECNICA PORTUGUESA, Consulting Engineers

2 - Partner, WW, Consulting Engineers

same for the submerged part, in consequence of the turbulence and the low transparency of the water. However this is the most vulnerable zone of the structure, mainly the zone just below the sea level.

**TYPES OF DAMAGES**

The possible types of damages in mound breakwaters are the following (Per Bruun, 1982 and Pita, 1984), see figs. 1 and 2:

Figure 1

- 1 - Going out of armoring blocks due to plunging breaking of the waves on the outer slope, with subsequent displacement of blocks, generally upwards.
- 2 - Going out of armoring blocks due to underpressures caused by the combination of the effects of going down waves with incoming breaking waves and with hydrostatic forces of the water existing inside the mound.

Figure 2

- 3 - Sliding of the armor layers. It happens often for very steep slopes or for very porous armor layers. It may be due to lack of support originated by berm deterioration (damages type 17).
- 4 - Falls or breakages of rocking blocks.
- 5 - Undermining of superstructure if it exists. The undermining may have several origins (differential settlements of the core, loss of fine elements, etc.).
- 6 - Instability of the top layers (and of the superstructure when it exists) and of the inner slope, due to overtoppings.
- 7 - Instability of the top layers (and of the superstructure when it exists) and of the inner slope, due to high underpressures. This may happen in consequence of too high porosity of filters and core.
- 8 - Bottom erosion in the base of the slope in consequence of wave action and/or currents.
- 9 - Rupture of the foundation.
- 10 - Damages provoked by bad quality of materials used.
- 11 - Damages originated by differences between the structure designed and the structure actually built, either in consequence of construction errors, or in consequence of adaptations of the design.
- 12 - Loss of weight and modifications in material properties due to chemical attack by sea water, to abrasion or to cavitation.
- 13 - Overturning of the curtain-wall, caused by the impact of waves.
- 14 - Sliding of the curtain-wall, caused by the impact of waves.
- 15 - Rupture of the superstructure, caused by wave action.
- 16 - Sliding of a wedge of the inner slope of the breakwater.
- 17 - Damages, by wave action, in the berm of support of the armor of both slopes (with possibility of damages of type 3).
- 18 - Functional deficiency of the structure, that is, loss (eventually temporary) of capacity of accomplishing its functions. This happens, for instance, when overtopping occur originating lack of shelter conditions inside the port.

## OBSERVATION TECHNIQUES

### General Comments

The approach used to monitor a mound breakwater is quite different from the approaches used in other structures.

A mound breakwater is a "collection" of thousands of blocks "randomly" placed, each one submitted to a different load and supported into a different way. It is impossible to identify a limited number of points representative of the stability of the breakwater, where forces, stresses and movements could be measured. To get these data, a large number of instrumented blocks would be required. Measurement devices acquisition and maintenance costs would be very high. Even if they were positioned, there would be a high probability of losing an important part of them if a major storm occurs.

It must be noted that to obtain relevant data, monitoring of a breakwater must be done on a permanent basis. In these conditions, simple and not expensive techniques must be used.

The information collected with a monitoring program should be completed by a wave and current measuring campaign, so that correlations between loads and breakwater behavior are possible. As the available measuring techniques for waves or currents are very well described in several documents, only the techniques of monitoring a breakwater are described in this paper.

### Available Techniques

#### **A - VISUAL OBSERVATIONS**

This technique is easy to perform frequently and regularly from the top of the structure or from a ship, specially in what concerns the emerged zone. Visual observation of the submerged zone is done by divers.

Anyway, this technique has some drawbacks:

- \* Damage is only detected when a certain level of it is reached;
- \* A detailed control of the submerged zone is difficult, due to turbulence and visibility problems.

The results of these observations can be influenced by the observer's criterion. To reduce this risk, a form must be fulfilled by the observer in accordance to the criteria presented in tables I and II. These criteria are adaptation of damage criteria used in model tests by Delft Hydraulics and by LNEC.

An important information collected easily and with sufficient accuracy by visual observations is the occurrence of overtoppings. In this case, it must be recorded:

- \* The date/hour at which overtopping begins and ends;
- \* Location of overtopping and its direction of propagation along the breakwater;
- \* Overtopping intensity and frequency, in accordance to classification presented in table III;
- \* Distance from the crownwall reached by the overtopping.

TABLE I  
REMOVED BLOCKS CLASSIFICATION

DEGREE	IDENTIFICATION	DESCRIPTION
0	Inexistent	There are not removed units or gaps in the armor layer.
1	Slight	Removed less than 1% of the units of upper layer of the armor. Gaps in this layer do not exceed 3 units.
2	Little	Removed less than 2% of the units of upper layer. Gaps in this layer do not exceed 3 units.
3	Moderate	Removed less than 3% of the units of upper layer. Gaps in this layer of 3 to 5 units.
4	Much	Removed more than 3% of the units of upper layer. Large gaps in this layer (more than 5 units).
5	Serious	Large gaps in the upper layer. Gaps in the second layer.
6	Destruction	The two armor layers were removed.

Note: Gap of X units: Removal of X adjacent blocks to positions distant from the original position more than a characteristic length.

TABLE II  
BREAKAGE CLASSIFICATION

DEGREE	IDENTIFICATION	DESCRIPTION
0	Inexistent	There are no broken units.
1	Hardly Any	Existing breakage has only a small effect on the weight and shape of armor units.
2	Slight	Broken units do not exceed 1% of the total number of units. No more than 3 adjacent broken units.
3	Small	Broken units do not exceed 2% of the total number of units. No more than 3 adjacent broken units.
4	Moderate	Broken units do not exceed 3% of the total number of units. The number of adjacent broken units is 3 to 5.
5	Many	Broken units do not exceed 5% of the total number of units. The number of adjacent broken units do not exceed 10
6	Serious	Broken units exceed 5% of total number of units. There are 10 or more adjacent broken units.

Note: Broken unit is a unit with a weight reduction of 10% or more of its original weight, or with an important change on its original shape.

TABLE III  
OVERTOPPING FREQUENCY AND INTENSITY

DEGREE	IDENTIFICATION	DESCRIPTION
0	Inexistent	No overtopping.
1	Hardly Any	Some waves produce a slight overtopping of "white water".
2	Little	Frequent overtopping of "white water". There is no "greenwater" overtopping.
3	Moderate	Some waves produce the passage of "green water" over the structure, but water quantities are not important.
4	Strong	Frequent overtopping of "green water", but water quantities are not important.
5	Very Strong	A few waves produce large overtopping water quantities.
6	Serious	Frequent overtopping of large water quantities.

#### B - PHOTOGRAPHY

Systematic photography of the breakwater at same scale and obtained from pre-defined points (to permit superposition of photos obtained at different observations) is an important tool to evaluate damage long term increase. These photos can be obtained from the crown of the breakwater or from a ship.

Photographic campaigns must be done in conditions that a photogrammetric treatment of the photos is possible, to evaluate the levels of the external surface of the breakwater.

#### C - TOPOGRAPHIC TECHNIQUES

Emerged area of the breakwater can be controlled by topographic record of the three coordinates (X,Y,Z) of selected points. As much as possible, the choice of these points must take into account the possibility of obtaining cross profiles of the breakwater (using sounding results for the submerged part).

#### D - SOUNDING

To quantify data on the behavior of the underwater part of the breakwater, sounding techniques must be used. The easier and less expensive technique is the manual sounding, done by a diver or from a ship. In both cases, the depths are measured in selected points located on lines perpendicular to the breakwater. The sounding with a diver has the advantage of visual observation and control of the actually sounded points (specially important in the case of a rubblemound breakwater, where the

sound can be done in the vertical of a unit or in the void between adjacent units).

More sophisticated sounding techniques involve the use of side scan sonar. They can be used to obtain cross profiles or 3-D restitutions of the underwater part of the structure. The use of 3-D scanning has difficulties, because measures are influenced by the effect of wind, waves and currents on the movement of the ship.

#### **E - AERIAL PHOTOGRAPHY**

Aerial photography is a very interesting complement of other techniques, specially because good restitutions of emerged zone can be obtained with photogrammetric treatment.

#### **F - UNDERWATER VIDEO RECORDING**

Underwater video recording has two main objectives:

- \* To record divers observations;
- \* When obtained from a remote operated vehicle (ROV), to permit the observation of areas not accessible to divers.

#### **G - TESTS OF THE MATERIALS**

To evaluate the deterioration of materials there are two possible kinds of tests:

- \* Non-destructive techniques, like the use of ultra-sounding equipment and sclerometers.
- \* Destructive techniques, where some samples are collected for laboratory tests.

### Identification and Quantification of Damages

No one of described techniques gives accurate information about the integrity of the breakwater. Anyway, with the simultaneous use of two or more techniques, it is possible to obtain reliable data to identify and quantify the several types of damages on mound breakwaters, described before. In table IV a synthesis of the use of these techniques for each type of damages is presented.

To make easier the treatment and analysis of collected data, the breakwater shall be considered split into small parts, with lengths of about 50 meters, each one being separately monitored.

### **THRESHOLDS FOR THE SEVERAL TYPES OF DAMAGES**

An attempt has been made to establish, for the several types of damages, thresholds above which it is considered necessary to carry out normal maintenance works, short term repair works (i.e. works to be carried out when the sea conditions or the constructive

TABLE IV  
OBSERVATION TECHNIQUES

DAMAGE	DESCRIPTION	POSSIBLE OBSERVATION TECHNIQUES
1 2	Removal of armor units	A - Visual observation (emerged and submerged zones).
3	Sliding of armor layers	B - Photography, eventually with photogrammetric treatment. C - Traditional topographic techniques.
4	Falls or breakages produced by rocking	D - Sounding techniques. E - Aerial photography, eventually with photogrammetry (emerged zone).
16	Sliding of a wedge of the inner slope	F - Submarine television.
5	Undermining of superstructure	A - Visual observation. B - Photography. C - Traditional topographic techniques. E - Aerial photography. G - Destructive tests
6 7 13 14 15	Instability of top layers and crownwall	A - Visual observation. B - Photography. C - Traditional topographic techniques. E - Aerial photography.
8	Bottom erosion	A - Visual observation (by divers).
9	Rupture of foundation	D - Soundings. F - Submarine television.
17	Damages in the berm of support of the armor of both slopes	
10	Bad mechanical properties of materials	A - Visual observation. G - Non-destructive tests. G - Destructive tests.
12	Physical and chemical deterioration of the materials	
18	Functional deficiency	Visual observations.

constraints allow) or as quick as possible repair works (even with provisional character and, therefore, designed for a very short life - only a few months).

These proposed thresholds, presented in table V, are based on the existing experience; as a matter of fact, they suffer very much from subjectiveness and therefore they will certainly require corrections and adjustments in the future.

TABLE V  
THRESHOLDS OF DAMAGES

Damage type	Description		Thresholds		
			Of normal maintenance	Of repair	
				Short term	As quick as possible
1 2	Going out of armor- ing blocks (outer and inner slopes)		Degree 1 falls or lacks of blocks	Degree 2 falls or lacks of blocks	Degree 3 or above falls or lacks of blocks
3	Sliding of the armor layers				
4	Falls or breakages of rocking blocks		Degree 1 falls or degree 2 fractures	Degree 2 falls or degree 3 fractures	Degree 3 or above falls or degree 4 fractures OR degree 2 falls and degree 3 fractures
5	Undermining of su- perstructure		If tendency to their occurrence is detec- ted, periodical recharges or repairs must be carried out	When detected	When detected, if if this detection happens in the beginning or during winter
6 13 14 15	Instability of top layers or of super- structure, due to the impact of waves or to overtoppings				
7	Too much porosity of filter layers or of core	Instability of top layers or of super- structure			
		Instability of inner slope	Degree 1 falls or lacks of blocks	Degree 2 falls or lacks of blocks	Degree 3 or above falls or lacks of blocks
8	Bottom erosion		-	If there is fear that foundation be affected	If the foundation is affected
9	Rupture of foundation		-	-	When detected (1)
10 12	Materials deterio- ration		When detected, even small	When the material strength of blocks or other important structural elements is reduced 30% or the weight of 3% of the blocks is reduced 40%	-
11	Differences between the structure de- signed and built		-	When detected, if the studies on the structure behavior show that the struc- ture actually built is not stable for the design wave	-

**MONITORING SINES BREAKWATERS**Brief Description of the Breakwaters

Sines is an artificial harbor, with shelter conditions obtained with two large breakwaters.

Main breakwater, the so called West Breakwater, is also the harbor oil terminal and has several cross-profiles:

- \* **Type A** - Along 173 meters, it is characterized by a single layer armor of 40 tons Antifer cubes, with a slope 2:1. Top of the armor is at +14,0 m CD.
  - Concrete crown wall has a top level of +16 m CD with an external vertical face.
  - Design wave is  $H_s = 9$  m.
  
- \* **Type B** - Along about 317 meters, this profile is composed by a double layer armor of 40 tons Antifer cubes with a slope of 2:1. Armor top is at +17,5 m CD, with a 15 m wide berm. The toe is composed by a 10 meters wide berm of 40 tons Antifer cubes.
  - The superstructure has a crown wall, with an initial part with external vertical face and top at +16m CD, and a final portion with a curved parapet to reverse the run-up flow with a top level of +19 m CD.
  - Design wave height is  $H_s = 9$  meters.
  
- \* **Type C** - Along about 450 meters, this profile has a double layer armor of 90 tons Antifer cubes extending from levels +18 m CD to -20 m CD, with a composite slope:
  - From +18,0 m CD to -3,0 m CD → Slope 2:1
  - From -3,0 m CD to -5,0 m CD → Slope 8:1
  - From -5,0 m CD to -20,0 m CD → Slope 3:1.
  - Inner slope is composed by 3 - 6 tons quarry stones at 4:3, between levels +1,4 m CD and -15,0 m CD. Below this level, a quarry run material with a slope of 4:3 is used.
  - Superstructure is similar to the one described for the outer part of type B profile.
  - Design wave height is  $H_s = 14,0$  m.
  
- \* **Type D** - Along 500 meters, this section is composed by a composite slope of 2 armor layers of 90 tons Antifer cubes, reaching levels of +13,2 m CD at the top and -20,0 m CD at the bottom. Slopes are as follows:
  - Between +13,2 m CD and +5,84 m CD → 3:1
  - Between +5,84 m CD and -7,0 m CD → 2:1
  - Between -7,0 m CD and -11,0 m CD → 7:1
  - Between -11,0 m CD and -19,85 m CD → 3:1

- Inner slope is composed also by 2 layers of 90 tons Antifer cubes with a slope of 3:1 between levels +13,2 m CD and +9,0 m CD and 2:1 between levels +9,0 m CD and -1,0 m CD. Below level -1,0 m CD, 9 - 12 tons quarry stones were used with a slope of 3:2 until level -4,0 m CD and 2:1 between this level and the bottom.
- The head of the breakwater armor is composed by high density 105 tons Antifer cubes.

The initial West Breakwater was 2 kilometers long. The final part, between profile type D and the previous head, around 280 meters long, will be abandoned.

The second breakwater, East Breakwater, gives shelter conditions for the operation of a coal terminal, is about 1100 meters long in depths of about 25 to 30 meters in a sand bottom. This breakwater has a double layer armor of 60 tons Antifer cubes with a slope of 2,5:1, between +14,25 m CD and -11,75 m CD. At the toe, this armor is supported by a 9 - 12 tons quarry stones berm 10 m wide.

Inner slope is composed by a 60 tons Antifer cubes armor at 3:2 between levels +12,5 m CD and -5,0 m CD.

The top of this profile is 6,25 m wide and has an in situ concreted cap platform.

### The Monitoring Plan

First of all, it is recommended that the two breakwaters will be divided into reaches 30 m long.

The following observations of the two structures must be carried out:

#### A - Routine observations

##### A.1 - Visual observations

To be carried out monthly between October and April and in midsummer, in a total of 8 observations per year. They must be performed by walking on the crest of the breakwaters during low tide and recording the results. These observations must be complemented through identical procedure from a small boat, also during low tide, parallel to both slopes of the breakwaters.

Yearly (in the early spring) an observation of the submerged part of the breakwaters must be carried out. This observation will allow the completion of the program with data concerning the submerged part.

##### A.2 - Photography

In the beginning of spring and autumn, the visual observations from the crest and the boat referred to above must be complemented with local photos of each

reach. These photos must be obtained in low water, concerning only the outer slope and the superstructure.

Yearly, in early spring, general photos of the outer slopes must be taken, also during low tide, from a boat moving parallel to the breakwaters at a distance of 150 m. These photos must allow the obtention of amplifications at constant scale, not below 1:500, for superposition with other ones obtained previously, to identify block displacements. In the same occasion, local photos of the submerged part of the slopes must be obtained to illustrate eventual deficiencies of the armor.

In what concerns the inner slope, the general and local photos will be taken only every two years, unless if the visual inspection referred to in A.1 would have shown any damage; in this later case photos of the two types must be taken. However, taking into account that east breakwater and the reconstructed part of the west one will be overtopped frequently, the general and local photos of their inner slopes must be taken with the same frequency than for the outer slopes, that is to say, general photos yearly, in early spring, and local photos twice a year, in April and September.

#### **A.3 - Topographical techniques**

Twice a year, in April and September, it must be carried out the topographical control, with basis in points in land, of one point in each module (15 m long) of the superstructure of the West Breakwater. In East Breakwater, without superstructure, it is considered enough the topographical control of one point every 30 m.

These points, in both breakwaters, will serve for the location of cross-sections of the part above water level. It is recommended the obtention of these cross-sections, once a year (in April), 60 m apart.

#### **A.4 - Soundings**

Soundings must be carried out, by any of the procedures described before, prolonging as much as possible the sounding of the submerged part of the breakwaters, both near the water surface and seaward of the base of the slope (in this later case not less than 30 m beyond this base). These soundings must be carried out simultaneously with the cross-sections above water level.

#### **A.5 - Aerial photography**

It must be made yearly, in early spring, simultaneously, as much as possible, with the surveys and cross-sections referred to above. The aerial photography must be submitted to photogrammetric treatment, with the scope of obtaining breakwater plans to a scale not below 1:500.

**A.6 - Underwater TV**

If the observations referred to above show any local damages in the submerged part of the breakwaters, video-records of these damages must be obtained.

**B - Extraordinary observations****B.1 - Overtoppings**

When overtoppings occur, they must be observed.

**B.2 - Just after a storm with Hs exceeding 5 m in deep waters**

A visual observation of the A.1 type must be carried out; if this observation advises it, observations of the A.2 type must be carried out too.

**B.3 - After a storm with Hs exceeding 8 m in deep waters**

Besides the visual observation referred to in B.2, just after the storm, a complete observation using all the techniques referred to in A must be carried out as quick as possible; the distances between cross-sections of the emergent and submerged zones must be reduced to 30 m (or even less, locally, if it is necessary to a better characterization of the damages).

Obviously, after every big repair of the breakwaters, a complete observation of type A must be done (identical to the one carried out regularly in April). This observation may be eventually restricted to the repaired zone.

Besides the observation of the structures themselves referred to above, the actions on them - waves, tides, currents and winds, must obviously be regularly recorded. However it is not the scope of this paper to consider in detail these observations.

**First Results****• Wave Records**

At Sines there are two Datawell directional wave recorders, one of which in deep water [CD (-100 m)]. The wave recording program is being done since 1973, with some gaps due to wave buoy problems. Data are available in real time.

**• Breakwaters Monitoring**

Construction profiles of the underlayers and the armor are available. The results of the usual construction material tests are also in Administração do Porto de Sines files.

There are some profiles collected since 1980 on a non-regular basis of Type C zone of West Breakwater.

Included in the Systematic Monitoring Program, APS has done some work, consisting of:

- Several visual observations;
- Photographic reports;
- Topographic observation of selected points in the superstructures;
- An aerial photography and a photogrammetric restitution of the part of the West Breakwater above sea level.

APS monitoring program is included in a proposal to EC Marine Science and Technology Program (MAST II), in which obtained data will be compared with data collected at Zeebrugge harbor using the same techniques and also with the equipment installed at its northwest breakwater (which comprises the measurement of wave characteristics, tidal currents and orbital velocities, water levels and water pressure fluctuations at several points in front of the breakwater, in the armor layer and in the core, air pressures in the core, impact pressures on the faces of armor units and video observations of uprush and downrush).

#### ACKNOWLEDGEMENT

The monitoring plan of the Sines Breakwaters was prepared for the Administração do Porto de Sines. The authors are in debt to APS for the permission of preparing this paper.

## CHAPTER 76

### Rear Side Stability of Berm Breakwaters

O.H. Andersen<sup>1</sup>, J. Juhl<sup>1</sup> and P. Sloth<sup>1</sup>

#### Abstract

With the aim of providing improved methods for preliminary design of berm breakwaters, a series of physical model tests and a parameter study with special emphasis on the rear side stability of a trunk section have been carried out at the Danish Hydraulic Institute (DHI). The model tests included different geometries of the berm breakwater profile and a range of wave conditions. For each profile, the wave condition resulting in sea side and/or rear side damage was determined. As a hydrodynamic description of the overtopping waves would be very comprehensive, and at present is not available, a surf similarity approach in combination with a force balance for the armour stones has been chosen. A parametric expression for the rear side stability has been established and found to be in fairly good agreement with the model test results.

#### Introduction

Existing experience with berm breakwaters provides some insight in the behaviour of the various parts of a berm breakwater. Most research during the last ten years has concentrated on the sea side stability of the trunk section, ie the development of the berm profile. No systematic work on the rear side stability has previously been reported and hence a comprehensive study focusing on the rear side stability of the trunk section was carried out at DHI. As it is still not possible to give an adequate hydrodynamic description of the overtopping phenomenon, eg in the form of a numerical model, it was decided to carry out a series of physical model tests and an associated parameter study.

---

<sup>1</sup> Danish Hydraulic Institute, Agern Allé 5, 2970 Hørsholm, Denmark

In the present study, the rear side stability is treated as a traditional static stability phenomenon. Emphasis has been put on inclusion of a large number of physical parameters enabling the description to cover a variety of berm breakwater designs: wave height and steepness, crest height, rear side slope, effective sea side slope, stone diameter, relative density and natural angle of repose.

The stability criterion established has been compared to the results of the model tests carried out and in addition to an expression given by Van der Meer and Veldman.

## Model setup and procedure

A wave flume with a length of 65 m and a width of 1.8 m was used for model testing in four water depths of 0.67 m, 0.77 m, 0.87 m and 0.97 m. The profile tested is shown in Figure 1. Crushed stones were used both for the core,  $D_{50} = 0.011$  m (50% exceedance), and for the berm and armour layer,  $D_{n50} = 0.034$  m.  $D_{n50}$  is the nominal diameter given as  $(M_{50}/\rho_s)^{1/3}$ , where  $M_{50}$  is the mass of the stones (50% exceedance) and  $\rho_s$  is the density of the stones. The grading of the berm and armour material equalled  $D_{n85}/D_{n15} = 1.35$  and the relative density equalled  $\Delta = 1.68$ . The armour layer thickness on the crest and rear side was twice the value of  $D_{n50}$ . The model study covered variations in the following parameters:

- $w_c$ , width of the crest, 0.175 m and 0.30 m
- $R_c$ , freeboard of the crest, 0.20 m, 0.30 m and 0.40 m
- $f_h$ , width of the berm, 0.45 m, 0.65 m, 0.85 m and 1.05 m
- $f_v$ , freeboard of the berm, 0.10 m and 0.20 m.

Figure 1. Test profile.

Tests were carried out in test series with successively increasing wave height,  $H_{m0}$ , and wave period,  $T_{02}$ , from test run to test run, with a fixed fictitious wave steepness  $s_{02} = 2\pi H_{m0}/gT_{02}^2$  equal to approximately 0.030 and 0.044 respectively. Each test series consisted of approximately 1,000 irregular waves. The incident wave characteristics in front of the berm breakwater,  $H_{m0}$  and  $T_{02}$ , and the reflection coefficient were calculated using a multi-gauge technique.

The berm profile was measured after each test run. Damage to the seaward side of the berm breakwater was defined to occur when the entire top of the berm was eroded. Rear side damage was defined as a settlement of the rear side armour layer which in some cases was followed by an exposure of the core.

Table 1 gives an overview of the 23 tested profiles for which rear side damage was observed prior to or coincident with damage of the sea side. The wave conditions,  $H_{m0}$  and  $T_{02}$ , resulting in rear side damage are also shown in Table 1.

*Table 1. Rear side damages.*

## Data Analysis

During the tests, it was observed that the developed sea side profile can be characterised as three slopes: an upper steep slope, a lower slope close to 1:4 or flatter and finally a steep slope intersecting the seabed, see Figure 2. This is a well known observation confirmed by several other researchers.

*Figure 2. Example of development of sea side profile.*

Rear side damage of a trunk section happens at almost fully developed sea side profile. A typical development is that a few stones just above still water level at the rear side are displaced downwards during a series of wave overtoppings (cf Figure 3), and after another few severe wave overtoppings, a settlement of the rear side armour layer occurs, possibly resulting in an exposure of the core.

*Figure 3. Initiation of rear side damage.*

The stability of the rear side depends on the sea side profile, crest height, crest width, rear side slope, stone diameter, relative density and natural angle of repose. It appears from the analysis of the present model test results that a variation with the crest width is not visible. New model tests with larger crest widths are presently being carried out in order to include this parameter as well. The following analysis is considered to be valid for the crests widths in Table 1, and hence  $w_c$  is not included in the analysis.

It is assumed that the speed of the overtopping water is the governing factor in determining the rear side stability. The speed at the crest,  $U_R$ , is chosen as a reference speed.

$U_R$  can be found by putting the potential at the crest equal to the potential at the still water level at the seaward side:

$$U_R^2 = 2g (R_{ui} - R_c) \quad (1)$$

where  $R_{ui}$  is the run-up on a hypothetical slope of the sea side, with index  $i$  indicating a fraction of the waves. The hydraulic parameters are defined in Figure 4.

Figure 4. Definition of hydraulic parameters.

Pilarczyk (1990) applied the same reference velocity for the description of the rear side stability of dikes, resulting in a final stability criterion with large resemblance to the criterion derived below.

For the berm breakwater rear side, a traditional static stability criterion is applied. The stability of a single stone at still water level is expressed by a force balance parallel to the rear side slope, cf Figure 5:

$$F_D + W_s \sin\beta - \mu (W_s \cos\beta - F_L) < 0 \quad (2)$$

where  $F_D$  is the drag force,  $F_L$  is the lift force,  $W_s$  is the submerged weight, and  $\beta$  is the rear side slope angle. The resistance against rolling and sliding  $\mu$  can be found as  $\mu = \tan\phi$ , where  $\phi$  is the natural angle of repose.

This yields:

$$F_D + \mu F_L < W_s (\mu \cos\beta - \sin\beta) \quad (3)$$

The submerged weight equals:

$$W_s = \Delta \rho g D_{n50}^3 \quad (4)$$

where  $\rho$  is the density of water and  $D_{n50}$  is the nominal diameter.

Figure 5. Forces acting on a single stone.

The left side can be expressed as:

$$F_D + \mu F_L = (C_D + \mu C_L) \frac{1}{2} \rho U_R^2 D_{nso}^2 \tag{5}$$

where  $C_D$  and  $C_L$  are force coefficients. For convenience, the nominal diameter is applied in the above expression. Combining (1), (3) (4), and (5) and re-arranging, the stability criterion now yields:

$$R_c > R_{ul} - \Delta D_{nso} \frac{\mu \cos \beta - \sin \beta}{C_D + \mu C_L} \tag{6}$$

For a relatively flat sea side slope, it is assumed that the run-up can be expressed as a function of the surf similarity parameter, cf CIRIA/CUR (1991):

$$R_{ul} = a \xi_{02} H_{mo} \tag{7}$$

where  $\xi_{02}$  is the surf similarity parameter (Iribarren number) given as:

$$\xi_{02} = \frac{\tan \alpha}{\sqrt{s_{02}}} \tag{8}$$

where  $\tan \alpha$  is the effective sea side slope and the factor  $a$  is a constant close to 1. In the following,  $a$  is kept equal to 1.

The effective sea side slope is for the present purpose defined as a straight line through the toe of the lower slope, where the influence of the breaking waves becomes significant, and up to the seaward face of the crest, cf Figure 4.

In general, the effective sea side slope represents the upper part of the berm area shaped by the incident waves. The effective sea side slope is considered to be

a good measure of the part of the berm area which is active in the wave deformation irrespective of the water depth in front of the structure.

For the specific test programme, the effective sea side slope for the cases with rear side damage has been plotted against the berm area, cf Figure 6. It is observed that the effective sea side slope decreases with the berm area.

Figure 6. Effective sea side slope vs berm area for the cases with rear side damage.

Combining (6), (7) and (8) gives for the stability criterion:

$$R_c > \tan \alpha \frac{H_{mo}}{\sqrt{s_{02}}} - \Delta D_{n50} \frac{\mu \cos \beta - \sin \beta}{C_D + \mu C_L} \quad (9)$$

The above expression is made dimensionless by  $H_{mo} \sqrt{s_{02}}$ .

$$\frac{R_c}{H_{mo}} \sqrt{s_{02}} > \tan \alpha - \left( \frac{H_{mo}}{\Delta D_{n50}} \frac{1}{\sqrt{s_{02}}} \right)^{-1} \frac{\mu \cos \beta - \sin \beta}{C_D + \mu C_L} \quad (10)$$

For the observed rear side damages, the effective sea side slopes,  $\tan \alpha$ , have been divided into three equidistant intervals with the following limits: 0.27, 0.33, 0.39 and 0.45.

For the stone material applied,  $\mu$  equals 0.9. For this value, the expression (10) has been calibrated to fit the observations. The best agreement was obtained with  $(C_D + \mu C_L)$  equal to 0.08. Four different curves representing  $\tan\alpha = 0.27, 0.33, 0.39$  and  $0.45$  respectively have been drawn in Figure 7. For all curves, the rear side slope equals the value of the actual test programme:  $\tan\beta = 1:1.5$ .

Figure 7. Stability of rear side.

Legend: Measurements:   
 +:  $0.27 < \tan\alpha < 0.33$ ,   
 x:  $0.33 < \tan\alpha < 0.39$ ,   
 o:  $0.39 < \tan\alpha < 0.45$

Full drawn curves show the stability criterion (10)

It is seen that a fairly good agreement between the measurements and the stability expression is obtained. The measurements show that  $R_c/H_{mo} \sqrt{s_{02}}$  increases with  $H_{mo}/\Delta D_{n50} / \sqrt{s_{02}}$ , which again shows that in the stability expression (10) the  $\tan\alpha$  term as well as the term including  $H_{mo}/\Delta D_{n50} / \sqrt{s_{02}}$  are of importance.

For a specified wave condition, the rear side stability can according to (10) be increased in several ways:

- increase of crest height,  $R_c$ , which is the most traditional method
- increase of stone diameter,  $D_{n50}$ . In Norway, a berm breakwater has been constructed with larger stones on the rear side than on the sea side, cf Tørum et al (1990)

- increase of relative density,  $\Delta$
- decrease of rear side slope,  $\tan\beta$

However, only the dependency on  $R_c$  has been studied experimentally.

The stability expression (10) bears some resemblance to the expression given by Van der Meer and Veldman (1992):

$$\frac{R_c}{H_s} s_{op}^{1/3} = K \quad (11)$$

- $H_s$  is the significant wave height  $\sim H_{mo}$   
 $s_{op}$  is the fictitious wave steepness based on the peak period  
 $K$  is a constant, which equals:  $K = 0.25$  for start of damage  
 $K = 0.21$  for moderate damage  
 $K = 0.17$  for severe damage

The above expression (11) is based on a parameter fitting procedure applied to two different sea side geometries (one of them in two different scale ratios). Comparing to the stability expression (10), the major difference is that in (11),  $R_c/H_{mo} s_{op}^{1/3}$  is constant, whereas the very similar quantity  $R_c/H_{mo} \sqrt{s_{02}}$  in (10) depends on  $H_{mo}/\Delta D_{n50} / \sqrt{s_{02}}$  and the effective sea side slope.

## Conclusions

- Model tests with a range of berm breakwater profiles have been carried out at DHI.
- A parametric expression for the rear side stability has been made, cf (10).
- The expression includes the wave height and steepness, crest height, rear side slope, effective sea side slope, stone diameter, relative density and natural angle of repose.
- The measurements show that the rear side stability increases with a decreasing effective sea side slope. A decrease in the effective sea side slope can be obtained by increasing the berm area.
- Applying the surf similarity approach for a bermed profile gives reasonably good agreement between the derived expression for the rear side stability and the model test observations.
- New model tests with different crest widths are being carried out in order to examine the variation of the rear side stability for a wider range of this parameter.

## Acknowledgements

The present study was carried out as a part of the research and technological development programme in the field of Marine Science and Technology (MAST) financed by the Commission of the European Communities, Directorate General for Science Research and Development, MAST I, Contract 0032, G6-S, Coastal Structures.

The authors wish to thank Mr Flemming John Andersen, Mr Christian Poulsen, Ms Bettina H. Sørensen and Mr Jakob Johannsen for carrying out the model tests, which were part of their B.Sc. dissertations at the Danish Academy of Engineering.

## CHAPTER 77

# Oblique wave attack on block revetments

Adam Bezuijen\* and Mark Klein Breteler†

November 12, 1992

### Abstract

The influence of the angle of the incoming wave on the stability of a placed block revetment on a filter layer has been investigated. A computer program is described to simulate the flow in the filter layer for various wave conditions. The flow in the filter layer together with the wave conditions determine the loading on the revetment. Two different boundary conditions have been studied, A schemed wave pressure distribution based on results obtained for wave loading perpendicular to the revetment and regular waves measured in a wave basin. The results show that for regular waves the influence of the angle of the incoming wave on the loading of a placed block revetment is small for a revetment with a leakage length equal or larger than the wave height. Oblique incoming waves can result in a considerable increase in loading when the leakage length is much smaller than the wave height and near transitions in the revetment.

## 1 Introduction

Model tests on placed block revetments are mostly carried out in a wave flume. In these tests the angle of the incoming waves is perpendicular to the revetment. In reality the incoming waves can make different angles with the slope. In the field the revetment will be loaded with oblique waves. A perpendicular wave loading will be an exception.

Until recently this was not considered to be a problem. The perpendicular wave loading was assumed to be the most severe wave loading on the revetment. However Gadd and Leidersdorf (1990) presented results of field observations which indicate that the loading on the revetment by oblique wave attack can be more severe than the loading by waves coming in perpendicular to the revetment. They found that a block mattress on a permeable core was damaged due to oblique incoming waves, while the same wave loading coming perpendicular to the revetment had not caused any damage.

†Head Coastal Structures group, Delft Hydraulics, P.O. Box 152, 8300 AD Emmeloord, the Netherlands.

The influence of oblique wave attack on the loading of a placed block revetment on a filter layer has been studied in a research programme commissioned by the Dutch Ministry of transport and public works (Rijkswaterstaat) and performed by Delft Geotechnics and Delft Hydraulics. Large scale experiments with oblique incoming waves are nearly impossible, because there are hardly facilities available for this type of research. On the other hand small scale experiments on placed block revetments cannot be done without scaling effects, Klein Breteler (1992). Therefore a small scale facility was used to measure only the wave pressures, the wave pressures apart from the wave impact can be measured without scaling effects and the wave impact is not the critical loading for the revetment. The filter flow in the revetment, the pore pressures and the loading on the revetment are simulated with a numerical finite difference program. The results of a comparable program for perpendicular wave attack are verified with the results of large scale model tests in a wave flume, Bezuijen et al. (1987). A comparable procedure, which combined the results of small scale model tests with the results of numerical simulations, is described by Bezuijen et al. (1988).

## 2 Description of numerical program STEEN3D

The numerical program is based on the STEENZET/1 program (Bezuijen et al., 1987; Bezuijen et al, 1990). The preliminary assumption, on which the STEENZET/1 program is based, is that the cover layer is relatively impermeable compared to the filter layer and that the flow through the base layer can be neglected. For most of the placed block revetments built in the Netherlands this appeared to be the case. In that case the pressure distribution can be described as a semi-confined aquifer. The flow in the filter layer is quasi-static. In the filter layer a mean potential  $\phi$  can be derived in a plane perpendicular to the slope assuming that the flow in the filter layer is in a plane parallel to the slope. Further the flow in the cover layer is assumed to be perpendicular to the slope. With these conditions the differential equation for the flow in the filter layer in two dimensions can be written as:

$$k_x \frac{\partial^2 \phi}{\partial x^2} + k_y \frac{\partial^2 \phi}{\partial y^2} = k' \frac{\phi - \phi'}{bD} \quad (1)$$

where:

$\phi$	: the mean piezometric head in the filter layer	(m)
$\phi'$	: the piezometric head on the cover layer	(m)
$x, y$	: co-ordinates, see figure 1	(m)
$k_x$	: the permeability of the filter layer in x direction	(m/s)
$k_y$	: the permeability of the filter layer in y direction	(m/s)
$k'$	: the permeability of the cover layer	(m/s)
$b$	: the thickness of the filter layer	(m)
$D$	: the thickness of the cover layer	(m)

Figure 1: Finite difference scheme used.

In case of laminar flow with constant permeabilities  $k = k_x = k_y$  and  $k'$ , this leads to the more familiar equation:

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = \frac{\phi - \phi_t}{\Lambda^2} \tag{2}$$

where:

$\Lambda$  : The leakage length (m)

The leakage length or leakage factor is then defined as:

$$\Lambda = \sqrt{\frac{k b D}{k'}} \tag{3}$$

Analytical solutions of this equation, for 1 dimension ( $\partial\phi/\partial y = 0$ ) with a schemed wave pressure distribution as a boundary condition have been presented by Sellmeijer (1981) and Burger et al. (1990). A numerical approach as STEENZET/1 can use measured wave pressures as a boundary condition and turbulent flow can be included. To obtain a numerical solution equation 1 is written as a set of finite difference equations, using the points presented in figure 1 and the general relation:

$$\frac{\partial^2 y}{\partial x^2} \approx \frac{y_{i-1} - 2y_i + y_{i+1}}{(\Delta x^2)} \tag{4}$$

Where  $\Delta x$  is the distance between the points  $i$  and  $i + 1$ . In figure 1 it is shown that the distance along the X axis between two points in the finite difference scheme is L and it is B along the Y axis. It is also shown for what part of the cover layer the permeability is  $k'_{i,j}$  and where in the filter layer the permeability is  $k_{i,j}$ . With the equations 1 and 4 a set of equations for the points  $\phi_{i,j}$  can be obtained:

$$\phi_{i,j} = \frac{B^2(k_{i-1,j}\phi_{i-1,j} + k_{i,j}\phi_{i+1,j}) + L^2(k_{i,j-1}\phi_{i,j-1} + k_{i,j}\phi_{i,j+1}) + \kappa_{i,j}\phi'_{i,j}}{\kappa_{i,j} + B^2(k_{i-1,j} + k_{i,j}) + L^2(k_{i,j-1} + k_{i,j})} \quad (5)$$

Where:

$$\kappa_{i,j} = \frac{B^2 L^2 k'_{i,j}}{bD}$$

The filter layer is assumed to be impermeable at the boundaries of the revetment. This means that when a point on a boundary has to be calculated with equation 5, the value of  $\phi$  just outside the boundary (for example  $\phi_{i,j-1}$  when  $\phi_{i,j}$  is the lower boundary) is given the same value as the point just inside the boundary (the point  $\phi_{i,j+1}$  at the lower boundary). The situation is a bit different for the upper boundary. Here are two possibilities. It can be the same impermeable boundary as for the other boundaries, or it is the phreatic surface in the filter layer. It is assumed that when there is a phreatic surface it is located at the upper boundary because there is no need to simulate the revetment above the phreatic surface. If the upper boundary is the phreatic surface, then the piezometric head in the filter layer is not calculated with equation 5, but the piezometric head is given the same value as the height of that point. The program developed, which is called STEEN3D, is a static program. Up to now it does not include time effects. For a given wave pressure distribution at a certain moment the pore pressure distribution in the filter layer and the resulting loading on the revetment is calculated. Since it is a static program the phreatic surface is an input parameter, as in the analytic solutions mentioned before. The permeability of both the cover layer and filter layer is described with the Forchheimer relation:

$$i = aq + bq^2 \quad (6)$$

where:

- i : the hydraulic gradient (-)
- q : the specific discharge (m/s)
- a : linear Forchheimer coefficient (s/m)
- b : turbulent Forchheimer coefficient (s/m)<sup>2</sup>

The coefficients a and b for the cover layer, as well as the different coefficients for the filter layer are calculated from the width of the joints, the dimensions of the blocks and grain size and porosity of the filter layer as described by Bezuijen and Klein Breteler (1988). The hydraulic gradient in the cover layer is  $(\phi'_{i,j} - \phi_{i,j})/D$ . The permeability of the filter layer ( $k_{i,j}$ ) is assumed to depend

only on the value of the hydraulic gradient in the filter layer ( $i_f$ ), not on the direction of it, leading to:

$$i_f = \sqrt{\left(\frac{\phi_{i+1,j} - \phi_{i,j}}{L}\right)^2 + \left(\frac{\phi_{i,j+1} - \phi_{i,j}}{B}\right)^2} \quad (7)$$

Equation 5 needs the linearized permeability ( $k = q/i$ ), which can be derived from equation 6:

$$k = \frac{-a + \sqrt{a^2 + 4bi}}{2bi} \quad (8)$$

By using equation 8 to calculate the permeabilities non-linearity is introduced in the set of equations 5. Therefore an iterative solution method is used. The starting values of  $\phi_{i,j}$  is the hydrostatic pressure for long leakage lengths ( $\Lambda$ ) and the pore pressure distribution on the slope for small leakage lengths. With these starting values and the equations 5 new values of  $\phi_{i,j}$  are calculated and new permeabilities. This procedure is repeated until the maximum difference between two solutions of  $\phi_{i,j}$  is less than  $10^{-4}$  m. Using the Forchheimer relation, as given in equation 6, The leakage length (equation 3) depends on the hydraulic gradient. To characterize a revetment the leakage length is calculated for a gradient 1 over the cover layer and a gradient equal to the sinus of the slope angle in the filter layer.

### 3 Boundary conditions

#### 3.1 Schemed boundary condition

A schemed boundary condition has been developed to investigate the influence of the angle of the incoming wave on the flow in the filter layer. It is based on a pressure distribution proposed by Burger et al. (1990) for regular waves propagating perpendicular to the revetment. It was found that the moment of maximum loading on the revetment is present just before the wave impact. The pressure distribution for that situation can be schemed as is shown in figure 2. In case of oblique wave attack it is assumed that the maximum loading on the revetment is the same as in case of perpendicular wave attack, but on one side of the revetment the angle  $\beta$  (see figure 2) becomes less, on the other side the angle  $\beta$  remains the same and  $d_b$  and  $\phi_b$  decrease, as is shown in figure 2. The obliqueness of the incoming wave is represented with an angle  $\gamma$  which represents the deviation from perpendicular incoming waves.

#### 3.2 Measured boundary condition

The wave pressures have been measured in a 3 dimensional wave basin (the Vinjé basin). This wave basin is capable in generating regular and irregular waves with a wave height up to 0.2 m. The irregular waves can be long and short crested. In this study only regular waves were used. In the basin a

Figure 2: Schemed pressure distribution proposed by Burger et al. (a) and 3-dimensional proposal for oblique wave attack (b).

model was constructed with a slope 1:4. Tests have been performed with a wave steepness of 2 and 4%. The angle of incidence of the incoming waves varied between 0 and 50 degrees, where again 0 degrees means perpendicular incoming waves. The wave height was measured with 5 wave gauges. The wave height and direction were measured with 3 multi-directional wave gauges (These are combined wave gauges and 2-axis current meters). The wave pressures were measured at 10 positions on the slope on a line with a constant X position along the slope with varying depth. A top view of the model in the basin is presented in figure 3. The position of the pore pressure gauges is shown in figure 4. The pore pressure gauges were sampled with a sampling rate of 25 Hz and the results were stored in a computer. Since the velocity of the waves propagating along the slope is constant the wave pressure measured at one line can be transformed in a pressure field over the slope. When the origin of the X-axis (see figure 3) is chosen at the location of the wave pressure gauges, then the wave pressures measured at X=0 at a certain moment  $t_0$  can be transferred to the wave pressures that can be measured at a different position at a different moment according to the formula:

$$\phi'(x, y, t + T \frac{x \sin \gamma}{L_g}) = \phi'(0, y, t) \tag{9}$$

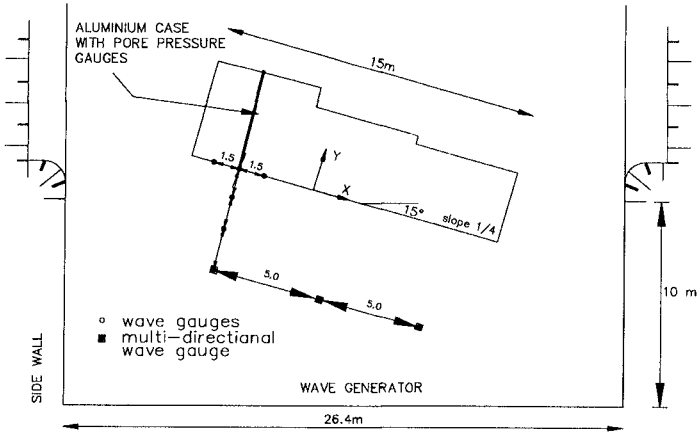

Figure 3: Top view of model in basin

Figure 4: Pore pressure gauges on slope

Figure 5: Wave pressure distribution under oblique wave attack on a slope 1:4 with wave height of 1.2 m and a wave period of 4.4 s. The angle of incidence of the incoming waves was 40 degrees (scaled up from a measured wave height of 0.12 m).

Where:

$L_g$  : the wave length in front of the slope (m)

$T$  : the wave period (s)

Figure 5 shows an example of a measured wave pressure distribution.

The plot shows the result of the fact that pore pressure gauges were present only below the still water level. The pressures higher on the slope were not measured. If a pressure was measured on the highest wave pressure gauge it is assumed that this pressure was present higher on the slope in a way that the piezometric head was constant. This leads to an interpolation error. However this error is only present higher on the slope and the maximum loading on the revetment is always well below the still water line.

From this plot it appeared that the schematisation used in the schemed boundary condition see figure 2 is reasonable for the area before wave impact. In that area there is clearly a steepening of the next incoming wave. The wave impact causes a pressure distribution very different from the schemed boundary

Parameter	Case 1	Case 2
top of revetment	2 m	1.5 m
toe of revetment	-1 m	-6.1 m
slope angle	18.43° and 14.03°	18.43° and 14.03°
block length and width	0.5 m	1.2 m
block thickness	0.2 m	0.23 m
width of joints	0.002 m	0.06 m
thickness filter layer	0.2 m	2 m
$d_{15}$ filter layer	0.02 m	0.001 m
porosity filter layer	0.4	0.35
leakage factor	1.1 m	0.92 m
still water level	1 m	0.0 m
wave height	1.2 m	3.3 m
wave angle $\gamma$	0 - 60	0 - 70
Wave steepness (measured)	0.04	0.04
$\phi_b$ in fig. 4 (schemed)	1.0 m	4.2 m
$d_b$ in fig. 4 (schemed)	0.8 m	2.78 m
$\beta$ in fig. 4 (schemed)	30°	46.5°

Table 1: Parameters used in the calculations

condition. Since the schemed boundary condition is reasonable in the area of maximum loading it still can be used for situations where no wave pressure recordings are available. However it should be taken into account that the angle of the wave on the revetment is less than the angle of the incoming wave due to refraction of the waves on the slope. For the wave shown in figure 5 with an angle of incidence of 40° for the incoming waves it was found that on the slope at a depth of 1.6 m below the still water level the angle of incidence of the wave pressures on the slope was approximately 25°, at 1 m below the still water line it was only 11°.

## 4 Results

The calculations were run with the parameters presented in table 1. Case 1 are the parameters of a revetment as can be expected in the Dutch estuaries. With the results of the field tests (see Stoutjesdijk et al., 1992) now available it must be stated that these are the parameters for a new revetment with no fine material in the filter layer and between the joints. The second case is an attempt to simulate the revetment described by Gadd and Leidersdorf (1990) at Northstar Island in the Beaufort Sea.

An example of a calculation with the schemed boundary condition presented in figure 2 is shown in figure 6, which showed the distribution of the difference in piezometric head over the blocks. A positive difference in this figure means

Figure 6: Contour plot of the calculated uplift pressure, schemed boundary condition  $\gamma = 30^\circ$ .

Figure 7: Contour plot of the calculated permeability in the filter layer.

that there is an uplift pressure over the blocks. If this uplift pressure is higher than the weight of the blocks and possible clamping forces blocks can be lifted from the revetment. In this calculation the parameters of case 1 in table 1 are used. Figure 7 showed the corresponding permeability in the filter layer. Due to turbulency the linearized permeability, see equation 8 is high in areas with a small hydraulic gradient and lower in area's with a higher gradient. It appeared from the calculations that using turbulency in the calculation leads to a slightly higher maximum uplift pressure than would result from a calculation with laminar flow. Comparing the calculated maximum uplift pressure with the boundary condition it appeared that the maximum uplift pressure can be found just before the impact of the next incoming wave as could be expected.

An example of the simulation results using a measured boundary condition for the revetment with the parameters of case 1 is shown in figure 8. It shows the difference in piezometric head as it is distributed over a placed block revetment at a certain time when loaded with oblique wave attack. The high values (the 'mountains' in the plot) correspond with a high uplift pressure. At these locations the blocks can be lifted out of the revetment. The difference in piezometric head is at maximum just in front of the areas of wave impact at X is approximately 9 and 50 m (the wave is propagating from high to low X values). Although the figure presents the result for an incoming wave angle of  $40^\circ$ , there is for each wave over a large part of the revetment only one Z value (one height on the revetment) with the largest difference in piezometric head and thus the

Figure 8: Example of calculated difference in piezometric head over the blocks. Calculation for a slope 1:4 by a wave attack of 1.2 m wave height, a period of 4.4 s and an incoming wave angle of  $40^\circ$ , the leakage length is 1.1 m.

Figure 9: Calculated maximum difference in piezometric head as a function of the angle of the incoming wave, case 1.

Figure 10: Calculated maximum difference in piezometric head as a function of the angle of the incoming wave, case 2.

maximum loading.

The influence of the angle of wave attack was tested by performing calculations for different angles of incoming waves. This was done for the schemed as well as the measured boundary conditions. For case 1 the results of the calculations are shown in figure 9 and for case 2 in figure 10. For case 1 it is clear that the influence of the angle of the incoming wave on the maximum calculated uplift pressure is small. The result shows that for angles of the incoming waves between 0 and 60° the maximum loading remains more or less the same. As is also shown in figure 9, differences found in the maximum uplift pressures for measured waves appear to correspond closely with differences in the amplitude of the piezometric head, measured with the lowest wave pressure gauge. These differences in amplitude correspond with small differences in wave height in front of the structure, which cannot be avoided in a wave basin. For case 2 there is an influence. The maximum calculated uplift pressure increases for measured as well as schemed boundary conditions. For schemed boundary conditions this increase goes on with an increasing angle of the incoming waves, for the measured boundary condition there seems to be a maximum for an angle of 40° for the incoming waves. In case 2 the ratio of the leakage length divided by the wave height of the incoming waves ( $\Lambda/H$ ) is much smaller than in case 1, see table 1. The results of the calculations show that in case  $\Lambda/H \approx 1$ , there is hardly any influence and this influence is larger for  $\Lambda/H = 0.33$ . It appears that for  $\Lambda/H = 0.33$  the loading is 50% higher for oblique incoming

Figure 11: Maximum loading near an impermeable transition in the revetment, case 1, wave conditions as shown in figure 5. In the plot is a drawing of an example of an impermeable transition.

waves ( $\gamma = 40^\circ$ ) than for perpendicular incoming waves ( $\gamma = 90^\circ$ ). Further the influence of the transition in a revetment have been investigated. The locations where one type of revetment changes to another type. In the calculations the situation is simulated that at such a transition the filter layer is impermeable. Various calculations have been run to simulate the situation that the moment of maximum loading on a revetment reaches such a transition. This will always happen when a transition is present, because in case of oblique wave attack it looks as if the waves are travelling along the revetment. The results of the calculations are shown in figure 11. The results show that near a transition the uplift pressures on the revetment are higher than far from the transition. This is caused by changes in the flow in the filter layer near the transition.

Normally the strength of the revetment is less when there is transition in the revetment. The discontinuity present at the transition can cause a reduction of the clamping forces between the blocks and difficulties in densification of the subsoil during construction of the revetment, leading to uneven settlement later. This decrease in strength in combination with the calculated increased loading means that during oblique wave attack the edges of the revetment are especially vulnerable.

## 5 Conclusions

The results show that for oblique wave attack with regular waves the angle of the incoming waves have little influence on the maximum loading on the

revetment, as long as the leakage length is larger or equal than the wave height. When the leakage length of the revetment is much shorter, then oblique wave attack with can result in up to 50 % higher loading on the revetment. Further near transitions in the revetment the loading on the revetment is increased in case of oblique wave attack.

## 6 Acknowledgement

The authors wish to thank P.E. Gadd and C.B. Leidersdorf for stimulating discussion and supplying detailed information about the revetment on Northstar island, where they have observed failure from oblique wave attack.

## CHAPTER 78

### THE PENETRATION OF SHORT-CRESTED WAVES THROUGH A GAP

N. Booij<sup>1</sup>, L.H. Holthuijsen<sup>1</sup> and P.H.M. de Lange<sup>1,2</sup>

#### Abstract

The propagation of long-crested and short-crested waves through a gap such as between two breakwaters is affected by diffraction. If the water depth is not uniform, refraction may also affect this penetration. It is shown with a navigation channel between two breakwaters (academic case and a realistic harbour case) that the effects of diffraction are small compared to those of refraction in regions where waves can penetrate with refraction only (e.g. where wave rays can penetrate). This region is relative large for short-crested waves. Outside these regions diffraction is dominant. With another example of waves penetrating through a tidal gap against a strong ebb current, it is shown that the short-crestedness of the waves destroys to a very large extent the waved guide effect of such currents. Both set of experiments show that the inclusion of short-crestedness in the wave computations causes some smoothing of the wave field, and that diffraction is a minor effect in regions with considerable wave motion. This is of some scientific and economic relevance as refraction can readily be combined in wave models with other physical phenomena such as wave generation and dissipation. Moreover, such models require less computer capacity than diffraction models which do not readily absorb wave generation and dissipation.

#### Introduction

To compute the propagation of waves through and beyond a gap between two obstacles such as breakwaters or islands, several aspects of the waves are important for modelling these waves numerically. As a boundary condition it is important to consider the waves as a harmonic, long-crested wave or as random, short-crested waves. In and beyond the gap several conservative and non-conservative processes should be considered. The conservative processes are: refraction, diffraction and

---

<sup>1</sup> Delft University of Technology, Stevinweg 1, 2628 CN Delft, the Netherlands

<sup>2</sup> Rijkswaterstaat, Division of Tidal Waters, the Hague, the Netherlands and College of Technology Enschede, Enschede, the Netherlands

reflection. The non-conservative processes are wave generation (by wind) and dissipation (by bottom friction and breaking, also during reflection). We are interested in these aspects from a modelling point of view because of the choice that has to be made between using a model for combined refraction-diffraction or a model for refraction only. A refraction-diffraction model requires considerable computing power, in particular for short-crested, random waves. Moreover, the inclusion of generation and dissipation is primitive or non-existent in such a model. A refraction model requires less computing power and is readily supplemented with generation and dissipation mechanisms, but it lacks diffraction. The question is, can a refraction model provide at least a reasonable estimate of a short-crested wave field in the absence of diffraction?

### Method of the study

To make a tentative step towards an answer, we consider three cases of waves propagating through a gap: (a) a fairly academic situation of waves propagating over a navigation channel between two breakwaters (b) a similar situation with a fairly realistic harbour beyond the gap and (c) an actual tidal inlet with a strong ebb-current.

We use the two different types of models mentioned in the introduction. The refraction-diffraction model is the PHAROS model of Delft Hydraulics (Kostense et al, 1988) and the refraction model is the HISWA model of Delft University of Technology (Holthuijsen et al, 1989). The major difference is that the refraction-diffraction model reconstructs the actual sea surface of an harmonic wave that is long-crested in deeper water by computing the phase and amplitude of the surface elevation whereas the refraction model computes the directional energy distribution of waves that are short-crested in deeper water. The short-crested cases are computed with the refraction-diffraction model by superimposing a number of computed harmonic waves. The long-crested cases are computed with the refraction model by considering a very narrow directional energy distribution in deeper water. For the interpretation of the results it is important to note that the HISWA model does not compute wave propagation in directions more than 60° at either side from a pre-determined direction (chosen as the initial wave directions in this study).

For economic reasons we consider only waves with one constant period. The waves that we consider are 10 s in period and either long-crested (PHAROS only) or short-crested with directional distributions of the type  $D(\theta) = A \cos^m(\theta)$  ( $m = 100$  for simulated long-crested waves in HISWA only or  $m = 4$  for simulated short-crested waves in PHAROS and HISWA).

We consider the similarities and differences in the results of the two models for the three cases mentioned above.

### The academic gap

The bottom topography for the situation with a navigation channel between two breakwaters is given in Fig 1.a. The channel originates in water of 15 m deep and the channel is maintained at that depth. Outside the channel the water depth decreases to a uniform depth of 11 m beyond the gap. The slope of the shoulders of the channel is 1:10 and the gap is 480 m wide (i.e. 5.5 wave lengths) The breakwaters and the circular boundary beyond the gap are fully absorbing. This means that the region beyond the gap may be interpreted as infinitely large.

Fig. 1 The penetration of waves from  $24^\circ$  incidence with channel through a gap in terms of relative (significant) wave height  $H/H_0$ . Panel a) bottom topography and position indication along absorbing circle. Panel b) combined refraction and diffraction, long-crested waves. Panel c) combined refraction and diffraction, short-crested waves. Panel d) refraction only, short-crested waves.

We computed the wave situation with various initial wave directions and we found that the shoulders of the channel refract the waves such as to spread wave energy in fingers to the sides. From the initial (mean) wave directions of  $0^\circ$ ,  $12^\circ$ ,  $24^\circ$  and  $36^\circ$  (angle of incidence with the channel axis), we selected the results of the  $24^\circ$  case as representative. The effects shown next are slightly more extreme for the  $12^\circ$  case (the critical angle for reflection on the channel shoulder is appr.  $24^\circ$ ) and slightly less extreme for the  $0^\circ$  and  $36^\circ$  cases).

In Fig. 1.b the results are shown for the refraction-diffraction computations for long-crested waves (in terms of the local wave height  $H$  divided by the incident wave height  $H_i$ ). The finger pattern of the wave penetration is obvious with energy concentration slightly over 1.25 just beyond the gap. The pattern is smoothed somewhat by introducing short-crestedness as shown in Fig. 1.c where the finger pattern is still obvious but not as concentrated. The effect of removing diffraction from the short-crested waves situation is shown in Fig. 1.d where the results of the refraction computations are shown. Again the finger pattern is obvious and in fact not very different from that in Fig. 1.c where diffraction was included.

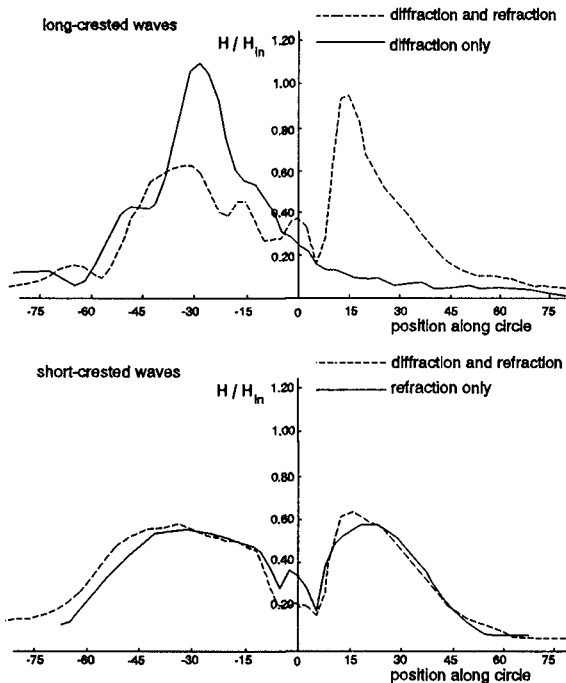

Fig. 2 The results of the computations of Fig. 1 along the absorbing circle. The results for the long-crested waves compared with the results for the short-crested waves for refraction only, diffraction only and combined refraction/diffraction. Diffraction only was achieved with constant water depth of 11 m.

A further comparison is made in Fig. 2. A pure diffraction computation for long-crested waves (obtained with the refraction-diffraction model with a uniform water depth of 11 m) is included (upper panel). Introducing the channel in these computations has the effect of splitting part of the energy propagation towards the right (looking down-wave, same panel, compare with Fig. 1.b). Adding short-crestedness in these computations gives a smoother distribution of the energy (lower panel of fig. 2, compare with Fig. 1.c). Using the refraction model instead of the refraction-diffraction model gives very similar results (lower panel), except where the refraction model does not compute (more than  $60^\circ$  from the incident wave direction), confirming the conclusion from Fig. 1.

### The harbour

The bottom topography for the harbour with a navigation channel very similar to the above is given in Fig. 3.a. The channel originates also in water of 15 m deep and the channel is maintained at that depth towards the deep basin in the harbour at the same depth. Beyond the deep basin, a shallow basin at 11 m depth is protected by a mole. The slope of the shoulders of the channel is 1:10 and the gap is 330 m wide (i.e. 4 wave lengths). For the purpose of this study the breakwaters and the quays are assumed to be fully absorbing.

We computed the wave situation with the initial (mean) wave direction along the channel axis and (of course) we again found that the shoulders of the channel refract the waves such as to spread wave energy in fingers to the sides.

In Fig. 3.b the results are shown for the refraction-diffraction computations for long-crested waves. The finger pattern of the wave penetration is obvious with energy concentration as high as 1 just beyond the gap and a fairly deep penetration behind the left breakwater. The pattern is smoothed considerably by introducing short-crestedness as shown in Fig. 3.c but the deep penetration behind the left breakwater is hardly affected. The effect of removing diffraction from the short-crested waves situation is shown in Fig. 3.d where the results of the refraction computations are shown. Again the pattern is obvious, including the deep penetration finger, and in fact not very different from that in Fig. 3.c. The patterns are nearly equal, although the penetration in the refraction-diffraction computations is slightly higher than in the refraction computation (5% difference where the finger behind the left breakwater touches the harbour contour). Again these computations demonstrate the marginal effect of diffraction in this case.

If reflection against breakwaters and quays is taken into account in the refraction-diffraction computation (not possible with the HISWA model) it appears that wave energy can penetrate virtually everywhere in the harbour and that diffraction remains relatively unimportant.

### Tidal inlet

To further illustrate the considerable effect of short-crestedness on the wave pattern, we compute the wave field in an actual tidal gap. It is the 3 km wide tidal entrance to the Wadden Sea between Den Helder and the island of Texel

Fig. 3 The penetration of waves parallel to the navigation channel between two breakwaters in terms of relative (significant) wave height  $H/H_i$ . Panel a) bottom topography. Panel b) combined refraction and diffraction, long-crested waves. Panel c) combined refraction and diffraction, short-crested waves. Panel d) refraction only, short-crested waves.

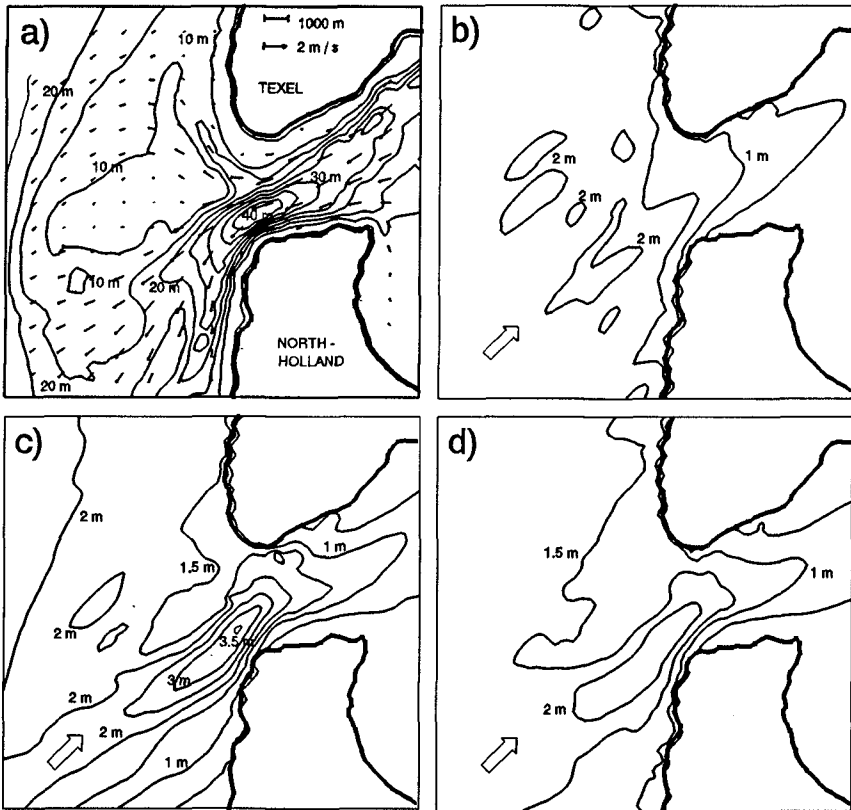

Figure 4. The penetration of waves into a tidal inlet computed with refraction model. Panel a) bottom topography and current velocity field. Panels b,c,d) isolines of significant waveheight. Panel b) long-crested waves without current. Panel c) long-crested waves with current. Panel d) short-crested waves with currents.

in the North of Holland. The bathymetry and the ebb-current pattern are given in Fig. 4.a. The current pattern has been computed with a two-dimensional nonlinear tidal model WAQUA (Leendertse et al., 1981 and Stelling, 1984) for a severe storm case. The waves that we consider propagate from deep water towards the gap from the South-west. The wave period is 6s and the significant wave height is 2m. For long-crested waves and no currents, the results of the refraction computations are shown in Fig. 3.b. Refraction-diffraction computations have not been carried out as the area is too large for that. The results show some increase in wave height before the waves reach the shallows (probably due to shoaling) and a considerable decrease at the shoal. Adding currents dramatically changes the results as the waves now increase just in front of the gap to 3.55 m (see fig. 3.c). This is almost certainly a wave guide effect,

that is, the waves are trapped by the counter current by current-induced refraction. However, adding short-crestedness to the computations destroys to a large extent the wave guide effect, resulting in dramatically lower waves (maximum 2.6 m, Fig. 3.d).

## Conclusions

From numerical experiments with a combined refraction-diffraction model and a refraction model, we come to the following conclusions.

Beyond a gap with a natural or dredged navigation channel, the shoulders of the channel may displace and focus waves in certain areas beyond the gap. This focussing is tempered by short-crestedness of the waves. In such cases and probably in similar cases, refraction computations without diffraction seem to provide a reasonable first estimate of the waves in those regions beyond the gap where waves can penetrate with refraction (e.g. where wave rays can penetrate). In other regions diffraction is essential.

In addition to these considerations of accuracy, the choice of using a refraction-diffraction model or a refraction model is one of convenience and economy. The computing power required for a refraction model without diffraction is considerably less than for a refraction-diffraction model (in the present study roughly a factor of 10). A refraction model without diffraction has the added advantage of readily combining other physical phenomena with the propagation of the waves, including current effects. Reflections (not considered in the present study) are relevant in harbours and can be included in both types of models. Reflection is included in the PHAROS model.

It further appears that diffraction models which assume a flat bottom are useless for any harbour with an entrance channel.

The above conclusions relate to wave computations in which short-crestedness is accounted for. The inclusion of the short-crestedness of waves also tends to smooth the wave guide effect of concentrated counter currents in a gap such as an ebb current between islands.

## Acknowledgements

We wish to thank Delft Hydraulics for its generous support and its permission to use the PHAROS model for this study. We are particularly grateful to J.K. Kostense for his guidance and assistance during this study.

## CHAPTER 79

# Design of Dolos armour units

Hans. F. Burcharth<sup>1</sup>    Zhou Liu<sup>2</sup>

### Abstract

The slender, complex types of armour units, such as Tetrapods and Dolosse are widely used. Many of the recent failures of such rubble mound breakwaters revealed that there is an imbalance between the strength (structural integrity) of the units and the hydraulic stability (resistance to displacements) of the armour layers.

The paper deals only with Dolos armour and presents the first design diagrams and formulae where stresses from static, quasistatic and impact loads are implemented as well as the hydraulic stability. The Dolos is treated as a multishape unit where the thickness can be adjusted to the strength needs.

### Introduction

Many of the recent dramatic failures of a number of large rubble mound breakwaters armoured with Dolosse and Tetrapods were caused by breakage of the units. Breakage took place before the hydraulic stability of intact units in the armour layers expired. Thus there was an imbalance between the strength (structural integrity) of the units and the hydraulic stability (resistance to displacements) of the armour layer.

The present paper deals only with Dolosse armour and presents the first design diagrams and formulae where stresses from static, quasistatic and impact loads are implemented as well as the hydraulic stability. Earlier publications only covered static and quasistatic stresses (e.g. Burcharth et al., 1991). The results are the outcome of a long-term research programme at Aalborg Hydraulic Laboratory (AHL), Aalborg University, which for the last three years has been coordinated with Dolosse research at CERC, Vicksburg.

Dolosse armour was chosen as research object because of its excellent hydraulic stability and because its structural strength can be adjusted by changing the waist ratio, cf. Fig. 1, which shows blocks with the three waist ratios applied in the experiments. By increasing the waist ratio in order to improve the structural behaviour the hydraulic stability will decrease somewhat. This must be taken into account in the design.

Fig. 1. Applied concrete Dolosse with different waist ratios but with equal mass.

**Description of the experiments**

A 1 : 1.5 slope armoured with 200 g concrete Dolosse of waist ratios as shown in Fig. 1 was exposed to irregular wave in a wave flume with a foreshore slope of 1 : 20. Fig. 2 shows the layout of the model and the cross section of the breakwater.

Measures and levels in meter

Fig. 2. Set-up of the wave flume and the cross section of the breakwater. Aalborg Hydraulic Laboratory (AHL) experiments.

To compensate for reflected waves two arrays of three wave gauges were installed. The incident wave spectrum was calculated by the least square method presented by Mansard et al., 1980.

The irregular waves were generated by a piston type paddle according to the five parameter JONSWAP spectrum. Table 1 lists the characteristics of the applied waves propagating towards the breakwater recorded at the paddle and at the toe of the breakwater.  $T_p$  is the spectral peak period,  $\xi_{m0} = \left(\frac{H_{m0}^2}{L_{p0}}\right)^{-0.5} \tan\alpha$ , where  $L_{p0}$  is the deep water wave length corresponding to  $T_p$ .

Table 1.  $H_{m0}$ ,  $T_p$  and  $\xi_{m0}$ .

$H_{m0}^p$	at the paddle (cm)	5 - 15
$H_{m0}^t$	at the toe (cm)	5.7 - 18.2
$T_p$	at the paddle (sec)	1.5 - 3
$\xi_{m0}$		3.23 - 11.7

The experiments were performed in series in which the wave height was increased step by step. The run time for each step was 5 minutes.

For each combination of  $H_{m0}$  and  $T_p$  the experiment was repeated 20 times in the study of the hydraulic stability and 3 times for each position of the instrumented Dolosse in the study of the stresses in Dolosse; all with the slope rebuilt.

In order to study the hydraulic stability of the Dolos armour layers a grid was put parallelly to the breakwater slope before and after wave attack and photos were taken. All displacements could then be visually registered.

The applied load cells are developed and produced by CERC. The load cell instrumented concrete Dolosse were calibrated for impact loaded conditions using prototype impact test data and were checked for dynamic amplification, cf. Burcharth et al. 1991. They were put in 6 positions on the slope as shown in Fig. 2.

### Hydraulic stability of Dolos armour

The following formula for hydraulic stability of Dolos armour on slope 1 : 1.5 is based on the present test results and results by Brorsen et al. 1974, Burcharth et al. 1986, and Holtzhausen et al. 1990.

$$N_s = \frac{H_s}{\Delta D_n} = (47 - 72r) \varphi_{n=2} D^{1/3} N_z^{-0.1} \quad (1)$$

- where  $H_s$  significant wave height in front of breakwater  
 $\Delta$   $(\rho_{concrete}/\rho_{water}) - 1$ ,  $\rho$  is the mass density  
 $D_n$  length of cube with the same volume as Dolosse  
 $r$  Dolos waist ratio  
 $\varphi_{n=2}$  packing density  
 $D$  relative number of units within levels SWL  $\pm 6.5 D_n$  displaced one Dolos height  $h$ , or more (e.g. for 2% displacement insert  $D = 0.02$ )  
 $N_z$  number of waves. For  $N_z \geq 3000$  use  $N_z = 3000$ .

Fig. 3 shows the case corresponding to damage level of 2% displacement.

Legend:

Reference	$\varphi_{n=2}$	Repeated Na	Duration (min.)	$\xi_{m0}$
▲ Brorsen et al. (1974)	1 (App.)	2	60	2.49-5.37
■ Burcharth et al. (1986)	0.61-0.7	5 or 15	20	3.04-4.49
○ Holtzhausen et al. (1990)	1	3 or 8	60	2.91-7.6
● Burcharth et al. (1992)	0.74	20	5	3.23-11.7

Fig. 3. Hydraulic stability of two layer randomly placed Dolos armour on a slope of 1 : 1.5. Damage level,  $D = 2\%$  displaced units within levels SWL  $\pm 6.5D_n$ . Note that the data points are average of repeated tests, cf. the legend.

The formula (1) covers both breaking and non-breaking wave conditions, with the limits given by

$$0.32 < r < 0.43$$

$$0.61 < \varphi_{n=2} < 1$$

$$1\% < D < 15\%$$

The uncertainty of the formula is estimated to correspond to a variational coefficient of 0.2. If the PIANC partial coefficient system is used (Burcharth 1991) the design equation reads

$$\frac{1}{\gamma_z} \Delta D_n (47 - 72r) \varphi_{n=2} D^{1/3} N_z^{-0.1} \geq \gamma_{H_s} H_s^T \quad (2)$$

For the calculation of the partial coefficients  $\gamma_z$  and  $\gamma_{H_s}$ , the coefficient values  $k_\alpha = 0.025$  and  $k_\beta = 38$  should be used.

In the following is given a discussion of the dependency of the hydraulic stability of Dolos armour on various parameters.

*Test area* One of the reasons for the big scatter in the hydraulic stability test results from the various laboratories is the difference in the reference test area. Obviously, the bigger the reference test area, the higher the stability number.

Fortunately, the test areas seem always to be chosen large enough to cover the whole area where units are moving. Therefore the test results can be converted to results corresponding to a certain test area, e.g. to SWL  $\pm 6.5 \times D_n$ , as is done in the present paper.

*Breakwater slope* The effect of the slope angle of Dolos armour on hydraulic stability has been one of the most controversial points. Hudson's formula, which was developed for rock armour, where the main resistance to wave-induced movement is due to the gravitational force, cannot represent Dolos armour, the stability of which relies both on weight and interlocking.

With regard to the contribution of Dolos weight to the hydraulic stability, the milder the slope, the bigger the contribution, as expressed in Hudson's formula. But on the other hand, the interlocking ability of Dolos armour builds up with the increase of the slope (before the slope reaches its natural angle of repose, which is found to be around  $79^\circ$ , Gravesen et al. 1978). This means that there is an optimum slope which maximize the stability of Dolos armour as a whole. Price (1979) demonstrated in the on-land static stability test with Dolosse that the resistance to pull-out attained its maximum for slope angles around  $28^\circ$  ( $\cot\alpha = 2$ ).

In the hydraulic model tests, Brorsen et al. (1974) reported that the stability number of Dolosse is independent of the slope within the range of slope 1 : 1 ~ 1 : 2. Holtzhausen et al. (1990) concluded that Dolosse stability number decreases with steeper slope, but some of his test results also show the independence of  $N_s$  on slope, cf. Fig. 4.

Fig. 4. Influence of slope on  $N_s$ .

**Wave period** The influence of the wave period on the stability of Dolos armour has been the subject of research over the years. HR Wallingford (1970) and Burcharth (1979) found that the stability number decreases with longer wave periods. Burcharth (1979) explained this tendency by *the reservoir effect of the voids* between the units.

The voids are filled with air during wave recession and with water during wave run-up. This reduces not only the wave run-up but also the overflow velocities. Armours with larger porosity, such as Dolosse, exhibit stronger reservoir effect which tributes to the higher hydraulic stability. However, the reservoir effect is reduced in the case of long waves, because such waves carry more water per wave onto the slope and, consequently, relative smaller portion of water can be stored in the voids. The result is higher overflow velocity and lower hydraulic stability of armour and, consequently, a relatively large reduction in stability for armour units with large porosity.

However, there are also some reports which predict increase of the stability number with the wave periods (Holtzhausen et al. 1990).

In the present test results there is no clear tendency about the influence of wave period on the hydraulic stability for which reason the wave period (or wave steepness or  $\xi$ ) is not included as an independent parameter in formula (1). This treatment of the wave period also reflects the fact that for a given design wave height there will be a range of wave periods anyway. The effect of wave period contributes to the uncertainty of the formula. This, however, is taken into consideration when the partial coefficient method is applied in the design.

**Packing density** Some research has been carried out previously to study the influence of Dolos packing density on the hydraulic stability.

Carver et al. (1978) collected data from different laboratories and depicted the Hudson formula stability coefficient  $K_D$  as a function of the packing density  $\varphi_{n=2}$ . If  $N_s = \frac{H_s}{\Delta D_n}$  is used instead of  $K_D$  an almost linear dependency of  $N_s$  on  $\varphi_{n=2}$  is seen.

Zwamborn (1978) first reported that the Dolos armour with three packing densities ( $\varphi_{n=2} = 0.83, 1$  and  $1.15$ ) displayed the same stability. But based on tests with a bigger packing density range ( $\varphi_{n=2} = 0.65, 0.83, 0.87, 1, 1.15$  and  $1.5$ ) Zwamborn et al. (1980) found a rather complicated relation between  $N_s$  and  $\varphi_{n=2}$ , with the general tendency that higher packing density increase the stability number.

A higher packing density gives more neighbour block support and interlocking and hence, fewer displaced units. Therefore, the increase of Dolos stability number with packing density is due to two effects, one is the reduction of displaced units, the other is the increase of total number of units. Eq (1) indicates that the Dolos stability number is linearly proportional to the packing density within the applied range ( $\varphi_{n=2} = 0.61 - 1$ ).

On the other hand a very high packing density ( $\varphi_{n=2} > 1$ ) might reduce the interlocking and the stability because limited space is available for legs to stick in between each other. Therefore, there exists an optimum packing density. SPM (1984) gives  $\varphi_{n=2} = 0.83$  while Zwamborn (1980) suggests  $\varphi_{n=2} = 1$ .

*Wave duration (number of waves  $N_z$ )* In the 50'ties and early 60'ties the storm duration parameter was not considered because the generated waves in laboratories were monochromatic waves, which are the same for every single wave. The equilibrium slope was reached in a short time.

In the case of irregular waves it takes longer time before a possible equilibrium state is reached. Font (1968) studied the effect of storm duration on the stability of rock armoured breakwater. He concluded that for mild wave climates, i.e. relative small  $\frac{H_s}{\Delta D_n}$  values, the duration of the storm is not important. However, the duration becomes relevant for more severe exposure.

Fig. 5. Influence of wave duration on  $N_s$ .

In the present tests two identical tests with 5,000 waves were performed with Dolosse of waist ratio 0.37. Little difference in the ratio  $\frac{N_s}{(N_s)_{N_z=300}}$  was found for the damage levels  $D = 1\%$ ,  $2\%$  and  $5\%$ . Moreover, it was found that the Dolos armour reached an equilibrium state after  $N_z = 3,000$ . The relationship between  $N_s$  and  $N_z$  could be approximated by  $N_s \sim N_z^{-0.1}$  for  $N_z \leq 3,000$ .

In Fig. 5 the information on rock, cube and Tetrapod is from van der Meer (1988).

### Stresses in Dolosse under wave attack

*Sampling frequency* The natural frequency of the instrumented Dolosse was found to be app. 1,500 Hz by the impact calibrations. The sampling frequency in the wave flume test was 6,000 Hz, i.e. app. 4 times of the natural frequency of the instrumented Dolosse. Theoretical investigations showed that on average the sampled peak stresses were lower than the real ones by 10% due to the limit of the sampling frequency. This one sided bias has been corrected for in the data processing.

*Strain signal processing* The recorded strain signals were converted into signals of maximum principal tensile stress by

$$\text{max. principal tensile stress } \sigma_T = \frac{\sigma}{2} + \sqrt{\left(\frac{\sigma}{2}\right)^2 + \tau^2}$$

$$\text{normal stress } \sigma = \frac{M_c}{W_b}$$

$$\text{combined bending moment } M_c = \sqrt{M_x^2 + M_y^2}$$

$$\text{shear stress } \tau = \frac{T}{W_b/2}$$

where  $M_x$ ,  $M_y$  and  $T$  are the measured bending moments and torsion, respectively.  $W_b$  is the modulus of the strain-gauged cross section of Dolosse. For more detailed explanation see Burcharth et al. 1991.

The converted max principal tensile stresses were separated into (*static + pulsating*) and *impact* stresses. The static and pulsating stress contributions were converted into a range of prototype Dolos sizes using the valid linear scaling law, while the impact stress contributions were converted into the same prototype ranges using the non-linear scaling law for impinging solid bodies. The signals were then synthesized and a statistical analysis performed.

*Stresses from static, pulsating and impact loads in Dolosse* The relative importance of static, pulsating and impact stresses depends of the type and the size of the units, the slope angle, the position on the slope and the wave characteristics.

The Dolos stresses are treated as an extreme value problem. No distinction with respect to the Dolos position on slope was made because in practice the same type of units will be used over the whole height of the slope.

Table 2 indicates typical ratios between the various types of stresses for slender and bulky Dolosse on slope 1 : 1.5.

Table 2. Relative contribution to total stress from static, pulsating and impact stresses. 2 % exceedence probability values. Slope 1 : 1.5.

Waist ratio	Mass	$\frac{H_s}{\Delta D_n}$	$K_D$	$\sigma_{total} = \sigma_{static} + \sigma_{pulsating} + \sigma_{impact}$			
				$\sigma_{static}$	$\sigma_{pulsating}$	$\sigma_{impact}$	
0.325	10t	0.9	0.49	1	0.2	0	
		1.8	3.89	1	0.4	0.1	
		2.6	11.72	1	0.5	0.4	
	50t	0.9	0.49	1	0.2	0	
		1.8	3.89	1	0.4	0	
		2.6	11.72	1	0.5	0.1	
	0.42	10t	0.9	0.49	1	0.2	0
			1.8	3.89	1	0.4	0.4
			2.6	11.72	1	0.6	2
50t		0.9	0.49	1	0.2	0	
		1.8	3.89	1	0.4	0.1	
		2.6	11.72	1	0.6	1.3	

Note that the zeros in the  $\sigma_{impact}$  column does not mean that there is no impacts in the signal. It means that the impact portion of the stresses is smaller than the static+pulsating portion after scaled up to the given size. The tests showed that the variation in the stress ratios with the exceedence probability level is rather weak in the interval 1-5%.

The variation with the slope angle is not known in general. However, because static stresses show only small variations in the slope range 1 : 1.33 to 1 : 2 it is assumed that the stress ratios given in Table 2 are typical for this range of slopes. On the other hand the ratios are probably not valid for very steep slopes as it is known that the static stresses can be up to 100% larger for a 1 : 1 slope than for a 1 : 1.5 slope. For flat slopes of app. 1 : 4 to 1 : 6 it was found from

the Crescent City prototype study with 38 t instrumented Dolosse (Howell et al. 1990) that the ratio of the 10 % exceedence probability stress values,  $\sigma_{Static} : \sigma_{pulsating}$ , was app. 1 : 0.12 for  $N_s = 1.2 - 1.4$ . No impact stresses were recorded in this study, maybe due to the small  $N_s$ -values, cf. also the figures given in Table 2.

### Design diagrams for Dolosse

Based on the model tests at Aalborg University with instrumented Dolosse exposed to irregular waves, complete design diagrams for trunk sections of breakwaters are presented. The diagrams contain curves for stresses and displacements corresponding to different exceedence probability levels. The diagrams provides the relationship between all the following properties, expressed in statistical terms where relevant.

- Dolos waist ratio
- Dolos size
- Concrete tensile strength
- Concrete tensile stress
- Incident wave climate
- Strength exceedence probability (structural integrity)
- Relative number of displaced Dolosse (hydraulic stability).

Figs. 6 and 7 show examples of the design diagrams. The hydraulic stability in terms of displacements is obtained by Eq (1). The amount of rocking is not given explicitly in the design diagrams because the effect of rocking is relevant only to the breakage aspect which are dealt with specifically by the stress curves.

In Burcharth (1993) more diagrams can be found, also showing the strength exceedence probability as function of  $H_{mo}^t$ , Dolos mass, waist ratio and concrete strength.

All information related to the design diagrams refers to one shank cross section. However, for a Dolos there are 6 vulnerable sections (4 in the flukes and 2 in the shank). Because fluke failures contribute less to the failure probability than shank failures and because there exists some moderate correlation between the stresses in the sections it is recommended to adjust the exceedence probability levels for stress given in Figs. 6 and 7 corresponding to the mean of the simple upper and lower bounds. This means that app. 50 % should be added to the failure probability levels, i.e. 2 % should be interpreted as 3 %.

### Abstract

This paper intends to present results of the research work on structural stability of tetrapods done at the University of Hannover. The results are brought in accordance with interpretations from the hydraulic tests made in the large wave flume and prototype realisations. The analysis of the data are supposed to bring a clarification of the similitude problems related to the transfer of the measured impact strains to prototype conditions.

### 1. Introduction

Some breakwater failures, mainly caused by the breakage of armour units, have led to world wide activities in this field. Within an extensive basic research program on structural stability, performed at the University of Hannover, a number of hydraulic and dry tests were undertaken to simulate the most relevant loads on tetrapods. The main objective of these investigations is to develop one guidance for the design of unreinforced armour units with respect to their structural integrity.

Even if the fracture mechanism of concrete armour units in breakwaters are complex, several aspects are now known, like direct loads from wave action on tetrapods, possible displacement of tetrapod elements, strain due to movement (rocking and displacement) of tetrapod elements, relation wave height/degree of rocking, impact characteristics etc..

### 2. Description of the Research Program

The investigations on the structural behaviour of concrete armour units constitutes a part of an extensive basic research program on rubble mound breakwaters conducted at the University of Hannover and supported by the German Research Council (DFG) within the scope of the "Sonderforschungsbereich 205" (SFB 205).

\*\*) Dipl.-Ing., formerly graduate student at Franzius-Institut  
\*\*\*) Prof. Dr.-Ing. Dr. phys., formerly Director of Franzius-Institut

Aside from the hydraulic test within the research program on structural behaviour of concrete armour units, a number of dry tests like static tests, pendulum tests, drop tests on model units as well on prototype units were performed (BÜRGER et al., 1990).

The main purpose of the hydraulic tests with respect to structural stability of the units was to determine the actual response of the units in a breakwater environment as a function of the incident waves and of the location of the units on the slope.

The results of the aforementioned experimental investigations, together with available results from basic research on impact and cyclic loading of concrete are intended to be used for the development of design criteria for the structural stability of the units.

### **3. Description of the Breakwater Model and the Instrumented Units**

The hydraulic tests described in the paper were conducted on a tetrapod armoured breakwater in the Large Wave Channel (GWK) (320.0 m \* 7.0 m \* 5.0 m) using 50 kg armour units and maximum wave heights up to 2.20 m. The instrumented tetrapods used in the hydraulic tests had a reduced cross-section in order to measure the wave-induced static loads, quasi-static loads and also dynamic loads. Fig. 1 shows the cross-section of the model investigated in the Large Wave Channel, Hannover.

Fig. 1: Cross-section in the Large Wave Channel (GWK)

#### **4. Testing and Recording Procedures for the Hydraulic Tests**

The forces acting on a unit show a large variability based on the units location and the wave climate. To cover up all those variabilities, the instrumented tetrapods were placed at critical locations on the breakwater and the tests were performed with both regular and irregular waves, started with low wave conditions and increased in steps of 0.10 - 0.20 m until a significant unit movement was observed. After every test series, the cover layer was completely removed and reconstructed.

The measured data were recorded at a sampling frequency of 400 Hz and at the same time also registered at a sampling frequency of 11000 Hz by a Video Pulse Code Modulator (Video PCM).

Since the quasi-static and the dynamic load could not be measured separately, the recorded load signal should be splitted into a quasi-static and a dynamic part by a computer program developed for this purpose. (BÜRGER et al., 1990)

#### **5. Results from hydraulic tests**

In a reliable design of concrete armour units with respect to their mechanical strength all loads and environmental impacts should be required (BÜRGER et al., 1989). The most relevant loads, however, are induced by the combined action of waves and the weight of the units. That means the breakage of the single breakwater units is strongly connected with the hydraulic stability of the whole armour layer.

#### **Displacement**

The wave load on the breakwater resulted in rocking, displacement and strain in the tetrapods as the cover layer. Before and after every test, photographs were taken in order to determine the changes which occur in the whole armour layer and the instrumented units. After the development of the pictures, an enlarged positive and negative mask with the size of 0.18 \* 0.24 [m] was made.

For each test, the picture of the initial position of the test (positive mask) was superimposed with the picture of the final position of the same test (negative mask) and against a source of light, the changes of the position of the armour units could be seen. On a transparent sheet, a line starting from the initial position to the final position of the moved unit could be drawn.

Because of the model scale in the large wave channel the evaluation could be done very exactly. Due to the limitation of the tip of the isograph used for drawing only the differences of congruence which were smaller than 0.25 [mm] has to be neglected. Taking into account the transfer to different prototype units, for a 25 t tetrapod, this limitation is already equivalent to 0.07 [m]. The movements shown in

Table 1 are not theoretical values, but were measured from superposed photographs. This points to the importance of large scales also for hydraulic stability tests.

Movement	W [t]	Scale		Movement of the unit					
				[mm]	0.25	1.00	2.50	5.00	7.50
on the mask	-	3.5:1	[mm]	0.25	1.00	2.50	5.00	7.50	15.00
in the model	0.05	1:1	[m]	0.01	0.03	0.09	0.17	0.26	0.52
in prototype	17.5	1:7	[m]	0.06	0.24	0.61	1.21	1.82	3.63

in prototype	50.0	1:10	[m]	0.09	0.35	0.87	1.73	2.60	5.19

Table 1: Movement of Model Units Compared to Prototype Units

Table 2 shows the movements of the tetrapods for a significant wave height of  $H_S = 0.70$  [m] and a peak period of  $T_p = 4.5$  [s].

In this test more than 14 % of the units in an area  $0.75 * H_D$  (design wave height) above SWL moved about 0.09 [m]. Transferring these results e.g. to a 25 t tetrapod, it could be expected that, for the equivalent wave parameter, 14 % of the units move about 0.70 [m].

Table 2: Movement of 50 kg Tetrapods and Comparison to 25 t Units

### Displacement and strain

The afore-mentioned displacement caused impact loading and strain in the legs of the displaced tetrapod itself (direct impact) or in the neighbour tetrapod (indirect impact). If the length of displacement and the dynamic strain are known it can be expected to find a relationship between these two values. A certain displacement could cause a certain strain like it was found in the drop test (BÜRGER et al., 1989).

The correlation between drop height and strain found in the drop tests cannot be transferred to the hydraulic test. There are many reasons. Two of them are:

- The distance measured from the overlaid pictures is the distance of the tetrapod before and after the whole hydraulic test. It cannot be proved if the tetrapod was displaced only ones or in more than one step.
- In a dry test the boundary conditions can be clearly defined. In the hydraulic tests the tetrapods are random placed and the impact points cannot be distinguished during and after the test.

### Strain

For the irregular wave tests, however, it is necessary to analyse the correlation between the single wave and the induced load. For the tests with more than one thousand waves the interaction between wave parameter and resulting load has to be described individually; i.e. separately for each wave.

Fig. 2: Positions of the instrumented tetrapods (BÜRGER et al. 1990)

From the analysis of the data related to the location of the instrumented tetrapods, the highest wave-induced strain within the tetrapods generally occur at and slightly above the still water level (BÜRGER et al., 1989). For this the signals of the instrumented tetrapods in position 1 and position 7 (see Fig. 2) are evaluated.

Fig. 3a) shows values from all the tests with tetrapods in a stable position. For a stable position the strain increases linearly with increasing wave heights.

Fig. 3 Quasi-Static Strain induced in a 50 kg Tetrapod

a) in a stable position

b) in an unstable position

In Fig. 3b), all tests with tetrapods in an unstable position are combined and more than 28,000 values are plotted. It could be seen, that due to the large scatter of the data, an attempt to determine a relationship between those strains and corresponding incident wave parameters will not be successful, particularly for large wave heights. A better correlation could be obtained by considering only the maximum strain-values. The envelope curve shows that the quasi-static strain for unstable position is increasing rapidly with increasing wave height.

### **Breakage due to Rocking**

It is understood that fracture in large multilegged blocks is mainly caused by rocking motion induced by wave action (BURCHART, 1985). The porosity of armours of multilegged units is quite large and can reach values up to 60 %.

Therefore those units are able to rock between two extreme positions. This process due to weight and interlocking of units will be observed when the significant wave height exceeds a certain value. The rocking mode considered is a rotation of the unit to drag and acceleration forces, followed by an opposite rotation returning the unit to its original position.

If the rocking distance or the angle of rotation is large, the unit will possibly break itself or break one of the neighbour units. This will be intensified, when the combined action of flow and gravity will act.

For dynamic loads, a distinction cannot be made between units in an unstable position and units in a stable position because the measured strain could result either from the unstable unit or from the unstable neighbour unit hitting the stable unit. Even though, the strain is increasing rapidly with increasing wave height, but will not reach higher values after a certain wave height.

BONZEL (1986) gives reference values for bending tensile strain for critical load of concrete. After BONZEL strain will be already critical when the bending tensile stress will reach values between 65 and 90 % of the maximum stress  $\sigma_{\max}$ . Breakage will be expected when the stress  $\sigma_{\max}$  will be exceeded and the strain  $\epsilon_{\max}$  will reach values higher than 0.30 ‰.

The values after BONZEL (1986) are shown in Table 3.

Bending Tensile Stress	Tensile Strain [‰]
critical (65 - 90 % of $\sigma_{\max}$ )	$\epsilon_{\text{crit}} = 0.05 - 0.15$
maximum ( $\sigma_{\max}$ )	$\epsilon_{\sigma_{\max}} = 0.10 - 0.30$
$> \sigma_{\max}$ (breakage)	$\epsilon_{\sigma_{\text{br}}} = 0.30 - 0.60$

Table 3: Reference Values for unreinforced concrete after BONZEL (1986)

In some tests the measured strains in the 50 kg tetrapods are higher than 0.10 [‰], but are not plotted in Fig. 4. For those values the maximum stress  $\sigma_{\max}$  is reached (Table 4).

Wave Height $H_s$ [m]	$T_p$ [s]	Test	$\max \epsilon_{dyn}$ [‰]	Values after BONZEL (1986)		
				0,05 - 0,15	0,10 - 0,30	0,30 - 0,60
0.90	4.5	21118801	0.15		$\epsilon_{\sigma max}$	
1.00	4.5	11118801	0.12		$\epsilon_{\sigma max}$	
1.10	6.0	24118804	0.17		$\epsilon_{\sigma max}$	

Table 4: Maximum Strain measured in the Hydraulic Tests

Fig. 4: Measured Dynamic Strain in a 50 kg Tetrapod

For dynamic strain especially the maximum values are most important. It was proved that the measured maximum dynamic strain values  $\epsilon_{\text{dyn}}$  in the hydraulic tests follow the distribution by GUMBEL. With increasing significant wave heights  $H_s$  also the possibility of occurrences of certain strain will increase. The extreme values of dynamic strain induced in a 50 kg tetrapod by waves of different significant wave heights plotted on GUMBEL paper is shown in Fig. 5.

Fig. 5: GUMBEL Distribution for Extreme Values of Dynamic Strain in a 50 kg Tetrapod

The purpose is to find the possibility of occurrence from high strain values which could be higher than the strain for the concrete which will cause breakage of the unit.

Because of effects of other mechanisms not included the results of the probabilistic calculations must be regarded as still preliminary. The failure probability of the breakwater due to fracture of armour units as a consequence of production, placing procedures and so on has to be added. Those probabilities has to be based on engineering judgement.

Fig. 6 shows the preliminary design diagram. For the calculation of the weight of the armour unit the well known HUDSON formula is applied.

Fig. 6: Expected Strain for a Probability of 95 % and different  $K_D$ -Values

The design diagram combines the hydraulic stability with the structural stability. From the GUMBEL distribution for different sizes of tetrapods the calculated strain for a possibility of 95 % is plotted for these tested  $K_D$ -values. It is shown, that with higher  $K_D$ -values and higher waves the strain in the calculated unit will reach values higher than  $\epsilon = 0.3$  ‰ when breakage is expected.

Even if the design diagram is preliminary it can be concluded that the tetrapods with a certain weight are structural unstable for those conditions built in the large tests.

## **6. Perspectives**

The design procedure with respect to the structural stability of tetrapods has to be continued with an extensive study of concrete literature. Based on the experimental results and the results of the literature study the final design diagram will be presented.

## **7. Acknowledgements**

This study is a part of an extensive research programme within the Coastal Engineering Research Unit "Sonderforschungsbereich 205" at the University of Hannover which is supported by the German Research Council (DFG), Bonn.

## CHAPTER 81

### The Movement of Submerged Bodies by Breaking Waves

M.J. Cooker <sup>1</sup> & D.H. Peregrine <sup>2</sup>

#### Abstract

This paper describes a mathematical model of the large but short-lived forces exerted on submerged solid bodies by a wave impacting on a plane impermeable surface nearby. We consider the forces on a hemispherical boulder situated close to a wave impact on (i) a vertical wall and (ii) a steep slope. We show that for certain positions of the body and for a sufficiently strong wave impact the impulsive force on the body can be much greater than either the flow drag or the weight of the boulder. For a body which is free to move under the wave impulse we compute the body's initial velocity.

#### Introduction

This paper describes recent work on the mathematical modelling of the large sudden forces exerted on submerged bodies by breaking waves. See figure 1. When a wave breaks against a wall the peak pressure at a point in the fluid can be ten times greater than hydrostatic, and the pressure can rise and fall in milliseconds. Richert (1968) measured high pressures on both walls and slopes. Nagai (1960) reports measurements in which the maximum peak pressure occurs at the bottom of the wall; this may have occurred because the bed was exposed before impact.

Cooker and Peregrine (1990a,1992) have shown theoretically that when a wave breaks against a vertical wall the peak fluid pressure can be significant all the way down the wall and along the bed. Grilli et al (1992) have measured impulsive wave impact pressures along the bed in front of a vertical wall. The theory and measurements show that for a given wave impact the peak pressure decreases along the bed with increasing distance from the wall. Suppose a small boulder lies on the bed. During the short time of wave impact the boulder experiences high pressure on the side near the wall and

Dept. of Mathematics, University of Bristol, Bristol BS8 1TW, UK.

FIGURE 1: Sketch of a wave impact on a wall with a body on the bed.

lower pressure on the side away from the wall. This impulsive fluid pressure must be treated differently to hydrostatic pressure: in order to find the net impulsive load on the body we must carry out calculations similar to those for finding added mass.

In this work it is more convenient to work with the *pressure impulse* than the peak pressure. The pressure impulse,  $P(\underline{x})$ , at the point  $\underline{x}$  due to a wave impact which begins at time  $t_b$  and ends at time  $t_a$ , is defined to be the time-integral of the pressure  $p(\underline{x}, t)$ :

$$P(\underline{x}) = \int_{t_b}^{t_a} p(\underline{x}, t) dt. \quad (1)$$

For an incompressible liquid  $P$  satisfies Laplace's Equation (Lamb, 1932, §11). We expect the highest impact pressures to be generated when the fluid contains few air bubbles and so the water may be treated as incompressible.  $P$  is useful for finding the velocity after impact,  $u_a$ , from the velocity before impact,  $u_b$ :

$$u_a(\underline{x}) = u_b(\underline{x}) - \frac{1}{\rho} \nabla P(\underline{x}) \quad (2)$$

where  $\rho$  is the water density, and the flows  $u_a$ ,  $u_b$  can contain

vorticity. The peak pressure  $p_{pk}(x)$  is connected to the pressure impulse by the approximate relation

$$p_{pk}(x) = 2P(x)/\Delta t \quad (3)$$

where the impact duration  $\Delta t = t_a - t_b$  must be chosen appropriately.

The observed decrease in peak pressure with distance along the bed in front of a wall which is undergoing wave impact, corresponds to a decrease in the pressure impulse along the bed. In general, where the water contains a gradient of pressure impulse it can exert an impulse on a solid body. We show below that the impulse on the body is directly proportional to the product of the volume of the body and the size of the pressure impulse gradient. The direction of the net impulse can be quite different to the direction of the pressure impulse gradient. The size of the impulse on the body also depends on its shape, and whether it is fixed or free to move.

The calculation of the impulsive force on a body has two stages. First the pressure impulse  $P_1$  is calculated from a boundary-value problem (b.v.p.) appropriate to the shape and speed of the impacting wave at the instant it meets, for example, a vertical wall. A point  $\tilde{x}$  is chosen at which we will place a small body and there we find the pressure impulse gradient  $G = \nabla P_1$ . In the second stage we solve a second b.v.p. for  $P_2$ , which is the pressure impulse close to the body and which accounts for the disturbance to  $P_1$  caused by the presence of the body. Finally the net impulse is found from an integral of  $P_2$  over the surface of the body. If the body is free to move we can also find its initial velocity.

The analysis can be used to find the force on a body in front of a vertical wall (see Cooker and Peregrine, 1992) or a steep slope. The measurements of Richert (1968) show that when a slope is subjected to wave impact significant pressure impulse gradients can occur. The impulsive forces estimated in this paper can be briefly much greater than the forces of flow drag or body weight. This work may explain the movement of large blocks seaward away from steeply sloping and vertical sea defences, when these same blocks are unmoved by the drag from the water motion of waves.

## 2. Pressure Impulse: A comparison with experiment.

Figure 2(a) is a sketch of a wave impact on a plane vertical wall. The peak pressures are greatest when the incident wave crest is parallel to the wall at the instant of impact, so the flow may be modelled in a two-dimensional plane perpendicular to the shore. The idealized boundary-value problem (b.v.p.) for the pressure impulse,  $P$ , is shown in figure 2(b). The total height of water is  $H$  and for simplicity we suppose the wave face impacts the wall between  $y = 0$  and  $y = -\mu H$ , where  $\mu$  must be chosen between 0 and 1. The component of water velocity normal to the wall before impact is supposed the same at all points and denoted  $U_0$ . The bed and wall are impermeable.

FIGURE 2(a): Sketch of the wave before impact on a vertical wall.

FIGURE 2(b): Boundary-value problem for pressure impulse  $P_1$ .

FIGURE 3(a): Comparisons of measured pressure impulse with theory, for impact as in figure 2.  $\mu = \frac{1}{2}$ ,  $U_0 = 1\text{m/s}$ ,  $H = 0.1\text{m}$ .

FIGURE 3(b): As fig. 3(a).  $\mu = \frac{3}{4}$ ,  $U_0 = 1\text{m/s}$ ,  $H = 0.1\text{m}$ . The disagreement may be due to the impact being more prolonged and less intense than in fig. 3(a): peak pressures are only  $\frac{1}{7}$  of those in fig. 3(a).

The b.v.p is solved by Cooker and Peregrine (1990a) and we compare this earlier result with the measurements of Hattori (1992). The values of  $\mu$ ,  $H$ ,  $U_0$  are estimated from high-speed video images:  $\mu = 0.53$ ,  $H = 0.1m$ , and  $U_0 = 1m/s$ . Figure 3 shows two comparisons between the theory (with parameters chosen from the video) and the pressure measurements of Hattori. The close agreement of figure 3(a) occurs for a wave impact of short duration with a very high maximum peak pressure of  $525gf/cm^2$ . The disagreement in figure 3(b) is interesting because it shows the pressure impulse with a maximum near the bed, indicating that  $P$  (and its gradient) may be significant along the bed. Also this second comparison corresponds to a low impact pressure maximum measured to be  $70gf/cm^2$ , so pressure impulse theory may be inappropriate for this less sudden impact. Further note that the values of pressure impulse in figure 3(a) and figure 3(b) are similar even though the maximum peak pressures differ by a factor of 7. This accords with the repeated wave experiments of Bagnold (1939) who observed the constancy of pressure impulse compared with the very wide variation of the peak pressures.

### 3. The Impulse on a Hemispherical Boulder: Vertical Wall.

Figure 4 shows the distribution of pressure impulse on the wall and along the bed for the solution  $P_1$  of the b.v.p. presented in figure 2(b). On the bed, the gradient of  $P_1$ , denoted  $\tilde{G}$ , is directed along the bed.  $|\tilde{G}|$  takes its greatest value of  $0.11\rho U_0$  at  $x = x_m = 0.48H$ , where  $x = 0$  is at the wall. We now place a boulder in the shape of a hemisphere on the bed at  $x = x_m$ , so that it can experience the greatest gradient of pressure impulse. Locally we can model the variation of  $P_1$  by a linear approximation:

$$P_1 = P_0 - G(x - x_m) \quad (4)$$

where  $P_0$  and  $G$  are the positive constants  $P_0 = P_1(x=x_m, y=-H)$  and  $G = \left| \frac{\partial P_1}{\partial x}(x=x_m, y=-H) \right|$ . We now compute the effect on  $P_1$  due to the presence of the boulder.  $P_2$  is the pressure impulse on and near the boulder. Let  $r, \theta, \phi$  be spherical polar coordinates centred on the hemisphere, where  $\theta$  is the angle subtended by the field point and the  $x$ -axis, at the centre of the hemisphere.  $P_2$  is harmonic and must match the variation of  $P_1$ , given by equation (4) (expressed in polar coordinates), at large distance from the boulder: i.e.

$$P_2(\tilde{x}) \longrightarrow P_1(\tilde{x}) = P_0 - G r \cos \theta \quad \text{as } |\tilde{x}| \equiv r \longrightarrow \infty. \quad (5)$$

On the boulder,  $r = a$ , we have the second boundary condition for  $P_2$ :

$$\frac{\partial P_2}{\partial r} = -\rho V \cos \theta \quad (6)$$

where  $V$  is the as yet unknown velocity component along the  $x$ -axis

FIGURE 4(a): The variation of pressure impulse up the wall for the wave impact illustrated in figure 2.  $\mu = \frac{1}{2}$ .

FIGURE 4(b): As figure 4(a). The pressure impulse on the bed for several values of  $\mu$ . At points where  $\partial P / \partial x$  is large the fluid can exert an impulsive load on a body.

acquired by the body due to the fluid impulse. Cooker and Peregrine (1992) show that the impulse on the hemisphere is

$$I = \frac{2}{3}\pi a^3 \left\{ 3G - \rho V \right\} . \tag{7}$$

For a free boulder we may equate the impulse I with momentum gained by the body: if  $\rho_b$  is the boulder's uniform density then the initial speed of unconstrained motion is

$$V = \frac{3G}{2\rho_b + \rho} . \tag{8}$$

If the body is fixed then  $V = 0$  in equation (7). If the body is free then equations (7) and (8) give

$$I = \frac{2}{3}\pi a^3 \left\{ \frac{3G\rho_b}{2\rho_b + \rho} \right\} . \tag{9}$$

Equation (3) suggests that the peak force is related to the impulse:

$$F = 2I/\Delta t. \tag{10}$$

EXAMPLE. Let  $H = 2m$  ,  $U_o = \sqrt{gH} = 4.4m/s$ , and  $\rho = 1035kg/m^3$ ,  $\rho_b = 2.7\rho$ . For impact on a vertical wall, with  $\mu = \frac{1}{2}$  , the position of maximum pressure impulse gradient is  $x_m = 0.48H = 1.2m$  from the wall.  $G = 0.1\rho U_o = 0.44\rho = 460$  Ns/m. Let the impact time  $\Delta t = 0.01s$ .

From equation (8)  $V = 0.21$  m/s and is the same for any hemisphere radius a.

From equation (9)  $I = 1.21 a^3$  kNs.

From equation (10)  $F = 240 a^3$  kN.

We estimate the flow drag, D, from that for a sphere for Reynold's numbers between  $10^4$  and  $10^6$  with a drag coefficient  $C_d = \frac{1}{2}$  and a typical flow speed of  $U_o$  (Batchelor, 1973, p341).

$$D = \frac{1}{2}C_d \left(\frac{1}{2}\pi a^2\right)\rho U_o^2 \tag{11}$$

$$D = 7.9 a^2 \text{ kN.}$$

Finally the dry weight  $W = \frac{2}{3}\pi a^3 \rho_b g$  (12)

Hence  $W = 57 a^3$  kN.

The following table compares the forces for several hemispheres of different radius, a, all much less than the local depth H.

a (m)	F (N)	D (N)	W (N)
0.05	30	19.7	7.2
0.1	240	79	57
0.2	1930	320	460

The impulsive force  $F$  is directed away from the wall and the drag  $D$  is directed toward the wall, at the instant of impact. In each case the impulsive force  $F$  is much greater than either the drag,  $D$ , or the dry weight,  $W$ . Also  $D$  is directly proportional to the cross-sectional area of the body, whereas  $F$  is directly proportional to its *volume*. So for larger bodies we expect the impulsive force to be even more important than the other forces acting. If the body is fixed then the impulsive force  $F$  is 19% greater than that tabulated.

#### 4. The Impulse on a Hemispherical Boulder: Steep Slope.

The effect of water impact is directly dependent on the inertia of the water, and during the short time of high impact pressures, gravity has no significant effect and so pressure impulse theory can be used for waves breaking directly onto a slope. For example figure 5 shows the distribution of  $P$  in a quarter-plane, adapted for a slope by simply turning it. We can choose any line  $P = \text{constant}$  as a free surface ( $\dot{P} = 0$ ), by subtracting the constant from the solution.

It is inadvisable to rely on pressure impulse theory near the impact region since the motion there is grossly simplified. Much energy is given to the small amount of water in the splash (see for example the jet flow computed in Cooker and Peregrine, 1990b). However, down the slope, the pressure impulse gradients are more reliably estimated. Proximity to the impact region leads to pressure impulse gradients which are much bigger than those on the bed in front of a wall.

In figure 5 the breaking wave face is modelled to strike the slope like a closing door which is hinged at  $y = -d$ , and has maximum speed  $U_0$  at  $y = 0$ . Figure 6 shows the variation on the slope of  $P$  and its derivative parallel to the slope. We place a hemisphere at  $y = -2d = -2m$  ( $d = 1m$ ), and we estimate  $U_0 = \sqrt{dg} = 3.13m/s$ . At the hemisphere position  $G = 0.065\rho U_0$ . The impact time  $\Delta t = 0.01s$ . From equations (9,10,11,12)

$$\begin{aligned} \text{The impulsive force is} & \quad F = 111 a^3 \text{ kN.} \\ \text{The flow drag force is} & \quad D = 4.0 a^2 \text{ kN.} \\ \text{The weight of the body is} & \quad W = 57 a^3 \text{ kN.} \end{aligned}$$

The following table compares the forces for several radii,  $a$ .

$a$ (m)	$F$ (N)	$D$ (N)	$W$ (N)
0.05	13.9	10	7.2
0.1	111	40	57
0.2	890	159	460

The impulsive force  $F$  is directed down the slope and the drag is directed up the slope. As  $a$  increases  $F$  becomes ever larger than the drag. The initial speed of each of the hemispheres is 0.09 m/s. The main difference between the two calculations of impulsive force on a body (in front of a wall and on a slope) is the value of  $G$ . Both  $F$  and  $V$  are directly proportional to  $G$ .

FIGURE 5: Contours of pressure impulse  $P$  for wave impact on a slope. A solution in a quarter-plane has been rotated to lie on the slope. By subtracting a constant from the solution a curved free surface can be obtained, (e.g. the bold contour shown). The impacting wave face is modelled as a closing door, hinged at  $y/d = -1$ , with speed  $U_0 = 1$  at  $y = 0$ . The contour increment is  $0.005 \rho U_0 d$ , with a maximum of  $0.240 \rho U_0 d$  on the slope at  $y/d = -0.4$ .

FIGURE 6: As figure 5. The distribution of  $P$  and its gradient on the slope. Note that  $G = \partial P / \partial y$  acts to thrust bodies down the slope below the impact zone (which lies between  $y/d = 0$  and  $y/d = -1$ ).

## 5. Conclusions

The hemisphere is an idealized boulder. Cooker and Peregrine (1992) discuss the impulsive force on a hemi-ellipsoid and they show that a body broadside on to an impact region receives a much larger impulse than a body pointing toward the impact region.

A hemisphere which is free to move may be expected to have a fluid layer between its base and the bed. If the layer has a narrow width  $h(x,y)$  then the pressure impulse obeys a certain partial differential equation:  $\nabla \cdot (h \nabla P) = 0$ . The distribution of pressure impulse in the layer may cause a net upthrust on the boulder. For the hemisphere, if the gap width is constant, it can be shown that the upthrust is equal and opposite to the downthrust on the upper curved surface. So in this special case there is zero net impulse normal to the bed (and hence no impulsive reaction between the boulder and

the bed due to friction). Nevertheless the pressure impulse distribution on the base of the hemisphere causes an impulsive overturning moment. In general the impulsive uplift and overturning moment depend in a complicated way on  $h(x,y)$  and the shape of the boulder, and is the subject of future study.

This work suggests that the impulsive pressure field created inside a wave when it impacts a solid surface may be large enough to move nearby bodies, such as armour units, and may explain some of the damage to the Sines breakwater which had a wall at its crest (see Baird et al, 1980). For a wave impact which is sufficiently high-speed and short-lived the impulsive loads on a hemisphere can be much greater than the flow drag or the weight of the body. Further, the impulse increases with the volume of the body, whereas the drag increases with its cross-sectional area. So we expect impulsive loading to be most important for the biggest boulders. The impulse is greater for a fixed body than one free to move (19% greater for a hemisphere).

The theory must be modified for a body which is so large that it alters the incident wave flow. Here a b.v.p in a domain containing both the wave and the boulder must be solved with modified boundary conditions. Despite the increased complexity we still expect the impulsive forces to be significant compared with the other types of load.

The solution for a body on a slope shows that a boulder can be thrust seawards down the beach if it is below the impact zone. Inside the impact zone the predicted pressure impulse gradients suggest they would force a body up the slope, but here we can be less certain of the applicability of pressure impulse theory.

## CHAPTER 82

### PLEA FOR THE PLACEMENT OF ARMOUR BLOCKS IN ORDERLY PATTERNS

Fernando Vasco Costa, F. ASCE (1)

#### Abstract

Just by placing hollow blocks in orderly patterns, all in the same direction and well interlocked among themselves, not only will their resistance against localized wave actions be greatly increased, but their resistance will vary little from one block to another. Furthermore, the risks of their breakage due to "rocking motions" and of the rapid spreading of damage once initiated, will be essentially eliminated.

To render possible the placement of blocks under the water surface in predetermined positions, in the presence of waves and currents, the blocks should be suspended simultaneously from three or four inclined cables.

#### Introduction

Blocks with a compact form, like quarry stones and cubic concrete blocks, were for a long time the only ones used in breakwater armours. Slender blocks, like tetrapodes and dolosse, came into use only after World War II. They were an improvement because they weighed much less and could be placed in steeper slopes. Hollow blocks, like Seabees and Diodes, were introduced quite recently, but primarily for use along river banks and for shore protection.

Different types of armour blocks should be compared, like alternative designs for any type of engineering structures, by taking into consideration the extreme high

- (1) Formerly Professor at Technical University of Lisbon, Consulmar, Rua Joaquim A. Aguiar, 27, 1000 Portugal.

actions their elements may be submitted to, the extreme low resistances some of the elements will not be able to oppose and how will the different modes and degrees of the failure of the elements affect the behaviour of the whole structure.

For compact blocks the more damaging wave actions will consist of pulling forces acting normal to the armour surfaces; for slender blocks the more damaging wave actions will consist of combinations of oblique forces and torques acting in particular orders and directions. The probability of occurrence of such combinations is very low, but it should not be ignored, especially in long breakwaters built in deep water.

The placing of hollow blocks in orderly patterns is advocated as a way to reduce the gravity of the consequences of wave actions, of reducing the dispersion of the resistance of the blocks and of reducing the risk of the rapid spreading of damage.

#### Oblique forces and torques as determining factors of the stability of armours of slender blocks

Static tests of several types of armour units have been described by Price (1979) and by Wang and Peene (1990). They showed that the mean value and the dispersion of the resistances of slender blocks against being pulled out by forces acting normal to the surface of the armours is not as much affected by the type of block as could be expected.

Had the slender blocks been submitted, during testing, to combinations of oblique forces and torques, not only would the average resistance of the blocks have been smaller but its dispersion would have been much greater.

Just by examining an armour of slender blocks, one can imagine the directions of the forces and torques that need to be applied in order to disentangle a particular block from its neighbours (Fig. 1). Sea waves can not see, or plan, but they can apply, for hours and days, a great variety of combinations of oblique forces and oblique torques. Once they succeed in removing the first block, neighbouring blocks, lacking the support of the block that left, will also start leaving the armour, one after the other, in a chain reaction (Vasco Costa, 1983).

Figure 1 - Forces plus torques are required to disentangle dolosse blocks from an armour

The probability of even well interlocked blocks being submitted to the right (or wrong) combinations of forces and torques that can pull them out of an armour increases with the duration of a storm (Lousada and Guimenez - - Curto, 1981), with the number of the blocks in the armour (Burcharth, 1983) and with the range of directions of the waves (Christensen et al. 1984). The deeper the water in front of a breakwater the wider will be the variety of combinations of directions from which the waves will be able to reach the armour.

Tests run in narrow flumes, in which all waves come from the same direction, do not give an adequate picture of the behaviour of armours made of slender blocks. Such tests are conducive to the underdesign of armours of slender blocks. The recommendation to adopt values of the coefficient  $K_d$  for dolosse, in the Hudson formula, about 10 times larger than that for rough angular quarrrystones, was probably based on tests run in flumes that did not properly represent the variety of directions of forces and torques to which such blocks are subjected to in prototype (Shore Protection Manual, 1984).

How can a designer benefit from the advantages offered by blocks of slender form (the use of lighter blocks on steeper slopes), without incurring their disadvantages (wide dispersion of resistances, risk of breakage during "rocking motions" and the spreading of damage once initiated)? Just by placing the blocks in orderly patterns, all with the same orientation, well interlocked with their neighbours and without free spaces between them, so as to avoid "rocking motions".

Recently a new type of armour blocks has been developed; it consists of hollow blocks placed in orderly patterns, so as to avoid "rocking motions". Examples are the COB, the SEABEE, the SHED and the DIODE. As the porosity of

armours of hollow blocks is high, about twice that of armours of compact blocks, and well distributed, such armours resist heavy seas effectively. They are so stable that such blocks can be used in a single layer. They have been applied quite successfully in the protection of beaches and shores, where blocks can be placed above the water surface.

By providing the faces of such hollow blocks with ridges and grooves, the resistance of the blocks against occasional localized wave actions can be greatly increased (Fig. 2).

As the blocks need to be placed in quite precise positions below the water surface, even when the water is being submitted to the action of currents and waves, they should be suspended not just from a single cable, as is the current practice, but simultaneously from several inclined cables (Fig. 3).

Figure 2 - Block with ridges and grooves on the faces in contact with neighbouring blocks

Figure 3 - The placing of blocks suspended from four cables

Importance of the blocks placing operation

Tetrapodes were a great success when they were first introduced because they permitted the use of lighter blocks in steeper slopes. Such success lasted as long as their use required the payment of patent rights to Sotramer. This company used to send technicians to the construction sites to instruct crane operators on how to place the tetrapodes so that the blocks would be well entangled with their neighbours. This procedure was essential not only to increase their average resistances against being pulled but, especially, to reduce the dispersion of such resistances.

In model tests conducted in narrow flumes, as all the blocks are submitted to almost the same flow conditions, the interlocking does not greatly affect their resistance against being pulled out. In prototype structures, however, the blocks are submitted to waves arriving from a great variety of directions and they can, now and then and here or there, exert strong localized actions on some of the blocks. The interlocking is then essential for the stability of the armour.

Dolosse were such a success when they were first used in their country of origin, South Africa, that they were promptly adopted for the armours of several long breakwaters built in the seventies in quite exposed locations. Such blocks did not behave as could be expected from the results of the model tests on which the design of the armours had been based. Because the larger a block the more brittle it becomes, plenty of large dolosse loosely placed broke during "rocking motions", even when submitted to relatively mild storms.

The natural periods of oscillation of suspended blocks have about the same order as those of sea waves. If, when entering the water, a block happens to move in the same direction the water is moving, the amplitude of oscillation is increased, and the risk of breakage during the placing operation is also increased (see Table I). In still water the oscillation would have been damped, but in moving water the oscillation of the suspended blocks can be greatly amplified.

Table I  
Period of Oscillation of a Suspended Block

$$T = 2 \pi \sqrt{l/g}$$

Lenght of the cable (l)	9m	16m	25m	36m	49m
Period of Oscillation(T)	6s	8s	10s	12s	14s

The placing operation is facilitated if the blocks have an octogonal form. The slanted faces will guide the blocks to occupy their proper position among other blocks; the horizontal faces will support the blocks weight; the vertical small faces will allow for minor deviations from the conventional pattern (Fig. 2).

Armours can have a behaviour approaching that of series systems or parallel systems

The way the failure of an armour spreads once a block breaks or leaves the armour needs be analyzed. Some armours fail like a chain, the classical example of a series system. As soon as its weakest link breaks, a chain is no longer useful. The wider the dispersion of the resistance of the links and the larger the number of links, the weaker a chain becomes. Engineers have tended, nevertheless, to base the design of all types of armours on the average resistance of the individual blocks, even when, as is the case with armours of slender blocks placed at random, their behaviour approaches that of a series system (Vasco Costa, 1983).

Armours composed of compact blocks that are placed at random, like natural stones and concrete cubes, can become more stable after being subjected to a few mild storms giving occasion to adjustments in the positions of poorly placed blocks. If a small percentage of the blocks leaves the armour during a storm, up to about 5%, the armour can still be regarded as sufficiently safe (Shore Protection Manual, 1984). As the leaving of a few elements does not imply that neighbouring blocks will also leave, and can even contribute to adjustments that will render such blocks more stable, armours of compact blocks can be regarded as having a behaviour approaching that of a parallel system (Fig. 4a).

The situation is quite different with armours composed of slender blocks, like tetrapodes and dolosse. Their resistances against being removed by strong wave actions exerted on particular blocks depends on how effectively each block is entangled with its neighbouring blocks. As soon as one block leaves its position, its neighbours, lacking the support of the block that left, are likely to leave also, one after the other, in a chain reaction. The larger the number of blocks, the less stable becomes an armour of slender blocks (Fig. 4b).

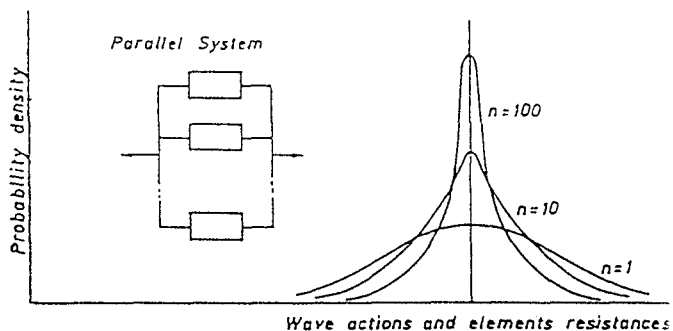

Figure 4 - Probability density of the failure of parallel and of series systems as affected by the number of the elements in a system.

Some of the accidents on very long breakwaters built in deep water during the seventies, with armours of large slender blocks, were attributed to the fragility of the blocks. They were due, however, at least in part, to the fact that the behaviour of their armours approached that of series systems.

The risk of the rapid spreading of the damage when a block occasionally breaks or leaves an armour will be greatly reduced in case of orderly placed and well interlocked blocks. If a block, of the type represented in Figure 5, breaks or leaves an armour, the six neighbouring blocks will lack its support on only one of their faces.

Figure 5 - Armour with a missing block

Side-scan sonar (SSS), already in use to detect damage under the water level of coastal structures, can also be used to guide and check the placement of blocks below the water surface (Kuckarski and Chauster, 1990).

#### Summary and Recommendations

Slender blocks have the advantage, over compact blocks, of opposing a much greater average resistance against being pulled out. Unfortunately such resistance, because it depends on how well each block is entangled with its neighbours, varies widely from one block to another. As the behaviour of armours of slender blocks approaches that of series systems, whenever a poorly placed block is submitted to strong localized wave actions, damage is likely to spread rapidly over the whole armour.

The placement of hollow blocks in orderly patterns, without clearances between blocks, helps to avoid "rocking motions". If their surfaces of contact are provided with ridges and grooves to assure a good interlocking, the blocks will present a great resistance against being removed and such resistance will be the same to all the blocks.

The placement of blocks in precise positions below the water surface will require the use of cranes especially built for the purpose, able to suspend the blocks simultaneously from three or four inclined cables, to avoid pendulation.

## CHAPTER 83

### Nonlinear Wave Transformation Over a Submerged Permeable Breakwater

Eric C. Cruz<sup>1</sup>, Masahiko Isobe<sup>2</sup> and Akira Watanabe<sup>2</sup>

#### Abstract

A set of nonlinear vertically integrated equations has been derived to predict the transformation of waves over a submerged permeable breakwater on a one-dimensional topography. The square of the relative water depth is assumed to be of the same order as the wave height to water depth ratio and a set of second-order governing equations which are equivalent to the Boussinesq equations is derived. The equations have been applied to simulate non-breaking and breaking wave transformations obtained from laboratory experiments, in the latter incorporating a model for breaking wave energy dissipation. When breaking is nonexistent on the breakwater, the wave height as well as the wave profile is well predicted. However, the disintegrating character of the transmitted waves is weakly predicted. For breaking transformation, the wave profiles are predicted well prior to the lee of the breakwater where disintegration occurs.

#### 1 Introduction

In recent years, submerged permeable breakwaters have been constructed in coastal zones to provide protection against wave attack. This type of breakwater has become popular mainly because of its advantages on aesthetic and environmental considerations. Submergence below the water surface and the porosity of the breakwater cause part of the incident wave energy to pass through the structure. Although the structure allows a level of wave transmission into the protected zone, it dissipates wave energy considerable enough to protect a beach from erosion by generating turbulence in the porous medium and causing the waves to break over the structure.

---

<sup>1</sup>Graduate Student, Department of Civil Engineering, University of Tokyo, Hongo 7-3-1, Bunkyo-ku, Tokyo 113, Japan

<sup>2</sup>Professor, Department of Civil Engineering, University of Tokyo, ditto

A model describing wave transformation is an indispensable tool in coastal planning and design. For submerged permeable breakwaters, mathematical models have been developed so far on the basis of the linear sinusoidal wave theory (Rojanakamthorn et. al., 1980). However, since the nonlinearity of waves cannot be neglected on the breakwater, the models must be improved to predict the transformation accurately.

In this paper, a model of wave transformation that considers the nonlinearity of the waves, arbitrary bathymetry of the bed and nonlinear wave damping due to the porosity of the submerged breakwater is presented. Since the model equations are unsteady, they can be applied to irregular waves with suitable boundary conditions.

## 2 Basic Equations and Boundary Conditions

Figure 1: Definition of variables

The region of interest is shown in Figure 1. The depth of the free water layer is  $h_1(x)$  and that of the porous layer is  $h_p(x) = h_0(x) - h_1(x)$ . The horizontal and vertical components of fluid particle velocity and pressure are  $u$ ,  $w$ ,  $p$  in the water layer and  $u_s$ ,  $w_s$ ,  $p_s$  in the porous layer. The subscript  $s$  refers to seepage quantities representing the flow within the pores only. The water surface displacement due to wave motion is  $\eta(x, t)$ . The fluid in the water layer is assumed inviscid and Euler's equation of motion in two dimensions are used:

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + w \frac{\partial u}{\partial z} = -\frac{1}{\rho} \frac{\partial p}{\partial x} \quad (-h_1 \leq z \leq \eta) \quad (1)$$

$$\frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + w \frac{\partial w}{\partial z} = -g - \frac{1}{\rho} \frac{\partial p}{\partial z} \quad (-h_1 \leq z \leq \eta) \quad (2)$$

where  $\rho$  is the mass density of water and  $g$  the gravitational acceleration.

The flow within the porous layer is governed by Euler's equation if proper account is taken for the effect of the divergence and convergence of streamlines caused by the presence of solid particles and for the loss of momentum caused by laminar flow along the granular surfaces and momentum loss through turbulence within the pores. The first effect is that of the virtual mass and the second is that of friction between the fluid and the grains. For steady flow in large granular medium, the drop in piezometric head results from laminar viscous resistance for low-velocity flow and a turbulent friction resistance for the high-velocity regime:

$$-\frac{1}{\rho}\nabla(p_s + \gamma z) = \frac{\nu}{K_p}\epsilon\vec{u}_s + \frac{C_f}{\sqrt{K_p}}\epsilon^2|\vec{u}_s|\vec{u}_s, \quad (3)$$

where  $\vec{u}_s = (u_s, w_s)$ ,  $\nabla = (\partial/\partial x, \partial/\partial z)$ ,  $\gamma$  the unit weight of water,  $\nu$  the kinematic viscosity of water,  $K_p$  the intrinsic permeability,  $C_f$  a turbulent friction coefficient and  $\epsilon$  the porosity. The constant  $K_p$  (dimension: length<sup>2</sup>) and the coefficient  $C_f$  are determined from laboratory tests under standard conditions. The investigations of Shuto and Hashimoto (1970) showed that the resistance characteristics of steady and oscillatory flows do not significantly differ so that Eq.(3) can be applied to wave motion, which is under consideration here. The equations of unsteady motion for the porous layer ( $-h_o \leq z \leq -h_1$ ) therefore become

$$C_r \left( \frac{\partial u_s}{\partial t} + u_s \frac{\partial u_s}{\partial x} + w_s \frac{\partial u_s}{\partial z} \right) = -\frac{1}{\rho} \frac{\partial p_s}{\partial x} - \frac{\epsilon\nu}{K_p} u_s - \frac{\epsilon^2 C_f}{\sqrt{K_p}} u_s \sqrt{u_s^2 + w_s^2} \quad (4)$$

$$C_r \left( \frac{\partial w_s}{\partial t} + u_s \frac{\partial w_s}{\partial x} + w_s \frac{\partial w_s}{\partial z} \right) = -g - \frac{1}{\rho} \frac{\partial p_s}{\partial z} - \frac{\epsilon\nu}{K_p} w_s - \frac{\epsilon^2 C_f}{\sqrt{K_p}} w_s \sqrt{u_s^2 + w_s^2} \quad (5)$$

The effect of the virtual mass is expressed by the inertial coefficient  $C_r = 1 + (1/\epsilon - 1)C_M$ , where  $C_M$  is the added mass coefficient.

For the incompressible fluid assumed here, the divergence of the velocity vector, as required by continuity, must vanish:

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0 \quad (-h_1 \leq z \leq \eta) \quad (6)$$

$$\frac{\partial u_s}{\partial x} + \frac{\partial w_s}{\partial z} = 0 \quad (-h_o \leq z \leq -h_1) \quad (7)$$

The passage of a wave creates oscillatory motion in the two layers. This motion is subjected to the following boundary conditions:

- At the free surface, the usual dynamic and kinematic boundary conditions are enforced:

$$p = 0 \quad (z = \eta) \quad (8)$$

$$\frac{\partial \eta}{\partial t} + u \frac{\partial \eta}{\partial x} = w \quad (z = \eta) \quad (9)$$

- At the bottom of the porous layer, the usual kinematic condition is applied:

$$w_s + u_s \frac{\partial h_0}{\partial x} = 0 \quad (z = -h_o) \tag{10}$$

- The pressure and mass flux must be continuous at the water layer-porous layer interface, that is,

interface continuity of pressure:

$$p = p_s \quad (z = -h_1) \tag{11}$$

interface continuity of mass flux:

$$w + u \frac{\partial h_1}{\partial x} = \epsilon \left( w_s + u_s \frac{\partial h_1}{\partial x} \right) \quad (z = -h_1) \tag{12}$$

Equations (1), (2), (4) to (7) govern the unsteady, incompressible fluid motion in the water and porous layers subject to the boundary conditions Eqs.(8) to (12).

### 3 Nonlinear Equations for One-dimensional Wave Transformation on a Porous Bed

#### 3.1 Assumption

In theory, the governing equations together with the boundary conditions can be solved for the primitive variables  $u, w, u_s, w_s, p$  and  $p_s$ . Since both sets of equations are highly nonlinear and involve  $\eta$  which is not known *a priori*, this undertaking is a tremendous, if not an impossible, task. In order to reduce the number of unknowns in these equations, a vertical integration of the governing equations is performed considering the nonlinear nature of the terms.

Let  $l$  be a characteristic length of the wave motion and  $h$  a characteristic depth giving a characteristic velocity  $\sqrt{gh}$ . Dimensional coordinates are nondimensionalized by  $l$  and  $h$ , velocities by  $\sqrt{gh}$ , pressures by  $\rho gh$  and time by  $l/\sqrt{gh}$  giving the nondimensional (primed) quantities:

$$x' = x/l \quad z' = z/h \quad t' = t/(l/\sqrt{gh}) \tag{13}$$

$$u' = u/\sqrt{gh} \quad w' = w(l/h)/\sqrt{gh} \quad u'_s = u_s/\sqrt{gh} \quad w'_s = w_s(l/h)/\sqrt{gh} \tag{14}$$

$$p' = p/\rho gh \quad p'_s = p_s/\rho gh \tag{15}$$

Applying Eqs.(13) to (15) in the momentum equations, the following nondimensionalized equations of motion along  $z$  are obtained:

From equation (2),

$$\rightarrow \left(\frac{h}{l}\right)^2 \left(\frac{\partial w'}{\partial t'} + u' \frac{\partial w'}{\partial x'} + w' \frac{\partial w'}{\partial z'}\right) = -1 - \frac{\partial p'}{\partial z'} \tag{16}$$

From equation (5),

$$\begin{aligned} &\rightarrow \left(\frac{h}{l}\right)^2 C_r \left(\frac{\partial w'_s}{\partial t'} + u'_s \frac{\partial w'_s}{\partial x'} + w'_s \frac{\partial w'_s}{\partial z'}\right) = \\ &-1 - \frac{\partial p'_s}{\partial z'} - \left(\frac{h}{l}\right)^2 \frac{\epsilon \nu l}{K_p \sqrt{g h}} w'_s - \left(\frac{h}{l}\right)^2 \frac{\epsilon^2 C_f l}{\sqrt{K_p}} w'_s \sqrt{u'^2_s + (h/l)^2 w'^2_s} \end{aligned} \tag{17}$$

To describe waves in shallow water, the dispersion and nonlinearity should be taken into account. As in the case of the Boussinesq equations, the following assumption is made:

$$u' \sim w' \sim u'_s \sim w'_s \sim O(\epsilon) \sim (h/l)^2 \sim \delta^2 \tag{18}$$

### 3.2 First-order Approximation

To get a first-order formulation of the governing equations, terms of order  $\epsilon^2$  and higher in the nondimensional equations of motion are dropped from the corresponding dimensional counterparts invoking the assumption Eq.(18). Hence Eq.(16) gives the dimensional equation

$$0 = -g - \frac{1}{\rho} \frac{\partial p}{\partial z} \tag{19}$$

Integrating from  $z = \eta$  to  $z = z$  and applying the dynamic free surface condition, the last equation becomes

$$p = \rho g(\eta - z) \tag{20}$$

Similarly, integrating the first-order form of Eq.(5) and invoking the interface continuity of pressure and Eq.(24) give

$$p_s = \rho g(\eta - z) \tag{21}$$

The first-order form of Eq.(1) reduces to

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial x}$$

and, invoking Eq.(20), becomes

$$\frac{\partial u}{\partial t} = -g \frac{\partial \eta}{\partial x} \tag{22}$$

Similarly, Eq.(4) reduces to

$$C_r \frac{\partial u_s}{\partial t} = -\frac{1}{\rho} \frac{\partial p_s}{\partial x} - \frac{\epsilon \nu}{K_p} u_s$$

and, using Eq.(21), gives

$$C_r \frac{\partial u_s}{\partial t} = -g \frac{\partial \eta}{\partial x} - \frac{\epsilon \nu}{K_p} u_s \quad (23)$$

From Eqs.(22) and (23),  $u$  and  $u_s$  do not depend on  $z$  (at least in the first order).

The kinematic boundary conditions are utilized after the continuity equations have been integrated. In the integration, Liebnitz rule is applied:

Integrating Eq.(7) from  $z = -h_0$  to  $z = z$ , the following is obtained:

$$0 = \frac{\partial}{\partial x} \int_{-h_0(x)}^z u_s dz + w_s|_z - \frac{\partial h_0}{\partial x} u_s|_{-h_0} - w_s|_{-h_0}$$

From the bottom boundary condition Eq.(10), the last two terms in the right-hand side vanish, giving

$$w_s(z) = -\frac{\partial}{\partial x} [u_s(z + h_0)] \quad (24)$$

Similarly, Eq.(7) is integrated from  $-h_0$  to  $-h_1$  and the bottom kinematic boundary condition is invoked, giving

$$w_{s,-h_1} + u_{s,-h_1} \frac{\partial h_1}{\partial x} = -\frac{\partial}{\partial x} [u_s(h_0 - h_1)] \quad (25)$$

Eq.(6) is integrated from  $-h_1$  to  $z$  resulting in

$$0 = \frac{\partial}{\partial x} [u(z + h_1)] + w(z) - \left( w_{-h_1} + u_{-h_1} \frac{\partial h_1}{\partial x} \right)$$
